The ideal treatment for urticaria/angioedema is identification and removal of its cause. Many patients with acute urticaria and angioedema probably are not treated by physicians because the cause is identified by the individual or the course is limited. Treatment of chronic urticaria focuses on measures that provide symptomatic relief. The physician should provide not only medications but also support and reassurance. In a questionnaire study, patients with chronic idiopathic urticaria considered the worst aspects to be pruritus and the unpredictable nature of the attacks. The presence of facial angioedema can be particularly disconcerting and tongue and/or pharyngeal edema is often considered life threatening. This is not the case and is confused with the potential for laryngeal edema seen with anaphylaxis, or anaphylactic-like reactions, C1 INH deficiency, or reactivity to ACE inhibitors. Affected individuals reported sleep disturbances, diminished energy, social isolation, and altered emotional reactions as well as difficulties in relation to work, home activities, social life, and sex life.[218,219] Another study showed a correlation between the severity of chronic idiopathic urticaria and depression. In a questionnaire study, individuals with delayed pressure urticaria and cholinergic urticaria had the most quality-of-life impairment.[220] Those with cholinergic urticaria suffered in relation to their sporting activities and sexual relationships. Although urticaria/angioedema may be a source of frustration to both physicians and patients, most individuals can achieve acceptable symptomatic control of their disease without identification of the cause. In some individuals, it is important to avoid aspirin and other NSAIDs. Antipruritic lotions, cool compresses, and ice packs may provide temporary relief. H_1-type antihistaminic drugs are the mainstays in the management of urticaria/angioedema. The older H_1-type antihistaminics are known as *classic*, *traditional*, or *first generation* H_1-type antihistamines. Newer, low-sedating, or second- and third-generation H_1-type antihistamines with reduced sedative and anticholinergic side effects have become the initial therapeutic agents of choice. The drug should be taken on a regular basis and not as needed. If the initial drug chosen is ineffective, an agent from a different pharmacological class should be used and nonsedating antihistaminics can be combined or the dose of any one of them increased. When this is ineffective, doses of hydroxyzine or diphenhydramine in the 25–50 mg qid may be tried. The same is true for the treatment of dermatographism when it is particularly severe. It should be noted that if the molar release of histamine in the skin exceeds that of the delivered antihistamine (as can be seen with dermatographism), the histamine will keep the receptors to which it is bound in the active conformation, and therapeutic efficacy with the antihistamine will be achieved only when its molar concentration is much greater than that of histamine. Diphenhydramine is an alternative to hydroxyzine or cetirizine for dermatographism but not for cholinergic urticaria.[221,222] Cold urticaria can be treated with most antihistaminics but cyproheptadine at 4–8 mg tid or qid seems to be particularly effective.[223–226] Excellent results have been recently reported with desloratadine at four times/day.[92] Local heat urticaria is treated with antihistaminics; no regimen is particularly favored. Although anecdotal reports suggest that delayed pressure urticaria will respond to NSAIDs, dapsone, cetirizine, or sulfasalazine, most require corticosteroids (used as in chronic urticaria) to control symptoms and cyclosporine can be a particularly effective alternative. Familial cold autoinflammatory syndrome (urticaria) responds to parenteral IL-1 receptor antagonist (anakinra) as does some cases of Schnitzler syndrome.

Treatment choices for chronic urticaria (idiopathic or autoimmune) have been reviewed[227] and are

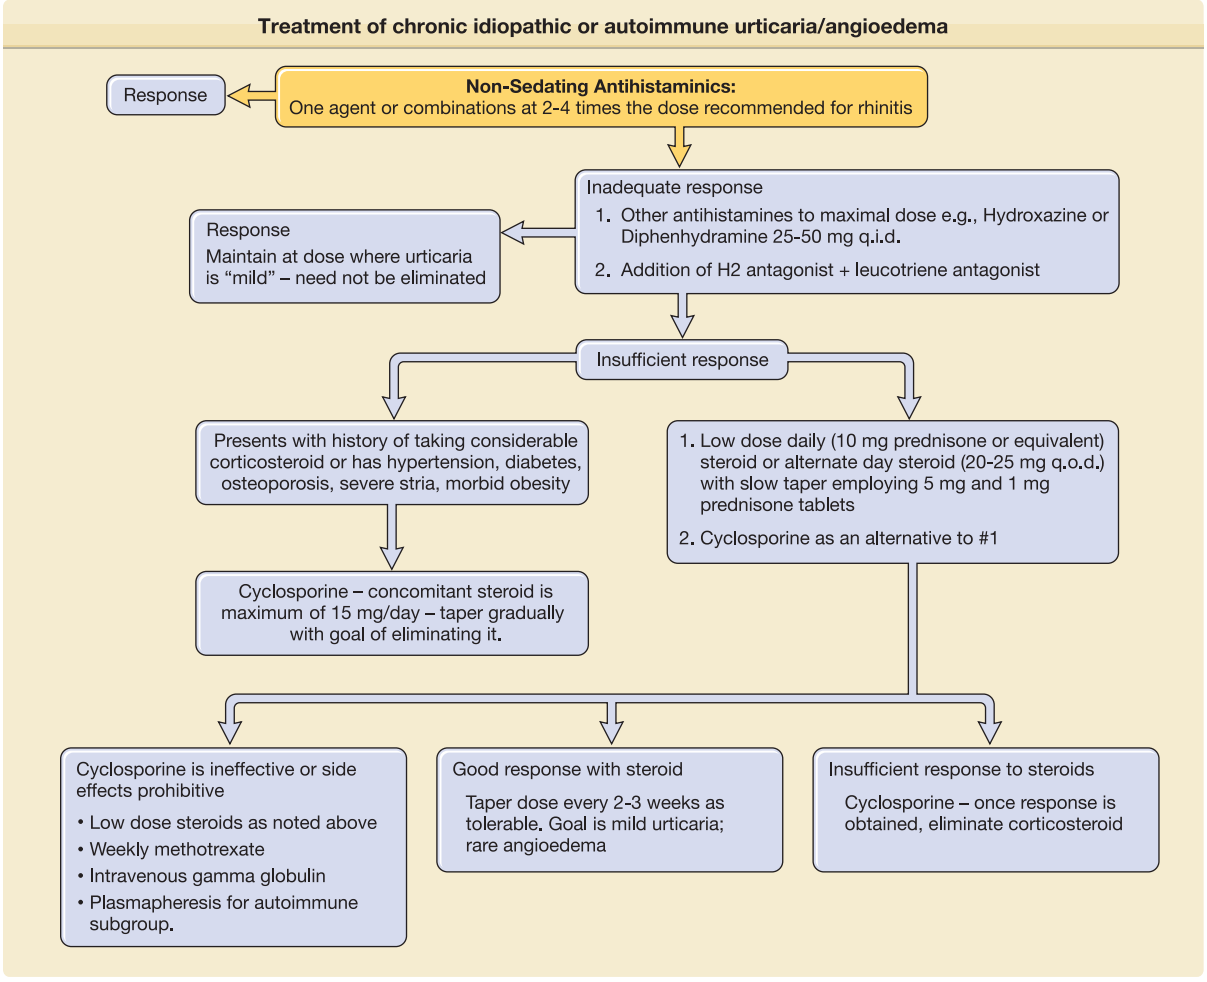

Figure 38-10 Treatment of chronic idiopathic or autoimmune urticaria/angioedema. Note that the following agents are expected to be effective rarely, if ever: hydroxychloroquine, colchicine, dapsone, sulfasalazine, mycophenolate mofetil. Hydroxychloroquine is, however, the drug of choice for the hypocomplementemic urticarial vasculitis syndrome. Urticarial vasculitis may respond to dapsone or colchicine. Omalizumab (IgG anti IgE monoclonal antibody), not yet approved for treatment of chronic spontaneously occurring urticaria and angioedema is as effective as cyclosporine with far less toxicity and when available, will be a major therapeutic advance.

summarized in Fig. 38-10. It is important to use first-generation antihistamines at a maximal dose if nonsedating antihistamines have not been helpful before resorting to corticosteroids or cyclosporine. H_2-receptor antagonists may yield some additional histamine receptor blockade, although their contribution is usually modest. The efficacy of leucotriene antagonists is controversial, with equal numbers of pro and con articles. If steroids are used, this author recommends not exceeding 25 mg q.o.d. or 10 mg daily. With either approach, attempts to slowly taper the dose should be made every 2–3 weeks. One mg prednisone tablets can be very helpful when the daily dose is less than 10 mg. Double-blind placebo-controlled studies of cyclosporine indicate that it is a good alternative to corticosteroid,[228,229] and can be safer when used appropriately. Measurement of blood pressure, blood urea nitrogen level, and creatinine level, and a urinalysis should be done every 6–8 weeks. The starting adult dose is 100 mg bid; it can be slowly advanced to 100 mg tid, but not higher. The response rate is 75% in the autoimmune groups and 50% in the idiopathic group. No comparable studies (or clinical effects) have been obtained with dapsone, hydroxychloroquine, colchicine, sulfasalazine, or methotrexate and only small numbers cases have been treated successfully with intravenous γ globulin or plasmapheresis.[230,231] Successful treatment of chronic autoimmune urticaria has been reported with Omalizumab[232] with results comparable to that seen with cyclosporine. The rate of response can be very striking, for example, remission with a single dose. Additional articles have appeared,[233,234] although uncontrolled.

Urticarial vasculitis is treated with antihistamines and if severe, with low-dose corticosteroid. Here dapsone or hydroxychloroquine may be steroid sparing. When urticarial vasculitis is part of a systemic disease, the treatment will focus on what is needed for the underlying disorders. The drug of choice for the hypocomplementemic urticarial vasculitis syndrome (with circulating immune complexes due to IgG anti-C1q)[195] is hydroxychloroquine.[235]

Angioedema caused by ACE inhibitors can be an acute emergency with laryngeal edema or tongue or pharyngeal edema that is so extensive the patient cannot manage secretions and intubation is necessary. Supportive therapy, epinephrine, and time are needed; there is no response to antihistamines or corticosteroids. Other antihypertensive agents can be substituted, including those that block angiotensin II receptors.

Acute attacks of HAE are unresponsive to antihistaminics or corticosteroid. Epinephrine may be given but a positive response is actually uncommon. Intubation or tracheostomy may be needed when severe laryngeal edema is encountered. Recently, a preparation of C1 INH (Berinert) has been approved in the United States for intravenous infusion to treat acute attacks of HAE. It is effective and has been available and employed in Europe and Brazil for over two decades. Icatibant,[236] a bradykinin B-2 receptor antagonist, has been approved for acute treatment in Europe but not in the United States. It is given by subcutaneous injection. Kalbitor, a plasma kallikrein inhibitor (ecallantide), has been approved for the treatment of acute attacks of HAE in the United States. It too is administered by subcutaneous injection.[237] In the past, fresh frozen plasma was an option. It has been used with excellent success for years, but occasional dramatic worsening of symptoms has been reported because all the plasma factors needed for bradykinin generation are also being infused.

A second C1 INH nanofiltered preparation (Cinryze) has been approved in the United States for prophylactic treatment of AHE types I and II. It is administered by intravenous injection up to twice weekly. Prophylaxis with androgens such as Danazol (200 mg tablets) or Stanazolol (2 mg tablets)[238,239] or antifibrinolytics such as E-aminocaprioc acid or tranexamic acid[240] have been employed (used) successfully for many years.[241,242] The androgens are more commonly used—one watches for hirsutisum, irregular menses, and abnormal liver chemistries, as potential side effects. In the long term, hepatic adenomas may appear. Increased dosages may be used when a patient undergoes elective surgical procedures (e.g., 3 tablets/day for 2–3 days before the procedure, the day of the procedure, and 1 day after). Fresh frozen plasma is a safe alternative given a few hours prior to the procedure and clearly C1 INH concentrate can be used. Acquired C1 INH deficiency can be treated with low-dose androgens in addition to therapy for the underlying condition. C1 INH concentrate may be helpful but the presence of anti-C1 INH will limit responsiveness to reasonable doses. Plasmapheresis and/or cytotoxic agents may be used.

ACKNOWLEDGMENT

I wish to thank Dr Nicholas Soter who reviewed this manuscript, made many helpful suggestions, and contributed two of the photos.

Chapter 39 :: Erythema Multiforme

:: Jean-Claude Roujeau

ERYTHEMA MULTIFORME AT A GLANCE

- Rare cutaneous and/or mucocutaneous eruption characterized by target lesions.
- Benign course but frequent recurrences.
- Most cases related to herpes simplex virus (HSV) infection. Medications are not frequent causes.
- Frequent recurrences can be prevented by long-term use of anti-HSV medications. Thalidomide is usually effective in recalcitrant recurrent cases.

Erythema multiforme (EM) is an acute self-limited, usually mild, and often relapsing mucocutaneous syndrome. The disease is usually related to an acute infection, most often a recurrent herpes simplex virus (HSV) infection. EM is defined only by its clinical characteristics: target-shaped plaques with or without central blisters, predominant on the face and extremities.

The absence of specific pathology, unique cause, and biologic markers has contributed to a confusing nosology. Recent medical literature still contains an overwhelming number of figurate erythema reported as EM, and the International Classification of Diseases (ICD9) still classifies Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) under the heading of EM.

The definition of EM in this chapter is based on the classification proposed by Bastuji-Garin et al.[1] The principle of this classification is to consider SJS and TEN as severity variants of the same process, i.e., epidermal necrolysis (EN), and to separate them from EM (see Chapter 40). The validity of this classification has been challenged by some reports, especially for cases in children and cases related to *Mycoplasma pneumoniae*. It has been confirmed by several others studies however, especially the prospective international Severe Cutaneous Adverse Reactions study.[2] That study demonstrated that, compared with SJS and TEN, EM cases had different demographic features, clinical presentation, severity, and causes.

The original name proposed by von Hebra was *erythema exudativum multiforme*. The term *erythema multiforme* has now been universally accepted (Box 39-1).

EM is usually called minor when mucous membranes are spared or minimally affected, for example, lips, and majus (or major) when at least two mucosal sites are involved.

EPIDEMIOLOGY

EM is considered relatively common, but its true incidence is unknown because largely cases severe enough to require hospitalization have been reported. Such cases are in the range of 1 to 6 per million per year. Even though the minor form of EM is frequent than the major form, many other eruptions (including annular urticaria and serum sickness-like eruption) are erroneously called EM.[3]

EM occurs in patients of all ages, but mostly in adolescents and young adults. There is a slight male preponderance (male–female sex ratio of approximately 3:2). EM is recurrent in at least 30% of patients.

No established underlying disease increases the risk of EM. Infection with human immunodeficiency virus and collagen vascular disorders do not increase the risk of EM, in contrast to their increasing the risk of epidermal necrolysis. Cases may occur in clusters, which suggests a role for infectious agents. There is no indication that the incidence may vary with ethnicity or geographic location.

Predisposing genes have been reported, with 66% of EM patients having HLA-DQB1*0301 allele, compared with 31% of controls.[4] The association is even stronger in patients with herpes-associated EM. Nevertheless, the association is relatively weak, and familial cases remain rare.

ETIOLOGY

Most cases of EM are related to infections. Herpes virus is definitely the most common cause, principally in recurrent cases. Proof of causality of herpes is firmly established from clinical experience, epidemiology,[2] detection of HSV DNA in the lesions of EM,[5,6] and prevention of EM by suppression of HSV recurrences.[7] Clinically, a link with herpes can be established in about one-half of cases. In addition 10% to 40% of cases without clinical suspicion of herpes have also been shown to be herpes related, because HSV DNA was detected

BOX 39-1 ERYTHEMA MULTIFORME SUBTYPES

- Erythema multiforme minor: Skin lesions without involvement of mucous membranes
- Erythema multiforme major: Skin lesions with involvement of mucous membranes
- Herpes-associated erythema multiforme
- Mucosal erythema multiforme (Fuchs syndrome, ectodermosis pluriorificialis): Mucous membrane lesions without cutaneous involvement

in the EM lesions by polymerase chain reaction (PCR) testing.[6] EM eruptions begin on average 7 days after a recurrence of herpes. The delay can be substantially shorter. Not all symptomatic herpes recurrences are followed by EM, and asymptomatic ones can induce EM. Therefore, this causality link can be overlooked by both patients and physicians. HSV-1 is usually the cause, but HSV-2 can also induce EM. The proportion probably reflects the prevalence of infection by HSV subtypes in the population.

M. pneumoniae is the second major cause of EM and may even be the first one in pediatric cases.[8–10] In cases related to *M. pneumoniae*, the clinical presentation is often less typical and more severe than in cases associated with HSV. The relationship to *M. pneumoniae* is often difficult to establish. Clinical and radiologic signs of atypical pneumonia can be mild, and *M. pneumoniae* is usually not directly detected. PCR testing of throat swabs is the most sensitive technique. Serologic results are considered diagnostic in the presence of immunoglobulin (Ig) M antibodies or a more than twofold increase in IgG antibodies to *M. pneumoniae* in samples obtained after 2 or 3 weeks. *M. pneumoniae*-related EM can recur.[11]

Many other infections have been reported to be causes of EM in individual cases or small series, but the evidence for causality of these other agents is only circumstantial. Published reports have implicated infection with orf virus, varicella zoster virus, parvovirus B19, and hepatitis B and C viruses, as well as infectious mononucleosis and a variety of other bacterial or viral infections. Immunization has been also implicated as a cause in children.

Drugs are a rare cause of EM with mucous membrane lesions. Most literature reports of "drug-associated EM" actually deal with imitators, for example, annular urticaria[12] or maculopapular eruption with some lesions resembling targets. "EM-like" dermatitis may result from contact sensitization. These eruptions should be viewed as imitators of EM, despite some clinical and histopathologic similarities.

Idiopathic cases are those in which neither HSV infection nor any other cause can be identified. Such cases are fairly common under routine circumstances. However, HSV has been found in situ by PCR in up to 40% of "idiopathic" recurrent cases.[9] Some such cases respond to prophylactic antiviral treatment and are thus likely to have been triggered by asymptomatic HSV infection; others are resistant.

PATHOGENESIS

The underlying mechanisms have been extensively investigated for herpes-associated EM.[13] It is unknown whether similar mechanisms apply to EM due to other causes.

Complete infective HSV has never been isolated from lesions of herpes-associated EM. The presence of HSV DNA in EM lesions has been reported in numerous studies using the PCR assay. These studies have demonstrated that keratinocytes do not contain complete viral DNA, but only fragments that always include the viral polymerase (*Pol*) gene. HSV Pol DNA is located in basal keratinocytes and in lower spinous cell layers, and viral Pol protein is synthesized. HSV-specific T cells, including cytotoxic cells, are recruited, and the virus-specific response is followed by a non-specific inflammatory amplification by autoreactive T cells. The cytokines produced in these cells induce the delayed hypersensitivity-like appearance in histopathologic evaluation of biopsy sections of EM lesions.

HSV is present in the blood for a few days during an overt recurrence of herpes. If keratinocytes are infected from circulation virus, one would expect disseminated herpes, rather than EM. In fact, HSV DNA is transported to the epidermis by immune cells that engulf the virus and fragment the DNA. These cells are monocytes, macrophages, and especially $CD34^+$ Langerhans cell precursors harboring the skin-homing receptor cutaneous lymphocyte-associated (CLA) marker. Upregulation of adhesion molecules greatly increases binding of HSV-containing mononuclear cells to endothelial cells and contribute to the dermal inflammatory response. When reaching the epidermis the cells transmit the viral *Pol* gene to keratinocytes. Viral genes may persist for a few months, but the synthesis and expression of the Pol protein will last for only a few days. This may explain the transient character of clinical lesions that are likely induced by a specific immune response to Pol protein and amplified by autoreactive cells. To the best of current knowledge, the mechanisms and regulation of this immune response are different from drug reactivity leading to SJS or TEN.[14,15]

Incomplete fragmentation of viral DNA, increased number of circulating $CD34^+$ cells, and/or increased immune response to Pol protein may explain why only a small proportion of individuals with recurrent herpes infections develop EM.

CLINICAL FINDINGS

The first step is to suspect EM, based on clinical features. A skin biopsy and laboratory investigations are useful mainly if the diagnosis is not definite clinically. The second step is to determine whether hospitalization is needed when EM major (EMM) occurs with oral lesions severe enough to impair feeding, when a diagnosis of SJS is suspected, or when severe constitutional symptoms are present. The third step is to establish the cause of EM by identifying a history of recurrent herpes, performing chest radiography, or documenting *M. pneumoniae* infection (Fig. 39-1).

HISTORY

Prodromal symptoms are absent in most cases. If present, they are usually mild, suggesting an upper respiratory infection (e.g., cough, rhinitis, low-grade fever). In EMM, fever higher than 38.5°C (101.3°F) is present in one-third of cases.[2] A history of prior attack(s) is found in at least one-third of patients and thus helps with the diagnosis. The events of the preceding 3 weeks should be reviewed for clinical evidence of any precipitating agent, with a special focus on recurrent herpes.

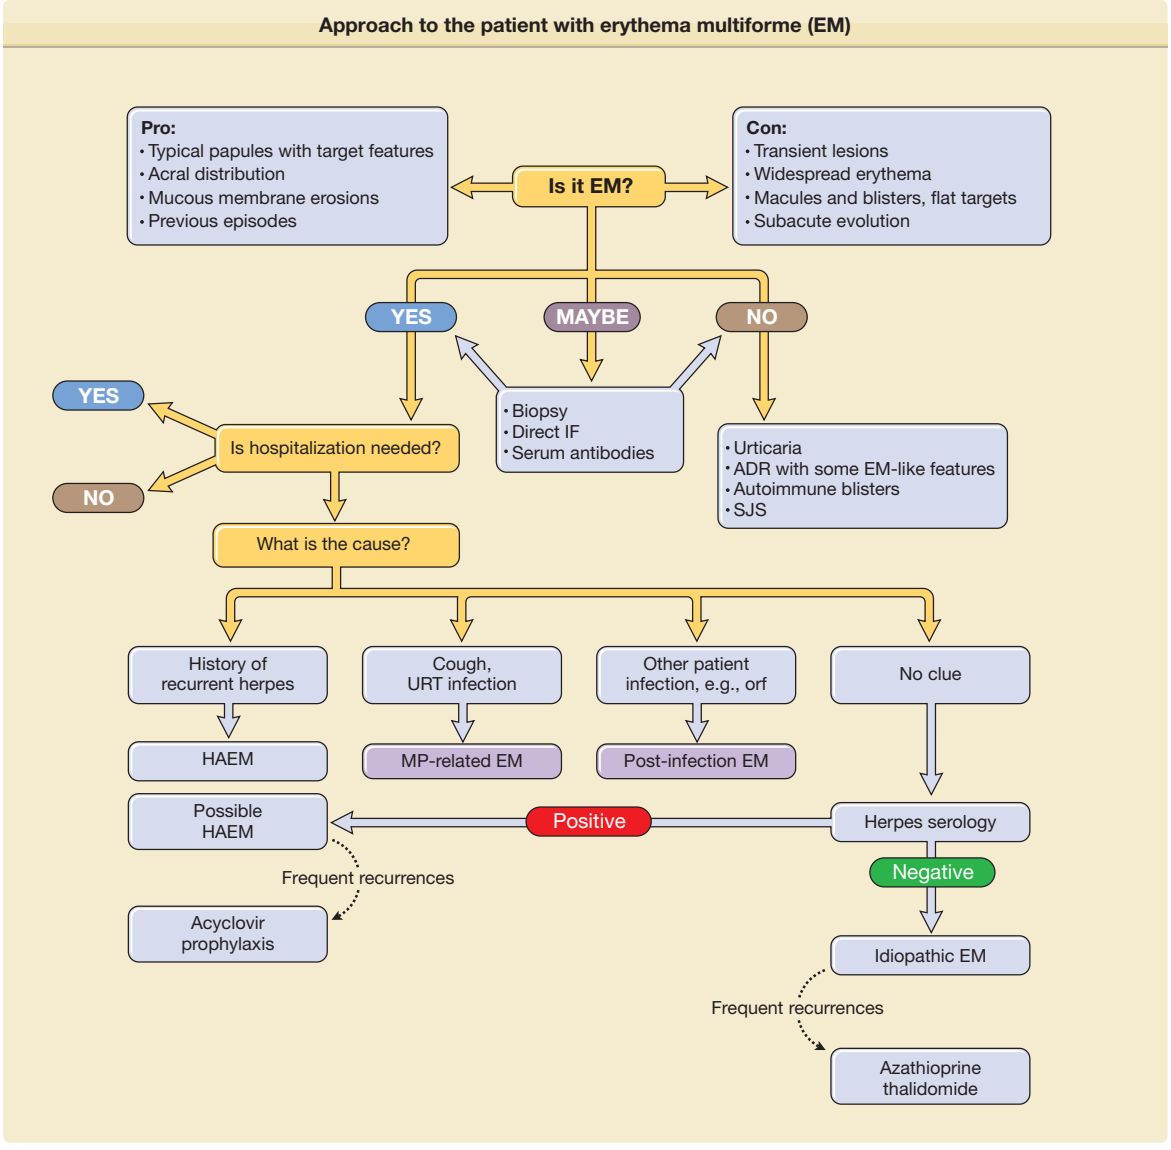

Figure 39-1 Approach to the patient with erythema multiforme (EM). ADR = adverse drug reaction; HAEM = herpes-associated erythema multiforme; IF = immunofluorescence; MP = *Mycoplasma pneumoniae*; SJS = Stevens–Johnson syndrome; URT = upper respiratory tract.

CUTANEOUS LESIONS

The skin eruption arises abruptly. In most patients, all lesions appear within 3 days, but in some, several crops follow each other during a single episode of EM. Often there are a limited number of lesions, but up to hundreds may form. Most occur in a symmetric, acral distribution on the extensor surfaces of the extremities (hands and feet, elbows, and knees), face, and neck, and less frequently on the thighs, buttocks, and trunk. Lesions often first appear acrally and then spread in a centripetal manner. Mechanical factors (Koebner phenomenon) and actinic factors (predilection of sun-exposed sites) appear to influence the distribution of lesions. Although patients occasionally report burning and itching, the eruption is usually asymptomatic.

The diversity in clinical pattern implied by the name *multiforme* is mainly due to the findings in each single lesion; most lesions are usually rather similar in a given patient at a given time. The typical lesion is a highly regular, circular, wheal-like erythematous papule or plaque that persists for 1 week or longer (Fig. 39-2). It measures from a few millimeters to approximately 3 cm and may expand slightly over 24 to 48 hours. Although the periphery remains erythematous and edematous, the center becomes violaceous and dark; inflammatory activity may regress or relapse in the center, which gives rise to concentric rings of color (see Fig. 39-2). Often, the center turns purpuric and/or necrotic or transforms into a tense vesicle or bulla. The result is the classic target or iris lesion.

According to the proposed classification, typical target lesions consist of at least three concentric components: (1) a dusky central disk, or blister; (2) more peripherally, an infiltrated pale ring; and (3) an

Figure 39-2 Mixture of typical targets and papules in a case of EM minor

erythematous halo. Not all lesions of EM are typical; some display two rings only ("raised atypical targets"). However, all are papular, in contrast with macules, which are the typical lesions in epidermal necrolysis (SJS–TEN). In some patients with EM, most lesions are livid vesicles overlying a just slightly darker central portion, encircled by an erythematous margin (Figs. 39-3–39-5, Fig. 39-8). Larger lesions may have a central bulla and a marginal ring of vesicles (herpes iris of Bateman) (Figs. 39-6 and 39-7).

Unusual presentations include cases in which recurrent EM in the same patient produces typical target lesions in one instance but plaques in a subsequent event. Mucous membranes can be severely involved in some episodes and spared in others (see section "Mucous Membrane Lesions").

Figure 39-3 Typical target lesions on the palm.

Figure 39-4 Late lesions of EM with nonspecific blisters and erosions but target shapes still visible.

In most cases, EM affects well under 10% of the body surface area. In 88 hospital cases of EMM prospectively included in the Severe Cutaneous Adverse Reactions study, the median involvement was 1% of the body surface area.[2] Very rare instances of extensive skin lesions with "giant" targets and prominent involvement of several mucous sites may be difficult to distinguish from SJS.

The duration of an individual lesion is shorter than 2 weeks, but residual discoloration may remain for months. There is no scarring.

MUCOUS MEMBRANE LESIONS

Mucosal lesions are present in up to 70% of patients, most often limited to the oral cavity.

Figure 39-5 Typical targets around the knee.

Figure 39-6 Giant targets in a case of recurrent EMM associated to recurrent *Mycoplasma pneumoniae* infection.

Figure 39-7 Multiple concentric vesicular rings (herpes iris of Bateman). This pattern may be more frequent in *Mycoplasma pneumoniae*-related cases of erythema multiforme major.

Figure 39-8 Unusual location of EM.

Predilection sites for mucosal lesions are the lips (eFig. 39-7.1 in online edition), on both cutaneous and mucosal sides, nonattached gingivae, and the ventral side of the tongue. The hard palate is usually spared, as are the attached gingivae. On the cutaneous part of the lips, identifiable target lesions may be discernible (see Fig. 39-9). On the mucosa proper there are erosions with fibrinous deposits, and occasionally intact vesicles and bullae can be seen (Fig. 39-10). The process may rarely extend to the throat, larynx, and even the trachea and bronchi.

Eye involvement begins with pain and bilateral conjunctivitis in which vesicles and erosions can occur (Fig. 39-11).

The nasal, urethral, and anal mucosae also may be inflamed and eroded.

Figure 39-9 Erythema multiforme major. Involvement of the lips with a target pattern.

Figure 39-10 Erythema multiforme major (EMM). Mouth lesions of EMM usually manifest as erosions.

Ectodermosis pluriorificialis (synonym Fuchs syndrome) is a rare occurrence characterized by severe involvement of two or three mucosal sites in the absence of skin lesions. Its often relapsing nature suggests that it is HSV related. Moreover, typical target lesions may arise on the skin with new attacks.

RELATIONSHIP TO RECURRENT HERPES

In more than 70% of patients with recurrent EM, an episode of recurrent HSV infection precedes the rash; the association with herpes labialis predominates over that with genital herpes or herpes in other locations. EM usually follows recurrent herpes but may also occur after primary HSV infection. The average interval is 7 days (range, 2 to 17 days); the duration of the lag period appears to be specific for individual patients. In a small number of patients, HSV recrudescence and EM may occur simultaneously. Not all episodes of EM are preceded by clinically evident HSV infection, and not all HSV episodes are followed by EM. Episodes of recurrent HSV infection may precede the development of HSV-related EM by many years.

Figure 39-11 Erythema multiforme major. Eye lesions. Conjunctivitis with erosions.

RELATED PHYSICAL FINDINGS

Fever and other constitutional symptoms are usually absent in EM minor, and the physical examination is normal. Fever higher than 38.5°C (101.3°F) is present in 32% of cases of EMM. Mouth erosions may be very painful and may impair alimentation. The patient may be unable to close the mouth and may constantly drool bloodstained saliva. Cervical lymphadenopathy is usually present in these patients. The pain of genital erosions may lead to reflex urinary retention. Cough, polypnea, and hypoxia may occur in *M. pneumoniae*-related cases.

LABORATORY FINDINGS

HISTOPATHOLOGIC ANALYSIS

Early lesions of EM exhibit lymphocyte accumulation at the dermal–epidermal interface, with exocytosis into the epidermis, lymphocytes attached to scattered necrotic keratinocytes (satellite cell necrosis), spongiosis, vacuolar degeneration of the basal cell layer, and focal junctional and subepidermal cleft formation (eFig. 39-11.1 in online edition). The papillary dermis may be edematous but principally contains a dense mononuclear cell infiltrate, which is more abundant in older lesions. The vessels are ectatic with swollen endothelial cells; there may be extravasated erythrocytes and eosinophils. Immunofluorescence findings are negative or nonspecific. In advanced lesions subepidermal blister formation may occur, but necrosis rarely involves the entire epidermis (see eFig. 39-11.2 in online edition). In late lesions, melanophages may be prominent.

The histopathologic appearance of EM lesions is different from that of SJS–TEN lesions, in which dermal inflammation is moderate to absent and epidermal necrosis much more pronounced (see Chapter 40). Still, the histopathologic appearances are somewhat overlapping and do not allow the distinction of EM from SJS–TEN in all instances. The main reason for performing a biopsy in EM is to rule out other diagnoses, for example, autoimmune blistering diseases, Sweet syndrome, and vasculitis.

OTHER LABORATORY TESTS

There are no specific laboratory tests for EM. In more severe cases, an elevated erythrocyte sedimentation rate, moderate leukocytosis, increased levels of

acute-phase proteins, and mildly elevated liver aminotransferase levels may occur. In the presence of respiratory symptoms a chest radiograph is needed, and documentation of *M. pneumoniae* infection by PCR assay of a throat swab and serologic testing (a pair at a 2- or 3-week interval) should be sought. Investigations to document causality are important in cases with frequent recurrences when prevention with long-term antiviral treatment is considered and when there is no clinical evidence of association with herpes. HSV can rarely still be isolated from the initial lesion of labial herpes. Amplification of HSV *Pol* gene from biopsy samples of EM lesions is not done routinely. A negative result on serologic testing for HSV may be helpful to exclude the possibility of herpes-associated EM. The positive predictive value of the presence of HLA-DQB1*0301 is too low to have any clinical value.

DIFFERENTIAL DIAGNOSIS

(Table 39-1)

In a retrospective analysis of 66 pediatric cases discharged from hospital with a diagnosis of EM 24 (36%) were clearly not EM.[8] Diseases that had been frequently erroneously called EM were urticaria (eFig. 39-11.3 in online edition) and maculopapular drug eruption (Fig. 39-12).[8,15]

The designation of *Rowell syndrome*[16,17] is used for a variety of cutaneous lupus erythematosus with often erosive circinate lesions resembling those of EM. Subacute evolution, a positive result on direct fluorescence testing, and the presence of antinuclear antibodies exclude EM.

Sweet syndrome can mimic EM minor; biopsy easily distinguishes the two.

Paraneoplastic pemphigus and more rarely other autoimmune blistering diseases occasionally present with target-like lesions that can be confused with those of EM (Figs. 39-13 and eFig. 39-14 in online edition).

Original cases were reported as EMM with anti-desmoplakin antibodies.[18] Clinical features resemble EMM in their acute and recurrent course, but the presence of acantholysis, deposits of IgG around basal cells, and serum antibodies against desmoplakin distinguish such cases from EM.

Better considered a separate disease, SJS should be recognized promptly for three reasons: (1) the possibility of life-threatening complications, (2) the risk of progression to TEN, and (3) the need for urgent withdrawal of suspected causative drug(s) (see Chapter 40). Pain, constitutional symptoms, severe erosions of mucosae, rapid progression, and dusky or violaceous skin lesions are alerting features.

In rare cases of EM affecting only mucous membranes, the diagnosis is especially difficult and often made when further bouts include a few skin lesions. In such cases, pemphigus, cicatricial pemphigoid, allergic or toxic contact stomatitis, toxic erosive stomatitis, aphthous lesions, and lichen planus should be considered.

COURSE AND COMPLICATIONS

EM runs a mild course in most cases, and each individual attack subsides within 1 to 4 weeks. Recovery is

TABLE 39-1
Differential Diagnosis of Erythema Multiforme (EM)

	Mucous Membrane Lesions	Clinical Pattern	Pathologic Findings	Laboratory Testing	Course
Urticaria	No	Circinate, transient	Edema		More acute than EM
Maculopapular drug eruption	Rare (lips)	Widespread polymorphous target-like lesions, macules, papules, plaques	Most often nonspecific		
Lupus (Rowell syndrome)	Possible (mouth)	Face and thorax Large target-like lesions, annular plaques	Interface dermatitis Positive result on DIF ("lupus band")	Antinuclear antibodies present	Subacute
Paraneoplastic pemphigus	Constant; always early and severe	EM-like lesion plus lichenoid papules Positive Nikolsky sign	Acantholysis Positive result on DIF	Antibodies present	Chronic
Cicatricial pemphigoid	Constant	Circinate erythematous patches	Subepidermal blister, Positive result on DIF	Antibodies present	Chronic
Antidesmoplakin "EM major"	Constant	EM-like lesions	Basal acantholysis Positive result on DIF	Antibodies present	Acute relapsing
Stevens–Johnson syndrome	Constant	Widespread small blisters Atypical targets Constitutional symptoms	Interface dermatitis Epidermal necrosis		Acute

DIF = direct immunofluorescence testing.

Figure 39-12 Figurate erythema in a cases of "drug eruption" to amoxicillin. Commonly and erroneously reported as drug-induced EM.

complete, and there are usually no sequelae, except for transient discoloration in some cases.

In rare instances the ocular erosions of EMM may cause severe residual scarring of the eye. *M. pneumoniae*-related EMM may be associated with severe erosive bronchitis that may rarely lead to sequelae.

Recurrences are common and may characterize the majority of cases. In reports of large series of patients with recurrent EM, the mean number of attacks was 6 per year (range, 2 to 36), and the mean total duration of disease was 6 to 9 years. In 33%, the condition persisted for more than 10 years.[19,20] Up to 50 recurrences have been described in a single patient. The severity of episodes in patients with recurrent EM is highly variable and unpredictable. The frequency of episodes and cumulative duration of disease are not correlated with the severity of attacks. The frequency and severity of recurrent EM tend to decrease spontaneously over time (after 2 years or longer), parallel with the improvement of recurring HSV infection when it is the cause. In a substantial proportion of recurrent cases a cause cannot be determined.[20] A small fraction of patients experience a prolonged series of overlapping attacks of EM; this has been labeled *continuous EM* or *persistent EM*.[19]

TREATMENT

The aims of treatment are to reduce the duration of fever, eruption, and hospitalization. Based on retrospective series or small controlled trials, the use of systemic corticosteroids seems to shorten the duration of fever and eruption, but may increase the length of hospitalization because of complications. However, the methodology of most studies was poor, with small series often mixing the various forms of idiopathic and virus-associated EM and drug-induced SJS. The use of systemic corticosteroids cannot be recommended.[21]

Figure 39-13 Figurate blisters, in a case of linear IgA blistering disease.

Several series indicate that administering anti-HSV drugs for the treatment of established episodes of postherpetic EM is useless. When symptomatic, *M. pneumoniae* infection should be treated with antibiotics (macrolides in children, macrolides or quinolone in adults). There is no evidence indicating whether it improves the evolution of the associated EM. Therefore, when asymptomatic infection is suggested by serologic testing, treatment is not mandatory.

Liquid antacids, topical glucocorticoids, and local anesthetics relieve symptoms of painful mouth erosions.

PREVENTION

Continuous therapy with oral anti-HSV drugs (see Chapter 231) is effective to prevent recurrences of herpes-associated EM with or without clinical evidence that herpes is the precipitating factor.[7] Topical acyclovir therapy used in a prophylactic manner does not prevent recurrent herpetic EM.

In a series of 65 patients with recurrent EM, 11 were treated with azathioprine when all other treatments had failed. Azathioprine was beneficial in all 11 patients.[19] Mycophenolate mofetil can be also useful.[20]

Retrospective uncontrolled analyses of thalidomide therapy have indicated that it is moderately effective for the treatment of EM.[22] However, thalidomide is probably the most effective treatment of recurrent/persistent cases when resistant to anti-HSV drugs.

In one randomized controlled trial, levamisole appeared useful. Because agranulocytosis is a severe and not exceptional adverse effect, levamisole use is permitted in only a few countries. The benefit–risk ratio is probably too low to support its use in the treatment of EM.

Chapter 40 :: Epidermal Necrolysis (Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis)

:: L. Valeyrie-Allanore & Jean-Claude Roujeau

EPIDERMAL NECROLYSIS AT A GLANCE

- Rare and life-threatening reaction, mainly drug induced.
- Widespread apoptosis of keratinocytes provoked by the activation of a cell-mediated cytotoxic reaction and amplified by cytokines, mainly granulysin.
- Confluent purpuric and erythematous macules evolving to flaccid blisters and epidermal detachment predominating on the trunk and upper limbs and associated with mucous membrane involvement.
- Pathologic analysis shows full-thickness necrosis of epidermis associated with mild mononuclear cell infiltrate.
  - A dozen "high-risk" drugs account for one half of cases.
  - Up to 20% of cases remain idiopathic.
- Early identification and withdrawal of suspect drugs are essential for good patient outcome.
- Treatment is mainly symptomatic.
  - Sequelae are nearly constant, needing systematic follow-up examinations.

Toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS) are acute life-threatening mucocutaneous reactions characterized by extensive necrosis and detachment of the epidermis. Stevens and Johnson first reported two cases of disseminated cutaneous eruptions associated with an erosive stomatitis and severe ocular involvement.[1] In 1956, Lyell described patients with epidermal loss secondary to necrosis and introduced the term *toxic epidermal necrolysis*.[2] Both SJS and TEN are characterized by skin and mucous membrane involvement. Because of the similarities in clinical and histopathologic findings, risk factors, drug causality, and mechanisms, these two conditions are now considered severity variants of an identical process that differs only in the final extent of body surface involved.[3–5] Therefore, it is better to use the designation *epidermal necrolysis* for both, as proposed by Ruiz-Maldonado (acute disseminated epidermal necrosis)[6] and Lyell (exanthematic necrolysis).[7]

EPIDEMIOLOGY

Epidermal necrolysis (EN) is rare. The overall incidence of SJS and TEN was estimated at 1 to 6 cases per million person-years and 0.4 to 1.2 cases per million person-years, respectively.[8,9] EN can occur at any age, with the risk increasing with age after the fourth decade, and more frequently affects women, showing a sex ratio of 0.6. Patients infected with human immunodeficiency virus and to a lesser degree patients with collagen vascular disease and cancer are at increased risk.[10–12] The overall mortality associated with EN is 20% to 25%, varying from 5% to 12% for SJS to more than 30% for TEN. Increasing age, significant comorbidity, and greater extent of skin involvement correlate with poor prognosis. In the United States, evaluation

TABLE 40-1
SCORTEN: A Prognostic Scoring System for Patients with Epidermal Necrolysis

SCORTEN	
Prognostic Factors	**Points**
■ Age >40 years	1
■ Heart rate >120 beats/minute	1
■ Cancer or hematologic malignancy	1
■ Body surface area involved >10%	1
■ Serum urea level >10 mM	1
■ Serum bicarbonate level >20 mM	1
■ Serum glucose level >14 mM	1
SCORTEN	**Mortality Rate (%)**
0–1	3.2
2	12.1
3	35.8
4	58.3
5	90

of death certificates suggested a seven time higher risk of dying from EN among blacks than whites.[13]

A prognosis score (SCORTEN) has been constructed for EN,[14] and its usefulness has been confirmed by several teams.[15–18] (See Table 40-1.)

ETIOLOGY

The pathophysiology of EN is still unclear; however, drugs are the most important etiologic factors. More than 100 different drugs have been implicated,[19–21] but fewer than a dozen "high-risk" medications account for about one half of cases in Europe (Table 40-2), as evidenced by two multinational case–control studies.[12,22–25] These high-risk drugs are antibacterial sulfonamides, aromatic anticonvulsants, allopurinol, oxicam nonsteroidal anti-inflammatory drugs, lamotrigine, and nevirapine.[26–27] The risk seems confined to the first 8 weeks of treatment. Slow dose escalation decreases the rate of rash with lamotrigine and nevirapine,[28,29] but there is no evidence that it decreases the risk of EN.[26] Oxcarbazepine, a 10-keto derivative of carbamazepine, which was considered to carry a lower risk, seems to significantly cross-react with carbamazepine.[30] Many nonsteroidal anti-inflammatory drugs (primarily oxicam derivatives and diclofenac) were suspected to be associated with EN.[12,31,32] A significant but much lower risk has also been reported for non-sulfonamide antibiotics such as aminopenicillins, quinolones, cephalosporins, and tetracyclines.[22]Corticosteroids were significantly associated with a high relative risk, but confounding was not excluded.[22]

The role of infectious agents in the development of EN is much less prominent than for erythema multiforme. However, cases of EN associated with *Mycoplasma pneumoniae* infection, viral disease, and immunization have been reported, particularly in children.[33,34] These rare observations underscore the fact that medications are not the only cause of EN, but there is still little evidence that infections can explain more than a very small percentage of cases.

Cases of EN have been reported after bone marrow transplantation. Some are an extreme form of acute graft-versus-host disease (see Chapter 28); others could be drug induced. The relationship between EN and graft-versus-host disease is difficult to assess because clinical and histological skin features are nearly indistinguishable.[35] Lupus erythematosus (systemic LE or subacute cutaneous LE) is associated with an increased risk of EN.[12,22] In such cases, drug causality is often doubtful and necrolysis might be an extreme phenotype of cutaneous lupus.[36] Finally, radiotherapy in addition to treatment with antiepileptic drugs, such as phenytoin, phenobarbital, or carbamazepine, can trigger EN with lesions localized predominantly at sites of radiation treatment.[37,38] In

TABLE 40-2
Medications and the Risk of Epidermal Necrolysis

High Risk	Lower Risk	Doubtful Risk	No Evidence of Risk
Allopurinol	Acetic acid NSAIDs (e.g., diclofenac)	Paracetamol (acetaminophen)	Aspirin
Sulfamethoxazole	Aminopenicillins	Pyrazolone analgesics	Sulfonylurea
Sulfadiazine	Cephalosporins	Corticosteroids	Thiazide diuretics
Sulfapyridine	Quinolones	Other NSAIDs (except aspirin)	Furosemide
Sulfadoxine	Cyclins	Sertraline	Aldactone
Sulfasalazine	Macrolides		Calcium channel blockers
Carbamazepine			β Blockers
Lamotrigine			Angiotensin-converting enzyme inhibitors
Phenobarbital			Angiotensin II receptor antagonists
Phenytoin			Statins
Phenylbutazone			Hormones
Nevirapine			Vitamins
Oxicam NSAIDs			
Thiacetazone			

NSAIDs = nonsteroidal anti-inflammatory drugs.

clinical practice, the causality of a medication can be clearly established in approximately 60% of cases and suspected in 20%. Other causes (infection, GVH, LE) are rarely apparent, about 20% of cases as idiopathic.[39]

PATHOGENESIS

Even if the precise sequence of molecular and cellular events is incompletely understood, several studies provided important clues to the pathogenesis of EN. The immunologic pattern of early lesions suggests a cell-mediated cytotoxic reaction against keratinocytes leading to massive apoptosis.[39–41] Immunopathologic studies have demonstrated the presence within early lesions of cytotoxic cells including natural killer T cells (NKT) and drug-specific $CD8^+$ T lymphocytes; monocytes/macrophages and granulocytes are also recruited.[42–44] However, it is generally accepted that specific and nonspecific cytotoxic cells are too few within the lesions to explain the death of cells on the full thickness and large areas of the epidermis and mucous membranes. Amplification by cytokines has been suspected for years, especially for factors activating "death receptors" on cell membranes, especially antitumor necrosis factor (TNF) α and soluble Fas ligand (Fas-L).[42,45] In the past decade it had been widely accepted that Fas-L was inducing the apoptosis of keratinocytes in EN,[45,46] despite partial evidence and discordant findings.[47–49] An important recent study has challenged this dogma by demonstrating the key role in EN of granulysin.[50] Granulysin was present in the blister fluid of EN at concentrations much higher than those of perforin, granzyme B, or Fas-L. At such concentrations, only granulysin, and to a much lesser degree perforin, were able to kill human keratinocytes in vitro; Fas-L was not. Furthermore injection of granulysin in the dermis of normal mice resulted in clinical and histological lesions of EN.[50]

When combined, the above results strongly suggest that the effector mechanisms of EN have been deciphered. Cytotoxic T-cells develop and are usually specifically directed against the native form of the drug rather than against a reactive metabolite, contrarily to what has been postulated for 20 years. These cells kill keratinocytes directly and indirectly through the recruitment of other cells that release soluble death mediators, the principal being granulysin.[50,51]

These advances on understanding the final steps of the reaction point to inhibition of release and/or blockade of granulysin as major aims of therapeutic interventions.

Little is known on what are the initial and intermediate steps. We still do not understand why very few individuals develop a violent immune response to medications and why effector cells are especially directed to the skin and other epithelia. Actually, most drugs associated with a "high risk" for EN can also induce a variety of milder and more frequent reactions. Drug-specific CD8 cytotoxic T-lymphocytes were also often found in skin reactions with more benign phenotype.[52] Hence, it is tempting to speculate on an abnormal regulation of immune response. Regulatory $CD4^+$ $CD25^+$ T cells have been demonstrated to be potentially important in the prevention of severe epidermal damage induced by reactive cytotoxic T lymphocytes in a mouse model of EN.[53] Similar regulatory cells may play a role in drug eruptions in humans.[54] Altered regulation of the immune response to medications in patients with EN could result from comorbidities that are frequent, for example, cancer, HIV infection, collagen vascular disease; from comedications, for example, corticosteroids; or from genetic background.

Genetic susceptibility plays an important role in the development of EN to a few "high-risk" medications. A strong association was observed in Han Chinese from Taiwan between the human leukocyte antigen HLA-B*1502 and EN induced by carbamazepine, and between HLA-B*5801 and EN induced by allopurinol.[55,56] B*1502 association with carbamazepine-related cases was confirmed in several Asian countries,[57,58] with the remarkable exceptions of Japan and Korea.[59,60] The association between carbamazepine-induced EN and HLA-B*1502 was not present in European patients who do not have Asian ancestry.[61] On the other hand, HLA-B*5801 was confirmed to be associated with allopurinol-related EN in Japan[59] and Europe,[62] but the strength of association was lower than in Taiwan.

CLINICAL FINDINGS

Even in cases requiring immediate referral to specialized wards, the dermatologist will have a specific role in the management of patients with EN (Fig. 40-1).

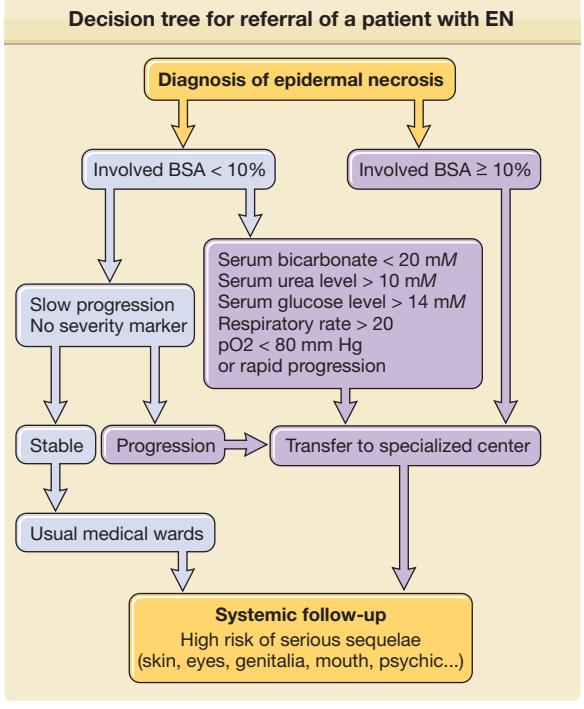

Figure 40-1 Decisional tree for referral of a patient with EN. (Adapted from Ellis MW: A case report and a proposed algorithm for the transfer of patients with Stevens-Johnson syndrome and toxic epidermal necrolysis to a burn center. *Mil Med* **167**:701, 2002)

HISTORY

EN clinically begins within 8 weeks (usually 4 to 30 days) after the onset of drug exposure for the first time. Only in very rare cases with prior reaction and inadvertent rechallenge with the same drug does it appear more rapidly, within a few hours. Nonspecific symptoms such as fever, headache, rhinitis, cough, or malaise may precede the mucocutaneous lesions by 1 to 3 days. Pain on swallowing and burning or stinging of the eyes progressively develop, heralding mucous membrane involvement. About one-third of cases begin with nonspecific symptoms, one-third with symptoms of mucous membrane involvement, and one-third with an exanthema. Whatever the initial symptoms are, their rapid progression, the addition of new signs, severe pain, and constitutional symptoms should alert one to the onset of a severe disease.

CUTANEOUS LESIONS

The eruption is initially symmetrically distributed on the face, the upper trunk, and the proximal part of limbs.[63] The distal portions of the arms as well as the legs are relatively spared, but the rash can rapidly extend to the rest of the body within a few days and even within a few hours. The initial skin lesions are characterized by erythematous, dusky red, purpuric macules, irregularly shaped, which progressively coalesce. Atypical target lesions with dark centers are often observed (Fig. 40-2A). Confluence of necrotic lesions leads to extensive and diffuse erythema. Nikolsky's sign, or dislodgement of the epidermis by lateral pressure, is positive on erythematous zones (Fig. 40-3 and eFig. 40-3.1 in online edition). At this stage, the lesions evolve to flaccid blisters, which spread with pressure and break easily (see Fig. 40-2B). The necrotic epidermis is easily detached at pressure points or by frictional trauma, revealing large areas of exposed, red, sometimes oozing dermis (see Figs. 40-2C and 40-2D). In other areas, epidermis may remain.

Patients are classified into one of three groups according to the total area in which the epidermis is detached or "detachable" (positive Nikolsky): (1) SJS, less than 10% of body surface area (BSA); (2) SJS/TEN overlap, between 10% and 30%; (3) TEN, more than 30% of BSA (eFig. 40-3.2 in online edition). Correct evaluation of the extent of lesions is difficult, especially in zones with spotty lesions. It is helpful to remember that the surface of one hand (palm and fingers) represents a little less than 1% of the BSA.

MUCOUS MEMBRANE INVOLVEMENT

Mucous membrane involvement (nearly always on at least two sites) is observed in approximately 90% of cases and can precede or follow the skin eruption. It begins with erythema followed by painful erosions of the oral, ocular, and genital mucosa. This usually leads to impaired alimentation, photophobia, conjunctivitis, and painful micturition. The oral cavity and the vermilion border of the lips are almost invariably affected and feature painful hemorrhagic erosions coated by grayish white pseudomembranes and crusts of the lips (Fig. 40-4). Approximately 80% of patients have conjunctival lesions,[64,65] mainly manifested by pain, photophobia, lacrimation, redness, and discharge. Severe forms may lead to epithelial defect corneal ulceration, anterior uveitis, and purulent conjunctivitis. Synechiae between eyelids and conjunctiva often occur. There may be shedding of eyelashes (see Fig. 40-4B). Genital erosions are frequent, often overlooked in women, and may lead to synechiae.[66]

Shedding of nails occurs in severe forms.

EXTRACUTANEOUS SYMPTOMS

EN is associated with high fever, pain, and weakness. Visceral involvement is also possible, particularly with pulmonary and digestive complications. Early pulmonary complications occur in approximately 25% of patients and are essentially manifested by elevated respiratory rate and cough, which should prompt strict surveillance.[67,68] Bronchial involvement in EN is not correlated with the extent of skin lesions or with the offending agent. In most cases chest radiographs are normal on admission but can rapidly reveal interstitial lesions that can progress to acute respiratory distress syndrome (ARDS). In all reported cases, when acute respiratory failure developed rapidly after the onset of skin involvement, it was associated with poor prognosis. In the case of respiratory abnormalities, fiberoptic bronchoscopy may be useful to distinguish a specific epithelial detachment in the bronchi from an infectious pneumonitis, which has a much better prognosis.

Gastrointestinal tract involvement is less commonly observed, with epithelial necrosis of the esophagus, small bowel, or colon manifesting as profuse diarrhea with malabsorption, melena, and even colonic perforation.[69,70] Renal involvement has been reported. Proteinuria, microalbuminuria, hematuria, and azotemia are not rare. Proximal tubule damage can result from necrosis of tubule cells by the same process that destroys epidermal cells.[71] Glomerulonephritis is rare.[72]

LABORATORY TESTS

LABORATORY VALUES

There is no laboratory test to support the diagnosis of EN. Laboratory examinations are essential to evaluation of severity and daily management as for all life-threatening conditions in intensive care units.

Evaluation of respiratory rate and blood oxygenation are among the first steps to take in the emergency room. Any alteration should be checked through measurement of arterial blood gas levels. Serum bicarbonate levels below 20 mM indicate a poor prognosis.[14]

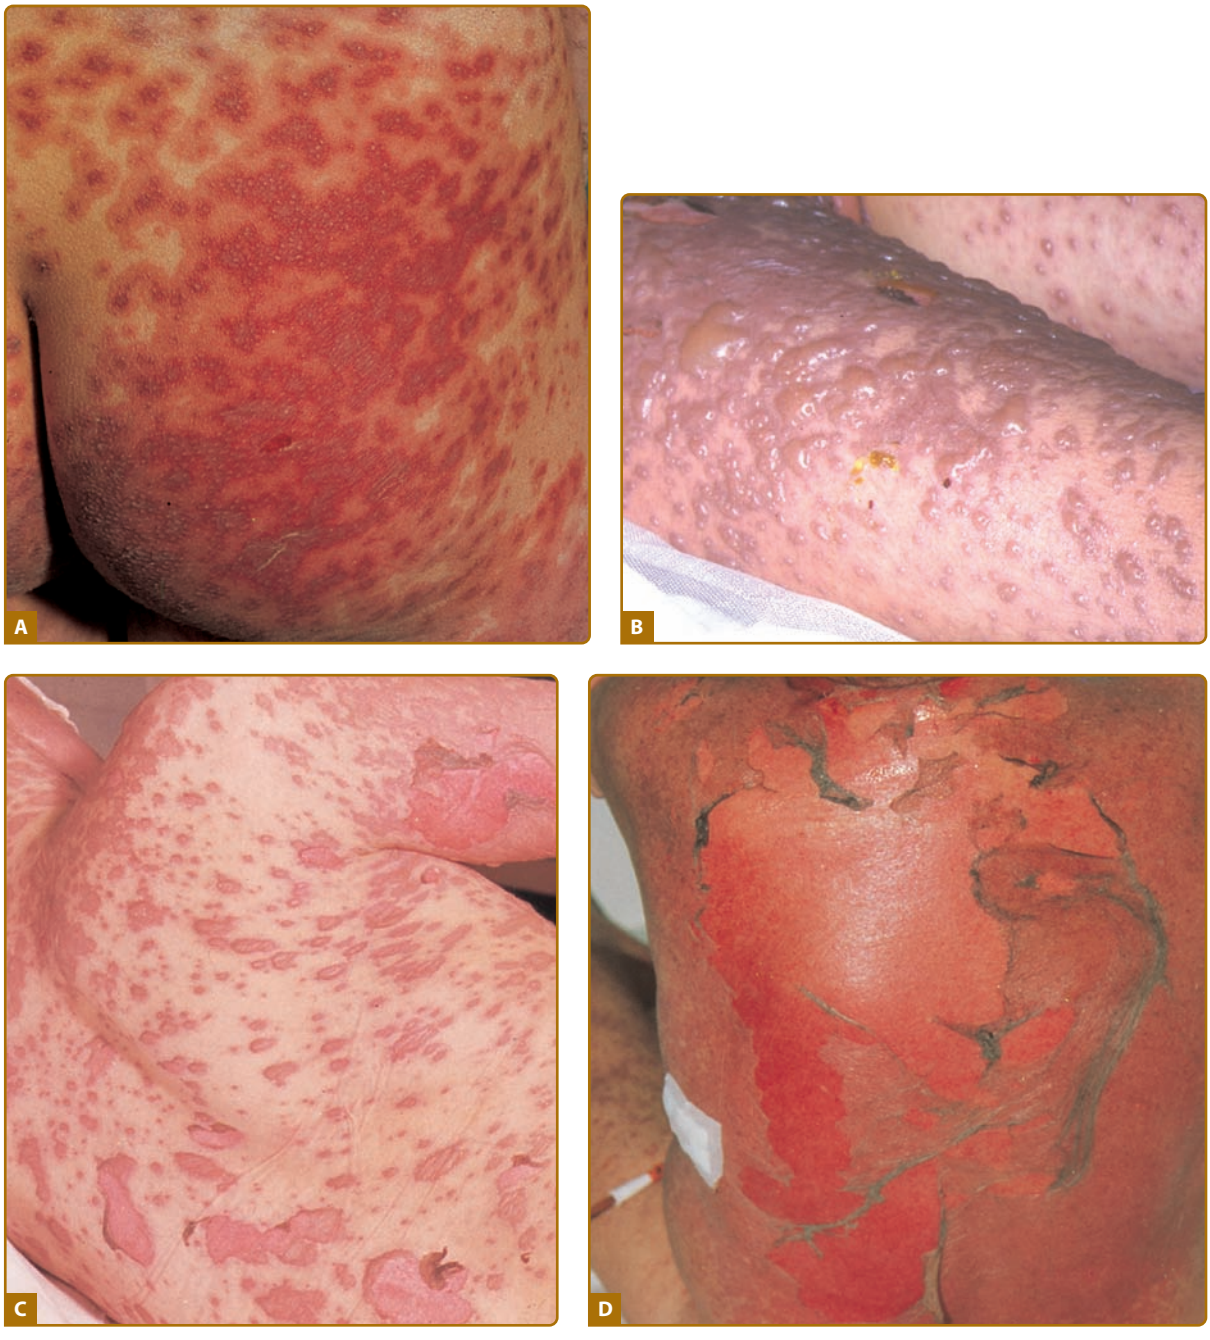

Figure 40-2 **A.** Early eruption. Erythematous dusky red macules (flat atypical target lesions) that progressively coalesce and show epidermal detachment. **B**. Early presentation with vesicles and blisters, note the dusky color of blister roofs, strongly suggesting necrosis of the epidermis. **C.** Advanced eruption. Blisters and epidermal detachment have led to large confluent erosions. **D.** Full-blown epidermal necrolysis characterized by large erosive areas reminiscent of scalding.

They usually result from respiratory alkalosis related to the specific involvement of bronchi and more rarely from metabolic acidosis.

Massive transdermal fluid loss is responsible for electrolyte imbalances, hypoalbuminemia, and hypoproteinemia, and mild and transient renal insufficiency and prerenal azotemia are common. Raised blood urea nitrogen level is one marker of severity. Anemia is usual, and mild leukocytosis as well as thrombocytopenia may occur. Neutropenia is often considered to be an unfavorable prognostic factor but is too rare to have a significant impact on SCORTEN. Transient peripheral $CD4^+$ lymphopenia is nearly always seen and is associated with decreased T-cell function. Mild elevation in levels of hepatic enzymes and amylase (most probably of salivary origin) are frequent but without impact on prognosis. A hypercatabolic state is responsible for inhibition of insulin secretion or insulin resistance, which results in hyperglycemia and occasionally overt diabetes. A blood glucose level above 14 mM is

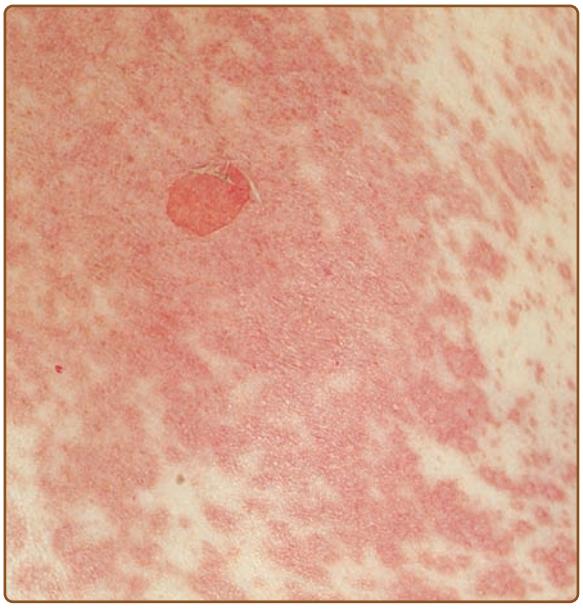

Figure 40-3 Early exanthematous phase with Nikolsky's sign.

one marker of severity.[14] Other abnormalities in laboratory values may occur, indicating involvement of other organs and complications such as sepsis.

HISTOPATHOLOGY

Skin biopsy for routine histologic and possibly immunofluorescence studies should be strongly considered, especially if there are alternative diagnoses to consider. In the early stages, epidermal involvement is characterized by sparse apoptotic keratinocytes in the suprabasal layers, which rapidly evolves to a full-thickness necrosis and subepidermal detachment (Fig. 40-5). Apoptosis of epithelial cells may involve sweat glands and hair follicles. A moderately dense mononuclear cell infiltrate of the papillary dermis is observed, mainly represented by lymphocytes, often $CD8^+$ and macrophages.[73,74] Eosinophils seems to be less common in patients with the most severe form of EN. Results of direct immunofluorescence study are negative. Histopathology of involved mucous membranes, rarely performed, would show similar alterations.[75]

DIFFERENTIAL DIAGNOSIS

(Box 40-1)

Milder presentations of EN must be distinguished from erythema multiforme minor (EMM) (see Chapter 39). Early EN cases are often initially diagnosed as varicella. The rapid progression of skin lesions and the severity of mucous membrane involvement should raise the probability of EN.

The absence of mucous membrane involvement or its restriction to a single site must always raise the suspicion of an alternative diagnosis: staphylococcal scalded skin syndrome in infants; purpura fulminans in children and young adults; acute generalized exanthematous pustulosis, phototoxicity, or pressure blisters in adults. Thermal burns or scalding are occasionally an issue when a transient loss of consciousness occurs.

Linear immunoglobulin (Ig) A bullous disease and paraneoplastic pemphigus present with a less acute progression. Pathologic findings and a positive result on direct immunofluorescence testing are important for these diagnoses.

In all aspects, including pathology, generalized bullous fixed drug eruption (GBFDE) resembles EN. It

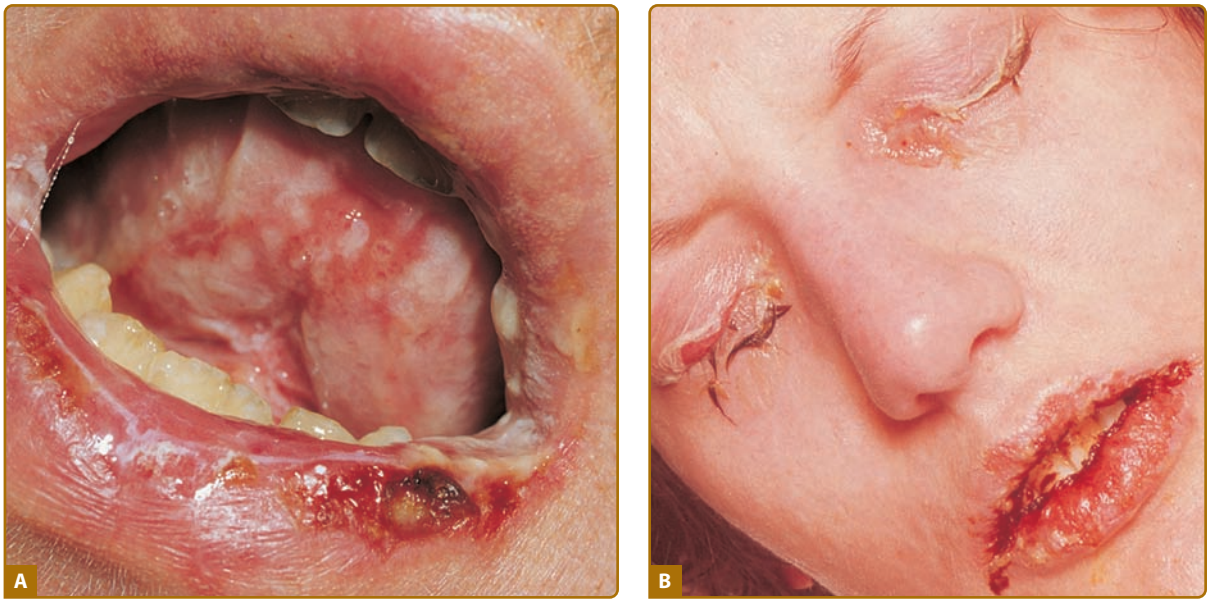

Figure 40-4 **A.** Extensive erosions and necroses of the lower lip and oral mucosa. **B.** Massive erosions covered by crusts on the lips. Note also shedding of eyelashes.

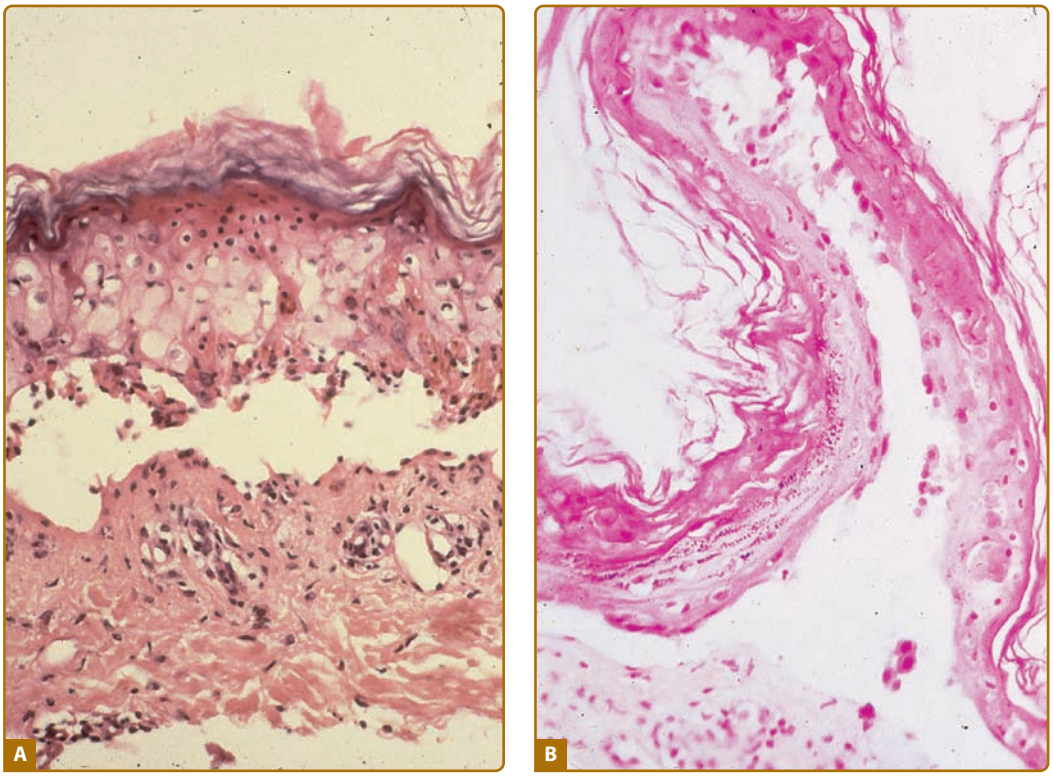

Figure 40-5 Histologic appearance of toxic epidermal necrolysis. **A.** Eosinophilic necrosis of the epidermis in the peak stage, with little inflammatory response in the dermis. Note cleavage in the junction zone. **B.** The completely necrotic epidermis has detached from the dermis and folded like a sheet.

BOX 40-1 DIFFERENTIAL DIAGNOSIS OF EPIDERMAL NECROLYSIS (EN)

Most Likely

- Limited EN (Stevens–Johnson syndrome)
  - Erythema multiforme major
  - Varicella
- Widespread EN
  - Acute generalized exanthematous pustulosis
  - Generalized bullous fixed drug eruption

Consider

- Paraneoplastic pemphigus
- Linear immunoglobulin A bullous disease
- Pressure blisters after coma
- Phototoxic reaction
- Graft-versus-host disease

Always Rule Out

- Staphylococcal scalded skin syndrome
- Thermal burns
- Skin necrosis from disseminated intravascular coagulation or purpura fulminans
- Chemical toxicity (e.g., colchicine intoxication, methotrexate overdose)

may have a similar drug-related mechanism. However, the distinction is worthwhile because GBFDE has a reputation for much better prognosis, probably because of the mild involvement of mucous membranes and the absence of visceral complications. Prior attacks, rapid onset after drug intake, and very large, well-demarcated blisters are the hallmarks of GBFDE.

Toxic destruction of epithelia, whether through contact (fumigants) or ingestion (colchicine poisoning, methotrexate overdose), may result in clinical features of EN, but with skin erosions often predominating in the folds. In these rare cases, causality is generally obvious.

Overreporting of SJS is common. It usually arises from confusion between desquamation and detachment of epidermis, and also between mucous membranes and periorificial skin. Because of such confusion, patients with a desquamative rash and scaly lips are not rarely diagnosed with and reported as having SJS.

COMPLICATIONS AND SEQUELAE

During the acute phase, the most common complication of EN is sepsis. The epithelial loss predisposes these patients to infections, which are the main causes of mortality.[4,63] *Staphylococcus aureus* and *Pseudomonas* are the most frequent pathogens, but about one-third of positive blood cultures contain enterobacteriae not present on the skin, a finding that suggests bacterial translocation from gut lesions.[76] Multisystem organ failure and pulmonary

complications are observed in more than 30% and 15% of cases, respectively.[77]

A very important advance in EN is the recent understanding that sequelae are more frequent and more severe than previously thought.[78] After the well-known risks of the acute stage, EN behaves as a chronic disease. More medical attention should be directed to that phase to better understand the frequency, mechanisms, and evolution of sequelae. Adequate management and prevention of sequelae are as important as saving the life during the acute phase.

A large European cohort has found that 90% of patients who survived EN suffered from sequelae at 1 year, with a mean of three different problems per patient and an important negative impact on the quality of life for about half of them (RegiSCAR group, unpublished data).

Symptoms suggesting posttraumatic stress disorder are not rare. Psychiatric consultation and/or psychological support are probably necessary in a majority of cases. Late ophthalmic complications are reported in 20% to 75% of patients with EN, with a credible figure of about 50% (Fig. 40-6).[64,65,78] The relationship between the initial severity of ocular involvement and the development of late complications seems now to be well established. Late ophthalmic complications are mainly due to functional alteration of the conjunctival epithelium with dryness and abnormal lacrimal film. This leads to chronic inflammation, fibrosis, entropion, trichiasis, and symblepharon. Long-term irritation and deficiency of stem cells in the limbus may result in metaplasia of corneal epithelium with painful ulcerations, scarring, and altered vision. Such severe eye lesions occasionally develop in patients who had no patent ocular signs during the acute phase of EN.[64]

Hypopigmentation and/or hyperpigmentation are most frequent; residual hypertrophic or atrophic scars rarely occur. Nail changes, including change in pigmentation of the nail bed, ridging, dystrophic nails, and permanent anonychia, occur in more than 30% of cases (Fig. 40-7). Mouth sequelae are present in about one-third of patients who complain of dryness, altered taste, and late alterations of teeth.[79]

Figure 40-6 Late ocular complications of SJS. Note opaque corneal epithelium, neovessels, and irritating eyelashes on lower eyelids. (Photograph provided by Julie Gueudry MD and Marc Muraine MD, PhD, Hôpital Charles Nicolle, Rouen, France.)

Figure 40-7 Abnormal regrowth of nails after SJS.

Vulvar and vaginal complications of EN are reported by about 25% of patients.[66] Dyspareunia is not rare and is related to vaginal dryness, itching, pain, and bleeding. Genital adhesions may lead to the requirement for surgical treatment. Esophageal, intestinal, urethral, and anal strictures may also develop in rare cases. Chronic lung disease can be observed after EN, often attributed to bronchiolitis obliterans, and occasionally requires lung transplantation.[68,80] Because these late complications and sequelae may develop insidiously, it is strongly suggested that all patients surviving EN have a clinical follow-up a few weeks after discharge and 1 year later, including examination by an ophthalmologist and by other organ specialist(s) as indicated by abnormal signs and symptoms.

PROGNOSIS AND CLINICAL COURSE

The epidermal detachment progresses for 5 to 7 days. Then, patients enter a plateau phase, which corresponds to progressive reepithelialization. This can take a few days to a few weeks, depending on the severity of the disease and the prior general condition of the patient. During this period, life-threatening complications such as sepsis or systemic organ failure may occur. The overall hospital mortality rate of EN is 22–25%, varying from 5% to 12% for SJS to more than 30% for TEN. The prognosis is not affected by the type or dose of the responsible drug or the presence of human immunodeficiency virus infection (see Table 40-1).[12,14,63,77]

Prospective follow-up has shown an additional abnormally increased mortality in the 3-month period following hospital discharge, which seems to result from the negative impact of EN on prior severe chronic conditions, for example, malignancies (RegiSCAR, unpublished data).

TREATMENT

EN is a life-threatening disease that requires optimal management: early recognition and withdrawal of the offending drug(s) and supportive care in an appropriate hospital setting.

Prompt withdrawal of offending agent(s) is associated with an increased rate of survival in patients with EN induced by drugs with short elimination half-lives.[81] On the other hand, it is preferable to continue every important and nonsuspected medication. That will avoid reluctance on the part of the patient's physicians to prescribe them in the future. In case of doubt, all nonlife-sustaining drugs should be stopped, and particularly those administered within the previous 8 weeks.

SYMPTOMATIC TREATMENT

Only patients with limited skin involvement, a SCORTEN score of 0 or 1, and a disease that is not rapidly progressing can be treated in nonspecialized wards. Others should be transferred to intensive care units or burn centers.[82] There is no "specific" treatment of demonstrated efficacy and supportive measures are the most important.[5] Supportive care consists of maintaining hemodynamic equilibrium and preventing life-threatening complications. The aims are basically the same as for extensive burns.

EN is associated with significant fluid loss from erosions, which results in hypovolemia and electrolyte imbalance. Fluid replacement must be started as soon as possible and adjusted daily. Volumes of infusions are usually less than for burns of similar extent, because interstitial edema is absent. Peripheral venous lines are preferred when possible, because the sites of insertion of central lines are often involved in detachment of epidermis and prone to infection. The environmental temperature should be raised to 28°C to 30°C (82.4°F to 86°F). The use of an air-fluidized bed improves patient comfort.

Early nutritional support is preferentially provided by nasogastric tube to promote healing and to decrease the risk of bacterial translocation from the gastrointestinal tract. To reduce the risk of infection, aseptic and careful handing is required. Skin, blood, and urine specimens should be cultured for bacteria and fungi at frequent intervals. Prophylactic antibiotics are not indicated. Patients should receive antibiotics when clinical infection is suspected. Prophylactic anticoagulation is provided during hospitalization.

We do not recommend extensive and aggressive debridement of necrotic epidermis in EN because the superficial necrosis is not an obstacle to reepithelialization, and might even accelerate the proliferation of stem cells due to the inflammatory cytokines. This is the single noticeable divergence between authors of this chapter and the recommendations of US Burn centers.[5] A few recent series suggest that debridement is necessary neither in superficial burns[81] nor in EN.[84,85] There is no standard policy on wound dressings and the use of antiseptics. It is a matter of experience for each center. Skillfulness on the part of specialized nurses, careful manipulation, and an aggressive protocol of prevention and treatment of pain are essential.

Eyes should be examined daily by an ophthalmologist. Preservative-free emollients, antibiotic or antiseptic eye drops, and vitamin A are often used every 2 hours in the acute phase, and mechanical disruption of early synechiae is indicated. Early graft of cryopreserved amniotic membrane has been proposed as capable to decrease the rate of severe eye sequelae.[64]

The mouth should be rinsed several times a day with antiseptic or antifungal solution.

SPECIFIC TREATMENT IN ACUTE STAGE

Because of the importance of immunologic and cytotoxic mechanisms, a large number of immunosuppressive and/or anti-inflammatory therapies have been tried to halt the progression of the disease. None has clearly proved its efficacy. The low prevalence of the disease makes randomized clinical trials hard to perform.

CORTICOSTEROIDS.

The use of systemic corticosteroids is still controversial. Some studies found that such therapy could prevent the extension of the disease when administered during the early phase, especially as intravenous pulses for a few days.[86] Other studies concluded that steroids did not stop the progression of the disease and were even associated with increased mortality and adverse effects, particularly sepsis. Thus, systemic corticosteroids cannot be recommended as the mainstay treatment of EN,[5] but a large cohort study has suggested a possible benefit that should be explored by a prospective study.[87]

INTRAVENOUS IMMUNOGLOBULIN.

The proposal to use high-dose intravenous Ig was based on the hypothesis that Fas-mediated cell death can be abrogated by the anti-Fas activity present in commercial batches of normal human Ig .[45] Benefits have been claimed by several studies and case reports,[45,88–90] but refuted by several others.[16,87,91,92] Thus, intravenous Ig cannot be considered the standard of care,[5] especially after recent findings that the Fas-L/Fas pathway was not, or only marginally, involved in the mechanisms of EN.[50] If used, a minimal precaution is to avoid preparations that are potentially nephrotoxic.

CYCLOSPORINE A.

Cyclosporine is a powerful immunosuppressive agent associated with biologic effects that may theoretically be useful in treatment of EN: activation of T helper 2 cytokines, inhibition of $CD8^+$ cytotoxic mechanisms, and antiapoptotic effect through inhibition of Fas-L, nuclear factor-κB, and TNF-α. Several case reports and series suggested some efficacy of cyclosporine A in halting the progression of EN without worrisome side effects when administered early.[93,94]

PLASMAPHERESIS OR HEMODIALYSIS.

The rationale for using plasmapheresis or hemodialysis is to prompt the removal of the offending medication, its metabolites, or inflammatory mediators such as cytokines. A small series reported their efficacy and safety in treating EN.[95–98] However, considering the absence of evidence and the risks associated with intravascular catheters, these treatments cannot be recommended.

ANTITUMOR NECROSIS FACTOR AGENTS.

Anti-TNF monoclonal antibodies have been successfully used to treat a few patients. Because a prior

randomized controlled trial of thalidomide, an anti-TNF agent, had to be interrupted due to significantly increased mortality,[99] extreme caution is suggested in the use of anti-TNF agents to treat EN.

TREATMENT OF SEQUELAE

Very promising treatments have now been developed for the ocular sequelae of EN, including gas permeable scleral lenses[100,101] and grafting of autologous stem cells from contralateral limbus or mouth mucosa.[102,103] With the exception of ocular sequelae, the literature contains only case reports related to treating sequelae. Photoprotection and cosmetic lasers may help resolve the pigmentation changes on the skin.

PREVENTION

Primary prevention is only feasible in populations where a strong association has been established between a simple genetic maker and the risk of EN. That is the case for HLAB*1502 and EN induced by carbamazepine. The FDA has issued the recommendation to test patients from "Asian ancestry" for HLAB*1502 before prescribing carbamazepine. This recommendation should be refined to exclude persons of Japanese or Korean origin. In individuals of Han Chinese origin, alternative antiepileptic drugs can be carefully prescribed, although there may be an association of EN with phenytoin and HLAB*1502 as well.[57] The present status of research on the pharmacogenetics of EN (RegiSCAR unpublished data) makes unlikely the finding of other genetic markers useful for primary prevention.

Secondary prevention is important for patients who experienced EN and are reluctant to take any medication. The most important issue is to evaluate drug causality. In vitro tests or patch tests to medications occasionally can be useful in the exploration of drug allergy. When used in EN patients, their sensitivity is low.[104,105] Careful inquiry into all exposures to medications in the few weeks preceding the onset of the reaction leads to the identification of a probable culprit drug in approximately 70% of cases. The most useful clinical criteria are duration of treatment before onset (typically 4 to 30 days), absence of prior intake, and use of a drug known for being associated with a high risk.[39]

The few published cases of recurrent SJS or TEN were always due to inadvertent readministration of the same or a very closely related medication. Epidemiology and in vitro studies suggest that the list of possible cross-reactive medications is rather narrow, based on close chemical similarities. As an example, there is no evidence that patients who experienced SJS or TEN in reaction to an anti-infectious sulfonamide are at increased risk for reaction to sulfonamide-related diuretics or antidiabetic medications. Only anti-infectious sulfonamides should be contraindicated in this situation.

A list of the suspected medication(s) and molecules of the same biochemical structure must be given to the patient on a personal "allergy card." It is also very useful to provide a list of drugs of common use that cannot be suspected. Because of recent indications of genetic susceptibilities to the development of EN, prescription of the offending agent to family members should also be avoided.

Chapter 41 :: Cutaneous Reactions to Drugs

:: Neil H. Shear & Sandra R. Knowles

CUTANEOUS ADVERSE DRUG ERUPTIONS AT A GLANCE

- Drug-induced cutaneous eruptions are common.
- They range from common nuisance rashes to rare life-threatening diseases.
- The spectrum of clinical manifestations includes exanthematous, urticarial, pustular, and bullous eruptions.
- These reactions may mimic other cutaneous diseases such as acne, porphyria, lichen planus, and lupus.
- Fixed drug eruptions are usually solitary dusky macules that recur at the same site.
- Drug reactions may be limited solely to skin or may be part of a severe systemic reaction, such as drug hypersensitivity syndrome or toxic epidermal necrolysis.

Complications of drug therapy are a major cause of patient morbidity and account for a significant number of patient deaths.[1] Drug eruptions range from common nuisance eruptions to rare or life-threatening drug-induced diseases. Drug reactions may be solely limited to the skin, or they may be part of a systemic reaction, such as drug hypersensitivity syndrome or toxic epidermal necrolysis (TEN) (see Chapter 40).

Drug eruptions are often distinct disease entities and must be approached systematically, as any other cutaneous disease. A precise diagnosis of the reaction pattern can help narrow possible causes, because different drugs are more commonly associated with different types of reactions.

EPIDEMIOLOGY

A systematic review of the medical literature, encompassing nine studies, concluded that cutaneous reaction rates varied from 0% to 8% and were highest for antibiotics.[2] Outpatient studies of cutaneous adverse drug reactions (ADRs) estimate that 2.5% of children who are treated with a drug, and up to 12% of children treated with an antibiotic, will experience a cutaneous reaction.[3]

ETIOLOGY

In the evaluation of a patient with a history of a suspected ADR, it is important to obtain a detailed medication history, including use of over-the-counter preparations and herbal and naturopathic remedies. New drugs started within the preceding 3 months, especially those within 6 weeks, are potential causative agents for most cutaneous eruptions (exceptions include drug-induced lupus, drug-induced pemphigus, and drug-induced cutaneous pseudolymphoma), as are drugs that have been used intermittently.

PATHOGENESIS OF DRUG ERUPTIONS

Constitutional factors influencing the risk of cutaneous eruption include pharmacogenetic variation in drug-metabolizing enzymes and human leukocyte antigen (HLA) associations. Acetylator phenotype alters the risk of developing drug-induced lupus due to hydralazine, procainamide, and isoniazid. HLA-DR4 is significantly more common in individuals with hydralazine-related drug-induced lupus than in those with idiopathic systemic lupus erythematosus.[4] HLA factors may also influence the risk of reactions to nevirapine, abacavir, carbamazepine, and allopurinol.[5–7]

Many drugs associated with severe idiosyncratic drug reactions are metabolized by the body to form reactive, or toxic, drug products.[8] These reactive products comprise only a small proportion of a drug's metabolites and are usually rapidly detoxified. However, patients with drug hypersensitivity syndrome, TEN, and Stevens–Johnson syndrome (SJS) resulting from treatment with sulfonamide antibiotics and the aromatic anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital, primidone, and oxcarbazepine) show greater sensitivity in in vitro assessments to the oxidative, reactive metabolites of these drugs than do control subjects.[9]

Acquired factors also alter an individual's risk of drug eruption. Active viral infection and concurrent use of other medications have been shown to alter the frequency of drug-associated eruptions. Reactivation of latent viral infection with human herpes virus 6 also appears common in drug hypersensitivity syndrome and may be partially responsible for some of the clinical features and/or course of the disease.[10,11] Viral infections may act as, or generate the production of, danger signals that lead to damaging immune responses to drugs, rather than immune tolerance.

Drug–drug interactions may also alter the risk of cutaneous eruption. Valproic acid increases the risk of severe cutaneous adverse reactions to lamotrigine, another anticonvulsant.[12] The basis of these

interactions and reactions is unknown, but they may represent a combination of factors, including alterations in drug metabolism, drug detoxification, antioxidant defenses, and immune reactivity.

The course and outcome of drug-induced disease are also influenced by host factors. Older age may delay the onset of drug eruptions and has been associated with a higher mortality rate in some severe reactions. A higher mortality rate is also observed in patients with severe reactions who have underlying malignancy.[13] The pathogenesis of most drug eruptions is not understood, although the clinical features of most drug reactions are consistent with immune-mediated disease. The immune system may target the native drug, its metabolic products, altered self, or a combination of these factors.[14]

MORPHOLOGIC APPROACH TO DRUG ERUPTIONS

Although there are many presentations of cutaneous drug eruptions, the morphology of many cutaneous eruptions may be exanthematous, urticarial, blistering, or pustular. The extent of the reaction is variable. For example, once the morphology of the reaction has been documented, a specific diagnosis [e.g., fixed drug eruption (FDE) or acute generalized exanthematous pustulosis (AGEP)] can be made. The reaction may also present as a systemic syndrome [e.g., serum sickness-like reaction or hypersensitivity syndrome reaction (HSR)]. Fever is generally associated with such systemic cutaneous ADRs.

EXANTHEMATOUS ERUPTIONS

Exanthematous eruptions, sometimes referred to as *morbilliform* or *maculopapular*, are the most common form of drug eruptions, accounting for approximately 95% of skin reactions[2] (Fig. 41-1). Simple exanthems are erythematous changes in the skin without evidence of blistering or pustulation. The eruption typically starts on the trunk and spreads peripherally in a symmetric fashion. Pruritus is almost always present. These eruptions usually occur within 1 week of initiation of therapy and may appear 1 or 2 days after drug therapy has been discontinued.[15] Resolution, usually with 7–14 days, occurs with a change in color from bright red to a brownish red, which may be followed by desquamation. The differential diagnosis in these patients includes an infectious exanthem (e.g., viral, bacterial, or rickettsial), collagen vascular disease, and infections.

Exanthematous eruptions can be caused by many drugs, including β-lactams ("the penicillins"), sulfonamide antimicrobials, nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine), and antiepileptic medications. Studies have shown that drug-specific T cells play a major role in exanthematous, bullous, and pustular drug reactions.[16] In patients who have concomitant infectious mononucleosis, the risk of developing an exanthematous eruption while being treated with an aminopenicillin (e.g., ampicillin) increases from 3%–7% to 60%-100%.[17] A similar drug–viral interaction has been observed in 50% of patients infected with human immunodeficiency virus (HIV) who are exposed to sulfonamide antibiotics.[14]

Figure 41-1 Exanthematous drug eruption: ampicillin. Symmetrically arranged, brightly erythematous macules and papules, which are discrete in some areas and confluent in others on the trunk and discrete on the extremities.

An exanthematous eruption in conjunction with fever and internal organ inflammation (e.g., liver, kidney, central nervous system) signifies a more serious reaction, known as the *hypersensitivity syndrome reaction*, drug-induced hypersensitivity reaction (DIHS) or drug reaction with eosinophilia and systemic symptoms (DRESS) (Table 41-1). It occurs in approximately 1 in 3,000 exposures to agents such as aromatic anticonvulsants, lamotrigine, sulfonamide antimicrobials, dapsone, nitrofurantoin, nevirapine, minocycline, metronidazole, and allopurinol (Fig. 41-2). HSR occurs most frequently on first exposure to the drug, with initial symptoms starting 1–6 weeks after exposure. Fever and malaise are often the presenting symptoms. Atypical lymphocytosis with subsequent eosinophilia may occur during the initial phases of the reaction in some patients. Although most patients have an exanthematous eruption, more serious cutaneous manifestations may be evident (Fig. 41-3). Internal organ involvement can be asymptomatic.[11] Some patients may become hypothyroid due to an autoimmune thyroiditis approximately 2 months after the first symptoms appear.[18]

The formation of toxic metabolites of the aromatic anticonvulsants may play a pivotal role in the development of HSR.[9] In most individuals, the chemically reactive metabolites that are produced are detoxified by epoxide hydroxylases. However, if detoxification is defective, one of the metabolites may act as a hapten and initiate an immune response, stimulate apoptosis,

TABLE 41-1
Clinical Features of Selected Cutaneous Reactions to Drugs

Clinical Presentation	Drug Eruption	Fever	Internal Organ Involvement	Arthralgia	Lymphadenopathy	Implicated Drugs
Hypersensitivity syndrome reaction	Exanthem, exfoliative dermatitis, pustular eruptions, SJS/TEN	Present	Present	Absent	Present	Aromatic anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine), sulfonamide antibiotics, dapsone, minocycline, allopurinol, lamotrigine
Serum sickness-like reaction	Urticaria, exanthem	Present	Absent	Present	Present	Cefaclor, cefprozil, bupropion, minocycline, infliximab, rituximab
Drug-induced lupus	Usually absent	Present/absent	Present/absent	Present	Absent	Procainamide, hydralazine, isoniazid, minocycline, acebutolol
Drug-induced subacute cutaneous lupus erythematosus	Papulosquamous or annular cutaneous lesion (often photosensitive)	Absent	Absent	Absent	Absent	Thiazide diuretics, calcium channel blockers, ACE inhibitors
Acute generalized exanthematous pustulosis	Nonfollicular pustules on an edematous erythematous base	Present	Absent	Absent	Absent	β Blockers, macrolide antibiotics, calcium channel blockers

ACE = angiotensin-converting enzyme; SJS = Stevens–Johnson syndrome; TEN = toxic epidermal necrolysis.

or cause cell necrosis directly. Approximately 70%–75% of patients who develop anticonvulsant HSR in response to one aromatic anticonvulsant show cross-reactivity to the other aromatic anticonvulsants. In addition, in vitro testing shows that there is a pattern of inheritance of HSR induced by anticonvulsants. Thus, counseling of family members and disclosure of risk are essential.

Sulfonamide antimicrobials are both sulfonamides (contain SO_2-NH_2) and aromatic amines (contain a benzene ring-NH_2). Aromatic amines can be metabolized to toxic metabolites, namely, hydroxylamines and nitroso compounds.[19] In most people, the metabolite is detoxified. However, HSRs may occur in patients who either form excess oxidative metabolites or are unable to detoxify such metabolite. Because siblings and other

Figure 41-2 Drug hypersensitivity syndrome: phenytoin. Symmetric, bright red, exanthematous eruption, confluent in some sites; the patient had associated lymphadenopathy.

Figure 41-3 Hypersensitivity syndrome reaction, characterized by fever, a pustular eruption, and hepatitis, in a 23-year-old man after 18 days of treatment with minocycline.

first-degree relatives may be at an increased risk (perhaps as high as 1 in 4) of developing a similar adverse reaction, counseling of family members is essential.

Other aromatic amine-containing drugs, such as procainamide, dapsone, and acebutolol, may also be metabolized to chemically reactive compounds. It is recommended that patients who develop symptoms compatible with a sulfonamide-induced HSR avoid these aromatic amines, because the potential exists for cross-reactivity. However, cross-reactivity is much less likely to occur between sulfonamides antimicrobials and drugs that are not aromatic amines (e.g., sulfonylureas, thiazide diuretics, furosemide, celecoxib, and acetazolamide).[20]

Allopurinol is associated with the development of serious drug reactions, including HSR. Active infection or reactivation of HHV-6 has been observed in patients who develop allopurinol HSR.[21] Allopurinol-induced severe adverse reactions, specifically HSR and SJS/TEN spectrum, have been strongly associated with a genetic predisposition in Han Chinese and Thai populations; presence of the HLA-B*5801 allele was found to be an important genetic risk factor.[6,22]

URTICARIAL ERUPTIONS

Urticaria is characterized by pruritic red wheals of various sizes. Individual lesions generally last for less than 24 hours, although new lesions can commonly develop. When deep dermal and subcutaneous tissues are also swollen, the reaction is known as *angioedema*. Angioedema is frequently unilateral and nonpruritic and lasts for 1–2 hours, although it may persist for 2–5 days.[21]

Urticaria and angioedema, when associated with drug use, are usually indicative of an immunoglobulin (Ig) E-mediated immediate hypersensitivity reaction. This mechanism is typified by immediate reactions to penicillin and other antibiotics (see Chapter 38). Signs and symptoms of IgE-mediated allergic reactions typically include pruritus, urticaria, cutaneous flushing, angioedema, nausea, vomiting, diarrhea, abdominal pain, nasal congestion, rhinorrhea, laryngeal edema, and bronchospasm or hypotension. Urticaria and angioedema can also be caused by non-IgE-mediated reactions that result in direct and nonspecific liberation of histamine or other mediators of inflammation.[15] Drug-induced non-IgE-mediated urticaria and angioedema are usually related to nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin converting enzyme (ACE)-inhibitors and opioids.

Serum sickness-like reactions (see Table 41-1) are defined by the presence of fever, rash (usually urticarial), and arthralgias 1–3 weeks after initiation of drug therapy. Lymphadenopathy and eosinophilia may also be present; however, in contrast to true serum sickness, immune complexes, hypocomplementemia, vasculitis, and renal lesions are absent.

Cefaclor is associated with an increased relative risk of serum sickness-like reactions. The overall incidence of cefaclor-induced serum sickness-like reactions has been estimated to be 0.024%–0.2% per course of cefaclor prescribed. In genetically susceptible hosts, a reactive metabolite is generated during the metabolism of cefaclor that may bind with tissue proteins and elicit an inflammatory response manifesting as a serum sickness-like reaction.[23]

Other drugs that have been implicated in serum sickness-like reactions are cefprozil, bupropion, minocycline, and rituximab[24] as well as infliximab.[25] The incidence of serum sickness-like reactions caused by these drugs is unknown.

PUSTULAR ERUPTIONS

Acneiform eruptions are associated with the use of iodides, bromides, adrenocorticotropic hormone, glucocorticoids, isoniazid, androgens, lithium, actinomycin D, and phenytoin. Drug-induced acne may appear in atypical areas, such as on the arms and legs, and is most often monomorphous. Comedones are usually absent. The fact that acneiform eruptions do not affect prepubertal children indicates that previous hormonal priming is a necessary prerequisite. In cases in which the offending agent cannot be discontinued, topical tretinoin may be useful.[26] An acneiform eruption often occurs during treatment with epidermal growth factor receptor inhibitors (e.g., gefitinib, erlotinib, cetuximab). The acneiform rash is often accompanied by paronychia, dry skin, and skin fissures. The eruption is dose dependent, with respect to both incidence and severity.[27] In a systemic review and meta-analysis encompassing over 1,000 patients receiving cetuximab as a single-agent, the incidence of an acneiform eruption was 81.6%.[28]

AGEP is an acute febrile eruption that is often associated with leukocytosis (Fig. 41-4 and Table 41-1). After initiation of the implicated drug, 1–3 weeks

Figure 41-4 Acute generalized exanthematous pustulosis in a 48-year-old man who developed nonfollicular pustules and fever after 7 days of treatment with diltiazem.

may elapse before skin lesions appear. The lesions often start on the face or major skin creases. Generalized desquamation occurs approximately 2 weeks later. The estimated incidence of AGEP is approximately 1–5 cases per million per year. AGEP is most commonly associated with β-lactam and macrolide antibiotics, anticonvulsants, and calcium channel blockers.[29] Differential diagnosis includes pustular psoriasis, HSR with pustulation, subcorneal pustular dermatosis (Sneddon–Wilkinson disease), pustular vasculitis, or in severe cases of AGEP, TEN. The typical histopathologic analysis of AGEP lesions shows spongiform subcorneal and/or intraepidermal pustules, an often marked edema of the papillary dermis, and perivascular infiltrates with neutrophils and exocytosis of some eosinophils. Discontinuance of therapy is usually the extent of treatment necessary in most patients, although some patients may require the use of corticosteroids. Patch tests have been used in the diagnosis of AGEP.[30]

BULLOUS ERUPTIONS

(Table 41-2)

PSEUDOPORPHYRIA. Pseudoporphyria is a cutaneous phototoxic disorder that can resemble either porphyria cutanea tarda in adults or erythropoietic protoporphyria in children (see Chapter 132). Pseudoporphyria of the porphyria cutanea tarda variety is characterized by skin fragility, blister formation, and scarring in photodistribution; it occurs in the presence of normal porphyrin levels. The other clinical pattern mimics erythropoietic protoporphyria and manifests as cutaneous burning, erythema, vesiculation, angular chicken pox-like scars, and waxy thickening of the skin. The eruption may begin within 1 day of initiation of therapy or may be delayed in onset for as long as 1 year. The course is prolonged in some patients, but most reports describe symptoms that disappear several weeks to several months after the offending agent is withdrawn. Because of the risk of permanent facial scarring, the implicated drug should be discontinued if skin fragility, blistering, or scarring occurs.[31] In addition, the use of broad-spectrum sunscreen and protective clothing should be recommended. Drugs that have been associated with pseudoporphyria include naproxen and other NSAIDs, and voriconazole.[32,33]

DRUG-INDUCED LINEAR IgA DISEASE. Both idiopathic and drug-induced linear IgA diseases (see Chapter 58) are heterogeneous in clinical presentation. Cases of the drug-induced type have morphologies resembling erythema multiforme, bullous pemphigoid, and dermatitis herpetiformis. The drug-induced disease may differ from the idiopathic entity in that mucosal or conjunctival lesions are less common, spontaneous remission occurs once the offending agent is withdrawn, and immune deposits disappear from the skin once the lesions resolve.

Biopsy specimens are necessary for diagnosis. Histologically, the two entities are similar. A study suggests that, as in the idiopathic variety, the target antigen is not unique in the drug-induced disease. Although 13%–30% of patients with sporadic linear IgA have circulating basement membrane zone antibodies, these antibodies have not been reported in drug-induced cases.[34] In patients with linear IgA bullous disease

TABLE 41-2
Drug Eruptions Mimicry

Clinical Presentation	Pattern and Distribution of Skin Lesions	Mucous Membrane Involvement	Implicated Drugs	Treatment
Stevens–Johnson syndrome	Atypical targets, widespread	Present	Aromatic anticonvulsants,[a] lamotrigine, sulfonamide antibiotics, allopurinol, piroxicam, dapsone	IVIg, cyclosporine, supportive care
Toxic epidermal necrolysis	Epidermal necrosis with skin detachment	Present	As above	IVIg, cyclosporine, supportive care
Pseudoporphyria	Skin fragility, blister formation in photodistribution	Absent	Tetracycline, furosemide, naproxen	Supportive care
Linear IgA disease	Bullous dermatosis	Present/absent	Vancomycin, lithium, diclofenac, piroxicam, amiodarone	Supportive care
Pemphigus	Flaccid bullae, chest	Present/absent	Penicillamine, captopril, piroxicam, penicillin, rifampin, propranolol	Supportive care
Bullous pemphigoid	Tense bullae, widespread	Present/absent	Furosemide, penicillamine, penicillins, sulfasalazine, captopril	Supportive care

IVIg = intravenous immunoglobulin.
[a]Aromatic anticonvulsants = phenytoin, carbamazepine, phenobarbital, oxcarbazepine, primidone.

proven by direct immunofluorescence, the index of suspicion of drug induction should be higher in cases with only IgA and no IgG in the basement membrane zone. Several drugs can induce linear IgA bullous dermatosis, the most frequently reported being vancomycin.[35]

DRUG-INDUCED PEMPHIGUS. Pemphigus may be considered as drug-induced or drug-triggered (i.e., a latent disease that is unmasked by the drug exposure; see Chapter 54). Drug-induced pemphigus caused by penicillamine and other thiol-containing drugs (e.g., piroxicam, captopril) tends to remit spontaneously in 35%–50% of cases, presents as pemphigus foliaceus, has an average interval to onset of 1 year, and is associated with the presence of antinuclear antibodies in 25% of patients.

Most patients with nonthiol drug-induced pemphigus manifest clinical, histologic, immunologic, and evolutionary aspects similar to those of idiopathic pemphigus vulgaris with mucosal involvement and show a 15% rate of spontaneous recovery after drug withdrawal. Treatment of drug-induced pemphigus begins with drug cessation. Systemic glucocorticoids and other immunosuppressive drugs are often required until all symptoms of active disease disappear. Vigilant follow-up is required after remission to monitor the patient and the serum for autoantibodies to detect an early relapse.[36]

DRUG-INDUCED BULLOUS PEMPHIGOID. Drug-induced bullous pemphigoid (see Chapter 56) can encompass a wide variety of presentations, ranging from the classic features of large, tense bullae arising from an erythematous, urticarial base with moderate involvement of the oral cavity, through mild forms with few bullous lesions, to scarring plaques and nodules with bullae. Medications that have been reported to cause bullous pemphigoid include furosemide, amoxicillin, and spironolactone. In contrast to patients with the idiopathic form, patients with drug-induced bullous pemphigoid are generally younger. In addition, the histopathologic findings are of a perivascular infiltration of lymphocytes with few eosinophils and neutrophils, intraepidermal vesicles with foci of necrotic keratinocytes, thrombi in dermal vessels, and a possible lack of tissue-bound and circulating anti-basal membrane zone IgG.[37]

In the acute, self-limited condition, resolution occurs after the withdrawal of the culprit agent, with or without glucocorticoid therapy. However, in some patients the drug may actually trigger the idiopathic form of the disease.

STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS. SJS and TEN or the SJS/TEN spectra represent variants of the same disease process. Differentiation between the two patterns depends on the nature of the skin lesions and the extent of body surface area involvement (see Chapters 39 and 40).

Recently, the understanding of the pathogenesis of severe cutaneous ADRs has expanded greatly. Various factors including pharmacogenetic and immunogentic determinants may influence the likelihood of a reaction and variability in innate and adaptive immunity may influence the clinical presentation.[38] In addition, the detection of drug-specific T-cell proliferation provides evidence that T cells are involved in severe skin rashes.[39]

Treatment of SJS/TEN includes discontinuance of the suspected drug(s) and supportive measures such as careful wound care, hydration, and nutritional support. The use of corticosteroids in the treatment of SJS and TEN is controversial.[40,41] Intravenous Ig (IVIg, up to 3–4 g over 3 days) has been shown in some reports to halt progression of TEN, especially when IVIg is started early. However, some studies have not found an improved outcome in patients with TEN who are treated with IVIg.[38] A recent study concluded that neither corticosteroids nor intravenous Ig had any significant effect on mortality in comparison to supportive care only.[42] Other treatment modalities include cyclosporine,[43] cyclophosphamide, and plasmapharesis. Patients who have developed a severe cutaneous ADR should not be rechallenged with the drug. Desensitization therapy with the medication may also be a risk.

FIXED DRUG ERUPTIONS

FDEs usually appear as solitary, erythematous, bright red or dusky red macules that may evolve into an edematous plaque; bullous-type lesions may be present, widespread lesions may be difficult to differentiate from TEN. FDEs are commonly found on the genitalia and in the perianal area, although they can occur anywhere on the skin surface (Fig. 41-5). Some

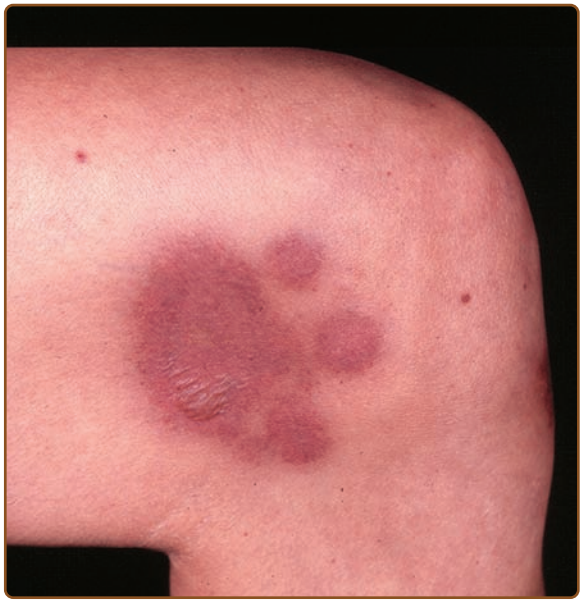

Figure 41-5 Fixed drug eruption: tetracycline. A well-defined plaque on the knee, merging with three satellite lesions. The large plaque exhibits epidermal wrinkling, a sign of incipient blister formation. This was the second such episode after ingestion of a tetracycline. No other lesions were present.

patients may complain of burning or stinging, and others may have fever, malaise, and abdominal symptoms. FDE can develop from 30 minutes to 8–16 hours after ingestion of the medication. After the initial acute phase lasting days to weeks, residual grayish or slate-colored hyperpigmentation develops. On rechallenge, not only do the lesions recur in the same location, but also new lesions often appear.

More than 100 drugs have been implicated in causing FDEs, including ibuprofen, sulfonamides, naproxen, and tetracyclines. A haplotype linkage in trimethoprim–sulfamethoxazole-induced FDE has been documented.

A challenge or provocation test with the suspected drug may be useful in establishing the diagnosis. Patch testing at the site of a previous lesion yields a positive response in up to 43% of patients. Results of prick and intradermal skin tests may be positive in 24% and 67% of patients, respectively.[44,45] Food-initiated fixed eruptions also exist and are important to consider when assessing causation.

ANTICOAGULANT-INDUCED SKIN NECROSIS

Anticoagulant-induced skin necrosis begins 3–5 days after initiation of treatment. The majority of cases of anticoagulant-induced skin necrosis have been attributed to coumarin congeners (bishydroxycoumarin, phenprocoumon, acenocoumarol, and warfarin) (Fig. 41-6). Early red, painful plaques develop in adipose-rich sites such as breasts, buttocks, and hips. These plaques may blister, ulcerate, or develop into necrotic areas. It is estimated that 1 in 10,000 persons who receive the drug is at risk of this adverse event. The incidence is four times higher in women, especially in obese women, with a peak incidence in the sixth and seventh decades of life. Affected patients often have been given a large initial loading dose of warfarin in the absence of concomitant heparin therapy. An accompanying infection such as pneumonia, viral infection, or erysipelas may be seen in up to 25% of patients. An association with protein C and protein S deficiencies exists, but pretreatment screening is not warranted. An association with heterozygosity for factor V Leiden mutation has been reported.

Figure 41-6 Skin necrosis in a patient after 4 days of warfarin therapy.

The pathogenesis of this adverse event is the paradoxical development of occlusive thrombi in cutaneous and subcutaneous venules due to a transient hypercoagulable state. This results from the suppression of the natural anticoagulant protein C at a greater rate than the suppression of natural procoagulant factors.

Treatment involves the discontinuation of warfarin, administration of vitamin K, and infusion of heparin at therapeutic dosages. Fresh frozen plasma and purified protein C concentrates have been used. Supportive measures for the skin are a mainstay of therapy. The morbidity rate is high; 60% of affected individuals require plastic surgery for remediation of full-thickness skin necrosis by skin grafting. These patients may be treated with warfarin in the future, but small dosages (2–5 mg daily) are recommended, with initial treatment under heparin coverage.[46,47]

DRUG-INDUCED LICHENOID ERUPTIONS

Drug-induced lichen planus produces lesions that are clinically and histologically indistinguishable from those of idiopathic lichen planus (see Chapter 26); however, lichenoid drug eruptions often appear initially as eczematous with a purple hue and involve large areas of the trunk. Usually, the mucous membranes and nails are not involved. Histologically, focal parakeratosis, cytoid bodies in the cornified and granular layers, the presence of eosinophils and plasma cells in the inflammatory infiltrate, and an infiltrate around the deep vessels favor a diagnosis of lichenoid drug eruption. Many drugs, including β-blockers, penicillamine, and ACE-inhibitors, especially captopril, reportedly produce this reaction. Lichen planus-like eruptions have also been reported with tumor necrosis factor-α (TNF) antagonists, such as infliximab, etanercept, and adalimumab.[48,49] The mean latent period is between 2 months and 3 years for penicillamine, approximately 1 year for β-adrenergic blocking agents, and 3–6 months for ACE-inhibitors. For anti-TNF treatments, the time to reaction is similar with onset occurring between 3 weeks and 62 weeks. The latent period may be shortened if the patient has been previously exposed to the drug. Resolution usually occurs with 2–4 months. Rechallenge with the culprit drug has been attempted in a few patients, with reactivation of symptoms within 4–15 days.[50]

DRUG-INDUCED CUTANEOUS PSEUDOLYMPHOMA

Pseudolymphoma is a process that simulates lymphoma but has a benign behavior and does not meet

the criteria for malignant lymphoma. Drugs are a well-known cause of cutaneous pseudolymphomas (see Chapter 146), but the condition may also be induced by foreign agents such as insect bites, infections (e.g., HIV), and idiopathic causes.[51]

Anticonvulsant-induced pseudolymphoma generally occurs after 1 week to 2 years of exposure to the drug. Within 7–14 days of drug discontinuation, the symptoms usually resolve. The eruption often manifests as single lesions but can also be widespread erythematous papules, plaques, or nodules. Most patients also have fever, marked lymphadenopathy and hepatosplenomegaly, and eosinophilia. Mycosis fungoides-like lesions are also associated with these drugs.[52]

DRUG-INDUCED VASCULITIS

Drug-induced vasculitis represents approximately 10% of the acute cutaneous vasculitides and usually involves small vessels (see Chapter 163). Drugs that are associated with vasculitis include propylthiouracil, hydralazine, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, allopurinol, cefaclor, minocycline, penicillamine, phenytoin, isotretinoin, and anti-TNF agents, including etanercept, infliximab, and adalimumab.[49] The average interval from initiation of drug therapy to onset of drug-induced vasculitis is 7–21 days; in the case of rechallenge, lesions can occur in less than 3 days.[15]

The clinical hallmark of cutaneous vasculitis is palpable purpura, classically found on the lower extremities. Urticaria can be a manifestation of small vessel vasculitis, with individual lesions remaining fixed in the same location for more than 1 day. Other features include hemorrhagic bullae, ulcers, nodules, Raynaud disease, and digital necrosis. The same vasculitic process may also affect internal organs such as the liver, kidney, gut, and central nervous system and can be potentially life threatening.[53]

Drug-induced vasculitis can be difficult to diagnose and is often a diagnosis of exclusion. In some cases, serologic testing has revealed the presence of perinuclear-staining antineutrophil cytoplasmic autoantibodies against myeloperoxidase. Alternative causes for cutaneous vasculitis such as infection or autoimmune disease must be eliminated. Tissue eosinophilia may be an indicator of drug induction in cutaneous small vessel vasculitis. Treatment consists of drug withdrawal. Systemic glucocorticoids may be of benefit.

DRUG-INDUCED LUPUS

(See Chapter 155)

Drug-induced lupus is characterized by frequent musculoskeletal complaints, fever, weight loss, pleuropulmonary involvement in more than half of patients, and in rare cases renal, neurologic, or vasculitic involvement (see Table 41-1). Many patients have no cutaneous findings of lupus erythematosus. The most common serologic abnormality is positivity for antinuclear antibodies with a homogenous pattern. Although antihistone antibodies are seen in up to 95% of drug-induced lupus, they are not specific for the syndrome and are found in 50%–80% of patients with idiopathic lupus erythematosus. Unlike in idiopathic lupus erythematosus, antibodies against double-stranded DNA are typically absent, whereas antisingle-stranded DNA antibodies are often present.[54] Genetic factors may also play a role in the development of drug-induced lupus. HLA-DR4 is present in 73% of the patients with hydralazine-induced lupus and in 70% of patients with minocycline-induced lupus.[55] Evidence now suggests that abnormalities during T-cell selection in the thymus initiate lupus-like autoantibody induction.[56]

In contrast, drug-induced subacute cutaneous lupus erythematosus is characterized by a papulosquamous or annular cutaneous lesion, which is often photosensitive, and absent or mild systemic involvement. Circulating anti-Ro (Sjögren syndrome A) antibodies have also been identified in many patients.

Many drugs have been implicated in causing drug-induced lupus syndromes, especially hydralazine, procainamide, isoniazid, methyldopa, and minocycline.[57] Drugs that have been associated with subacute cutaneous lupus erythematosus include thiazide diuretics, calcium channel blockers, and ACE inhibitors. The number of patients who develop subacute cutaneous lupus erythematosus during treatment with these medications is very low, and these drugs are thought to have a low risk for causing or exacerbating cutaneous lupus.[58] Other drugs that have been associated with drug-induced lupus include terbinafine, proton pump inhibitors, and anti-TNF treatments.[58]

The identification of minocycline as a cause of drug-induced lupus makes it important for dermatologists to recognize this syndrome. Minocycline-induced lupus typically occurs after 2 years of therapy. The patient presents with a symmetric polyarthritis. Hepatitis is often detected on laboratory evaluation. Cutaneous findings include livedo reticularis, painful nodules on the legs, and nondescript eruptions. Antihistone antibodies are seldom present. A study of HLA class II alleles revealed the presence of HLA-DR4 or HLA-DR2 in many of the patients.[55]

DIAGNOSIS AND MANAGEMENT

The iatrogenic disorders described here are distinct disease entities, although they may closely mimic many infective or idiopathic diseases. A drug cause should be considered in the differential diagnosis of a wide spectrum of dermatologic diseases, particularly when the presentation or course is atypical.

The diagnosis of a cutaneous drug eruption involves the precise characterization of reaction type. A wide variety of cutaneous drug-associated eruptions may also warn of associated internal toxicity (Table 41-3). Even the most minor cutaneous eruption should trigger a clinical review of systems, because the severity of systemic involvement does not necessarily mirror that of the skin manifestations. Hepatic, renal, joint, respiratory, hematologic, and neurologic changes should be sought, and any systemic symptoms or signs investi-

TABLE 41-3
Clinical Features That Warn of a Potentially Severe Drug Reaction

Systemic
- Fever and/or other symptoms of internal organ involvement such as pharyngitis, malaise, arthralgia, cough, and meningismus
- Lymphadenopathy

Cutaneous
- Evolution to erythroderma
- Prominent facial involvement ± edema or swelling
- Mucous membrane involvement (particularly if erosive or involving conjunctiva)
- Skin tenderness, blistering, or shedding
- Purpura

gated. Fever, malaise, pharyngitis, and other systemic symptoms or signs should be investigated. A usual screen would include a full blood count, liver and renal function tests, and a urine analysis.

Skin biopsy should be considered for all patients with potentially severe reactions, such as those with systemic symptoms, erythroderma, blistering, skin tenderness, purpura, or pustulation, as well as in cases in which the diagnosis is uncertain. Some cutaneous reactions, such as FDE, are almost always due to drug therapy, and approximately 40%–50% of SJS/TEN cases are also drug related.[59] Other more common eruptions, including exanthematous or urticarial eruptions, have many nondrug causes.

There is no gold standard investigation for confirmation of a drug cause. Instead, diagnosis and assessment of cause involve analysis of a constellation of features such as timing of drug exposure and reaction onset, course of reaction with drug withdrawal or continuation, timing, and nature of a recurrent eruption on rechallenge, a history of a similar response to a cross-reacting medication, and previous reports of similar reactions to the same medication. Investigations to exclude nondrug causes are similarly helpful.

Several in vitro investigations can help to confirm causation in individual cases, but their exact sensitivity and specificity remain unclear. Investigations include the lymphocyte toxicity and lymphocyte transformation assays.[60] The basophil activation test has been reported to be useful to evaluate patients with possible drug allergies to β-lactam antibiotics, NSAIDs, and muscle relaxants.[14] Penicillin skin testing with major and minor determinants is useful for confirmation of an IgE-mediated immediate hypersensitivity reaction to penicillin.[14] Patch testing has been used in patients with ampicillin-induced exanthematous eruptions, AGEP reactions,[61] abacavir-induced hypersensitivity,[62] and in the ancillary diagnosis of FDEs. Patch testing has greater sensitivity if performed over a previously involved area of skin.

Cutaneous drug eruptions do not usually vary in severity with dose. Less severe reactions may abate with continued drug therapy (e.g., transient exanthematous eruptions associated with commencement of a new HIV antiretroviral regimen). However, a reaction suggestive of a potentially life-threatening situation should prompt immediate discontinuation of the drug, along with discontinuation of any interacting drugs that may slow the elimination of the suspected causative agent. Although the role of corticosteroids in the treatment of serious cutaneous reactions is controversial, most clinicians choose to start prednisone at a dosage of 1–2 mg/kg/day when symptoms are severe. Antihistamines, topical corticosteroids, or both can be used to alleviate symptoms.[63] Resolution of the reaction over a reasonable time frame after the drug is discontinued is consistent with a drug cause but also occurs for many infective and other causes of transient cutaneous eruptions. Drug desensitization, also known as induction of drug tolerance, has been used primarily for IgE-mediated reactions caused by drugs such as penicillin or more recently, monoclonal antibodies such as rituximab and infliximab.[14,64] Patients should not be rechallenged or desensitized if they have suffered a potentially serious reaction.

PREVENTION

Cutaneous reactions to drugs are largely idiosyncratic and unexpected; serious reactions are rare. However, once a reaction has occurred, it is important to prevent future similar reactions in the patient with the same drug or a cross-reacting medication. For patients with severe reactions, wearing a bracelet (e.g., MedicAlert) detailing the nature of the reaction is advisable, and patient records should be appropriately labeled.

Host factors appear important in many reactions. Some of these can be inherited, which places first-degree relatives at a greater risk than the general population for a similar reaction to the same or a metabolically cross-reacting drug. This finding appears to be important in SJS, TEN, and drug hypersensitivity syndrome.

Reporting reactions to the manufacturer or regulatory authorities is important. Postmarketing voluntary reporting of rare, severe, or unusual reactions remains crucial to enhance the safe use of pharmaceutical agents.

Chapter 42 :: Pityriasis Rosea

:: Andrew Blauvelt

PITYRIASIS ROSEA AT A GLANCE

- Common acute papulosquamous eruption normally lasting 4–10 weeks.
- Most often begins as a single 2- to 4-cm thin oval plaque with a fine collarette of scale located inside the periphery of the plaque ("herald patch").
- Similar-appearing, but smaller, lesions appear several days to weeks later, typically distributed along the lines of cleavage on the trunk ("Christmas tree" pattern).
- Usually asymptomatic, sometimes pruritic with mild flu-like symptoms.
- Occurs most commonly in teenagers and young adults.
- Probably a viral exanthem associated with reactivation of human herpes virus (HHV)-7 and sometimes HHV-6.
- Treatment is usually supportive, although midpotency topical corticosteroids can reduce pruritus; high-dose acyclovir for 1 week may hasten recovery.

The term *pityriasis rosea* (PR) was first used by Gibert in 1860 and means pink (rosea) scales (pityriasis).[1] PR is a common acute, self-limited skin eruption that typically begins as a single thin oval scaly plaque on the trunk ("herald patch") and is typically asymptomatic. The initial lesion is followed several days to weeks later by the appearance of numerous similar-appearing smaller lesions located along the lines of cleavage of the trunk (a so-called *Christmas tree* pattern). PR most commonly occurs in teenagers and young adults, and is most likely a viral exanthem associated with reactivation of human herpes virus 7 (HHV-7) and sometimes HHV-6,[2–5] the viruses responsible for rubeola (see Chapter 192). Possible treatment may focus on associated pruritus. One study suggests that administration of high-dose acyclovir for 1 week, if initiated early in the disease course, hastens recovery from PR.[6]

EPIDEMIOLOGY

PR is reported in all races throughout the world, irrespective of climate.[7–9] The average annual incidence at one center was reported to be 0.16% (158.9 cases per 100,000 person-years).[9] Although PR is usually considered to be more common in the spring and fall months in temperate zones, seasonal variation has not been borne out in studies performed in other parts of the world. Clustering of cases can occur and has been used to support an infectious etiology for PR, although this is not a consistent feature observed in all communities.[8] Most studies have shown a slight female preponderance of approximately 1.5:1.[7,9] PR most commonly occurs between the ages of 10 and 35 years.[9] It is rare before age 2 years and after age 65 years. Recurrences of PR are rare, which suggests lasting immunity after an initial episode of PR.

ETIOLOGY AND PATHOGENESIS

Historically, PR has been considered to be caused by an infectious agent, given (1) the resemblance of the rash to known viral exanthems; (2) rare recurrences of PR that suggest lifelong immunity after one episode; (3) occurrence of seasonal variation in some studies; (4) clustering in some communities; and (5) the appearance of flu-like symptoms in a subset of patients. Numerous studies over the past 50 years have explored various pathogens as possible causes of PR. These pathogens have included bacteria, fungi, and, most notably, viruses. Beginning with a study by Drago and colleagues in 1997,[2] most recent PR etiologic and pathogenic studies have been focused on two ubiquitous viruses: (1) HHV-7 and (2) HHV-6. Critical evaluation of the medical and scientific literature on PR reveals neither credible nor reproducible evidence that PR is associated with any pathogen other than HHV-7 and HHV-6.[10]

Indeed, the best scientific evidence suggesting that PR is a viral exanthem associated with reactivation of either HHV-7 or HHV-6 (and sometimes with both viruses) is strong.[2–5,11–13] The most definitive and compelling study on HHVs and PR was by Broccolo and colleagues in 2005.[4] Using sensitive and quantitative techniques, investigators have collectively shown that (1) HHV-7 DNA, and less commonly HHV-6 DNA, can be readily detected in cell-free plasma or serum samples from many patients with PR, but not in serum or plasma from healthy individuals or patients with other inflammatory skin diseases; (2) HHV-7 messenger RNA and protein, and less commonly HHV-6 messenger RNA and protein, can be detected in scattered leukocytes found in perivascular and perifollicular regions within PR lesions, but not in normal skin or skin from patients with other inflammatory skin diseases; (3) HHV-7- and HHV-6-specific immunoglobulin (Ig) M antibody elevations in the absence of virus-specific IgG antibodies do not occur in PR patients, whereas in primary viral infections elevation of IgM antibodies alone is typical; and (4) HHV-7 and HHV-6 DNA are present in saliva of individuals with PR, which is not observed in those with a primary infection with these viruses. Taken together, these data strongly suggest that PR is

a viral exanthem associated with systemic reactivation of HHV-7 and, to a lesser extent, HHV-6. Patients are viremic, which may explain associated flu-like symptoms in some patients, and they generally do not have infected epithelial cells or large viral loads within skin lesions, which explains the difficulty in detecting these viruses by electron microscopy and by nonnested polymerase chain reaction testing.

Despite these findings, there is still controversy over the role of HHV-7 and HHV-6 in the etiology of PR, because a number of studies with "negative" results have failed to support a causative role for HHV-7 and HHV-6 in this disease.[14–16] Whereas the studies with positive results have used the most sensitive, specific, and calibrated techniques for virologic studies and reports have been published in high-quality journals, the studies with negative results either used laboratory methods that were not particularly sensitive, calibrated, or quantifiable, or focused on peripheral blood mononuclear cells rather than cell-free plasma or serum.

Correct interpretation of the recent viral literature on PR also requires proper understanding of the biology of HHV-7 and HHV-6. HHV-7 and HHV-6 are closely related β-herpes viruses, and the clinical diseases and biology associated with this group of HHVs are not as well studied as those of the α-herpes viruses (herpes simplex virus 1 and 2, varicella-zoster virus) and the γ-herpes viruses (Epstein–Barr virus and Kaposi sarcoma-associated herpes virus). HHV-6 and HHV-7 are ubiquitous, with 90% of the US population infected with HHV-6 by the age of 3 years[17] and 90% of the US population infected with HHV-7 by the age of 5 years.[18] Unlike the α-herpes viruses, HHV-7 and HHV-6 do not infect keratinocytes, but instead infect $CD4^+$ T cells within blood and are retained within these cells in a latent form in most individuals.[10,17–19] These cells are the likely source of cell-free viral DNA found in plasma or serum samples of patients with PR. They are also the likely source of the scattered perivascular and perifollicular virus-positive cells observed within some lesions of PR.[3,4]

It is important to note that the concept that PR represents a reactive viral exanthem containing few infected cells within skin lesions and viral reactivation within circulating blood $CD4^+$ T cells is perfectly analogous to that of the disease roseola, which is well accepted to be caused by primary infection with either HHV-6 or HHV-7[20,21] (see Chapter 192). Children with roseola are viremic and skin lesions generally do not contain infected cells.[22] Complete understanding of the role of HHV-7 and HHV-6 in the pathogenesis of PR is lacking at this time. For example, the mechanisms by which HHV-7 and HHV-6 are reactivated are unknown. As well, the characteristic distribution of lesions and differences in lesional and nonlesional skin are unexplained.

CLINICAL FINDINGS

HISTORY

In classic PR, patients usually describe the onset of a single truncal skin lesion followed several days to weeks later by the onset of numerous smaller lesions on the trunk. Pruritus is severe in 25% of patients with uncomplicated PR, slight to moderate in 50%, and absent in 25%. In a minority of patients, flu-like symptoms have been reported, including general malaise, headache, nausea, loss of appetite, fever, and arthralgias.

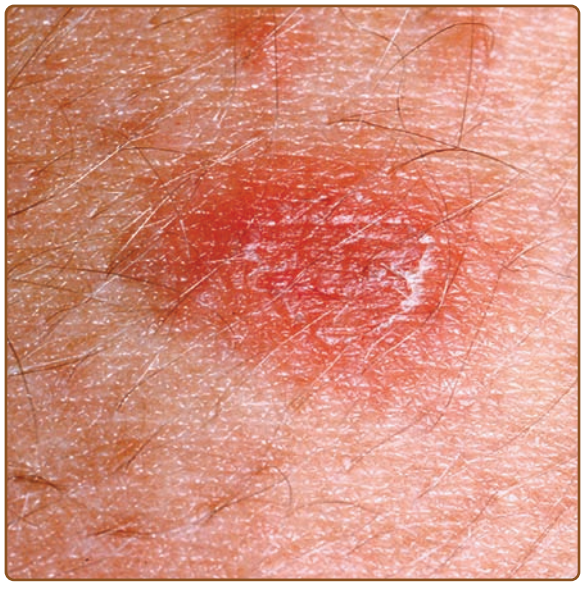

Figure 42-1 A typical primary plaque (herald patch) of pityriasis rosea, demonstrating an oval shape and fine scale inside the periphery of the plaque.

CUTANEOUS LESIONS

The primary plaque of PR, or herald patch (Figs. 42-1–42-3 and see eFigs. 42-3.1 and 42-3.2 in online edition), is seen in 50%–90% of cases. It is normally well demarcated; 2–4 cm in diameter; oval or round; salmon

Figure 42-2 A nonscaly purpuric primary plaque (herald patch) of pityriasis rosea.

Figure 42-3 A double herald patch of pityriasis rosea.

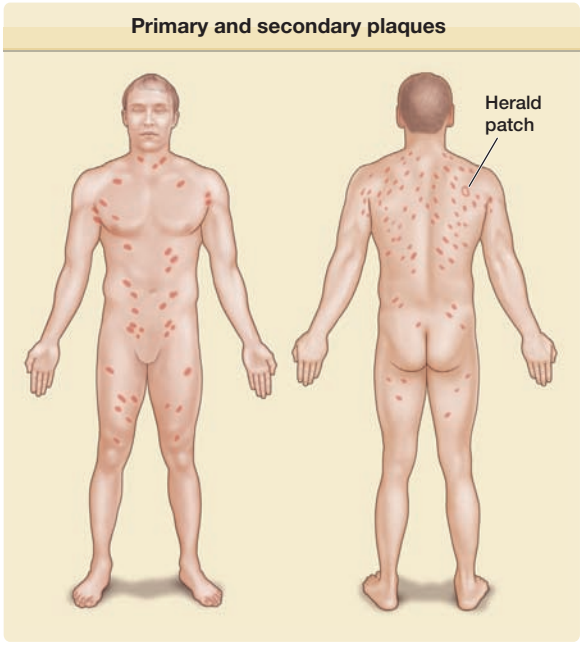

Figure 42-4 Schematic diagram of the primary plaque (herald patch) and the typical distribution of secondary plaques along the lines of cleavage on the trunk in a Christmas tree pattern.

colored, erythematous, or hyperpigmented (especially in individuals with darker skin); and demonstrates a fine collarette of scale just inside the periphery of the plaque. When the plaque is irritated, it may have an eczematous papulovesicular appearance (eFig. 42-3.3 in online edition). The primary plaque is usually located on the trunk in areas covered by clothes, but sometimes it is on the neck or proximal extremities. Localization on the face or penis is rare. The site of the primary lesion does not differ between males and females.

The interval between the appearance of the primary plaque and the secondary eruption can range from 2 days to 2 months, but the secondary eruption typically occurs within 2 weeks of the appearance of the primary plaque. At times, the primary and secondary lesions may appear at the same time. The secondary eruption occurs in crops at intervals of a few days and reaches its maximum in approximately 10 days. Occasionally, new lesions continue to develop for several weeks. The symmetric eruption is localized mainly to the trunk and adjacent regions of the neck and proximal extremities (Fig. 42-4). The most pronounced lesions extend over the abdomen and anterior surface of the chest as well as over the back (Figs. 42-5–42-7 and eFigs. 42-7.1 and 42-7.2 in online edition). Lesions distal to the elbows and knees can occur. Two main types of secondary lesions occur: (1) small plaques resembling the primary plaque in miniature, aligned with their long axes along lines of cleavage and distributed in a Christmas tree pattern, and (2) small, red, usually nonscaly papules that gradually increase in number and spread peripherally. The two types of lesions may coexist.

In approximately 20% of patients, the clinical picture diverges from the classic one described above. The primary plaque may be missing or present as double or multiple lesions (Fig. 42-3 and see eFig. 42-3.1 in online edition), often close together. The primary plaque may be the sole manifestation of the disease or only one of the two lesions (eFig. 42-3.2 in online edition). The distribution of the secondary eruption may be exclusively peripheral. Facial and scalp involvement occurs more commonly in black children. Localized forms of disease may involve

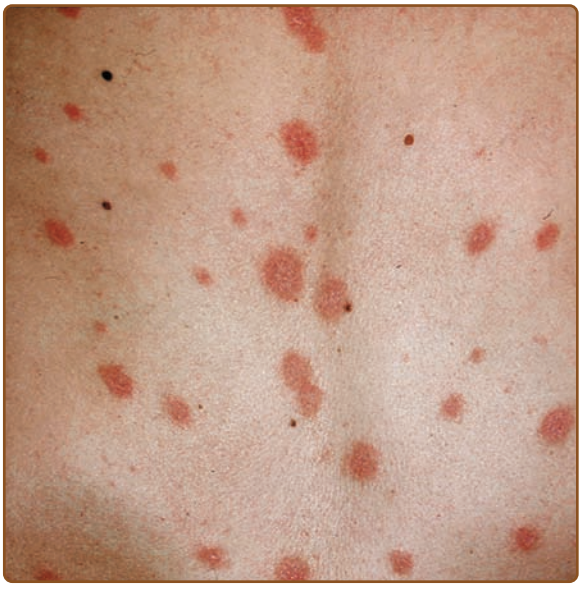

Figure 42-5 Typical distribution of secondary plaques along the lines of cleavage on the back in a Christmas tree pattern.

Figure 42-6 Typical distribution of secondary plaques along the lines of cleavage on the chest of a black individual.

certain body regions such as the palms, soles, axillae, vulva, and groin (eFigs. 42-3.3 and 42-7.1 in online edition) and also may be localized to one side of the body.

The morphology of the secondary lesions may also be atypical, and in these cases, the diagnosis of PR can be more challenging. Macules lacking scales may occur, papules may be follicular, and typical plaques may be absent or resemble psoriasis (eFig. 42-7.3 in online edition). The palms and soles are involved at times, and the clinical picture in these patients may simulate a widespread eczematous eruption. A vesicular type of PR (eFig. 42-3.3 in online edition) uncommonly affects children and young adults. Urticarial, pustular, purpuric (Fig. 42-2 and eFig. 42-7.4 in online edition), and erythema multiforme-like variants of PR also exist. Many patients will have classic PR plaques admixed with the atypical vesicles, follicular papules, and purpura.

Figure 42-7 Vesicular pityriasis rosea, showing typical primary plaque and secondary papulovesicles. Note Christmas tree distribution.

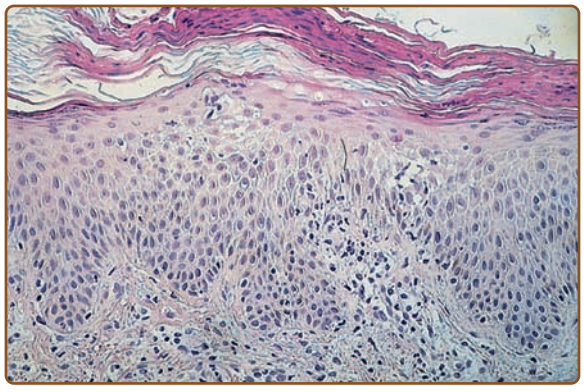

Figure 42-8 Typical nonspecific histologic features of pityriasis rosea, including patchy parakeratosis, absence of a granular cell layer, slight acanthosis, spongiosis, and a lymphohistiocytic infiltrate in the superficial dermis.

RELATED PHYSICAL FINDINGS

In rare cases enanthema may occur with hemorrhagic macules and patches, bullae on the tongue and cheeks, or lesions that resemble aphthous ulcers. Nail dystrophy after PR has also been reported. Lymphadenopathy may occur in patients with PR, especially early in the course of the disease and in association with flu-like symptoms.

In cases of classic PR, most patients do not require skin biopsies because the diagnosis is straightforward on clinical grounds and the histologic findings are nonspecific. Typical histopathologic features include focal parakeratosis, a reduced or absent granular cell layer, mild acanthosis, mild spongiosis, papillary dermal edema, a perivascular and superficial dermal interstitial infiltrate of lymphocytes and histiocytes, and focal extravasation of erythrocytes (Fig. 42-8).[23,24] Similar histologic findings are observed in both primary and secondary plaques. The histologic picture is indistinguishable from that of superficial gyrate erythema. In older lesions, the perivascular infiltrate is often both superficial and deep, with less spongiosis and more pronounced acanthosis. These late lesions may be difficult to distinguish from psoriasis and lichen planus.

LABORATORY TESTS

Routine blood studies usually give normal results and are not recommended. However, leukocytosis, neutrophilia, basophilia, lymphocytosis, and slight increases in erythrocyte sedimentation rate and levels of total protein, α_1- and α_2-globulins, and albumin have been reported.

DIFFERENTIAL DIAGNOSIS

(Box 42-1)

Secondary syphilis may present with slightly scaly lesions and can mimic papular PR with no primary plaque. Mucosal lesions and lymphadenopathy may occur in both PR and syphilis, but as with involvement of the palms and soles, these findings are much more common in the latter. Serologic tests for syphilis will differentiate the two. Tinea corporis may resemble PR, especially when PR occurs as only a primary plaque or when it is localized to the groin area. Scaling will be at the periphery of the plaques in tinea corporis as opposed to inside the periphery of plaques in PR. Mycologic investigation is often necessary to rule out dermatophyte infection. The lesions of nummular dermatitis are usually round, not oval, and pinpoint papules and vesicles are more prominent than in PR. Guttate psoriasis may be difficult to distinguish from PR when only a few lesions are present, when lesions follow lines of cleavage, and when the disease course is chronic. Histologic examination may be useful in these cases. Pityriasis lichenoides chronica may present with a Christmas tree pattern on the trunk, but as a rule, typical lesions will be found on the extremities.

Many drugs have been reported to cause PR-like rashes. Thus, it is always important to obtain a drug history to investigate this possibility. These include arsenic, barbiturates, bismuth, captopril, clonidine, gold, interferon-α, isotretinoin, ketotifen, labetalol, organic mercurials, methoxypromazine, metronidazole, omeprazole, D-penicillamine, salvarsan, sulfasalazine, terbinafine, lithium, and tripelene amine hydrochloride. Of note, more recent additions to this list include imatinib,[25] a drug used in the treatment of chronic myeloid leukemia, and tumor necrosis factor (TNF)-α blockers used to treat psoriasis.[26,27] Drug-induced PR may closely resemble classic PR, but it often shows atypical features, a protracted course, large lesions, subsequent marked hyperpigmentation, and transformation to lichenoid dermatitis.

BOX 42-1 DIFFERENTIAL DIAGNOSIS OF PITYRIASIS ROSEA (PR)

- *Secondary syphilis:* history of primary chancre, no herald patch is present, lesions typically involve palms and soles, condyloma lata may be present, usually more systemic complaints and lymphadenopathy, presence of plasma cells on histology, positive serologic test for syphilis [e.g., a Venereal Disease Research Laboratory (VDRL) test].
- *Tinea corporis:* scale is usually at periphery of plaques, plaques usually not oval and distributed along lines of cleavage, positive KOH examination.
- *Nummular dermatitis:* plaques usually circular and not oval, no collarettes of scale, tiny vesicles common. When in doubt, perform a biopsy.
- *Guttate psoriasis:* plaques usually smaller than PR plaques and do not follow lines of cleavage, scales are thick and not fine. When in doubt, perform a biopsy.
- *Pityriasis lichenoides chronica:* longer disease course, smaller lesions, thicker scale, no herald patch, more common on extremities. When in doubt, perform a biopsy.
- *PR-like drug eruption:* see text for extensive list. When in doubt, obtain a drug history.

COMPLICATIONS

Patients may experience flu-like symptoms, but these are relatively mild if they occur. About one-third of patients with PR experience significant levels of anxiety and depression, mostly centered around uncertainty over the cause of the disease and the length of disease recovery.[28] Reassurance is important for these individuals. No serious complications occur in otherwise healthy PR patients. However, PR during pregnancy is of concern. In one series of 38 pregnant women with PR, Drago and colleagues reported nine premature deliveries, although all babies born to women who had PR during their pregnancy showed no birth defects.[29] Five women had miscarriages, which was most common in the first trimester. Thus, pregnant women who develop PR should warrant careful evaluation and follow-up.

PROGNOSIS AND CLINICAL COURSE

All patients with PR have complete spontaneous resolution of their disease. The disease duration normally varies between 4 and 10 weeks, with the first few weeks associated with the most new inflammatory skin lesions and the greatest likelihood of flu-like symptoms. Both postinflammatory hypopigmentation and hyperpigmentation can follow PR. As with other skin diseases, this occurs more commonly in individuals with darker skin color, with hyperpigmentation predominating.[30] Treatment with ultraviolet light phototherapy may also worsen postinflammatory hyperpigmentation and should be used with caution. Otherwise, patients have no residual effects secondary to the occurrence of PR. Recurrent disease is possible, but it is rare.

TREATMENT

Because PR is self-limited, there is no need to treat uncomplicated cases.[31] Patient education and reassurance is warranted in all cases. Midpotency topical corticosteroids may be used for symptomatic relief of pruritus. Interestingly, Drago and colleagues have

BOX 42-2 TREATMENT OF PITYRIASIS ROSEA

- For all patients, education about the disease process and reassurance.
- For patients with associated pruritus, topical corticosteroids.
- For patients early in the disease course who demonstrate associated flu-like symptoms and/or extensive skin disease, oral acyclovir 800 mg five times daily for 1 week (or equivalent acyclovir derivative) may hasten recovery from disease.
- For selected patients, phototherapy may be useful.

reported that patients given high-dose acyclovir (i.e., 800 mg five times daily for 1 week) experienced more rapid resolution of PR than patients treated with placebo for 1 week.[6] Specifically, 79% of 42 patients had complete resolution of PR within 2 weeks of starting acyclovir therapy, whereas 4% of 45 patients treated with placebo experienced resolution of their disease at 2 weeks. Although patients were blinded to the type of treatment they received, the trial was limited in that the investigators were not blinded and the patients were not randomly assigned to one of the two treatment groups. Given that acyclovir and its derivatives are relatively inexpensive and well-tolerated drugs, this form of therapy should be considered in PR patients presenting early in their disease course who demonstrate associated flu-like symptoms and/or extensive skin disease. Erythromycin was reported to be of benefit to patients with PR,[32] but clinical experience and more recent reports have not confirmed this initial result.[33–35] Some patients with PR may benefit from phototherapy,[36] although this should be used with caution given that it can increase the risk of postinflammatory hyperpigmentation after disease resolution (Box 42-2).

PREVENTION

There are no data on how PR can be prevented.

Chapter 43 :: Erythema Annulare Centrifugum and Other Figurate Erythemas

:: Walter H.C. Burgdorf

ERYTHEMA ANNULARE CENTRIFUGUM AT A GLANCE

- Clinical pattern of annular expanding erythematous rings, which enlarge rapidly, fade, and then disappear, as new lesions appear.
- Diagnosis of erythema annulare centrifugum is one of the exclusions.
- Superficial and deep variants can be separated clinically and histologically. Deep form is usually lupus tumidus or erythema migrans.

The figurate erythemas include a variety of eruptions characterized by annular and polycyclic lesions. Classification of this group has always been controversial; the literature abounds with contradictions, uncertainties, and a bewildering array of synonyms. Darier in 1916 was the first to use the term *erythema annulare centrifugum*[1] (EAC), although similar lesions had been described previously under other names. Table 43-1 lists the figurate erythemas and the differential diagnoses to consider.

EPIDEMIOLOGY

EAC is an uncommon disorder. No epidemiologic data are available. There are only three large series in the literature: (1) 66 cases identified clinically,[2] (2) 73 first

TABLE 43-1
Migratory Erythemas

Disorder	Key Features	
Erythema annulare centrifugum (EAC)	Slowly migrating lesions; often idiopathic.	This chapter
Erythema gyratum repens	Rapidly moving; usually cancer marker.	153
Erythema chronicum migrans	Annular lesions originating from tick bite; skin sign of Lyme borreliosis.	187
Lupus erythematosus	Most deep EAC is lupus tumidus. Annular lesions common in neonatal and subacute cutaneous LE; Ro/La antibodies should be sought; overlaps with Sjögren syndrome (especially in Asians).	155
Urticaria	Giant urticaria is often annular and migratory; patients have ordinary urticaria elsewhere and more pruritus.	38
Pityriasis rosea	Individual lesions closely resemble superficial EAC but pattern and course different	42
Bullous pemphigoid	Early lesions often urticarial and may be annular.	56
Erythema multiforme	Target lesions, usually acral, often mucosal disease; some lesions annular.	39
Dermatophyte infections and tinea versicolor	Many fungal infections are annular (ringworm); the scale contains hyphae or spores.	188
Psoriasis	Pustular and occasionally ordinary psoriasis may have annular lesions.	18
Erythema marginatum	Transient, rapidly spreading annular erythema; specific for rheumatic fever.	160
Necrolytic migratory erythema	Marker for glucagonoma; erosive perioral and acral lesions, but truncal lesions may be polycyclic.	153
Carrier state chronic granulomatous disease	Female carriers may have annular lupus erythematosus-like rash.	143
Hereditary lactate dehydrogenase M-subunit deficiency	Rare genodermatosis with annular erythematous and scaly lesions.	This chapter
Familial annular erythema	Extremely rare.	This chapter
Annular erythema of infancy	Many different disorders; must rule out neonatal lupus erythematosus.	This chapter

diagnosed histologically,[3] and (3) 90 carrying either a clinical or histological diagnosis.[4] EAC appears to have no predilection for either sex or for any age group.

ETIOLOGY AND PATHOGENESIS

Both the annularity and the peripheral spread of EAC have attracted speculation as to a possible mechanism. Most hypotheses have centered on interactions among inflammatory cells, their mediators, and ground substance as foreign antigens diffuse through the skin.[5,6]

While many possible triggers have been suggested, all are common problems and EAC is very rare, so a direct causality is impossible to prove. It is better to view EAC as idiopathic. In one series, 24 patients were closely evaluated, and in none of the cases was any definite cause found.[7] Suspected triggers include bacterial[8] and candidal[9] infections, autoimmune diseases,[10] menses,[11] pregnancy,[12] and even stress.[13] Although medications are often identified as causing EAC in case reports, none regularly induces such lesions. EAC may be coupled with malignant neoplasms, with the eruption disappearing after treatment of the tumor and often returning as the tumor recurs.[14–16] This paraneoplastic marker must be distinguished from metastatic tumors with an annular pattern.[17,18]

CLINICAL FINDINGS

HISTORY

The history is most important in exploring the differential diagnostic considerations. In general, the lesions are asymptomatic but may be cosmetically disturbing.

CUTANEOUS LESIONS

EAC presents as one or more lesions that begin as erythematous macules or urticarial papules and enlarge by peripheral extension to form ringed, arcuate, or polycyclic figures. They are usually asymptomatic. EAC has traditionally been divided into superficial and deep forms. In the superficial form, the bands have fine scales, which are more prominent on the inner aspect rather than the advancing edge. The lesions spread

Figure 43-1 Superficial erythema annulare centrifugum. A large annular plaque with trailing scale behind the advancing erythematous edge.

Figure 43-2 Superficial erythema annulare centrifugum. Multiple lesions, once again demonstrating scale. (Used with permission from Wilfried Neuse and Thomas Ruzicka, Düsseldorf, Germany.)

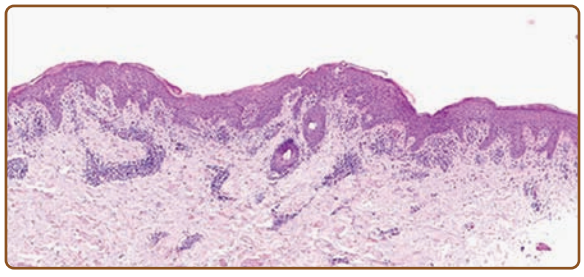

Figure 43-3 Superficial erythema annulare centrifugum showing perivascular lymphocytic infiltrates in papillary dermis. (Used with permission from Heinz Kutzner, Friedrichshafen, Germany.)

gradually to form large rings with central clearing, with the edges of the lesions often advancing several millimeters a day (Fig. 43-1 and Fig. 43-2). After a variable period of time, the lesions disappear, often to be replaced by new ones. In some cases annual recurrence has been described.

In the deep form of EAC, there is no scale and the rings are infiltrated (eFig. 43-2.1 and eFig. 43-2.2 in online edition); almost all these cases represent either lupus erythematosus or erythema migrans caused by infection with *Borrelia burgdorferi*.[4] A few may be drug-induced.

HISTOPATHOLOGY

Superficial EAC has epidermal changes of parakeratosis and spongiosis, with a superficial perivascular infiltrate (eFig. 43-2.1 in online edition, Figs. 43-3 and Fig. 43-4). There is minimal papillary dermal edema and no spongiosis. Thus, there are histological similarities to pityriasis rosea. The deep form has superficial and deep perivascular infiltrates (Fig. 43-5). Histopathology is important in excluding common differential diagnostic considerations; interface change or mucin helps identify lupus erythematosus; a plasma cell infiltrate suggests erythema chronicum migrans; and eosinophils are a possible clue to drug reactions.

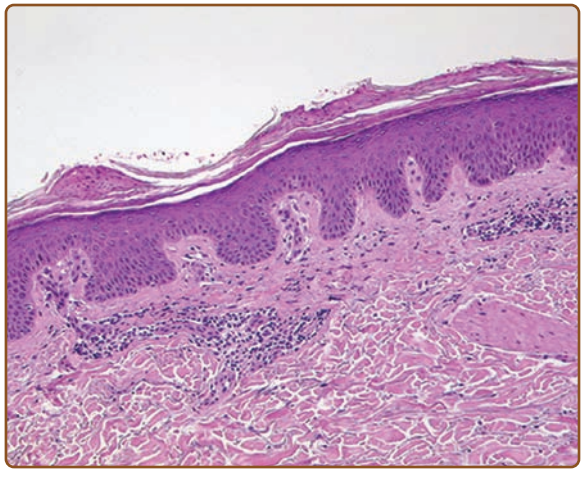

Figure 43-4 Higher view of superficial erythema annulare centrifugum with parakeratosis and focal spongiosis. (Used with permission from Heinz Kutzner, Friedrichshafen, Germany.)

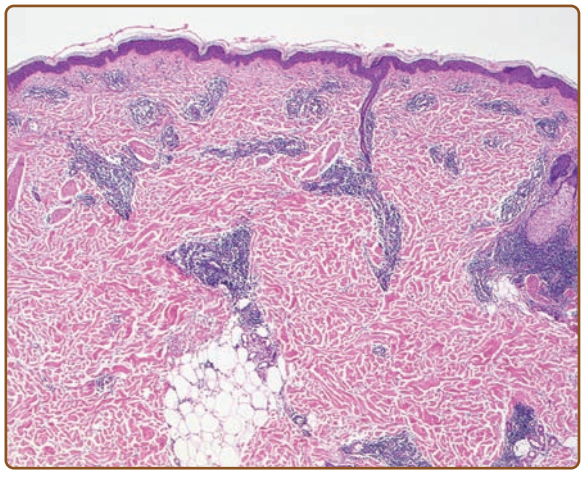

Figure 43-5 Deep erythema annulare centrifugum with normal epidermis and lymphocytic infiltrates about vessels of superficial and deep dermis. Many such lesions are lupus tumidus, so a careful search for mucin is mandatory. None is seen here. (Used with permission from Heinz Kutzner, Friedrichshafen, Germany.)

OTHER LABORATORY TESTS

There are no other laboratory tests diagnostic for EAC.

DIFFERENTIAL DIAGNOSIS

(Box 43-1)

The differential diagnostic challenge in EAC is multiple. First, one must exclude lupus erythematosus and erythema migrans. We view superficial EAC as a specific entity; the annular variants of diseases such as dermatophyte infections, psoriasis, urticaria, bullous diseases, leukocytoclastic vasculitis, secondary syphilis, and sarcoidosis are not EAC. While a relationship to chronic pityriasis rosea has been suggested,[4] there are so many clinical differences that we prefer not to make this association.

There also are a number of rare figurate erythemas that cause problems. Erythema gyratum repens, which is generally more rapidly moving, usually reflects an underlying malignancy (see Chapter 153). Annular erythemas are seen in the carrier state of chronic granulomatous disease or a lactate dehydrogenase M-subunit deficiency. Annular lichenoid dermatitis of youth is clinically similar. Familial EAC, originally described as erythema gyratum perstans, is rare. Finally, there is the broad spectrum of annular erythemas of infancy,[19] including neonatal lupus erythematosus, *Malassezia furfur* infections, and the idiopathic variants which themselves may show eosinophilic or neutrophilic infiltrates, as well as atrophy.

PROGNOSIS AND CLINICAL COURSE

EAC tends to be a chronic disease, which waxes and wanes.

BOX 43-1 DIFFERENTIAL DIAGNOSIS OF ERYTHEMA ANNULARE CENTRIFUGUM (EAC)

Most Likely

- Dermatophyte infections
- Tinea versicolor
- Erythema migrans
- Annular urticaria
- Lupus erythematosus
- Annular psoriasis

Consider

- Erythema multiforme
- Pityriasis rosea
- Granulomatous diseases (granuloma annulare, actinic granuloma, sarcoidosis)
- Bullous pemphigoid (urticarial phase)
- Leukocytoclastic vasculitis (especially in children)
- Erythema marginatum
- Erythema gyratum repens
- Necrolytic migratory erythema
- Hypereosinophilic syndrome
- Carrier state chronic granulomatous disease
- Hereditary lactase dehydrogenase M-subunit deficiency
- Familial annular erythema
- Annular erythemas of infancy

Always Rule Out

- Lupus erythematosus
- Lyme borreliosis
- Underlying tumor or annular metastasis

TREATMENT

Only symptomatic relief is available. Systemic glucocorticoids usually suppress EAC, but recurrence is common when these drugs are stopped. Systemic therapy with antipruritics may help. Topical vitamin D analogs, perhaps combined with ultraviolet irradiation, are another option.[20,21] Empiric use of antibiotic, antifungal, or anticandidal agents has sometimes been useful. Biologics may represent yet another option.[22]

Chapter 44 :: Granuloma Annulare

:: Julie S. Prendiville

GRANULOMA ANNULARE AT A GLANCE

- Relatively common disorder; exact prevalence is unknown; favors children and young adults.
- A localized ring of beaded papules on the extremities is typical; generalized, subcutaneous, perforating, and patch subtypes also occur.
- The cause is unknown, and the pathogenesis is poorly understood.
- Pathologic features consist of granulomatous inflammation in a palisaded or interstitial pattern associated with varying degrees of connective tissue degeneration and mucin deposition.
- Most cases resolve spontaneously within 2 years.

Granuloma annulare is a benign self-limited disease, first described by Colcott-Fox[1] in 1895 and Radcliffe-Crocker[2] in 1902.

EPIDEMIOLOGY

Granuloma annulare is a relatively common disorder.[3] It occurs in all age groups, but is rare in infancy.[3–5] The localized annular and subcutaneous forms occur more frequently in children and young adults. The generalized variant is more common in adults. Many studies report a female preponderance,[3] but some have found a higher frequency in males.[6] Granuloma annulare does not favor a particular race or geographic area, with the possible exception of the perforating type, which may be more common in Hawaii.[7]

Most cases of granuloma annulare are sporadic. Occasional familial cases are described with occurrence in twins, siblings, and members of successive generations.[3,8,9] Attempts to identify an associated HLA subtype have yielded disparate results in different population groups.[10,11]

ETIOLOGY AND PATHOGENESIS

The etiology of granuloma annulare is unknown, and the pathogenesis is poorly understood. Most cases occur in otherwise healthy children. A variety of predisposing events and associated systemic diseases is reported, but their significance is unclear. It is possible that granuloma annulare represents a phenotypic reaction pattern with many different initiating factors.[12]

PREDISPOSING EVENTS

Nonspecific mild trauma is considered a possible triggering factor because of the frequent location of lesions on the distal extremities of children. An early study of subcutaneous granuloma annulare found a history of trauma in 25% of children,[3] but this observation has not been replicated. Trauma is also a suspected factor in auricular lesions.[13] Granuloma annulare has occurred after a bee sting,[14] a cat bite,[15] and an octopus bite,[16] and insect bite reactions have also been implicated.[3] There is a report of perforating granuloma annulare in long-standing tattoos.[17] Widespread lesions have developed after waxing-induced pseudofolliculitis[18] and erythema multiforme minor,[19] and in association with systemic sarcoidosis.[3,20] Severe uveitis without other evidence of sarcoidosis has occurred in a few patients with granuloma annulare.[21,22,23]

INFECTIONS AND IMMUNIZATIONS. There are several reports of the development of granuloma annulare within herpes zoster scars, sometimes many years after the active infection.[24] It is also described after chickenpox.[25] Generalized, localized, and perforating forms of granuloma annulare may occur in association with human immunodeficiency virus (HIV) infection (see eFig. 44-0.1 in online edition).[26–31] Adenovirus was isolated from a lesion in one HIV-positive patient.[32] Epstein–Barr virus was excluded as a causative agent in these cases.[26,27] However, in other

instances generalized granuloma annulare has been linked to viral infections, including Epstein–Barr virus infection,[33] chronic hepatitis B,[34] and hepatitis C.[35] Vaccinations for tetanus,[36] diphtheria toxoid,[37] and hepatitis B vaccination[38] have been implicated as triggering factors, although vaccination sites were spared in one case of generalized granuloma annulare.[39]

Lesions compatible with granuloma annulare may occur in patients with active tuberculosis.[12] There are also reports of granuloma annulare after tuberculin skin tests[3] and Bacille Calmette-Guérin immunization.[40] Evidence of *Borrelia burgdorferi* infection was detected in two reports,[41,42] but this association was not confirmed in a serologic study.[43] A case in which chronic relapsing granuloma annulare flared during scabies infestation was attributed to the Koebner phenomenon.[44]

SUN EXPOSURE. Granuloma annulare with a predilection for sun-exposed areas[45–48] and seasonal recurrence[45] has been described. Photosensitive granuloma annulare has been observed in patients with HIV infection.[49] One patient developed generalized disease after psoralen plus ultraviolet A (UVA) light therapy,[50] but it is of note that phototherapy and psoralen/UVA phototherapy have also been used to treat generalized granuloma annulare.[51–54]

Actinic granuloma, also known as *annular elastolytic giant cell granuloma*, develops on photodamaged skin and is believed to represent a granulomatous reaction to actinic elastosis.[55] Its relationship to granuloma annulare is debated.

DRUGS. Granuloma annulare-like drug reactions are reported for gold therapy and treatment with allopurinol, diclofenac, quinidine, intranasal calcitonin, and amlodipine.[56]

An interstitial granulomatous drug reaction linked to the use of angiotensin-converting enzyme inhibitors, calcium channel blockers, and other medications is considered a distinct entity but may mimic granuloma annulare.[57–59]

DIABETES MELLITUS AND THYROID DISEASE. Development of granuloma annulare in patients with diabetes mellitus is extensively documented. Whether this is a true relationship has long been debated. The link is primarily with type 1 insulin-dependent diabetes,[60] but cases are also reported with type 2 noninsulin-dependent disease.[61–63] Localized[60] and generalized[46,63,64] as well as subcutaneous nodular[61,65,66] and perforating[5,7] forms of granuloma annulare have been observed. Granuloma annulare rarely predates the onset of diabetes.[60,66] The histopathologic similarity between granuloma annulare and necrobiosis lipoidica diabeticorum and the coexistence of both conditions in occasional diabetic patients[62] suggest a true association. However, most patients with granuloma annulare do not have diabetes mellitus. Studies attempting to establish a causal correlation have yielded conflicting results.[60,67,68]

Granuloma annulare has also occurred in a number of patients with thyroiditis, hypothyroidism, and thyroid adenoma.[64,69–72]

MALIGNANCY. An association between granuloma annulare and malignancy in adult patients is reported primarily with Hodgkin and non-Hodgkin lymphoma, including mycosis fungoides, Lennert lymphoma, B-cell disease,[73–76] T-cell leukemia/lymphoma,[77,78] and angioblastic T-cell lymphoma.[79] It is reported less commonly with myeloid leukemias[80] and with solid tumors, particularly of the breast.[46,73] The skin lesions of cutaneous lymphoma and other hematologic malignancies can mimic granuloma annulare both clinically and histopathologically.[81,82] It may be difficult to distinguish whether they represent true granuloma annulare with atypical lymphocytes, or cutaneous lymphoma obscured by a granulomatous infiltrate.[75,76]

PATHOGENETIC MECHANISMS

The pathogenetic mechanisms that result in foci of altered connective tissue surrounded by a granulomatous inflammatory infiltrate are not understood. Proposed mechanisms include (1) a primary degenerative process of connective tissue initiating granulomatous inflammation,[83] (2) a lymphocyte-mediated immune reaction resulting in macrophage activation and cytokine-mediated degradation of connective tissue,[30,84–88] and (3) a subtle vasculitis or other microangiopathy leading to tissue injury.[84]

CLINICAL FINDINGS

HISTORY

The typical history is of one or more papules with centrifugal enlargement and central clearing. These annular lesions are often misdiagnosed as tinea corporis and treated unsuccessfully with topical antifungal agents. Subcutaneous nodules may raise suspicion about malignancy or rheumatoid disease.[89]

Granuloma annulare is usually asymptomatic. Mild pruritus may be present, but painful lesions are rare.[90,91] Nodular lesions on the feet may cause discomfort from footwear.[92] Cosmesis is often a concern for adolescent and adult patients, particularly with generalized disease.

CUTANEOUS LESIONS

Clinical variants of granuloma annulare include the localized, generalized, subcutaneous, perforating, and patch types. Linear granuloma annulare,[93,94] a follicular pustular form,[95] and papular umbilicated lesions in children[96] have also been described. There is overlap between the different variants, and more than one morphologic type may coexist in the same patient.

LOCALIZED TYPE. The most common form of granuloma annulare is an annular or arcuate lesion. It may be skin colored, erythematous, or violaceous. It usually measures 1–5 cm in diameter.[3] The annular margin is firm to palpation and may be continuous or

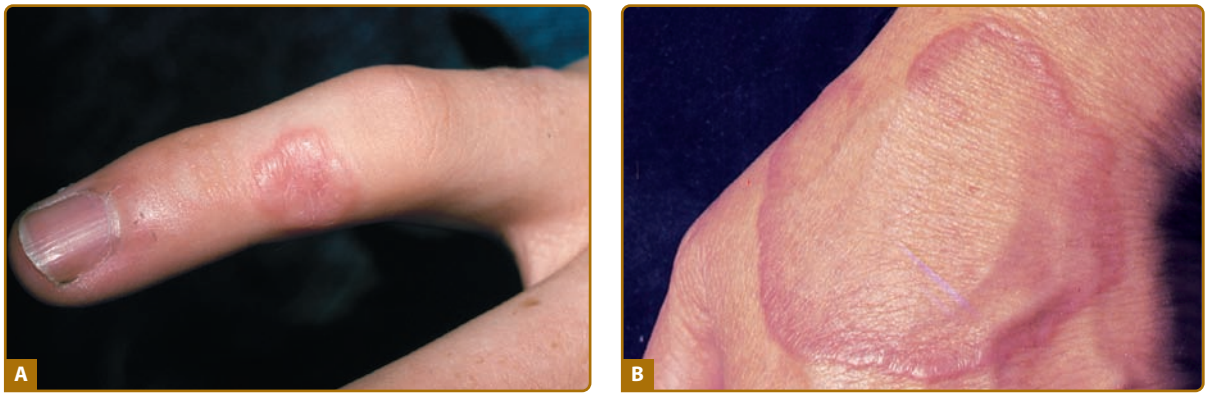

Figure 44-1 **A.** Typical annular lesion of granuloma annulare on a finger. **B.** A larger annular lesion of granuloma annulare on the dorsum of the hand.

consist of discrete or coalescent papules in a complete or partial circle (Fig. 44-1). The epidermis is usually normal, but surface markings may be attenuated over individual papules. Within the annular ring, the skin may have a violaceous or pigmented appearance. Solitary firm papules or nodules may also be present. Papular lesions on the fingers may appear umbilicated.

The dorsal hands and feet, ankles, lower limbs, and wrists are the sites of predilection (see Figs. 44-1 and 44-2). Less commonly, lesions occur at other sites, including the eyelids.[97] The palms and soles are occasionally involved.[90,91] Localized annular lesions may coexist with the subcutaneous or patch forms.

GENERALIZED TYPE. The generalized form of granuloma annulare is said to comprise 8%–15% of cases.[3,46] The majority of patients are adults, but it may also be seen in childhood.[46,98] Unlike in localized disease, the trunk is frequently involved, in addition to the neck and extremities. The face, scalp, palms, and soles may also be affected.[46]

Generalized granuloma annulare presents as widespread papules (Fig. 44-3A), some of which coalesce to form small annular plaques or larger discolored patches with raised arcuate and serpiginous margins (see Fig. 44-3B). Lesions may be skin colored, pink, violaceous, tan, or yellow. An annular or nonannular morphology may predominate.[46] A generalized form of perforating granuloma annulare has also been described.[5,7]

Figure 44-2 Localized granuloma annulare with nodule on the hand of a child.

SUBCUTANEOUS TYPE. The subcutaneous form of granuloma annulare occurs predominantly in children,[89,99,100] but is also described in adult patients.[101–103] It is characterized by firm to hard, usually asymptomatic nodules located in the deep dermis and subcutaneous tissues. They may extend to underlying muscle, and nodules on the scalp and orbit are often adherent to the underlying periosteum.

Individual lesions measure from 6 mm to 3.5 cm in diameter.[100,104] They are distributed most often on the anterior lower legs in a pretibial location.[99] Other sites of predilection are the ankles, dorsal feet, buttocks, and hands.[103,105] Nodules on the scalp,[104,106] eyelids,[107–109] and orbital rim[65,110,111] may present a diagnostic challenge. Subcutaneous granuloma annulare may also be found on the penis.[112–114]

PERFORATING TYPE. The perforating type of granuloma annulare is a rare variant characterized by transepidermal elimination of the necrobiotic collagen. It may be localized, usually to the dorsal hands and fingers (see eFig. 44-3.1 in online edition), or generalized over the trunk and extremities.[5,7] It has been described on the ears,[115] on the scrotum,[116] and within herpes zoster scars and tattoos.[16] Superficial small papules develop central umbilication or crusting, and there may be discharge of a creamy fluid. Lesions heal with atrophic or hyperpigmented scars. In one series, 24% of patients complained of pruritus and 21% of pain.[117] Papular umbilicated granuloma annulare on the hands of children[96] and a generalized follicular pustular type of granuloma annulare[95] may be clinical variants.

PATCH TYPE. Macular lesions that present as erythematous, red–brown, or violaceous patches without an annular rim are reported in adult women.[88,118] An arcuate dermal erythema is also observed. General-

Figure 44-3 **A.** Generalized granuloma annulare. Small papular lesions that are too small to exhibit annular configuration. **B.** Multiple annular lesions on the lower arm.

ized confluent erythema has been described in an HIV-positive patient.[30]

RELATED PHYSICAL FINDINGS

Most patients with granuloma annulare are healthy and have no other abnormal physical findings. Arthralgia is reported in association with painful lesions on the hands.[91] Granuloma annulare-like skin lesions and joint disease characterize a multisystem disorder described as interstitial granulomatous dermatitis with arthritis.[119]

Oral involvement was observed in one patient with HIV-associated disease.[27]

LABORATORY TESTS

A diagnosis of localized granuloma annulare is made on clinical examination, and further evaluation is rarely indicated. Biopsy to obtain a specimen for histopathologic examination is necessary when the presentation is atypical, when lesions are symptomatic, and when the diagnosis is otherwise in doubt. Histopathologic analysis may be required to confirm a diagnosis of generalized granuloma annulare or subcutaneous nodular disease on the head and orbital region.

HISTOPATHOLOGIC FINDINGS

The diagnosis is best made at low magnification. Changes are usually observed in the upper and middle dermis, although any part of the dermis or subcutis can be involved. The characteristic histopathologic finding is a lymphohistiocytic granuloma associated with varying degrees of connective tissue degeneration and mucin deposition. The inflammatory infiltrate may have a palisaded or interstitial pattern, or a mixture of both patterns.[120–122] Occasionally, a sarcoid-like pattern with large epithelioid histiocytes is seen.[120]

The typical appearance is of single or multiple foci of inflammation with a central core of altered collagen (necrobiosis) surrounded by a wall of palisaded histiocytes (Fig. 44-4). The necrobiotic centers are usually oval, slightly basophilic, devoid of nuclei, and marked by a loss of definition of the collagen bundles and diminished or absent elastic tissue fibers. Stains for mucin and lipid often give positive results.

An interstitial, nonpalisaded pattern of inflammation with histiocytes infiltrating among fragmented collagen bundles may be predominant, particularly in the generalized form. This interstitial pattern is also observed in the absence of apparent connective tissue change. Stains for mucin may be helpful in detecting connective tissue alteration within the infiltrate.

Lymphocytes are admixed with histiocytes in the granuloma and in a perivascular distribution. Multinucleated giant cells may be present but are not as numerous as in actinic granuloma.[123] Neutrophils and eosinophils are occasionally seen, but plasma cells are rare. Evidence of vascular reactivity includes variable endothelial cell swelling, red cell extravasation, fibrin, leukocytoclasis, and neutrophilic infiltration in blood vessel walls.[124] When leukocytoclastic vasculitis or nuclear debris is a prominent finding, a diagnosis of palisaded neutrophilic and granulomatous dermatitis of immune complex disease should be considered.[124]

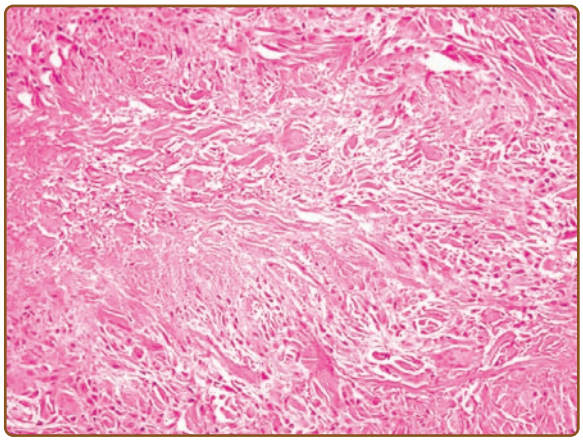

Figure 44-4 Palisading granulomatous inflammation surrounding degenerating collagen within the dermis. (Hematoxylin and eosin stain, ×200.) (Used with permission from Dr. Richard Crawford.)

In subcutaneous granuloma annulare the foci of necrobiosis are larger and lie within the deep dermis and subcutaneous fat. They may be distinguished from rheumatoid nodules by the presence of mucin in the necrobiotic zone.[107] Central ulceration and communication between the area of necrobiosis and the surface are characteristic of perforating granuloma annulare. Examination of serial sections may be necessary to demonstrate the necrobiotic plug. An interstitial pattern of inflammation with diffuse necrobiosis is reported in the patch type of granuloma annulare.[119] Palisaded granulomas have also been observed in macular lesions.[88]

Immunofluorescence testing may show deposition of fibrin, immunoglobulin (Ig) M, and C3 as a variable finding around vessel walls or at the basement membrane zone; IgM cytoid bodies are also reported.[119] Immunohistochemistry may be useful to confirm the histiocytic nature of equivocal disease.[125] Ultrastructural changes in the connective tissue and capillaries have been described.[83]

SPECIAL TESTS

A diagnosis of granuloma annulare is made clinically or by skin biopsy. Special investigations are usually not necessary. Further evaluation to rule out systemic disease such as infection, sarcoidosis, or malignancy may be required in atypical cases of granuloma annulare.[12,77,81,82,118] Investigation for endocrine disease is indicated if the patient has signs or symptoms of diabetes or thyroid dysfunction.

Imaging studies may be performed in subcutaneous granuloma annulare when the clinical features are not recognized or when the presentation is atypical with rapid enlargement or pain.[126] Radiographs show a nonspecific soft tissue mass without calcification

BOX 44-1 DIFFERENTIAL DIAGNOSIS OF GRANULOMA ANNULARE

ANNULAR TYPE

Consider

- Tinea corporis
- Subacute cutaneous lupus erythematosus
- Neonatal lupus erythematosus
- Annular lichen planus
- Acute febrile neutrophilic dermatosis
- Erythema chronicum migrans
- Actinic granuloma/annular elastolytic giant cell granuloma
- Necrobiosis lipoidica diabeticorum

Rule Out

- Infections (e.g., tuberculosis, atypical mycobacteria, syphilis)
- Interstitial granulomatous dermatitis with arthritis
- Interstitial granulomatous drug reaction
- Annular sarcoidosis
- Lymphoma

GENERALIZED TYPE

Consider

- Lichen planus
- Lichen nitidus
- Molluscum contagiosum

Rule Out

- Lichenoid and granulomatous dermatitis of acquired immunodeficiency syndrome
- Infections (e.g., tuberculosis, atypical mycobacteria, syphilis)
- Sarcoidosis
- Blau syndrome (familial granulomatous arthritis, skin eruption, and uveitis)
- Interstitial granulomatous drug reaction
- Lymphoma

SUBCUTANEOUS TYPE

Consider

- Erythema nodosum
- Dermoid cyst
- Rheumatoid nodules

Rule Out

- Epithelioid sarcoma
- Benign or other malignant tumors
- Deep infections

PERFORATING TYPE

Consider

- Molluscum contagiosum
- Insect bites
- Pityriasis lichenoides
- Perforating collagenosis and other perforating disorders
- Foreign body granuloma
- Papulonecrotic tuberculid
- Palisaded neutrophilic and granulomatous dermatitis of immune complex disease

PATCH TYPE

Consider

- Morphea
- Erythema annulare centrifugum
- Parapsoriasis

Rule Out

- Lymphoma

BOX 44-2 TREATMENT OPTIONS FOR GRANULOMA ANNULARE

- Await spontaneous resolution
- Apply topical corticosteroid with or without occlusion
- Administer intralesional triamcinolone 2.5 mg/mL[129]

ANECDOTAL REPORTS OF BENEFIT

- Topical
  - Tacrolimus 0.1% ointment[130]
  - Pimecrolimus cream[131]
  - Imiquimod 5% cream[132,133a]
- Intralesional
  - Interferon-γ[135]
  - Interferon-β[135]
  - Sterile water or saline[129]
- Systemic
  - Antimalarials[98]
  - Retinoids[136–140]
  - Antibiotics[141,142]
  - Corticosteroids[92,108]
  - Cyclosporine[77,143]
  - Zileuton with vitamin E[144]
  - Fumaric acid esters[145,146]
  - Hydroxyurea,[147] chlorambucil, niacinamide, potassium iodide, dapsone[3,46,92]
  - Etanercept[148b]
  - Infliximab[150b]
  - Efalizumab[151b]
  - Adalimumab[152–154]
- Other
  - Phototherapy[51–54]
  - Photodynamic therapy[155,156]
  - Skin biopsy[157]
  - Cryotherapy[158]
  - Pulsed dye, Nd:YAG or CO_2 laser[159–162]

[a]Application of 5% imiquimod cream has been reported to worsen granuloma annulare in a child.[134]
[b]Development of granuloma annulare has been reported during therapy with etanercept, infliximab, and adalimumab.[149]

or bone involvement. Ultrasonographic examination reveals a hypoechoic area in the subcutaneous tissues.[126,127] Magnetic resonance imaging shows a mass with indistinct margins, isointense or slightly hyperintense to muscle with T1-weighted images and with a heterogeneous but predominantly high signal intensity on T2-weighted images.[126,128]

DIFFERENTIAL DIAGNOSIS

See Box 44-1.

TREATMENT

The usual treatment options include awaiting spontaneous resolution, topical steroids and intralesional steroids. These and more anecdotal reports are summarized in Box 44-2.

CLINICAL COURSE AND PROGNOSIS

Most cases of localized granuloma annulare resolve spontaneously without sequelae. Lesions may clear within a few weeks or persist for several years. The majority disappear within 2 years.[92] Recurrent lesions may develop months or even years later, frequently at the same site. Generalized granuloma annulare often runs a more protracted course.[46] Perforating granuloma annulare results in scarring.[117] There are a number of reports of anetoderma or middermal elastolysis following generalized granuloma annulare and annular elastolytic giant cell granuloma.[47,163–166] One case of generalized granuloma annulare in a photosensitive distribution healed with scarring and milia formation.[167]

SECTION 7

Disorders of Epidermal Differentiation and Keratinization

Chapter 45 :: Epidermal Stem Cells

:: Rebecca J. Morris

EPIDERMAL STEM CELLS AT A GLANCE

- The epidermis is a continually renewing tissue the function of which is maintained by a hierarchy of stem cells, transit amplifying cells, and terminally differentiating cells.
- In the proliferative hierarchy, stem cells have the highest proliferative potential.
- Epidermal stem cells may be identified by their functional characteristics, by distinctive cell cycle patterns, or by characteristic proteins.
- Epidermal stem cells usually exist in characteristic proliferative units with little lateral migration.
- The regulation of epidermal stem cells comprises complex pathways many of which are shared by embryonic, morphogenetic, and homeostatic processes.
- Epidermal diseases are associated with or may arise from proliferative dysfunction in the stem cell or transit amplifying cell compartments.
- Epidermal stem cells are attractive targets for cell and gene therapies.

The cutaneous epithelium is a continually renewing tissue maintained in a dynamic equilibrium of proliferation in the basal layer and loss through terminal differentiation from the suprabasal layers. This process is orchestrated with great elegance by a hierarchy of stem cells, transient amplifying cells, and terminally differentiating cells. These populations of cells work together to maintain lifelong tissue function and to bring about tissue repair. This chapter focuses on the role of stem cells and their identification in the epidermis.

CONCEPT OF STEM CELLS IN RENEWING TISSUES

Proliferation in the cutaneous epithelium begins with the stem cells.[1,2] Stem cells in this regard lack many characteristics of terminal differentiation, and have an intrinsically high proliferative potential relative to the other proliferating cells, but are generally capable of lifelong proliferation.[3] Upon division, a stem cell produces off one daughter that remains a stem cell, and one daughter that goes on to produce a series of transit amplifying cells that serve to magnify or amplify the stem cell's division resulting in the production of many differentiated cells with minimal input from the stem cell. This hierarchical system that usually involves decreasing proliferative potential is illustrated in Fig. 45-1. Stem cells typically interact with their surroundings in a supportive, protective niche.[1]

GENERAL METHODS FOR STEM CELL IDENTIFICATION AND ISOLATION

Stem cells may be studied by the presence or absence of proteins on their surface that distinguish them from other proliferative cells.[2] Such proteins may be internal, or more desirably, proteins on the cell surface that render the cells selective by various methods such as by magnetic bead separation or by fluorescence activated cell sorting (FACS).[2] Stem cells may also be studied by cellular kinetic characteristics such as in slowly cycling label-retaining[4] cells or through their patterns of mitotic activity.[5] Stem cells can sometimes be identified and isolated according to their special physical properties such as cell size or buoyant density,[6] or in conjunction with other properties such as in the so-called "side population" cells[7] that have active Abcg2 transporters. Candidate stem cells identified or isolated by any of these methods may then be characterized by functional tools such as in vitro colony forming assays,[8–10] or in an in vitro or in vivo skin reconstitution assay.[2]

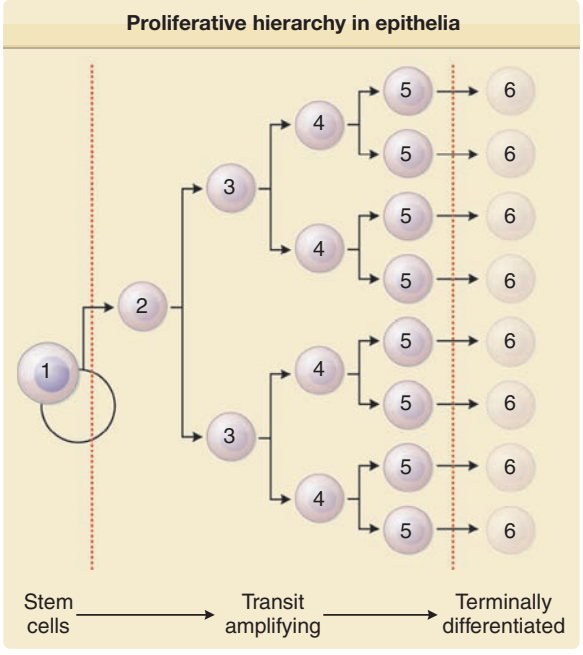

Figure 45-1 The proliferative hierarchy in epithelia: the stem cell concept. The ultimate progenitor cells are termed *stem cells*. They are slow cycling, long-lived, phenotypically undifferentiated, reside in specialized microenvironments, and constitute only a small percentage of the total epithelial cell population. Stem cell division produces transit amplifying or committed progenitor cells, which cycle rapidly and produce a clonal expansion of the offspring arising from an initial stem cell division. These cells eventually become the mature, terminally differentiated cells that constitute the bulk of a given epithelial population. Numbers indicate generation.

ASYMMETRIC DIVISION

The hierarchical model for cell proliferation in the cutaneous epithelium implies some degree of cellular, genetic, or population asymmetry.[3,11] The model of the stem cell hierarchy suggests a level of asymmetry that could be due to infrequent cell division or to chromosomal segregation.[3] As the stem cell mechanism is thought to provide protection for the tissue as well as the cellular DNA, Cairns[12,13] hypothesized that perhaps stem cells have a special mechanism for segregating their DNA and retaining an "immortal strand" at each division. Although there is some fairly convincing evidence that stem cells of the breast[14] and intestinal epithelium[15] may reserve an immortal DNA strand, recent investigation of the multipotential stem cells of the mouse hair follicles suggest that chromosome segregation does not occur.[16,17] Moreover, the Tumbar laboratory developed a method to trace the proliferation history of hair follicle bulge keratinocytes and thus provided direct evidence in support of the infrequent division model for these particular stem cells.[16]

LATERAL MIGRATION

Cellular proliferation and terminal differentiation in the epidermis are usually thought to occur in columns. However, lateral migration is common during wound healing where a tongue of proliferating epithelium migrates over denuded dermis and reestablishes an epithelium complete with vertical proliferative units and terminal differentiation.[18] In addition, Brash and colleagues have suggested that following irradiation of skin with ultraviolet light, clonal patches, each with its own *p53* mutation, might reflect epidermal cell proliferation and differentiation beyond the confines of single proliferative units.[19]

IDENTIFICATION OF STEM CELLS IN THE CUTANEOUS EPITHELIUM

Slowly cycling epidermal stem cells were first identified by of their cell kinetic behavior in the context of the epidermal proliferative units. Hence, Mackenzie identified mitotic basal keratinocytes beneath the edges of the hexagonal squames.[20] In vertical cross sections of skin, Christophers[21] had found that some basal cells in the shape of a hand mirror stained with a fluorescent dye characteristic of suprabasal cells. These studies were quantified by Potten in 1974[22] who called these units of structure epidermal proliferative units (EPUs). He focused on the central basal cells, noting that they were rarely mitotic and also rarely incorporated [3H]thymidine administered as a single pulse, and conjectured that the quiescent central cells might have stem cell activity whereas the peripheral cells may have transit amplifying cell activity. The next major advance in understanding the function of the EPU came with the identification of slowly cycling label-retaining cells in the center of the EPUs. Bickenbach[4] and later Bickenbach and Mackenzie,[23] Morris,[24] and Potten[25] found that administration of [3H]thymidine continuously for 3 days followed by a 4–8 week chase, could identify these central cells in light microscopic autoradiographs. Further characterization of the central stem cells and peripheral transit amplifying cells has been performed by a variety of in vivo and in vitro techniques.[2] The presence of EPUs in some areas of thin human skin has also been noted, and may be as large as 2 millimeters in diameter.[20] The EPU concept in skin is illustrated in Fig. 45-2.

The distribution of stem cells within the epidermis has been a subject of debate. Hence, Lavker and Sun[26] found that mitotic cells and cells that were rarely mitotic (putative stem cells) were located respectively in the upper and lower aspects of the rete ridges. These investigators postulated that the deeper cells were physically more protected than the superficial cells. In contrast, further studies have demonstrated that cells with stem cell characteristics in human epidermis can vary depending upon the site.[27] Ghazizadeh and Taichman[28] used retrovirally marked human epidermal keratinocytes followed by grafting onto athymic nude mice to visualize proliferative units in human skin. These studies found presumptive stem cells to be distributed throughout the epithelium.

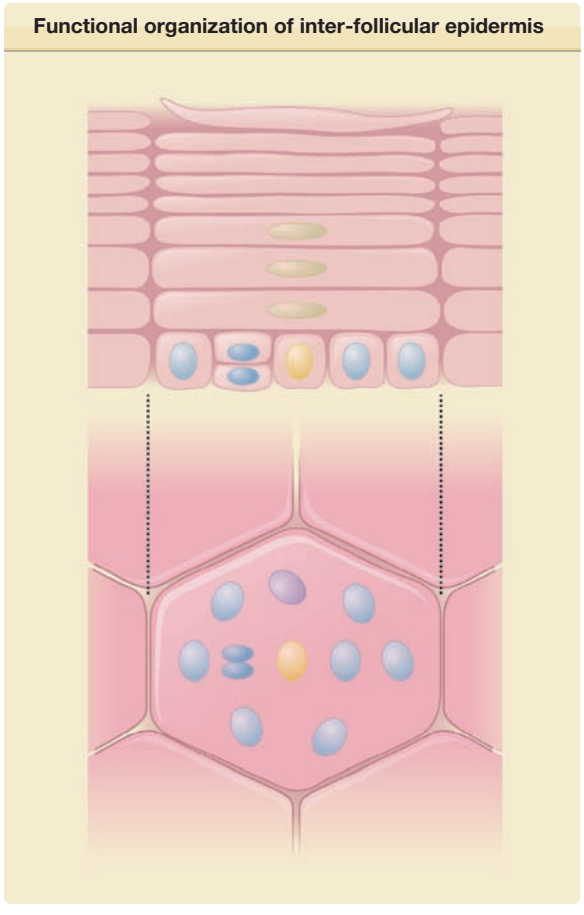

Figure 45-2 Functional organization of interfollicular epidermis: the epidermal proliferative unit (EPU) concept. Interfollicular epidermis of the skin of certain body sites is histologically organized into columns termed *EPUs*; each consists of approximately ten basal cells, including a single putative stem cell (*yellow*), its immediate transit-amplifying cell progeny (*blue*), and early-differentiating cells (*purple*). More differentiated keratinocytes (*green*) and then mature enucleated squames lie directly above them, in an ordered stack rising above the basal layer. EPUs represent functionally independent packets of self-renewing interfollicular epidermis that are ultimately dependent on a single putative stem cell for lifelong cell production. Constant self-renewal within the basal layer of skin compensates for the continual loss of differentiated squames from its surface. (Redrawn from Kaur P: Interfollicular epidermal stem cells: Identification, challenges, potential. *J Invest Dermatol* **126**:1452, 2006.)

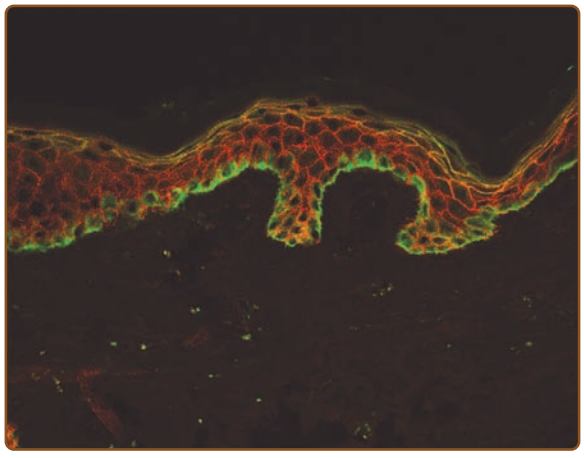

Figure 45-3 A confocal microscopic image of human scalp tissue stained for the EGFR (*red*) and LRIG1 (*green*). Immunostaining such as this has provided valuable information on the role and function of stem cells in the epidermis. The significance of these two markers is reported in Jensen KB, Watt FM: Single cell expression profiling of human epidermal stem and transit amplifying cells. LRIG1 is a regulator of stem cell quiescence. *Proc Natl Acad Sci USA* **103**:11958-11963, 2006 and Jensen KB et al: LRIG1 expression defines a distinct multipotent stem ell population in mammalian epidermis. *Cell Stem Cell* **4**:427-439, 2009. (Used with permission from Drs Kim Jensen and Fiona Watt.)

MARKERS AND SELECTABLE DETERMINANTS

Compared with the plethora of markers and selectable determinants for various hair follicle stem cells, few such markers have been identified in the epidermis. Notable exceptions are β-1 integrin,[10] CD71 (the transferrin receptor),[29] and LRIG1 (Fig. 45-3).[30] β-1 integrin is a cell adhesion molecule and can be used as a selectable determinant to enrich for keratinocytes that have a high proliferative potential in vitro and that can reconstitute a graft. Cells staining brightly with a fluorescently labeled antibody to β-1 integrin keratinocytes are found in human epidermis situated at the bottom of the rete ridges or atop the dermal papillae depending on the location of the skin. CD71 is expressed on all proliferating cells and can be used in conjunction with α-6 integrin (the external component of the hemidesmosomes present on epidermal basal cells) to enrich for a population that reacts with a fluorescently labeled antibody to α-6 integrin, but does not bind to fluorescently labeled CD71. This is enriched for epidermal keratinocytes that have in vitro and in vivo properties of stem cells. In the mouse, cells with this phenotype are located in the hair follicle bulge. LRIG1 is a marker of human interfollicular stem cells and helps to maintain stem cell quiescence.[30] In the mouse, LRIG1 immunoreactive cells are found in the hair follicle junctional zone between the sebaceous glands and the infundibulum.[31]

ALTERNATIVE MECHANISMS FOR REGULATING EPIDERMAL PROLIFERATION

The stem cell concepts presented above have not gone unchallenged. Clayton et al have studied clonal expansion in the mouse tail epidermis together with mathematical modeling.[32] These investigators conclude that the presence of stem cell/transit amplifying cell model in the tails is incompatible with a long-lived stem cell

population and a short-lived transit amplifying cell population. Moreover, this group infers that clones of two basal cells in the tail can adopt any of the three fates: (1) both cells can remain proliferative, (2) both can differentiate and exit the cycle, or (3) that one cell can remain proliferative and the other differentiates. Thus, epidermis from different sites may have different mechanisms for proliferation and terminal differentiation. At the present time, there are no reports of this model being applied to mouse dorsum or human epidermis from any site.

RELATIONSHIPS AMONG VARIOUS EPITHELIAL STEM CELL COMPARTMENTS

Cellular kinetic and labeling data suggest that there are multiple stem and progenitor compartments within the cutaneous epithelium. Under homeostatic conditions, these compartments are stable over intervals with essentially no interactions.[33] Hence, there are multiple proliferative units within the hair follicles: the infundibulum of the follicle, the bulge, the upper isthmus, and the sebaceous gland. The progeny of these follicular and sebaceous proliferative units all appear to be able to contribute to the repair of wounded epidermis.

REGULATION OF EPIDERMAL STEM AND TRANSIT AMPLIFYING CELLS

Identification and functional characterization of molecules regulating epidermal stem cells and transit amplifying cells is currently a subject of intense investigation.[34–37] Mediators under study comprise complex pathways often shared by embryonic, morphogenetic, and adult homeostatic and repair processes. Regulatory "switches"[34] include (1) stimuli that direct progenitor cells toward a particular type of terminal differentiation, (2) molecules and pathways characteristic of the niche and stem cell homeostasis, (3) molecules that differentially alter stem cell and transit amplifying cell proliferation, and (4) positive and negative regulators involved in commitment to terminal differentiation. Examples of such regulatory molecules are given in Table 45-1.

SKIN DISEASES ARISING FROM PROLIFERATIVE DYSFUNCTION

Skin cancer is thought to arise from aberrant proliferation of keratinocyte stem cells.[3,38] In this regard, a stem cell is a candidate for a tumor-initiating cell because of its long-term persistence in the tissue and because of its inherently high proliferative potential. The relationship between the epidermal stem cell and the so-called cancer stem cell is not known at the present time; however, current thinking is that the tissue stem cells, when corrupted, may become cancer stem cells that retain such stem cell properties as long-term self renewal, an ability to cast off transit amplifying cells, and production of terminally differentiated cells. Although stem cells are well protected against carcinogen-induced damage by virtue of being a rare and well-protected population, unlike the relatively short-lived transit amplifying cells, stem cells persist to endure the multiple mutations that lead to malignancy.

Psoriasis is thought to be an example of hyperproliferation of transit amplifying cells, which among inflammatory and dermal changes, is characterized by increased numbers of β-1 integrin dim cells in the suprabasal layers.[39] Additionally, markers of proliferation such as Ki67 and *C*-myc are upregulated.

TABLE 45-1
Examples of "Molecular Switches" that Direct Epidermal Stem Cell Behavior

Stimuli that Direct Progenitor Cells toward a Particular Type of Terminal Differentiation
■ Epithelial to hair follicle: Wnt/β-catenin; Negatively regulated by Dikk1 and Lef1/Tcf
■ Hair follicle stem cells to sebaceous cells: BLIMP1
Molecules and Pathways Characteristic of the Niche and Stem Cell Homeostasis
■ Maintenance of stem cell quiescence in hair follicles: NFATc1, Bmp6
■ Maintenance of stem cell quiescence in the epidermis: Lrig1
Molecules that Differentially Alter Stem Cell and Transit Amplifying Cell Proliferation
■ Stem cell to transit amplifying cell and stem cell renewal: Myc, p63, miR203 microRNA, histone modification
Positive and Negative Regulators Involved in Commitment to Terminal Differentiation
■ Basal to spinous transition and barrier function: turn off K5/K14 and turn on K1/K10
■ Pathways: Notch, MAPK, NFκ-B, p63, AP2 family, EGF receptor signaling
■ Negative regulators of terminal differentiation: extracellular matrix repression, PcG repression

EPIDERMAL STEM CELLS AND CELL THERAPY

Epidermal stem cells can be cultivated and expanded in tissue culture.[8,40] This has led to an application of epidermal cells in cell therapy of burn victims. Hence, from a small biopsy from nonaffected skin, skin cells including stem cells can be expanded *ex vivo* and then reapplied to affected skin. The transplanted tissue "takes" to debrided skin regions and ultimately forms a new epithelium with the capacity to persist for many years. This application is now standard therapy in many burn units.[40] In the transplanted epithelium, it is noteworthy that epithelial appendages such as hair follicles, sebaceous glands, or eccrine glands are absent because techniques for in vitro morphogenesis of these tissues have not yet been developed. The lack of skin appendages in the grafted epidermis results in fragility as well as dryness due to lack of sebaceous glands, and poor thermoregulation due to lack of eccrine glands in the transplanted epithelium. These problems highlight the urgent need to develop in vitro methods to recapitulate embryonic morphogenesis of the cutaneous appendages. *Ex vivo* expanded epidermal keratinocytes are also used for treating ulcers and other chronic wounds.[41]

EPIDERMAL STEM CELLS AND GENE THERAPY

The accessibility of skin makes it an attractive target for gene therapy.[42] Here, one goal is to correct mutant genes in the stem cells *ex vivo* and transplant resulting normalized epithelium to patients.[42] Another goal is to correct defective expression of certain secreted proteins in skin stem cells and to apply the corrected epithelium to patients.[43] Although the use of epidermal cells including stem cells was proposed more than a decade ago, these applications still have not been developed for clinical practice. It is possible that the predilection of epidermis to develop into vertical proliferative units rather than to expand laterally precludes these applications. However, the field of gene therapy is still considered to be in its infancy, and identification and targeting of multipotential skin stem cells, as well identification of factors resulting in the lateral migration of epithelium during wound healing will increase therapeutic applications. Additionally, other related means of manipulating the keratinocytes such as siRNA show great promise.[44]

OUTLOOK

In this chapter, I have discussed general properties of epidermal stem cells and some of the techniques for studying them. In this regard, keratinocyte stem cells together with transit amplifying cells and terminally differentiating cells play a role in the normal turnover and repair of the epidermis. Additional studies, perhaps with novel approaches are needed for better identification of epithelial stem and transit amplifying cells. Especially, more investigation is needed for an understanding of the molecular "switches" that regulate stem cell and transit amplifying cell homeostases, fate determination, and repair mechanisms. Moreover, there is a great need for understanding stem cell targeting as well as the lateral migration in wound healing, as these are key questions in making cell and gene therapy a reality. Finally, it must be understood that there will never be a "pure" population of stem cells. Rather, each new marker or selectable determinant discovered, and each new functional assay developed is essential for ultimately designing new treatments for skin diseases and skin cancer.

Chapter 46 :: Epidermal Growth and Differentiation

:: Pierre A. Coulombe, Stanley J. Miller, & Tung-Tien Sun

EPIDERMAL GROWTH AND DIFFERENTIATION AT A GLANCE

- The interfollicular epidermis is maintained by a population of stem cells.
- Slow-cycling stem cells give rise to transit amplifying cells, which yield terminally differentiated cells.
- Abnormalities in epidermal stem cells may be involved in pathogenesis of skin cancers and other proliferative epidermal diseases.
- Epidermal differentiation is accompanied by orchestrated expression of keratins and subunits of cornified envelope.
- Keratins contribute to the mechanical stability and pliability of the epidermis.
- Mutations in major epidermal differentiation products are underlying causes of important skin diseases.

INTRODUCTION

Although thin, human skin is a marvelously resilient and multifunctional organ. It performs immunomodulatory and thermoregulatory functions, is involved in social, cultural, and reproductive behaviors, and provides broad protection against water loss and environmental insults such as trauma, infection, and exposure to radiation or chemicals. The outermost layer of skin, termed the epidermis, consists of a stratified squamous epithelium and its appendages, including hair follicles, sebaceous, apocrine, and eccrine glands. This chapter discusses epidermal differentiation, with the primary focus placed on keratin filaments that are formed as major structural elements within the epidermis. Defects in epidermal keratins are known to play key roles in a number of important blistering epidermal diseases. Additional major epidermal differentiation markers, including keratohyalin granules and the cornified envelope, are also discussed.

KERATINS AND EPIDERMAL DIFFERENTIATION

KERATINS AND THEIR CLASSIFICATION

Keratins (also known as cytokeratins) are structural proteins that belong to the superfamily of intermediate filament (IF) proteins. They are heterogeneous in size (40–70 kDa) and charge (pI 4.7–8.4), and notoriously insoluble. Sequencing the human genome revealed the presence of 54 functional keratin genes that are nearly perfectly conserved in other mammals.[1] The tremendous diversity of keratin genes had not been fully appreciated until the advent of database mining and genomics, and could not be accommodated in the original nomenclature system aptly devised by Roland Moll, Werner Franke and colleagues in 1982.[2] In 2006, an international effort culminated in a revised nomenclature (Table 46-1) that accommodates the newly discovered keratins, adheres to the guidelines of the Human and Mouse Gene Organization Gene Nomenclature Committee, and maintains the original designation of keratins devised by Moll and colleagues.[1]

Sequence homology and gene substructure (number and position of introns) reveal two distinct groups of keratins of roughly equal size, designated type I and II IF genes[1,3] (Fig. 46-1A). In *Homo sapiens*, functional type I and type II keratin genes are clustered on the long arms of chromosomes 17 (Fig. 46-1B) and 12 (Fig. 46-1C), respectively.[1,4] Keratin genes are highly conserved across mammals, at the level of their organization, structure, sequence, and regulation.[5] Mature filaments contain type I and II keratins in a 1:1 molar ratio.[3,6] This requirement underlies the coordinated transcription of type I and II keratin genes. Remarkably, most type I and II keratin genes are regulated in a pairwise, tissue type-related, and differentiation-related fashion.[7–9] This is illustrated particularly well in stratified epithelia such as epidermis (Fig. 46-2). Given their large number, differential regulation, and ease of detection (owing to abundance), keratin mRNAs and proteins represent unparalleled markers for staging the fate and differentiation of epithelial cells, under healthy and diseased conditions.

KERATIN PROTEINS FORM THE INTERMEDIATE FILAMENT NETWORK OF EPITHELIAL CELLS

Despite sequence differences, all keratins display the tripartite domain structure that is typical of IF-forming

proteins (Fig. 46-1D). The central domain consists of an extended α helix featuring long-range heptad repeats that mediate coiled-coil dimerization. This "rod" domain is ~310 amino acids long and is flanked by highly variable sequences at the *N*- terminal head and *C*-terminal tail domains (Fig. 46-1D).[3] Neither terminal domain exhibits known functional motifs other than the glycine loops seen in epidermal keratins.[10] The head and tail domains are readily protease-accessible at the surface of the filament, where they can foster interactions with neighboring filaments, other proteins, or serve as substrates for posttranslational modifications involved in their regulation.[11] Given their heterogeneity of size and primary structure, the head and tail domains are expected to make key contributions to the differential function and regulation of keratin proteins in vivo.[12]

The central rod domain of keratins is the main determinant of self-assembly, with important contributions from the head domain as well.[13] Assembly begins with the formation of heterodimers in which the α-helical central rod domains of type I and II keratins are aligned in parallel and perfect register. Heterodimers interact along their lateral surfaces and in an end-to-end fashion to give rise to the 10–12-nm wide filaments (Fig. 46-2A) which, depending on IF protein type and assembly conditions, may contain a variable number of subunits in cross section.[13] Mature IFs lack a structural polarity, a direct consequence of the antiparallel orientation of their constituent coiled–coiled dimers.

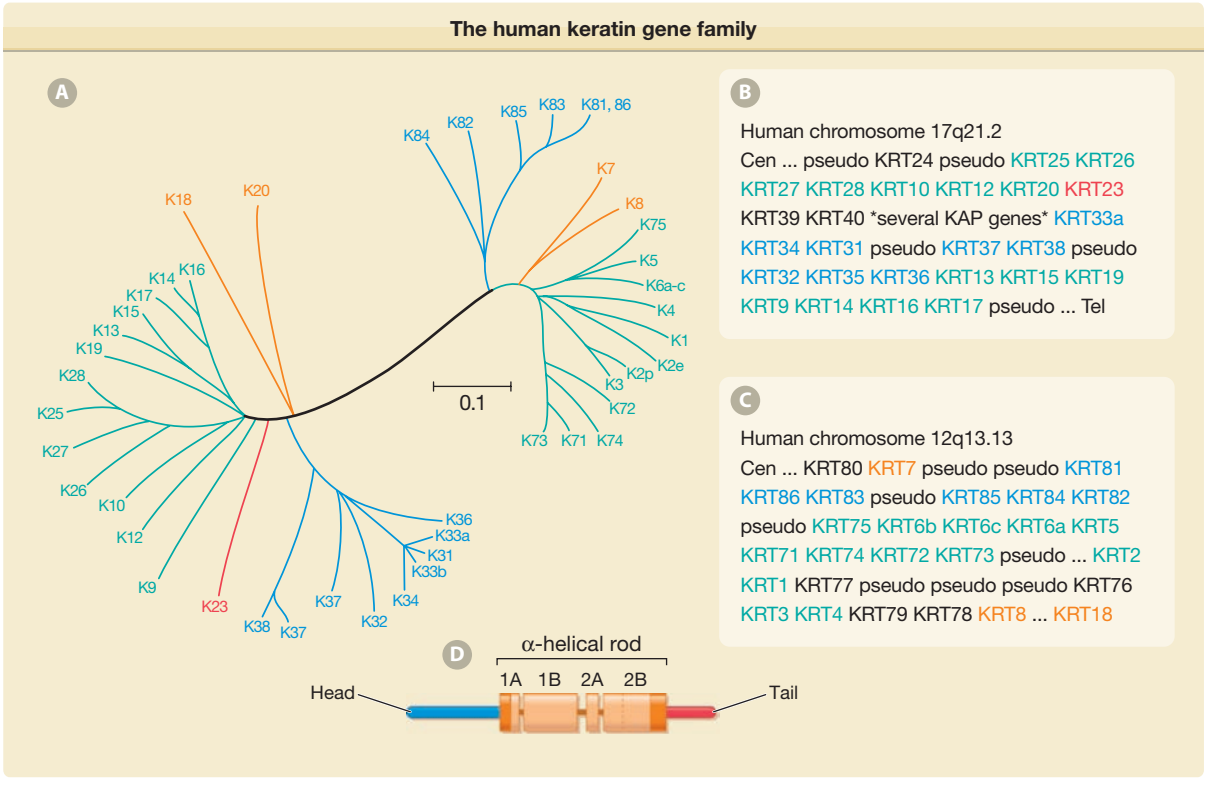

Figure 46-1 The human keratin gene family. **A.** Comparison of the primary structure of human keratins using the publicly available ClustalW and TreeView software. Sequence relatedness is inversely correlated with the length of the lines connecting the various sequences, and to the number and position of branch points. This comparison makes use of the sequences from the head and central rod domain for each keratin. A few keratins were left out for clarity purposes. Two major branches are seen in this tree display, corresponding to type I and type II sequences. Beyond this dichotomy, each subtype is further segregated into major subgroupings (denoted by different colors). **B.** Organization of functional type I keratin genes, all which are clustered on human chromosome 17, with the only exception being *K18* (see "*" in **C**), which is located at the telomeric (Tel) boundary of the type II gene cluster. (Cen = centromere.) A large number of genes encoding keratin-associated proteins (KAP) interrupts the type I gene cluster, between *KRT40* and *KRT33A*. [Pseudo = pseudogene (nonfunctional).] **C.** Organization of functional type II keratin genes, which are clustered on human chromosome 12. The *K8* and *K18* genes are separated by 450,000 bp. **D.** Schematic representation of the tripartite domain structure shared by all keratin and other IF proteins. A central α-helical "rod" domain acts as the major determinant of self-assembly. This rod domain is partitioned into subdomains 1A, 1B, 2A, and 2B, and flanked by nonhelical "head" and "tail" domains at the *N*- and *C*-termini, respectively. Both ends of the rod domain contain 15–20 amino acid regions (*red*) that are highly conserved among all IF proteins.

The extraordinary stability of keratin subunits reflects the tightness of interactions between type I and type II keratins.[14] Most of the intracellular pool of keratin proteins (>95%) is polymerized.[4] There is evidence that keratin IF assembly is initiated at the cell periphery, near the cortical F-actin cytoskeleton, in cultured epithelial cells.[15]

Keratins form the major IF network in all epithelial cells.[2,3,9] The abundance and organization of keratin IFs in vivo differ among epithelia. Keratin proteins are highly abundant (10%–80% of total cellular proteins) in surface-exposed stratified squamous epithelia (e.g., epidermis, oral mucosa, corneal epithelium, etc.).[7] In epithelial cells of such tissues, keratin IFs are organized in a pancytoplasmic network extending from the surface of the nucleus to the cytoplasmic periphery, where they are membrane-anchored at sites of cell–matrix and cell–cell adhesion (hemidesmosomes, desmosomes) (Fig. 46-2B). In simple epithelia (e.g., liver, gut, pancreas, etc.), keratins are less abundant. In such tissues, polarized epithelial cells often feature asymmetrically organized keratin IFs concentrated mostly at the cytoplasmic periphery and, particularly, the apical pole.[4] Several associated proteins contribute to the organization and regulation of keratin IFs in these various settings.[16] Some of these proteins promote the bundling of keratin IFs (e.g., filaggrin, trichohyalin), their association with microtubules and actin microfilaments (e.g., plectin, BPAG isoforms) and/or with desmosomes or hemidesmosomes (desmoplakin, plakophilin, BPAG isoforms, etc.) (Fig. 46-2). Other partners, for example, TRADD, 14–3-3, Akt, reflect the newly discovered participation of keratin IFs in signaling roles.[17]

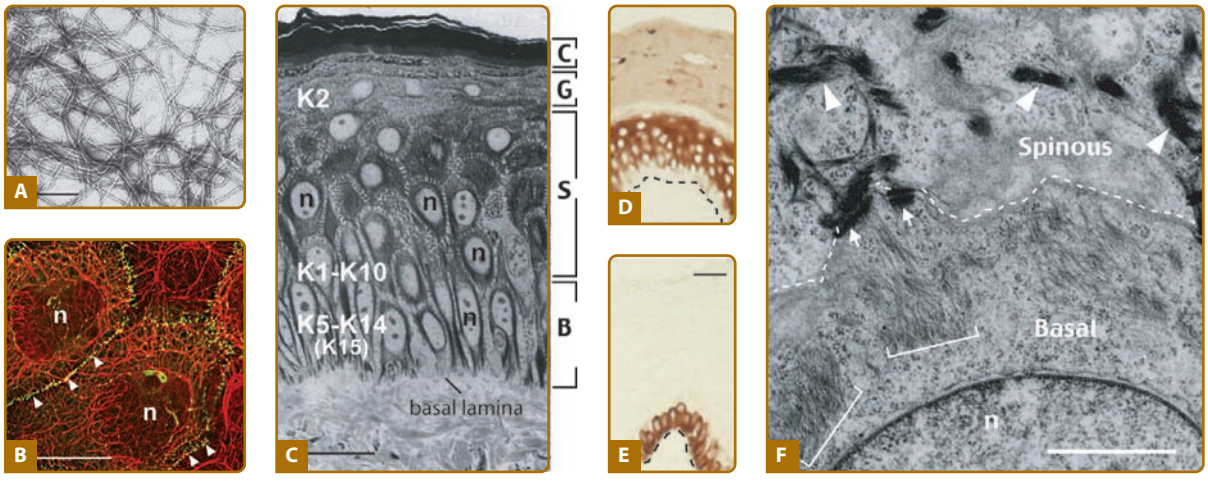

Figure 46-2 Keratin filaments and interfollicular epidermis. **A.** Visualization of filaments, reconstituted in vitro from purified human *K5* and *K14*, by negative staining and electron microscopy. (Bar = 150 nm.) **B.** Double-labeling for keratin (*red chromophore*) and desmoplakin, a desmosome component (*green chromophore*), by indirect immunofluorescence of human epidermal cells in culture. Keratin IFs are organized in a network that spans the entire cytoplasm and are attached at desmosomal cell–cell contacts (*arrowheads*) between cells. (n = nucleus; bar = ~50 µm.) [Micrograph used with permission from Dr Kathleen Green (Northwestern University).] **C.** Histological cross section of resin-embedded human trunk epidermis, revealing the basal (B), spinous (S), granular (G), and cornified (C) cell layers. (Bar = ~50 µm; n = nucleus.) **D** and **E.** Differential distribution of keratin epitopes on human skin tissue cross sections as visualized by an antibody-based detection method. **D.** *K10* is primarily concentrated in the differentiating, suprabasal layers of epidermis. **E.** *K14* occurs in the basal layer, where the epidermal progenitor cells reside. Dashed line indicates the basal lamina. (Bar = ~50 µm.) **F.** Ultrastructure of the boundary between the basal and suprabasal cells in mouse trunk epidermis, as seen by routine transmission electron microscopy. The sample, from which this micrograph was taken, is oriented in the same manner as frame **C**. Organization of keratin filaments as loose bundles correlates with the expression of *K5–K14* in basal cells (*brackets*), whereas the formation of denser, electron-dense filament bundles reflects the onset of *K1–K10* expression in early differentiating cells (*arrowheads*). Arrows point to desmosomes connecting the two cells. (Bar = 2 µm; n = nucleus.)

KERATIN GENE EXPRESSION MIRRORS EPITHELIAL DIFFERENTIATION: THE CASE OF EPIDERMIS

Skin provides a beautiful example of the tight relationship that has evolved between keratin gene regulation and epithelial differentiation. More than half of all known keratin genes are expressed in mature mammalian skin tissue alone. The architectural complexity of adult skin epithelia is achieved through a temporally and spatially regulated expression of keratin genes and a number of other epithelial differentiation-related genes.[7,18] In the clinical setting, keratin typing is often exploited in diagnosing cancer type, its differentiation status (and therefore prognosis), as well as the origin of the cells forming metastatic foci. This strategy is also applied for diseases other than cancer (see below).[4]

In "thin" interfollicular epidermis (e.g., trunk; Fig. 46-2), mitotically active cells of the basal layer act as progenitors, and consistently express *K5* and *K14* as their main keratin pair, along with low levels of *K15*. Onset of differentiation coincides with the appearance of the *K1/K10* pair through a robust transcriptional induction that occurs at the expense of the *K5/K14* genes, which are downregulated.[7,18] Accordingly, *K1/K10* keratins are readily detectable in the lowermost suprabasal layer of epidermis (Fig. 46-2D). The appearance of *K1* and *K10* correlates with a sudden and dramatic shift in the organization of keratin IFs, which now exhibit significant bundling.[19] Another type II gene, *K2e*, is expressed at a later stage of differentiation, i.e., the granular layer.[20]

The epidermis of palm and sole skin is specialized for resisting a high degree of mechanical stress, and thus is markedly thicker. This function is reflected in its architecture of alternating stripes of primary and secondary ridges,[21] and again, in keratin expression. In the thick, stress-bearing, primary ridges, the major differentiation-specific (type I) *K9* is presumed to foster a more resilient cytoskeleton. In the thinner secondary ridges, postmitotic keratinocytes preferentially express the (type II) *K6a* and (type I) *K16* and *K17*.[22] Relative to *K1*, *K9*, and *K10*, the properties of *K6a*, *K16*, and *K17* likely foster greater cellular pliability, thereby providing flexible "hinge" regions between the more rigid, *K1/K9*-rich primary ridges.[22] While this attractive model remains to be supported by direct experimentation, it is consistent with the dramatic upregulation of *K6a*, *K6b*, *K16*, and *K17* that occurs in keratinocytes recruited from wound margins to participate in the restoration of the epidermal barrier following injury.[23,24]

Epidermal disease states are often accompanied by a deviation from normal terminal differentiation and, not surprisingly, they are almost always accompanied by altered keratin gene expression. For instance, *K6a*, *K6b*, *K16*, and/or *K17*, normally restricted to wound repair in trunk epidermis, are ectopically induced in

psoriasis and related hyperproliferative disorders, nonmelanoma skin cancers, viral infections, and other conditions accompanied by inflammation.[23,25,26] Similar "replacement" of the *K1* and *K10* keratin pair by *K6*, *K16*, and *K17* occurs when normal human keratinocytes are placed in culture.[23,25,27] During early progression toward malignancy, cutaneous squamous cell carcinoma progressively shifts from being *K6/K16*-positive while maintaining some degree of *K1/K10* expression, thus reflecting a differentiated state, to being entirely negative for *K1/K10* and positive for the simple epithelial keratins *K8/K18*, indicative of a less differentiated and more aggressive state.[28] These variations in keratin gene expression likely impact the biological properties of keratinocyte in a significant way.

FUNCTION OF KERATIN IN THE EPIDERMIS AND OTHER SKIN EPITHELIA

A major function fulfilled by keratins and all other IF proteins is to enhance the cell's ability to withstand trauma. This structural support function[3,4] is made possible by the unique mechanical properties exhibited by IF networks.[24] This function is enhanced by attachment of IFs to adhesion complexes (desmosomes, hemidesmosomes), and to F-actin and microtubules.[3,4,16] Partial or complete loss of this function, for example, through inherited mutations, underlies a wide variety of rare diseases that render cells fragile and unable to sustain mechanical stress (Table 46-2). In vivo, the mechanical properties of IF networks likely need to be modulated, in a dynamic fashion, to meet the demands placed on cells by changing physiological circumstances. To a degree, varying needs along a continuum of viscoelastic properties likely account, at least in part, for the dynamic regulation of keratin IF genes and their proteins in vivo.[17,24]

The recent discovery of nonmechanical functions for keratin proteins has placed the field on an exciting new path.[17] In hair follicles, *K17* promotes the anagen (growth) phase by attenuating TNF-α-induced apoptosis in matrix keratinocytes.[29] In the epidermis, the suprabasally expressed *K10* regulate proliferation in the basal layer of epidermis and in sebaceous glands, likely through a noncell-autonomous mechanism,[30,31] while *K17* cell autonomously regulates protein synthesis and cell size in wound-proximal keratinocytes.[32] Keratins influence the melanin pigment distribution and, thus, skin pigmentation.[33–35] In polarized epithelia, keratin IFs impact the distribution of organelles, routing of specific outer membrane proteins, and response to stress.[36] These newly defined keratin functions, which are just beginning to be understood, involve regulated interactions between keratin proteins and noncytoskeletal proteins, many exerting key roles in specific signaling pathways.[16,17,24,36] Interference with these functions could play a role in the pathogenesis of disorders linked to IF gene mutations.[4] The discovery of these novel keratin functions provides an opportunity to better understand the diversity and context-dependent regulation of IF genes and their proteins.

MUTATIONS IN EPIDERMAL KERATINS UNDERLIE SEVERAL INHERITED SKIN BLISTERING DISEASES

In the 1980s, ultrastructural studies showed that epidermal basal keratinocytes of patients with the Dowling-Meara form of epidermolysis bullosa simplex (EBS) contained dense cytoplasmic aggregates,[37,38] later shown to contain mispolymerized keratin.[39,40] In parallel, reverse genetic studies showed that expression of dominant-negative keratin mutations cause keratin IF aggregation in cultured cells, and epithelial fragility in vivo.[41,42] In the early 1990s, the first mutations in keratins *K5* and *K14* were linked to EBS.[39,43,44] In EBS, *K5/K14*-expressing basal layer keratinocytes literally rupture in response to mild mechanical trauma to the skin. Fragility is occasionally seen in other sites of *K5/K14* expression, such as the cornea and oral mucosa.[45] Similarly, dominant mutations in the suprabasally expressed *K1*, *K10*, and *K2e* were found to cause epidermolytic hyperkeratosis (EHK),[46,47] ichthyosis bullosa of Siemens,[48] and related diseases (Table 46-2). Such efforts established that compromising keratin function engenders structural failure and fragility. In specific instances, depending on the disorder, this primary defect is accompanied by enhanced proliferation and hyperkeratosis,[4,30] or aberrations in skin pigmentation.[33–35] Since then, a broad range of additional diseases affecting either epidermal appendages (e.g., hair, nail) or nonskin epithelia (e.g., oral mucosa, cornea) have been linked to keratin mutations.[4,49]

The following general principles can be drawn from the large body of data accumulated to date while studying keratin-based disorders. The majority of cases involve single missense mutations acting in a dominant-negative fashion. Small insertions and deletions are also seen with some frequency.[49] In this setting, dominance implies that disease-causing mutant keratin proteins do not markedly alter the early stages of assembly (dimer, tetramer formation) up to the step(s) involving subunit incorporation in a growing IF polymer.[4] Depending on their nature and location within the keratin protein backbone, these mutations exert a wide range of effects on the assembly or organization of IFs in keratinocytes, with a corresponding impact on the severity of clinical presentation. This concept can be readily illustrated for EBS.[50] Mutations altering residues that are highly conserved within the central rod domain tend to dramatically alter the structure of keratin IFs, foster the formation of aberrantly polymerized keratin aggregates, and cause severe disease (as seen in the Dowling-Meara form of EBS). Conversely, mutant proteins that elicit a clinically milder version of the disease (e.g., Weber-Cockayne EBS) affect keratin assembly more subtly, and do not cause keratin aggregation.[50] The extent to which a given keratin mutant compromises the function of the entire IF network is also a function of the number and abundance of potentially redundant IF proteins occurring in a given cell, or its ability to overexpress an alternate IF protein.[4] While it is assumed that these mutations elicit a cell fragility phenotype in part through their ability to alter cellular mechanics,[51–53] there is evidence that they alter

TABLE 46-2
Keratin-based, Inherited Skin Bullous Disease Affecting Primarily the Epidermis[a]

Disease	Relevant OMIM Catalog Number(s)[a]	Target Genes	Affected Cell Type	Comments
Epidermolysis Bullosa Simplex	131800 (Koebner subtype) 131800 (Weber-Cockayne) 131760 (Dowling-Meara)	K5 or K14	Basal keratinocyte	K, WC, and DM correspond to different degrees of severity; the position/nature of the mutation in K5 0r K14 is a key determinant Rare mutations in the same genes result in recessive inheritance (OMIM #60100)
Epidermolysis Bullosa Simplex with mottled pigmentation	131960	K5	Basal keratinocyte	A single dominant allele, K5P28L, has been found in multiple pedigrees. Typified by hyperpigmentation of healed skin blisters
Epidermolysis Bullosa Simplex with limb girdle muscular dystrophy	226670 (also,131950)	Plectin	Basal keratinocyte	Plectin is a cytolinker protein attaching IFs to adhesive complexes and F-actin/microtubules in keratinocytes and myocytes
Dowling-Degos disease	179850	K5 (null)	Basal keratinocyte	Inherited recessively; Features multiple aberrations in skin pigmentation
Epidermolytic Hyperkeratosis	113800	K1 or K10	Spinous keratinocyte	Same as Bullous congenital ichthyosiform erythroderma. As for EBS, there is wide variation in severity of clinical presentation, correlating with position and nature of the mutation affecting either K1 or K10
Ichtyosis hystrix (Curth-Macklin)	146490; 146600	K1 or K10	Spinous keratinocyte	Characteristic ridges or spikes present at the skin surface. Ultrastructurally, presence of large bundles of densely packed IFs around nucleus
Ichtyosis Bullosa of Siemens Palmoplantar keratodermas:	146800	K2e	Granular keratinocyte	Affects primarily flexural areas; Blistering confined to the upper suprabasal layers; Can be confused with mild EHK/BCIE Confined to the epidermis of palms and soles
■ Epidermolytic	144200	K9	Spinous keratinocyte	Reflects the unique distribution of this large type I keratin
■ Non-epidermolytic	139350 (diffuse) 600962 (focal)	K1 K1 or K16	Spinous keratinocyte	This is one of the rare conditions for which the pathogenesis is not indicative of cell fragility; May reflect a non-mechanical role for keratins
■ Striate	607654	DP, Dsg1 or K1	Spinous keratinocyte	Desmoplakin (DP) and desmoglein 1 (Dsg1) are structural components of desmosomes, to which keratin IFs are attached in epidermis

[a]Note: See the Intermediate Filament Database (www.interfil.org) and Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim/) websites for further information.

keratin regulation, for example, via posttranslational modifications,[11] and elicit a cellular stress response.[4,54] Treatment options for EBS are currently limited, and are primarily palliative in nature.[50] They consist of supportive care for skin, management of skin blisters as they heal so as to prevent infection, and preventive avoidance of mechanical trauma.

CORNIFIED ENVELOPE

Alongside the substantial build up in keratin IFs inside differentiating keratinocytes, two specializations allow the epidermis to build a remarkably effective and mechanically resilient barrier: (1) the cornified envelope (CE), a covalently cross-linked protein polymer that forms underneath the plasma membrane, and (2) an extracellular hydrophobic phase that is made up of specialized lipids synthesized by terminally differentiating keratinocytes.[55] Epidermal lipids are discussed in detail in Chapter 47, and will not be discussed further here.

The CE represents a complex assembly of covalently cross-linked proteins that forms underneath, and eventually replaces, the outer keratinocyte membrane in the granular layer of epidermis, as part of the final push to complete terminal differentiation. This 20-nm thick sheath, which is so insoluble and stable it resists extended boiling in the presence of strong denaturants, encases the cell's interior, and significantly contributes to the physicochemical properties of the stratum corneum compartment.[56] The extraordinary stability of the CE results in large part from the large number of ε-(-γ-glutamyl)-lysine isopeptide bonds between its primary constituents (see below), which are further reinforced by disulfide bridges. These isopeptide bonds are catalyzed by transglutaminases, a family of calcium-dependent enzymes.[57] The outer aspect of the CE is covalently linked to ceramides and other specialized lipids that are produced by, and secreted from, differentiated granular keratinocytes, whereas large bundles of tightly packed keratin IFs are cross-linked to its inner aspect.

The major protein constituents of the CE are loricrin, involucrin, filaggrin, elafin, cystatin A, cornifelin, several small proline-rich (SPR) proteins and calcium-binding S100 proteins, and "late-envelope proteins" (LEPs). In addition to these proteins, key components of desmosomes (e.g., desmoplakin, envoplakin, and periplakin) and several type II keratins (*K1*, *K2*, *K5*) are also cross-linked into the CE[56–58] (Table 46-3). CE proteins have several interesting features in common. First, many CE proteins are encoded by genes clustered as part of the epidermal differentiation complex (EDC) locus on human chromosome 1q21. In addition to obvious evolutionary implications, this genomic clustering brings up the distinct possibility of coordinated regulation through *cis*-acting determinants.[55,58] Second, many of these proteins are made as precursors that are activated by proteolytic cleavage, calcium binding, or other modifications at the time of CE formation. Third, many CE proteins are made of repeated units that lack an intrinsically defined three-dimensional structure. Fourth, virtually all CE proteins are transglutaminase substrates.[55,57]

Involucrin, loricrin, and filaggrin, in particular, are well-characterized components of the CE.[56,57] Involucrin biosynthesis is initiated in the spinous compartment, soon after the onset of *K1/K10* keratin expression, in differentiating epidermal keratinocytes. It is the first major component to be activated and cross-linked into the emerging CE, possibly reflecting a scaffolding role, and is concentrated in the outermost aspect of the mature CE. Profilaggrin and loricrin are synthesized in precursor forms and stored in keratohyalin granules. Loricrin is the major structural component of the CE (~80% by weight)—this largely unstructured but highly flexible protein features glycine loops as described for type II keratins. Once activated via dephosphorylation and proteolytic cleavage, filaggrin participates in the bundling of keratin IFs in the late granular compartment of epidermis (hence accounting for its incorporation into the CE) and also is degraded to free amino acids that contribute to the cornified cell's ability to retain water. Basic information about other CE components is provided in Table 46-3.[56,57] The protein composition and fine structure of the epidermal CE differs to a degree from those of the other stratified squamous epithelia; the underlying significance of this CE heterogeneity is unclear.[56,57]

The important contribution of the CE toward proper barrier function in epidermis is reflected in the clinical symptoms associated with mutations altering their primary constituents in the context of human diseases[55] (Table 46-3). This is particularly well illustrated by the recently documented role of filaggrin mutations in ichtyosis vulgaris, atopic dermatitis (AD), and AD-associated hay fever or asthma (the so-called atopic march; see Chapter 14).[59–61] The partial or complete loss of filaggrin protein engendered by frameshift mutations in the corresponding gene compromises the epidermal barrier function and allows for the entry of irritants and allergens into the skin,[62] thereby eliciting local (and even systemic) inflammation accompanied by itching, erythema, and flaking reflecting improper cornification (for further information see Chapter 14). Barrier status in the epidermis thus sets our degree of exposure to external elements and contributes to define the relationship that we have with our environment.

CONCLUDING REMARKS

In this chapter, we have discussed epidermal differentiation viewed through the prism of keratin gene regulation and CE formation. While it is well established that specific type I and type II keratins are coexpressed as pairs associated with various stages of normal and pathological epidermal differentiation, and that mutations of major epidermal keratins cause various forms of skin blistering diseases, the functional implications of these different keratins, not only in terms of structural roles, but also in terms of their novel involvements in signal transduction and organelle transport, are just beginning to be understood. Additional studies are needed to better understand the roles of regulatory molecules in epidermal proliferation, homeostasis, and disease; and how the

TABLE 46-3
Protein Composition of the Cornified Envelope (CE)[a]

Protein	Mol. Weight (kDa) (Precursor Form)	Chromos Location	CE Percent Contribution	Comments/Disease Association
Loricrin	26	1q21	80	Rich in Gly, Ser, Cys residues; Contains glycine loops; Flexible; Stored in keratohyalin granules; Mutated in Vohwinkel syndrome, a mutilating keratoderma with ichtyosis, and in progressive symmetric erythrokeratodermia, a related condition.
Involucrin	65	1q21	5	Made up of repeated units; Highly α-helical; Gly-, Asp-rich; Early TG substrate; May act as a scaffold during CE assembly
SPR	6–18	1q21	3–5	SPR: small proline-rich proteins; encoded by 15 genes that are differentially regulated in various stratified epithelia; Great transglutaminases substrates; Influence CE's mechanical properties
Cystatin A	12	3cen-q21	2–5	Cysteine protease inhibitor; Also stored in keratohyalin granules; Mutations in cystatin M/E cause Harlequin ichtyosis
LCEs	9–12	1q21	unknown	LCE: late cornified envelope proteins; Encoded by 18 genes; Synthesized and incorporated at a late stage of CE formation
Profilaggrin/ Filaggrin	>400 36	1q21	<1	Also bundles keratin filaments; Degraded to single amino acids, which markedly contribute to retain H_2O, in stratum corneum layers; Mutated in ichtyosis vulgaris, a mild but very common condition; Risk factor in individuals with atopic dermatitis and asthma
S100A	10–14	1q21	<1	Family of EF-hand containing, calcium binding proteins; Believed to transmit calcium-dependent signals
Proelafin	10	20q12-q13	<1	Elafin is the active entity, and acts as a serine protease inhibitor
Annexin 1	36	9q12-q21	<1	Also known as lipocortin; Interacts with S100A11
Keratins (K1, K2, (K5, K10, K14)	56–70	12q13	<1	Type II keratins are transglutaminase substrates; Keratin IFs become covalently linked to the inner aspect of the CE
Desmosomal proteins	195–330	Various	<1	Includes desmoplakin, envoplakin, periplakin, and others. Assembly of CE is initiated at desmosome cell-cell contacts

[a]Note: A review article by Eckert et al., *J Invest Dermatol.* 124:481-12 (2005) served as a direct inspiration for this Table.

keratin filaments function, at the atomic level, in normal and diseased epidermis. These future studies should lead to new modalities, including cell and gene therapies, for a better treatment of some of the devastating skin diseases.

Chapter 47 :: Skin as an Organ of Protection

:: Ehrhardt Proksch & Jens-Michael Jensen

SKIN BARRIER AT A GLANCE

- The most important function of the skin is to form a barrier between the organism and the environment.
- The skin barrier prevents excessive water loss (inside–outside barrier) and the entry of harmful substances from the environment (outside–inside barrier).
- The physical barrier is predominantly located in the stratum corneum.
- The stratum corneum barrier is composed of corneocytes and intercellular lipids, cholesterol, free fatty acids, and ceramides.
- Keratins and cornified envelope proteins are important for the mechanical stability of the corneocytes.
- The cornified envelope protein involucrin binds ceramides covalently, forming a backbone for the subsequent attachment of free ceramides.
- The nucleated epidermis through tight junctions and desmosomes also contributes to the barrier.
- Experimental barrier disruption increases epidermal lipids and changes in epidermal differentiation.
- The signals for barrier recovery are cytokines and the calcium ion gradient.
- Several diseases are characterized by a probably genetically disturbed barrier function. The disturbed barrier function contributes to disease pathology, in particular in contact dermatitis, atopic dermatitis, forms of ichthyosis, and psoriasis.
- Lipid or lipid-like creams and ointments can repair disturbed barrier function.

The skin's most important function is to form an effective barrier between the "inside" and the "outside" of the organism. Life on dry land requires the presence of a barrier to regulate water loss and prevent desiccation, commonly referred to as the "inside–outside" barrier. Additionally, skin provides an "outside–inside" barrier to protect against mechanical, chemical, and microbial assaults from the external environment (Fig. 47-1).[1] To perform these functions the epidermis undergoes keratinization, a process in which epidermal cells progressively mature from basal cells with proliferative potential to the lifeless, flattened squames of the stratum corneum (SC) (Fig. 47-2). Both the SC and the deeper skin layers protect the skin from mechanical forces, ultraviolet (UV) radiation, cold and hot temperatures, and invasion of chemicals and microbes. To effectively perform this multiplicity of functions, the skin contains different types of barriers. The physical barrier consists mainly of the SC, but the nucleated epidermis, in particular the tight junctions, provides another important barrier component. The chemical/biochemical (antimicrobial) barrier consists of lipids, acids, lysozymes, and antimicrobial peptides (discussed in Chapter 10). The humoral and cellular immune system provides a barrier to infectious disease, but immune hyperactivity may lead to allergy (Table 47-1).

Although the skin is of central importance for preventing water loss in a dry environment, aquatic animals also require a skin barrier to protect them from the high salinity of their surrounding environment. Terrestrial mammals with dense fur have much thinner skin than animals without this protective coat, demonstrating that fur itself is a considerable barrier. The relatively hairless skin of pigs shows much

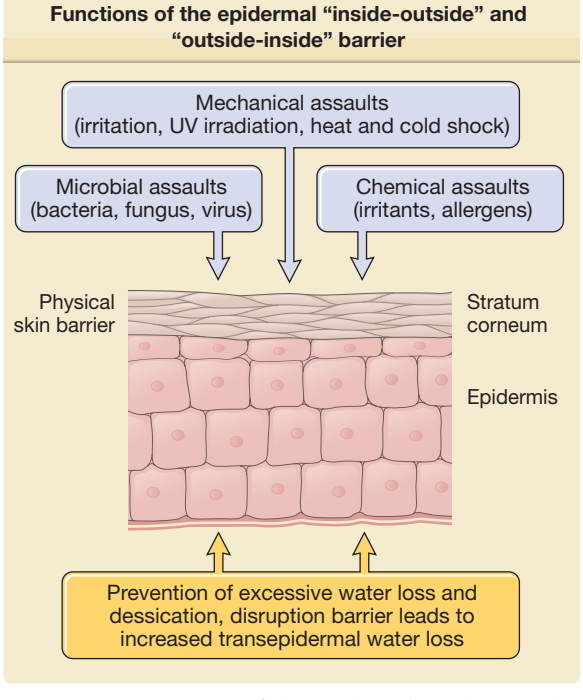

Figure 47-1 Functions of the epidermal "inside–outside" and "outside–inside" barrier.

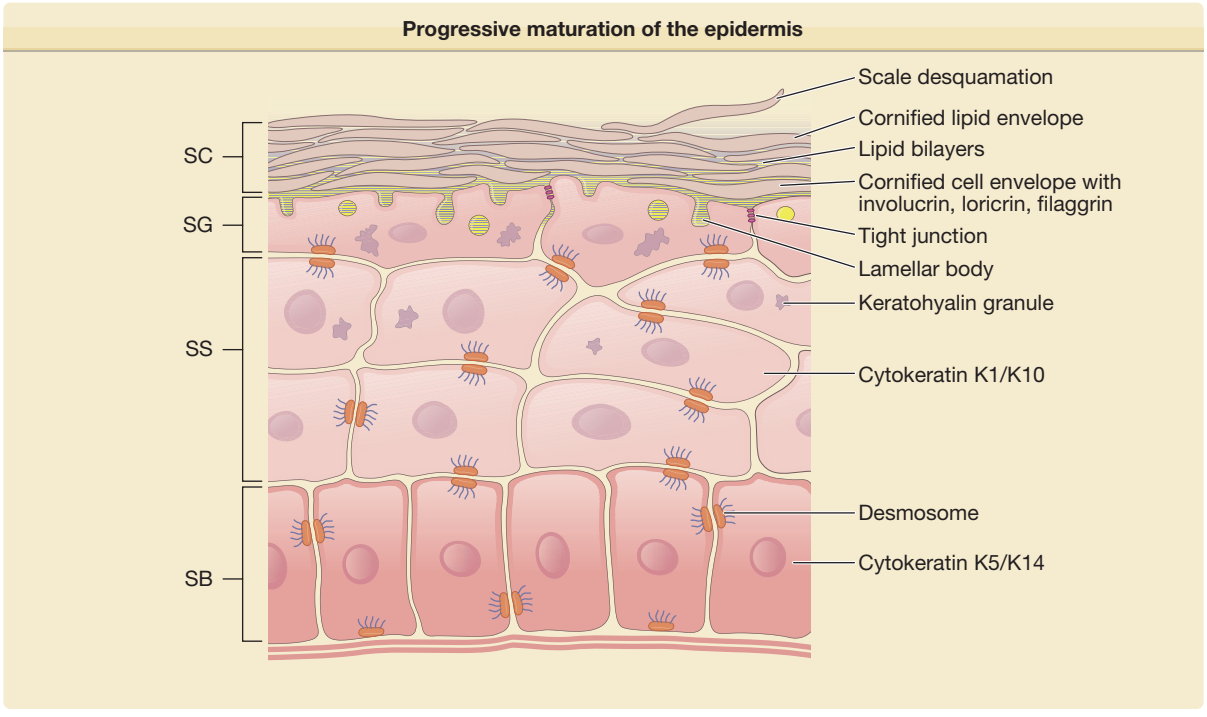

Figure 47-2 The nucleus in the stratum granulosum (SG) should be flattened. In the basal cell layer please add a hemidesmosome towards the basal membrane (please review the former graphic). The lamellar bodies should be hatched (including the membrane fused bag shaped lamellar bodies).

similarity to human skin and is therefore a good model for skin research.

In addition to the SC the entire skin, as a whole, serves a protective function. The innermost region of human skin, the subcutaneous fat layer, offers mechanical shock protection, insulates the body against external heat and cold, and is active in general energy metabolism and storage. The dermis is composed of collagen bundles and elastic fibers and is very important for the mechanical strength of the skin. The epidermis, the skin's outer layer, consisting primarily of stratified nucleated keratinocytes and the SC, is most important for skin protection—the focus of this chapter. Sweat glands and blood vessels regulate body temperature. Sebaceous glands secrete specialized lipids to protect the hair from the environmental stress (see Chapter 79). In animals, these lipids serve as a water repellent for the fur, aiding in buoyancy and temperature regulation, and also preventing desiccation of the body and UV damage. The role of sebaceous lipids for SC barrier function and for dry skin is under active investigation.[2,3] Sebaceous glands also transport glycerol to the skin surface, which is important for SC hydration.[4] Nerve fibers are chemosensitive and act as a warning system against external trauma (see Chapter 102).

TABLE 47-1
Different Skin Barriers

Physical barrier	Stratum corneum (corneocytes, lipid lamellae), nucleated epidermis (desmosomes, tight junctions)
Chemical/biochemical (antimicrobial) barrier (innate immunity)	Lipids, organic acids, lysozymes, antimicrobial peptides
Immune barrier humoral and cellular immune systems	Lymphocytes, neutrophils, monocytes, Langerhans cells

STRUCTURE OF THE STRATUM CORNEUM: THE PHYSICAL PERMEABILITY BARRIER

(Table 47-2)

Research from the 1940s and 1950s established that the SC is the specific location of the physical barrier.[5,6] The SC barrier structure visualized by electron microscopy and ruthenium tetroxide fixation (Fig. 47-3) is a better indicator of its barrier function than the typical "basket-weave" appearance of the SC in routine formalin-embedded tissue sections. Regulation of water permeation is not absolute. The normal movement of water from the SC into the atmosphere is known as transepidermal water loss (TEWL), previously called insensible water loss. The SC serves as the principal barrier against the percutaneous penetration of chemicals and microbes[1] as well.

The 10–20 µm thick SC forms a continuous sheet of protein-enriched cells, embedded in an intercellular matrix, enriched in nonpolar lipids, and organized as

TABLE 47-2
Protection Functions of the Stratum Corneum

Functions	Structural Bases	Biochemical Mechanisms
Permeability barrier	Lamellar bilayers	Hydrophobic lipids
Mechanical integrity/resilience	Cornified envelope, cytosolic filaments	Cross-linked peptides; e.g., involucrin, loricrin. Keratin filaments
Hydration	Lamellar bilayers; corneocyte cytosolic matrix	Sebaceous gland-derived glycerol; filaggrin breakdown amino acids; natural moisturizing factors (NMFs), hornerin
Cohesion/desquamation	Corneodesmosomes	Serine proteases
Antimicrobial defense	Lamellar bilayers; extracellular matrix	Free fatty acids; antimicrobial peptides
UV protection	Corneocyte cytosol	Structural proteins; *trans*-urocanic acid (tUCA)
Antioxidant defense	Corneocytes and extracellular matrix	Keratins; sebaceous gland-derived vitamin E and other antioxidants
Waterproofing/repellence	Lamellar bilayers	Keratinocyte and sebum-derived lipids
Cytokine signaling	Corneocyte cytosol	Storage and release of pro-IL-α; serine proteases
Xenobiotic defense	Lamellar bilayers	Lipid solubility; cytochrome P450 system (outer epidermis)

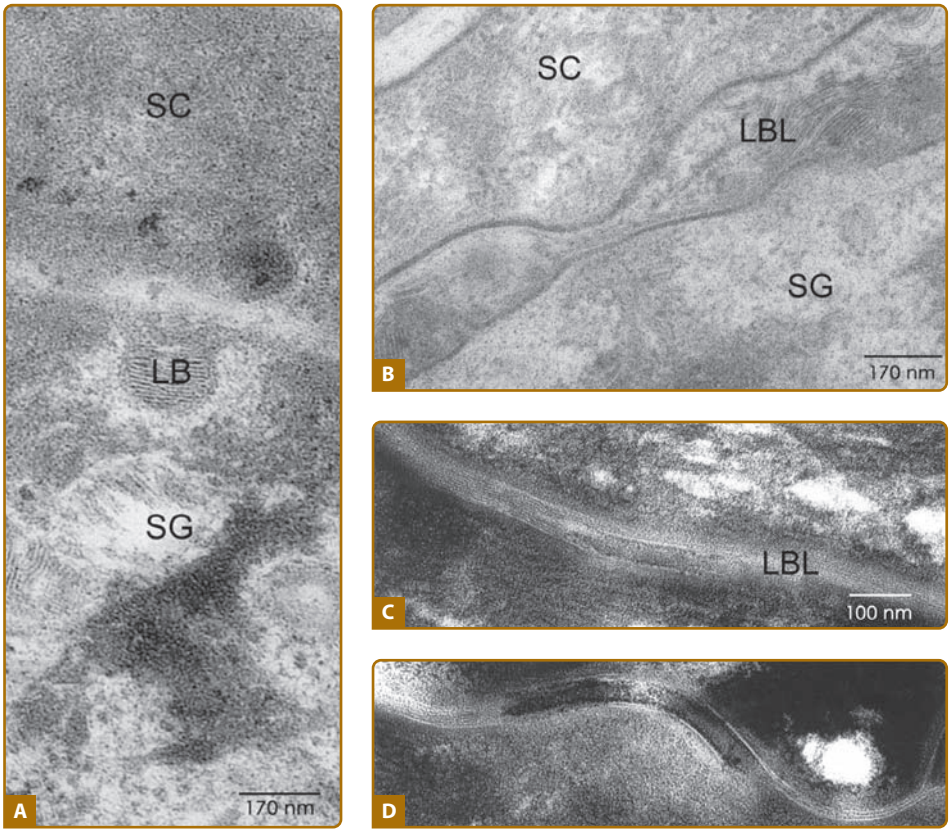

Figure 47-3 Electron microscopy reveals that in the stratum granulosum (SG)–stratum corneum (SC) interface the lamellar bodies (LB) content is extruded to the intercellular space (**A**), thus forming continuous bilayers. (**B** then **C**). Desmosomes are becoming corneosomes in the process of cornification (**D**).

lamellar lipid layers. The viable epidermis is a stratified squamous epithelium, consisting of basal, spinous, and granular cell layers. Upon leaving the basal layer, keratinocytes begin to differentiate and undergo a number of changes in both structure and composition during the apical migration into the stratum spinosum and stratum granulosum (see Chapter 46). Keratinocytes synthesize and express numerous structural proteins and lipids during their maturation. The final steps in keratinocyte differentiation are associated with profound changes in their structure, resulting in their transformation into flat and anucleated squamous cells of the SC, consisting mainly of keratin filaments and surrounded by a cell envelope composed of cross-linked proteins (cornified envelope proteins) as well as a covalently bound lipid envelope (Fig. 47-2). Extracellular nonpolar lipids surround the corneocytes to form a hydrophobic matrix. The cornified envelope proteins as well as the covalently bound lipid envelope are thought to be important for the chemical resistance of the corneocytes (Fig. 47-4). Desmosomes, which interconnect adjacent keratinocytes, are important for SC cohesion and are shed during the desquamation process in the SC. In the upper spinous and granular layers characteristic lamellar vesicles appear, which are called epidermal lamellar bodies (Figs. 47-3 and 47-5). These are enriched in polar lipids, glycosphingolipids, free sterols, phospholipids, and hydrolytic enzymes that deliver the lipids required for the SC's extracellular layers. The lamellar bodies may also contain proteins such as human β-defensin 2.[7] In response to certain signals, for example, an increase in calcium concentration during the transition from the granular layers to the SC, the lamellar bodies move to the apex of the uppermost granular cells, fuse with the plasma membrane, and secrete their content into the intercellular spaces through exocytosis. The lipids derived from the lamellar bodies are subsequently

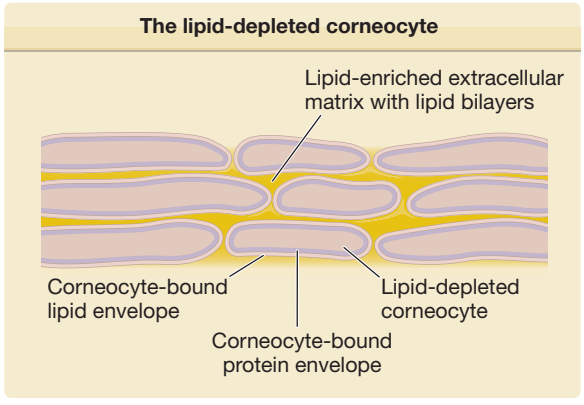

Figure 47-4 The lipid-depleted corneocyte is surrounded by an inner protein envelope and an outer lipid envelope. Special ceramides are covalently bound to cornified envelope proteins, in particularly to involucrin.

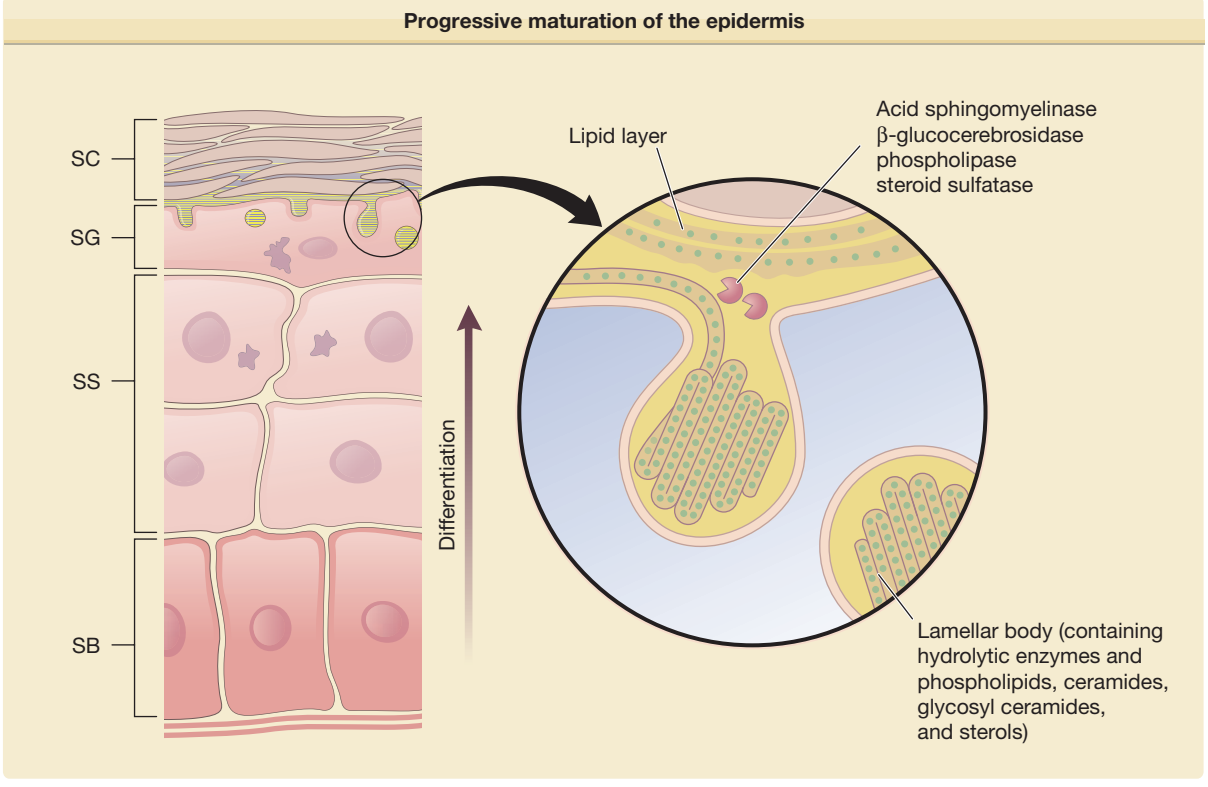

Figure 47-5 During differentiation, the upper stratum spinosum (SS) and the stratum granulosum (SG) cells generate lamellar bodies containing preformed lipid structures and hydrolytic enzymes. Their content is extruded into the SG–stratum corneum (SC) interface and undergoes profound remodeling. SB = stratum basale.

modified and rearranged into intercellular lamellae positioned approximately parallel to the cell surface. The covalently bound lipid envelope acts as a scaffold for this process. After the extrusion of the lamellar bodies into the stratum granulosum–SC interface, the polar lipids are enzymatically converted into nonpolar products. Hydrolysis of glycosphingolipids generates ceramides while phospholipids are converted into free fatty acids. These changes in lipid composition and cell structure result in the formation of a very dense structure packed into the interstices of the SC (Table 47-2).[8]

LIPID COMPOSITION AND ROLE OF LIPIDS IN THE STRATUM CORNEUM PERMEABILITY BARRIER

Confocal laser scanning microscopy and X-ray microanalysis studies have shown that the major route of penetration results in a tortuous pathway between the corneocytes, confirming that intercellular lipids play an irreplaceable role in regulating skin permeability barrier function.[8] The major lipid classes in the SC are cholesterol, free fatty acids, and ceramides (see eFig. 47-5.1 in online edition).[9–11]

CHOLESTEROL. Cholesterol is probably the most abundant lipid in the entire body and part of the plasma membrane, but also part of the intercellular lipid lamellae in the SC. Although basal cells are capable of resorbing cholesterol from circulation, most cholesterol in the epidermis is synthesized in situ from acetate.[12] The epidermal keratinocyte, the main cell type in the epidermis, is highly active in the synthesis of several lipids, including cholesterol and free fatty acids. The rate-limiting step in cholesterol biosynthesis is catalyzed by hydroxymethylglutaryl CoA (HMG CoA) reductase (Fig. 47-6). Epidermal cholesterol synthesis is regulated by these enzymes and increases during permeability barrier repair.[13]

FREE FATTY ACIDS. The skin contains free fatty acids as well as fatty acids bound in triglycerides, phospholipids, glycosylceramides, and ceramides. The chain length of free fatty acids in the epidermis ranges from C_{12} to C_{24}. The rate-limiting enzymes acetyl-CoA carboxylase and fatty acid synthase in the epidermis are largely autonomous (Figs. 47-6 and 47-7).[14] Saturated and monounsaturated fatty acids are synthesized in the epidermis, in contrast to di- and polyunsaturated acids. The nomenclature of the fatty acids is determined from the position of the first double bond in the molecule, starting from the terminal methyl group. In particular, the essential ω-6-unsaturated acids are obtained from food and reach the epidermis by the circulation but can also be obtained by topical treatment. The nonessential monounsaturated fatty acid, the oleic acid, is an ω-9-fatty acid. The most important double unsaturated fatty acid, linoleic acid, is an ω-6 fatty acid. Also of importance is α-linoleic acid (ω-3). No skin changes due to ω-3-fatty acid deficiency are currently known; however, it has been proposed that these fatty acids are important for the resolution of inflammation. ω-3-fatty acids are obtained from fish, whereas ω-6-fatty acids are obtained from plant oils.[15,16] Essential fatty acid deficiency (EFAD) caused by unusual diets or malabsorption in humans or experimentally induced in rats and mice leads to the EFAD syndrome, characterized by profound changes in epithelia including the epidermis.[17] In this condition, the epidermis is rough, scaly, and red and shows a severely disturbed permeability barrier function. In addition, severe bacterial infection, impaired wound healing, and alopecia may occur. Linoleic acid is part of phospholipids, glucosylceramides, ceramide 1, ceramide 4, and ceramide 9.[18] It has been proposed that the linoleic acid metabolite γ-linoleic acid is of special importance for atopic eczema.

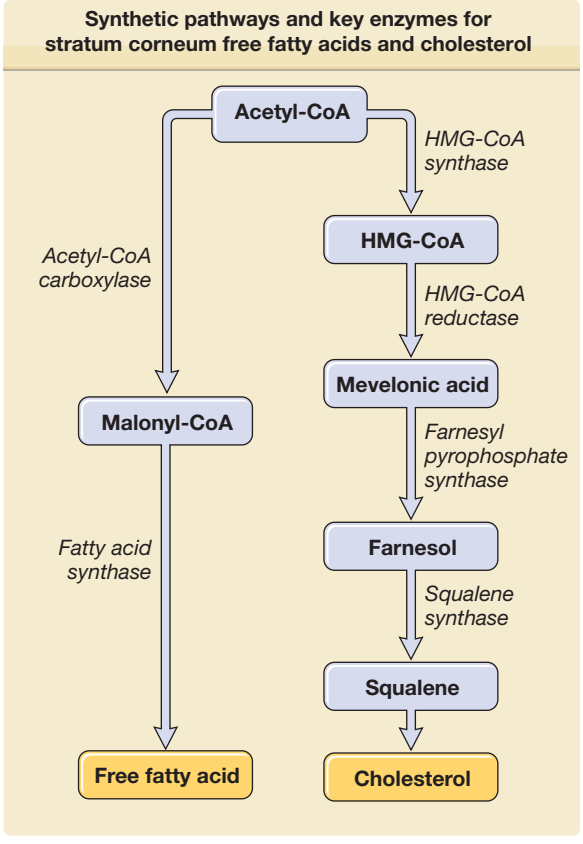

Figure 47-6 Synthetic pathways and key enzymes for stratum corneum free fatty acids and cholesterol. CoA = coenzyme A; HMG-CoA = hydroxymethylglutaryl CoA.

CERAMIDES. Ceramide is an amide-linked fatty acid containing a long-chain amino alcohol called sphingoid base. The carbon chain lengths of amide-linked fatty acids and sphingoid bases in most mammalian tissues are 16 to 26 and 18 to 20, respectively (see eFig. 47-5.1 in online edition). Although sphingolipids, including glycosphingolipids and phosphosphingolipids, are ubiquitously distributed in mammalian tissues, tissue-specific molecular distribution has been described. Glucosylceramide is

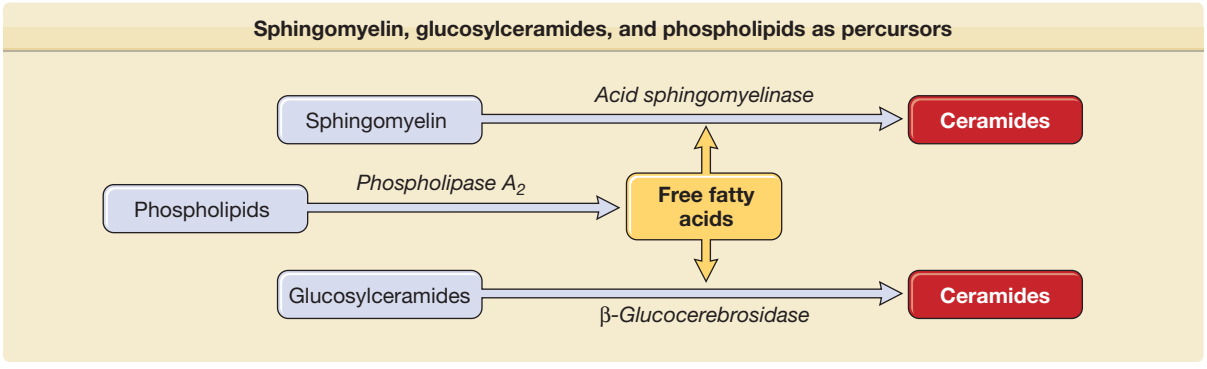

Figure 47-7 Sphingomyelin and glycosylceramides are precursors for ceramide generation, while phospholipids are precursors of fatty acids.

enriched in the epidermis and spleen while galactosylceramide is enriched in the brain, but is not detected in keratinocytes. Whereas ceramide is a minor lipid component, comprising less than 10% of cholesterol or phospholipids in other mammalian tissues, ceramide is a major lipid component in the SC, accounting for 30%–40% of lipids by weight. Moreover, such a high content of ceramides in the SC is not observed in the epidermal stratum granulosum, stratum spinosum, or stratum basale. This also suggests that terminal differentiation is a key factor in accumulating ceramide. The SC contains at least nine different ceramides.[18] In addition, there are two protein-bound ceramides: (1) ceramide A and (2) ceramide B (see eFig. 47-5.1 in online edition).[8] These ceramides are covalently bound to cornified envelope proteins, most importantly to involucrin.

Ceramides are synthesized by serine-palmitoyltransferase as rate-limiting enzyme and by hydrolysis of both glucosylceramide (by β-glucocerebrosidase)[19] and sphingomyelin (by acid sphingomyelinase) (Figs. 47-7 and 47-8).[20] Whereas all kinds of ceramides are derived by synthesis from serine-palmitoyltransferase and from β-glucocerebrosidase, only ceramide 2 and ceramide

TABLE 47-3
Additional Protective Functions of the Nucleated Epidermis

Functions	Biochemical Correlates
Antimicrobial systems	Antimicrobial peptides and lipids, iron-binding proteins, complement
Antioxidants	Glutathione, oxidases, catalase, cytochrome P450 system, vitamins C and E
Inflammatory mediators	Prostaglandins, eicosanoids, leukotrienes, histamine, cytokines
UV-absorbing molecules	Melanin, *trans*-urocanic acid, vitamin D, vitamin C metabolites, filaggrin metabolites
Xenobiotic-metabolizing enzymes	Glucoronidation, sulfation, hydroxylation mechanisms

5 are obtained from sphingomyelinase because sphingomyelinase contains nonhydroxy acids.[21]

LIPID TRANSPORT

Keratinocytes require abundant cholesterol for cutaneous permeability barrier function. ABCA1 is a membrane transporter responsible for cholesterol efflux and plays a pivotal role in regulating cellular cholesterol levels. It was demonstrated that ABCA1 is expressed in cultured human keratinocytes and murine epidermis. Liver X receptor (LXR) activation and activation of peroxisome proliferator-activated receptor (PPAR)-α, PPAR-ss/δ, and retinoid X receptor (RXR) increased ABCA1 expression in keratinocyte cultures. Thus, cholesterol levels for permeability barrier function are regulated by ABCA1, LXR, and PPARs.[22] The cellular fatty acid transport and metabolism is regulated by fatty acid-binding proteins (FABPs).[23,24]

Additional protective functions of the epidermis are not discussed in this chapter, but are listed in Table 47-3.

EPIDERMAL PROLIFERATION AND DIFFERENTIATION IN SKIN BARRIER FUNCTION

To provide the physical barrier of the SC, not only intercellular lipids, but also corneocytes are of crucial importance.[25,26] The epidermis undergoes keratinization in which epidermal cells progressively mature from basal cells with proliferative potential to lifeless flattened squames of the SC (Fig. 47-2). Keratinocytes arise from stem cells in the basal layers and transient amplification cells and move to a series of differentiation events until they are finally brought to desquamation.[27] Thus, in the normal epidermis, there is a balance between the processes of proliferation and desquamation that results in a complete renewal approximately every 28 days. In some forms of ichthyosis, the rate of desquamation may be decreased, leading to epidermal cell retention (retention hyperkeratosis).[28] (See Chapter 49.) In inflammatory skin diseases like psoriasis there is an increase in proliferation resulting in a disturbance in differentiation and parakeratotic squames (hyperproliferative hyperkeratosis).[29]

Keratins are major structural proteins synthesized in keratinocytes (see Chapter 46). They assemble into a web-like pattern of intermediate filaments that emanate from a perinuclear ring, extend throughout the cytoplasm, and terminate at junctional desmosomes and hemidesmosomes. During the final stages of normal differentiation, keratins are aligned into highly ordered and condensed arrays through interactions with filaggrin, a matrix protein. In keratin disorders, the filament networks collapse around the nucleus, preventing attachment with the filament-matrix complex and the inner surface of squames, and alter interaction between neighboring cells, thereby affecting desquamation. Filaggrin aggregates the keratin filaments into tight bundles. This promotes the collapse of the cell into a flattened shape, which is characteristic of corneocytes in the cornified layer. Together, keratins and filaggrin constitute 80%–90% of the protein mass of mammalian epidermis.[25,26]

The structural proteins involucrin, loricrin, trichohyalin, and the class of small proline-rich proteins (SPRRs) are synthesized and subsequently cross-linked by transglutaminases to reinforce the cornified envelope just beneath the plasma membrane. The proteins of the cornified envelope constitute about 7%–10% of the mass of the epidermis. These corneocytes provide the bulwark of mechanical and chemical protection, and together with their intercellular lipid surroundings, confer water-impermeability. The cornified cell envelope is a tough protein/lipid polymer structure formed just below the cytoplasmic membrane and subsequently resides on the exterior of the corneocytes (Fig. 47-4). It is resistant to 10% KOH and is the rigid structure seen on KOH skin scrapings. It consists of two parts: (1) a protein envelope and (2) a lipid envelope. The protein envelope contributes to the biomechanical properties of the CE as a result of cross-linking of specialized cornified envelope structural proteins by both disulfide bonds and *N*(ε)-(γ-glutamyl)lysine isopeptide bonds formed by transglutaminases.[26,30] The isopeptide bonds are resistant to most common proteolytic enzymes. The corneocyte-bound lipid envelope is plasma membrane-like structure, which replaces the plasma membrane on the external aspect of mammalian corneocytes.[31] Involucrin, envoplakin, and periplakin serve as substrates for the covalent attachment of ω-hydroxyceramides with very long-chained *N*-acyl fatty acids by ester linkage.[32] These not only provide a coating to the cell, but also interdigitate with the intercellular lipid lamellae (Table 47-2).[26]

EXPERIMENTAL BARRIER DISRUPTION AND GENE MODIFICATION IN EPIDERMAL DIFFERENTIATION

Experimental barrier disruption leads to changes in epidermal differentiation, epidermal lipid keratin, and cornified envelope protein expression and, vice versa, overexpression and deficiency of these lipids and proteins in mice result in barrier defects. A number of diseases displaying defective epidermal barrier function are also the result of genetic defects in the synthesis and metabolism of either lipids, keratins, cornified envelope proteins, or the transglutaminase 1 cross-linking enzyme.

Inhibition of HMG CoA reductase by topical application of the lipid-lowering drug lovastatin in mice resulted in a disturbed barrier function and in epidermal hyperproliferation. Therefore, the specific relationship between barrier function and epidermal DNA synthesis was examined. After acute skin barrier disruption (local acetone treatment or by tape-stripping) (Fig. 47-9) and in a model of chronic barrier disruption (EFAD diet), an increase in DNA synthesis leading to epidermal hyperplasia was noticed.[33] The increase in DNA, and in lipid synthesis, was partially prevented by occlusion.[15,33,34]

Also, the described acute and chronic barrier disruption leads to specific changes in epidermal keratin and cornified envelope protein expression. Increased expression of the basal keratins K5 and K14 and a reduction of the differentiation-related keratins K1 and K10 were noted. In addition, there was expression of the proliferation-associated keratins K6 and K16 as well as the inflammation-associated keratin K17 (see eFig. 47-9.1 in online edition).[35] The importance of keratins for skin barrier function was supported by studies in K10-deficient mice. Heterozygotes and homozygotes showed a mild or severe permeability barrier disruption, respectively. Importantly, homozygous neonatal K10-deficient mice exhibited an extremely delicate epidermis and died a few hours after birth. Heterozygous littermates showed a normal skin at birth but developed increasing hyperkeratosis as they grew up.[36] Barrier repair in heterozygous K10-deficient mice was delayed and skin hydration was impaired.[37] Changes in ceramide composition, a reduced amount of glucosylceramide and sphingomyelin, and reduced acid sphingomyelinase activity, as well as increased involucrin content, were also noted.[38] This shows that genetically determined changes in structural proteins lead to an impaired skin barrier function and changes in differentiation and lipid composition.

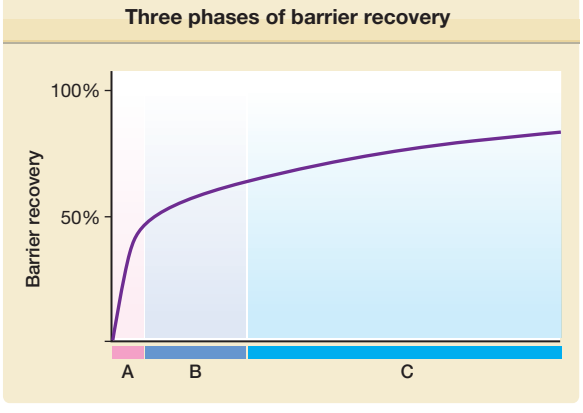

Figure 47-9 Three phases of barrier recovery with distinct metabolic activities occurring after acute barrier disruption. **A** = Secretion of preformed pool of lamellar bodies (0 to 30 minutes). **B** = Increased lipid synthesis (free fatty acids, ceramide, and cholesterol) (30 minutes to 6 hours), accelerated lamellar body formation and secretion (2 to 6 hours). **C** = Increased glucosylceramide processing (9 to 24 hours), increased keratinocyte proliferation and differentiation (16 to 24 hours).

The importance of keratins for skin barrier function is further supported by studies in diseases that are caused by monogenetic defects of these structural proteins. Epidermolysis bullosa simplex (EBS) shows mutation in the basal layer keratins K5 or K14 (details in Chapter 62). Genetic defects in the suprabasal keratins results in hyperkeratosis and a mild barrier defect (details in Chapters 49 and 59). Epidermolytic hyperkeratosis (EHK) has spinous layer K1 or K10 defects, epidermolytic palmoplantar keratoderma (EPPK) has granular layer K9 defects (because this keratin is expressed only in palmar and plantar skin, the disease is restricted to that area), and ichthyosis bullosa of Siemens (IBS) has granular layer defects K2 (formerly K2e) defects.[25]

Experimental permeability barrier disruption leads to a premature expression of involucrin, but not loricrin.[35] Overexpression of filaggrin in mice in the suprabasal epidermis resulted in a delay of barrier repair.[39] Loss of normal profilaggrin and filaggrin is the cause for the flaky tail in an autosomal recessive mutation in mice that results in a dry, flaky skin, and annular tail and paw constrictions in the neonatal period. Targeted ablation of the murine involucrin gene did not show changes in skin barrier function under basal conditions[40] but resulted in a reduced barrier repair. In addition, knockdown of filaggrin was shown to increase UV-sensitivity in a human skin model.[41] Loricrin deficient mice do not show a disturbed barrier function, but a greater susceptibility to mechanical stress which may alter skin barrier function secondarily.[42,43]

Changes in epidermal proliferation and differentiation are also seen in inflammatory skin diseases with a disturbed skin barrier function (see eFig. 47-9.1 in online edition). Increased proliferation is one of the main characteristics of psoriasis, but in atopic dermatitis lesional skin also there is a considerable increase in epidermal proliferation. Also, changes in keratins and cornified envelope proteins occur in inflammatory skin diseases.[44] Overall, this shows that there is undoubtedly a connection between epidermal proliferation, differentiation, and skin barrier function.

FUNCTIONS OF THE SUBCORNEAL EPIDERMAL LAYERS

Although the SC is recognized as the most important physical barrier, the lower epidermal layers are also significant in barrier function. A low-to-moderate increase in TEWL occurs after removal of the SC by tape stripping, whereas loss of the entire epidermis through suction blisters leads to a severe disturbance in barrier function. Loss of the SC and parts of the granular layers in staphylococcal scalded skin syndrome (SSSS) are not usually life-threatening.[45] In contrast, the suprabasal and subepidermal blistering diseases pemphigus vulgaris, toxic epidermal necrolysis and severe burns, respectively, are life-threatening when large areas of the body are involved. Patients die because of extensive water loss or sepsis induced by external bacteria infection—outcomes directly resulting from perturbed barrier function. Survival rates can be greatly improved with application of an artificial barrier in the form of a foil or a grease ointment, often containing active antimicrobial substances. These clinical observations confirm the importance of the nucleated epidermal layers in skin barrier function in both directions, both in preventing excessive water loss and the entry of harmful substances into the skin.[46]

TIGHT JUNCTIONS: A SECOND-LINE EPIDERMAL BARRIER

Tight junctions are cell-junctions connecting neighboring cells sealing the intracellular space and controlling the paracellular movements of molecules (Fig. 47-2). The most important tight junction proteins in the human epidermis are occludin, claudins, and zonal occluding proteins (ZOs). Localization of occludin is restricted to the stratum granulosum, ZO-1 and claudin 4 are found in suprabasal layers, and claudins 1 and 7 are found in all epidermal layers. In various diseases with perturbed SC barrier function, for example, psoriasis vulgaris, lichen planus, acute and chronic eczema, and ichthyosis vulgaris, tight junction proteins that were formerly restricted to the stratum granulosum and upper stratum spinosum, were also found in deeper layers of the epidermis. Claudin 1-deficient mice die within 1 day of birth due to tremendous water loss.[47] Altered barrier function of the skin has also been demonstrated in mice overexpressing claudin 6 in the epidermis.[48,49]

DESMOSOMAL PROTEINS: STRUCTURAL CELL–CELL INTERFACES

A perturbation in SC barrier function has also been found after the alteration of desmosomal proteins. Desmogleins are desmosomal cadherins that play a major role in stabilizing cell–cell adhesion in the living layers of the epidermis (Fig. 47-2, see Chapter 53). Autoantibodies against these transmembrane glycoproteins cause blisters in pemphigus vulgaris due to loss of keratinocyte adhesion. In acute eczema, which shows disturbed skin barrier function a reduction in keratinocyte membrane E-cadherin in areas of spongiosis has been found.[50,51] In transgenic mice in which the distribution of desmoglein 3 in epidermis was similar to that in mucous membrane, a highly increased TEWL resulted in lethality during the first week of life due to dehydration.[52] Mice with conditionally inactivated E-cadherin in the epidermis died perinatally due to the inability to retain a functional epidermal water barrier. Absence of E-cadherin leads to improper localization of key-tight junctional proteins and impermeable tight junctions and thus altered epidermal barrier function.[53,54]

CONNEXINS: INTERCELLULAR GATEKEEPERS

Connexins are transmembrane proteins that homo- or heteromerize on the plasma membrane to form a connexon. Connexons on adjoining cells that associate to form gap junctions and allow the passage of ions and small molecules between cells. Connexin 26 is one of the most highly upregulated genes in psoriatic plaques. Missense mutations in connexin 26 result in five distinct ichthyosis-like skin disorders. In mice overexpressing connexin 26, a hyperproliferative state, infiltration of immunocells, and a delayed epidermal barrier recovery were noted.[55]

PROTEASES

Proteases are important for epidermal differentiation. The characteristic resistance of the cornified envelope is based on the formation of very stable isopeptide bonds that are catalyzed by transglutaminase 1, 3, and 5. Transglutaminase 1-deficient mice showed a defective SC and early neonatal death.[56] Mutations in transglutaminases 1 have been found to be the defect in lamellar ichthyosis.[57] Cathepsin D is involved in the processing of transglutaminase 1. Cathepsin D-deficient mice expressed a defect in barrier function and hyperproliferation.[58] Evidence suggests that cystatin M/E and cathepsin L may be upstream proteases of the cathepsin D–transglutaminase pathway and must exist in a tightly regulated balance in order to ensure tissue integrity in the epidermis, hair follicles, and corneal epithelium.[59] There is further evidence that disruption of the cystatin M/E–cathepsin pathway contributes to the underlying skin barrier dysregulation characteristic of inflammatory dermatoses, such as psoriasis and atopic dermatitis.[60]

Netherton syndrome, a severe autosomal recessive genodermatosis (see Chapter 49) is caused by mutations in SPINK5, encoding the serine protease inhibitor LEKTI. In Netherton syndrome, there is often an atopic eczema-like skin disease with a disrupted permeability barrier. SPINK5$^{-/-}$ mice replicate key features of Netherton syndrome, including altered desquamation, impaired keratinization, hair malformation, and a skin barrier defect. LEKTI deficiency causes abnormal des-

mosome cleavage in the upper granular layer through degradation of desmoglein 1 due to SC chymotryptic enzyme (SCCE)-like hyperactivity. This leads to defective SC adhesion and results in loss of skin barrier function.[61,62]

CYTOKINE SIGNALING: REGULATION OF EPIDERMAL HOMEOSTASIS AND REPAIR

Cytokines are very important for the regulation of wound healing in which reepithelization and differentiation to form a competent barrier are the last steps[63] (see Chapter 248). Besides the immune cells, keratinocytes are able to produce a large variety and amounts of cytokines (Fig. 47-10). Of special importance are the so-called primary cytokines tumor necrosis factor (TNF), interleukin (IL)-1, and IL-6. IL-1, TNF, and IL-6 are potent mitogens and stimulators of lipid synthesis in cutaneous and extracutaneous tissues. After acute permeability barrier disruption, an increase in the expression of TNF, IL-1, and IL-6 on the mRNA and the protein level occurs.[20,64,65,66] In mice deficient in TNF receptor 1 or IL-1 receptor 1/TNF receptor 1-double knockout mice and in IL-6-deficient mice, a delay in permeability barrier occurs.[20,66] Moreover, topical application of TNF enhances permeability barrier repair, and topical application of IL-6 in IL-6-deficient mice restores the normal speed in permeability barrier repair (Fig. 47-10). In TNF-receptor 1-deficient mice, the generation of lipids for skin barrier repair was delayed and the activity of acid sphingomyelinase that generates ceramides for skin barrier repair was reduced.[20] STAT 3 tyrosine phosphorylation was induced after barrier disruption in wild type, but markedly reduced in IL-6-deficient mice. The acute increase in TNF, IL-1, and IL-6 after barrier disruption is crucial for skin barrier repair. However, if barrier disruption is prolonged and a chronic increase in cytokine production occurs, it could have a harmful effect leading to inflammation and epidermal proliferation. This disrupted permeability barrier, epidermal hyperproliferation, and inflammation, and is well known in several diseases like irritant and allergic contact dermatitis, atopic dermatitis, and psoriasis, and could aggravate the disease.

IONIC MODULATIONS: EPIDERMAL CALCIUM AND POTASSIUM LEVELS

A perturbed barrier recovers normally when exposed to an isotonic, hypertonic, or hypotonic external solution instead of air. If the solution contains both calcium and potassium, the barrier recovery is inhibited. Inhibitor studies using both L-type calcium channels and calmodulin and ultrastructural examination by ion-capture cytochemistry showed that there is a calcium gradient in the epidermis. There is a relatively low calcium concentration in the basal epidermis, and an even lower concentration in the spinous layers, while the highest calcium concentrations are found in the granular layers. Calcium in the SC is very low because the relatively dry SC with extracellular lipids is not able to solve the high polar ions. After disruption of the permeability barrier there is influx of water in the SC and the ion gradient is lost (Fig. 47-11). This depletion of calcium regulates lamellar body exocytosis.[67–69] Calcium is a very important regulator of protein synthesis in the epidermis, including regulation of transglutaminase 1 activity.[70] Furthermore, extracellular calcium ions are important for cell-to-cell adhesion and epidermal differentiation. Intracellular calcium is controlled by more than one mechanism as demonstrated by the two genetic diseases discussed below.

Disturbed regulation of calcium metabolism and increased TEWL[71] occur in Darier disease, characterized by loss of adhesion between suprabasal epidermal cells associated with abnormal keratinization, and in Hailey–Hailey disease which shows loss of

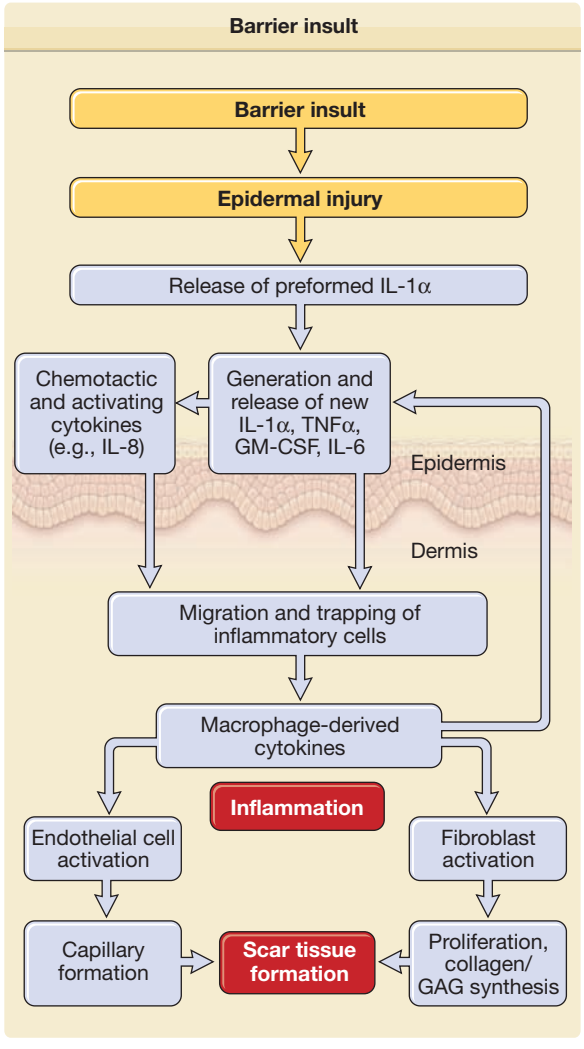

Figure 47-10 A barrier insult from the outside results not only in the release of cytokines for epidermal cell signaling, but also interacts with dermal processes, which may result in inflammation and ultimately scar tissue formation in case of destructions of the dermis. GAG = glycosaminoglycan; GM-CSF = granulocyte macrophage-colony stimulating factor; IL = interleukin; TNF = tumor necrosis factor.

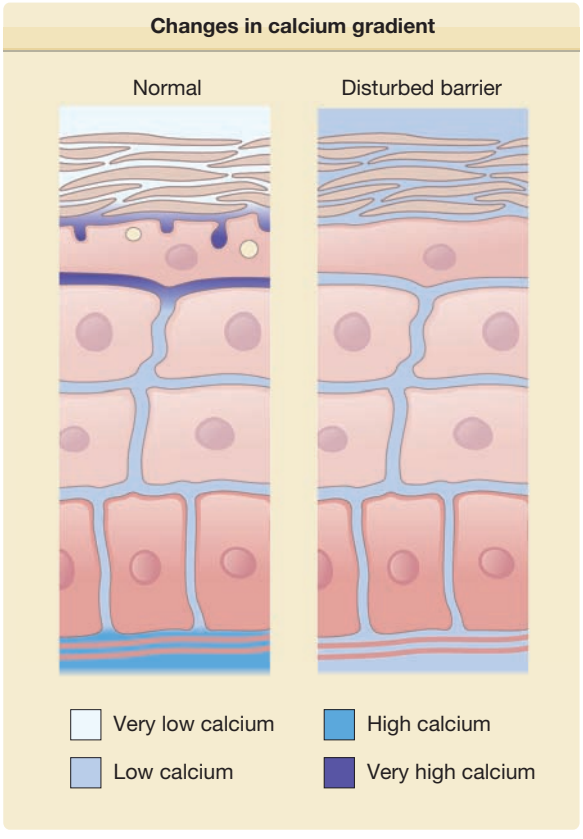

Figure 47-11 Changes in calcium gradient after barrier disruption regulates lamellar body secretion and epidermal differentiation.

epidermal cell-to-cell adhesion (see Chapter 51). The gene for Darier disease (*ATP2A2*) encodes a calcium transport ATPase of the sarco(endo)plasmic reticulum (SERCA2),[72,73] while the gene for Hailey–Hailey disease (*ATP2C1*) codes for a secretory pathway for calcium and manganese transport ATPase of the Golgi apparatus (SPCA1).[74]

NEUROTRANSMITTERS IN THE KERATINOCYTES: COMMON ORIGINS OF THE BRAIN AND SKIN

Neurotransmitters are found in keratinocytes and may regulate skin permeability barrier function. The receptors can be categorized in two groups: (1) ionotropic (calcium or chloride ion) receptors and (2) G-protein-coupled receptors. Topical application of calcium channel agonists delays the barrier recovery while antagonists accelerate barrier repair.

The G-protein-coupled receptors modulate intracellular cAMP level, increase of intracellular cAMP in epidermal keratinocytes delays barrier recovery, while cAMP antagonists accelerate the barrier recovery. Activation of dopamine 2-like receptors, melatonin receptors, or serotonin receptor (type 5-HT 1) decreases intracellular cAMP and consequently accelerates barrier recovery, while activation of adrenergic β2 receptors increases intracellular cAMP and delays the barrier repair. Many agonists or antagonists of neurotransmitter receptors are used clinically to treat nervous disorders. Some of them might also be effective for treating skin diseases.[75]

PATHOLOGICAL SKIN BARRIERS: SKIN BARRIER FUNCTION IN DERMATOSES

Mild impairment of the skin barrier is found in monogenetic diseases expressing an impaired epidermal differentiation or lipid composition without inflammation, for example, ichthyosis vulgaris and X-linked recessive ichthyosis (XLRI).[71] The diseases with a more pronounced barrier disruption are inflammatory diseases, for example, irritant and allergic contact dermatitis, atopic dermatitis, seborrheic dermatitis, psoriasis, and T-cell lymphoma. Also, blistering diseases, most of them inflammation-related, show an increase in TEWL, especially after loosening of the blister roof and the development of erosions (Table 47-4). Since HIV patients are known to display a xerotic phenotype, it seems likely that allergen penetration due to a disturbed skin barrier activates the Th2 pathway and consequently aggravates the underlying skin barrier disturbance (Table 47-4).[76]

Most inflammatory skin lesions are covered with dry scales or scale-crusts due to the disturbed epidermal differentiation and an SC with poor water-holding capacity. Inflammatory skin diseases can be produced by either exogenous or endogenous causes. In contact dermatitis, disruption of the barrier by irritants and allergens (which can also be irritants) is the primary event,

TABLE 47-4
Potential Role of the Cutaneous Barrier in the Pathophysiology of Skin Disorders

Barrier abnormality represents a primary or intrinsic process:
- Irritant contact dermatitis
- Allergic contact dermatitis
- Burns
- Ulcers (ischemic, vascular, diabetic)
- Bullous disorders by friction or keratin abnormalities
- Premature infant's skin
- Ichthyosis, Gaucher's (II), Niemann–Pick (I)

A primary barrier abnormality triggers immunologic reactions, but vice versa primary immunological reactions may trigger barrier abnormalities in yet unknown subgroups of the diseases:
- Atopic dermatitis
- Psoriasis

Immunologic abnormality triggers barrier abnormality:
- T-cell lymphoma (mycosis fungoides)
- Autoimmune bullous diseases
- Lichen planus
- Dry skin in HIV

followed by penetration of the chemicals into the living epidermal layers, irritation of the cell membrane, contact with immune cells, sensitization, inflammation, increased epidermal proliferation, and changes in differentiation. In T-cell lymphoma (mycosis fungoides), an endogenous cause for barrier disruption, changes in epidermal proliferation, and differentiation by expansion of clonal malignant $CD4^+$ T-cells are obvious.[77] In atopic dermatitis and in psoriasis, it is debatable whether permeability barrier disruption is followed by inflammation or whether inflammation leads to epidermal changes including barrier dysfunction. The vast majority of reports on the pathogenesis of atopic dermatitis and even more on psoriasis focused on the primary role of abnormalities in the immune system.[78] However, others have proposed an "outside–inside" pathogenesis for atopic dermatitis and other inflammatory dermatoses with barrier abnormalities,[79–81] as an alternative to the previous "inside–outside" paradigm.[82]

ATOPIC DERMATITIS: THE CONSEQUENCE OF A CHRONICALLY DISTURBED BARRIER

(See also Chapter 14)

The existence of a defective permeability barrier function in atopic dermatitis is now widely accepted. A genetically impaired skin barrier function is already present in nonlesional and more pronounced in lesional skin in atopic dermatitis. Increased epidermal proliferation and disturbed differentiation, including changes in keratins and cornified envelope proteins involucrin, loricrin, and filaggrin, and in lipid composition, cause impaired barrier function in atopic dermatitis (AD) (Fig. 47-12 and see eFig. 47-9.1 in online edition).[81] Mutations in the filaggrin gene have been described by several research groups.[83–85] Two loss-of-function genetic variants in the gene encoding filaggrin are strong predisposing factors for atopic dermatitis in atopic kindreds of European origin.[86] Slightly different mutations are found in Asian patients with atopic dermatitis and ichthyosis vulgaris.[87] These mutations were also significantly associated with asthma, independent of atopic dermatitis, which means that genetic factors that compromise the epidermal barrier could also underlie mucosal atopic diseases (filaggrin is a protein that is unique to keratinizing epithelia). The atopic syndrome represents a genetically impaired skin barrier function as well as impaired nasal, bronchial, and intestinal mucous membrane barriers leading to atopic dermatitis, allergic rhinitis, bronchial asthma, or aggravation of atopic dermatitis. Defective permeability barrier function enables penetration of environmental allergens into the skin and initiates immunological reactions and inflammation (Fig. 47-13). Filaggrin mutation is the first strong genetic factor identified in this complex disease. Filaggrin hydrolysis generates amino acids in their deiminated products that probably serve, together with hornerin, as endogenous humectants.[88,89] This may explain the dry skin of atopic dermatitis. Also, gene polymorphisms in the gene for SPINK5, which encodes the serine protease inhibitor LEKTI, have been reported[90] and variations within two serine proteases of the kallikrein family, the SC chymotryptic enzyme that degrades corneodesmosomal proteins, involved in the cohesion between the corneocytes of the SC, have been found in some cohorts with AD.

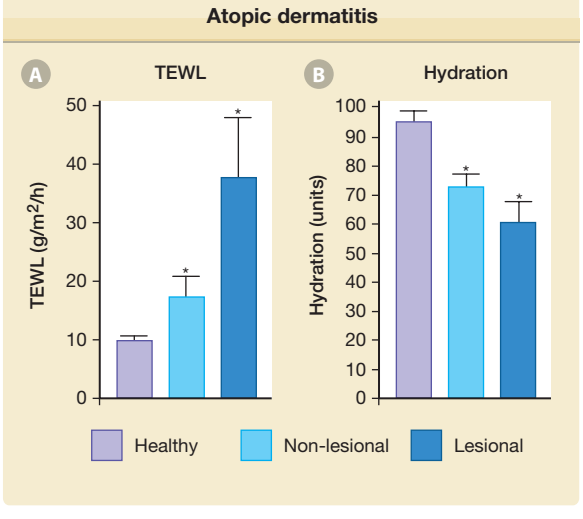

Figure 47-12 Transepidermal water loss (TEWL) (**A**) and stratum corneum hydration (**B**) are impaired in atopic dermatitis. Reduced stratum corneum hydration and enhanced TEWL are already seen in nonlesional skin and are more pronounced in lesional skin in atopic dermatitis.

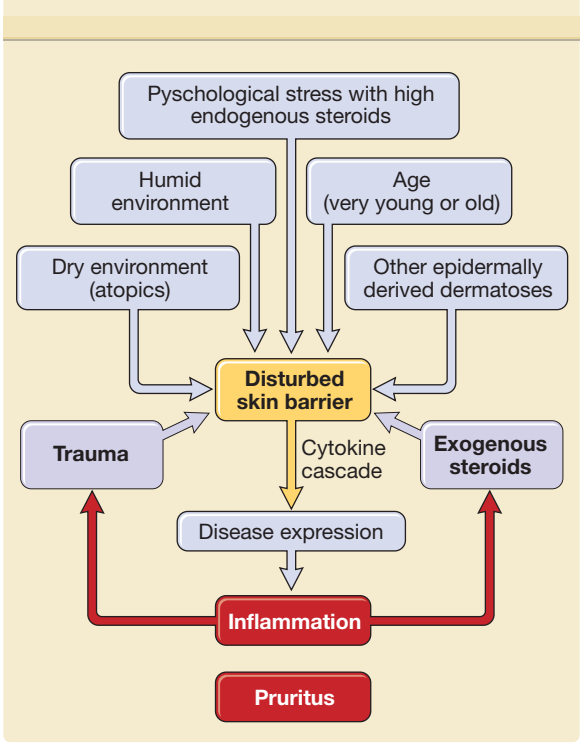

Figure 47-13 Endogenous and exogenous insults lead to a disturbance in skin barrier function, thus inducing or maintaining inflammatory skin diseases in atopic dermatitis.

The impaired skin barrier function in atopic dermatitis is also caused by a reduced lipid content or impaired lipid composition in the epidermis atopic dermatitis. In particular, a decreased content for the total amount and for certain types of ceramides has been described.[80] A decrease in covalently bound ceramides[91] and a reduced sphingomyelinase activity have been found in atopic dermatitis. Also, decreased lamellar body secretion, which is predominantly composed of lipids, with subsequent entombment of lamellar bodies within corneocytes, has been reported.[92]

PSORIASIS: EPIDERMAL HYPERPROLIFERATION AND THE SKIN BARRIER

(See also Chapter 18)

Psoriasis is a chronic, generalized, and scaly erythematous dermatosis that is primarily localized in the epidermis, showing highly enhanced proliferation and disturbed differentiation, which leads to hyperkeratosis and parakeratosis. In addition, there is a neutrophilic infiltrate in the beginning and in particular in severe cases of psoriasis; later on a moderate T-lymphocytic infiltrate is present. Because of this severely disturbed proliferation and epidermal differentiation, there is an impaired barrier function.[93] The level of TEWL is directly related with the clinical severity of the lesion: high TEWL in acute exanthematous psoriasis; a moderate increase in TEWL in the chronic plaque type of the disease. Abnormalities in the SC intercellular lipids, especially a significant reduction in ceramide 1, have been found.[94] Electron microscopy studies disclosed severe structural alteration of the intercellular lipid lamellae.[95] A genetic linkage of psoriasis to the epidermal differentiation complex 1q21 has been found. Within the epidermal differentiation complex, the SPRRs are highly upregulated in psoriasis plaques.[96] Also, the association of psoriasis with cytokeratin K17 has been discussed.

ICHTHYOSIS: THE PATHOLOGICAL LACK OF MOISTURE IN THE EPIDERMIS

(See Chapter 49)

Ichthyosis comprises a group of monogenetic diseases expressing a disturbed desquamation resulting in scales and a mild-to-moderate barrier defect. They are caused either by changes in epidermal lipids or by changes in epidermal differentiation. XLRI is a non-congenital ichthyosis, consisting of a generalized desquamation of large, adherent, and dark brown scales. The metabolic basis of XLRI is an enzymatic lysosomal deficiency of steroid sulfatase or arylsulphatase C. Complete deletions of the *STS* gene mapped to the Xp22.3-pter region have been found in up to 90% of patients. The reduced cholesterol sulfatase activity leads to accumulation of cholesterol sulfate and a reduction of cholesterol and consequent abnormality in the structural organization of the intercorneocyte lipid lamellae.[97–99]

Ichthyosis vulgaris is the most common monogenetic skin disease. Recently, loss-of-function mutations in the gene encoding filaggrin that cause ichthyosis vulgaris have been described. During terminal differentiation, profilaggrin is cleaved into multiple filaggrin peptides that aggregate keratin filaments. The resultant matrix is cross-linked to form a major component of the cornified cell envelope. Reduction of this major structural protein leads to an impaired keratinization and to a moderate defect in skin barrier function.[100]

Transglutaminase 1 is responsible for the cross-linking of several cornified envelope proteins. Therefore, deficiency in transglutaminases 1[57] leads to lamellar ichthyosis which is a more severe disease than ichthyosis vulgaris with a defect in filaggrin only.

TREATMENT IMPLICATIONS AND APPROACHES: RESTORING THE SKIN'S PROTECTIVE FUNCTION

Treatment strategies in inflammatory diseases often address immunogenic abnormalities and barrier function. Treatments with cyclosporine, tacrolimus, pimecrolimus, and UV light have been shown to reduce cell inflammation as well as to improve barrier function, thus helping to normalize proliferation and differentiation. Topical steroids, although clinically effective, do not lead to the repair of the disturbed skin barrier function seen in AD.[101] However, because of their side effects, all of these treatments should be used for a short time only. In contrast, application of bland creams and ointments containing lipids and lipid-like substances, hydrocarbons, fatty acids, cholesterol esters, and triglycerides can be used without side effects for long-term treatment of mild-to-moderate inflammatory diseases. Creams and ointments partially correct or stimulate barrier repair and increase SC hydration,[44,102–104] thus influencing epidermal proliferation and differentiation.[15] It has been proposed that a lipid mixture containing the three key lipid groups [(1) ceramides, (2) cholesterol, and (3) free fatty acids] is able to improve skin barrier function and SC hydration in AD.[105] Also, the efficacy of ceramide 3 in a nanoparticle cream in atopic dermatitis has been described.[106] However, because several research groups and companies report that creams containing ceramides and a mixture of the three key lipids are not superior to "classical" cream or ointment preparations, such preparations have not yet been widely used.

Chapter 48 :: Irritant Contact Dermatitis

:: Antoine Amado, Apra Sood, & James S. Taylor

IRRITANT CONTACT DERMATITIS AT A GLANCE

- Irritant contact dermatitis (ICD) is a nonimmunologic inflammation of the skin caused by contact with a chemical, physical, or biologic agent.
- Up to 80% percent of contact dermatitis is irritant and is commonly related to occupation.
- The most important exogenous factor for ICD is the inherent toxicity of the chemical for human skin.
- Endogenous factors, such as skin barrier function and preexisting dermatitis, play an important role in the pathogenesis of ICD.
- Atopic dermatitis is a major risk factor for irritant hand dermatitis because of impaired barrier function and a lower threshold for skin irritation.
- Patch testing should be performed in cases with suspected chronic irritant dermatitis to exclude an allergic contact dermatitis.
- Identification and avoidance of the potential irritant is the mainstay of treatment.

Dermatitis or eczema is a pattern of cutaneous inflammation that presents with erythema, vesiculation, and pruritus in its acute phase. Its chronic phase is characterized by dryness, scaling, and fissuring. Irritant contact dermatitis (ICD) is a cutaneous response to contact with an external chemical, physical, or biologic agent; endogenous factors such as skin barrier function and preexisting dermatitis also play a role (Figs. 48-1 and 48-2). The spectrum of presentation after contact with an irritant varies from overt dermatitis to subjective symptoms, contact urticaria, caustic and necrotic reactions as well as pigmentary changes and other dermatoses.

EPIDEMIOLOGY

In contrast to allergic contact dermatitis (ACD), no previous exposure to the causative agent is necessary in eliciting irritant reactions.[1] ICD accounts for 80% of all cases of contact dermatitis,[2,3] and is often occupation-related (occupational ICD is discussed in detail in Chapter 211). ICD caused by personal care products and cosmetics is also common; however, very few patients with these irritant reactions seek medical help because they manage by avoiding the offending agent.[4]

The incidence of ICD is difficult to determine because the accuracy of the epidemiologic data is limited. European cross-sectional studies for eczema due to all causes in the general population have shown point prevalence rates of 0.7%–40% and 1-year to lifetime prevalence rates of 7.2%–11.8%.[5] Data from the U.S. Bureau of Labor Statistics show that of the 257,800 cases of nonfatal occupational illnesses reported in 2008 for

Figure 48-1 Irritant contact dermatitis in a welder.

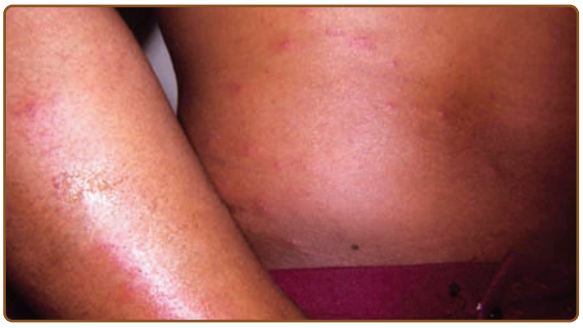

Figure 48-2 Irritant pustular dermatitis from nickel salts.

all industries including state and local government and private industry, 18.9% (48,600 cases) were skin diseases, the second most frequent cause of all occupational illnesses reported.[6] Based also on annual surveys of the Bureau of Labor Statistics incidence rates of occupational diseases in the American working population, contact dermatitis constitutes 90%–95% of all occupational skin diseases, and ICD constitutes about 80% of occupational contact dermatitis.[7]

ETIOLOGY AND PATHOGENESIS

Four interrelated mechanisms have been associated with ICD: (1) removal of surface lipids and water-holding substances, (2) damage to cell membranes, (3) epidermal keratin denaturation,[8–11] and (4) direct cytotoxic effects.[11] There is a clearly demonstrated immunologic-like component to the irritant response,[12] which is characterized by the release of proinflammatory mediators, particularly cytokines, from nonimmune cutaneous cells (keratinocytes) in response to chemical stimuli. This is a process that does not require previous sensitization.[10] Disruption of the skin barrier leads to release of cytokines such as interleukin (IL) 1α, IL-1β, and tumor necrosis factor-α (TNF-α). A tenfold increase in the levels of TNF-α and IL-6, and a threefold increase in the levels of granulocyte-macrophage colony-stimulating factor and IL-2 have been observed in ICD. TNF-α is one of the key cytokines in irritant dermatitis, leading to the increased expression of major histocompatibility complex class II and intracellular adhesion molecule 1 on keratinocytes.[10,13] The chemokine CCL21 that hones naive T-lymphocytes to the skin, has also been shown to be elevated in the skin during irritant reactions.[14]

Loss of function polymorphisms in the filaggrin gene, an important protein for skin barrier function, have been associated with an increased susceptibility to chronic ICD.[15] At the same time, it is hypothesized that upregulation of ceramide 1 synthesis in the epidermis plays a major role in inducing the hardening phenomenon in cutaneous irritation.[16]

INFLUENCING FACTORS

ICD is a multifactorial disease where both exogenous (irritant and environmental) and endogenous (host) factors play a role.

EXOGENOUS FACTORS

(See Table 48-1)

Other than with strong acids and alkalis, it has not been possible to predict the irritant potential of a chemical based on molecular structure. The irritant potential of compounded formulations may be more difficult to predict. Factors to be considered include: (1) chemical properties of the irritant: pH, physical state, concentration, molecule size, amount, polarization, ionization, vehicle, and solubility; (2) characteristics of exposure: amount, concentration, duration and type of contact, simultaneous exposure to other irritants, and interval after previous exposure;[4,17] (3) environmental factors: body region and temperature; (4) mechanical factors such as pressure, friction, or abrasion;[2] and (5) ultraviolet (UV) radiation. Low ambient humidity and cold temperature decrease the water content of the stratum corneum, making it more permeable to irritants. Larmi et al[18] demonstrated that UVB radiation diminished the nonimmunological reactions caused by sodium lauryl sulfate (SLS)-induced irritation, probably as a result of anti-inflammatory effects.

When one or more irritants are combined or used simultaneously, a synergistic or antagonistic effect may occur as a consequence of specific cellular interactions between the compounds, or an alteration in the skin permeability by one or more of the compounds, that would not occur when an irritant is used alone.[4,12] This is known as the *crossover phenomenon*. In a study by Wigger-Alberti et al,[19] concurrent application of SLS and toluene twice daily for 30 minutes to the volar forearms of healthy volunteers induced significantly stronger irritant reactions than those caused by twice-daily application of each chemical alone. This study suggests a crossover phenomenon between the two compounds by which one irritant caused an increased susceptibility to the other. On the other hand, McFadden and

colleagues[20] demonstrated the neutralizing effect of benzalkonium chloride over the irritant effect of SLS.

ENDOGENOUS FACTORS

(See Table 48-2)

GENETIC FACTORS. It has been hypothesized that an individual's ability to quench free radicals, to change the levels of antioxidant enzymes, and the ability to form protective heat shock proteins may all be under genetic control. These factors also determine the variability in responsiveness to irritants.[21] Additionally, a genetic predisposition to irritant susceptibility may be specific for each irritant.[22]

GENDER. The majority of clinical ICD affects the hands, and women account for a majority of these patients.[23] Rather than a gender-related skin susceptibility, this demographic may reflect the facts that women have more extensive exposure to irritants and wet work and are more likely to seek treatment than men.[4,17,24] On the other hand, there are anecdotal reports that suggest that the menstrual cycle can affect the sensitivity of women to primary irritants and can affect their dermatological response.[25] No gender difference for ICD has been established experimentally.

AGE. Children younger than 8 years of age are more susceptible to percutaneous absorption of chemicals and to irritant reactions.[4] Most studies show no compromise in skin barrier permeation with increasing age. Data on the influence of aging on experimental skin irritation are conflicting. Visible skin irritation (erythema) is decreased in older persons while invisible skin irritation (barrier damage) might be increased in the elderly.[26]

ETHNICITY. There are no studies that demonstrate a significant influence of skin types on the development of ICD.[27–29] Because erythema is difficult to measure in dark skin, early studies[30] using erythema as the only parameter to quantify irritation may have led to an erroneous interpretation that black skin is more resistant to irritation than white skin. It is also possible that variations among individuals rather than ethnicity play a role in the intensity of an irritant response.[31]

SKIN SITE. There are significant site differences in barrier function, making the skin of the face, neck, scrotum, and dorsal hands more susceptible to ICD. The palms and soles are comparatively more resistant.[32]

ATOPY. A history of atopy is a well-known risk factor for irritant hand dermatitis (see Chapter 14). A history of atopic dermatitis seems to be linked to an increased susceptibility to irritant dermatitis because of a lower threshold for skin irritation, impaired skin barrier function, and a slower healing process.[33]

In summary, the most important ICD risk factors are the inherent toxicity of the chemical for human skin and its penetration.[34] The most important endogenous factors are an atopic diathesis and skin barrier function.[26]

CLINICAL TYPES OF IRRITANT CONTACT DERMATITIS

ICD has a spectrum of clinical features, which can be divided into several different categories, depending on the irritant and its exposure pattern.[35] But these manifestations also depend on mechanical, thermal, climatic, and constitutional factors.[17] The clinical types of ICD vary according to the irritant in question: ulceration (e.g., strong acids or alkalis), folliculitis (e.g., oils and greases), miliaria (e.g., aluminum chloride), hyperpigmentation (e.g., heavy metals), hypopigmentation (e.g., *p*-tert-butylphenol),[10] alopecia (e.g., borax), urticaria (e.g., foods and plants), and granulomas (e.g., silica, talc)[36] (see Table 211-1).

At least ten clinical types of ICD have been described. They are listed in Table 48-3 along with a number of clinical subtypes of acute and chronic ICD.

1. *Irritant reaction:* An irritant reaction clinically presents as an acute monomorphic reaction that includes scaling, low-grade erythema, vesicles, or erosions and is usually localized on the dorsum of the hands and fingers. It is often seen in individuals who are exposed to wet work. An irritant reaction can resolve or progress to cumulative irritant dermatitis.[10,12]
2. *Acute ICD:* Acute ICD usually results from a single skin exposure to a strong irritant or caustic chemical, such as alkalis and acids, or as a result of a series of brief chemical or physical contacts. Most cases of acute irritant dermatitis are a consequence of accidents at work. A sensation of burning, itching, or stinging may occur immediately after the exposure to the irritant. The patient may present with erythema,

edema, and vesiculation and with exudation, bullae formation, and tissue necrosis in more severe cases. The healing process of acute ICD occurs as a decrescendo phenomenon, where the irritant reaction quickly peaks and then immediately begins to heal upon removal of the irritant. Complete healing may take 4 weeks, with a good prognosis.[4,12,17]

Other forms of acute irritant reaction have been also described (see Table 48-3), such as airborne contact dermatitis resulting from exposure to irritant volatile substances and fumes or powders and dusts and particles (Table 48-4).[4,17] Irritant cheilitis may result from lip licking or use of cosmetics and medication. Diaper dermatitis and perianal dermatitis may be the result of prolonged or too frequent contact with urine or fecal residues.[17] Dermatitis resulting from sodium azide released by airbag deployment has also been described,[37] causing an alkaline chemical burn; the accompanying talc powder may also contribute to the dermatitis.

3. *Delayed acute irritancy:* The delayed irritant reaction is acute but without visible signs of inflammation appearing until 8–24 hours or more after exposure. Otherwise, the clinical appearance and course are similar to those of an acute ICD.[4,12] The delayed presentation may simulate that of an ACD, sometimes making differentiation of the two disorders difficult, even with patch testing. Substances causing delayed irritancy are listed in Table 48-5. Delayed acute irritancy in general has a good prognosis.[10,12,17]
4. *Chronic cumulative ICD:* This is the most frequent type of contact dermatitis encountered in clinical practice. Also called *traumiterative ICD*, cumulative ICD develops as a result of repeated insults to the skin, where the chemicals involved

TABLE 48-3
Types of Irritant Contact Dermatitis (ICD)

Irritation	Onset
Irritant reaction	Acute, often multiple exposures
Acute ICD	Acute, often single exposure
Delayed acute ICD	Delayed (12–24 hours or longer)
Chronic (cumulative) ICD	Slowly developing (weeks to years)
Subjective (sensory) irritation	Acute
Suberythematous (nonerythematous) irritation	Slowly developing
Frictional dermatitis	Moderate–slow developing (weeks to months)
Traumatic ICD	Slowly developing after preceding trauma
Pustular or acneiform ICD	Moderately slowly developing (weeks to months)
Asteatotic irritant eczema (exsiccation eczematid)	Moderate–slow developing
Other clinical subtypes of acute and chronic ICD	
Interdigital	Slowly developing (days to weeks)
Frictional melanosis	Slowly developing (months to years)
Diaper dermatitis	Acute or delayed
Chemical burns	Acute or delayed
Nonimmunologic contact urticaria	Acute
Airborne	Acute
Scalp irritation	Acute or delayed
Nail irritation	Delayed to slow
Tandem[a]	Acute or delayed
Photoirritation[a]	Acute

are often multiple and weak and would not in themselves be strong enough to cause irritant dermatitis.[10,12,17] The most common marginal irritants include soap, detergents, surfactants, organic solvents, and oils,[2] which may also act as perpetuating factors once the dermatitis has become established. Cosmetic cumulative ICD is not infrequent in women, particularly involving the eyelids.[17]

Initially, cumulative contact dermatitis can appear with itch, pain, and a few localized patches of dry skin; then erythema, hyperkeratosis, and fissuring can develop.[2,4,12,17] The symptoms do not immediately follow exposure to the irritant, appearing after days, months, or years of exposure. With extensive and frequent exposure to some irritants, the skin becomes hardened, with better resistance to future irritant exposures. Hardened skin appears coarse and lichenified, which may contribute to resistance. However, even brief periods away from exposure lower the resistance, and with reexposure, patients are once again at risk for irritation. Chronic cumulative ICD can be confused with ACD because of the delayed and variable presentation, and appropriate diagnostic patch testing is indicated to exclude ACD. The prognosis of cumulative ICD is variable.[4,12]

5. *Subjective (symptomatic, sensory) irritancy:* Patients complain of itching, tingling, stinging, burning, or smarting sensation within minutes of contact with an irritant, but without visible cutaneous changes.[12,35] Subjective irritancy usually occurs on the face, head, and neck. Cosmetics, sunscreens, and woolen garments are commonly implicated.[3,4,35] Other common sensory irritants include lactic acid (a model for this phenomenon), propylene glycol, and aluminum salts. Stimulation of cutaneous type C nociceptors has been implicated in this form of irritancy,[12] although recently changes in cutaneous vasculature have been implicated. Some sensory irritation may be nonimmunologic contact urticaria. Screening raw ingredients or final formulations with the guinea pig ear swelling test or the human forehead assay may allow one to minimize subclinical contact urticaria.[38]
6. *Suberythematous (nonerythematous) irritation:* This is a state in which the irritation is not visually apparent, but is histologically visible. Common symptoms include burning, itching, or stinging. Suberythematous irritation has been linked with the use of consumer products containing significant amounts of surfactant.[4,12]
7. *Frictional dermatitis:* Mechanical irritation can result from repeated microtrauma and friction. Nipple dermatitis in patients with ill-fitting bras, and dermatitis from prosthetic limbs, mechanical injury from thorns and spines in plants, adhesive tape, or from handling coarse paper, glass, and rock wool fiber are only some.[10,17] This type of contact irritation usually leads to dry, hyperkeratotic abraded skin, making it more vulnerable to the effects of irritants.[4]
8. *Traumatic reactions:* Traumatic reactions can develop after acute skin trauma as burns or lacerations and most commonly occurs on the hands and persists for about 6 weeks or longer. The healing process in this type of dermatitis is prolonged, and erythema, scaling, papules, or vesicles can appear. The clinical course can resemble that of nummular dermatitis.[4,12]
9. *Pustular or acneiform reactions:* Pustular or acneiform reactions are usually seen after occupational exposures to oils, tars, heavy metals, and halogens but also after the use of some cosmetics. The pustular lesions are sterile and transient and may develop several days after exposure. This type of dermatitis is seen especially among atopic and seborrheic patients.[4,9,12]
10. *Asteatotic irritant eczema (exsiccation eczematid):* Exsiccation eczematid usually occurs in elderly patients who frequently shower without applying moisturizers to their skin. Intense itching, dry skin, and ichthyosiform scaling are clinical features that characterize this irritant reaction.[12]

COMMON IRRITANTS

(Table 48-6)

Water is a hypotonic element that acts as a cytotoxic agent on eroded skin.[17] Hard water has been found to be more irritating than soft water.[39] Skin cleansers cause irritation depending on the chemistry of their constituents. They remove surface lipid film, denature proteins, and damage the cell membrane. Soaps, detergents, and waterless cleansers are the most common irritants. Preservatives, especially quaternary ammonium compounds, have an irritant effect.[17] Löffler and Kampf[40] investigated the biological response of regular human skin to alcohol-based disinfectants and detergents and demonstrated that the degree of skin irritation is significantly lower after application of alcohol in comparison to detergents.

Foods, such as citrus peels, garlic, flour, and spices, can act as irritants.[17] Capsaicin produces hand irritation after handling hot peppers and is also present in some personal defense sprays used by police or by civilians.[1] Pineapple juice contains bromelain, an irritating proteolytic enzyme.[41]

Other potential irritants include animal products from seafood and meat, from caterpillars, carpet beetles, and moths, from insect secretions[42]; cosmetics, especially when applied to the eyelids; alkalis, present in soap, bleaches, detergents, oven cleansers, and toilet bowl cleaners;[1] topical medicaments, such as gentian violet, tar, potassium permanganate, mercury, hexachlorophene, etc.[17] The majority of skin reactions due to transdermal drug delivery systems would be a form of ICD, this may be minimized by rotation of the application site, careful removal of the patch, and appropriate use of moisturizers and topical corticosteroids.[43] Fiberglass dermatitis can develop from wearing clothes that have been washed together with fiberglass-contaminated work clothes or with fiberglass curtains.[44] Other tear gases, [e.g., 2-chlorobenzylidene malononitrile, known as *CS* (pepper spray) and, rarely, 1-chloroacetophenone, known as *CN* (Mace)] are present in a variety of self-defense or riot-control sprays[1] and cause lacrimation, sternutation (sneezing), and, occasionally, cutaneous irritation and sensitization.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

(Box 48-1)

ICD is often diagnosed by excluding other causes for the dermatitis, including ACD.[2] A detailed inquiry, including occupational, recreational (hobbies), and past medical histories, and a meticulous clinical examination are important for making the correct diagnosis. History of exposure to friction, wet work, soaps, and detergents or exposure to organic or alkaline solvents; and/or an environmental relative humidity of less than 35% are key factors that support a diagnosis of irritancy.[45] When an allergic component is considered, diagnostic patch testing should be performed.[33] A biopsy often cannot differentiate allergic, irritant, or atopic dermatitis, but may be helpful in excluding psoriasis, in the case of palmar involvement. Measuring transepidermal water loss (TEWL) can indicate barrier impairment but cannot distinguish between ACD and ICD. Rietschel[11] has proposed criteria with subjective and objective features, each with major and minor findings for the diagnosis of ICD. The more features identified, the stronger the case for ICD (Table 48-7).

PREDICTIVE TESTS, GENETICS AND BIOENGINEERING METHODS

In their review of premarket predictive tests for irritants, Basketter and Kimber[46] conclude that except where appropriate human tests, such as the 4-hour prophetic patch test, can be conducted; skin irritation tests, especially in animals, are of limited value in the characterization of the potential effects associated with actual exposure of humans to irritants. In the clinical setting there is likely to be exposure to multiple irritants.

In attempts to predict individual susceptibility to irritants, a number of tests have been studied, including alkali resistance with sodium hydroxide, ammonium hydroxide, dimethyl sulfoxide, threshold response to various irritants (SLS, nonanoic acid, benzalkonium chloride, kerosene, croton oil, and anthralin), lactic acid stinging, minimal erythema dose with UVB radiation, and measurement of TEWL. In their review, Frosch and John[34] conclude that none is so simple and reliable that it can be used on a large scale. A number of these procedures have been used experimentally, usually with individual chemicals, with the results having limited applicability, but they may be of some value in predicting thresholds of irritation. Of the bioengineering methods used, TEWL measurement is the most frequently used procedure to quantify impaired functions of the stratum corneum. Clinically invisible subtle damage, such as by detergents, can be reliably detected by an increase in TEWL.

BOX 48-1 DIFFERENTIAL DIAGNOSIS OF IRRITANT CONTACT DERMATITIS (MAJOR TYPES)

Most Likely

- Localized
  - Atopic eczema
  - Asteatosis
  - Seborrheic dermatitis
  - Stasis dermatitis
- Disseminated
  - Atopic eczema
  - Asteatosis
  - Autoeczematization
  - Tinea corporis

Consider

- Localized
  - Corticosteroid acne
  - Dermatophytosis
  - Factitial dermatitis
  - Herpes simplex
  - Herpes zoster
  - Lichen simplex chronicus
  - Rosacea
- Disseminated
  - Dermatophytosis
  - Drug eruption
  - Nummular eczema
  - Psoriasis
  - Parapsoriasis
  - Polymorphous light eruption

Always Rule Out

- Localized
  - Allergic contact dermatitis
  - Bowen disease
- Disseminated
  - Allergic contact dermatitis
  - Cutaneous T-cell lymphoma

Data from Denig NI, Hoke AW, Maibach HI: Irritant contact dermatitis. Clues to causes, clinical characteristics, and control. *Postgrad Med* **103**:199-200, 207-208, 212-213, 1998; Rietschel RL: Clues to an accurate diagnosis of contact dermatitis. *Dermatol Ther* **17**:224-230, 2004.

A TNF-α gene polymorphism offers a novel approach to detect susceptibility to ICD. In humans, a G to A transition polymorphism has been identified at position P308 within the promoter region of the TNF-α gene. An analysis of different genotypes revealed a correlation between the A allele and a low threshold to irritants.[47]

According to Astner and colleagues,[48] reflectance-mode confocal microscopy facilitates the differentiation of acute ACD from ICD. Stratum corneum disruption, epidermal necrosis, and hyperproliferation were found to be the hallmarks of ICD, whereas ACD was more typically presented with vesicle formation.

A recent study[49] found the use of polarized light as an enhanced visual scoring method to increase the ability to detect low (subclinical) levels of irritation, indicating this noninvasive method has the potential to increase the sensitivity of all clinical dermatological studies.

TABLE 48-7
Diagnostic Criteria of Irritant Contact Dermatitis

Major	Minor
Subjective	
Onset of symptoms within minutes to hours of exposure	Onset of dermatitis within 2 weeks of exposure
Pain, burning, stinging, or discomfort exceeding itching early in the clinical course	Many people in the environment affected similarly
Objective	
Macular erythema, hyperkeratosis, or fissuring predominating over vesiculation	Sharp circumspection of the dermatitis
Glazed, parched, or scalded appearance of the epidermis	Evidence of gravitational influence, such as dripping effect
Healing process begins promptly on withdrawal of exposure to the offending agent	Lack of tendency of the dermatitis to spread
Patch testing is negative	Morphologic changes suggesting small concentration differences or contact time produce large differences in skin damage

Adapted from Rietschel RL: Clues to an accurate diagnosis of contact dermatitis. *Dermatol Ther* **17**:224-230, 2004.

PATCH TESTING

Patch testing is often essential to distinguish ACD from ICD or to diagnose concomitant ICD and ACD. Negative patch tests may favor a diagnosis of ICD "by exclusion" of ACD. A diagnosis of ACD may be missed with false-negative patch test results (see Chapters 13 and 211).[11,33] Conversely, patch testing with obvious irritants, or nonstandard chemicals or mixtures can lead to false-positive patch test results. Irritant patch test reactions may present as erythema with or without papules and often remain confined to the test site and are sharply demarcated. These irritant reactions also show a decrescendo pattern, in which a decreasing severity is seen, although this is not always a reliable indicator.[3,33] Irritant patch test reactions do not equate with ICD but only reflect the irritating patch test concentration or procedure. It is important to perform comprehensive patch testing with the appropriate substances and concentrations to prevent incorrect conclusions.[11]

TREATMENT

Identification and elimination of the irritants and protection from further exposure are important in the management of ICD.[4] Once dermatitis develops, topical treatment is helpful. The role of topical corticosteroids in the management of ICD is controversial, but they may be helpful because of their anti-inflammatory effect.[4,50] However, prolonged use of topical corticosteroids may lead to epidermal atrophy and increased susceptibility to irritants. Emollients or occlusive dressings may improve barrier repair in dry, lichenified skin.[4,17] Traditional petrolatum-based emollients are accessible, inexpensive, and have been shown to be as effective as emollient containing skin-related lipids.[51] Other "barrier creams" are of limited value.[52] Topical calcineurin inhibitors (e.g., pimecrolimus) may be used as an alternative to low-potency topical corticosteroids in chronic ICD.[53,54]

In severe or chronic cases, phototherapy (psoralens with UVA or UVB) or systemic drugs, such as azathioprine and cyclosporine, may be effective.[17,50] Bacterial superinfection can be treated with topical or systemic antibiotics.[17] In sensory irritation, strontium salts act by selectively blocking the activation of cutaneous type C nociceptors.[12]

PREVENTION

ICD is a risk factor for the development of ACD because the impaired skin barrier may facilitate the potential for the induction and elicitation of ACD. Thus, the prevention of irritant dermatitis reduces the risk of ACD.[10,55]

Although long established behavior patterns may be difficult to change,[55] once an irritant has been identified as the causal factor, patients should be educated about irritant avoidance, including everyday practices that may cause or contribute to the ICD.

The use of personal protective equipment, especially in high-risk jobs, is very important. Protective gloves should be worn for any wet work. However, patients should avoid wearing waterproof gloves for long periods of time to help reduce sweating. If prolonged wearing is required, gloves should have a fabric lining or alternatively, thin cotton gloves can be worn inside waterproof gloves.[3] Bock et al[56] evaluated the impact of semipermeable glove membranes (GoreTex® and Sympatex®) on skin barrier repair following SLS-induced irritation and demonstrated an improved barrier recovery and reduced inflammation compared to either occlusive membranes (vinyl) or an uncovered control. These results suggest a unique benefit by semipermeable protective gloves for preventing occupational skin disease by minimizing glove-induced irritation and by enhancing barrier recovery in cases of preexisting minor irritant dermatitis. In another study, the use of gel-filled anti-impaction gloves such as those used for hand-arm vibration exposure, has been shown to aid in the return-to-work process for those patients with occupational frictional hand dermatitis but not with hyperkeratotic hand dermatitis.[57]

If used correctly, protective gloves can reduce or eliminate exposure of the hands to hazardous substances, but if not selected and used properly, gloves can actually cause or worsen ICD of the hands by increasing exposure to hazardous chemicals. Hence, the correct use of gloves is at least as important as selection of gloves made of the appropriate material.[58]

Less irritating substances, such as emollients and soap substitutes, should be used rather than soap when washing. Moisturizers are thought to increase hydration or prevent TEWL, thereby maintaining skin barrier function and reducing the risk of ICD. Care should be taken for several months after the dermatitis has healed, as the skin remains vulnerable to flares of dermatitis for a prolonged period.[3,33,35]

PROGNOSIS

The prognosis for acute ICD is good if the causative irritant can be identified and eliminated. The prognosis for cumulative or chronic irritant dermatitis is guarded and may be worse than that of ACD.[59] An atopic background, lack of knowledge about the disease, and/or a delayed diagnosis and treatment are factors that lead to a worse prognosis.[17] Persistent post-occupational dermatitis has been reported in 11% of individuals.[60]

Chapter 49 :: The Ichthyoses

:: Philip Fleckman & John J. DiGiovanna

ICHTHYOSES AT A GLANCE

- A heterogeneous group of skin diseases characterized by generalized scaling, and often areas of thickened skin.
- Most types are inherited, and these usually present at birth. However, some forms are acquired.
- Scales may vary in size, color, and body site.
- May be accompanied by erythema, abnormalities in other parts of skin and adnexal structures.
- May be associated with systemic findings, such as failure to thrive, increased susceptibility to infection, atopic dermatitis, neurosensory deafness, neurologic and other disease.
- Pathology is usually nonspecific with the exception of epidermolytic hyperkeratosis, neutral lipid storage disease, Refsum disease, and acquired ichthyosis associated with sarcoidosis.

The ichthyoses are a heterogeneous group of skin diseases characterized by generalized scaling. Scaling reflects altered differentiation of the epidermis. In this chapter, the terms epidermal differentiation, keratinization, and cornification will be used synonymously. The name *ichthyosis* is derived from the Greek *ichthys*, meaning "fish," and refers to the similarity in appearance of the skin to fish scale. Both inherited and acquired forms are found. Early reports of ichthyosis in the Indian and Chinese literature date back to several hundred years BC, and the condition was discussed by Willan in 1808.[1]

Ichthyosis can present at birth or develop later in life. It can occur as a disease limited to the skin or in association with abnormalities of other organ systems. A number of well-defined types of ichthyosis with characteristic features can be reliably diagnosed. However, because of the great clinical heterogeneity and the profound effect of the environment on scaling, a specific diagnosis can be challenging in certain patients and families.

Siemens introduced genetic concepts into the ichthyoses.[2] Wells and Kerr classified the ichthyoses on a genetic basis[3] and separated X-linked recessive ichthyosis from ichthyosis vulgaris (IV).[4] Gassman developed the concept of retention versus hyperproliferation hyperkeratosis[5]. Van Scott, Frost, and Weinstein subsequently proposed a classification of the ichthyoses based on differences in rates of epidermal turnover, characterizing them as either disorders of epidermal hyperproliferation or disorders of prolonged retention of the stratum corneum.[6] Subsequently, Williams and Elias proposed a classification that lists the disorders of cornification in which clinical, genetic, or biochemical data suggest a distinct disease.[7] Traupe reviewed the ichthyoses and suggested classification on a clinical level.[5]

Genetic approaches to understanding the ichthyoses have revealed the gene defects underlying many of these genodermatoses.[8] A new classification is evolving based on the underlying molecular and genetic bases of these disorders. Knowing which gene is mutated directs us to the underlying pathophysiologic process. Understanding and describing these disorders on the basis of common molecular processes leads to more rational approaches to understanding their pathophysiology and treatment. A listing of the more common and the better understood hereditary ichthyoses according to pattern of inheritance and clinical features is shown in Tables 49-1 to 49-3. Grouping these disorders according to underlying gene defect (Table 49-4) facilitates understanding of the clinical phenotypes in terms of underlying mechanism. However, further work is necessary to clearly understand how the gene mutations and resultant protein disruptions result in clinical disease, and furthermore, how therapeutic interventions can be creatively developed.

Online Mendelian Inheritance in Man, OMIM,[10] (trademark Johns Hopkins University), a catalog of human genes and genetic disorders, is a useful reference with links to additional resources.

CLINICAL PRESENTATION

A specific diagnosis in an individual or family with ichthyosis can help to predict prognosis, is important for genetic counseling, and may direct treatment. Several features are useful in distinguishing different forms of ichthyosis. These include the age of onset, presence of collodion membrane at birth, quality of scale, presence/absence of erythroderma, abnormalities in other parts of the skin (e.g., palms and soles, ectropion, eclabium) and adnexal structures (e.g., alopecia, hair follicle, or shaft abnormality), and involvement of other organ systems. In different types of ichthyosis, the appearance of the surface of the skin may vary. Visible scaling may be seen in some patients, with flakes of stratum corneum varying in size from fine to coarse. There may also be thickening of the skin with or without visible scale. The term hyperkeratosis has been used clinically to describe thickened skin, with or without scale, that reflects thickening of the stratum corneum. A family pedigree may clarify the pattern of inheritance. However, many autosomal

TABLE 49-1
Features of Selected Ichthyoses, Dominant

A—Autosomal Dominant/Semidominant

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
Autosomal Semidominant							
Ichthyosis vulgaris OMIM #146700	Infancy/ childhood	Fine or centrally tacked-down scale with superficial fissuring. Relative flexural sparing; worse on lower extremities. Hyperlinear palms/soles.	Keratosis pilaris; atopy	*FLG*	Absence of filaggrin	Uncertain	Hyperkeratosis; reduced or absent granular layer
Autosomal Dominant							
EHK (bullous CIE) OMIM #113800	Birth	Heterogeneous. May have verrucous, firm, hyperkeratotic (hystrix) spines, often linearly arrayed in flexural creases; blisters; may have erythroderma and/or palmar/plantar keratoderma	Frequent skin infections; characteristic pungent odor	*KRT1, KRT10;* in Vörner type (confined to palms/soles) *KRT 9*	Keratin 1 or 10; in Vörner type, keratin 9	Structural protein abnormality leading to keratin intermediate filament dysfunction—epidermal fragility	Hyperkeratosis; vacuolated degeneration of the epidermal granular (and often deeper) layer; large, irregular keratohyalin granules
Ichthyosis bullosa of Siemens OMIM #146800	Birth	Redness and blistering at birth. Later develop hyperkeratosis, accentuated over flexures. Mauserung (molting): collarette-like lesion where uppermost epidermis has been lost.		*KRT2*	Keratin 2, which is expressed in superficial epidermis	As above for EHK	Similar to epidermolytic hyperkeratosis, but confined to the upper spinous and granular layer
Ichthyosis hystrix of Curth and Macklin OMIM #146590	Birth	Resembles EHK, varies from palmar/ plantar keratoderma to generalized. Thick "porcupine-like" spines. No blistering.		*KRT1*—mutation in variable region	Keratin 1	As above for EHK	Upper epidermal keratinocytes have perinuclear vacuolization/ perinuclear shells of tonofilaments

Annular epidermolytic erythema OMIM #607602 Erythrokeratodermia variabilis— OMIM #133200	Birth/infancy Annular plaques develop later	Severe, intermittent scaling with blisters or pustules. Evolves to widespread, migratory, annular plaques.		*KRT1, KRT10*	Keratin 1 or 10	As above for EHK	As above for EHK
Generalized type	Birth	Generalized hyperkeratosis and figurate, migratory red patches	Red patches move over minutes to hours, may be triggered by changes in temperature	*GJB3* or *GJB4*	Connexin 31 or 30.3; connexins form gap junction channels between cells	Abnormal intercellular communication	Hyperkeratosis, acanthosis, papillomatosis, capillary dilatation; epidermis may have "church spire" appearance
Localized type	Variable	Localized hyperkeratotic plaques with figurate, migratory red patches.	Hyperkeratotic plaques may be induced by trauma. Considerable intrafamilial variability				
Progressive symmetric erythrokeratodermia OMIM #602036	Shortly after birth	Erythematous, scaly plaques, symmetrically distributed over extremities, buttocks, and face; stabilize in early childhood. Trunk tends to be spared.		*LOR or GJB4*	Connexin 30.3	Cornified envelope precursor	Nonspecific
Keratitis–ichthyosis–deafness (KID) syndrome Recessive has been reported OMIM #148210	Birth/infancy	Progressive corneal opacification; either mild generalized hyperkeratosis or discrete erythematous plaques, which may be symmetric; neurosensory deafness.	Follicular hyperkeratosis, scarring alopecia, dystrophic nails, susceptibility to infection	*GJB2, GJB6*	Connexin 26, 30; connexins form gap junction channels between cells	Abnormal intercellular communication	Nonspecific

CIE = congenital ichthyosiform erythroderma; EHK = epidermolytic hyperkeratosis; OMIM = Online Mendelian Inheritance in Man.
Note: These are the predominant modes of inheritance.

TABLE 49-2
Features of Selected Ichthyoses, X-linked

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
X-linked recessive ichthyosis OMIM #308100	Birth/infancy	Fine to large scales; comma-shaped corneal opacities on posterior capsule	Cryptorchidism; female carriers may have corneal opacities and delay of onset or progression of labor in affected pregnancies	*STS*	Steroid sulfatase	Lipid metabolism—abnormal cholesterol metabolism with accumulation of cholesterol sulfate	Hyperkeratosis, may have hypergranulosis; nonspecific
Chondrodysplasia punctata X-linked recessive (CDPX) OMIM #302950	Birth	May begin as erythroderma, linear or whorled atrophic areas or hyperkeratosis, alopecia, skeletal abnormalities, short stature	Cataracts, deafness	*ARSE*	Arylsufatase E	Lipid metabolism—ill defined: failure of hydrolysis of sulfate ester bonds	
X-linked dominant chondrodysplasia punctata (Conradi–Hünermann–Happle syndrome) (CDPX2) OMIM #302960	Birth	CIE at birth, clears and is replaced by linear hyperkeratosis, follicular atrophoderma and pigmentary abnormalities, stippled calcifications on radiographs	Occurs almost exclusively in females; hair shaft abnormalities, short stature, cataracts	*EBP*	Emopamil binding protein (EBP)—also known as 3β-hydroxysteroid-$\Delta^{8,7}$-isomerase	Lipid metabolism—abnormal cholesterol biosynthesis	
CHILD syndrome X-linked dominant OMIM #308050	Birth	Congenital hemidysplasia, ichthyosiform erythroderma, limb defects	Almost exclusively in females	*NSDHL*; *EBP* reported	NSDHL (3 β-hydroxysteroid dehydrogenase); EBP reported	Lipid metabolism—postsqualene cholesterol biosynthesis	

CHILD = *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects; CIE = congenital ichthyosiform erythroderma; EBP = emopamil binding protein; NSDHL = *N*AD(P)H steroid *deh*ydrogenase-*l*ike protein; OMIM = Online Mendelian Inheritance in Man.
Note: These are the predominant modes of inheritance.

TABLE 49-3
Features of Selected Ichthyoses, Autosomal Recessive

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
ARCI (See Table 49-5)							
ARCI/LI	Birth; often collodion presentation	Large, plate-like, brown scale over most of the body; accentuated on lower extremities. Ectropion; eclabium; alopecia. Palmar/ plantar involvement varies.	Heat intolerance	See Table 49-5	See Table 49-5	See Table 49-5	Hyperkeratosis, acanthosis, may show parakeratosis. Nonspecific.
ARCI/CIE		Fine, white scale; generalized erythroderma. Palmar/plantar involvement varies.					
ARCI/overlap		Varies between "lamellar" and "CIE."					
Harlequin ichthyosis OMIM #242500	Birth	Markedly thickened skin with geometric, deep fissures. Survivors develop severe CIE phenotype.	Restricted respiration, feeding; neonatal sepsis; often leads to neonatal death. Failure to thrive.	*ABCA12*	ATP-binding cassette, subfamily A, member 12	Lipid metabolism—Membrane transport, abnormality of lipid metabolism	Massively thickened, orthokeratotic stratum corneum; variable acanthosis; granular layer variably decreased
Ichthyosis prematurity syndrome OMIM #608649	Birth	Premature delivery of infants with erythrodermic, edematous, caseous scaling skin resembling excessive vernix caseosa, evolves into dry, scaly skin with follicular accentuation with signs of atopy	Respiratory distress, and transient peripheral eosinophilia. The respiratory signs resolve.	*FATP4 (SLC27)*	Fatty acid transport protein 4	Lipid metabolism—fatty acid transport	Trilamellar membrane inclusions are seen in the stratum corneum by electron microscopy.
Netherton syndrome OMIM #256500	Birth	Ichthyosis linearis circumflexa or similar to congenital ichthyosiform erythroderma; trichorrhexis invaginata	Atopy; high serum levels of IgE; may have aminoaciduria; failure to thrive	*SPINK5*	LEKTI (a serine protease inhibitor)	Protein metabolism—may result in premature desmosomal and profilaggrin degradation in stratum corneum.	Nonspecific

(continued)

TABLE 49-3
Features of Selected Ichthyoses, Autosomal Recessive (Continued)

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
Sjögren–Larsson syndrome OMIM #270200	Ichthyosis apparent at birth	Generalized fine to coarse hyperkeratosis; spastic diplegia; mental retardation; retinal glistening white dots	Short stature, seizures	*FALDH (ALDH10, ALDH3A2)*	Fatty aldehyde dehydrogenase	Lipid metabolism—Fatty aldehyde metabolism	Nonspecific
Refsum disease OMIM #266500	Ichthyosis develops in adulthood	Progressive neurologic dysfunction; skeletal, cardiac, and renal abnormalities	Retinitis pigmentosa, elevated plasma phytanic acid	Most *PAHX; PEX 7* also reported (see RCPD below)	Phytanoyl-CoA hydroxylase (PhyH)	Peroxisome abnormality—Deficiency of phytanic acid catabolism; results in phytanic acid accumulation.	Lipid-containing vacuoles in basal keratinocytes
Trichothiodystrophy (Tay syndrome; *PIBI(D)*S, *IBI(D)*S, *BI(D)*S) OMIM #278730 OMIM #601675 OMIM #234050	Some have ichthyosis, which may be apparent at birth; may have collodion presentation	*B*rittle hair, *P*hotosensitivity, *S*hort stature, *I*chthyosis, *I*ntellectual impairment, microcephaly, recurrent infections	Abnormally low sulfur content of hair.	Majority have defect in *ERCC2* (XPD). A few have mutations in *ERCC3* (XPB), *GTF2H5* (TTDA), or *TTDN1*.	Most XPD. XPB, TTDA, or TTDN1 in a few	Components of transcription factor TFIIH	Tiger tail banding of shafts under polarizing microscopy; hair shaft abnormalities (trichoschisis, trichorrhexis nodosa-like fraying; ribboning)
Chanarin–Dorfman syndrome (neutral lipid storage disease) OMIM #275630	Birth; may have collodion membrane	Generalized scaling, resembles CIE; variable extracutaneous involvement: cataracts, decreased hearing, psychomotor delay.	Severe pruritus; neurologic abnormalities; hepatic abnormalities; lipid droplets in circulating leukocytes	*CGI-58*	Unknown	Lipid metabolism—Activates adipose-triglyceride lipase for lipolysis of tryglycerides	Lipid droplets in dermal and epidermal cells, and acrosyringia of eccrine ducts
Neonatal ichthyosis–sclerosing cholangitis syndrome #6073718	Birth	Neonatal cholestatic jaundice, mild ichthyosis with fine, white scales.	Scarring alopecia of the scalp and eyebrows, enamel dysplasia	*CLDN1*	Claudin 1	Abnormal tight junction	Intracytoplasmic vacuoles in keratinocytes that do not stain with oil red O

Multiple sulfatase deficiency OMIM #272200	Birth	Ichthyosis resembling X-linked recessive	Neurological deterioration; skeletal abnormalities; facial dysmorphism	*SUMF1*	C_{α}-formylglycine generating enzyme	Generates catalytic residue in active site of eukaryotic sulfatases	Nonspecific
Peeling Skin Syndrome							
Type A (noninflammatory) OMIM #270300	Birth	Generalized peeling in superficial, thin flakes		Unknown	Unknown	Unknown	Intracellular split within corneocytes in stratum corneum
Type A—acral variant OMIM #609796		Limited to over hands and feet		*TGM5*	Transglutaminase 5	Protein cross-linking	Nonspecific
Type B (inflammatory)		Presents as CIE; evolves to migratory, scaling patches	Pruritus, elevated IgE, aminoaciduria, short stature	Unknown	Unknown	Unknown	Intercellular split between stratum corneum and granular layer; between keratinocytes

ARCI = autosomal recessive congenital ichthyosis; ATP = adenosine triphosphate; CIE = congenital ichthyosiform erythroderma; CoA = coenzyme A; LEKTI = *l*ympho-*e*pithelial *K*azal-*t*ype related *i*nhibitor; LI = lamellar ichthyosis; OMIM = Online Mendelian Inheritance in Man.
Note: These are the predominant modes of inheritance.

TABLE 49-4
Ichthyoses Organized by Pathophysiology

Disorder	Protein/Function Abnormality
Structural Proteins	
Ichthyosis vulgaris	Filaggrin
Cytoskeleton	
Annular epidermolytic ichthyosis	Keratins
Epidermolytic hyperkeratosis (EHK)	
Ichthyosis bullosa of Siemens	
Ichthyosis hystrix of Curth and Macklin	
Pachyonychia congenita[a]	
Palmar/plantar keratoderma[a]	
Palmar/plantar keratoderma with EHK

[a]Discussed in Chapter 50.
[b]Discussed in Chapter 51.
[c]Discussed in Chapter 139.

dominant diseases [e.g., *epidermolytic hyperkeratosis* (EHK)] have a high frequency of spontaneous mutation, and the lack of a positive family history does not rule out autosomal dominant inheritance. Alternatively, the presence of parental consanguinity may suggest autosomal recessive inheritance. Light microscopic features are usually diagnostic in epidermolytic hyperkeratosis and can be helpful in selected ichthyoses (e.g., Refsum disease, neutral lipid storage disease, acquired ichthyosis of sarcoidosis and mycosis fungoides), but histopathologic examination may not be useful to distinguish other ichthyoses. In many cases, the clinical diagnosis may be clarified by genetic analysis, although mutations are not always demonstrable. The development of ichthyosis in adulthood may be a marker of systemic disease.

ETIOLOGY AND PATHOGENESIS

The fully differentiated end product of the epidermis is the stratum corneum, which is composed of terminally differentiated keratinocytes, corneocytes ("bricks"), surrounded by an intercellular matrix ("mortar") (see Chapter 47). The corneocyte bricks are protein-enriched, and the intercellular mortar is composed of hydrophobic, lipid-enriched membrane bilayers.[7] The keratin-laden corneocytes are thought to be primarily responsible for the resilience and water retention properties of the stratum corneum, while the matrix forms most of the permeability barrier to water loss. The normal stratum corneum undergoes desquamation in an organized and invisible manner, with individual corneocytes separating from each other and shedding as single cells. Ichthyotic skin has an abnormal quality and quantity of scale, the barrier function of the stratum corneum is compromised, and there may be alterations in the kinetics of epidermal cell proliferation (see Chapter 46). The stratum corneum can be viewed as a compartment, with thickening of the stratum corneum being the result of cells entering the compartment at an increased rate, or leaving (corneocyte desquamation) too slowly, or both.

The process of epidermal differentiation is complex and not completely understood. Defects in many different aspects and steps of this process can lead to a similar end result: abnormal stratum corneum and scale. In some of these disorders, the underlying gene defect has been identified. For example, mutations in the genes that encode the suprabasal epidermal keratins, keratins 1 and 10, cause epidermolytic hyperkeratosis.[11] Mutations in the gene encoding transglutaminase-1, an enzyme that catalyzes the cross-linking of proteins and attachment of ceramides during the formation of corneocytes, are found in up to 55% of patients with *autosomal recessive congenital ichthyosis*.[12–15] The observation that key components of this process cause ichthyosiform disorders highlights the importance and complexity of normal keratinocyte differentiation.

Steroid sulfatase controls the hydrolysis of cholesterol sulfate in corneocytes and is thought to be important in the regulation of corneocyte desquamation. Deficiency of steroid sulfatase causes X-linked recessive ichthyosis.[16,17] The observation that several drugs that lower serum cholesterol (e.g., nicotinic acid, triparanol) can induce ichthyotic skin changes indicates the importance of lipid homeostasis in normal keratinization.[7] Further evidence is the identification of mutations in the genes encoding cholesterol biosynthetic enzymes as a cause of X-linked dominant chondrodysplasia punctata and CHILD (congenital hemidysplasia with ichthyosiform erythroderma and limb defects) syndrome, and genes encoding other aspects of lipid biosynthesis in the autosomal recessive congenital ichthyoses.[18] The identification of mutations in *SPINK5* (*s*erine *p*rotease *in*hibitor, *K*azal type *5*), encoding a serine protease inhibitor, in Netherton syndrome confirms a role for proteolysis and protease inhibitors in normal epidermal differentiation.[19] The discoveries of connexin abnormalities as causes for erythrokeratodermia variabilis, KID (keratitis, ichthyosis, and deafness) syndrome, and other disorders involving ectodermal tissues highlight the role of intercellular communication for properly functioning skin.[20,21] Mutations in the *FLG* gene result in reduced or absent filaggrin and decreased moisture binding in the stratum corneum of patients with IV.[22] Mutations in *FLG* may also result in more severe clinical phenotype in other skin disorders.[23,24]

These examples highlight the complexity of the process of forming a normally functioning stratum corneum and demonstrate that diverse abnormalities can result in similar clinical phenotypes of thickened stratum corneum and scaling. How do diverse processes result in similar phenotype? The answers are unclear, although studies suggest that defects in the barrier may result in inflammation and hyperproliferation.[25] Furthermore, our evolving understanding of these mechanisms continues to clarify the multisystem, clinical phenotypes observed in several ichthyosiform disorders.

ICHTHYOSIS VULGARIS

Ichthyosis vulgaris (OMIM #146700), the most common ichthyosis, is relatively mild. While infants usually have normal skin, the disease often manifests within the first year. The scale of IV is usually most prominent on the extensor surfaces of the extremities, with flexural sparing (Fig. 49-1). The diaper area tends to be spared. There may be fine, white scales over large areas. Particularly on the lower extremities, which are often the most severely involved area, the scales may be centrally attached, with "cracking" (superficial fissuring through the stratum corneum) at the edges. This turning up at the edges can lead to the skin feeling rough.

A number of other findings are commonly observed in association with IV.[26] Hyperlinear palms are usually present, and some patients may have palmar/plantar thickening approaching a keratoderma. Keratosis pilaris is common, even in individuals with mild IV, and usually involves the outside of the arms, extensor thighs, and buttocks. Atopy is also frequently observed and can manifest as hay fever, eczema, or asthma. These findings can confound an accurate diagnosis,

Figure 49-1 Ichthyosis vulgaris. Full presentation of IV in individuals with mutations in both alleles of the profilaggrin gene (**A**, **C**, **E**); milder presentation in an individual with a profilaggrin mutation in a single allele (**B**, **D**, **F**). **A** and **B**. Fine, white scale on lower abdomen. **C**–**F**. Hyperlinear palms. (From Smith FJ et al: Loss-of-function mutations in the gene encoding filaggrin cause ichthyosis vulgaris. *Nat Genet* **38**:337, 2006, with permission.)

because hyperlinear palms and keratosis pilaris may be seen in atopic individuals who do not have IV. Rarely, individuals with IV may have hypohidrosis with heat intolerance. There is great variation in the severity of clinical manifestations between affected individuals in the same family. The condition usually worsens in climates that are dry and cold and improves in warm, humid environments where the disease may clear dramatically.

The disease was thought to be autosomal dominant and in a study of English school children was found to affect 1 in 250.[4] Recently, mutations in the gene encoding profilaggrin have been found to cause IV. Profilaggrin is the precursor protein for multiple copies of filaggrin, which functions during cornification. The inheritance pattern has been clarified to be semidominant; individuals who carry one mutated allele have a mild phenotype, while those with mutations in both

profilaggrin alleles (homozygotes or compound heterozygotes for the mutations) (Fig. 49-1) manifest a severe clinical phenotype. In the Anglo-European population, the prevalence of clinical disease is as high as 1 in 80.[22,27,28]

It is difficult to distinguish some patients with mild IV from simple dry skin (xerosis). Evolving understanding of this very common condition is beginning to clarify how a spectrum of underlying mutations can cause the diverse clinical severity of dry skin from xerosis to severe IV. In addition, on the basis of skin findings alone, males with severe IV may be difficult to differentiate from those affected with X-linked recessive ichthyosis.[26,29] The histopathologic findings of IV (Fig. 49-2A) may, as the clinical severity, be more pronounced, with hyperkeratosis and absent granular layer in individuals with two abnormal alleles.

Filaggrin is an epidermal protein involved in the aggregation of keratin intermediate filaments[30] and retention of moisture in the stratum corneum.[31] Keratin filaments form a network, or cell matrix, that gives structural integrity to the epidermal keratinocytes. As keratinocytes mature into corneocytes, the keratin filaments collapse and are cross-linked to the cornified cell envelope. Filaggrin is synthesized as a high-molecular weight precursor, profilaggrin, that contains multiple filaggrin molecules and is localized to keratohyalin granules. Biochemical studies of epidermis from patients with IV have shown absence of or decrease in filaggrin and its precursor, profilaggrin.[32,33] In the Anglo-European population, null mutations in the gene encoding profilaggrin (*FLG*) are very strong predisposing factors for atopic dermatitis. A strong association is also found with individuals who have sensitivity to common allergens, allergic rhinitis, early onset and persistent eczema, and asthma in the presence of atopic dermatitis.[27,34]

X-LINKED RECESSIVE ICHTHYOSIS

In the 1960s, *X-linked recessive ichthyosis* (OMIM #308100) was distinguished clinically from other ichthyoses.[4] Shortly thereafter, the syndrome of placental steroid sulfatase deficiency was described in pregnancies with failure to initiate labor in association with low maternal urinary estrogens. Because the majority of maternal urinary estrogens are derived from the fetal adrenal and are metabolized by the placenta, low levels can reflect fetal abnormalities or death. However, in this condition low levels do not indicate severe fetal morbidity. The association between failure to

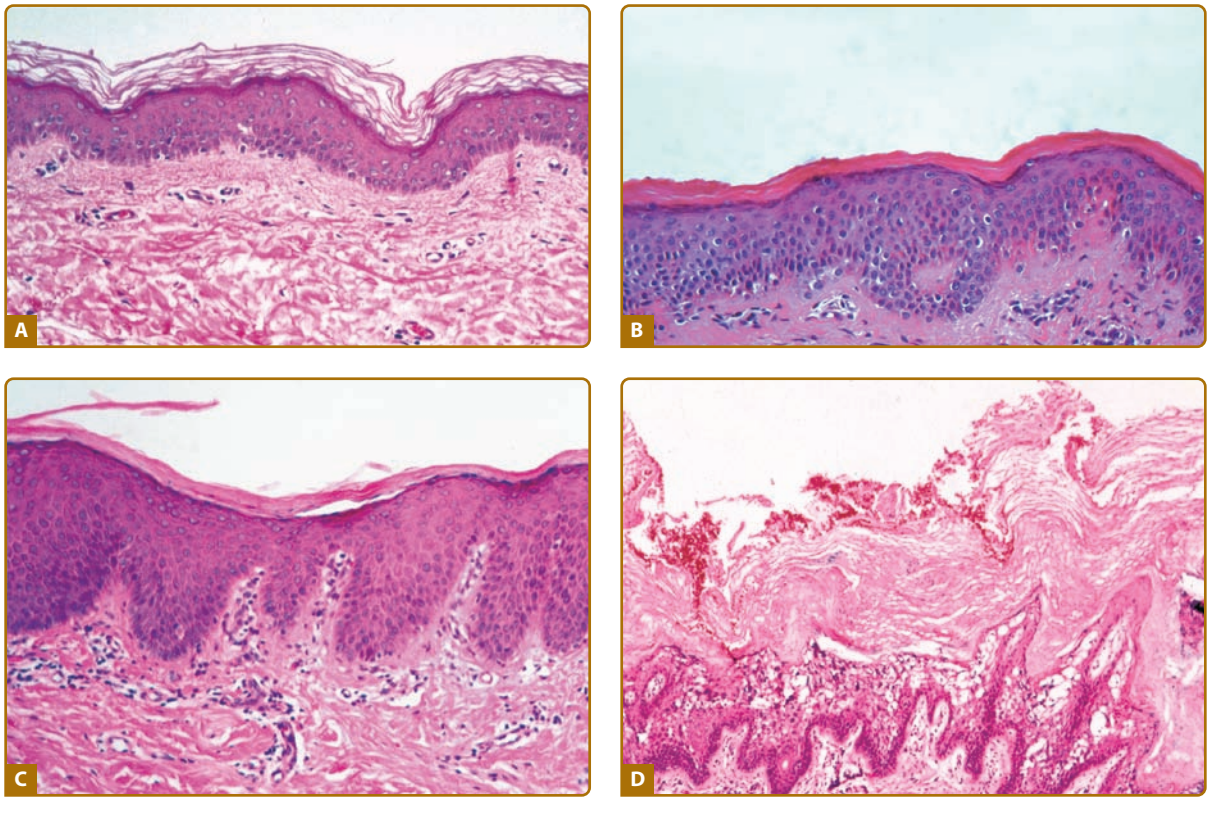

Figure 49-2 Histopathology. **A.** Ichthyosis vulgaris. Note absent granular layer. **B.** X-linked recessive ichthyosis. Note compact hyperkeratosis and accentuated granular layer. (Used with permission from Rob McFarlane, MD). **C.** Autosomal recessive congenital ichthyosis (CIE). The stratum corneum is thickened (hyperkeratosis) and there is prominent vacuolar degeneration of suprabasalar epidermis most marked at the granular layer.

initiate or progress labor and ichthyosis in the male offspring was not appreciated until 1978.[16,17] Steroid sulfatase hydrolyzes sulfate esters, which include cholesterol sulfate and sulfated steroid hormones.[35] Sulfated fetal adrenal hormones undergo desulfation to estrogens, which are excreted in maternal urine. The absence of steroid sulfatase enzyme in the fetal placenta leads to low maternal urinary estrogens, and in some pregnancies, to a failure of labor to initiate or to progress normally. In males with X-linked recessive ichthyosis, steroid sulfatase enzyme activity is decreased or absent in many tissues, including epidermis, stratum corneum, and leukocytes, and in cultured fibroblasts.[36] In addition, cholesterol sulfate, an enzyme substrate, accumulates in serum and in scale. Carrier females have been found to have leukocyte steroid sulfatase levels intermediate between those observed in normal individuals and those in affected males.

X-linked recessive ichthyosis occurs in approximately 1 in 2,000 to 6,000 males.[4,37] Scaling may begin in the newborn period and is usually most prominent on the extensor surfaces, although there is significant involvement of the flexural areas. While the extent and degree of scaling are variable, X-linked ichthyosis can usually be distinguished from IV on clinical criteria.[4,38] The latter tends to be associated with hyperlinear palms and soles, keratosis pilaris, and a family history of atopy. X-linked ichthyosis tends to have more severe involvement with larger scale, and comma-shaped, corneal opacities may be present in half of adult patients[39,40] (Fig. 49-3). Corneal opacities do not affect vision and may be present in female carriers.[40] Affected males have an increased risk of cryptorchidism, and independently they are at increased risk for the development of testicular cancer.[41] Histopathologic examination shows compact orthohyperkeratosis, acanthosis, and papillomatosis. The granular layer is usually thickened (Fig. 49-2).

Cholesterol sulfate levels are elevated in the serum, epidermis, and scale,[42] and there is increased mobility of β-lipoproteins (low-density lipoproteins) on electrophoresis, a feature that can suggest the diagnosis. Steroid sulfatase is one of a group of arylsulfatases located on chromosome Xp22. More than 90% of the mutations in X-linked ichthyosis are deletions that can often be detected by fluorescence in situ hybridization (FISH), available in many clinical laboratories. Confirmation of the diagnosis can also be made by finding an elevation in serum cholesterol sulfate levels. Unfortunately, cholesterol sulfate determination in serum and scale may not be readily available for laboratory confirmation of the clinical diagnosis. In the rare case where deletions are not detected and a clinical diagnosis is necessary, arylsulfatase C (steroid sulfatase) enzyme activity can be measured in cultured fibroblasts. Deletions that include adjacent sulfatases explain the overlap syndromes involving chondrodysplasia punctata and X-linked ichthyosis.[43] The X-linked form of Kallmann syndrome, in which hypogonadotropic hypogonadism and anosmia are found, often with renal abnormalities, obesity, synkinesis (mirror image

Figure 49-3 X-linked recessive ichthyosis. **A.** The scales are large and dark and most evident on the flexural areas in this patient. **B.** The blue arc is a cross-section of the cornea as seen by slit-lamp examination. The opacities appear white.

movements of the extremities), cleft palate, and spastic paraplegia, can also be seen in association with X-linked recessive ichthyosis as part of a contiguous gene deletion syndrome.[43] Because of this, and because of the association with testicular carcinoma, patients with X-linked recessive ichthyosis should be queried about anosmia and have periodic testicular examination.[44]

In the epidermis, steroid sulfatase catalyzes the hydrolysis of cholesterol sulfate. The identification of steroid sulfatase deficiency in X-linked ichthyosis supports the importance of cholesterol sulfate hydrolysis in normal desquamation. Topical application of cholesterol sulfate in mice can induce a scaling disorder, further supporting the role of cholesterol sulfate hydrolysis in corneocyte desquamation.

A family was described with an ichthyosis inherited in an X-linked pattern but with normal steroid sulfatase activity and the absence of corneal opacities.[45] This demonstrates heterogeneity within X-linked ichthyosis. Because of its frequent occurrence, steroid sulfatase deficiency accounts for most cases of X-linked ichthyosis, but a normal steroid sulfatase level in a male with ichthyosis does not rule out an X-linked pattern of inheritance.

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSIS

The term *autosomal recessive congenital ichthyosis* (ARCI) is useful to describe a heterogeneous group of disorders that present at birth with generalized involvement of the skin. Autosomal recessive ichthyosis is rare and has been estimated to occur in about 1 in 300,000 persons.[4]

In older literature, *nonbullous congenital ichthyosiform erythroderma* (NCIE) [*lamellar ichthyosis* (LI), with autosomal recessive inheritance] was distinguished from *bullous congenital ichthyosiform erythroderma* (BCIE) (EHK, with autosomal dominant inheritance) based on clinical appearance (bullae) and pattern of inheritance.[6,46] That the term LI was used interchangeably with NCIE and included a spectrum of phenotypes has led to some confusion. Williams and Elias distinguished LI from NCIE [usually called *congenital ichthyosiform erythroderma* (CIE)], a milder erythrodermic form.[47] Some patients with LI can be clearly distinguished from those with CIE on the basis of clinical features. In LI one sees large, dark, plate-like scales, and while infants may be red at birth, adults have little to no erythroderma (Fig. 49-4). In the more severe, classic presentation of LI, tautness of the facial skin leads to traction on the eyelids and lips, resulting in ectropion and eclabium. Scarring alopecia, most prominent at the periphery of the scalp, may be partly due to traction at the hairline. In contrast, CIE has generalized redness and fine, white scales (Fig. 49-5). Patients with classic CIE have little to no ectropion, eclabium, or alopecia. However, many patients do not fit neatly into these two clinical descriptions,[48] in that they have features of both LI and CIE with a clinical phenotype intermediate between both disorders. Therefore, it can be useful to consider these two distinctive presentations as ends of a spectrum, between which lie a

Figure 49-4 Classic lamellar ichthyosis phenotype. **A.** Ectropion. **B** and **C.** Large, brown, plate-like scales. (From Russell LJ et al: Linkage of autosomal recessive lamellar ichthyosis to chromosome 14q. *Am J Hum Genet* **55**:1146, 1994, with permission.)

gradation of clinical phenotypes with variable degrees of erythema and coarseness of scale. Individual features such as collodion membrane (discussed below), ectropion, and alopecia can occur across the spectrum. While attempts to refine the categorization of these disorders by biochemical and ultrastructural observations have failed to yield a consistent and replicable classification scheme,[5] identification of the spectrum of specific molecular defects underlying these conditions will undoubtedly help.[49] Identification of mutations has, so far, found ARCI to be caused by six different genes (Table 49-5) which are important for the formation of the intercellular lipid layer or the cornified envelope of keratinocytes.

Most patients with LI or CIE inherit the disease in an autosomal recessive pattern. Rarely, families have been described with similar phenotypes, where the disease is inherited as an autosomal dominant trait.[5] This is an important consideration for genetic counseling.

LAMELLAR ICHTHYOSIS

LI is apparent at birth, and the newborn usually presents encased in a collodion membrane. At this time the skin may be red. Over time, the skin develops large, plate-like scales, which appear to be arranged in a mosaic pattern (see Fig. 49-4). In some areas, the scales are centrally attached with raised borders. The scales tend to be largest over the lower extremities, where the large, plate-like scales separated by superficial fissuring can lead to an appearance similar to that of a dry riverbed. During childhood and into adulthood the degree of erythema may vary, but usually is minimal or absent in the severe presentation of classic LI. Involvement of the palms and soles in LI is variable and ranges from minimal hyperlinearity to severe keratoderma.

The lips and mucous membranes tend to be spared in LI, but the adnexal structures may be compromised by the adherent, firm scales. Thick stratum corneum on the scalp tends to encase hairs, and in conjunction with the tautness of the skin, may lead to a scarring alopecia, most marked at the periphery of the scalp. The hyperkeratosis can interfere with normal sweat gland function, resulting in hypohidrosis, but the degree of impairment varies between patients. Some patients have severe heat intolerance and must be vigilant to avoid overheating. Treatment with oral retinoids can improve or prevent some sequelae of LI. Patients frequently notice an increase in sweating, with improved heat tolerance. While retinoid therapy can cause blepharitis or even conjunctivitis, it is usually well tolerated by patients with LI. Moreover, the ability of systemic retinoid (and in some cases, topical retinoid) therapy to decrease thick periocular scale can decrease the tendency to develop ectropion. Nevertheless, patients with severe, classic LI usually require careful eye maintenance. Because of the ectropion (see Fig. 49-4), the lids

TABLE 49-5
Mutated Genes Identified in ARCI

Gene[a]	Protein	Function
TGM1[b]	Transglutaminase 1	Cornified envelope formation

may fail to close fully, particularly during sleep; hydration with liquid tears during the day and ophthalmic lubricants at night can prevent exposure keratitis.

Histopathologic examination typically shows orthokeratotic hyperkeratosis with mild to moderate acanthosis. Rates of epidermal proliferation are normal or only slightly elevated in patients with LI, in contrast to those with CIE, which has significantly greater labeling indices.[50]

Mutations in *TGM1*, the gene encoding transglutaminase 1, were found in several families with LI, solidifying the role for transglutaminase 1 in the formation of a normal stratum corneum and its role as a cause of LI.[12,13] The lamellar phenotype is more commonly associated with mutations in *TGM1*.[15,49] The transglutaminases catalyze calcium-dependent cross-linking of proteins through the formation of ε-(γ-glutamyl)lysine isodipeptide bonds. During the formation of the stratum corneum, transglutaminase catalyzes the cross-linking of cellular proteins, including involucrin, loricrin, small proline-rich proteins, and others. The resulting protein complex is deposited on the inner side of the plasma membrane to form the cornified envelope. Transglutaminase also attaches ceramides secreted into the intercellular space by lamellar bodies to cornified envelope proteins, notably involucrin, and thereby is important in the formation of both the protein and lipid components of the stratum corneum.[14]

Bathing suit ichthyosis is an unusual form of LI where affected individuals develop the scaling typical of LI, but limited to the bathing suit area.[51] The distribution correlates with warmer areas of skin. Decreased transglutaminase is found in these areas, and unique, temperature-sensitive mutations in *TGM1* have been identified in affected individuals.[52]

In a human skin/immunodeficient mouse xenograph model, transfer of a transglutaminase-1 gene into transglutaminase-1-deficient keratinocytes from LI patients resulted in normalization of transglutaminase expression and epidermal architecture in addition to restoration of cutaneous barrier function.[53] Additional disease-causing loci have been found (see below).

CONGENITAL ICHTHYOSIFORM ERYTHRODERMA

As with LI, CIE is apparent at birth, and the newborn usually presents with a taut, shiny, collodion membrane. After shedding of the membrane, the skin of infants with CIE remains red, usually with a fine, white, generalized scale (see Fig. 49-5). On the lower legs, the scale may be larger and darker. In contrast to LI, the classic presentation of CIE may have little to no ectropion, eclabium, or alopecia. As in LI, there is a wide variation in the ability to sweat, and patients with CIE may have minimal sweating with severe heat intolerance. Mucous membranes are usually spared. Palm/sole involvement is variable. Nails may have ridging, but they are often spared. As with all the ichthyoses, dermatophyte infection of the skin and nails is common.

Histopathologic examination shows hyperkeratosis, acanthosis, and often parakeratosis (Fig 49-2C). Studies of epidermal proliferation have shown markedly increased epidermal cell turnover, in contrast to LI.[50]

A small subset of patients with CIE have been found to have mutations in *TGM1*, and two siblings with a collodion presentation, CIE, and palmoplantar keratoderma had an autosomal dominant mutation in the cornified envelope protein, loricrin.[54] Further genetic heterogeneity within ARCI has been demonstrated, with exclusion of *TGM1* as the disease-causing gene in families with phenotypes within the spectrum of classic LI and CIE and identification of mutations in other genes. To date, mutations have been identified in five additional genes in ARCI (Table 49-5). In addition, two other genetic loci (12p11.2-q13 and 19p13.1-13.2) have been found to be associated with ARCI; the responsible genes have not been identified. The enzymes coded for by these genes (Table 49-5) are hypothesized to function together to convert arachidonic acid to a specific hepoxilin in a newly described pathway thought to form a common link in ARCI.[18,55]This hypothesis remains to be tested, and how the most common mutation in ARCI, that of *TGM1*, might relate to lipid abnormalities is unclear.

EPIDERMOLYTIC HYPERKERATOSIS

In 1902, Brocq described bullous ichthyotic erythroderma and distinguished the blistering type from the nonblistering type of congenital ichthyotic erythroderma.[56] The original description included three unrelated patients whose clinical manifestations varied. However, this was probably the first description of *epidermolytic hyperkeratosis* (EHK; OMIM #113800). The disease is named for the distinctive histopathologic features of vacuolar degeneration of the epidermis (i.e., epidermal lysis) and associated hyperkeratosis. EHK is also known as BCIE, an earlier descriptive name signifying the blistering, neonatal presentation, scaling, and redness.

EHK is transmitted as an autosomal dominant trait with a prevalence of approximately 1 in 200,000 to 300,000 persons. However, there is a high frequency of spontaneous mutation, and as many as one-half of the cases have no family history[46] and represent new mutational events. The disease usually presents at birth with blistering, redness, and peeling (Fig. 49-6). With time, generalized hyperkeratosis may develop, which may or may not be associated with erythroderma. EHK skin usually has a characteristic pungent odor, thought to be related to superinfection by mixed flora.

In contrast to most other ichthyoses, the histopathologic picture of EHK is almost always distinctive. A tremendously thickened stratum corneum and vacuolar degeneration of the upper epidermis are seen, leading to the histologic term EHK (see Fig. 49-2D). The vacuolar degeneration usually involves the upper epidermis and occasionally all of the suprabasilar keratinocytes. Granular cells exhibit dense, enlarged, irregularly shaped masses that appear to be keratohyalin

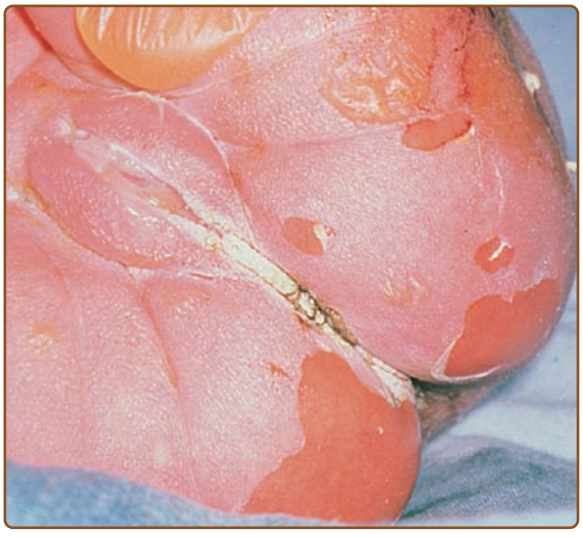

Figure 49-6 Epidermolytic hyperkeratosis. Newborn showing blistering and erosions.

granules.[6] On electron-microscopic examination, clumping of filaments is observed to begin in the first suprabasal layer. These aggregated filaments are clumps of keratin intermediate filaments that contain the suprabasal keratins 1 and 10.[57]

There is striking clinical heterogeneity between EHK families. Six distinctive clinical phenotypes have been described.[58] Several clinical features can be useful to distinguish between the different subtypes, including the presence versus absence of severe palmar/plantar hyperkeratosis and of erythroderma, quality of scale, extent of involvement, presence of digital contractures, and gait abnormality (Table 49-6). Three types without palm/sole hyperkeratosis are called NPS types. Patients with the NPS-1 clinical phenotype have generalized involvement with thick, brown verrucous hyperkeratosis, most prominent over joints. Palms and soles are spared. Cobblestone or hystrix (porcupine-like) spiny papules are characteristic; this severe clinical presentation is one of the more commonly recognized types of EHK (Fig. 49-7A). NPS-2 is similar, but much milder, without the hystrix spines and with relative sparing of the skin between joints (Fig. 49-7B). Generalized exfoliative erythroderma is found in NPS-3 (Fig. 49-7C). Three types with severe palm/sole hyperkeratosis are called PS types. Patients with the PS-1 type have a smooth palmar/plantar hyperkeratosis with a sharp border, often delineated by a red halo. Blisters may be present at the border. There may be limited involvement of the trunk, usually confined to areas over joints (Fig. 49-8A). The PS-2 type is characterized by generalized erythroderma and scaling. Volar involvement may be severe, with contractures of the digits and ainhum-like constricting digital bands (Fig. 49-8B). The PS-3 type has generalized skin involvement with a pebbly hyperkeratosis that is arrayed in a distinctive, cerebriform pattern on the palms and soles (Fig. 49-8C).

Sporadic EHK due to a postzygotic, spontaneous mutation during embryogenesis can present in a mosaic pattern of skin involvement. Areas of hyperkeratosis alternating with normal skin are often distributed in streaks along Blaschko lines (Fig. 49-9A). These may be limited to a few streaks, or there may be many, with widespread, patchy involvement. Unilateral localization can also occur. This clinical mosaic pattern correlates with underlying genetic mosaicism in that keratin mutations characteristic of EHK, which were found in lesional skin, were absent in normal skin.[59] If the germ line is involved, individuals with mosaic EHK can transmit the mutation, which leads to generalized EHK in affected offspring (Fig. 49-9B).[60]

Within keratinocytes, keratin intermediate filaments form an elaborate network that confers structural stability to the cells. In the suprabasilar, differentiating keratinocytes of interfollicular epidermis, this network is formed by keratins 1 and 10. In EHK, failure of this network leads to keratinocyte fragility (particularly of the upper epidermis), easy blistering, altered barrier

TABLE 49-6
Characteristics of Epidermolytic Hyperkeratosis[a]

	NPS-1	NPS-2	NPS-3	PS-1	PS-2	PS-3

[a]NPS = types without severe palm/sole hyperkeratosis; PS = types with severe palm/sole hyperkeratosis; minus sign = absent; plus sign = present.

Figure 49-7 Clinical phenotypes of epidermolytic hyperkeratosis. NPS (no severe palm/sole hyperkeratosis) types are shown. **A.** NPS-1 (NPS-type 1): Generalized involvement with thick, brown verrucous hyperkeratosis. Palms are spared. Over the dorsal foot, hyperkeratosis is arrayed in a characteristic cobblestone or hystrix (porcupine-like) pattern. **B.** NPS-2 (NPS-type 2): Brown hyperkeratosis over the trunk, and accentuated over joints. Palms are spared. Compared to the verrucous hyperkeratosis in NPS-1, involvement is much milder. On the lower legs, note the blistering, hypertrichosis, and relative sparing of the skin between the joints. **C.** NPS-3 (NPS-type 3): Generalized erythroderma with white scale and hyperkeratosis.

function,[61] abnormal epidermal kinetics (hyperproliferation), and thickened stratum corneum (hyperkeratosis). Keratin 10 is the coexpressed partner of keratin 1, both of which are required to form keratin intermediate filaments in the cells of the suprabasal layers of the epidermis. Mutations in genes coding for either keratin 1 or 10 have been identified in a number of EHK families.[57,62] In most cases, palmar/plantar involvement implies mutations in K1; this may reflect the "redundancy" of K9 (a keratin that occurs only in the suprabasal epidermis of palmar and plantar skin) and K10 in palmar/plantar epithelium. Mutations in keratin 9 have been found in families with the type of EHK limited exclusively to the palms and soles (Vörner)[63] (see Chapter 50).

DISORDERS RESEMBLING EPIDERMOLYTIC HYPERKERATOSIS

ICHTHYOSIS BULLOSA OF SIEMENS

Ichthyosis bullosa of Siemens (OMIM #146800) is a rare autosomal dominant genodermatosis that is similar in clinical appearance to EHK. Patients are born with redness and blistering. The redness subsides over the subsequent weeks to months, while the skin develops dark gray hyperkeratosis, particularly over flexural areas. In some areas, there may be a lichenified appearance to the skin. As with EHK, the epidermis is fragile;

Figure 49-8 PS (Severe palm/sole hyperkeratosis) types are shown. **A.** PS-1 (PS-type 1): Palmar and plantar hyperkeratosis with sharp border delineated by a red halo. Blisters are present at the border. Note the relatively smooth surface. There is characteristic involvement at the joints but sparing most of the trunk and extremities. **B.** PS-2 (PS-type 2): Hands (left) of a 36-year-old patient with severe palmar hyperkeratosis, contractures, and ainhum-like constricting digital bands. The palmar hyperkeratosis limits spreading of the fingers. Palms (right) of a 15-year-old patient with severe palmar hyperkeratosis and contractures. Flank (lower right) exhibiting generalized erythroderma and scaling. **C.** PS-3 (PS-type 3): Hyperkeratosis in a cobblestone pattern on the knees. Four-year-old patient with hyperkeratosis in a distinctive cerebriform pattern on the palms and soles (not shown). (Adapted from DiGiovanna JJ, Bale SJ: Clinical heterogeneity in epidermolytic hyperkeratosis. *Arch Dermatol* **130**:1026, 1994 with permission.)

Figure 49-9 Mosaic epidermolytic hyperkeratosis. **A.** Streaks of hyperkeratosis distributed along Blaschko's lines in a sporadic case due to postzygotic occurrence of new mutation. **B.** Grandchild of patient shown in Panel **A**. Generalized involvement (in this case the NPS-2 clinical phenotype) is transmitted to subsequent generations in an autosomal dominant inheritance pattern.

however, the fragility is more superficial. This can result in loss of the uppermost epidermis (predominantly stratum corneum), yielding a characteristic, collarette-like depressed area that has been described as "mauserung" (molting). Histologically, the epidermis shows hyperkeratosis and vacuolization similar to EHK, but it may be confined to the granular layer. Mutations have been found in the gene encoding keratin 2,[64] a differentiation keratin of the suprabasilar epidermis that is expressed in the more superficial epidermal layers.

ICHTHYOSIS HYSTRIX OF CURTH AND MACKLIN

Ichthyosis hystrix of Curth and Macklin (OMIM #146590) is a rare, autosomal dominant disorder that clinically resembles EHK. Clinical expression varies, even within families, from palmoplantar keratoderma to severe generalized involvement. There can be widespread patchy, thick, gray–brown hyperkeratosis, most marked on the extensor arms and legs. Patients with extensive involvement resemble those with severe EHK without palmar/plantar involvement, with verrucous or porcupine-like (hystrix) hyperkeratosis. However, in contrast to EHK, blistering does not occur. Histologic examination of the epidermis shows acanthosis, papillomatosis, and severe orthokeratotic hyperkeratosis, with frequent binucleate cells. Keratinocytes within the granular and upper spinous layers may have perinuclear vacuolization, and some have prominent perinuclear shells. On electron microscopy, there are concentric, unbroken shells of tonofilaments surrounding the nucleus. Study of a three-generation family with ichthyosis hystrix of Curth and Macklin identified a mutation in the variable tail domain (V2) of the keratin 1 gene. Structural analyses of the resulting abnormal keratin showed a failure of keratin intermediate filament bundling, retraction of the cytoskeleton from the nucleus, and failure of localization of loricrin to desmosomal plaques.[65]

ANNULAR EPIDERMOLYTIC ERYTHEMA

Annular epidermolytic erythema (cyclic ichthyosis with EHK; OMIM #607602) presents at birth or in the first few months afterward with severe, intermittent scaling and blistering that resolves during puberty.[66] Residual, limited thickened plaques of verrucous scale in linear rows can be seen in flexural and intertriginous skin. In some cases, explosive bouts of widespread erythema with blisters and pustules are seen.[67] Patients subsequently develop widespread, migratory, polycyclic, and annular scaling plaques. Light and electron microscopy reveals findings of EHK. Mutations in keratin 10[68] and keratin 1[67] have been found.

A unifying designation of *keratinopathic ichthyosis* for all ichthyoses with underlying keratin mutations has been suggested recently.[9]

ICHTHYOSIS IN THE NEWBORN

COLLODION BABY

A *collodion baby* is born encased in a translucent, parchment-like membrane that is taut and may impair respiration and sucking. Involvement may vary from mild to severe, but this variation has not been well characterized. In addition, the birth is often premature, which adds to morbidity. During the first 2 weeks of life, the membrane breaks up and peels off, often leaving fissures, with impairment of the barrier to infection and water loss. This can lead to an increased risk of infection, difficulties in thermal regulation, and hypernatremic dehydration.[69] Newborn care should include careful monitoring for infection and of temperature, hydration, and electrolytes, and measures to keep the peeling membrane soft and lubricated to facilitate flexibility and desquamation. Appropriate pain management and eye care should be employed, when indicated. These newborns usually benefit from a humidified incubator where the air is saturated with water; wet compresses followed by bland lubricants can be used to further hydrate the membrane and achieve maximum pliability.[70] If during peeling, residual areas of the membrane are allowed to dry and harden in areas such as the extremities, the taut membrane can constrict and lead to distal swelling. Collodion presentation can develop into a wide spectrum of ichthyotic phenotypes as the child grows (Box 49-1). It is the usual presentation of ARCI (see Fig. 49-10) and is less commonly seen in several other forms of ichthyosis, and rarely Gaucher disease (Box 49-1). In addition, an autosomal recessive, self-healing collodion baby has been described, where the skin greatly clears within the first few weeks and transitions into mildly affected or normal skin.[71] Eleven Swedish and four Danish patients with a self-improving ichthyosis resulting in xerosis, hyperlinear palms, red cheeks, and anhidrosis were found to have mutations in *ALOX12B*, *ALOX3E*, or *TGM1*.[72]

Figure 49-10 Collodion baby. The infant is 36 hours old and is covered with a macerated membrane that shows fissures; note ectropion and eclabium. The condition may develop over time into various clinical phenotypes including ARCI and self-healing collodion baby (Table 49-3).

BOX 49-1 DISORDERS ASSOCIATED WITH COLLODION MEMBRANE

- AEC syndrome
- Autosomal recessive congenital ichthyosis (LI, CIE, overlap)
- Chondrodysplasia punctata
- Gaucher disease
- Loricrin keratoderma
- Neutral lipid storage disease
- Self-healing collodion baby
- Sjögren–Larsson syndrome
- Trichothiodystrophy
- X-linked hypohydrotic ectodermal dysplasia
- Other

Note: This box does not distinguish the frequency in which collodion membrane is found in the different disorders listed. In some cases, severe peeling may be mistaken for collodion membrane. (From Okulicz JF, Schwartz RA: Hereditary and acquired ichthyosis vulgaris. *Int J Dermatol* **42**:95, 2003.)

EPIDERMOLYTIC HYPERKERATOSIS

The newborn affected with one of the more severe, generalized types of *EHK* usually has erythema, blistering, widespread erosions, and denuded skin (see Fig. 49-6). Because there is a high frequency of new mutations, the disease may be unexpected and the diagnosis may be unknown. Epidermolysis bullosa or staphylococcal scalded-skin syndrome may be suspected, and the infant treated with antibiotics. The newborn may require intensive care with fluid and electrolyte monitoring. Specialized skin care can minimize blistering and enhance healing of erosions and may include lubrication to decrease friction and mechanical trauma, protective padding, and specialized wound dressings. The newborn with extensive erosions is prone to bacterial infection and sepsis, and carefully chosen topical and systemic antibiotics can minimize the extent of infection.

HARLEQUIN ICHTHYOSIS

A dramatic, severe, and often fatal presentation of ichthyosis is that of *harlequin ichthyosis* (OMIM #242500) (Fig. 49-11). The child is often premature and born with massive, shiny plates of stratum corneum separated by deep, red fissures that tend to form geometric patterns, as seen in the patched costumes of the harlequin clowns from the Italian Commedia dell'Arte dating from the sixteenth and seventeenth centuries. There are poorly developed or absent ears and marked ectropion and eclabium. The first report is from the diary of Rev. Oliver Hart, of Charleston, South Carolina, who described these features in 1750.[73] These children are at great risk during the neonatal period and often die

Figure 49-11 Harlequin ichthyosis. Note rudimentary ears and the distorted appearance as a result of the thick "plates" of stratum corneum. This baby died a few days after birth.

shortly after birth. Abnormal water loss through the skin and poor temperature regulation lead to risk of fluid and electrolyte imbalance. The infants are also at risk for infection beginning in the skin, but at the same time (because of poor temperature regulation) do not show the usual signs of infection. Normal respiration may be restricted by the taut skin. Treatment with systemic retinoids during the newborn period can facilitate desquamation of the membrane.[74,75] Advances in neonatal intensive care, together with facilitating desquamation by judicious use of systemic retinoid therapy have led to improvements in survival and to the use of the name "harlequin baby" rather than "harlequin fetus." Some babies have suffered from failure to thrive and require tube feeding. The skin of those who survive the newborn period usually resembles the skin of those with a severe phenotype of CIE.[74,75]

In harlequin ichthyosis, normal lamellar granules are not found; instead, there are small vesicles that lack internal structure. There is also no evidence of the lipid lamellae that form between granular and cornified cells as a result of discharge of lamellar granule contents into the intercellular space.[76] The disorder results from autosomal recessive inheritance of mutations in *ABCA12*, which codes for an adenosine triphosphate (ATP)-binding cassette (ABC) transporter involved in lamellar granule secretion and epidermal lipid transport. Premature termination mutations underlie harlequin ichthyosis,[77–79] while missense mutations in *ABCA12* have been identified in a subset of individuals with less severe ARCI[80] (Table 49-5).

NETHERTON SYNDROME

Netherton syndrome (OMIM #256500) is a rare, autosomal recessive disorder characterized by the concurrence of ichthyosis, a structural hair shaft abnormality, and atopy.[81,82] The usual cutaneous manifestation is *ichthyosis linearis circumflexa*, a distinctive condition of generalized hyperkeratosis and polycyclic and serpiginous erythematous plaques with a characteristic, migratory, double-edged scale at the margins (Fig. 49-12A). At birth, affected children may present with generalized erythroderma. Infants and children may have feeding problems, with poor absorption and failure to thrive.[83] With atopic dermatitis, there may be pruritus, and scratching can lead to lichenification at the flexures. In some patients, the ichthyosis resembles LI or CIE.[5,81] Histopathologic examination is not specific and may show features of hyperkeratosis, psoriasis, and atopic dermatitis. Most patients have a specific hair shaft abnormality called *trichorrhexis invaginata*, in which the distal hair segment is telescoped into the proximal one, forming a ball-and-socket-like deformity on microscopic examination (Fig. 49-12B). This is also known as "bamboo hair" and is due to abnormal cornification of the internal root sheath. Hair from multiple areas should be examined, because only 20–50% of hair may be affected; the characteristic abnormality may be more commonly observed on eyebrow hair.[84] Trichorrhexis nodosa and pili torti (see Chapter 88) may also occur. The hair defects may not be detectable at birth, and may disappear with age. Atopy in these patients may manifest as atopic dermatitis asthma, or severe food allergy (particularly to nuts), and marked elevations of serum immunoglobulin (Ig) E may occur. In some patients, generalized aminoaciduria, mild developmental delay, and impaired cellular immunity may also be present.[85]

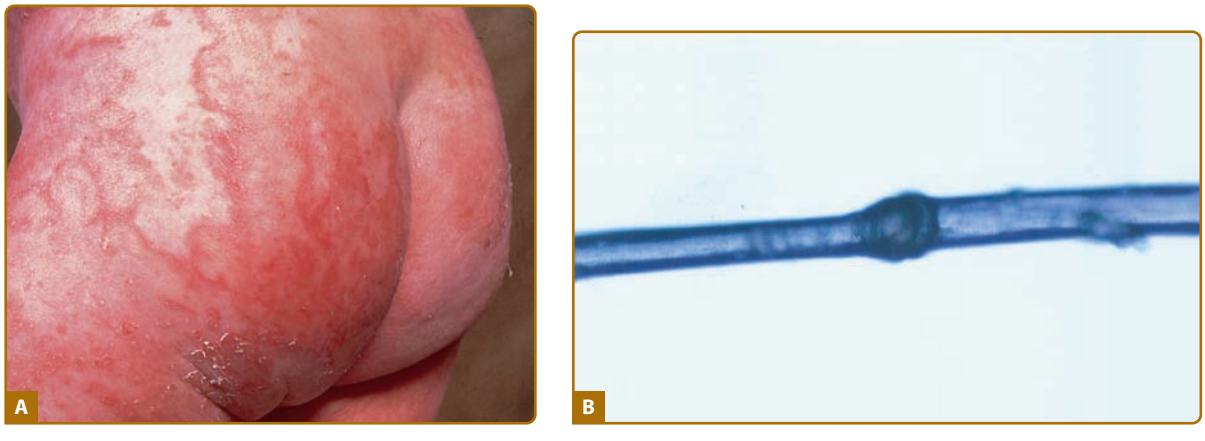

Figure 49-12 Netherton syndrome. **A.** Ichthyosis linearis circumflexa showing typical annular lesions. (Used with permission from James Stroud, A MD.) **B.** Bamboo hair shaft shows features of trichorrhexis invaginata.

Netherton syndrome has been found to be due to mutations in *SPINK5,* a gene encoding LEKTI (*l*ympho-*e*pithelial *K*azal-*t*ype related *i*nhibitor).[19] LEKTI is a serine protease inhibitor that is predominantly expressed in epithelial and lymphoid tissues, and may be important in the downregulation of inflammatory pathways. This discovery highlights the importance of the regulation of proteolysis in the overlap between epithelial barrier function and the hypersensitivity of atopy. Subsequently, LEKTI polymorphisms were associated with common atopy and atopic dermatitis.[86] Prenatal testing for Netherton syndrome using molecular data has been successfully accomplished.[87] Tacrolimus ointment, a topical immunomodulator (see Chapter 221), is effective in common atopic dermatitis with minimal systemic absorption. However, Netherton syndrome is complicated by an abnormal skin barrier, allowing increased percutaneous absorption and associated risk for systemic toxic effects. This should be considered when using topical agents such as tacrolimus, where monitoring of serum levels may be necessary,[88] and topical steroids, where iatrogenic Cushing syndrome has been reported.[89]

LESS COMMON ICHTHYOSES

ARC

ARC (OMIM #208085) is a rare autosomal recessive, multisystem disorder characterized by *a*rthrogryposis, *r*enal tubular dysfunction, and *c*holstasis often with ichthyosis and other abnormalities. Mutations have been found in the *VPS33B* gene that encodes a protein involved in intracellular trafficking pathways.[90]

CEDNIK

*Ce*rebral *d*ysgenesis, *n*europathy, *i*chthyosis, and *k*eratoderma (CEDNIK) syndrome (OMIM #609528) is an autosomal recessive neurocutaneous syndrome characterized by severe psychomotor retardation, ichthyosis, and palmoplantar keratoderma thought to result from abnormal lamellar granule maturation and secretion.[91] In CEDNIK syndrome, lamellar granules are retained within the cornified cell layer resulting in reduced secretion of lipids and proteases into the extracellular space. This results in impaired barrier formation and decreased corneocyte disadhesion.

CHANARIN–DORFMAN SYNDROME

Chanarin–Dorfman syndrome (neutral lipid storage disease; OMIM #275630) is an autosomal recessive disorder characterized by accumulation of triglycerides in the cytoplasm of leukocytes, muscle, liver, fibroblasts, and other tissues. However, blood lipid levels are normal. To date, approximately 30 patients have been reported, mainly from the Mediterranean basin. The ichthyosis is a generalized fine scaling with variable erythema, resembling congenital ichthyosiform erythroderma. Presentation is often that of a collodion baby with ectropion and eclabium. Skin changes may evolve to orange–red with brown scale, and are associated with pruritus. Extracutaneous involvement, which is variable and may be mild, includes cataracts, decreased hearing, hepatosplenomegaly with abnormal liver enzymes and fatty liver, psychomotor delay, myopathy with elevations in serum muscle enzymes, and neurologic abnormalities.

Histopathology of an oil red O or Sudan III stain of frozen sections of the skin shows lipid droplets in dermal cells, in the basal layer (and, to a lesser extent, suprabasally), as well as in the acrosyringia of the eccrine ducts. Examination of peripheral blood smears shows lipid vacuoles within granulocytes, eosinophils, and monocytes, a feature that may also be present in carriers.[92] Mutations in the *CGI-58* gene have been identified.[93] CGI-58 belongs to a large family of proteins, most of which are enzymes, and appears to activate adipose-triglyceride lipase in the initial step in lipolysis of triglycerides. In the absence of CGI-58, triglycerides accumulate.[94]

CHILD SYNDROME

The *CHILD syndrome* (OMIM #308050) is a rare disorder consisting of *c*ongenital *h*emidysplasia, *i*chthyosiform erythroderma, and *l*imb *d*efects, which is found almost exclusively in females.[95] The disorder is related to *X-linked dominant chondrodysplasia punctata* (CDPX2), which also has skin and skeletal abnormalities, but is distinguished by a sharp midline demarcation of the psoriasiform ichthyosis, with minimal linear or segmental contralateral involvement. Involvement of the right side occurs more frequently than the left. There may be bands of normal skin on the affected side. A case with bilateral involvement has been described. Limb defects occur ipsilateral to the ichthyosis and range from digital hypoplasia to agenesis of the extremity. There may be punctate calcification of cartilage. Unilateral hypoplasia can involve the central nervous system and cardiovascular, pulmonary, renal, endocrine, and genitourinary systems. The inheritance pattern is thought to be X-linked dominant, with the condition being lethal in males. Peroxisomal deficiency has been described, and mutations in either of two peroxisomal genes were found to cause CHILD syndrome. One patient was found to have a mutation in the gene encoding EBP (3β-hydroxysteroid-δ8-δ7-isomerase) (the gene underlying CDPX2)[96] and six patients (including one boy) were found to have mutations in *NSDHL* [NAD(P)H *s*teroid *deh*ydrogenase-*l*ike protein] encoding a 3β-hydroxysteroid dehydrogenase.[97] Each enzyme functions in the postsqualene cholesterol biosynthetic pathway, catalyzing intermediate steps in the conversion of lanosterol to cholesterol.[98]

CHONDRODYSPLASIA PUNCTATA

Chondrodysplasia punctata is a clinically and genetically diverse group of rare diseases, first described by

Conradi, that share the features of stippled calcification of the epiphyses and skeletal changes. They are characterized by abnormal deposition of calcium in the areas of enchondral bone formation during fetal development and early infancy. Several forms also include ichthyosiform changes. Clinical severity ranges from severe dwarfism and death during infancy to a self-limited radiographic abnormality in others. An autosomal recessive (rhizomelic) type and both X-linked dominant[99] and recessive forms[100] have been described. The validity of the originally described autosomal dominant Conradi–Hünermann type has been questioned, because some reported cases were later shown to belong to the X-linked dominant type, and occurrences previously considered sporadic have subsequently been recognized as resulting from warfarin (Coumadin) anticoagulant embryopathy.[99,101]

RHIZOMELIC CHONDRODYSPLASIA PUNCTATA. *Rhizomelic chondrodysplasia punctata* (RCDP) (autosomal recessive; OMIM #215100) is also known as peroxisomal biogenesis disorder complementation group 11 (CG11). It is a rare, multisystem developmental disorder characterized by dwarfism due to symmetric shortening of the proximal long bones (i.e., rhizomelia), specific radiologic abnormalities (i.e., the presence of stippled calcifications of cartilage, vertebral body clefting), joint contractures, congenital cataracts, ichthyosis, and severe mental retardation. Skin changes are present in approximately 25% of patients. Patients have low levels of red cell plasmalogens and accumulation of phytanic acid, starting with normal levels at birth and increasing to more than 10 times normal by age 1 year. RCDP is a disorder of peroxisomes, membrane-bound multifunctional organelles found in all nucleated cells. Their functions vary with cell type and include a variety of pathways (e.g., hydrogen peroxide-based respiration, fatty acid β-oxidation, and lipid and cholesterol synthesis) involving the synthesis and degradation of various compounds. Hereditary human peroxisomal disorders are subdivided into disorders of peroxisome biogenesis, in which the organelle is not formed normally, and those involving a single peroxisomal enzyme. RCDP is one of the groups of peroxisome biogenesis disorders, which are characterized by loss of multiple peroxisomal metabolic functions and have been sorted into at least 12 different complementation groups. Many have been found to be due to defects in peroxins, factors required for the import of proteins into the organelle. RCDP is caused by mutations in *PEX7,* a gene that encodes peroxin 7, a receptor required for targeting a subset of enzymes to peroxisomes.[102] Refsum disease, another peroxisome disorder, exhibits genetic heterogeneity. In Refsum disease due to mutations in *PAHX,* the gene for phytanoyl-CoA hydroxylase (PhyH), there is deficiency of the single peroxisomal enzyme PhyH. Refsum disease can also result from mutations in *PEX7;* fibroblasts from those patients show deficiency of several peroxisomal enzymes, similar to fibroblasts from patients with RCDP. It is remarkable that different mutations in the same gene can result in such a wide spectrum of clinical disease.

X-LINKED RECESSIVE CHONDRODYSPLASIA PUNCTATA. *X-linked recessive chondrodysplasia punctata* (CDPX; OMIM #302950) can involve skin (linear or whorled atrophic or ichthyosiform hyperkeratosis, follicular atrophoderma; may begin as erythroderma) (Fig. 49-13), hair (coarse, lusterless, cicatricial alopecia), short stature and skeletal abnormalities, cataracts, and deafness. Curry et al studied a family who had atypical ichthyosis and elevated cholesterol sulfate in two affected males and identified an X chromosomal deletion (Xp22) that included the gene for steroid sulfatase.[100] There is a cluster of arylsulfatase genes at this location. Mutations in *ARSE,* the gene encoding the enzyme arylsulfatase E, were found in five patients; however, it is possible that the disorder may also be caused by mutations in adjacent arylsulfatase genes.[103] The similarity to warfarin embryopathy suggests that warfarin embryopathy may be due to drug-induced inhibition of the same enzyme.

X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA. Happle and coworkers identified *X-linked dominant chondrodysplasia punctata* (CDPX2) (Conradi–Hünermann–Happle syndrome; OMIM #302960) as a distinct variant characterized by a mosaic pattern of skin involvement and occurrence almost exclusively in females, with loss of the gene function hypothesized to be lethal to males.[99] Affected females have a normal life expectancy and there may be increased disease expression in successive generations (anticipation). Occurrence in a male has been observed in association with a 47,XYY karyotype. CDPX2 presents at birth as a congenital ichthyosiform erythroderma that clears over months and is replaced by linear hyperkeratosis, follicular atrophoderma, and pigmentary abnormalities. Happle hypothesized that the linear involvement is due to mosaic X-chromosome inactivation (lyonization). Hair shaft abnormalities and cicatricial alopecia can also occur. Stippled calcifications are

Figure 49-13 Erythrokeratodermia variabilis. Generalized type with widespread hyperkeratosis and migratory, figurate, red patches.

seen in radiographs of areas of endochondral bone formation during childhood but may no longer be visible after puberty. Stature may be short, with asymmetric shortening of the legs. Cataracts occur, usually asymmetrically, in about two-thirds of patients. Histochemical staining for calcium may show calcifications within the epidermis, especially within hair follicles in young children, which may not be present in older children.[104] Mutations in the gene encoding the emopamil-binding protein (EBP) cause the Conradi–Hünermann–Happle Syndrome. EBP was first identified as a binding target for the drug emopamil, a calcium-channel blocker. It was later found to be 3β-hydroxysteroid-δ8-δ7-isomerase that catalyses an intermediate step in the conversion of lanosterol to cholesterol.[105] How this defect causes clinical manifestations is unclear.

CONGENITAL RETICULAR ICHTHYOSIFORM ERYTHRODERMA

This rare disorder, also known as *ichthyosis variegata* or *ichthyosis en confetti(s)*, presents as congenital ichthyosiform erythroderma. Small islands of normal appearing skin begin to appear late in childhood. Band-like parakeratosis, psoriasiform acanthosis and vacuolated, binuclear upper epidermal keratinocytes with a filamentous perinuclear shell by electron microscopy and dermal amyloid deposits are seen.[106] Normal areas of skin have been shown to arise from loss of heterozygosity on chromosome 17q via mitotic recombination of disease-causing mutations in the gene encoding keratin 10 (KRT10).[107]

ERYTHROKERATODERMIAS

The *erythrokeratodermias* are a clinically and genetically heterogeneous group of disorders characterized by hyperkeratosis and localized erythema. Within a broad spectrum of phenotypes, at least two disorders can be delineated: (1) erythrokeratodermia variabilis and (2) progressive symmetric erythrokeratodermia. There are overlapping clinical features and phenotypic variability within these two designations.[108]

ERYTHROKERATODERMIA VARIABILIS. *Erythrokeratodermia variabilis* (OMIM #133200), described by Mendes da Costa in 1925, is a rare disorder that usually presents at birth or during the first year of life. Both autosomal dominant and recessive inheritance have been described.[109] At least two distinct clinical presentations can be distinguished. One type (Fig. 49-14) is characterized by generalized, persistent, red–brown hyperkeratotic plaques, and accentuated skin markings. A second, localized type has involvement that is limited in extent and characterized by sharply demarcated, hyperkeratotic plaques; these are symmetrically arrayed and remain relatively fixed for months to years. In the localized type, there may be considerable variability between affected family members, and the disorder may not be apparent until later in life. Both types are characterized by striking, sharply demarcated,

Figure 49-14 KID syndrome. Discrete, symmetric hyperkeratotic plaques are present on the face. There is a scarring alopecia.

migratory red patches, which vary in size from a few to many centimeters. These geographic, figurate red patches appear or regress over minutes to hours; some individuals complain of burning at these sites, while in others they are asymptomatic. The red patches develop independently of the hyperkeratosis. Systemic retinoid treatment clears the hyperkeratotic lesions and may also clear the figurate red patches. The hyperkeratotic skin lesions may be triggered by trauma to the skin and the red patches may be triggered by a change in temperature. Palmoplantar hyperkeratosis may be present in either type, but hair, nails, and mucous membranes are unaffected. Histopathologic features are nonspecific and include hyperkeratosis, acanthosis, papillomatosis, and capillary dilatation. Epidermis involved with severe papillomatosis and suprapapillary thinning may result in a "church spire" appearance.

Several variants have been described. Erythrokeratodermia *en cocardes* was described in a family in which the erythematous component was in a target-like configuration.[110] In a possible clinical variant of erythrokeratodermia *en cocardes*, erythema gyratum repens-like erythema (see Chapter 153) was described in a large kindred.[111] Another family with erythema annulare centrifugum-like lesions (see Chapter 43) has also been described.[112] A child with atypical erythrokeratodermia with neurosensory deafness, bilateral talipes (clubfoot) deformity, and neuropathy was described in which erythematous component changed only slowly over the year.[113] Erythrokeratodermia with ataxia (Giroux-Barbeau type) is an autosomal dominant disorder that presents during infancy with well-defined, symmetric hyperkeratotic plaques, and underlying erythema distributed over the extensor surface of the extremities.[114] Skin lesions regress during adulthood while a progressive spinocerebellar ataxia develops.

Both the localized type of erythrokeratodermia variabilis and erythrokeratodermia with ataxia have been

mapped to a common region (chromosome 1p34-35).[115] Subsequently, mutations in *GJB3*, the gene encoding connexin 31, were identified in four families with erythrokeratodermia variabilis.[116] Connexins are a family of proteins that aggregate to form gap junctions, which are important channels for intercellular communication. This intercellular signaling system is crucial for maintaining tissue homeostasis, growth control, development, and synchronized response of cells to stimuli. The identification of connexin mutations as the cause of erythrokeratodermia variabilis implicates this pathway in epidermal differentiation and in the mechanism of skin response to external factors. Different mutations in the same connexin 31 gene (*GJB3*) have been found in other patients with deafness and also in some with peripheral neuropathy. Mutations in the related connexin 30.3 (*GJB4*) have been found in other families with erythrokeratodermia variabilis[117]; in the variants with erythema gyratum repens-like erythema that have been studied, connexin 30.3 mutations appear to be found exclusively.[109]

PROGRESSIVE SYMMETRIC ERYTHROKERATODERMIA. *Progressive symmetric erythrokeratodermia* (OMIM #602036), first definitively described by Darier in 1911,[118] is characterized by well-demarcated, erythematous, hyperkeratotic plaques that are symmetrically distributed over the extremities and buttocks, and often the face.[119] The trunk tends to be spared, but palms and soles may be involved. The plaques appear shortly after birth, progress slowly during the first few years, and then stabilize in early childhood. The plaques usually remain stable in location and appearance but may undergo partial regression at puberty. The variable, migratory erythema that defines erythrokeratodermia variabilis is absent. The disorder is inherited in an autosomal dominant pattern but with incomplete penetrance and variable expressivity. A mutation in the cornified envelope protein loricrin was found in one family,[120] although the diagnosis (and the distinction from erythrokeratodermia variabilis) has been disputed.[121] Recently, a mutation in *GJB4*, which encodes connexin 30.3, was found in patients from the Netherlands with either progressive symmetric erythrokeratodermia or erythrokeratodermia variabilis, demonstrating that both clinical presentations can arise from the identical mutation.[122]

ICHTHYOSIS FOLLICULARIS, ALOPECIA, AND PHOTOPHOBIA SYNDROME

Noninflammatory follicular hyperkeratosis, total nonscarring alopecia, photophobia, and characteristic facies are seen in the IFAP syndrome (OMIM #308205). Less constant features include recurrent respiratory infections, nail abnormalities, angular cheilitis, keratotic plaques on the extensor surface of the extremities, inguinal hernia, cryptorchidism, short stature, seizures, and psychomotor developmental delay.[123,124] Inheritance is thought to be X-linked recessive, although an autosomal dominant form and a third type, with "psoriasiform plaques," have been postulated.[125] Mutations in the *MBTPS2* gene result in impaired cholesterol homeostasis and ability to cope with endoplasmic reticulum stress.[126]

ICHTHYOSIS PREMATURITY SYNDROME

Polyhydramnion complicates the second trimester in the ichthyosis prematurity syndrome (OMIM #608649), resulting in premature delivery of infants with erythrodermic, edematous, caseous scaling skin resembling excessive vernix caseosa, respiratory distress, and transient peripheral eosinophilia.[127] The respiratory signs, erythema and skin changes resolve, leaving signs of atopy and dry, scaly skin with follicular accentuation more pronounced than is seen in keratosis pilaris. Characteristic trilamellar membrane inclusions are seen in the stratum corneum by electron microscopy. Mutations in the fatty acid transport protein 4 gene, *FATP4* (*SLC27*) have been identified in affected members of one family.[128]

KERATITIS, ICHTHYOSIS, AND DEAFNESS SYNDROME

KID syndrome (OMIM #148210) is a rare disorder characterized by *k*eratitis (with progressive corneal opacification), *i*chthyosis, and *d*eafness (neurosensory). Involvement of multiple ectodermal tissues qualifies KID syndrome as an ectodermal dysplasia. Most cases are compatible with autosomal dominant inheritance. However, occurrence in an inbred sibship suggests the existence of an autosomal recessive form. The disease is characterized by discrete erythematous plaques, and there may be mild, generalized hyperkeratosis. The distinctive plaques may have a discrete border and a verrucous appearance with crusting and may be conspicuously figurate and symmetric on the face (Fig. 49-15).

Figure 49-15 Chondrodysplasia punctata. Newborn child. Generalized erythroderma with scales forming a whorled pattern.

Furrowing about the mouth results in characteristic facies. There may be prominent follicular hyperkeratosis, which can result in a scarring alopecia of the scalp. "Leather-like" palmar/plantar keratoderma is almost always seen.[129] Several authors have suggested that because the plaques do not scale, this disorder is more accurately designated an erythrokeratodermia rather than an ichthyosis.[5,129] Descriptions of nail changes vary from absent, delayed appearance after birth, atrophic, or brittle to thickened, with loss of or "rough" cuticles, subungual hyperkeratosis, and leukonychia. The teeth may be small. Auditory evoked potential studies allow detection of the hearing deficit in infancy. Keratitis may develop. Affected individuals can have an increased susceptibility to bacterial, fungal, or viral infections. Squamous cell carcinoma of the skin and tongue has also been reported. In contrast to many other ichthyotic conditions, treatment of these patients with oral retinoids has been reported to be of little benefit and possibly to exacerbate the corneal neovascularization.

Dominant mutations in *GJB2,* the gene encoding connexin 26, have been detected in sporadic cases and one family with KID syndrome. Functional studies of cells expressing mutated connexin 26 demonstrated failure of a fluorescent tracer to pass through gap junction channels to neighboring cells, consistent with disruption of intercellular communication.[21] Different mutations in the same gene (*GJB2*) encoding connexin 26 have also been found in a family with a mutilating palmoplantar keratoderma (Vohwinkle's disease) and deafness (without ichthyosis)[130] (discussed in Chapter 50), and a mutation in *GJB6*, the gene for connexin 30, has been demonstrated in one child with KID syndrome.[131] The identification of mutations in the genes encoding a variety of connexin proteins has highlighted the role of connexin-mediated intercellular communication through gap junctions in the development and maintenance of ectodermal tissues. Connexins 26, 30, and 31 are expressed in the stratified epithelia of the cochlea and epidermis, and abnormalities in these proteins can cause sensorineural hearing impairment and/or skin disorders.[20]

KERATOSIS LINEARIS WITH ICHTHYOSIS CONGENITA AND SCLEROSIS KERATODERMA

*K*eratosis *l*inearis with *i*chthyosis *c*ongenital and sclerosing *k*eratoderma (KLICK) syndrome (OMIM #601952) is a rare ichthyosis with palmoplantar keratoderma, constricting bands and flexural deformities of the fingers, and linear keratotic papules at the flexures. Mutations in the proteasome maturation protein gene (POMP) suggest a role for the proteasome in the process of cornification.[132]

MEDNIK

*M*ental retardation, *e*nteropathy, *d*eafness, peripheral *n*europathy, *i*chthyosis, and *k*eratodermia (MEDNIK) syndrome is an autosomal recessive disorder described in a Quebec population with a founder mutation in the *AP1S1* gene that encodes a protein involved in protein trafficking by intracellular vesicles.[133]

MULTIPLE SULFATASE DEFICIENCY

Multiple sulfatase deficiency (OMIM #272200) is a rare autosomal recessive disorder that is characterized by a deficiency of several sulfatases, which results in the accumulation of sulfatides, glycosaminoglycans, sphingolipids, and steroid sulfates in tissues and body fluids.[134] The activity of both lysosomal (arylsulfatases A and B) and microsomal (arylsulfatase C/steroid sulfatase of X-linked ichthyosis) arylsulfatases is impaired. The disorder is a composite of the clinical features of both metachromatic leukodystrophy and of a mucopolysaccharidosis. Clinical features include neurologic deterioration, skeletal abnormalities, facial dysmorphism, and ichthyosis resembling that seen in X-linked steroid sulfatase deficiency. This disorder has been proposed to be due to a defect, common to all sulfatases, in posttranslational protein modification that is required for generating a catalytically active enzyme.[135] The gene coding for sulfatase modifying factor 1 (*SUMF1*), which generates a unique amino acid derivative, C_{α}-formylglycine, necessary for catalytic activity of all sulfatases, is mutated in individuals with multiple sulfatase deficiency.[136,137]

NEONATAL ICHTHYOSIS WITH SCLEROSING CHOLANGITIS

Neonatal cholestatic jaundice and mild ichthyosis with fine, white scales are the presenting signs in the NISCH syndrome (OMIM #607626). Hypotrichosis with scarring alopecia affecting the scalp and eyebrows, enamel dysplasia and intracytoplasmic vacuoles within keratinocytes that do not stain with oil red O are also seen.[138] In addition to different staining properties, the syndrome differs from Chanarin–Dorfman syndrome in the absence of ocular or muscle findings and of fatty liver. Mutations in *CLDN1* the gene coding for claudin-1 have been identified.[139]

PEELING SKIN SYNDROME

The *peeling skin syndrome* (OMIM #270300) is an autosomal recessive disorder characterized by lifelong peeling of the stratum corneum. It may be associated with pruritus, short stature, and easily removed anagen hairs. Low plasma tryptophan levels and aminoaciduria have also been reported.[140] Traupe suggested that there are two types of peeling skin syndrome.[5] *Type A*, which is noninflammatory and asymptomatic, is characterized by generalized peeling in thin superficial flakes of differing size and shape. On electron microscopy, the *intracellular* separation occurs in the stratum corneum, within the corneocytes and not between adjacent cells. Intercellular electron-dense globular deposits representing abnormal lipids have

been observed localized to the stratum corneum.[141] An acral variant (OMIM #609796), in which peeling was limited to over the hands and feet, has been described.[142,143] Abnormal keratohyalin granules were seen by electron microscopy. Mutations in the gene coding for transglutaminase 5, a ubiquitously expressed transglutaminase with widespread expression in skin, have been identified in two families with the acral form.[143] In contrast, *type B* presents with congenital ichthyotic erythroderma and evolves into erythematous, scaling, migratory patches. This type is pruritic and may be associated with elevated levels of IgE, aminoaciduria, and short stature. The stratum corneum is easily separated mechanically from the lower epidermis, and histologically the split, which occurs *intercellularly*, is seen between the stratum corneum and the granular layer. On electron microscopy, electron-dense, irregularly vacuolated bodies have been observed in the granular layer, but observations have been variable.[144] Although the type B is clinically similar to Netherton syndrome, mutations in *SPINK5* have not been identified and the protein product of *SPINK5* is overexpressed. Human tissue kallikreins and elevated stratum corneum protease activity have been demonstrated; this is thought to result in excessive desquamation and loss of barrier function.[145] A variant, clinically similar to the inflammatory type B but with associated hair shaft abnormalities, has been described.[144]

REFSUM DISEASE

Refsum disease (heredopathia atactica polyneuritiformis; OMIM #266500) is a rare, progressive, degenerative disorder of lipid metabolism resulting from the failure to break down dietary phytanic acid and its subsequent accumulation in tissues. This autosomal recessive condition affects mostly the Scandinavians and populations originating from Northern Europe. Clinical manifestations include retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, cranial nerve dysfunction (neural deafness, anosmia), miosis, electrocardiographic abnormalities, cardiomyopathy, renal tubular dysfunction, and skeletal abnormalities (epiphyseal dysplasia). Ichthyosis, which is variable, generally develops in adulthood after the neurologic and ophthalmologic manifestations. Often there are small white scales over the trunk and extremities resembling IV. Routine hematoxylin and eosin histologic examination shows variably sized vacuoles in the epidermal basal and suprabasal cells, which correspond to lipid accumulation seen with lipid stains of frozen sections.[146]

Phytanic acid (a 20-carbon, branched-chain fatty acid) is derived from a variety of dietary sources including dairy products, ruminant fats, and chlorophyll-containing foods, although chlorophyll-bound phytol cannot be absorbed in man. Phytanic acid and other chlorophyll metabolites bind the *retinoid X receptor* (RXR), as does its natural ligand, 9-*cis*-retinoic acid, and they may be physiologically active in coordinating cellular metabolism through RXR-dependent signaling pathways[147]; however, the role of RXR in the pathogenesis of Refsum disease is unclear. The disease is caused by a deficiency of PhyH, a peroxisomal protein that catalyzes the α-oxidation of phytanic acid. This is the first step in the breakdown of phytanic acid, and PhyH deficiency leads to the accumulation of phytanic acid in the serum and tissues, where it substitutes for the fatty acids normally present. While mutations in *PAHX,* the gene encoding PhyH are responsible for most cases of Refsum disease,[148] there is genetic heterogeneity.[149] Some affected patients have mutations in the *PEX7* gene, which is the same gene mutated in RCDP (see above). Refsum disease is distinguished from infantile Refsum disease, a fulminant generalized peroxisomal biogenesis disorder in which young children present with severe neurologic abnormalities, mental retardation, hepatomegaly, and dysmorphic features in addition to the other signs of adult Refsum disease.[150]

The diagnosis can be made by detection of elevated levels of plasma phytanic acid. In children who do not have elevated plasma levels of phytanic acid, the diagnosis may be made by measuring PhyH activity in cultured fibroblasts.[147] Treatment includes dietary restriction of foods containing phytanic acid and its precursors, and can include plasmapheresis or lipapheresis. In the clinical setting of a delayed onset of ichthyosis in association with neurologic impairment, this disease should be considered since therapy can arrest progression.

RUD SYNDROME

Rud syndrome (OMIM #308200) is a poorly characterized disorder, probably of recessive inheritance, that includes epilepsy, mental retardation, infantilism, congenital ichthyosis, and retinitis pigmentosa. Steroid sulfatase deficiency has been reported in some patients. Traupe critically reviewed the literature and suggested that the clinical constellation usually labeled Rud syndrome is associated with steroid sulfatase deficiency (X-linked recessive ichthyosis) and likely reflects a heterogeneous group of disorders; because both the neurologic involvement and the ichthyosis are ill defined, the term *Rud syndrome* should be abandoned.[5]

SJÖGREN–LARSSON SYNDROME

In 1957, Sjögren and Larsson reported on 13 families from north Sweden with a syndrome of congenital ichthyosis, spastic paralysis, and mental retardation. *Sjögren–Larsson syndrome* (SLS; OMIM #270200) is a rare, autosomal recessive disorder that presents at birth with an ichthyosis that may range from fine scaling to generalized hyperkeratosis. Erythema may be present at birth but tends to gradually clear by 1 year of age. Collodion-like membranes are rarely seen. The ichthyosis manifests as fine scale, large scale, or a thickening of the stratum corneum without scale and may be pruritic. Thickened areas may be yellow to brown in color and have a lichenified appearance with

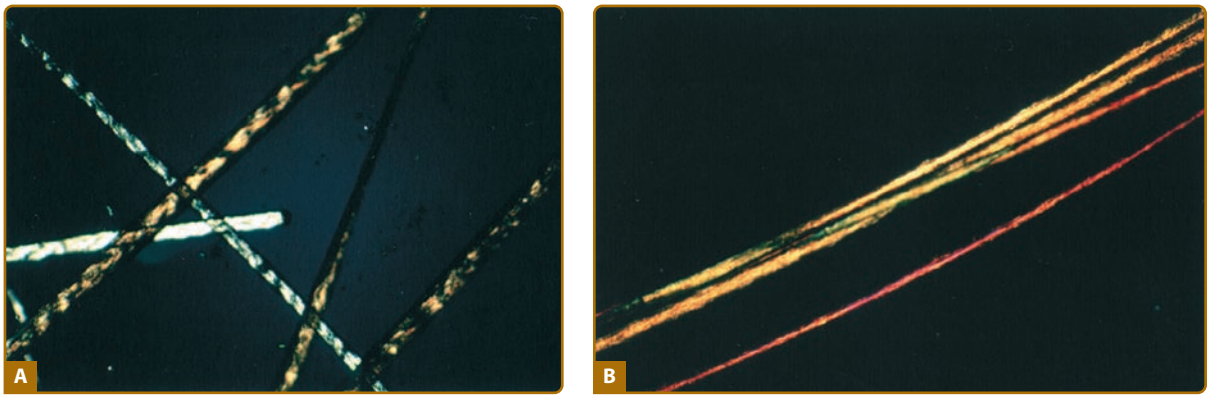

Figure 49-16 Trichothiodystrophy hair shows tiger-tail banding (**A**) under polarization, which is not observed with normal hair (**B**).

accentuated skin markings. The most involved areas are the sides and back of the neck, lower abdomen, and flexures. Hair, nails, and the ability to sweat are generally normal.[151] During the first 2 to 3 years, neurologic manifestations of spastic diplegia or tetraplegia and mental retardation develop and can be accompanied by speech defects and seizures. A characteristic ophthalmologic finding is the presence of glistening white dots in the macula of the retina; these occur after 1 year of age and may not be present in all patients. Histologic findings of hyperkeratosis, papillomatosis, acanthosis, and a mildly thickened granular layer are nonspecific. Electron-microscopic examination of the skin shows lamellar membranous inclusions in the granular and cornified cells.

Rizzo et al linked SLS to *fatty alcohol:NAD oxidoreductase* (FAO) deficiency. FAO is a complex enzyme with two separate proteins that sequentially catalyze the oxidation of fatty alcohol to fatty aldehyde and subsequently to fatty acid. Further work identified the fatty aldehyde dehydrogenase (FALDH) activity in cultured fibroblasts from patients with SLS component as the affected component of FAO in SLS. FALDH is a microsomal enzyme that catalyzes the oxidation of medium- and long-chain aliphatic aldehydes derived from metabolism of fatty alcohol, phytanic acid, ether glycerolipids, and leukotriene B4.[152] Mutations found in the FALDH gene (*FALDH*, *ALDH10*, recently renamed *ALDH3A2*) confirmed the role for this enzyme in the etiology of this disorder and the importance of this pathway for normal desquamation.[153] Most mutations are specific to families, although several common mutations suggest founder effect or favored sites for mutation.[154] The identification of decreased fibroblast FAO activity in a family with atypical cutaneous findings (lack of ichthyosis or discrete plaques rather than generalized ichthyosis) has expanded the spectrum of clinical phenotypes associated with abnormal FAO activity.[155]

TRICHOTHIODYSTROPHY

Trichothiodystrophy (TTD) (OMIM #601675) is an autosomal recessive disorder that includes a broad spectrum of clinical phenotypes linked by the characteristic features of sulfur deficient, brittle hair that exhibits tiger tail banding when viewed under polarizing microscopy (Fig. 49-16).[156] Hair shaft abnormalities include trichoschisis, trichorrhexis nodosa-like defects and ribboning[157,158] (see also Chapter 139). Patients may have photosensitivity, ichthyosis, intellectual impairment, short stature, microcephaly, characteristic facial features (protruding ears, micrognathia) recurrent infections, cataracts, dystrophic nails, and other features.[159] The spectrum of clinical involvement is broad, ranging from only hair to severe multisystem abnormalities. A survey of 112 cases reported in the literature found ichthyosis (65%) as the most common skin finding, followed by photosensitivity (42%). The photosensitivity can range from subtle to severe. Of the patients with ichthyosis, about one-third presented with a collodion membrane at birth. Collodion newborns may have an erythroderma which decreases over weeks with evolution into a generalized ichthyosis, usually without erythema, which varies from fine, translucent scaling to large, dark yellow–brown hyperkeratosis (Fig. 49-17B).[160,161] Some largely resolve and are left with mild ichthyosis. There may be flexural sparing and palmoplantar keratoderma. Nail findings are found in over half of the patients and include dystrophic nails (ridging, splitting) (Fig. 49-17A), hypoplasia, brittle nails, and koilonychia.[159] Ectropion usually does not occur.

A series of mnemonics have been used to describe the constellation of findings as BIDS (*b*rittle hair, *i*ntellectual impairment, *d*ecreased fertility, and *s*hort stature); patients who also have *i*chthyosis have been called IBIDS, and with the addition of *p*hotosensitivity, PIBI(D)S has been used.[162] However, these terms do not account for the other multisystem findings commonly present.

The majority of TTD patients have a defect in XPD (*ERCC2*). A few have mutations in XPB (*ERCC3*) or TTDA (*GTF2H5*), genes which are components of the transcription factor IIH (TFIIH) that regulates both DNA repair and transcription. Some TTD patients have mutations in *TTDN1*.[163] Although many TTD patients have photosensitivity, in contrast to xeroderma pigmentosum, these photosensitive patients have not been observed to be at high risk for the

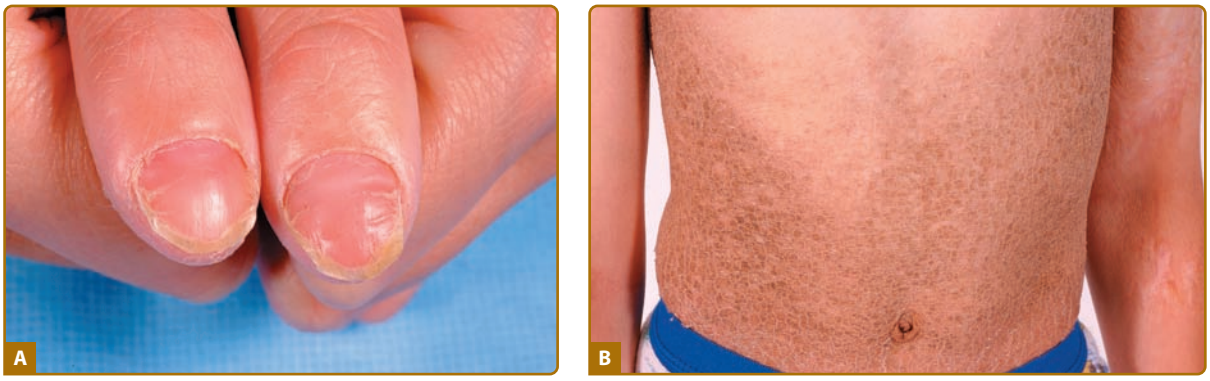

Figure 49-17 Trichothiodystrophy. **A.** The nails are thinned and brittle, with onychoschizia, cracking, and irregular transverse depressions of the dorsal surface. **B.** Skin involvement in TTD can vary from absent to severe ichthyosis. This patient has a more severe ichthyotic involvement with dark colored, adherent scale. Note involvement of the antecubital fossae.

development of skin cancer. Nucleotide excision repair is one normal cellular mechanism by which structural DNA damage (e.g., ultraviolet-induced cyclobutane pyrimidine dimers) is removed and repaired (see Chapters 110 and 139). TFIIH is involved in the initiation of transcription and also in nucleotide excision repair, and consists of a complex of proteins including the XPD and XPB proteins. In the vicinity of the damage, these two helicase subunits of TFIIH unwind the DNA in opposite directions.

ACQUIRED ICHTHYOSIS

The development of ichthyosis in adulthood can be a manifestation of systemic disease, and has been described in association with malignancies, drugs, endocrine and metabolic disease, malnutrition, HIV and other infections, and autoimmune conditions.[164,165] The granular layer is often attenuated in this disorder and the scale often resembles to that seen in mild IV. While Hodgkin disease is the most common malignancy reported with acquired ichthyosis, non-Hodgkin lymphomas and a variety of other malignancies have also been observed.[166] Histology may be diagnostic in acquired ichthyosis associated with mycosis fungoides.[167] Skin involvement may follow the course of malignancy and clear with effective cancer treatment. Acquired ichthyosis is commonly seen in association with AIDS; ichthyotic or xerotic skin has been observed in up to 30% of AIDS patients.[168] A study of HIV-1-positive intravenous drug users found acquired ichthyosis occurred only after profound helper T cell depletion, more frequently with coinfection with human T cell leukemia/lymphoma virus type II (HTLV-II), and suggested that it may be a marker for concomitant infection with both viruses.[169]

In acquired ichthyosis occurring in association with sarcoidosis, skin biopsy can be diagnostic, showing noncaseating granulomas in the dermis.[170] Acquired ichthyosis may be a marker of autoimmune disease, occurring with systemic lupus erythematosus, dermatomyositis, mixed connective tissue disease, and eosinophilic fasciitis.[171,172] It has been described in bone marrow transplant recipients, where it may be related to graft-versus-host disease.[173]

While occurrence in association with cholesterol-lowering agents (nicotinic acid, triparanol) highlights the relationship between cholesterol metabolism and normal desquamation, acquired ichthyosis has been observed with a variety of drugs, including cimetidine, clofazimine, hydroxyurea, cholesterol-lowering agents, and others.[174–178] Kava is a psychoactive beverage made from the root of a pepper plant and used for thousands of years by Pacific Islanders. Heavy kava drinkers can acquire a reversible ichthyosiform eruption called kava dermopathy. In Western nations, kava is sold in health food stores as a relaxant.[179]

PITYRIASIS ROTUNDA

Sharply demarcated, round or oval scaly patches with hypo- or hyperpigmentation are seen in *pityriasis rotunda*. Although this uncommon disorder is usually acquired, occasional familial cases have been described.[180]

RETICULATED PAPILLOMATOSIS OF GOUGEROT AND CARTEAUD

Confluent and reticulated papillomatosis of Gougerot and Carteaud is an uncommon but distinctive acquired ichthyosiform dermatosis seen in young adults and characterized by persistent brown, scaly macules, papules, patches, and plaques. Lesions tend to be localized predominantly on the neck, upper trunk (intermammary and interscapular regions), and axillae where they tend to be confluent and become reticulated towards the periphery (Fig. 49-18). The lesions bear a clinical resemblance to tinea versicolor, a skin infection with *Pityrosporum* species. A variety of treatment approaches have been reported, including topical (keratolytics, derivatives of vitamin A and D, antimicrobials) and systemic (antibiotics, retinoids) agents. Minocycline has been suggested as a first-line treatment; successful retreatment of recurrences supports the concept that this condition is an abnormal response to an infection or inflammation.[181,182]

TREATMENT

Current therapies for the inherited ichthyoses are symptomatic and focus on hydration, lubrication, and keratolysis.[183,184] Ichthyotic skin, even if thickened, has a decreased barrier function and increased transepidermal water loss. Because pliability of the stratum corneum is a function of its water content, hydration can soften the surface of the skin. In moist, humid climates, most ichthyoses improve, and mild ichthyoses (e.g., IV) may undergo extensive clearing. Moistening the skin with, for example, long baths can hydrate it. Well-hydrated areas of hyperkeratosis can more easily be thinned with mild abrasives (sponges, buff puffs, pumice stones, etc.). Addition of bath oils or application of lubricants before drying can prolong the hydration and softening. Depending on the ichthyosis and environmental conditions, individual patients may prefer specific lubricating agents, which can take the form of lotions, creams, oils, ointments, or petrolatum. In dry climates and winter months, humidifiers can be used to create a more hospitable environment.

Keratolytic agents are used to enhance corneocyte desquamation and thereby remove scale and thin hyperkeratotic stratum corneum. There are many commercially available keratolytic creams and lotions containing urea, salicylic acid, or α-hydroxy acids (e.g., lactic acid, glycolic acid). Urea may function by its capacity to bind water. Propylene glycol (40–60% in water), with or without occlusion, can also be effective in scale removal. Occlusion can effectively increase skin hydration and facilitate desquamation; it can also enhance the effect of keratolytic agents. Special care should be taken when using extensive areas of occlusion with keratolytic agents and in individuals who may be heat intolerant. Topical retinoid or vitamin D preparations may also be effective but can be irritating in some patients. The markedly impaired barrier function in ichthyosis should be considered when using topical preparations over large areas of body surface. For example, widespread use of topical salicylic acid preparations can lead to significant absorption, intoxication (e.g., nausea, tinnitus, dyspnea, hallucinations), and even death.[185] Children are at greater risk because they have a greater body surface area per unit weight than adults, a situation that effectively heightens the possibility of developing systemic toxicity from topicals. Although the use of topical retinoids in most of the ichthyoses appears to be safe,[186] the abnormal skin barrier should be considered when treating concomitant dermatoses in ichthyosis patients. Topical 0.1% tacrolimus ointment or 1% pimecrolimus cream is effective in atopic dermatitis with minimal systemic absorption. However, the atopic dermatitis of Netherton syndrome is complicated by a defective ichthyotic skin barrier. The defective barrier is associated with increased percutaneous absorption and risk for systemic toxic effects. This should be considered when using topical agents such as tacrolimus, pimecrolimus, or topical steroids, where increased systemic absorption has been observed and monitoring of serum levels may be necessary.[88,89]

Another risk to children is that in several types of ichthyosis nutritional requirements may be high, and inadequate nutrition can lead to failure to thrive. This was thought to be related to the large turnover of scale; however, recent studies suggest energy loss from impaired barrier function is the cause.[187] Some patients with ichthyosis (particularly LI and CIE) have decreased sweating with heat intolerance. It is important for the parents of a newborn with ichthyosis to be aware of the possibility of decreased sweating and to be attentive for signs of heat intolerance, such as flushing and lethargy, particularly during hot weather and, as the child grows, during exercise. Avoiding hot environments, carrying spray bottles with water to moisten the skin and cool it through evaporation, and cooling vests can minimize heat stress.

Systemic retinoid therapy with isotretinoin or acitretin (see Chapter 228) can induce dramatic improvement in many ichthyoses and is particularly useful in LI, CIE, and erythrokeratodermia variabilis. The decision to initiate systemic retinoid therapy should be weighed carefully, because once the drug is started, continued benefit usually requires chronic therapy. Treatment of the harlequin newborn with systemic retinoid therapy during the newborn period can be lifesaving due to enhanced desquamation of a constricting membrane. Retinoic acid metabolism blocking agents, which increase endogenous retinoid levels, offer a possible alternative.[188]

Fungal infections are common, both of skin and nails, and are often undiagnosed because of the generalized scaling. A high index of suspicion can help diagnose tinea corporis, capitis, or versicolor where the only symptom may be localized pruritus and the only sign a difference in the character of scale or a localized area of alopecia.

The management of EHK varies with the clinical type. Areas of thick, hard hyperkeratosis, which are not pliable and have a hard rough surface, are prone to mechanical trauma. In patients with the hystrix type of porcupine-like hyperkeratosis, the rough surface causes high traction with objects moving across the skin surface, which tend to catch on the hyperkeratotic horn and peel it off. Topical agents such as lubricants and keratolytics can reduce the thickened, rough areas and help to minimize blistering and erosion. In contrast, patients with erythroderma and peeling, who do not have the thick areas of hyperkeratotic spines, have less need for keratolytics but still need lubricants. Acute exacerbations may occur from skin infections. Bacterial infection of the skin is common, often leads to enhanced blistering, and may require frequent therapy with topical and oral antibiotics. In patients with extensive involvement, systemic retinoid therapy can be dramatically effective in decreasing the hyperkeratosis and the frequency of infections. Because these drugs can enhance blistering in EHK patients, they should be administered carefully and started at low doses.

PRENATAL DIAGNOSIS

Molecular diagnosis is preferred when possible. Alternative methods, including fetoscopy and fetal skin biopsy, are limited to later times in pregnancy, harbor a risk of fetal mortality, and are rarely performed.[189] When it is possible to do prenatal diagnosis by molecular analysis of a fetal sample, it is optimally performed early in pregnancy. This can be done with chorionic villous sampling in the first trimester (10–12 weeks after last menstrual period) or by amniocentesis in the second trimester[190] in disorders where the underlying genetic defect is known and the specific mutation in the family has been identified. Prenatal diagnosis by mutational analysis has been accomplished in a number of the ichthyoses. If a specific mutation has not been identified, in some circumstances where there is an appropriate family structure, prenatal diagnosis can be done using linkage analysis. Prenatal diagnosis of X-linked recessive ichthyosis by FISH analysis[191] and of TTD by defective DNA repair capacity[192] has been reported. In SLS, the diagnosis can be made by assay of enzyme activity in cultured amniocytes, even if the mutation in the *ALDH10* gene is undefined. Preimplantation genetic diagnosis is a reasonable alternative, and has been accomplished for many inherited disorders, including LI and EHK (S. Bale, personal communication). The procedure requires that the couple undergo in vitro fertilization to obtain embryos. The embryos are then screened by molecular methods to detect the mutation that is segregating in the family. Only those embryos that screen negative for the mutation are selected and then can be used for implantation in the uterus to achieve pregnancy. Noninvasive methods of molecular diagnosis (evaluation of fetal DNA circulating in the mother's blood) offer the potential for the future.[188] For autosomal recessive disorders where the mutation is known (e.g., LI and SLS), carrier detection may be performed for at-risk relatives.

The Foundation for Ichthyosis and Related Skin Types provides support and information for affected individuals, family members, friends, and health care providers. (FIRST, Tel: 800-545-3286; http://www.firstskinfoundation.org/; e-mail: info@ firstskinfoundation.org.)

GeneTests (http://www.genetests.org/) provides disease reviews, genetic testing resources, and educational materials.

Online Mendelian Inheritance in Man, OMIM, (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM) (trademark Johns Hopkins University), a catalog of human genes and genetic disorders, is a useful reference with links to additional resources.

The National Registry for Ichthyosis and Related Disorders is a resource for investigators to improve diagnosis and treatment of these disorders (University of Washington, Dermatology, Box 356524, 1959 NE Pacific St., Seattle, WA 98195-6524 Tel: 1-800-595-1265; http://www.skinregistry.org/; e-mail: info@skinregistry.org).

Chapter 50 :: Inherited Palmoplantar Keratodermas

:: Mozheh Zamiri, Maurice A. M. van Steensel, & Colin S. Munro

INHERITED PALMOPLANTAR KERATODERMAS AT A GLANCE[1–8]

- Palmoplantar keratoderma (PPK) is chronic and pathological thickening, predominantly due to hyperkeratosis, of the hairless skin of palms and soles.
- PPK may be acquired in inflammatory skin diseases such as eczema, psoriasis, and lichen planus, and has been reported as a paraneoplastic phenomenon.
- Genetically determined PPKs are a heterogeneous group of individually rare disorders inherited by a variety of mechanisms or occurring sporadically.
- PPK may form part of ectodermal syndromes or be associated with other systemic anomalies. Important associations of specific PPKs include cardiomyopathy, impaired hearing, neuropathy and neurodevelopmental defects, and esophageal cancer.
- The mechanisms of inherited PPK include altered differentiation arising from defects in synthesis, distribution or function of structural components such as intermediate filaments, desmosomes and gap junction proteins, or altered inflammatory responses.
- The severity of palmoplantar hyperkeratosis varies from inconvenience to major functional and social disability. Plantar pain in focal keratoderma is one of the most debilitating features, with hyperhidrosis and secondary dermatophyte infection contributing to symptoms.
- Treatment is unsatisfactory, as it relies largely on physical treatments and appropriate foot care, but oral retinoids are of value in some cases.

EPIDEMIOLOGY

Inherited palmoplantar keratodermas are individually rare; the prevalence of epidermolytic keratoderma in Northern Ireland was 4.4 per 100,000.[9] Autosomal recessive keratodermas may occur with locally high prevalence in sequestered populations or communities amongst whom consanguineous union is common.

ETIOLOGY AND PATHOGENESIS

Palmoplantar skin is structurally specialized,[10] with absence of hair and increased epidermal thickness and rugosity, features necessary to cope with increased friction and mechanical stress. Dermatoglyphics together with eccrine sweat also enhance grip. Localized palmoplantar hypertrophy (callus) is a physiological response to sustained friction, for example, from ill-fitting footwear or manual work. In the inherited PPKs, excessive epidermal thickening is the result of a broad range of pathogenic pathways.

Many keratodermas are associated with defects of keratinocyte structure. The major structural component of keratinocytes is the 10-nm (intermediate) filament cytoskeleton. Keratins are a family of rod-like proteins, expressed in pairs in a tissue and differentiation specific manner, which initially dimerize then assemble to form multimeric intermediate filaments.[7] Defects in individual keratins affect skin in a distribution corresponding to the expression pattern of the particular keratin.[3] Keratin 9 (K9) is specific to palmoplantar skin, although its likely partner in these sites, keratin 1, is also expressed in hair-bearing skin. Other keratins constitutively or facultatively expressed in palmoplantar skin include K6, K16 (also found in mucosa, hair follicles, and nail bed), and K17 (hair follicles and nail bed[11]). There are multiple K6 isoforms,[12,13] and defects in K6a, K6b, and K6c as well as all the other keratins named above can result in keratoderma. The majority of pathogenic mutations in keratins occur in the highly conserved boundary peptides of the α-helical rod domain regions, which are thought vital for end-to-end overlap interactions during the elongation phase of filament assembly.[3] Typically, keratin defects result in a disrupted intermediate filament cytoskeleton. The intermediate filament network is attached to desmosomes, intercellular junctions which in turn form paired plaques with the corresponding structures in adjacent keratinocytes. Defects in desmosomal proteins such as desmoglein 1, desmoplakin 1, plakoglobin, and plakophilin 1 also cause PPK.[6] Structural weakness due to keratin and desmosome defects has the potential to cause epidermolysis or acantholysis of keratinocytes, of which hyperkeratosis may be an indirect consequence, but nonmechanical mechanisms are also probable. Keratins, for example, are also involved in the regulation of proliferation, apoptosis, and skin pigmentation.[14,15] Moreover, cell stress as a nonspecific response to an accumulation of misfolded proteins may contribute to pathogenesis. Mechanically stressed keratinocytes containing mutant keratins of the type which cause severe epidermolysis bullosa simplex show greater resistance to apoptosis than wild-type keratinocytes; the increased resistance was dependant on an increase in extracellular signal-regulated kinase (ERK) and Akt signaling.[16] Keratoderma in tyrosinemia type II may be also due to tonofilament accumulation secondary to excessive intracellular tyrosine.[17]

Another large group of PPK syndromes are due to defects in connexins, the proteins that make up gap junction communication channels between cells.[5] Gap junctions are assembled in plaques containing multiple connexon units, each of which consists of a pair of hemichannels with a central channel through which small molecules (<1 kDa) can pass between the cytoplasm of adjacent cells. Each hemichannel in turn contains six homomeric or heteromeric connexin proteins. The 21 human connexin proteins, like keratins, are expressed in a tissue and differentiation specific manner and the phenotype of gap junction diseases in part reflects their expression pattern. For example, most mutations in the gene (*GJB2*) encoding connexin 26 (Cx26) cause impaired hearing because the gene is expressed in the inner ear where it is necessary for the circulation of endolymph. Cx26 is also expressed in skin, and some Cx26 defects also cause a cutaneous phenotype, such as PPK. PPK is also found in syndromes due to mutations affecting connexin 30 (Cx30, associated with hidrotic ectodermal dysplasia[18,19]) and connexin 43 (Cx43; oculo-dental digital dysplasia[20]). However, point mutations in a single connexin can cause a range of phenotypes depending on the specific amino acid affected. While some pathogenic mutations interfere with the formation of functional gap junctions, others exhibit defects in trafficking to the cell membrane and the connexins instead accumulate within organelles.[21] Recent evidence in erythrokeratoderma variabilis (EKV) suggests that accumulation of mutant proteins causes the unfolded protein response.[22] In the case of connexin mutations associated with palmoplantar keratoderma, this endoplasmic reticulum stress may be responsible for hyperkeratosis and inflammation.

Other mechanisms of PPK are extremely varied. In loricrin keratoderma, a barrier abnormality is associated with a defective CE scaffold that results in increased extracellular permeability defect.[23] The *C*-terminal peptide of the mutant loricrin includes polybasic nuclear recognition signals which cause the aberrant protein to accumulate in the nucleus, which is likely to interfere with terminal differentiation.[24–26] In Papillon–Lefèvre syndrome (PLS), in which PPK is associated with predisposition to pyogenic infection, the cysteine protease cathepsin C is inactive.[27] This lysosomal enzyme is important in intracellular protein degradation[28] and in the activation of neutrophil serine proteases.[29] Its absence may have consequences for the regulation of inflammation,[30] but the mechanism of keratoderma may also relate to aberrant desmosomal cleavage. In Mal de Meleda, a secreted nicotinic acetylcholine receptor ligand, SLURP-1, is deficient. The normally expressed protein may act by modulating

keratinocyte behavior or inflammatory responses.[31–33] Keratoderma is a feature of rare neurodevelopmental syndromes due to defective intracellular vesicle trafficking,[34,35] and of keratosis linearis with ichthyosis congenita and sclerosing keratoderma (KLICK) syndrome where there is a defect in proteasome production.[36]

Known gene defects causing keratoderma are listed in Table 50-1.

TABLE 50-1
Gene Defects in Syndromes Which Include Palmoplantar Keratoderma

Presentation (Syndrome)	Inheritance	Gene(s)/Locus	Protein(s)
Epidermolytic PPK (Vörner)	AD	*KRT9*	Keratin 9
Transgredient epidermolytic PPK	AD	*KRT1*	Keratin 1
Diffuse NEPPK (includes Unna–Thost)	AD	*KRT1*	Keratin 1 (V1 domain)
Ichthyosis hystrix	AD	*KRT1*	Keratin 1
Focal nonepidermolytic PPK	AD	*KRT16, KRT6c*	Keratin 6c, 16
Pachyonychia congenita type 1	AD	*KRT6a, KRT16*	Keratin 6a, 16
Pachyonychia congenita type 2	AD	*KRT6b, KRT17*	Keratin 6b, 17
Ectodermal dysplasia/skin fragility syndrome	AR	*PKP1*	Plakophilin 1
Striate PPK	AD	*DSG1, DSP, KRT1*	Desmoglein 1, Desmoplakin 1, Keratin 1
Keratoderma with cardiomyopathy and wooly hair (Carvajal–Huerta and others)	AR/AD	*DSP*	Desmoplakin 1
Keratoderma with ARVC and wooly hair (Naxos)	AR	*JUP*	Plakoglobin
Keratoderma with hearing loss (Vohwinkel, Bart–Pumphrey, and others)	AD	*GJB2, GJB6*	Connexin 26, 30
Keratitis/Hystrix, ichthyosis, and deafness (KID/HID)	AD	*GJB2*	Connexin 26
Hidrotic ectodermal dysplasia (Clouston)	AD	*GJB6*	Connexin 30
Erythrokeratoderma variabilis	AD/AR	*GJB3, GJB4*	Connexin 31, 30.3
Oculo-dento-digital dysplasia (of the face, eyes, skeletal system, heart, and dentition)	AD	*GJA1*	Connexin 43
Mitochondrial keratoderma with hearing loss	Mito	*MSST1*	Serine transfer RNA
Loricrin keratoderma	AD	*LOR*	Insertion mutation in Loricrin
Keratoderma and periodontitis (Papillon–Lefèvre and Haim–Munk)	AR	*CTSC*	Cathepsin C
Mal de Meleda	AR	*ARSB*	SLURP-1
Tylosis with Oesophageal carcinoma (Howel-Evans)	AD	*RHBDF2*	Inhibitor of active rhomboid protease *RHBDL2*
Odonto-onycho-dermal dysplasia (includes Schöpf–Schultz–Passarge)	AR	*WNT10a*	Signaling molecule implicated in development
Tyrosinemia type 2 (Richner–Hanhart)	AR	*TYR1*	Tyrosinase
KLICK	AR	*POMP*	Proteasome maturation protein
CEDNIK	AR	*SNAP29*	SNARE protein involved in vesicle fusion
MEDNIK	AR	*AP1S1*	Subunit σ1A of adaptor protein-1 complex
Mapped Disorders			
Sclerotylosis (Huriez)	AD	4q23	
Diffuse NEPPK (includes Unna–Thost)	AD	12q11–13	
Punctate PPK	AD	15q22.2–15q22.31	

AD = autosomal dominant; AR = autosomal recessive; ARVC = arrhythmogenic right ventricular cardiomyopathy; CEDNIK = cerebral dysgenesis, neuropathy, ichthyosis, keratoderma; KLICK = keratosis linearis with ichthyosis congenita and sclerosing keratoderma; MEDNIK = mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis, keratoderma; NEPPK = nonepidermolytic PPK; PPK = Palmoplantar keratoderma; SLURP1 = Secreted LY6/uPAR domain containing protein 1; SNAP29 = Synaptosomal-associated protein 29kD; WNT10A = wingless-type MMTV integration site family member 10a.

CLINICAL FINDINGS

Clinical findings vary between different genetic forms of PPK. The hyperkeratosis may present as multiple papular lesions (punctate PPK), as callosities localized to points of particular stress (focal/areate, or striate PPK) or may extend over the whole palm or sole (diffuse PPK). The distinction between focal, striate, and diffuse forms is not always easy to make, and the severity of PPK may vary, even within a family. Hyperhidrosis is a common complaint amongst patients with focal or diffuse keratodermas. Corynebacterial overgrowth leading to keratolysis and malodor, and secondary dermatophyte infection, is common. Transgredient keratoderma extends onto the dorsa of the hands and other cutaneous sites; circumferential keratoderma of digits is associated with the formation of constricting bands ("pseudoainhum," see Chapter 68) and sometimes autoamputation (cicatrizing or mutilating keratoderma). It may also cause tapering of the digits (sclerodactyly) with bony atrophy and nail dystrophy. A number of keratoderma syndromes, in particular Huriez and Olmsted syndromes (see below) are characterized by the frequency of squamous cell carcinoma in affected skin; melanoma has also been reported in various PPKs.

APPROACH TO THE PATIENT WITH KERATODERMA

In the history, early age of onset is usual. Punctate keratodermas present in adulthood, but new presentations of diffuse PPK at this age are more likely to be papulosquamous disorders (see Section "Differential Diagnosis"). In inherited PPKs, hyperhidrosis is commonly reported. Pain is a particular feature of focal keratodermas, but in all forms of keratoderma functional, occupational, or social disability should be recorded. A family history, including consanguinity, may be helpful but it is unwise to draw firm conclusions about either clinical type or inheritance patterns without having examined all available members of a pedigree, even if said to be affected. Family history of early onset systemic malignancy or skin cancer should be noted.

The distribution of keratoderma (punctate, focal, striate, or diffuse) is not an absolute guide. Feet tend to be more markedly and diffusely involved, so that in severe cases the underlying pattern may be more obvious on the hands. The appearance of the hyperkeratosis—for example, honeycomb patterned, waxy, or fissured—may be significant. Sharp, livid margins or the presence of transgredient hyperkeratosis on dorsa of hands, feet, and digits should be noted. The possibility of secondary fungal or bacterial infection, and of the development of malignancy, should be considered. It is important to examine the whole skin for signs of other skin diseases such as eczema, psoriasis, and lichen planus. In inherited PPK, mild acral hyperkeratosis may indicate a generalized cutaneous disorder that is locally severe on palms and sole; fissures at the oral commissures and follicular hyperkeratosis are also common. Mild ichthyosis seen in loricrin PPK may be missed if not specifically sought. Many PPKs involve mucosa, including genital mucosa. The presence of other ectodermal abnormalities should be documented, i.e., abnormalities of nails, teeth, hair and hair follicles, sweat glands, and sweating. Finally, specific features associated with syndromic keratoderma should be elicited by history and examination. These include hearing impairment (which may be subtle), neuropathy, and cardiac disease (conduction defects or cardiomyopathy).

A pathway to aid diagnosis (Fig. 50-1) is provided, but is neither comprehensive nor absolute. Individual presentations are discussed in more detail below.

KERATODERMAS WITH MAINLY CUTANEOUS FEATURES

PUNCTATE KERATODERMA. Punctate keratoderma (Buschke–Fischer–Brauer syndrome; MIM 146800) is usually inherited as an autosomal dominant trait.[37] Unlike most other inherited PPKs, punctate PPK presents in adult life as multiple keratinizing papules (Fig. 50-2A). It may be an incidental finding, although plantar lesions can produce significant disability and also cause secondary focal keratoderma. From the gradual accumulation of discrete individual lesions it may be inferred that there is a defect in one inherited allele, and the disease is expressed when the remaining allele is damaged. An association with malignancy of kidney, stomach, breast, and colon, has been reported in a few pedigrees,[38,39] but has not been generally substantiated. In any case, the condition is probably genetically heterogeneous. The size of the papules in different families varies from a few millimeters to tiny filiform lesions (music-box spine keratoderma) (see eFigs. 50-2.1 and 50-2.2 in online edition). Similarly, histology of the lesions may show orthokeratotic or parakeratotic hyperkeratosis. At least two genetic loci have been suggested[40,41] although that at 15q22.2–15q22.31 is most certain. Other clinically similar conditions include punctate keratoderma of the palmar creases, and focal acral hyperkeratosis of the margins of palms and soles, with or without elastoidosis. Papular palmoplantar lesions may be seen in other genodermatoses, notably Darier disease (see Chapter 51), in which the pitted lesions common in younger cases become papular with age. Acquired causes of punctate palmoplantar lesions include dioxin toxicity and chronic arsenicism.

EPIDERMOLYTIC KERATODERMA. An example of uncomplicated diffuse keratoderma is epidermolytic PPK (EPPK; Vörner syndrome; MIM 144200). EPPK is probably the commonest PPK,[9] and is an autosomal dominant trait due to defects in keratin 9, the one keratin specific to palmoplantar skin.[42] It presents in childhood as diffuse PPK with a sharp, livid transition to normal skin at the edge of palms and soles (Fig. 50-2C; see also eFig. 50-2.3 in online edition). Severe cases may be accompanied by blistering,

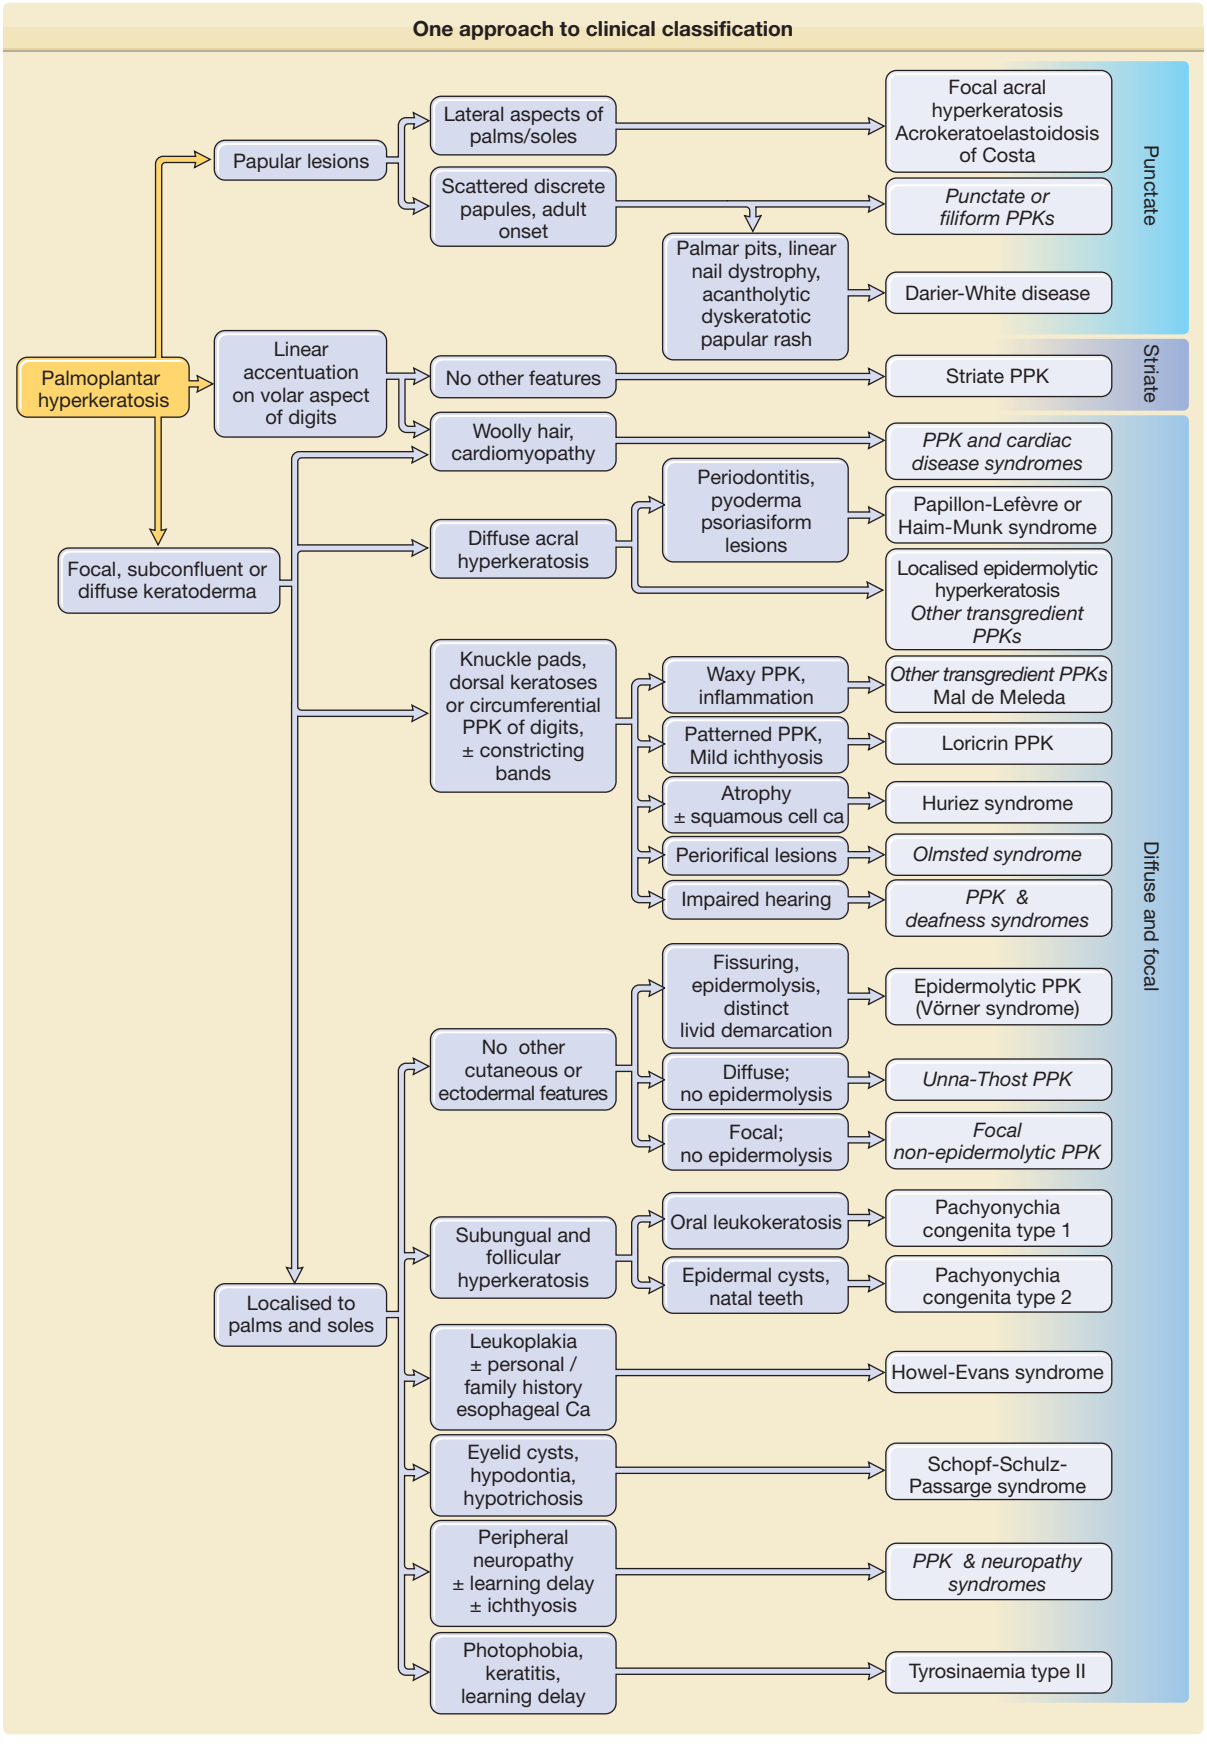

Figure 50-1 One approach to clinical classification. Diagnoses shown in italics are pragmatic groups rather than genetically defined syndromes (see text). It is unwise to use the pattern of keratoderma (i.e., papular, focal, striate, diffuse) as the primary means of classification, since this can vary even within families. It is a good principle to look for ectodermal and syndromic associations in all new cases.

Figure 50-2 Patterns of familial keratoderma. **A.** Punctate, which usually does not appear until adulthood. The lesions have been accentuated by immersion in water for a few minutes. **B.** Striate, often due to desmosomal disorders. **C.** Diffuse, in this case with fissuring and the sharp demarcation typical of keratin 9 defects. **D.** Focal, seen as an isolated finding due to keratin 6c mutations. In practice the distinction between these patterns may not be clear, especially on plantar skin.

although in adults the epidermal weakness is more commonly manifested by fissuring. Histology of the stratum spinosum shows vacuolated keratinocytes with keratin filament aggregates at electron microscopic level, accompanied by orthohyperkeratosis of the stratum corneum. Defects in keratin 1, the presumed partner of keratin 9 in palmoplantar skin, also cause diffuse transgredient keratoderma with epidermolytic hyperkeratosis at other cutaneous sites, but extrapalmoplantar involvement may be subtle (see eFig. 50-2.4 in online edition). A specific defect of the 1B domain of keratin 1 causes tubular tonofilament structures to form in some pedigrees.[43] Keratoderma may also be a feature of epidermolysis bullosa of the severe Dowling–Meara type (MIM 131760; [44]) due to mutations in the basal layer keratins 5 and 14 (see Chapter 62). The mechanism(s) by which keratin gene defects may give rise to the palmoplantar hyperkeratosis are discussed above.

NONEPIDERMOLYTIC DIFFUSE PPK. Nonepidermolytic diffuse PPK restricted to palmoplantar skin is heterogeneous. The term Unna–Thost syndrome (MIM 600962) should probably be discarded, as even the original Thost family in fact had epidermolytic PPK.[45] In one pedigree a diffuse nonepidermolytic phenotype was due to a defect in the variable region of the keratin 1 gene,[46] and in another was mapped to a locus including the type II keratin gene cluster.[47] Another locus proximal to the type II keratin gene cluster has been identified.[48]

FOCAL PPK. Focal PPK (see Fig. 50-2 and eFig. 50-2.5 in online edition) may complicate punctate PPK on the feet, or may occur in isolation; in the latter situation it may be difficult to distinguish from physiological callosities, and indeed the tendency to these may have a genetic basis.[49] Early onset focal keratoderma of whatever cause leads to disability ("hereditary painful callosities"), and patients may be so severely affected as to become wheelchair bound. Autosomal dominant pedigrees of focal PPK are commonly associated with nail dystrophy and mucosal features as part of the pachyonychia spectrum, but even in the absence of nail dystrophy may be due to mutation in keratin 16.[50] In the majority of cases of focal PPK in isolation, genetic causes have not been identified, but in three pedigrees it has been ascribed to mutations in keratin 6c.[49] Painful focal PPK is also found in tyrosinemia type II (see below and Chapter 131).

STRIATE PPK. Striate PPK (SPPK; MIM 148700) is a distinct variant of focal PPK in which there is prominent linear involvement of the volar surfaces of the digits (see Fig. 50-2B) and less distinctly of corresponding areas of the soles. Histology of autosomal dominant inherited striate PPK shows subtle widening of the intercellular spaces (see Fig. 50-5C). [51,52] Most cases

are due to defects in gene encoding desmosomal plaque proteins of which desmoglein 1 (*DSG1*) is most commonly implicated, but mutations in desmoplakin 1 are also reported.[53,54] Keratoderma due to defects in these genes is believed to be due to haploinsufficiency, i.e., reduced amounts of the relevant structural protein expressed in the desmosomal plaque result in mechanical weakness which manifest at points of greatest stress. However, as with keratins, demosomal components are implicated in intracellular signaling and growth regulation. Striate PPK may also be seen with some mutations in keratin 1,[55] and indeed striate accentuation is a nonspecific component of milder diffuse keratodermas. Most cases of autosomal dominant SPPK are simple, but defects in desmoplakin also give rise to syndromes of cardiomyopathy and wooly hair (see below).

LORICRIN KERATODERMA. Loricrin keratoderma (syn. Camisa syndrome; MIM 640117) was described as a variant of Vohwinkel syndrome (VS).[56] It is characterized by a similar "honeycomb" patterned and transgredient keratoderma (Fig. 50-3A; see also eFig. 50-3.1 in online edition), leading to circumferential digital involvement, cicatrizing bands, and sometimes autoamputation. However, there is also a mild generalized ichthyosis, and collodion babies or generalized desquamation at birth are reported.[57,58] Compared with true VS, due to mutations in Cx26, the edge of the keratoderma at the wrists is diffuse, and deafness is not a feature. Multiple mutations are reported of which the most frequent mutation, *730insG*, has been found in families from the United Kingdom, Japan, Germany, and Italy.[24,57,59–64] In all cases they are single nucleotide insertions resulting in a shift of the reading frame and a termination codon delayed by 22 amino acids. In the elongated carboxyl-terminal domain many of the glycine residues are replaced by arginine, drastically altering the properties of the loricrin polypeptide by producing nuclear recognition signals (see above).

HURIEZ SYNDROME. Huriez syndrome (PPK with scleroatrophy, sclerotylosis; MIM 181600), an autosomal dominant disorder, is characterized by diffuse PPK that affects mainly palmar skin (Fig. 50-3C).[65–70] The underlying gene defect is unknown but linkage to chromosome 4q23 has been reported.[71] Sclerodactyly,

Figure 50-3 Rare forms of transgredient PPK. **A.** Patterned keratoderma in a case of loricrin PPK; note circumferential keratoderma and early constricting bands. **B.** Confluent papules in Vohwinkel PPK with impaired hearing due to connexin 26 mutations; honeycomb lesions and circumferential PPK with constricting bands also occur in this syndrome. **C.** Huriez syndrome (sclerotylosis), which carries a high risk of squamous cell carcinoma. (Used with permission from Dr. Cameron Kennedy, Bristol Royal Infirmary, United Kingdom.) **D.** Mal de Meleda due to mutations in ARS component B, with a waxy hyperkeratosis, sclerodactyly, and constricting bands.

brachydactyly, and cutaneous erythema and/or atrophy are typical, as are various nail changes; hypohidrosis is also reported. A deficiency of Langerhans cells in affected skin has been identified.[72] The condition predisposes to squamous cell carcinomas of affected skin, occurring in the third to fourth decade, which are unusually prone to metastasis.[67,68] Causal treatment is not available, but benefit from oral retinoids is recorded.[67]

MAL DE MELEDA. Mal de Meleda (MIM 248300) is a rare autosomal recessive disorder originally described in communities of the Mediterranean littoral. The transgredient (i.e., it extends over the lateral margin of the palms and proximally over the wrists) hyperkeratosis has a waxy ivory to yellow appearance and is typically inflamed or macerated, with a livid margin.[73] Dermatophyte superinfection, to which many keratodermas are prone, may mimic these appearances. Knuckle pads, similar waxy lesions on acral sites, angular cheilitis, and circumferential sclerosing and cicatrizing lesions of the digits are typical (Fig. 50-3D; see also eFig. 50-3.2B in online edition); not surprisingly nails are often dystrophic. The typical Mediterranean disorder is due to mutations in the *ARSB* gene encoding SLURP-1, an acetylcholine receptor analog.[31,74,75]

OTHER TRANSGREDIENT KERATODERMAS. Recessive transgredient and/or mutilating disorders with phenotypes resembling Mal de Meleda are reported,[76,77,78,79,80] but appear to be genetically distinct. A very rare autosomal recessive disorder (KLICK syndrome) has been described in which a cicatrizing PPK is associated with ichthyosis and a bizarre striate hyperkeratosis of flexures.[81,82] This has recently been shown to be due to defects in *POMP* which encodes a protein which is a chaperone for proteasome maturation.[36] Similarly, pedigrees of autosomal dominant transgredient PPKs have been described. The term Greither syndrome has been used,[2,83,84] but may not be a single entity.[85] Some autosomal dominant transgredient keratodermas within this spectrum are due to mutations in keratin 1 (Fig. 50-4A),[86] but other such pedigrees, for example, Sybert syndrome[87] appear not to be keratin disorders.

KERATODERMAS WITH ECTODERMAL DYSTROPHY

PACHYONYCHIA CONGENITA. Pachyonychia congenita (PC) is a spectrum of dominantly inherited disorders associated with focal PPK. In addition to painful focal PPK and hypertrophic dystrophy of the distal nail, there are numerous reported associations[88] (see eFig. 50-4.1 in online edition). Two main syndromes are recognised clinically,[89] in which various associated features can cause significant additional morbidity and disability. PC-1 (Jadassohn–Lewandowsky; MIM 167210) is associated with follicular keratoses, oral leukokeratosis and hoarseness. Severe oral lesions can resemble mucosal candidiasis[90] and laryngeal involvement may produce infantile respiratory obstruction.[91] The rarer PC-2 (Jackson–Lawler; MIM 167210) is distinguished by multiple pilosebaceous cysts, teeth present at birth, and hair changes such as protuberant eyebrows. Extensive and infected flexural, vulval or scrotal cysts can present as hidradenitis suppurativa.[92] PC-1 is typically associated with mutations in *KRT6A* or *KRT16* and PC-2, with mutations in *KRT6B* or *KRT17*, reflecting the expression patterns of the

Figure 50-4 The pattern of plantar PPK is often not diagnostic. **A.** Diffuse fissured PPK due to mutation in keratin 1 but with only localized epidermolytic hyperkeratosis of elbows, knees and flexures. **B.** Similar changes in Papillon-Lefèvre syndrome due to mutation in Cathepsin C. (Used with permission from Barts and the London NHS Trust, United Kingdom.) **C.** Howel–Evans syndrome (PPK with familial esophageal carcinoma) showing subconfluent keratoderma sparing the instep. **D.** Similar changes due to an insertion mutation in keratin 1. **E.** Focal PPK with impaired hearing due to *A7445G* mutation in mitochondrial DNA.

relevant keratins[3]: for example K16 is a major secondary keratin in orogenital epithelia. Severity varies within and between families, and incomplete phenotypes such as PPK without nail dystrophy or steatocystoma multiplex without PPK may be caused by mutations in the same genes. However, detailed analysis of patients with *KRT16* mutations suggests that mutations which predict a more disruptive effect on K16 protein structure produce a more severe phenotype.[93] A recent large study casts doubt on the consistency of the association of clinical syndrome and mutated keratin[94] and it has been proposed instead that PC be designated according to the affected keratin—PC-6a, PC-6b, etc. and PC-U (unknown).[95] Genotypic classification has the aim of individualising targeted molecular therapy, already promising in this disorder.[8]

SCHÖPF–SCHULZ–PASSARGE SYNDROME.

Schöpf–Schulz–Passarge syndrome (SSPS[96]; MIM 227450) appears to be allelic with onycho-odontodermal dysplasia (OODD; MIM 257980), a spectrum of autosomal recessive ectodermal dysplasias with a core phenotype of abnormal nails, oligodontia with abnormal teeth, and hypotrichosis.[97] Dental anomalies may occur in heterozygotes. Features in addition to palmoplantar keratoderma (see eFig. 50-4.2 in online edition) include erythematous facial lesions and atrophic lingual papillae. In SSPS, patients commonly develop benign adnexal tumors. Apocrine hydrocystoma, presenting as eyelid cysts is characteristic of SSPS: eccrine poroma and syringofibroadenoma also occur.[98] Squamous and basal cell carcinomas and porocarcinomas are reported in affected skin. Disorders within the OODD spectrum are due to mutations in *WNT 10a*[97,99–101]; the protein encoded by this gene is a member of a family of secreted signaling molecules which inhibit degradation of the β-catenin complex and hence allow it to modulate gene expression. WNT signaling is important in many developmental pathways, and WNT10a is implicated in dental and hair follicle morphogenesis, and the formation of ectodermal ridges.

OLMSTED SYNDROME.

Olmsted syndrome (mutilating palmoplantar keratoderma with periorificial plaques,[102–105]) is a severe disorder. Congenital diffuse, sharply demarcated, and progressive keratoderma of palms and soles causes flexion deformities, constrictions, autoamputation, and obliteration of digits. Periorificial keratoses are characteristic but associated symptoms include a variety of nail dystrophies and hypotrichosis. The disease usually manifests within the first 6 months of life and is progressive. A number of patients have developed squamous cell carcinoma in affected skin. The genetic basis is unknown. Most cases are sporadic but it may be autosomal dominant. In children, the disorder must be distinguished from recessive transgredient PPKs including Mal de Meleda and, because of the periorificial keratoses, acrodermatitis enteropathica.

OTHER ECTODERMAL SYNDROMES WITH KERATODERMA.

PPK is found in the Naegeli–Franceschetti–Jadassohn syndrome (MIM 161000) and dermatopathia pigmentosa reticularis (MIM 125595), allelic syndromes due to dominant mutations in the nonhelical E1/V1 domains of keratin 14.[106] Other features include absent dermatoglyphics, reticulate pigmentary anomalies, hypohidrosis, and other subtle ectodermal defects. PPK also occurs with keratin 5 and 14 defects in the severe Dowling–Meara form of epidermolysis bullosa simplex[44] in Kindler syndrome, due to mutations in *FERMT1* encoding kindlin-1, a cell adhesion molecule involved in signaling via the actin filament network,[107] and in ectodermal dysplasia with skin fragility due to defects in the desmosomal protein plakophilin 1.[54] PPK is found in hidrotic ectodermal dysplasia (Clouston syndrome, MIM 129500), due to mutations in *GJB6* encoding connexin 30 (Cx30, see Chapter 142),[18] which can mimic PC,[108] and in oculodento-digital-dyplasia (ODDD; MIM 164200) due to mutations in *GJA1* encoding Cx43.[20] Similarly, PPK may be part of the presentation of erythrokeratoderma variabilis (MIM 133200; Chapter 49) which is due to mutations in *GJB3* or *GJB4*.[4]

OTHER KERATODERMAS WITH ORAL OR MUCOSAL FEATURES

HOWEL–EVANS SYNDROME.

Howel–Evans syndrome [Tylosis and (o)esophageal cancer, TOC; MIM 148500] is an exceptionally rare autosomal dominant disorder; only a few families are known. In the original report by Howel–Evans et al,[109] 18 of 48 individuals who had PPK developed squamous cell carcinoma of the esophagus at an average age of 43 years. Palmoplantar hyperkeratosis appeared on average 30 years earlier. The keratoderma is characterized by thick yellow focal hyperkeratosis most prominent on the pressure sites (Fig. 50-4C; see also eFig. 50-4.3 in online edition).[110] Pain is not a major feature, and the palms are only involved in manual workers. Confluent hyperkeratoses over pressure sites on the feet may lead to more diffuse involvement. Oral leukoplakia precedes plantar lesions in children. Follicular hyperkeratosis also occurs and the major differential distinction to be made is with PC or focal PPK with oral leukokeratosis. In the latter disorders, nail abnormalities are usually present, although sometimes subtle. The disorder has long been mapped to chromosome 17q25.[111] Causative mutations have recently been found in RHBDF2.[112] This inactive member of the rhomboid family of intramembrane serine proteases may normally inhibit an active rhomboid protease; mutations may interfere with epidermal growth factor and EphrinB3 signalling.

PAPILLON–LEFÈVRE SYNDROME.

PLS (PPK with periodontitis, MIM 245000) is an autosomal recessive disorder caused by mutations in the *CTSC* gene coding for the proteolytic enzyme cathepsin C.[27,113] PLS is characterized by a diffuse palmoplantar erythematous and fissured hyperkeratosis (Fig. 50-4B) with transgredient erythema, and peridontitis.[114] If untreated, deciduous teeth may be lost by the age of 4–5 years, and subsequently, permanent dentition may

also be lost. Redness and thickening of the palms and soles usually occur in the first years of life, coincidental with eruption of the deciduous teeth.[115] Typically, PLS patients show scaly erythematous psoriasiform lesions over knees, elbows, and interphalangeal joints. Transverse ridging of nails, onychogryphosis, sheeted follicular hyperkeratosis and a subtle, generalized white opalescence of oral mucosa, and dural calcification, have also been reported. Associated plantar hyperhidrosis can cause malodor. Patients are susceptible to skin infections (with *Staphylococcus aureus*) and pyogenic liver abscesses.[116] Loss of permanent dentition will lead to improvement of the periodontitis, but patients benefit greatly from adequate dental hygiene and care. Haim–Munk syndrome (HMS, MIM 245010) is allelic with PLS,[117] but is a distinct disorder which appears to have arisen in the Jewish population of Kochi, Kerala, India. In HMS, the features are more severe and extensive, and there are additional manifestations of arachnodactyly, acroosteolysis, atrophic nails, and pes planus. The recently described autosomal dominant hypotrichosis–acro-osteolysis–onychogryphosis–palmoplantar keratoderma–periodontitis (HOPP) syndrome combines periodontitis, acro-osteolysis, and psoriasiform skin lesions with a unique focal or reticular keratoderma and progressive scarring alopecia[118,119]; *CTSC* mutations have been excluded in the three reported cases.

KERATODERMAS WITH CARDIAC DISEASE

NAXOS DISEASE. Naxos disease (MIM 601214), first reported in pedigrees from the eponymous Greek island, is an autosomal recessive disorder.[120] Patients have a diffuse, gray–yellow fissuring but nonepidermolytic keratoderma, wooly hair, and arrhythmogenic right ventricular cardiomyopathy (ARVC) causing heart failure and sudden death. The disease is due to homozygosity for a deletion mutation in the gene for the desmosomal plaque protein junctional plakoglobin (JUP), which causes a frameshift and premature termination of the protein.[121] More than 90% of homozygous individuals have electrocardiographic abnormalities (mostly T wave inversion in V1–V3 leads), associated with arrhythmias, syncope, heart failure, and sudden death,[122–125] but heterozygotes show no overall increased cardiac morbidity or mortality. Another mutation in *JUP* caused dominant ARVC without cutaneous features.[126] Conversely, in two pedigrees with keratoderma, skin fragility and wooly hair in the absence of cardiac disease, homozygosity for novel recessive mutations in *JUP* has recently been reported.[127]

CARVAJAL–HUERTA SYNDROME. Carvajal–Huerta syndrome (MIM 605676) is the association of striate keratoderma, wooly hair, and dilated left ventricular cardiomyopathy.[128] It is a recessive disorder due to truncating mutations in the desmoplakin gene (*DSP*) which cause the protein to lose its *C*-terminus.[129] Affected family members present with striate PPK, with some extravolar involvement at sites of pressure. The associated dilated left ventricular cardiomyopathy, developing in teenage years, is characterized by cardiac enlargement and disrupted cardiac contraction.[123] A range of phenotypes with right, left, or biventricular arrthymogenic cardiomyopathy in isolation or combined with wooly hair and other ectodermal features including keratoderma, are due to dominant or recessive mutations in desmoplakin.[125,130–132] Larger truncations in *DSP* give rise to lethal acantholytic ectodermal dysplasia.[133]

Mild PPK with ARVC and wooly hair due to recessive mutation in desmocollin-2 has been reported.[134]

KERATODERMAS WITH IMPAIRED HEARING

Many autosomal dominant palmoplantar keratoderma syndromes with sensorineural hearing loss are caused by mutations in the gap junction genes *GJB2* or *GJB6*, encoding the gap junction proteins Cx26 and Cx30, respectively.[4,19,135–138] Mutations in *GJB2*, encoding Cx26, usually cause nonsyndromic deafness, but a minority are responsible for most of the PPK-deafness syndromes. There is a wide range of overlapping phenotypes, and almost every Cx26 mutation associated with PPK has a clinically distinct phenotype.[139,140] Amongst these, VS is most dramatic, with honeycomb patterned keratoderma, "starfish" acral keratoses, constricting bands, and autoamputation[141–143] (Fig. 50-3B; see also eFig. 50-4.4 in online edition). Even in this syndrome the PPK may be focal, papular, or diffuse. Acral hyperkeratosis is found in other Cx26 PPKs; in the case of Bart–Pumphrey syndrome as knuckle pads. Constricting bands around the fingers and autoamputation occur when there is confluent transgredient PPK. The genotype–phenotype correlation is poorly understood, but mutations that cause PPK and deafness tend to cluster in the extracellular domains of Cx26.[5,140] Other mutations in *GJB2* give rise to more severe syndromes in which PPK is part of a generalized oculo-cutaneous disorder: keratitis ichthosis and deafness (KID; MIM 148210) and hystrix ichthyosis and deafness (HID; MIM 602540).[144,145] These disorders are described in Chapter 49.

A specific mutation in mitochondrial DNA, *A7,445G*, has been reported as causing the combination of hearing loss and a variable keratoderma (Fig. 50-4E) with matrilineal inheritance in pedigrees from New Zealand, Scotland, Japan, Portugal, and Hungary.[146–149] This segment of the mitochondrial genome encodes a serine transfer RNA, MTTS1. Penetrance of both features is incomplete, and the same mutation has been reported as a familial cause of impaired hearing in the absence of observed keratoderma.

KERATODERMAS WITH NEUROPATHY OR MENTAL RETARDATION

Two autosomal recessive syndromes with the combination of neuropathy and mental retardation have been

documented genetically. CEDNIK (cerebral dysgenesis, neuropathy, ichthyosis, and keratoderma; MIM 609528) is due to a 1-bp deletion in *SNAP29*, which encodes a SNARE protein involved in vesicle fusion.[34,150] MEDNIK (mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis, and keratoderma) is due to a splicing defect in the *AP1S1* gene, encoding a subunit of one of the adaptor protein complexes which regulate vesicle assembly, protein cargo sorting, and vesicular trafficking between organelles.[35] The similarities between the disorders may be explained by the fact that the AP1 complex interacts with the *SNAP29* gene product in the transport vesicles. In other reported pedigrees, PPK was combined with spastic paraplegia or motor and sensory neuropathy,[151–153] but as yet causative mutations have not been identified.

TYROSINEMIA TYPE II. Tyrosinemia type II (Richner–Hanhart syndrome, MIM 276600) is a very rare autosomal recessive disorder[154,155] due to deficiency of tyrosine aminotransferase, leading to accumulation of tyrosine and phenolic acid metabolites[156] (see Chapter 131). Clinical characteristics include painful focal palmoplantar hyperkeratosis, photophobia, and corneal erosions that may cause scarring or glaucoma.[154–159] Eye lesions precede the skin phenotype but the latter may occur in the absence of ocular involvement. Histopathological examination shows eosinophilic inclusions in the basal layer of the epidermis and increased keratohyaline granules. It is suggested that excess tyrosine enhances cross-links between aggregated tonofilaments and stabilizes microtubules.[17] The untreated syndrome causes psychomotor retardation, but a diet low in phenylalanine and tyrosine will both ameliorate cutaneous symptoms and prevent further mental deterioration.

INVESTIGATION OF KERATODERMA

Histologically, keratodermas are characterized by definition by increased stratum corneum thickness often with hypergranulosis but acanthosis, papillomatosis, and increased stratum lucidum vary. Where vacuolar degeneration and epidermolysis are present, it suggests keratin 9 defects (Fig. 50-5A), but it may be necessary to biopsy weight-bearing sites to maximize the chance of finding it. Normal palmoplantar skin contains increased numbers of tonofilaments on electron microscopy.[10] Abnormal aggregated keratin intermediate filaments in EPPK[160] and tonotubular structures in a rare variant form[43,161] are identifiable. Overt epidermolysis is not a major feature of PPK due to defects of other keratins, but prominent eosinophilic cytoplasm and keratin aggregates can be identified in most cases of PC (Fig. 50-5B[52]; Zamiri, unpublished data). Increased tonofilaments and microtubules are also reported in tyrosinemia type II.[17]

In desmosomal disorders, there is increased separation between keratinocytes, although frank acantholysis is unusual with desmoglein mutations (Fig. 50-5C).[51,52] Ultrastructurally, desmosomal plaques may be reduced in number or poorly formed, and keratin aggregation and compaction has also been noted with desmoplakin mutations.[51,162,163] In loricrin keratoderma, retained nuclei may be seen in the stratum corneum in which the mutant loricrin is detectable.[164] In Mal de Meleda, and in PLS, perivascular inflammation may be prominent, although this is a nonspecific finding in other keratodermas. The pathologist should also look for fungal spores or hyphae.

Punctate keratoderma may be orthokeratotic or parakeratotic. The latter in two dimensions resembles

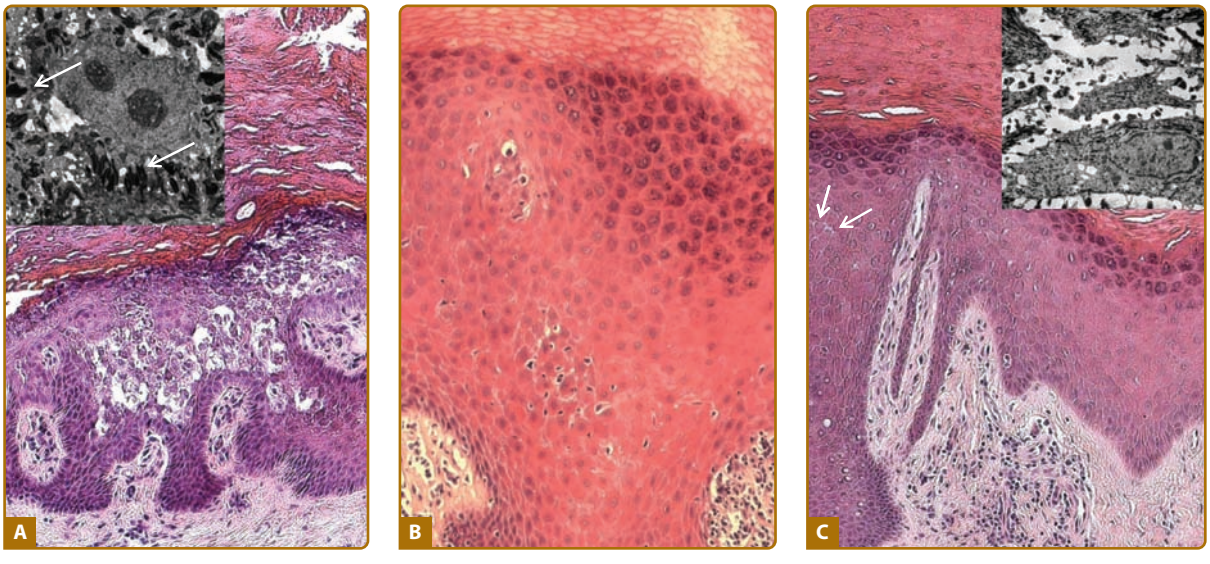

Figure 50-5 Histology of keratoderma. **A.** Vacuolation of spinous layer keratinocytes in epidermolytic PPK due to keratin 9 mutations; inset, tonofilament aggregates (*arrows*), and cytolysis on electron microscopy. **B.** Eosinophilic cytoplasm but without overt epidermolysis and inflammatory infiltrate in pachyonychia congenita due to keratin 17 mutation. **C.** Subtly increased cell separation (*arrows*) in striate PPK due to desmoglein 1 mutation; inset of electron microscopic appearances shows overtly increased cell separation.

the coronoid lamella of porokeratosis, but nonannular lesions are not true porokeratoses. Whether these variations are of nosological significance remains to be determined.

The cysts of PC include epidermoid and vellus hair cysts as well as true steatocysts, and indeed a single cyst may vary in its histology in different sections. The periodontal lesions of PLS show pockets of epithelium with ulceration and a mixed inflammatory cell infiltrate.

It is important to bear in mind the possibility of the development of squamous cell carcinoma or melanoma within keratoderma, and any changing or suspicious area should be biopsied.

Further investigation will be determined by the clinical syndrome; for example, audiometry, cardiac, or esophageal studies. In Olmsted syndrome, acrodermatitis enteropathica should be excluded by measuring serum zinc. Skin scraping for mycology remains the most useful investigation for many patients with keratoderma.

It is increasingly possible to obtain confirmation of the gene defect in familial keratodermas, particularly those involving connexins, by sending DNA to specialist commercial, or academic laboratories, but a reasonably strong clinical suspicion of the gene responsible is usually needed. Molecular diagnosis is particularly useful to distinguish focal PPKs with oral lesions, due for example, to keratin 16 mutations, from Howel–Evans syndrome.

DIFFERENTIAL DIAGNOSIS

See Box 50-1 and eFig. 50-5.1 in online edition.

BOX 50-1 DIFFERENTIAL DIAGNOSIS

- Onset late in life generally indicates acquired keratoderma, although genetic factors may still be relevant. Predisposition to callus formation and hyperkeratosis of the heels is common, exacerbated by obesity. Hypothyroidism should be excluded. The term Haxthausen's disease is used for acquired plantar hyperkeratosis in menopausal women.
- Hyperkeratotic eczema is distinguished by pruritus, erythema, the presence of vesiculation, and response to topical steroid preparations.
- In palmoplantar psoriasis, lesions elsewhere and typical nail changes may help confirm the diagnosis.
- Pityriasis rubra pilaris of the palms is distinguished by characteristic color and associated nail changes.
- Reiter's syndrome is readily distinguished by its acute presentation and associated arthropathy.
- Keratoderma due to chronic dermatophyte infection and in crusted (Norwegian) scabies can be diagnosed by appropriate tests and response to treatment.
- Sudden onset of diffuse keratoderma may be paraneoplastic, particularly carcinoma of the bronchus.
- Keratoderma has been reported in SLE. Autoantibodies to desmocollin 3 were associated with a diffuse acquired PPK.[178]
- Punctate keratoderma of late onset should raise the possibility of arsenical poisoning.

MANAGEMENT OF KERATODERMA

Many patients with PPK, particularly those with diffuse varieties, tolerate the condition without specific treatment. Patient-led self-help groups catering for rare and orphan disorders offer valuable support, but the rarity of individual conditions means that specific advice is difficult to obtain. An important exception is the Pachyonychia Congenita Project (www.pachyonychia.org).

For patients with focal keratoderma, which is often painful and sometimes disabling, regular paring by a podiatrist or the patient him/herself helps to control hyperkeratosis. Topical keratolytic agents such as salicylic acid ointment (5%–20%) or benzoic acid compound ointment help to soften the hyperkeratosis prior to abrasion. Propylene glycol (40%–60% in aqueous cream under occlusion at night) can also soften hyperkeratosis and aid reduction of callosities.

Many patients complain of hyperhidrosis for which simple measures such as topical aluminum chloride hexahydrate may be used. Suitable ventilated footwear, insoles, and "wicking" socks (available from suppliers of outdoor walking equipment) may offer some relief. Botulinum toxin has been successfully used to reduce plantar pain but requires regional anesthesia.[165] Malodor due to keratolytic corynebacterial infection of macerated hyperkeratosis, and fungal superinfection are also common. Where present, topical or systemic antimicrobials produce worthwhile benefit, but need to be repeated.

Oral retinoids are frequently tried but there are few systematic studies. Acitretin (10 mg/day or more), etretinate, or isotretinoin may all help, particularly in keratin, loricrin, or connexin disorders; successful use in PLS and Mal de Meleda is also reported. However, individual dosimetry may need to be adjusted carefully as excessive shedding of hyperkeratosis can cause palmar and plantar skin to become tender. In conditions with painful callosities such as PC, retinoids may reduce the thickness of the hyperkeratoses but aggravate the pain. If successful, lifelong treatment is required, with its associated risks. Oral retinoids have also been used to rescue impending autoamputation due to circumferential constricting bands.[166–168] A few reports suggest topical (or systemic) 5-fluorouracil may benefit punctate or filiform keratoderma.[169–171] Surgical treatment, including excision and grafting, has been reported,[172] most commonly used to prevent permanent contracture in Olmsted syndrome.[173–176] Surgical release of constricting bands has had poor outcomes and asymptomatic lesions are probably best left alone.[177]

For severe disorders where the genetic etiology is known, prenatal diagnosis is technically possible as a preventive strategy. Specific gene therapy is an exciting but still distant prospect for disorders of known etiology. However, a recent study in PC has shown that inhibition of mutant gene expression by repeated

injection of a specific small interfering RNA (siRNA) was effective in reducing hyperkeratosis.[8]

Chapter 51 :: Acantholytic Disorders of the Skin

:: Susan Burge & Alain Hovnanian

ACANTHOLYTIC DISEASES AT A GLANCE

- The acantholytic diseases are a heterogeneous group of diseases with overlapping clinical and histological features.
- Darier (or Darier–White) disease (DD) and Hailey–Hailey disease (HHD) are autosomal dominant disorders that are caused by defective calcium pumps—a sarco/endoplasmic reticulum pump in DD and a Golgi apparatus pump in HHD.
- Typical DD presents with greasy keratotic papules in a seborrheic distribution while HHD is characterized by painful oozing erosions in flexures and at sites of trauma.
- Signs in the nails (DD, HHD), flat-topped warty papules on dorsa of hands and feet (DD) and palmar pits (DD, HHD) or palmar keratotic papules (DD) help to confirm the diagnosis.
- Hypertrophic malodorous flexural disease is particularly disabling in DD and HHD.
- Grover disease (GD) is a sporadic papular condition of uncertain etiology that presents most often in sun-damaged skin. Intractable pruritus is common.
- Histopathological examination of involved skin in DD, HH, and GD reveals breakdown of intercellular contacts between suprabasal keratinocytes (acantholysis) with variable dyskeratosis.
- Acrokeratosis verruciformis of Hopf (AKV) is autosomal dominant and characterized by signs that mimic acral DD: flat-topped warty papules on dorsa of hands and feet and nail dystrophy. The histology in AKV is not acantholytic, but some (if not most) cases may be limited variants of DD.
- Treatment options for these diseases include topical corticosteroids (DD, HHD, GD) and topical or oral retinoids (DD, GD, AKV).

DARIER DISEASE

EPIDEMIOLOGY

Darier disease (DD) (OMIM #124200) is an autosomal dominant disease affecting both sexes and all ethnic groups. DD was described independently by Darier and White in 1889 (also known as Darier–White disease or keratosis follicularis).[1] Estimates of prevalence range from 1 in 30,000 (Northeast England, Scotland, Slovenia)[2–4] to 1 in 100,000 (Denmark).[5] Penetrance is complete, but spontaneous mutations are frequent.

ETIOLOGY AND PATHOGENESIS

The gene for DD was mapped by linkage analysis to chromosome region 12q23-24 in 1993[6] and *ATP2A2* was identified as the defective gene in 1999.[7] *ATP2A2*

encodes sarco/endoplasmic reticulum Ca^{2+} adenosine triphosphatase (ATPase) isoform 2 (SERCA2), a calcium pump transporting Ca^{2+} from the cytosol to the lumen of the endoplasmic reticulum (ER).[8–11] DD is caused by mutations inactivating one *ATP2A2* allele.

ATP2A2 spans 76 kilobases (kb), is organized in 21 exons, and encodes a 4.4-kb transcript, which is alternatively spliced into three isoforms: (1) SERCA2a, (2) SERCA2b, and (3) SERCA2c.[12,13] SERCA2a is expressed in the slow-twitch skeletal muscles and cardiac muscle, unaffected in DD.[14,15] SERCA2b and SERCA2c are expressed ubiquitously, but SERCA2b is the major isoform detected in the human epidermis.[16] Mutations specific for SERCA2b are sufficient to cause DD (despite the presence of functional SERCA2a), confirming the important role of SERCA2b in epidermis.[17,18] Most tissues may compensate for deficiencies in SERCA2 by mechanisms such as SERCA3, which is not expressed in keratinocytes.[16]

SERCA2 pumps belong to the P-type Ca^{2+} ATPase family. The pumps catalyze the hydrolysis of adenosine triphosphate (ATP) coupled with the translocation of two Ca^{2+} ions from the cytosol to the ER lumen, where Ca^{2+} is stored at high concentrations. SERCA pumps comprise three cytoplasmic domains [(1) the actuator, (2) phosphorylation, and (3) ATP-binding domains] linked to a transmembrane domain with ten transmembrane helices that contain the two Ca^{2+}-binding sites. After binding of cytosolic Ca^{2+} ions and phosphorylation, the pump undergoes conformational changes and releases Ca^{2+} into the ER lumen.[19]

More than 140 pathogenic *ATP2A2* mutations have been reported, including missense mutations (50%), frameshift mutations (23%), and in-frame deletions or insertions (8%). No consistent correlation has been demonstrated between genotype and phenotype, but missense mutations may be associated with more severe forms.[7,17,18,20–33] The considerable phenotypic variability suggests that other genetic or environmental factors modify the phenotype.

Although the etiology has been explained, the pathogenesis of DD is less clear. High concentrations of Ca^{2+} are required for normal keratinocyte intercellular adhesion and differentiation. Normally, the epidermis displays an increasing epidermal Ca^{2+} gradient from the basal to the superficial layers, but in DD this gradient is disturbed. The level of Ca^{2+} is reduced in basal cells from both affected and unaffected skin.[34]

The earliest ultrastructural change is breakdown of desmosomes with aggregation of keratin filaments around the cell nucleus.[35] Immunohistological studies of acantholytic cells reveal internalization of desmosomal components.[36–38] The dyskeratotic cells in the epidermis (grains, corps ronds) are formed through apoptosis, which appears to be triggered by the loss of adhesion.[39] The expression of antiapoptotic proteins in the *Bcl-2* gene family is reduced in DD, possibly as a secondary phenomenon, but an alteration in Bcl-2 proteins might also contribute to apoptosis.[39–42]

SERCA pumps replenish the ER Ca^{2+} pool from cytosolic Ca^{2+}, but mutations disrupting critical functional domains reduce activity of the pump in DD. A reduced ER Ca^{2+} pool may impair processing of desmosomal proteins by affecting the function of molecular chaperones such as calreticulin and calnexin that prevent protein misfolding and are involved in posttranslational modification.[43] Intracellular signaling through release of ER Ca^{2+} regulates trafficking of proteins to the cell membrane, including those required for the assembly of desmosomes and adherens junctions.[44] The trafficking of desmoplakin to the cell membrane is impaired in cultured DD keratinocytes.[45] Variations in cellular Ca^{2+} concentrations are also likely to have an effect on the expression of Ca^{2+}-dependent genes involved in keratinocyte differentiation and adhesion.

The epidermis is papillomatous and differentiation is abnormal, with the expression of hyperproliferative keratins and premature expression of cornified envelope precursors such as involucrin.[34,38,46–48] Alterations in ATP-mediated signaling may contribute to dyskeratosis and hyperproliferation.[8,34] Extracellular Ca^{2+} binds to purinergic ATP receptors that transmit calcium signals into the cytosol. Activation of the G-protein-coupled ATP receptor (P2Y) generates inositol 1,4,5-tris-phosphate (IP3), a calcium-signaling messenger (Fig. 51-1). Binding of IP3 to surface receptors on the ER and Golgi apparatus triggers release of Ca^{2+} stores and a rise in cytosolic Ca^{2+} which activates a further influx of extracellular Ca^{2+} through plasma membrane Ca^{2+} channels (store-operated Ca^{2+} entry), including transient receptor potential canonical1 (TRPC1). In DD, depleted ER Ca^{2+} appears to upregulate TRPC1 and enhances influx of Ca^{2+}.[8,49]

Elevated cytosolic Ca^{2+} may drive keratinocyte proliferation by activation of Ca^{2+}-dependent messenger systems that regulate cell division and differentiation.[49] Mice with reduced SERCA2 develop papillomas and SCCs.[50] SERCA2 haploinsufficiency in cultured mouse keratinocytes is linked to upregulation of proliferation but downregulation of differentiation.[51] SCC has been reported rarely in DD, sometimes in association with HPV16.[52–56]

Much of the skin may be able to compensate for the deficiency in SERCA2 by increasing the expression of the normal SERCA2 allele or by upregulating other mechanisms such as the human secretory-pathway Ca^{2+}/Mn^{2+} ATPase isoform 1 (SPCA1) in the Golgi (see section "Hailey–Hailey Disease"). However, external factors such as ultraviolet B (UVB) irradiation or friction, which are known to exacerbate DD, may disrupt this subtle balance by downregulating ATP2A2 or by increasing the requirement for SERCA2 until the protein reaches a critical level.[8,57] This hypothesis is supported by the observation that UVB irradiation and proinflammatory cytokines reduce levels of ATP2A2 mRNA in cultured normal keratinocytes and that retinoids and corticosteroids (used in treatment of DD) prevent this reduction.[58] Lithium, another well-known trigger for DD, reduces epidermal expression of SERCA2 in rats.[59]

CLINICAL FINDINGS

HISTORY. (Box 51-1). The first manifestations usually appear between the ages of 6 and 20 years with a peak

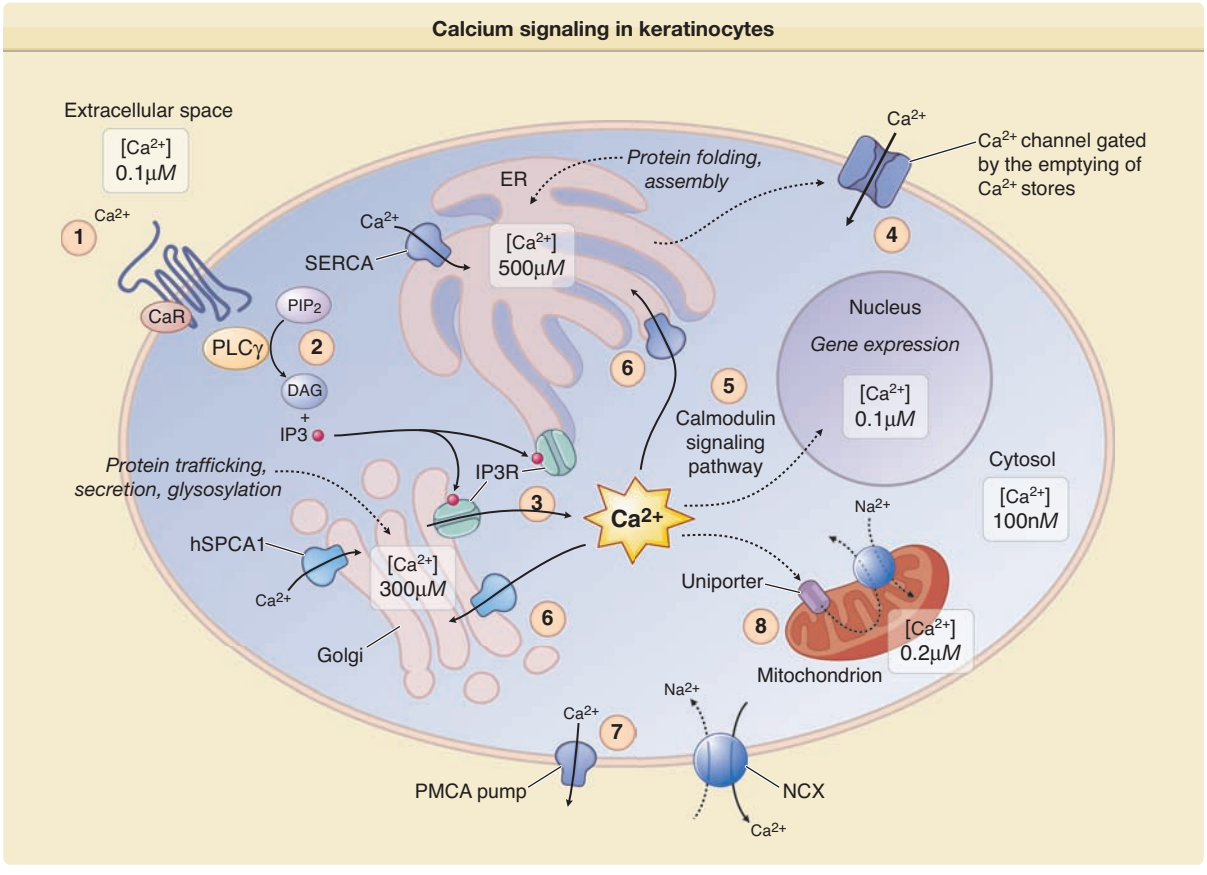

Figure 51-1 A simplified representation of Ca^{2+} signaling in keratinocytes. **1.** Ca^{2+} binding to its plasma membrane receptor (CaR) activates phospholipase Cγ (PLCγ). **2.** This causes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol 1,4,5-tris-phosphate (IP3) and diacylglycerol (DAG). **3.** IP3 binds to its receptor (IP3R) at the surface of the endoplasmic reticulum (ER) and Golgi apparatus, which causes the depletion of intracellular stores and induces an increase in intracellular Ca^{2+} levels. **4.** This increase triggers the opening of Ca^{2+} release-activated channels in the plasma membrane, which leads to a sustained increase in Ca^{2+} intracellular levels. **5.** Ca^{2+} binds to calmodulin; this activates calcineurin and calmodulin-dependent protein kinases, which regulate gene transcription through phosphorylation/dephosphorylation of transcription factors. **6.** Active Ca^{2+} transport by the different sarco/endoplasmic reticulum calcium adenosine triphosphatase (ATPase) pumps (SERCA1 to SERCA3) and human secretory pathway Ca^{2+}/Mn^{2+}–ATPase (SPCA1) pump is essential to replenish ER and Golgi Ca^{2+} stores, respectively. SPCA1 is also required for Mn^{2+} influx into the Golgi apparatus (not indicated here). **7.** Ca^{2+} efflux to the extracellular space involves plasma membrane Ca^{2+}–ATPases (PMCA) and Na^{+}/Ca^{2+} exchangers (NCX). **8.** Mitochondria take up Ca^{2+} released from the internal stores during Ca^{2+} signaling via the Ca^{2+} uniporter and return it to the cytosol through an NCX. Thus, Ca^{2+} homeostasis requires differential Ca^{2+} concentrations in the cytosol, the sarco/endoplasmic reticulum, the Golgi apparatus, the mitochondria, and the nucleus of the cell. The largest store of cellular Ca^{2+} is located in the ER lumen and in Ca^{2+}-binding proteins. Ca^{2+} signaling is highly regulated and generated by influx through Ca^{2+} receptors, release from internal stores (ER, Golgi apparatus, mitochondrion), and sequestration by Ca^{2+} pumps (SERCAs, SPCA1) and Ca^{2+} exchangers. mNCX = mitochondria Na^{2+}/Ca^{2+} exchanger.

BOX 51-1 DARIER DISEASE: WHAT SHOULD I LOOK FOR?

- A family history
- Symptoms such as malodor (many patients are relieved to have an opportunity to discuss this distressing problem) or pain (may indicate infection with *Herpes simplex* virus).
- Exacerbating factors—what happens in heat or sun, for example, summer?
- History of cold sores. Discuss the risk of eczema herpeticum and how to recognize.
- Explore the impact of disease, including mood change. DD is associated with depression including suicidal ideation.

between 11 and 15 years, but DD may develop in infants or old age.[1,60] Symptoms include itch, malodor, and pain. Heat, sweating, friction, and sunlight (UVB) exacerbate the signs that may be noticed for the first time in hot summer months.[1,2,61]

CUTANEOUS LESIONS. The discrete, greasy, yellowish-brown keratotic papules (only some are perifollicular) have a predilection for seborrheic areas: central chest and upper back, scalp (hair growth is not affected), forehead, neck including supraclavicular fossae, ears, and skin creases (axillae, groins, and perineum) (Figs. 51-2 and 51-3). Papules tend to coalesce into crusted plaques (Fig. 51-4). Foul-smelling, hypertrophic disease in the groin is particularly disabling (Fig. 51-5). In 1889, White noted the "intolerable stench" that accompanies severe disfiguring disease.[62] DD may affect schooling, work, and relationships.[1,61,63]

Hands and/or nails are affected in >96% of patients and may show the first signs of disease.[1,2] Look for nail fragility, painful longitudinal splits, or distinctive red and white longitudinal bands terminating in V-shaped nicks (Fig. 51-6). Pits or keratotic papules on palms and, sometimes, soles, help to confirm the diagnosis (Fig. 51-7). Many patients (50–70%) have skin-colored, flat-topped papules on the dorsa of hands and/or feet like those of acrokeratosis verruciformis of Hopf (AKV).[64] Hemorrhagic macules with jagged margins, possibly linked to trauma, are the least common acral sign and may blister (Fig. 51-8). Hemorrhagic DD has been reported in some kindreds as well as individuals.[65–68]

Oral,[1,69–71] esophageal,[72,73] rectal,[74] and cervical[75] mucosa may be affected. Corneal abnormalities have been recorded.[76–78]

CLINICAL VARIANTS. Variants include painful erosive DD,[79] vesiculobullous DD,[80] grossly hyperkeratotic plaques (cornifying DD),[81–83] nipple hyperkeratosis,[84] keratoderma (Fig. 51-9), comedonal DD,[33,85,86] freckled "Groveroid" DD[87] and, in pigmented skin, guttate leukoderma with confetti-like hypopigmented macules, and/or papules.[88,89]

Segmental Disease. Type 1 mosaicism presents with one or more unilateral bands of keratotic papules

Figure 51-2 Hyperkeratotic pigmented papules on the trunk of a patient with Darier disease.

Figure 51-3 Darier disease: inflammatory plaques with fissures and maceration may simulate Hailey–Hailey disease. Note that the fingernails are dystrophic.

Figure 51-4 Malodorous confluent keratotic papules on the chest with fissuring and hyperkeratosis of nipples in Darier disease.

Figure 51-5 Hypertrophic flexural Darier disease may suggest an SCC.

Figure 51-6 Dystrophic fingernails showing fragility, splitting, and red and white longitudinal bands in Darier disease.

following Blaschko's lines. Hands and/or nails may be affected on the same side[90,91] (Fig. 51-8). This distribution reflects a postzygotic somatic mutation in *ATP2A2* early in embryogenesis.[92–94] Theoretically, patients with gonadal mosaicism could transmit generalized disease, but no such cases have been reported. Type 2 mosaicism is rare and characterized by a severely affected linear band of DD, superimposed on generalized disease. A postzygotic mutation causes loss of heterozygosity at the *ATP2A2* locus in the more severely affected skin.[95]

RELATED PHYSICAL FINDINGS

DD has occasionally been reported in association with neuropsychiatric disease including seizures, bipolar disorder, and schizophrenia.[1,32,96–98] Lithium, which may be prescribed for bipolar disorder, exacerbates disease, possibly by suppressing levels of epidermal SERCA2.[59,99–101] The lifetime prevalence of major depression (30%), suicide attempts (13%), and suicidal thoughts (31%) appears higher than in the general population, highlighting the need for careful assessment.[98,102] Reports of cosegregation of DD with bipolar disorder in some families support the existence of a bipolar disorder susceptibility gene in the DD region, but *ATP2A2* has been excluded as a common susceptibility gene for bipolar disease.[103–105] Learning difficulties reported in some patients may be, at least in part, secondary to social handicap caused by disfigurement. Bone changes, particularly bone cysts, have been reported infrequently.[106–108]

Figure 51-7 Keratotic papules of the palms in Darier disease.

Figure 51-8 Hemorrhagic macule and nail dystrophy in Darier disease.

LABORATORY TESTS—HISTOPATHOLOGY

Histologic examination shows downgrowths of narrow cords of keratinocytes, suprabasal acantholysis with suprabasal clefts (lacunae), dyskeratosis (premature and abnormal keratinization), and hyperkeratosis

Figure 51-9 Keratoderma in Darier disease.

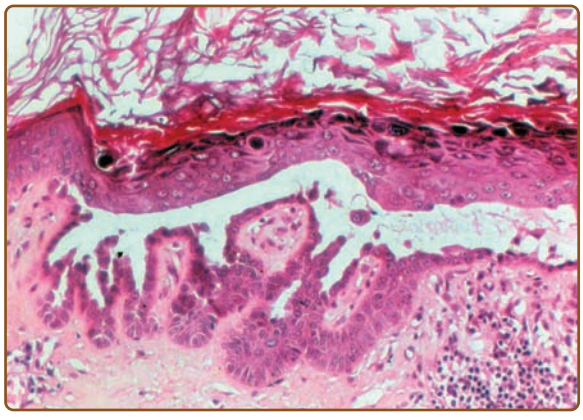

Figure 51-10 Histologic preparation of affected skin in Darier disease showing suprabasal cleft of the epidermis containing acantholytic cells, rounded eosinophilic dyskeratotic cells in the epidermis (corps ronds), hyperkeratosis, and flattened parakeratotic cells in the horny layer (grains).

(Fig. 51-10). Apoptosis results in rounded eosinophilic dyskeratotic cells in the epidermis (corps ronds) and flattened parakeratotic cells in the horny layer (grains).[39] The warty papules on the backs of the hands show the histology of AKV (see below).

DIFFERENTIAL DIAGNOSIS

(Box 51-2)

DD may be misdiagnosed as seborrheic dermatitis or acne, particularly in patients without a family history. Look for signs of DD in the hands or nails. Acneiform facial DD may be confused with familial dyskeratotic comedones[109,110] or comedo-like acantholytic dyskeratosis.[111]

Erosive, bullous, or hypertrophic flexural disease simulates Hailey–Hailey disease (HHD), but HHD tends to present later and patients do not have keratotic papules or nail fragility.[112] Erosive or hypertrophic DD may also resemble pemphigus vulgaris or vegetans (see Chapter 54), but patients do not have mucosal ulcers and intracellular immunoglobulin (Ig) and complement are not detected in the epidermis. Localized hypertrophic DD may suggest malignancy (Fig. 51-5). Freckled or papulovesicular forms may resemble Grover disease (GD),[87] but GD is not familial (see below), or the rare acantholytic variant of Dowling–Degos disease (Galli–Galli disease).[113,114]

Acral papules resemble plane warts or AKV (which may be a form of DD).[64,115,116] Localized papular vulvocrural acantholytic disease may be part of the spectrum of DD or HHD.[117–120]

BOX 51-2 DARIER DISEASE: DIFFERENTIAL DIAGNOSIS

SEBORRHEIC

- Seborrheic dermatitis (scalp, trunk)
- Grover disease (trunk)
- Acne (forehead)
- Confluent and reticulate papillomatosis (trunk)
- *Candida* infection (inframammary)

EROSIVE

- *Herpes simplex* infection
- Bullous impetigo
- Hailey–Hailey disease
- Pemphigus vulgaris

VEGETATING FLEXURAL

- Hailey–Hailey disease
- Pemphigus vegetans
- SCC

COMEDONAL

- Acne
- Familial dyskeratotic comedones
- Comedo-like acantholytic dyskeratosis

ACRAL

- Plane warts
- Acrokeratosis verruciformis of Hopf

FRECKLED

- Grover disease
- Dowling–Degos disease—acantholytic variant (Galli–Galli disease)

GENITAL

- Genital warts
- Vulval intraepithelial neoplasia
- Hailey–Hailey disease
- Papular vulvocrural acantholytic disease

COMPLICATIONS

Impetiginization and eczematization may complicate the picture and patients have an increased susceptibility to widespread infection with *Herpes simplex* (eczema herpeticum) (Fig. 51-11) or *Herpes zoster*.[121,122] Blockage of salivary glands has been reported.[1,69,80,123] SCC (scalp, scrotal, vulval, thigh, subungual) has been recorded infrequently, sometimes linked to the presence of HPV16.[52–56]

CLINICAL COURSE

DD pursues a chronic relapsing course. Severity is unpredictable, but in about 30% of patients disease becomes less severe in old age, while in others DD persists or gradually worsens.[1,61]

TREATMENT

(see Table 51-1)

The physician should take the time to answer questions, explain that treatments may control but not cure

Figure 51-11 Widespread vesicular rash caused by infection with *Herpes simplex* virus in Darier disease.

DD, and offer genetic counseling if appropriate. It is important to discuss how to reduce the impact of triggers such as heat and sun, and use emollients containing urea or lactic acid to reduce hyperkeratosis. Topical antiseptics (washes, bath additives), antibiotics, and antifungals will help to prevent or treat infection. *Herpes simplex* causes painful flares that require oral acyclovir.[121] Topical corticosteroids in combination with antibiotics reduce inflammation. Limited disease may respond to a topical retinoid, for example, 0.1% tazorotene[124,125] or 0.05% isotretinoin,[126] prescribed in combination with a topical corticosteroid to reduce irritation. Other topical agents such as adapalene,[127,128] 5-fluorouracil,[129–131] or tacrolimus[132] have been reported to be effective in small numbers of cases.

Oral acitretin 0.25–0.5 mg/kg or isotretinoin 0.5 mg/kg reduces hyperkeratosis and malodor, but will take 3 to 4 months to achieve maximal effect.[133] Tailor dose to the response and monitor for adverse effects (see Chapter 228). Pregnancy is contraindicated for 2 years after stopping treatment with acitretin and for 1 month after stopping isotretinoin. Oral cyclosporine has been advocated for eczematization[134] and in severe vulval disease,[135] but controlled trials are lacking.

Approaches for severe hypertrophic or erosive disease include dermabrasion, laser ablation, and photodynamic therapy, but controlled studies are needed to evaluate these approaches.[79,133,136,137] Botulinum toxin may control flexural exacerbations by reducing sweating and mammoplasty has been advocated for severe inframammary disease.[138,139]

ACROKERATOSIS VERRUCIFORMIS OR ACRAL DARIER DISEASE

AKV is a rare inherited disease described by Hopf in 1931 that may be a variant of DD.[64,116]

ETIOLOGY AND PATHOGENESIS

AKV (OMIM #101900) is inherited in an autosomal dominant fashion.[115] Sporadic cases have been reported. A missense mutation in *ATP2A2*, the gene that is affected in DD, was identified in a large British pedigree. The heterozygous Pro602Leu mutation caused complete loss of Ca^{2+} transport activity.[116] Thus, in some instances, AKV and DD are allelic disorders, a conclusion that is entirely consistent with the overlapping clinical features. However, mutations in *ATP2A2* were not identified in a Chinese family.[140]

CLINICAL FINDINGS

AKV usually presents at birth or in early childhood. The asymptomatic, skin-colored, flat-topped warty papules are distributed symmetrically on the dorsum of the hands and feet (Fig. 51-12). Papules may also develop on knees, elbows, and extensor aspects of legs

TABLE 51-1
Darier Disease: Treatment

First Line	Second Line	Third Line (Unproven Efficacy)
Discuss how to avoid triggers (heat, sweating, friction) and minimize UVB-induced exacerbations. Emollients containing urea or lactic acid. Soap substitutes and topical antiseptics. Moderate or potent topical corticosteroids with topical antibiotics. Topical retinoids: isotretinoin (0.05%, 0.1%), tretinoin, tazarotene gel, adapalene 0.1% gel.	Oral acitretin 0.25–0.5 mg/kg/day. Takes 3 months to have a maximal effect. Acitretin should be stopped for 2 years before a woman attempts to conceive. Oral isotretinoin 0.5 mg/kg/day. Less effective than acitretin but may be indicated in young women. Isotretinoin should be stopped for 1 month before a woman attempts to conceive.	Topical 5-fluorouracil. Oral cyclosporine for eczematization. Initially 2.5 mg/kg/day. Laser surgery, electrosurgery, or dermabrasion. Photodynamic therapy. Botulinum toxin to reduce sweating in recalcitrant flexural disease. Mammaplasty for severe inframammary disease.

Figure 51-12 Small, flesh-colored papules over the dorsum of the hand in acrokeratosis verruciformis of Hopf.

and forearms.[64] As in acral DD, punctate keratoses and pits may be present on palms and soles, palmar skin may be thickened, and patients may have subungual hyperkeratosis, longitudinal striations, splits, and V-shaped nicks at the free margin of the nail plates. A linear variant with persistent localized unilateral lesions has been reported in two unrelated Saudi patients.[141]

LABORATORY TESTS—HISTOPATHOLOGY

The classic histopathologic findings are hyperkeratosis, hypergranulosis, and acanthosis with papillomatosis. The spiky elevations of the epidermis are said to resemble "church spires" (Fig. 51-13). Epidermis is neither dyskeratotic nor acantholytic.

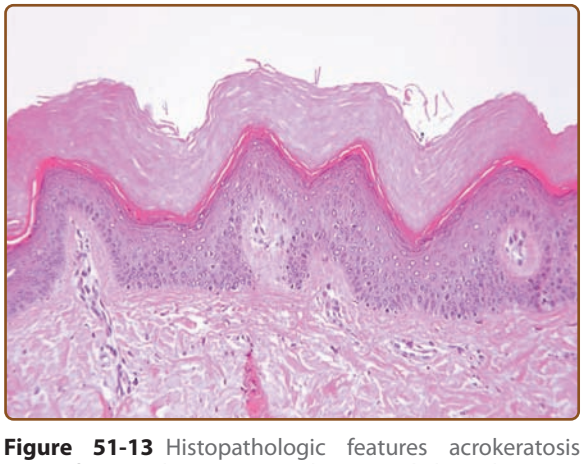

Figure 51-13 Histopathologic features acrokeratosis verruciformis showing acanthosis and hyperkeratosis with "church spike" elevations of the epidermis, but no acantholysis or dyskeratosis. (Used with permission from Dr. Laurence Lamant, Department of Pathology, Purpan Hospital, Toulouse, France.)

DIFFERENTIAL DIAGNOSIS

Acral DD may be indistinguishable from AKV, particularly in childhood, when other features of DD may not be apparent. AKV may resemble plane warts, stucco keratoses, or seborrheic warts, but the family history, symmetrical distribution, and nail changes will suggest the diagnosis.

COURSE

AKV persists and may worsen slowly with age.

TREATMENT

None may be needed. Topical retinoids may flatten lesions. Destruction by cryosurgery, shave, curettage, or laser surgery can be effective. Oral acitretin has been helpful.[142]

HAILEY–HAILEY DISEASE

EPIDEMIOLOGY

HHD (OMIM #169600), also known as familial benign chronic pemphigus, was described by the Hailey brothers in 1939. HHD has an incidence of at least 1 in 50,000, but prevalence may be higher as misdiagnosis is frequent.[112]

ETIOLOGY AND PATHOGENESIS

The discovery of the crucial role of SERCA2 in DD raised the possibility that defects in another calcium pump could underlie acantholysis in HHD. The defective gene, *ATP2C1*, was identified in chromosome region 3q21-24. *ATP2C1* encodes an ATP-powered calcium channel pump on the Golgi membrane, the human secretory-pathway Ca^{2+}/Mn^{2+} ATPase isoform 1 (SPCA1).[143–145] SPCA1 belongs to the family of P-type cation transport ATPases. HHD is dominantly inherited with complete penetrance and is caused by mutations inactivating one *ATP2C1* allele.

The gene spans approximately 30 kb on 3q21 and comprises 28 exons encoding a 4.5-kb transcript. The predicted protein is approximately 115 kDa. Alternative splicing of *ATP2C1* primary transcripts in keratinocytes leads to four splice variants, *ATP2C1a* to *ATP2C1d*, which differ by different splicing of exon 27 and/or 28. *ATP2C1d* is the largest variant, containing exons 27 and 28 in their entirety. The structure of SPCA is similar to that of SERCA (see section "Darier Disease"), but the SPCA-binding site only transports a single Ca^{2+} or Mn^{2+} ion into the Golgi lumen.[19,144,146,147]

Around 100 mutations have been reported in HHD scattered across the *ATP2C1* gene.[143,144,148–161] No correlations have been found between genotype and phenotype; clinical features vary.[149] Mutations predict marked reduction of SPCA1 or cause changes in highly

conserved domains that are critical for function.[143,145,153,162–165] Haploinsufficiency appears to be the mechanism for dominant inheritance, but it is not clear how loss of one functional *ATP2C1* allele causes acantholysis.

Ultrastructural studies of acantholytic cells reveal desmosomal breakdown with retraction of keratin filaments from desmosomal plaques to form perinuclear aggregates.[166,167] Desmosomal components, E-cadherin, and connexins are internalized in acantholytic cells and the expression of keratins is abnormal in lesional skin.[34,36–38,168–172] The abnormality in cell adhesion may be revealed in normal-looking skin in patients with HHD using suction.[173]

Immunohistochemical studies suggest that SPCA1 is localized to the basal layer of normal epidermis.[174] Total [Ca^{2+}] in the epidermal granular layer is reduced and the normal epidermal Ca^{2+} gradient attenuated in both affected and unaffected skin.[143,163] Golgi Ca^{2+} stores are reduced, Ca^{2+} signaling is abnormal and the normal upregulation of transcription of *ATP2C1* mRNA by Ca^{2+}-stimulation is suppressed in HHD keratinocytes.[143,145,163,175–177] Elevated cytosolic Ca^{2+} levels could influence gene expression or alter posttranslational modification of target proteins. Alternatively, low Ca^{2+} or Mn^{2+} concentrations in the Golgi lumen could impair posttranslational modifications (proteolytic processing, glycosylation, trafficking, or sorting) of proteins important in epidermal cell-to-cell adhesion.

Cultured keratinocytes from involved skin display altered patterns of calcium metabolism and reduced proliferative capacity. Increased oxidative stress in HHD keratinocytes may lead to reduced expression of proteins involved in regulation of the balance between proliferation and differentiation such as Itch and Notch1.[161,178] Reorganization of actin is defective, cellular ATP decreased, and synthesis of involucrin is reduced.[161,179–181] Mice deficient for SPCA1 develop squamous cell papillomas and carcinomas similar to those seen in SERCA2 deficient mice (see section "Darier Disease").[176]

Although *ATP2C1* mRNA is expressed ubiquitously, HHD is limited to the skin. Keratinocytes may be more sensitive to levels of SPCA1 than other cells because, unlike most other cells, the Golgi in keratinocytes lack SERCA to compensate for deficient SPCA1.[147] UVB irradiation and proinflammatory cytokines reduce expression of *ATP2C1* mRNA in cultured normal keratinocytes, but suppression is inhibited by retinoids, corticosteroids, cyclosporine, tacrolimus, and vitamin D_3.[58] External factors (UVB, sweating, friction) may reduce the amount of SPCA1 to a critical level leading to the expression of disease.[147]

HISTORY AND CLINICAL FINDINGS

(Box 51-3)

HHD usually presents between the second and fourth decades, predominantly at sites of friction (neck, axillae, inframammary, groin, perineum).[112] The diagnosis is often delayed because HHD simulates common dermatoses such as eczema, tinea, and impetigo.[112] Itch, pain, and malodor are common complaints.

BOX 51-3 HAILEY–HAILEY DISEASE: WHAT SHOULD I LOOK FOR?

Consider the possibility of HHD in any young adult with chronic "eczema" at sites of friction such as the neckline, axilla, or groins. The diagnosis is often missed. Look for:

- Family history
- Exacerbating factors: wearing stiff collars, in heat, or when exercising
- Postinflammatory hyperpigmentation (common)
- Longitudinal white bands in nails (uncommon but very helpful if present)

Signs include crusted weeping erosions, vesicopustules, expanding annular plaques with peripheral scaly borders and vegetating plaques with fissures (rhagades). Postinflammatory hyperpigmentation is frequent (Figs. 51-14 and 51-15). Some patients have longitudinal white lines on the fingernails and these can help to confirm the diagnosis[112,182,183] (Fig. 51-16). Disease may be limited to one or two sites, more widespread or rarely generalized with erythroderma,[184–186] but even mild disease reduces quality of life.[63,187] Painful malodorous inguinal or perineal disease is particularly disabling. HHD koebnerizes into inflammatory dermatoses and has been exacerbated (or diagnosed) after triggers such as contact dermatitis, removal of adherent patch tests, UV irradiation, cutaneous

Figure 51-14 Crusted plaques with postinflammatory hyperpigmentation in a patient with Hailey–Hailey disease.

Figure 51-15 Hailey–Hailey disease with a hypertrophic macerated axillary plaque and painful fissures (rhagades).

infections, and scabies infestation.[173,186,188–196] Generally, HHD does not involve mucosa. Rare instances of conjunctival, oral, esophageal, or vaginal involvement may have been initiated by trauma or infection.[197–203]

SEGMENTAL DISEASE. In Type 1 mosaicism, a postzygotic mutation in ATP2C1 manifests as one or more localized streaks of HHD along Blaschko's lines.[204] Type 2 mosaicism has been confirmed in a patient with severe linear involvement superimposed on symmetrical HHD. In the more severely affected skin, a postzygotic mutation had caused loss of heterozygosity at the ATP2C1 locus.[205]

LABORATORY TESTS—HISTOPATHOLOGY

Involved skin displays widespread partial loss of cohesion (keratinocytes may still be linked together by adherens junctions[206]) between suprabasal keratinocytes with an appearance likened to a dilapidated brick wall (Fig. 51-17). Clusters of loosely coherent cells float in suprabasal clefts or bullae. Dyskeratosis, when present, is usually mild, but changes may resemble those in DD.

Figure 51-16 White longitudinal lines on the nail of a patient with Hailey–Hailey disease.

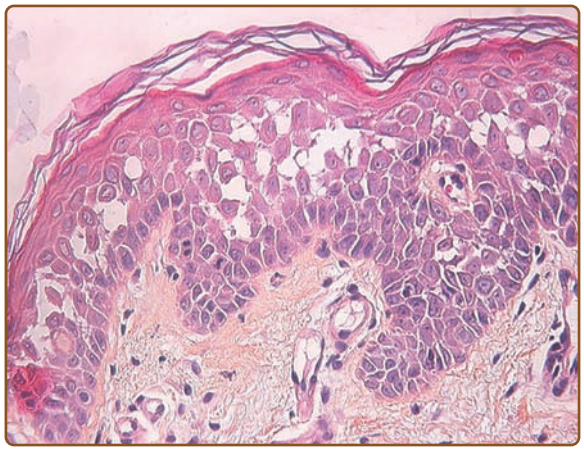

Figure 51-17 Hailey–Hailey disease. Extensive partial loss of intercellular contacts within the epidermis produces the appearance of a "dilapidated brick wall."

DIFFERENTIAL DIAGNOSIS

(Box 51-4)

Eczema or infection (bacterial, fungal, or viral) is the most common misdiagnosis. Hypertrophic flexural

BOX 51-4 HAILEY–HAILEY DISEASE: DIFFERENTIAL DIAGNOSIS

ANNULAR OR CRUSTED PLAQUES

- Eczema including allergic contact dermatitis
- Impetigo
- *Candida* infection
- Tinea corporis
- Darier disease

VESICOPUSTULES

- Eczema
- Bullous impetigo
- *Herpes simplex*
- Grover disease
- Pemphigus vulgaris
- Toxic epidermal necrolysis (if widespread)

VEGETATING FLEXURAL

- Darier disease
- Pemphigus vegetans
- SCC

LOCALIZED GENITAL

- Papular vulvocrural acantholytic disease
- Genital warts
- Darier disease
- Vulval intraepithelial neoplasia

HHD resembles DD, but acantholysis is more widespread and dyskeratosis less prominent in HHD than in DD. Eroded or vesiculobullous HHD may simulate toxic epidermal necrolysis[207] or pemphigus vulgaris (intracellular IgG and complement are not detected in the epidermis). Genital HHD may simulate viral warts[119,208,209] or vulval intraepithelial neoplasia.[210] Papular acantholytic disease limited to the genitalia may be a separate entity, but the identification of an *ATP2C1* mutation in one case suggest that some cases are part of the spectrum of HHD.[117,120,209,211,212]

COMPLICATIONS. Superimposed bacterial or candidal infections are common.[213] *Herpes simplex* causes painful exacerbations, which may disseminate.[214–216] Tinea was a cause of treatment failure in one patient.[217] Allergic contact dermatitis has been described, but the frequency of positive patch tests is probably not increased.[218,219] Skin cancers (SCC more often than BCC) have been reported in association with HHD. SCC may be linked to the presence of human papillomas virus.[220–225] Affective disorder cosegregated with HHD in three families.[226–228]

COURSE

The course is chronic, punctuated by relapses and remissions, but some patients improve in old age.

TREATMENT

(Table 51-2)

Triggers such as heat, sweating, and friction should be minimized. Clothing should be soft, loose-fitting, and cool. Weight loss may be helpful. Patients should be offered genetic counseling.

Treatment is difficult and no controlled trials have been performed. Recommendations in the literature are subject to citation bias and most are based on the response of one or two cases without any long-term follow-up.

It is appropriate to culture skin for bacteria and yeasts, and control infection with antibacterial and/or antifungal agents. It has been suggested that topical gentamicin may be particularly effective in patients harboring a nonsense mutation in *ATP2C1*, because aminoglycosides induce read-through of nonsense mutations in human cells.[229] The role of long-term, low-dose systemic antibiotics is unproven.

Pain may limit application of topical agents, but potent or ultrapotent topical corticosteroids (aqueous lotions, foams, creams, or ointments) can be effective.[112,230] Cutaneous atrophy after prolonged treatment with potent corticosteroids increases skin fragility. Other topical agents that have been recommended include calcitriol,[231,232] tacalcitol,[233] and topical 5-fluorouracil.[234] Tacrolimus helped some cases,[230,235–238] but was ineffective in others.[239] Analgesia is crucial and morphine may be needed in severe disease.

Systemic corticosteroids are a short-term option for widespread disease.[240] Other systemic agents that have been advocated include calcitriol,[241] retinoids,[242,243] methotrexate,[244] cyclosporine,[245,246] dapsone,[247,248] etanercept,[249] and alefacept.[250] Surgical approaches that have been used in recalcitrant disease include excision with or without grafting,[251–253] dermabrasion,[254–256] and laser surgery.[256–259] Other interventions that have been tried include mammoplasty for inframammary disease, superficial X-ray therapy (unhelpful),[260] electron beam therapy,[261] and photodynamic therapy (very painful with variable outcomes).[262,263] Botulinum toxin may help flexural disease by reducing sweating.[256,264,265]

GROVER DISEASE

EPIDEMIOLOGY

Grover disease (GD, transient or persistent acantholytic dermatosis) is an acquired condition, first described in 1970, that is most common in fair skinned men >age 40 years. The male to female ratio is 3:1.[266–269]

TABLE 51-2
Hailey–Hailey Disease: Treatment

First Line	Second Line	Third Line (Unproven Efficacy)
Minimize friction and sweating Emollients containing antibacterials Soap substitutes Antiseptic bath additives Moderately potent or potent topical corticosteroids in combination with topical or oral antibiotics and/or antifungal agents to control secondary infection Pain relief—topical or oral (some patients require morphine)	Ultrapotent topical corticosteroid in combination with topical or oral antibiotics and/or antifungal agents to control secondary infection Prednisolone 20–30 mg/day reduced gradually to control acute exacerbations	Antistaphylococcal antibiotics, e.g., low-dose tetracycline for 6 months or longer Topical tacrolimus Topical tacalcitol or calcitriol Topical 5-fluorouracil Oral cyclosporine 2.5 mg/kg Oral retinoids—start in a low dose to minimize irritation Methotrexate 10–15 mg/week Excision, laser surgery, or dermabrasion Botulinum toxin to reduce sweating in recalcitrant flexural disease Mammoplasty for severe inframammary disease

Figure 51-18 Grover disease. Itchy papules on the trunk resembling folliculitis in a 60-year-old man.

Figure 51-19 Grover disease. Discrete papulovesicular lesions with crusts in a 53-year-old man.

ETIOLOGY AND PATHOGENESIS

Although GD shares clinical, histologic, and ultrastructural features with DD, *ATP2A2* (the defective gene in DD) does not appear to be involved.[270,271] GD may be triggered by factors that promote sweating, for example, febrile illnesses or occlusion,[272–275] but is also common in the winter in elderly men with dry skin.[269,276–278] Other associations include UV or ionizing radiation, inflammatory dermatoses such as atopic eczema, renal failure, HIV infection, malignancies, organ transplants, and some drugs.[268,269,279–283] Electron microscopy shows clumping of keratin filaments with loss of desmosomes and immunostaining reveals that desmosomal components are internalized.[36,37]

CLINICAL FINDINGS

Most often GD presents with an itchy rash on sun-damaged skin of the trunk. Itch may be intense and out of proportion to the signs, which comprise scattered pinkish or red–brown papules with variable hyperkeratosis, papulovesicles (rarely bullae) or, less often, eczematous plaques (Figs. 51-18 and 51-19). Neck and/or proximal limbs can be affected.[269,278,284–287] GD has been described in association with widespread

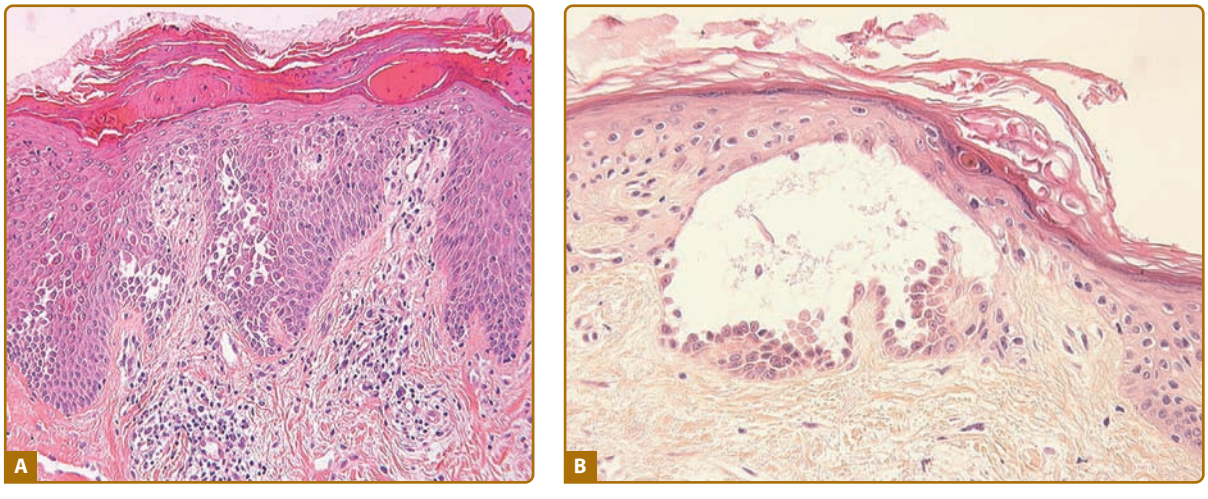

Figure 51-20 **A.** Hailey–Hailey-like histological pattern in Grover disease with detached keratinocytes (acantholysis), focal spongiosis, and epidermal hyperplasia. **B.** Pemphigus-like pattern in Grover disease with suprabasal acantholytic cleavage.

- Scabies
- Insect bites
- Miliaria rubra
- Darier disease
- Hailey–Hailey disease
- Pemphigus vulgaris

sun-induced lentigines.[271,288] Guttate leukoderma, similar to that seen in DD, has been observed in dark skin.[289] Unilateral GD has been reported, but this may have been segmental DD.[290,291]

LABORATORY TESTS—HISTOPATHOLOGY

The histological picture is variable and may suggest spongiotic dermatitis, DD, HHD, or pemphigus (no Ig or complement is found in the epidermis). Acantholysis is often subtle and focal.[267,278,285] (See Fig. 51-20).

DIFFERENTIAL DIAGNOSIS

(See Box 51-5)

Other causes of itching such as scabies, insect bites, and eczema should be excluded. Clinicopathological correlation, including family history and examination of nails and mucous membranes, will help to exclude other causes of acantholysis.

COURSE

GD may clear within a few months (transient acantholytic dermatosis), or the itch may persist with fluctuating intensity for years (persistent acantholytic dermatosis), especially in the elderly.[292,293]

TREATMENT

Precipitating factors, including soap and other topical irritants, should be avoided. Emollients, antipruritics, or wet dressings may be soothing. Sometimes topical medicaments such as corticosteroids, retinoids, calcipotriol, or tacalcitol relieve irritation. Oral retinoids, oral corticosteroids, UVB, PUVA, and methotrexate have been advocated for persistent disease, but controlled trials are needed to confirm efficacy. The response to treatment is often disappointing.[269,287,294–298]

Chapter 52 :: Porokeratosis

:: Grainne M. O'Regan & Alan D. Irvine

POROKERATOSIS AT A GLANCE

- A chronic progressive disorder of keratinization, characterized clinically by hyperkeratotic papules or plaques surrounded by a thread-like elevated border that expands centrifugally.
- At least six clinical variants of porokeratosis have been described.
- The classic form, porokeratosis of Mibelli, presents in infancy or childhood as asymptomatic small brown to skin-colored annular papules with a characteristic raised border.
- Disseminated superficial actinic porokeratosis is the most common type, with multiple papules distributed symmetrically on sun-exposed areas.
- Linear porokeratosis presents at birth or in childhood with lesions distributed along Blaschko's lines.
- Punctate porokeratosis appears during or after adolescence as 1- to 2-mm papules on the palms or soles.
- In all variants, a thin column of parakeratotic cells (*cornoid lamella*) corresponds to the hyperkeratotic border and extends throughout the stratum corneum in histologic sections.
- A genetically heterogeneous disorder; the majority of forms may be inherited as autosomal dominant traits.
- Malignant epithelial neoplasms are reported in all subtypes except the punctate variety.

Porokeratosis is a morphologically distinct disorder of keratinization, characterized clinically by hyperkeratotic papules or plaques surrounded by a thread-like elevated border that expands centrifugally. Histologically, a thin column of parakeratotic cells extends throughout the stratum corneum and is seen in all variants. This distinctive histopathologic feature, known as the *cornoid lamella*, corresponds to the raised hyperkeratotic border evident clinically.

At least six clinical variants of porokeratosis are recognized; however, the clinical distinction between these morphological variants may not be justified (Box 52-1). Reports of one type of porokeratosis coexisting with other forms and different types developing in multiple members of an affected family suggest more similarities than disparities, particularly in the disseminated forms.[1–3]

ETIOLOGY AND PATHOGENESIS

Porokeratosis is a genetically heterogeneous disorder with multiple loci identified to date; however, the pathogenetic mechanisms remain elusive. Loci at chromosome bands 12q23.2–24.1 and 15q25 (DSAP1 and DSAP2) have been reported in familial disseminated superficial actinic porokeratoses; a further locus has been identified for disseminated superficial porokeratosis (DSP) at 18p11.3.[4,5] The locus at DSAP1 corresponds to a candidate gene, *SART3* (squamous cell antigen recognized by T cells 3); this encodes a tumor rejection antigen thought to be involved in the regulation of messenger RNA splicing. Fine mapping of the locus at DSAP1 has also revealed mutations in another potential candidate gene, *SSH1* (slingshot 1), and a variation in the promoter region of *ARPC3*, which play a key role in actin dynamics.[6–8] Missense mutations in *SSH1* in this kindred have been shown to result in loss of heterozygosity in DSAP.[9] However, microarray expression and real time quantative polymerase chain reaction (PCR) profiles of *SART3*, *SSH1*, and *ARPC3* have failed to show differential expression patterns.[10,11] Porokeratosis punctata palmaris et plantaris maps to a

6.9-centimorgan region at chromosome band 12q24.1–24.2, overlapping with the region identified for DSAP1, suggesting that the two forms may be allelic.[12] The centrifugal expansion of lesions is postulated to reflect the migration of a mutant clone of keratinocytes.[13] Supporting this mutant clone theory are findings of abnormal DNA ploidy and chromosomal abnormalities in lesional keratinocytes.[14] The tumor suppressor proteins p53 and pRb are overexpressed in keratinocytes immediately beneath and adjacent to the cornoid lamella, although to date p53 mutations have not been identified, and there is no significant expression of p53 at an mRNA level.[15–19,11] Cytogenetic abnormalities in fibroblasts, particularly on chromosome 3, have also been documented.[20,21] Decreased mdm2, abnormal expression of psi-3, cytokeratins, filaggrin, and involucrin have also been reported.[22,23] The increased prevalence of porokeratosis in immunosuppressed patients suggests that impaired immunity may be permissive in genetically predisposed individuals.[24–27] Other reported triggering factors such as exposure to ultraviolet (UV) light, together with the increased potential for malignant transformation, highlight the dysplastic potential of affected keratinocytes. Malignant degeneration has been described in all variants of porokeratosis, with the exception of the punctate variety.[28–30]

CLINICAL FINDINGS

POROKERATOSIS OF MIBELLI

Classic porokeratosis of Mibelli begins during infancy or childhood as asymptomatic small brown to skin-colored annular papules with a characteristic annular border (Fig. 52-1). The well-demarcated hyperkeratotic border is usually more than 1 mm in height, with a characteristic longitudinal furrow. The center of the lesion may be hyperpigmented, hypopigmented, depressed, atrophic, or anhidrotic. Lesions range in diameter from millimeters to several centimeters, but giant lesions measuring up to 20 cm may occur. Such giant porokeratoses are rare and occur predominantly on the lower leg and foot. Large lesions are associated with a higher malignant potential.[30] Multiple lesions may arise; however, they are usually regionally localized and unilateral. The condition may be familial and inherited as an autosomal dominant trait. Lesions persist indefinitely.

Figure 52-1 Porokeratosis of Mibelli is characterized by a single large lesion with a clearly defined edge. The scaling is not clearly seen at the border because of the interdigital location of this lesion.

DISSEMINATED SUPERFICIAL ACTINIC POROKERATOSIS

Disseminated superficial actinic porokeratosis (DSAP) is the most common of the porokeratoses. Lesions are characteristically uniformly small, annular, asymptomatic, or mildly pruritic papules ranging from 2 to 5 mm in diameter, distributed symmetrically on the extremities. Lesions are more generalized than other forms of porokeratosis, with typically in excess of 50 lesions located predominantly in sun-exposed sites (Fig. 52-2A and B). Although widespread, lesions typically spare palms, soles, and mucous membranes. Compared with porokeratosis of Mibelli, the hyperkeratotic border is characteristically more subtle. As the lesions progress, the older, central area becomes atrophic and anhidrotic. DSAP tends to be inherited as an autosomal dominant disorder, with the earliest reported age of onset at 7 years, and is usually fully penetrant by the third or fourth decade of life.[5] Initial reports of induction of lesions by exposure to UV light and hypersensitivity of DSAP-derived fibroblasts to X-rays have not been consistently reproduced, and the pathogenesis of DSAP remains unknown.[15,31–33]

DISSEMINATED SUPERFICIAL POROKERATOSIS

DSP also shows an autosomal dominant pattern of inheritance and has its onset in the third or fourth decade of life. Lesions primarily are morphologically identical to those of DSAP, occur on the extremities, and are typically distributed symmetrically, but do not spare sun-protected areas as in DSAP. As with DSAP, in excess of 100 lesions may be disseminated, with a predilection for the extensor surfaces of the extremities. Notably, involvement of the face is rare in both DSAP and DSP. In both disseminated forms, there is a reported female predominance, with a female–male ratio of 3:1.

DISSEMINATED SUPERFICIAL POROKERATOSES OF IMMUNOSUPPRESSION

Disseminated superficial porokeratosis in the context of immunosuppression is recognized following renal, hepatic, and cardiac transplantation, electron beam irradiation,[34] immunosuppressive chemotherapy, and

Figure 52-2 **A.** Disseminated superficial actinic porokeratosis with multiple lesions on the forearm in this severely affected individual. **B.** The characteristic furrowing (*arrows*) is clearly demonstrated on the forearm of this patient.

the use of systemic corticosteroids; with hematopoietic malignancies[35]; and in the setting of human immunodeficiency virus infection.[36] Porokeratosis has also been reported after bone marrow transplantation in the absence of ongoing immunosuppressive therapy, which suggests a more complex association than immunosuppression alone.[37] The distribution and morphology of DSP of immunosuppression are similar to those of DSAP, but a history of sun exposure is less evident.

LINEAR POROKERATOSIS

Linear porokeratosis is an uncommon variant, traditionally categorized as a separate entity, but is increasingly recognized as mosaic manifestation of one of the other types of porokeratosis.[38] Typically, it presents in early childhood, although congenital presentations have been reported.[39] Two distinct clinical variants have been described. The more common presentation consists of a unilateral lesion confined to an extremity following Blaschko's lines (Fig. 52-3). In the rare generalized form, multiple lesions affect several extremities and may involve the trunk. Linear variants have the highest potential for malignant degeneration of all the porokeratoses. It has been postulated that this association can be attributed to allelic loss due to a postzygotic mutation.[40] The proband in Mibelli's original publication most likely had coexistent linear porokeratosis and DSAP, with several subsequent reports confirming this phenomenon.[4,38,41,42] These findings may be explained by the loss of heterozygosity for the DSAP allele and provides an example of the type 2 segmental manifestations of an autosomal dominant disorder.[43,44]

POROKERATOSIS PALMARIS ET PLANTARIS DISSEMINATA

Porokeratosis palmaris et plantaris disseminata (porokeratosis punctata palmaris et plantaris) is a genodermatosis with an autosomal dominant inheritance

Figure 52-3 Linear porokeratosis showing the characteristic distribution along Blaschko's lines.

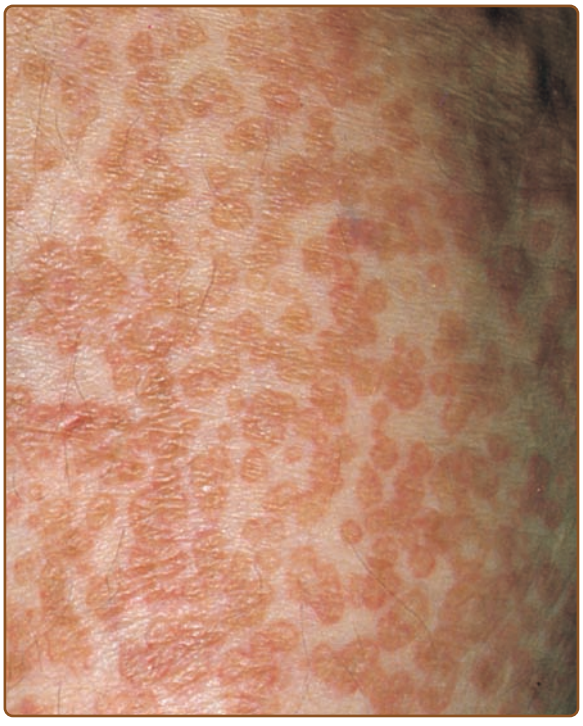

Figure 52-4 Porokeratosis palmaris et plantaris disseminata showing multiple superficial lesions on the calf. Note the similarity to disseminated superficial actinic porokeratosis shown in Fig. 52-2A.

pattern characterized by small, relatively uniform lesions (Fig. 52-4) that initially appear on the palms and soles. Subsequently, lesions spread to involve other parts of the body, including the mucous membranes and nonsun-exposed sites. The palmar and plantar lesions are generally more hyperkeratotic, and the characteristic longitudinal furrow along this ridge may be quite pronounced (Fig. 52-5). Typically, the

Figure 52-5 Sole of the foot in a patient with porokeratosis palmaris et plantaris disseminata. The ridge and furrow are clearly seen.

lesions appear during adolescence or early adulthood and are bilateral and distributed symmetrically. Porokeratosis palmaris et plantaris disseminata affects males twice as often as females.

PUNCTATE POROKERATOSIS

Punctate porokeratosis usually appears during adolescence or adulthood and may be seen concomitantly with other types of porokeratosis. Multiple minute and discrete punctate, hyperkeratotic lesions surrounded by a thin, raised margin are present on the palms and soles. Lesions may occur in a linear arrangement, or they may aggregate to form plaques. Punctate porokeratosis must be differentiated clinically and histologically from punctate keratoderma, also referred to as punctate porokeratotic keratoderma or as porokeratosis punctata palmaris et plantaris (see Chapter 50).

CDAGS SYNDROME

CDAGS syndrome (*c*raniosynostosis and clavicular hypoplasia, *d*elayed closure of the fontanel, *a*nal anomalies, *g*enitourinary malformations, *s*kin eruption), also referred to as *CAP syndrome* (*craniosynostosis*, a*nal anomalies, and p*orokeratosis), is a rare genodermatosis reported in four ethnically diverse families to date.[45,46] The main phenotypic features consist of craniosynostosis and clavicular hypoplasia, anal anomalies, and porokeratosis. It appears to segregate as an autosomal recessive trait, with possible linkage to chromosome band 22q12–13. The cutaneous manifestations are strikingly consistent, with the development of small, widespread porokeratotic papules from 1 month of age in affected individuals, predominantly affecting the face and extremities, with reported photoaggravation of lesions.

HISTOPATHOLOGY

Histopathologic patterns are similar in all forms of porokeratosis, with the characteristic changes evident at the raised and advancing edge of the lesion. The stratum corneum is hyperkeratotic, with a thin column of poorly staining parakeratotic cells, the cornoid lamella, running through the surrounding normal-staining cells (Fig. 52-6). The underlying keratinocytes are edematous with spongiosis and shrunken nuclei, and a striking dermal lymphocytic pattern may be evident. Underlying the cornoid lamella, the granular layer is either absent or markedly reduced but is of normal thickness in other areas of the lesion. The epidermis in the central portion of porokeratosis may be normal, hyperplastic, or atrophic. Although characteristic of porokeratosis, the cornoid lamella is not pathognomonic and may also be found in other conditions, such as viral warts, some ichthyoses, and nevoid hyperkeratoses.

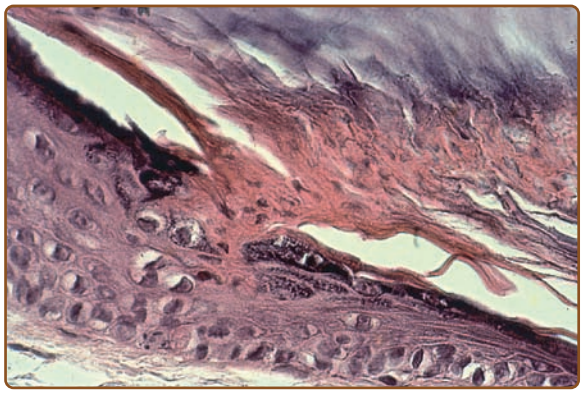

Figure 52-6 The cornoid lamella arises from an indentation of the epidermis and extends as a thin column throughout the stratum corneum. The underlying granular layer is either absent or reduced.

DIFFERENTIAL DIAGNOSIS

The classic lesions of porokeratosis are clinically distinctive, and the diagnosis is usually clinically apparent. However, atypical lesions may require differentiation (Box 52-2). Actinic keratoses, for example, may show cornoid lamellae, but also show cytologic atypia. Verruca vulgaris often shows mounds of parakeratosis that are sometimes identical to cornoid lamellae, but koilocytosis is usually present. Linear porokeratosis may be clinically confused with other linear lesions (Box 52-2), none of which has a cornoid lamella.

BOX 52-2 DIFFERENTIAL DIAGNOSIS OF POROKERATOSIS

LOCALIZED LESIONS

Most Likely

- Granuloma annulare
- Tinea corporis
- Actinic keratosis
- Viral warts

Consider

- Elastosis perforans
- Lichen planus
- Focal dermal hypoplasia (Goltz syndrome)

LINEAR

Consider

- Linear inflammatory verrucous epidermal nevus
- Incontinentia pigmenti (stage II)
- Linear lichen planus
- Ichthyosis linearis circumflexa

TREATMENT

Lesions of porokeratosis are chronic, slowly progressive, and relatively asymptomatic, although intense pruritus has been reported.[47] Intervention is usually unnecessary, and disease surveillance is standard. If the lesions are problematic or cosmetically unacceptable, treatment with potent topical steroids, keratolytics, topical retinoids, topical 5-fluorouracil,[48] imiquimod 5%, calcipotriol,[49] anthralin,[50] cryotherapy,[51] carbon dioxide laser,[52] pulsed dye laser,[53] or neodymium: yttrium-aluminum–garnet laser may be considered (Box 52-3). In order to prevent residual lesions or recurrence, ablative measures that reach the middermis are required. Techniques such as curettage, excision, and dermabrasion,[54] have been used with variable degrees of success. Oral retinoids have been shown to give the most reproducible results, although the disease typically recurs after their discontinuation. Given the association with malignancy, closer disease surveillance and a lower threshold for biopsy of suspicious lesions may be warranted in cases of giant porokeratoses, linear lesions, and in immunosuppressed individuals.

BOX 52-3 TREATMENT FOR POROKERATOSIS

	TOPICAL	SURGICAL	SYSTEMIC
First line	Photoprotection 5-Fluorouracil	Cryotherapy	
Second line	Calcipotriol Imiquimod Topical corticosteroids Topical retinoids	CO_2 laser vaporization	Oral retinoids
Third line	Dermabrasion Neodymium:yttrium-aluminum–garnet laser Grenz ray	Surgical excision	

COURSE AND PROGNOSIS

The porokeratoses are generally chronic and progressive, with lesions increasing in size and number with time. Typically, this process occurs over decades in porokeratosis of Mibelli, but may be rapid in DSAP, particularly after sun exposure. In cases of immunocompromise, fluctuations in severity may parallel the state of immunocompetence, and there are reports of remission after removal of primary malignancy.[27] The disease is generally considered a benign process; however, malignant degeneration may occur. Malignancy is thought to arise in 7% to 11% of individuals, although these figures are likely overestimated. Squamous cell carcinoma is the most frequently associated tumor and may be invasive. Bowen disease and basal cell carcinoma have also been reported. Spontaneous resolution of lesions has been reported, although it is exceptionally rare.[55]

Disorders of Epidermal and Dermal–Epidermal Adhesion and Vesicular and Bullous Disorders

Chapter 53 :: Epidermal and Epidermal–Dermal Adhesion

:: Leena Bruckner-Tuderman & Aimee S. Payne

EPIDERMAL AND EPIDERMAL–DERMAL ADHESION AT A GLANCE

- The adhesive structures in the skin include desmosomes, focal adhesions, hemidesmosomes, and basement membranes.
- Desmosomes are primarily responsible for epidermal adhesion.
- The major components of desmosomes are the desmosomal cadherins (desmogleins and desmocollins), plakins (desmoplakin, envoplakin, and periplakin), and armadillo family proteins (plakoglobin and plakophilins).
- The hemidesmosomal components comprise plakin homologs, integrins, and collagenous transmembrane proteins.
- All basement membranes contain collagen IV, laminins, nidogens, and perlecan.
- Functional specificity of basement membranes is provided by additional tissue-specific glycoproteins.
- In addition to their structural roles, desmosomes, hemidesmosomes, and the epidermal basement membrane are biologically active in cellular signaling.
- Mutations in the genes encoding the above proteins cause hereditary skin diseases, ranging from hypotrichosis and keratoderma to epidermolysis bullosa and Kindler syndrome.
- Protein components of desmosomes, hemidesmosomes, and epidermal basement membrane are targeted in autoimmune blistering diseases of the pemphigus or pemphigoid group and in epidermolysis bullosa acquisita.

The cell–cell and cell–basement membrane adhesion in the epidermis provides the skin with its resistance against environmental influences; epidermal integrity is required for protection of the entire organism against mechanical, physical, or microbial insults. The major cellular structures involved are the desmosomes at cell–cell junctions in the epidermis and the hemidesmosome–basement membrane adhesion complexes and related structures at the dermal–epidermal junction. Ultrastructurally, the hemidesmosome closely resembles one-half of the desmosome; however, at the molecular level, these two structures are distinct. Both represent specifically organized assemblies of intracellular and transmembrane molecules. The desmosome anchors cytoskeletal filaments to cell–cell junctions, and the hemidesmosome anchors cytoskeletal filaments of basal epithelial cells to the basement membrane. Our knowledge of the desmosomal, hemidesmosomal, and basement membrane molecules has expanded drastically in recent years due to the great power of both molecular genetics and proteomics. After keratinocyte transmembrane proteins were initially identified as autoantigens in pemphigus and pemphigoid, a multitude of molecules have now been characterized at both protein and gene levels, and their expression, regulation, and functions have been discerned. The antigenic epitopes in different autoimmune blistering skin diseases have been carefully mapped and, to date, mutations in at least 24 different genes have been shown to underlie heritable disorders of epidermal or epidermal–dermal adhesion in humans and mice. Morphologic, molecular, and functional aspects of these adhesion structures are delineated in this chapter.

EPIDERMAL ADHESION

ULTRASTRUCTURE OF DESMOSOMES

The desmosome (or *macula adherens*) is the major cell adhesion junction of the epidermis, serving to anchor apposing keratinocyte cell surface membranes to the intracellular keratin intermediate filament network. Desmosomes are present in almost all epithelial tissues, including the oropharynx, gut, liver, heart, lung, bladder, kidney, prostate, thymus, cornea, and central nervous system, although the desmosomal protein isoforms and intermediate filament proteins vary by cell type.[1] The primary role of desmosomes in epidermal cell adhesion is evidenced by the histologic findings in epidermal spongiosis, or intercellular edema, in which adjacent keratinocytes remain attached to each other only at desmosomal junctions (Fig. 53-1). These "intercellular bridges" served as the earliest description of desmosomes in tissues, their observation made possible with the advent of light microscopy in the nineteenth century.[2] The development of electron microscopy techniques in the mid-twentieth century allowed for higher resolution micrographs that revealed the ultrastructure of these intercellular junctions. Even in the twenty-first century, the desmosome still remains best defined by its electron micrographic appearance, with an electron-dense midline

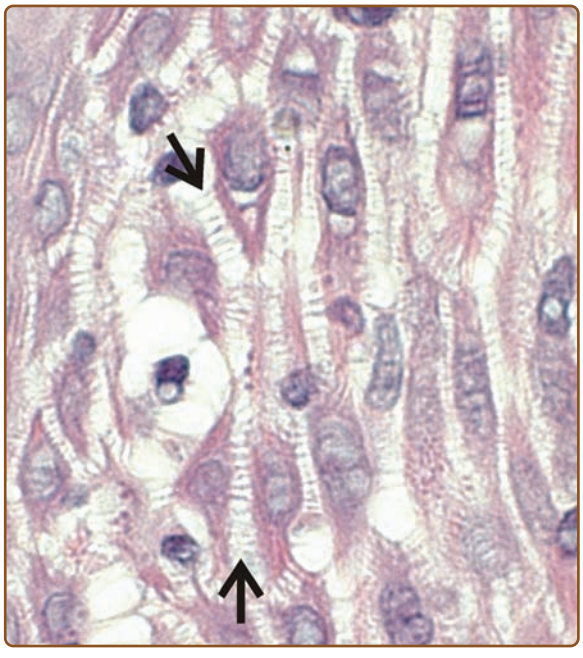

Figure 53-1 Desmosomes are the primary cell adhesion junction in the epidermis. Epidermal spongiosis, or intercellular edema due to inflammation, causes separation of keratinocytes, which remain attached by intercellular bridges representing desmosomal junctions (*arrows*). in the intercellular space halfway between apposing plasma membranes, sandwiched by two pairs of electron-dense cytoplasmic plaques (Fig. 53-2A).[3] The intercellular space between plasma membranes was called the *desmoglea* (from the Greek for "desmosomal glue"), because it was presumed to provide the adhesion that kept cells together.[4]

STRUCTURE AND FUNCTION OF DESMOSOMAL PROTEINS

In anchoring the cell surface to the intermediate filament network, desmosomes create a three-dimensional scaffolding of proteins that extend from the cell surface all the way to the nuclear envelope. This scaffolding is critical to stabilize epithelia in the face of shear stress or external trauma. Early morphologic studies led to the perception of the desmosome as a static structure, a "spot weld" functioning only to maintain intercellular adhesion.[5] Over the last three decades, the individual proteins comprising the desmosome have been biochemically characterized and cloned, shedding light on both the dynamic nature of the desmosome structure and the diversity of desmosomal protein function.

Desmosomal proteins fall into three major categories: (1) desmosomal cadherins (desmogleins and desmocollins), (2) armadillo family proteins (plakoglobin and plakophilins), and (3) plakins (desmoplakin, envoplakin, and periplakin). Additional proteins, such as Perp, ninein, kazrin, and corneodesmosin, have also been localized to epidermal desmosomes.[6–9] Immunogold electron microscopy labeling studies have further refined our understanding of how these molecular components of desmosomes are ordered within the desmosome ultrastructure[10] (Fig. 53-2B). The desmosomal cadherins are transmembrane proteins whose extracellular amino-terminal domains interact to form the trans-adhesive interface between cells, represented by the electron-dense midline of the desmoglea. Intracellularly, approximately 10–20 nm from the plasma membrane, the outer dense plaque contains the desmosomal cadherin cytoplasmic tails, plakoglobin, the desmoplakin amino-terminal domain, and plakophilin. Approximately 40–50 nm from the plasma membrane, the desmoplakin carboxyl-terminus interacts with keratin intermediate filaments, producing the inner dense plaque. The biochemistry, expression pattern, and diseases of each desmosomal component are discussed in further detail below. Although the specific physiologic roles and pathophysiologic mechanisms affecting many of the desmosomal proteins remain under active investigation, current knowledge clearly indicates the importance of desmosomes and their components beyond just cell adhesion.

DESMOSOMAL CADHERINS.

Desmogleins and desmocollins are part of the cadherin superfamily of transmembrane glycoproteins. Members of this superfamily, which includes the adherens junction protein E-cadherin, mediate calcium-dependent adhesion in a variety of epithelial tissues. In humans, there are four desmoglein (Dsg) isoforms and three

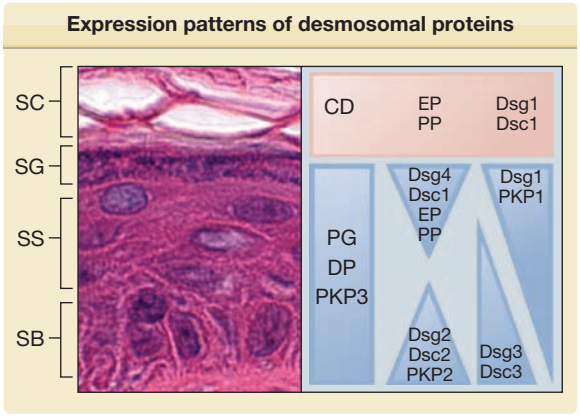

Figure 53-3 Expression patterns of desmosomal proteins in normal human epidermis. SC = stratum corneum, SG = stratum granulosum, SS = stratum spinosum, SB = stratum basale.

desmocollin (Dsc) isoforms, each with varying expression patterns within and among epithelia.[11–13] Within normal human epidermis, Dsg1, Dsg4, and Dsc1 are expressed predominantly in the differentiated cells of the superficial epidermis, while Dsg2, Dsg3, Dsc2, and Dsc3 are expressed more strongly in the basal and/or suprabasal layers[14,15] (Fig. 53-3). Among different epithelial tissues, Dsg1 and Dsg3 expression are largely limited to stratified squamous epithelia in the skin and oropharynx, as well as thymic epithelial cells. Dsg3 is also strongly expressed in squamous cell carcinomas and other head and neck cancers, where it has been proposed as a potential molecular target for therapy.[16] Dsg2 is the major desmoglein isoform in most simple and transitional epithelia, as well as cardiac myocytes.[17] Dsg4 is prominent in desmosomes of the hair follicle, testis, and prostate.[18,19] The expression pattern of the human desmocollins is less well characterized. In normal tissues, Dsc1 expression is largely limited to skin and oral epithelia, while Dsc2 is more widely expressed in most desmosome-containing epithelia and is the only desmocollin isoform in cardiac tissue.[11] Dsc3, like Dsg3, is most strongly expressed in the stratified squamous epithelia of the skin and oropharynx,[20] although UniGene data suggest weaker expression in a variety of other epithelial tissues. Desmocollin switching has been described in colorectal cancer, with downregulation of Dsc2 and upregulation of Dsc1 and Dsc3.[21]

The extracellular domains of the desmosomal cadherins consist of four cadherin repeats plus an extracellular anchor domain, each separated by a calcium-binding motif. All cadherins are synthesized as preproproteins, which include an amino-terminal signal sequence and propeptide. The propeptide is thought to prevent intracellular aggregation of newly synthesized cadherins within the secretory pathway of the cell. Proprotein convertases in the late Golgi network cleave the cadherin propeptide, thereby producing the mature adhesive protein.[22] Although the crystal structure of the desmosomal cadherins remains unsolved, studies comparing the structure of desmosomes analyzed by cryo-electron tomography

of vitreous sections with the solution structure of the classical cadherins suggest common mechanisms of intercellular adhesion, in which a conserved amino-terminal tryptophan residue on one cadherin molecule interacts with a hydrophobic acceptor pocket in the first extracellular domain of another cadherin molecule on a neighboring cell to form the trans-adhesive interface.[23–26] Additionally, cadherins may participate in "cis" interactions with cadherin molecules on the same cell through their membrane proximal domains, which may facilitate desmosome assembly. Desmosomal cadherins can engage in both homophilic (i.e., Dsg–Dsg or Dsc–Dsc) as well as heterophilic (i.e., Dsg–Dsc) interactions, although heterophilic interactions are thought to contribute most to strong intercellular adhesion.[27–29]

The cytoplasmic domains of the desmosomal cadherins are less conserved. Desmocollins have a full length "a" and a shorter "b" splice isoform. The cytoplasmic domains of desmoglein and desmocollin "a" isoforms bind plakoglobin, and some desmoglein and desmocollin isoforms may also directly bind plakophilins[30,31] (Fig. 53-2B). Increasing data suggest that desmosomal cadherins are not just adhesive molecules but may also actively regulate intracellular signaling, transcription, and other cellular processes.[1] Consistent with this, desmocollin 3-deficiency in mice causes embryonic lethality at day 2.5 before implantation, indicating a central role for desmocollin 3 in early tissue morphogenesis independent of its desmosomal adhesive function.[32]

In dermatology, the desmosomal cadherins are best known for their role as autoantigens in the immunobullous disease pemphigus (see Chapter 54). The desmoglein 3 gene was originally discovered and cloned because it was the autoantigen in pemphigus vulgaris[33] (Fig. 53-4A). Since then, all of the desmosomal cadherins have been associated with human autoimmune, infectious, and/or genetic diseases (summarized below and in Table 53-1).

Desmoglein 1 is the target of pathologic proteolytic cleavage in the infectious disorders bullous impetigo and staphylococcal scalded skin syndrome, as well as the inherited ichthyosis associated with Netherton syndrome (see Chapter 49).[34,35] Cleavage of desmoglein 1 by staphylococcal exfoliative toxin occurs between extracellular domains 3 and 4.[36] Pathogenic autoantibodies to desmoglein 1 are found in pemphigus foliaceus, mucocutaneous pemphigus vulgaris, and paraneoplastic pemphigus (see Chapters 54 and 55). Most pathogenic pemphigus foliaceus autoantibodies bind the first two extracellular domains of desmoglein 1, overlapping sites that are critical for desmoglein trans-adhesion.[37–39] Autosomal dominant mutations causing haploinsufficiency of desmoglein 1 result in palmoplantar keratoderma (PPK; see Chapter 50). The PPK is classically striate (Fig. 53-4B), occurring at sites of greatest trauma or friction, but focal and diffuse forms have also been described.[40–42]

Desmoglein 2 has been implicated in human cardiovascular disease as a cause of autosomal dominant arrhythmogenic right ventricular cardiomyopathy (ARVC).[43] The lack of skin phenotypes in affected patients indicates that desmoglein 2 is not required for epidermal adhesion, likely due to compensatory adhesion from other more highly expressed epidermal desmosomal cadherin isoforms.

Desmoglein 3 is the target of pathogenic autoantibodies in mucosal and mucocutaneous pemphigus vulgaris and paraneoplastic pemphigus (see Chapters 54 and 55.) Most pathogenic autoantibodies in pemphigus vulgaris target the amino-terminal extracellular (EC1–2) domains of desmoglein 3.[37,44,45] Because desmoglein 3 deficiency in mice phenotypically resembles autoimmunity to desmoglein 3 in mucosal pemphigus vulgaris with oral suprabasal erosions, pemphigus autoantibodies are thought to cause loss of desmosomal cadherin function.[46] More recent research has focused on signaling pathways activated after binding of pemphigus vulgaris autoantibodies to keratinocytes, as several biochemical inhibitors have been shown to prevent blistering in a neonatal mouse passive transfer model[47] (discussed in further detail in Chapter 54).

Figure 53-4 Desmosomal proteins are pathophysiologic targets in human autoimmune and genetic diseases. **A.** Indirect immunofluorescence on monkey esophagus with pemphigus serum that contains autoantibodies to desmoglein 3. The cell surface–intercellular pattern staining is diagnostic of pemphigus. **B.** Striate palmoplantar keratoderma is associated with haploinsufficiency of desmoglein 1 or desmoplakin.

TABLE 53-1
Desmosomal Targets in Human Disease

	Desmosome Component	Autoimmune Target	Genetic Target
Desmosomal cadherins	Desmoglein 1[a]	Pemphigus foliaceus, pemphigus vulgaris	Striate PPK (AD)
	Desmoglein 2		ARVC (AD)
	Desmoglein 3	Pemphigus vulgaris, paraneoplastic pemphigus	
	Desmoglein 4	Pemphigus foliaceus,[b] pemphigus vulgaris[b]	Hypotrichosis (AR); Monilethrix (AR)
	Desmocollin 1	IgA pemphigus (subcorneal pustular dermatosis)	
	Desmocollin 2		ARVC (AR and AD)
	Desmocollin 3	Pemphigus vulgaris	Hypotrichosis (AR)
Desmosomal plaque proteins	Desmoplakin I/II	Paraneoplastic pemphigus	Striate PPK (AD); Carvajal syndrome (AR): diffuse PPK, wooly hair, left ventricular cardiomyopathy; lethal acantholytic epidermolysis bullosa (AR); skin fragility–wooly hair syndrome (AR): PPK, wooly hair, nail dystrophy
	Other plakins[c]	Paraneoplastic pemphigus	
	Plakoglobin		Naxos disease: diffuse PPK, wooly hair, ARVC (AR)
	Plakophilin 1		Skin fragility and ectodermal dysplasia (AR)
	Plakophilin 2		ARVC (AD)
Stratum corneum desmosome protein	Corneodesmosin		Hypotrichosis simplex of the scalp (AD)

[a]Also targeted by exfoliative toxin in bullous impetigo and staphylococcal scalded-skin syndrome and hyperactive serine proteases in Netherton syndrome.
[b]Desmoglein 4 immunoreactivity is due to cross-reactivity with desmoglein 1 in pemphigus sera.
[c]Including envoplakin, periplakin, and bullous pemphigoid antigen 1.
AD = autosomal dominant; AR = autosomal recessive; PPK = palmoplantar keratoderma; ARVC = arrhythmogenic right ventricular cardiomyopathy.

Desmoglein 4 mutations have been described in rare autosomal recessive forms of hypotrichosis and monilethrix.[48–51] One patient demonstrated transient scalp erosions during the first 2 weeks of life. Most of the mutations in Dsg4 are frameshift or nonsense mutations that would be predicted to lead to haploinsufficiency, although missense mutations have also been reported,[52] Desmoglein 4 immunoreactivity is observed in pemphigus vulgaris and pemphigus foliaceus sera,[51] but subsequent studies have attributed this to cross-reactivity from Dsg1 autoantibodies.[53]

Desmocollin 1 is the target of autoantibodies in the subcorneal pustular dermatosis of IgA pemphigus (see Chapter 54.)

Desmocollin 2, like desmoglein 2, is mutated in both autosomal dominant and recessive forms of ARVC, with no epidermal phenotype in affected patients.[54,55]

Desmocollin 3 mutations were found in one Pakistani kindred with autosomal recessive hypotrichosis.[56] Autoantibodies to desmocollin 3 have also been found in pemphigus vulgaris patients, particularly those with vegetative lesions.[57]

PLAKOGLOBIN. Plakoglobin (also known as γ-catenin) directly binds the cytoplasmic tails of the desmogleins and desmocollin "a" isoforms, as well as E-cadherin, the major transmembrane protein of adherens junctions in epidermal keratinocytes.[58,59] It is expressed throughout all layers of the epidermis and is ubiquitously expressed in all epithelia. Plakoglobin, like plakophilin, is a member of the armadillo gene family, characterized by a conserved protein structure with head and tail domains that flank multiple homologous arm repeats.[60] Various domains of plakoglobin modulate its binding to the desmosomal cadherins.[61–63] Other domains bind to desmoplakin, thus linking desmogleins and desmocollins to desmoplakin.[64] Plakoglobin can also localize to the nucleus, where it may modulate gene transcription by TCF/LEF family members.[65,66] Although most depictions of the desmosome show both plakoglobin and plakophilin binding to desmoplakin, biochemical studies suggest that these interactions are mutually exclusive.[67] Likely, the armadillo family proteins play more dynamic roles in recruitment of desmosomal proteins to the plaque, similar to α-catenin in adherens junctions.[68,69]

Plakoglobin mutations result in Naxos disease, an autosomal recessive syndrome of diffuse PPK, wooly hair, and arrhythmogenic right ventricular cardiomyopathy, the latter of which may present in late childhood to adolescence.[70]

DESMOPLAKIN. Desmoplakin exists in two RNA splice variants, desmoplakin I and II.[71,72] It is unknown whether different isoforms perform different cellular functions, although human disease mutations suggest that desmoplakin I is required for normal desmosomal function.[73] Desmoplakin is part of the plakin gene family,[74] which includes the hemidesmosomal proteins bullous pemphigoid antigen 1 and plectin, as well as envoplakin and periplakin. Similar to other desmosomal components, desmoplakin is a modular protein, with different modules fulfilling different functions. The central part of one desmoplakin molecule coils around the central part of another to form a rod-like center. The amino-terminal head domain binds to plakoglobin,[64] and the carboxyl-terminal tail binds to keratin.[75] Therefore, desmoplakin provides the major link between the keratin filaments and the desmosomal plaque. Desmoplakin also plays a critical role in development independent of its function in desmosomes, as desmoplakin-null mice die early in embryogenesis at E6.5, before desmosomes are formed.[76]

A broad range of desmoplakin mutations have been associated with human disease, leading to variable phenotypic combinations of PPK (striate or diffuse), dilated cardiomyopathy (left or right), wooly hair, nail abnormalities, and/or skin blisters.[52] Haploinsufficiency of desmoplakin leads to autosomal dominant striate PPK.[77] Autosomal recessive mutations in desmoplakin were described in three Ecuadorian families with Carvajal syndrome, consisting of diffuse PPK, wooly hair, and arrhythmogenic *left* ventricular cardiomyopathy.[78] A Naxos-like syndrome of PPK, wooly hair, and ARVC occurs with the p.R1267X nonsense mutation, which affects only the desmoplakin I splice isoform, indicating that desmoplakin II is not sufficient to restore normal desmosomal function in epidermis.[73] Lethal acantholytic epidermolysis bullosa (widespread epidermolysis, generalized alopecia, anonychia, and neonatal teeth) was attributed to compound heterozygous mutations in desmoplakin that caused loss of the desmoplakin tail.[79] Additionally, desmoplakin autoantibodies are observed in paraneoplastic pemphigus sera (see Chapter 55).

PLAKOPHILINS. Plakophilins, like plakoglobin, can localize both to the plasma membrane as well as the nucleus, although their function outside of desmosomal adhesion is not well characterized. Plakophilins directly bind to desmoplakin, and may also directly bind keratins and desmosomal cadherins, which is thought to aid in clustering and lateral stability of the desmosomal plaque.[30,31,67] Plakophilin 1 also associates with the eukaryotic translation initiation factor eIF4A1 in the mRNA cap complex, where it functions to regulate translation and cell proliferation.[80]

Mutations in plakophilin 1 cause ectodermal dysplasia-skin fragility syndrome, suggesting a role for plakophilin 1 in epidermal morphogenesis as well as adhesion.[81] Plakophilin 2 mutations are the most common cause of autosomal dominant ARVC.[82] Currently, there are no known human diseases associated with plakophilin 3.

OTHER DESMOSOMAL PROTEINS. *Envoplakin* and *periplakin* are desmosomal plaque proteins expressed in the superficial layers of the epidermis. Both proteins incorporate into the corneodesmosomes of the stratum corneum. Mice deficient in envoplakin, periplakin, and involucrin do not demonstrate adhesion defects, but instead show impaired desquamation and epidermal barrier function.[83] Envoplakin and periplakin autoantibodies are characteristic of paraneoplastic pemphigus sera (see Chapter 55).

Corneodesmosin is a secreted glycoprotein that incorporates into corneodesmosomes and is also expressed in the inner root sheath of the hair follicle. Heterozygous mutations in corneodesmosin are associated with an autosomal dominant hypotrichosis simplex of the scalp.[84] Loss of cohesion in the inner root sheath and aggregates of proteolytically cleaved corneodesmosin around the hair follicle are observed in scalp biopsies of affected patients.

EPIDERMAL–DERMAL ADHESION

STRUCTURAL AND FUNCTIONAL CHARACTERISTICS OF BASEMENT MEMBRANES

Basement membranes underlie epithelial and endothelial cells and separate them from each other or from the adjacent stroma. Another form of basement membrane surrounds smooth muscle or nerve cells. The physiologic functions of basement membranes are diverse: in the various organ systems they provide support for differentiated cells, maintain tissue architecture during remodeling and repair, and, in some cases, acquire specialized functions, including the ability to serve as selective permeability barriers (e.g., the glomerular basement membrane or the blood–brain barrier) or acquire strong adhesive properties, like the basement membrane at the dermal–epidermal junction, or that surrounding smooth muscle cells, which provide the tissues resistance against shearing forces. All of these characteristics of basement membranes are also used during development and differentiation of multicellular organisms (Box 53-1).

Ultrastructurally, basement membranes most often appear as trilaminar structures, consisting of a central electron-dense region, known as the *lamina densa*, adjacent on either side to an apparently less-dense area, known as the *lamina lucida* or *lamina rara*. The lamina lucida directly abuts the plasma membranes of the adherent cells. The relative size of each of these regions varies in different tissues, among the basement membranes of the same tissue at different ages, and as a consequence of diseases. For example, the trilaminar glomerular basement membrane in humans varies from 240 nm to 340 nm in width, whereas the bilaminar basement membrane of the dermal–epidermal junction measures 50 nm to 90 nm. This ultrastructure demonstrates that basement membranes serve as substrates for the attachment of cells and fix their polarity. Their continuity throughout the various organ systems stabilizes

BOX 53-1 MAJOR FUNCTIONS OF BASEMENT MEMBRANES

- Scaffold for tissue organization and template for tissue repair.
- Selective permeability barriers. The renal basement membranes serve for the ultrafiltration of plasma, and other basement membranes also demonstrate selective filtration.
- Physical barriers between different types of cells or between cells and their underlying extracellular matrix.
- Firmly link an epithelium to its underlying matrix or to another cell layer and provide polarity.
- Regulate cellular functions.

the tissue orientations and provides a template for orderly repair after traumatic injury. Major disruptions in the basement membrane result in the formation of scar tissue and the loss of function in that area.

Different basement membranes contain both common and unique components. All share a basic network structure to which specific macromolecules have been appended. These molecules are responsible for the specialized functions of different basement membranes. The basic constituents of these structures are collagen IV, laminins, nidogens, and proteoglycans of the perlecan type, which all are highly conserved, although the isoforms, the number of the polypeptide subunits, and their individual structures vary among species.[84,85] The nearly ubiquitous distribution of heparan sulfate proteoglycans in all basement membranes suggests that these serve as selective permeability barriers in multiple locations, including the kidney and the blood–brain barrier. Ultrafiltration may be especially important during development and morphogenesis of all tissues.

Basement membranes also provide physical separation between epithelia and their underlying extracellular matrices. This barrier is especially important in the containment of tumors. With the exception of certain cells of the immune system, nonmalignant cells seldom cross a basement membrane. In contrast, malignant cells bind the basement membrane, regionally disrupt its structure, and migrate through the rupture. Laminins and integrins mediate the tumor-cell binding, and the basement membrane dissolution is catalyzed at least in part by metalloproteases produced by the tumor cell. The absence of distinguishable basement membranes in tumor biopsies is used as an indicator of malignancy, and there appears to be a high correlation between metastasis and basement membrane disruption. These observations underline the importance of the basal lamina as an obstacle to cell migration.

By binding biologically active signaling molecules, basement membranes regulate a multitude of biologic events. The constituent proteoglycans can bind growth factors that can be released from the complexes. Thus, the basement membranes are potent regulators of cell adhesion and migration, cytoskeleton and cell form, cell division, differentiation and polarization, and apoptosis.[85]

ULTRASTRUCTURE OF THE DERMAL–EPIDERMAL JUNCTION

The dermal–epidermal junction is an example of a highly complex form of basement membrane,[86,87] which underlies the basal cells and extends into the upper layers of the dermis (Fig. 53-5A). This basement membrane is continuous along the epidermis and skin appendages, including sweat glands, hair follicles, and sebaceous glands. The dermal–epidermal junction can be divided into three distinct zones. The first zone contains the keratin filament–hemidesmosome complex of the basal cells and extends through the lamina lucida to the lamina densa. The plasma membranes of the basal cells in this region contain numerous electron-dense plates known as hemidesmosomes. The intracellular architecture and organization of the basal cells are maintained by keratin intermediate filaments,

7 nm to 10 nm in diameter that course through the basal cells and insert into the desmosomes and hemidesmosomes. External to the plasma membrane is a 25-nm to 50-nm-wide lamina lucida that contains anchoring filaments, 2 nm to 8 nm in diameter, originating in the plasma membrane and inserting into the lamina densa. The anchoring filaments can be seen throughout the lamina lucida but they are concentrated in the regions of the hemidesmosomes. Thus, the anchoring filaments appear to secure the epithelial cells to the lamina densa.

The existence of the lamina lucida in vivo has been questioned.[86,88] When the ultrastructure of the basement membrane is evaluated after high-pressure preservation techniques, the lamina densa appears intimately associated with the epithelial cell surface. When the dermal–epidermal junction is similarly prepared, no distinct lamina lucida is seen (see Fig. 53-5B). This suggests that the lamina lucida may result from shrinkage of the cell surface away from the lamina densa due to dehydration. The appearance of anchoring filaments spanning the lamina lucida may then result from the firm attachment of constituents of the lamina densa at the hemidesmosome that is subsequently pulled from the lamina densa by shrinkage. Other components that are also tightly fixed to the keratinocyte plasma membrane, either at the hemidesmosomes or at other sites along the membrane, may similarly become displaced into the shrinkage space. Regardless of its actual occurrence in vivo, the evaluation of the lamina lucida by standard electron microscopy techniques has allowed identification of specific structures that would otherwise have been difficult to detect. In addition, the morphologic term *lamina lucida* remains practical in the scientific communication and continues to be used.

The second zone, the lamina densa, appears as an electron-dense amorphous structure 20 nm to 50 nm in width. At high magnification, it has a granular–fibrous appearance.[86] The major molecular components of the lamina densa are collagen IV, nidogens, perlecan, and laminins, which all can polymerize to networks of variable thickness.[84,86]

The subbasal lamina contains microfibrillar structures. Two of these are readily distinguishable. *Anchoring fibrils* appear as condensed fibrous aggregates 20 nm to 75 nm in diameter.[89] At high resolution, they appear to have a cross-striated banding pattern (see Fig. 53-5A). The length of the anchoring fibril is difficult to measure because of its random orientation in relation to the plane of the section. In toad skin, these structures have lengths of approximately 800 nm. The anchoring fibrils in human skin appear to be somewhat shorter. The ends of the fibrils appear less tightly packed, giving a somewhat frayed appearance. The proximal end inserts into the basal lamina, and the distal end is integrated into the fibrous network of the dermis.[90] Many of the anchoring fibrils originating at the lamina densa loop back into the lamina densa in a horseshoe-like manner; others insert their opposite ends into amorphous-appearing structures, termed *anchoring plaques*.[90] These structures are believed to be independent "islands" of electron-dense material, although some controversy exists in the literature.[91] Anchoring fibrils are primarily aggregates of collagen VII.

Fibrillin-containing *microfibrils*, 10 nm to 12 nm in diameter, are also localized in the sublamina densa region. These are elastic-related fibers, because elastic components of the dermis are formed from microfibrillar and amorphous components.[92] The microfibrillar component in the presence of abundant amorphous component is known as the *elastic fiber*. In the papillary dermis, the microfibrils insert into the basal lamina perpendicular to the basement membrane and extend into the dermis, where they gradually merge with the elastic fibers to form a plexus parallel to the dermal–epidermal junction. These two elastic components appear to be continuous with the elastic fibers present deep within the reticular dermis.[92]

In summary, the ultrastructure of the dermal–epidermal junction strongly suggests that the lamina densa functions as a structural scaffold for the attachment of the epidermal cells at one surface, secured by anchoring filaments extending from the lamina densa to the hemidesmosomes. The latter also serve as insertion points for intracellular keratin filaments that form scaffolding for the basal cells. On the opposite surface, the extracellular matrix suprastructures of the dermis are firmly attached to the lamina densa. The interaction of collagen-containing dermal fibers with the lamina densa appears to be mediated by the anchoring fibrils. The elastic system of the dermis inserts directly into the basal lamina via the microfibrils. Thus, the dermal–epidermal junction provides a continuous series of attachments between the reticular dermis and the cytoskeleton of the basal cells. These observations suggest four major functions for the epidermal basement membrane: (1) a structural foundation for the secure attachment and polarity of the epidermal basal cells; (2) a barrier separating the epidermis and the dermis; (3) firm attachment of the dermis to the epidermis through a continuous system of structural elements; and (4) modification of cellular functions, such as organization of the cytoskeleton, differentiation, or rescue from apoptotic signaling via outside-in signaling mechanisms.

BIOCHEMICAL CHARACTERIZATION OF THE BASEMENT MEMBRANE

Basement membranes contain collagenous and noncollagenous glycoproteins and proteoglycans. The content of the collagen-specific amino acids hydroxyproline and hydroxylysine suggests that collagens account for 40% to 65% of the total basement membrane protein. All basement membranes contain certain isoforms of collagen IV, laminin, nidogen, and the heparan sulfate proteoglycan perlecan (Box 53-2). For example, the α3 chain of collagen IV is localized in the basement membrane of the kidney and lung, but not in those of the skin and blood vessels. In contrast, collagens VII and XVII are associated with the squamous epithelia of skin but are not found in glomerular and alveolar

basement membranes. In addition, many other tissue-specific components are found in basement membranes, including different collagens, laminins, fibulins, and fibronectin.[84,85,92,93] Differences in macromolecular composition are responsible for morphologic and functional variance of basement membranes.

UBIQUITOUS COMPONENTS OF BASEMENT MEMBRANES

COLLAGEN IV. Collagen IV is a heterotrimer of three α chains.[84,94] Each of these contains three distinct domains (Fig. 53-6A): (1) the *N*-terminal cysteine-rich (7-S) domain, (2) a central triple-helical domain, and (3) a *C*-terminal globular domain (NC-l). The trimer composition is determined by the NC-l domains, and the α chains are linked to each other by covalent interactions through these domains.[95] The triple helix of collagen IV is long and contains several discontinuities, which result in increased flexibility in the collagen IV helix, but also render it susceptible to proteases.

The suprastructure of collagen IV has been partially elucidated by rotary shadowing electron microscopy that indicated that the major interactions among collagen IV molecules occur at their amino- and carboxyl-terminal domains, and by lateral association of their triple helices (see Fig. 53-6A).[84,95] Covalent interactions among 7-S regions of different molecules are the basis for the specialized network characteristic of basement membranes (see Fig. 53-6B). The individual 7-S regions overlap in both the parallel and antiparallel directions, producing a characteristic four-legged "spider" form. The NC-l domains at the end of each leg of the spider interact with the NC-l domain of the adjacent aggregates (see Fig. 53-6B). Association is stabilized by covalent bonds. These end-to-end interactions result in an extended two-dimensional network that is the basis of basement membrane organization.

The high flexibility of the basement membrane network structure makes the possibility of interactions with other molecules very attractive. An open meshwork of collagen IV with, for example, laminins or perlecan, can be easily visualized (Fig. 53-7).[85] The implied porosity of this structure would then be limited by the size of the pores in the collagen network and by structural elements associated with it. This model of the basement membrane structure allows considerable mechanical stability while retaining physiologic flexibility. These properties of strength and elasticity would be expected for a dynamic surface, such as that seen in the dermal–epidermal junction and surrounding blood vessels.

Collagen IV molecules in different basement membranes contain genetically distinct but structurally homologous α chains. The α1 and α2 chains are ubiquitous, but the α3, α4, α5, and α6 chains show restricted distribution among tissues.[93] The chain organization and discriminatory interactions between the NC-1 domains govern network assembly in the basement membranes.[95] The six chains of collagen IV are distributed in three major networks, (1) α1–α2, (2) α3–α4–α5, and (3) α1–α2–α5–α6, whose chain composition is determined by the NC-l domains. Two networks, namely α1–α2-containing and α3–α4–α5-containing networks, exist in the glomerular basement membrane. Smooth muscle basement membranes have an α1–α2–α5–α6-containing network in addition to the classic α1–α2 network. Within the dermal–epidermal junction, the α1–α2-containing collagen IV network dominates, but α1–α2–α5–α6-containing network is also likely to be present.[96]

Mutations in the genes encoding the α1 and α2 chains cause pathologies in different organs, ranging from small-vessel disease, which often underlies ischemic strokes and intracerebral hemorrhages to the eye and the HANAC (hereditary angiopathy with nephropathy, aneurysms, and muscle cramps) syndrome.[93,97,98] Interestingly, despite the ubiquitous presence of the α1 and α2 chains of collagen IV in basement membranes, aberrations do not occur in all basement membranes, suggesting varying tissue-specific roles for collagen IV. Structural aberrations in the genes encoding the α3, α4, α5, and α6 chains cause different forms of Alport syndrome, a genetic disease characterized by nephritis and deafness.[93] The α3(IV) chain is the antigen recognized by the circulating autoantibodies in the Goodpasture syndrome.[93]

Laminins. Laminins are very large glycoproteins (600 to 950 kDa) within the lamina lucida/lamina densa of all basement membranes.[99] Three types of subunit chains have been designated α, β, and γ chains, and each laminin is a trimeric aggregate of one α, β, and γ chain. The trimers have semirigid and extended structures, which appear as an asymmetric cross in rotary shadowing electron microscopy (see Fig. 53-6C). The long arm of the cross is approximately 125 nm in length; the short arms are variable. Each laminin molecule contains globular and rod-like domains that have been individually implicated in various functions, such as aggregation with itself and with other components of the lamina densa (Fig. 53-8), cell attachment and spreading, neurite outgrowth, or cellular differentiation.[85,99] The *C*-terminal laminin-type globular (LG) domain of the α chain, at the foot of the long arm of the laminin cross, harbors the binding site for integrins.[99]

To date, 15 laminin isoforms have been identified. These represent different trimeric combinations of five distinct α chains, three β chains, and three γ chains known so far. Historically, laminins were named as *laminin-1* to *laminin-15*, in the order of their discovery, but this classification had grown quite impractical, with the need to memorize the numbers. The current,

simplified nomenclature is based on the chain composition and the number of each α, β, and γ chain (Table 53-2).[100] For example, the classic "prototype" laminin-1, with α chain composition α1β1γ1, is now called *laminin 111*. The major laminin of the epidermal basement membrane, the previous laminin-5, with α chain composition α3β3γ2, is now called *laminin 332*.

The α2 chain containing laminins are present primarily within the basement membranes of the muscle fibers, nerves, neuromuscular junction, and glomerulus. The α3 chain is involved in epithelial adhesion, and the α4 and α5 chains are found in a variety of tissues including endothelia, epithelia, neuromuscular junction, and glomerulus.[101] Laminin 511 is present in

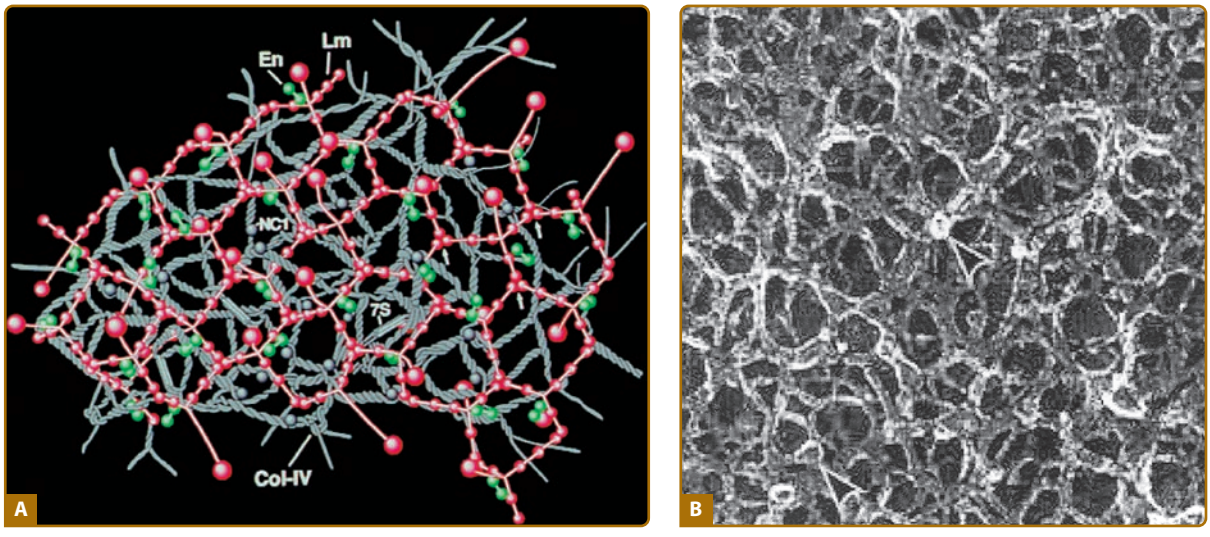

Figure 53-7 **A.** Representation of the networks formed by the ubiquitous components of the basement membranes. Monomeric collagen IV (Col-IV) self-assembles into dimers and tetramers that further aggregate into a complex lattice. Laminins self-polymerize into networks. Perlecan can oligomerize in vitro, and the glycosaminoglycan side chains interact with the Col-IV framework. Nidogen is thought to bind components of all three networks and also fibulins. Therefore, nidogen plays a central role as a stabilizer of the lamina densa framework. Individual molecules are not drawn to scale. (Drawing used with permission from Peter Yurchenco, MD, Robert Wood Johnson Medical School, Piscataway, NJ, USA.) **B.** Rotary shadowing image of a quick-freeze, deep-etch replica of Col-IV polymers. The replica shows an extensive, branching, and anastomosing network with occasional globular structures (*arrowhead*), which can be visualized as a model for the structure of the lamina densa. Figure 53-8 A schematic representation of laminin molecules. Each laminin is a heterotrimer of an α, a β, and a γ chain. On the left, the classic prototype laminin 111 consisting of α1β1γ1 chains is shown. The *N*-terminal short arm of each chain is free, the long *C*-termini fold to a coiled-coil and form the long arm. The distal *C*-terminus of the α chain contains five globular LG domains, which harbor the integrin-binding site. Laminin 332 exists in two forms, 3A32 and 3B32. These represent splice variants of the α chain, the short variant is 3A and the "full length" chain 3B. The *N*-termini of the β3 and γ2 chains are proteolytically processed to yield mature laminin 332.

TABLE 53-2
Most Common Laminin Isoforms[a]

Name	Chain Composition	Tissue Distribution
Laminin 111	α1β1γ1	Developing epithelia
Laminin 121	α1β2γ1	Myotendinous junction
Laminin 211	α2β1γ1	Muscle, nerves
Laminin 213	α2β1γ3	Muscle
Laminin 221	α2β2γ1	Neuromuscular junction, glomerulus
Laminin 3A11	α3β1γ1	Stratified epithelia
Laminin 3A21	α3β2γ1	Amnion, maybe other stratified epithelia
Laminin 3A32	α3β3γ2	Stratified epithelia
Laminin 3B32	α3β3γ2	Stratified epithelia, uterus, lung
Laminin 411	α4β1γ1	Endothelia, nerves, smooth muscle, adipose tissue
Laminin 421	α4β2γ1	Endothelia, neuromuscular junction, smooth muscle, glomerulus, adipose tissue
Laminin 423	α4β2γ3	Retina, central nervous system, kidney, testis
Laminin 511	α5β1γ1	Mature epithelia and endothelia, smooth muscle
Laminin 521	α5β2γ1	Mature epithelia and endothelia, smooth muscle, neuromuscular junction, glomerulus
Laminin 523	α5β2γ3	Retina, central nervous system, muscle, kidney

[a]See Durbeej M: Laminins. *Cell Tissue Res* **339**:259-268, 2010.

the basement membrane of the epidermis and the hair follicles, where it is believed to be involved in developmental signaling.[99,100] The distribution of the β2 chain is largely restricted to the neuromuscular junction, but it is also found in nonmuscle tissues such as the kidney glomerulus and the capillary basal lamina.[99] The β3 chain is involved in epithelial adhesion. Three γ chain variants—γ1, γ2, and γ3—are known. The γ2 chain is found only in laminin 332 in the skin. The γ3 chain, a component of laminins 423 and 523, binds nidogens and is localized in basement membrane zones of adult and embryonic brain, kidney, skin, muscle, and testis. It is present in much lower concentrations than the γ1 chain, a fact that may indicate highly specialized functions.[99] The functions of all laminins are not yet fully understood, but by interacting with integrins and other cell surface components laminins control cellular activities such as adhesion, migration, proliferation, and polarity in a wide variety of organs.[99,100]

Several human congenital diseases are caused by mutations in the laminin chains.[99] Since some chains can be components in several different laminins, the mutations can affect functions of multiple laminins in different tissues. For example, mutations in the α2 chain cause congenital muscular dystrophy and a significant decrease in the amount of basement membrane accumulated surrounding muscle cells.[99] The absence of the basement membrane leads to progressive degeneration of the muscle due to cell death. Therefore, the prediction is that laminins, and basement membranes in general, are required to prevent apoptosis by the cell types they surround.[99] Mutations in the α3, β3, or γ2 chains underlie junctional epidermolysis bullosa, and mutations of the α4 chain are associated with cardiomyopathy. Pierson syndrome, a severe congenital condition affecting mainly the kidney and the eye, is caused by mutations of the β2 chain.

Nidogens. Two nidogens, nidogen 1 and 2, previously known as *entactin*, are distinct gene products. Both are relatively small molecules (see Fig. 53-6D), which bind laminins at a specific site within the γ1 and the γ3 chain,[93,102] but also collagen IV, perlecan, and fibulins. Nidogens are likely to act as connecting elements between the collagen IV and laminin networks and integrate other basement membrane components into this specialized extracellular matrix.[84] Targeted ablation of nidogens in mice showed that the loss of either isoform has no effect on basement membrane formation and organ development, but lack of both results in severe defects of the lung and the heart[102] that are not compatible with life. Interestingly, despite the ubiquitous presence of nidogens in basement membranes, aberrations did not occur in all basement membranes, suggesting distinct roles for nidogens in different basement membranes.[102]

Heparan Sulfate Proteoglycans. Another class of ubiquitous integral basement membrane constituents are the proteoglycans. Three proteoglycans are characteristically present in vascular and epithelial basement membranes: (1) perlecan, (2) agrin, and

(3) collagen XVIII.[103] They consist of a core protein of various lengths, and carry primarily heparan sulfate side chains. The name *perlecan* is derived from its rotary shadowing appearance reminiscent of a string of pearls. Perlecan represents a complex multidomain proteoglycan with enormous dimensions and a number of posttranslational modifications. Knockout mice lacking perlecan exhibited abnormalities in many tissues, including basement membranes, and embryonic lethality. The basement membranes deteriorated in regions under increased mechanical stress, such as myocardium or skin, resulting in lethal cardiac abnormalities and skin blistering.[103] Agrin is a major heparan sulfate proteoglycan of neuromuscular junctions and renal tubular basement membranes. Collagen XVIII is considered to be a hybrid collagen—proteoglycan in various organs.[104] In collagen XVIII knockout mice, basement membranes were broadened in different organs, accompanied with mesangial expansion and reduced function of the kidney. The proteoglycans can interact with several other basement membrane components and are believed to contribute to the overall architecture of the basement membrane as well as provide tissue-specific functions. The high sulfate content makes them highly negatively charged and hydrophilic, and the charge density is responsible for providing the selective permeability of the glomerular basement membrane.

Syndecans are transmembrane heparan sulfate proteoglycans present on most cell types, including basal keratinocytes of the epidermis. The extracellular domains have affinity for laminins and, presumably through these interactions, they engage in outside-in signaling and regulate cellular processes ranging from growth factor signaling, cell adhesion, and cytoskeletal organization, to infection of cells with microorganisms.[105]

Fibulins. Fibulins are a family of six highly conserved, calcium-binding extracellular matrix proteins. They are located in vessel walls, basement membranes, and microfibrillar structures and they have overlapping binding sites for a variety of ligands, both basement membrane proteins and components of the interstitial connective tissues.[106] Therefore, fibulins are believed to function as intermolecular bridges that stabilize the supramolecular organization of extracellular membrane structures, such as elastic fibers and basement membranes. Genetic defects of the genes encoding fibulin 4 and 5 cause different forms of cutis laxa.

EPITHELIUM-SPECIFIC BASEMENT MEMBRANE COMPONENTS

The dermal–epidermal junction of skin is an excellent example of specific divergence in basement membrane structure. The structural components of hemidesmosomes, anchoring filaments, and anchoring fibrils in the basement membrane zone are quite well characterized.[84–87,107,108] A cartoon depicting the relative locations of the proteins found at the dermal–epidermal junction is shown in Fig. 53-9. These proteins are listed in Table 53-3 and discussed in the following sections.

HEMIDESMOSOMES

Ultrastructurally, the hemidesmosome closely resembles one-half of the desmosome at cell–cell junctions in the epidermis. However, the components of these two structures are distinct. The 230-kDa BPAG1 (bullous pemphigoid antigen 1, or BP230) is a coiled-coil dimeric protein with homology to plakins, which bind intermediate filaments. BPAG1 is the major component of the hemidesmosomal inner dense plaque. Ablation of BPAG1 is associated with epidermolysis bullosa simplex in mice and humans.[72,109] The 180-kDa BPAG2 or BP180, and the major antigen in bullous pemphigoid (Fig. 53-10), is a transmembrane collagen now known as *collagen XVII*, where the collagenous domain is extracellular. In fact, collagen XVII is a prototype of the novel protein family of collagenous transmembrane proteins, type II transmembrane molecules with one or more collagenous stretches in the extracellular domain.[110] The intracellular ligands of collagen XVII are plectin, BPAG1 and β4 integrin, and the extracellular ligands α6 integrin and laminin 332.[107,108] The 120-kDa ectodomain of collagen XVII is shed from the cell surface by proteinases of the ADAM (a disintegrin-like and metalloproteinase-containing) family through cleavage within the juxtamembranous NC-16 domain (Fig. 53-11).[111] Mutations in collagen XVII cause junctional epidermolysis bullosa (see Chapter 62), indicating that it stabilizes interactions of basal keratinocytes with the basement membrane.[112] Ablation of the mouse *Col17a1* gene resulted in moderate skin blistering, dental anomalies, and graying hair.[113,114] Plectin, another dimeric plakin homolog, is also a component of the hemidesmosome. However, its tissue distribution is not limited to hemidesmosome-containing basement membranes. Mutations of plectin result in epidermolysis bullosa simplex and progressive muscular dystrophy and, in some cases, epidermolysis bullosa simplex with pyloric atresia,[115] indicating a role for plectin in the stability of cell–basement membrane adhesion in a variety of tissues.

One key component of the hemidesmosome is the integrin α6β4.[107] It has a high affinity for laminin 332 and is essential to integration of the hemidesmosome with the underlying basement membrane and stroma.[107,108] Mutations in either the α6 or β4 chains result in junctional epidermolysis bullosa associated with pyloric atresia.[108,112]

A member of the widely expressed cell surface transmembrane proteins of the tetraspanin family, CD151, is also a component of the hemidesmosome. It forms complexes with α3β1 and α6β4 integrins at the basolateral surface of basal keratinocytes and stabilizes their functions.[116] CD151-null mice have apparently normal hemidesmosomes, but exhibit some functional aberrations, for example, poor keratinocyte migration in explant cultures. A very rare human genetic condition delivered indirect information on the functions of CD151. In addition to the expression of CD151 in

Hypothetical relationships of molecules within the dermal-epidermal junction basement membrane

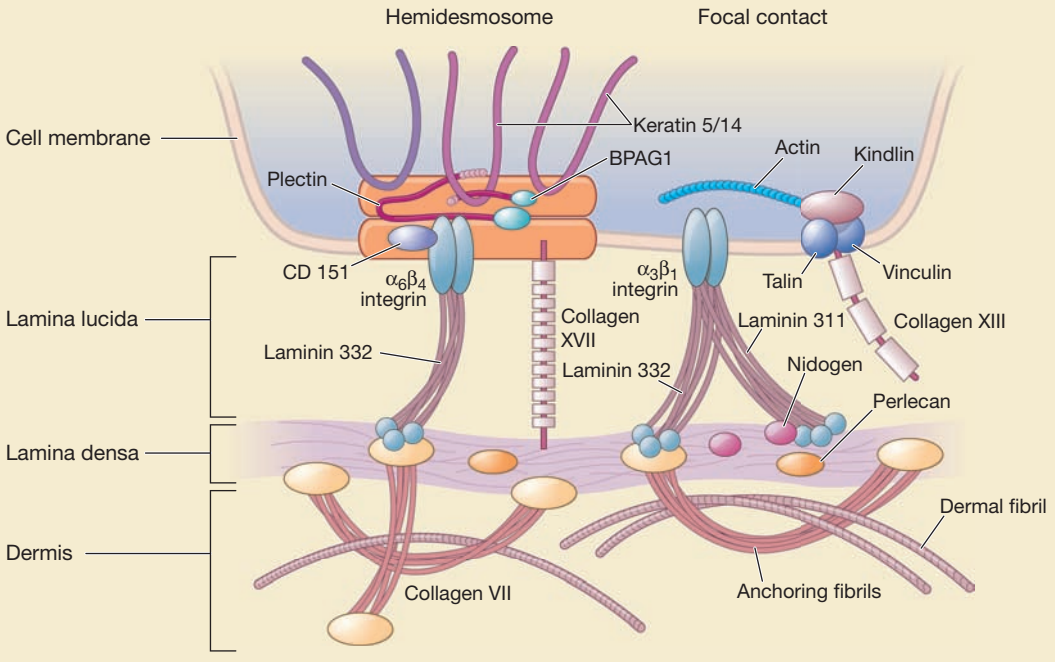

Figure 53-9 Model of the hypothetical relationships of molecules within the dermal–epidermal junction basement membrane. The illustration depicts laminin 332 as the bridge between the transmembrane hemidesmosomal integrin α6β4 and the collagen VII NC-1 domain. The tight binding of laminin 332 to α6β4 and to collagen VII provides the primary resistance to frictional forces. The transmembrane collagen XVII also participates in this stabilization, because its extracellular domain also binds laminin 332. Within the epithelial cell, the transmembrane elements bind the proteins of the hemidesmosomal dense plaque, bullous pemphigoid antigen (BPAG)1 and plectin, which then associate with the keratins. Collagen XVII binds BPAG1, integrin α6β4, and plectin, and integrin α6β4 binds plectin. The laminin 332–311 complex is shown within the basement membrane between hemidesmosomes, bound by integrin α3β1, and associated with the intracellular proteins kindlin-1, talin, and vinculin. This complex presumably maintains basement membrane stability. In vitro, integrin α3β1, kindlin-1, talin, and vinculin, and another transmembrane collagen, type XIII, are localized to the focal contacts, which may function as the link between the basement membrane and the epithelial cortical actin network. In the lamina densa, collagen IV and perlecan networks are stabilized by nidogen. Anchoring fibrils are secured to the lamina densa by the NC-1 domain of collagen VII. The fibrils project into the dermis and either terminate in anchoring plaques or loop back to the lamina densa. The anchoring fibril network entraps dermal fibrils, thus securing the adhesion of the lamina densa to the papillary dermis. None of the molecules is drawn to scale.

several tissues like the kidney and the skin, its gene also encodes the MER2 blood group antigen on erythrocytes. Homozygous CD151-null mutations were identified in three MER2-negative patients, who also presented with hereditary nephritis, sensorineural deafness, pretibial epidermolysis bullosa, and β-thalassemia minor.[117] These symptoms suggest that CD151 is important for the assembly of the basement membrane in the kidney, skin, and inner ear and plays a role in erythropoiesis.

OTHER EPIDERMAL ADHESION COMPLEXES

In addition to the hemidesmosomal components, other adhesion molecules are known to be present at the basolateral aspect of basal keratinocytes, for example, integrin α3β1, the receptor for the laminin 332–311 complex in the basement membrane between the hemidesmosomes,[118] and another transmembrane collagen, type XIII.[94] Since these proteins are localized to focal contacts in vitro, together with vinculin and talin, they are predicted to function as the link between the basement membrane and the epithelial cortical actin network. A novel intracellular component of this complex, kindlin-1, or fermitin-family-homolog 1, was identified by the genetic studies. The kindlin-1 gene, *FERMT1*, is mutated in the Kindler syndrome,[119,120] a disorder with skin blistering in infancy, progressive poikiloderma, skin atrophy, pigment anomalies, and, occasionally, skin cancer. In the epidermis, kindlin-1 is expressed at the basolateral surface of basal keratinocytes and has important functions in β1 integrin-mediated outside-in signaling that regulates cell–matrix adhesions, cell migration, and polarity.[121,122] Thus, kindlin-1 is

TABLE 53-3
Hemidesmosomal and Basement Membrane Zone (BMZ) Targets in Skin Disease

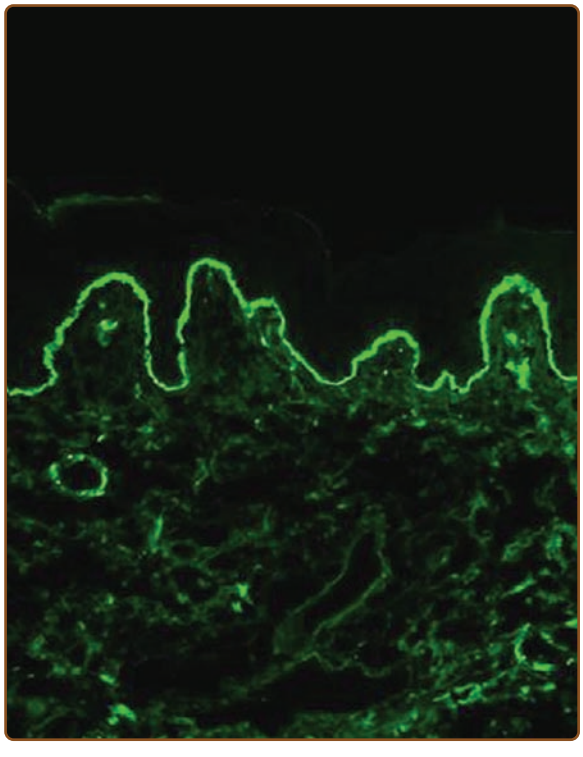

Figure 53-10 Indirect immunofluorescence staining of human skin with a pemphigoid serum that contains autoantibodies to collagen XVII.

necessary for the stability of the dermal–epidermal junction and that, in addition to hemidesmosomes, tethering the actin cytoskeleton to cell–matrix adhesions offers alternative means to anchor basal epithelial cells to the basement membrane.

ANCHORING FILAMENTS

The anchoring filaments contain laminin 332 and the ectodomain of collagen XVII, two ligands that interact with each other through noncovalent bonds.[99,100,108] The ectodomain of collagen XVII, which protrudes from the plasma membrane into the lamina lucida, has a loop structure consistent with its role as an anchoring filament protein.[123] Laminin 332 is a disulfide-bonded complex of α3, β3, and γ2 chains. The two splice variants of the α3 chain, α3A and α3B, associate with the α3 and γ2 chains to form laminin 3A32 and 3B32 (see Fig. 53-8).[99,100] Rotary shadowing imaging indicates that laminin 332 has a rod-like structure terminating in the globular regions (see Fig. 53-6F), a shape consistent with its role as an anchoring filament protein. The individual chains are considerably truncated relative to other laminin chains, and this truncation is reflected in the loss of the structures equivalent to the short arms of other laminins. Additionally, the α3 and γ2 chains are proteolytically processed after secretion from the keratinocyte, further trimming the short arms.[99,100] The

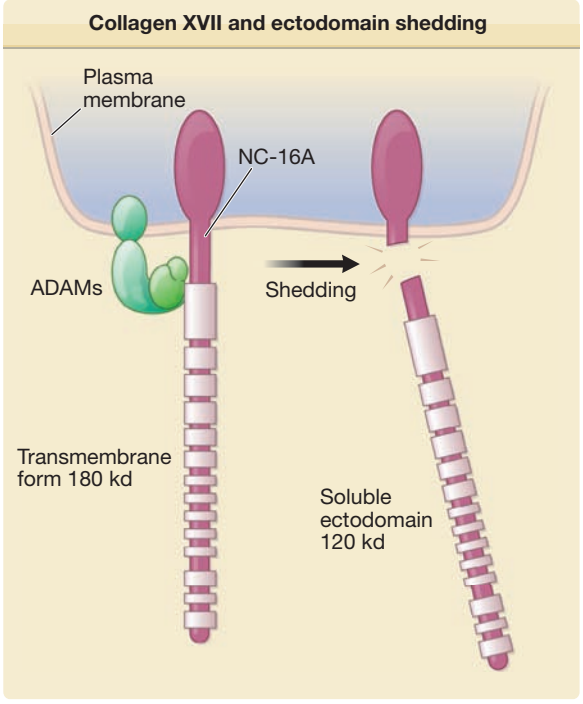

Figure 53-11 Schematic representation of collagen XVII and its ectodomain shedding. Collagen XVII is a hemidesmosomal transmembrane protein with an intracellular *N*-terminus. The extracellular *C*-terminus (ectodomain) contains several collagenous subdomains (*brown*) and intervening noncollagenous sequences (*beige*). The ectodomain can be shed from the cell surface by proteinases of the ADAMs (a disintegrin-like and metalloproteinase-containing) family, themselves transmembrane proteins. Thus, the 180-kDa full-length molecule yields a shorter soluble ectodomain of 120 kDa. The 180-kDa full-length molecule is the classic bullous pemphigoid antigen-2, and the ectodomain is the 120-kDa linear immunoglobulin A (IgA) dermatosis antigen. Further degradation of the *C*-terminus of the ectodomain results in the 97-kDa linear IgA dermatosis antigen.

C-terminus of the α chain, longer than that of the β and γ chains, comprises five globular LG modules, LG1 through LG5, which interact with cell surface receptors. The α3β1 and α6β4 integrins have affinity for the LG1-3 domains, whereas the LG4-5 tandem has affinity for syndecans and β-dystroglycan on the keratinocyte surface.[99,105] The LG4-5 modules are proteolytically cleaved in most laminins, a process which may modulate interactions with cell surface receptors.[99,100] Laminin 332 forms covalent complexes with laminin 311 (α3β1γ1), binds to the NC-1 domain of collagen VII, the anchoring fibril protein.[124] and to the distal ectodomain of collagen XVII.[123] Genetic evidence demonstrates that laminin 332 is essential in keratinocyte adhesion, as null mutations in any of its component α3, β3, or γ2 chains result in severe Herlitz junctional epidermolysis bullosa[112] (see Chapter 62). Targeted disruption of the mouse *lama3* gene prevented the synthesis of both laminin 332 and 311 molecules and resulted in abnormal hemidesmosomes, severe junctional blistering, abnormalities of ameloblast differentiation in developing teeth, and perinatal lethality.[125] Therefore, the severity of the laminin 332 null phenotype indirectly emphasizes its functional importance in bridging the hemidesmosomes and the anchoring fibrils.

EPITHELIAL LAMINA DENSA

The basement membrane beneath and between the hemidesmosomes contains the α1–α2-containing collagen IV network, probably some α1–α2–α5–α6-containing collagen IV network, as well as nidogen, perlecan, and α3 and α5-chain containing laminins.[93] The laminin α3 chain can associate with the β1 and γ1 chains of laminin 311, which has the unique property of forming disulfide-bonded dimers with laminin 332.[99,100] The major α3-containing laminin in the lamina densa between hemidesmosomes is probably the laminin 332–311 complex.[99,100,108] As the laminin α3 chain is a ligand for integrin α3β1 present between hemidesmosomes, binding of laminin 332–311 complex to the intracellular actin cytoskeleton is likely to be mediated by this integrin. This is consistent with studies in mice in which targeted ablation of the integrin α3 chain causes loss of the basement membrane between hemidesmosomes but not beneath them.[93,99] The *N*-termini of laminin 332 bind to collagen VII, the main component of the anchoring fibrils in the sublamina densa, so that anchoring filaments and fibrils are directly connected.[93] The laminin 332–311 complex and laminin 511 (α5β1γ1) contain a γ1 chain and can therefore bind nidogens and the collagen IV network.[93,99] Further, nidogen 1 and fibulin 1 and 2 were shown to be ligands for the laminin γ2 chain.[93] These interactions are important for the integration of laminin 332 into the extracellular matrix before the maturation of the γ2 chain, as a substantial portion of *N*-terminus of the γ2 chain is cleaved in human adult skin.[108] Yet another link, which strengthens dermal–epidermal cohesion, is provided by molecular interactions between perlecan within the lamina densa and fibrillin 1 in the microfibrils.[126]

ANCHORING FIBRILS

Collagen VII is the major component of the anchoring fibrils.[90,124] The collagen VII molecule is distinguished from other collagens in that it has a very long triple-helical domain, 450 nm in length. Globular domains exist at both ends of the triple helix, and the *N*-terminal domain NC-1 is very large and trident-like (see Fig. 53-6E). The smaller *C*-propeptide, NC-2, is believed to facilitate the formation of the antiparallel, centrosymmetric dimers, before it is removed by the metalloproteinase bone morphogenetic protein 1[127] to yield a mature collagen VII. The dimers are covalently cross-linked through disulfide bonds at the carboxyl terminus, and they aggregate laterally to form the anchoring fibrils. The fibrils are further stabilized by tissue transglutaminase, which catalyzes the formation of covalent γ-glutamyl-ε-lysine cross-links.[128]

The NC-1 domain of collagen VII binds to laminin 332 and collagen IV within the lamina densa (see Fig. 53-5A).[124] The triple helical domains of an antiparallel collagen VII dimer make the length of the anchoring fibril. It extends perpendicularly from the lamina densa and either loops back into the lamina densa or inserts into the anchoring plaques.[90,91] The anchoring plaques are electron-dense structures that contain collagen IV and laminin 332, and perhaps other basement membrane components, but which are believed to be independent of the lamina densa itself.[90] They are distributed randomly in the papillary dermis below the lamina densa and are interrelated by additional anchoring fibrils. The anchoring fibril network forms a scaffold that entraps large numbers of dermal fibrils and, most probably, binds them through covalent cross-links between collagen VII and collagen I,[129] thus securing the lamina densa to the subjacent dermis.[124] In the acquired form of epidermolysis bullosa, epidermolysis bullosa acquisita (see Chapter 60), and in bullous systemic lupus erythematosus (see Chapter 155), autoantibodies target mainly the NC-1 domain of collagen VII.[130]

Mutations in *COL7A1*, the gene encoding collagen VII, result in dystrophic epidermolysis bullosa (see Chapter 62). Almost 500 *COL7A1* mutations have been found in both recessive and dominant forms of dystrophic epidermolysis bullosa (Fig. 53-12), and the spectrum of biologic and clinical phenotypes is very broad.[131] In mouse models, complete or partial deficiency of collagen VII recapitulated the clinical and morphologic characteristics of recessive dystrophic epidermolysis bullosa in humans.[132,133] These mice have been useful for testing of molecular therapy strategies for dystrophic epidermolysis bullosa. Both cell therapy approaches using fibroblasts[134] or bone marrow-derived mesenchymal stem cells[135] and protein[136] therapy have shown promise in terms of increasing collagen VII and stabilizing the dermal–epidermal junction. A human clinical trial to treat recessive dystrophic epidermolysis bullosa using bone marrow transplantation is currently ongoing.[137]

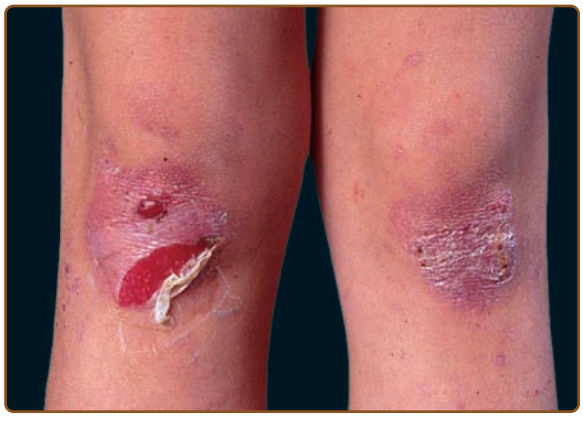

Figure 53-12 Skin fragility and blistering in dystrophic epidermolysis bullosa. Functional deficiency of collagen VII as a result of mutations in the *COL7A1* gene leads to trauma-induced separation of the epidermis and the dermis. The blister roof is below the lamina densa, leading to scar formation on healing of the blisters.

CELLULAR ORIGIN OF THE DERMAL–EPIDERMAL BASEMENT MEMBRANE

The basement membrane constituents are products of both epithelial and mesenchymal cells. In vitro modeling of basement membrane formation using different skin equivalent culture models has demonstrated that a tight interplay between fibroblasts and keratinocytes contributes to the dermal–epidermal basement membrane. Differentiated fibroblasts adjacent to epithelia in vivo produce basement membrane components and assist in basement membrane assembly.[138–141] Of the known basement membrane components, only laminins 332 and 311A are exclusively produced by the epidermis. Conditional knockout of collagen VII has demonstrated that both epithelial and mesenchymal cells manufacture collagen VII,[142] whereas mainly mesenchymal cells synthesize collagen IV, nidogen, perlecan, and the laminin α2 chain.[93] Because the mesenchymal products are translocated to the baso-lateral epithelial surface where they condense, that surface must provide the localization cues. Integrins α6β4 and α3β1 and collagen XVII have been implicated in this process, suggesting that the laminins coordinate basement membrane polymerization.[99] An interesting regulatory step may be added by dermal enzymes (e.g., bone morphologic protein 1), which process epithelial cell products, such as laminin 332 and procollagen VII, to mature basement membrane molecules.[99,127]

Chapter 54 :: Pemphigus

:: Aimee S. Payne & John R. Stanley

PEMPHIGUS AT A GLANCE

- Two major types: pemphigus vulgaris and pemphigus foliaceus.
- Pemphigus vulgaris: erosions on mucous membranes and skin; flaccid blisters on skin.
- Pemphigus foliaceus: crusted, scaly skin lesions.
- Diagnosis depends on histology showing intraepidermal acantholysis and immunofluorescence studies documenting the presence of cell surface autoantibodies, either bound to patient skin or in the serum.
- Pemphigus vulgaris histology: suprabasal acantholysis.
- Pemphigus foliaceus histology: subcorneal acantholysis.
- Direct immunofluorescence shows immunoglobulin G (IgG) on the keratinocyte cell surface of the patient's skin; indirect immunofluorescence shows IgG in patient serum that binds the cell surface of normal keratinocytes.
- Autoantigens are desmogleins, transmembrane desmosomal adhesion molecules.
- Therapy includes topical and systemic corticosteroids and immunosuppressive agents.

The term *pemphigus* refers to a group of autoimmune blistering diseases of skin and mucous membranes that are characterized histologically by intraepidermal blisters due to acantholysis (i.e., separation of epidermal cells from each other) and immunopathologically by in vivo bound and circulating immunoglobulin (Ig) directed against the cell surface of keratinocytes. The nosology of this group of diseases is outlined in Box 54-1. Essentially, pemphigus can be divided into four major types: (1) vulgaris, (2) foliaceus, (3) paraneoplastic (see Chapter 55), and (4) IgA pemphigus (see Chapter 54). In pemphigus vulgaris (PV), the blister occurs in the deeper part of the epidermis, just above the basal layer, and in pemphigus foliaceus (PF), also called *superficial pemphigus*, the blister is in the granular layer.

The history of the discovery of pemphigus, and its various forms, is covered in Walter Lever's classic monograph *Pemphigus and Pemphigoid*.[1] Both PV and PF display a spectrum of disease. Various points along these spectra have been given unique names, but because the presentation of these diseases is fluid, patients' disease usually crosses these artificial designations over time. Thus, patients with PV may present with more localized disease, one form of which is called *pemphigus vegetans of Hallopeau*. This may become slightly more extensive and may merge into *pemphigus vegetans of Neumann*. Finally, with more severe disease, full-blown PV may appear. Similarly, patients with PF may present with more localized disease, represented by *pemphigus erythematosus*. However, these patients often go on to more widespread PF.

The discovery by Ernst Beutner and Robert Jordon in 1964 of circulating antibodies against the cell surface of keratinocytes in the sera of patients with PV pioneered our understanding that PV is a tissue-specific autoimmune disease of skin and mucosa.[2] Ultimately, their work led the way to the discoveries of autoantibodies in other autoimmune bullous diseases of the skin.

EPIDEMIOLOGY

INCIDENCE AND PREVALENCE

A few prospective and several retrospective surveys of patients with pemphigus clearly indicate that the epidemiology of pemphigus is dependent on both the area in the world that is studied as well as the ethnic population in that area.[3–10] PV is more common in Jews and probably in people of Mediterranean descent and from the Middle East. This same ethnic predominance does not exist for PF. Therefore, in areas where the Jewish, Middle Eastern, and Mediterranean population predominates, the ratio of PV to PF cases tends to be higher. For example, in New York, Los Angeles, and Croatia, the ratio of PV to PF cases is approximately 5:1; in Iran the ratio is 12:1; whereas in Singapore it is 2:1; and in Finland, it is only 0.5:1. Similarly, the incidence of pemphigus varies by region. In Jerusalem, the incidence of PV has been estimated to be 1.6 per 100,000 people per year and in Iran approximately 10.0 per 100,000 people per year. Elsewhere in Europe, the incidences are lower, ranging from a high of 0.7 PV cases per 100,000 person years in the United Kingdom to tenfold less, 0.5–1.0 per million person years, in Finland, France, Germany, and Switzerland.

The prevalence and incidence of PF are also very dependent on its location, as best exemplified by the finding of endemic foci of PF in Brazil, Colombia, and Tunisia. The first recognition of endemic PF was in

BOX 54-1 DIFFERENTIAL DIAGNOSIS OF PEMPHIGUS

PEMPHIGUS SUBTYPES

- Pemphigus vulgaris
- Pemphigus vegetans
- Pemphigus foliaceus
- Pemphigus erythematosus
- Endemic pemphigus foliaceus (e.g., fogo selvagem)
- Immunoglobulin A (IgA) pemphigus
- Subcorneal pustular dermatosis
- Intraepidermal neutrophilic dermatosis
- Paraneoplastic pemphigus

INTRAEPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES

- Familial benign pemphigus (Hailey–Hailey disease)
- Bullous impetigo, staphylococcal scalded-skin syndrome
- Blisters from herpes simplex and zoster
- Allergic contact dermatitis (e.g., rhus dermatitis)
- Epidermolysis bullosa simplex
- Incontinentia pigmenti

MOUTH ULCERS/EROSION WITHOUT AUTOANTIBODIES

- Aphthous ulcers
- Candidiasis
- Lichen planus
- Behçet disease

SUBEPIDERMAL BLISTERING DISEASES WITH AUTOANTIBODIES

- Bullous pemphigoid
- Herpes gestationis
- Cicatricial pemphigoid
- Epidermolysis bullosa acquisita
- Linear IgA disease and chronic bullous disease of childhood
- Dermatitis herpetiformis
- Bullous lupus erythematosus

SUBEPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES

- Erythema multiforme
- Toxic epidermal necrolysis
- Porphyria
- Junctional or dystrophic epidermolysis bullosa

Brazil and is called *fogo selvagem*, which means "wild fire" in Portuguese. It is a disease that is clinically, histologically, and immunopathologically the same as sporadic PF in any individual patient, but its epidemiology is unique.[11,12] Fogo selvagem is endemic in the rural areas of Brazil, especially along inland riverbeds. The geographic distribution of disease clustering is similar to that of a black fly, *Simulium nigrimanum*, thought by natives to be a vector of this disease. A study of potential environmental risk factors has also implicated the bite of this black fly, showing it to be significantly more frequent among those with the disease compared to an age-, sex-, and occupation-matched control population with unrelated dermatoses.[13] The prevalence on some well-studied Indian reservations in rural Brazil can be as high as 3.4%, with the incidence up to 0.8–4.0 new cases per 1,000 people per year.[12,14] On the reservation in Limao Verde, up to 55% of unaffected individuals have a low-level IgG1 antibody response against desmoglein 1, the PF autoantigen, which becomes an IgG4 response of higher titer against a more pathogenic epitope in disease.[12] These results suggest that some environmental agent (e.g., insects or other infectious disease agent) may trigger a low-level autoantibody response that becomes pathogenic by intramolecular epitope spreading in genetically susceptible individuals. With this theory in mind, it is interesting that 40%–80% of patients from Brazil with the insect-borne diseases onchocerciasis, leishmania, and Chagas disease have low-level antidesmoglein 1 antibodies, but patients with other infectious diseases from Brazil rarely have such antibodies.[15]

Fogo selvagem occurs often in children and young adults, unlike sporadic PF, which is a disease of mostly middle-aged and older patients. Also unlike PF, fogo selvagem occurs not infrequently in genetically related family members, although it is not contagious. This fact probably implies a common exposure, as well as susceptibility. There is no known racial or ethnic predominance, and anyone moving into an endemic area may be susceptible to disease. Again supporting the presence of an environmental trigger, the development of the rural endemic areas of Brazil decreased the incidence of disease. Certainly, this fascinating disease holds clues to understanding how this autoimmune response is triggered.

SEX RATIO

The sex ratio of pemphigus cases is difficult to estimate accurately due to the overall low incidence. Larger epidemiologic studies (i.e., those identifying greater than 100 cases) have shown that the sex ratio of pemphigus in women versus men ranges from 1.33 or 2.25 to 1.[7,9,16–20] Notable exceptions are the predominance of women (4:1) in an endemic focus of PF in Tunisia,[6] and a predominance of men (19:1) in an endemic focus of PF in Colombia.[21]

AGE OF ONSET

The average age of disease onset also varies by region. In Turkey, Saudi Arabia, Tunisia, and Iran, the mean age of onset is approximately 40 years.[6,16,18,22] Studies in the United States and elsewhere in Europe demonstrate an average age of onset between 50 and 70 years.[5,6,9,10,17,19,23,24,25] Pemphigus rarely occurs in children,[26] except in regions of endemic disease.

ETIOLOGY AND PATHOGENESIS

The discovery of pemphigus as an organ-specific, autoantibody-mediated disease of desmosomes highlights the synergy between clinical care and basic science research. The development of light microscopy and electron microscopy allowed dermatologists to identify the morphology and immunopathology of disease. Patient serum IgG served as a key reagent to help identify both the PF and PV antigens.[27–29] The cloning and characterization of the pemphigus antigens have subsequently led to the development of enzyme-linked immunosorbent assay (ELISA) tests to improve the sensitivity and specificity of disease diagnosis, and continued studies on pemphigus pathophysiology aim to develop safer and effective therapies for these potentially fatal diseases.

PEMPHIGUS AUTOANTIGENS

Pemphigus antigens are desmogleins, transmembrane glycoproteins of desmosomes (cell-to-cell adhesion structures, reviewed in Chapter 53).[30,31] Desmogleins are part of the cadherin superfamily of calcium-dependent cell adhesion molecules. The original members of this family (e.g., E-cadherin) demonstrate homophilic adhesive interactions (binding between like molecules). Desmogleins similarly demonstrate homophilic binding but can also participate in heterophilic adhesion by binding desmocollins, the other major transmembrane glycoprotein of desmosomes.[32,33]

The PF antigen (as well as the fogo selvagem antigen) is desmoglein 1, a 160-kDa protein.[27,28,34] The PV antigen is desmoglein 3, a 130-kDa protein that is 64% similar and 46% identical in amino acid sequence to desmoglein 1.[29] All patients with PV have antidesmoglein 3 antibodies, and some of these patients also have antidesmoglein 1 antibodies.[35,36] Patients with mucosal-dominant PV tend to have only antidesmoglein 3 antibodies, whereas those with mucocutaneous disease usually have both antidesmoglein 3 and antidesmoglein 1 antibodies.[37–39] PF patients typically have antibodies against only desmoglein 1.

Several lines of evidence indicate that antidesmoglein 1 and 3 antibodies in pemphigus patients directly cause blisters and hence are the etiologic agents of disease. Passive transfer of PV or PF IgG to neonatal mice or human skin causes blisters that clinically and histologically mimic the corresponding type of pemphigus in patients.[40–42] The antidesmoglein antibodies are responsible for blister formation in the passive transfer model, since affinity purified antidesmoglein 1 and 3 autoantibodies cause PF and PV blisters, respectively, and adsorption of desmoglein-reactive autoantibodies from PF or PV IgG abrogates disease.[43–46] Similar passive transfer "experiments" have been described in humans, where mothers with even mild PV can pass IgG autoantibodies to the fetus, causing blistering oral and skin disease that resolves by approximately 6 months, concurrent with the disappearance of maternal IgG from the circulation.[47]

Desmoglein 4, which is expressed in the developing hair cortex and the superficial epidermis, is a target of some pemphigus antibodies.[48] However, the antidesmoglein 4 antibodies in mucocutaneous PV and in PF have been shown to be a result of cross-reactivity from desmoglein 1 autoantibodies, and the desmoglein 4 reactivity has not been shown to be necessary or sufficient for acantholysis.[49] Other cell surface molecules such as acetylcholine receptors and E-cadherin have also been identified as immunologic targets of pemphigus autoantibodies, although their direct involvement in the pathophysiology of pemphigus is similarly unclear.[50,51]

PATHOPHYSIOLOGY OF ACANTHOLYSIS

Unlike many other autoantibody-mediated diseases, such as pemphigoid and epidermolysis bullosa acquisita, in which the constant region of the antibody is required for blister formation to activate complement or bind antibody receptors on inflammatory cells, in pemphigus the variable region of the antibody is sufficient to cause blisters in neonatal mice or human skin.[42,60–62] For this reason a significant amount of research on disease pathophysiology has focused on the epitopes bound by pathogenic autoantibodies, as these regions are likely critical for maintaining desmosomal cell adhesion.

Epitope mapping studies have shown that pathogenic PV and PF autoantibodies bind calcium-sensitive, conformational epitopes in the amino-terminal extracellular domains of desmogleins, whereas nonpathogenic antibodies tend to bind more membrane proximal extracellular domains.[63–66] The amino-terminal domains bound by pathogenic autoantibodies are the same domains that are predicted to form the key molecular interactions for desmoglein intercellular adhesion, based on studies of cadherin ultrastructure.[67,68] This evidence is the primary basis for the "steric hindrance" hypothesis, which proposes that pathogenic antibodies directly interfere with desmoglein adhesive interactions, causing acantholysis.

Studies on cultured keratinocytes have indicated that loss of intercellular adhesion by pathogenic autoantibodies leads to internalization and degradation of desmogleins,[69–72] indicating that pemphigus antibody binding leads to loss of desmoglein function. If this is the case, then other model systems with loss of desmoglein function should mimic pemphigus. Indeed, mice genetically deficient for desmoglein

3 demonstrate suprabasal blisters in the oral mucosa histologically identical to PV patients.[73] Additionally, cleavage of desmoglein 1 by staphylococcal exfoliative toxin (in bullous impetigo or staphylococcal scalded skin syndrome) causes blisters histologically identical to those seen in PF patients.[74]

If inactivation of desmoglein isoforms results in blistering, then why do blisters in PV and PF have specific tissue localizations that do not necessarily correlate with the sites at which the antibodies bind by immunofluorescence? In PF, for example, the antidesmoglein 1 antibodies bind throughout the epidermis and mucous membranes,[75] yet blisters occur only in the superficial epidermis. This apparent paradox can be explained by desmoglein compensation, as outlined in Fig. 54-1. The concept of desmoglein compensation originates in the assumption that autoantibodies against one desmoglein isoform inactivate only that isoform and that another isoform coexpressed in the same area can compensate in adhesion.[76–78] Desmoglein compensation explains why neonatal PF is so unusual, because even though the maternal antidesmoglein 1 antibodies cross the placenta, in neonatal skin, but not in adult skin, desmoglein 3 is coexpressed with desmoglein 1 in the superficial epidermis, thereby providing protection against the loss of desmoglein 1-based adhesion.[77,79] Desmoglein compensation also offers an explanation for the differing sites of blister formation in PV and PF, both in regard to the histology (i.e., suprabasal or superficial), as well as the areas of involvement (mucosa and/or skin.)

In potential challenge to the steric hindrance hypothesis, several studies have suggested that modulation of cell signaling pathways can prevent blister formation after passive transfer of pemphigus IgG in the neonatal mouse model, including p38 mitogen activated protein kinase (MAPK) and ρ GTPases, among others.[80–82] Whether signaling is upstream or downstream of the loss of intercellular adhesion is controversial. Nevertheless, the current general consensus is that desmosomal adhesion is a dynamic process that is perturbed by pemphigus autoantibodies. Therefore, therapies that aim to strengthen keratinocyte adhesion by modulation of signaling pathways may have a beneficial effect on pemphigus, regardless of whether cell signaling is a primary pathologic cause of disease.

GENETIC RESTRICTION OF THE PEMPHIGUS IMMUNE RESPONSE

Compared to a matched population, patients with PV have a markedly increased frequency of certain class II major histocompatibility complex (MHC) antigens. Among Ashkenazi Jews with PV, the serologically defined HLA-DR4 haplotype is predominant, whereas in other ethnic groups with PV, the DQ1 allele is more common.[83] However, the association with disease susceptibility becomes even more striking in an analysis of these MHC alleles at a genetic level. Patients with the DR4 serotype almost all have the unusual allele DRB1*0402, and patients with the DQ1 serotype almost all have the rare allele DQB1*0503. Similar, but less restricted, HLA-DR alleles are associated with PF.[84] The protein chains encoded by these PV MHC II alleles vary from those found in HLA-DR4 and DQ1 controls without disease by only a few amino acids.

MHC class II alleles encode cell surface molecules that are necessary for antigen presentation to the immune system; therefore, it is hypothesized that PV-associated MHC class II molecules allow presentation of desmoglein 3 peptides to T cells.[85] Consistent with this hypothesis, certain peptides from desmoglein 3, predicted to fit into the DRB1*0402 peptide-binding pocket, were found to stimulate T cells from patients.[86]

Other studies have confirmed that the immune response in pemphigus is restricted to certain desmoglein peptides and MHC class II alleles.[87–89] An unexpected observation was that T cells of normal people with the DRB1*0402 or DQB1*0503 respond just as well as those of pemphigus patients to the same desmoglein 3 peptides,[85,90] indicating that T-cell reactivity to desmoglein 3 peptides is not sufficient for disease onset. The factor that may determine who gets pemphigus and who does not has been proposed to be the presence of regulatory T cells that can suppress the autoimmune response in those who do not.[91]

Cloning of antidesmoglein antibodies from PV and PF patients has indicated a marked restriction of antibody gene usage by the antidesmoglein antibodies, most notably for the heavy chain variable region.[61,62,92] These studies also show that pathogenic antibodies from different patients bind at or near common epitopes on desmogleins and may share common idiotypes. In comparison to the restricted B-cell antibody variable region gene usage, there is more heterogeneity of the T-cell receptor variable gene usage in pemphigus patients.[90,93] If specific antibody or T-cell receptor gene usage patterns are found to be shared among multiple pemphigus patients, these may serve as clinical markers for targeting disease-specific immune cell populations in pemphigus patients.

CLINICAL FINDINGS

PEMPHIGUS VULGARIS

CUTANEOUS LESIONS. The skin lesions in PV can be pruritic or painful. Exposure to ultraviolet radiation may exacerbate disease activity.[94,95] The primary lesion of PV is a flaccid blister, which may occur anywhere on the skin surface, but typically not the palms and soles (Fig. 54-2). Usually, the blister arises on normal-appearing skin, but it may develop on erythematous skin. Because PV blisters are fragile, the most common skin lesions observed in patients are erosions resulting from broken blisters. These erosions are often quite large, as they have a tendency to spread at their periphery (Fig. 54-3).

A characteristic finding in pemphigus patients is that erosions can be extended into visibly normal skin by pulling the remnant of the blister wall or rubbing at the periphery of active lesions; additionally, erosions can be induced in normal-appearing skin distant from

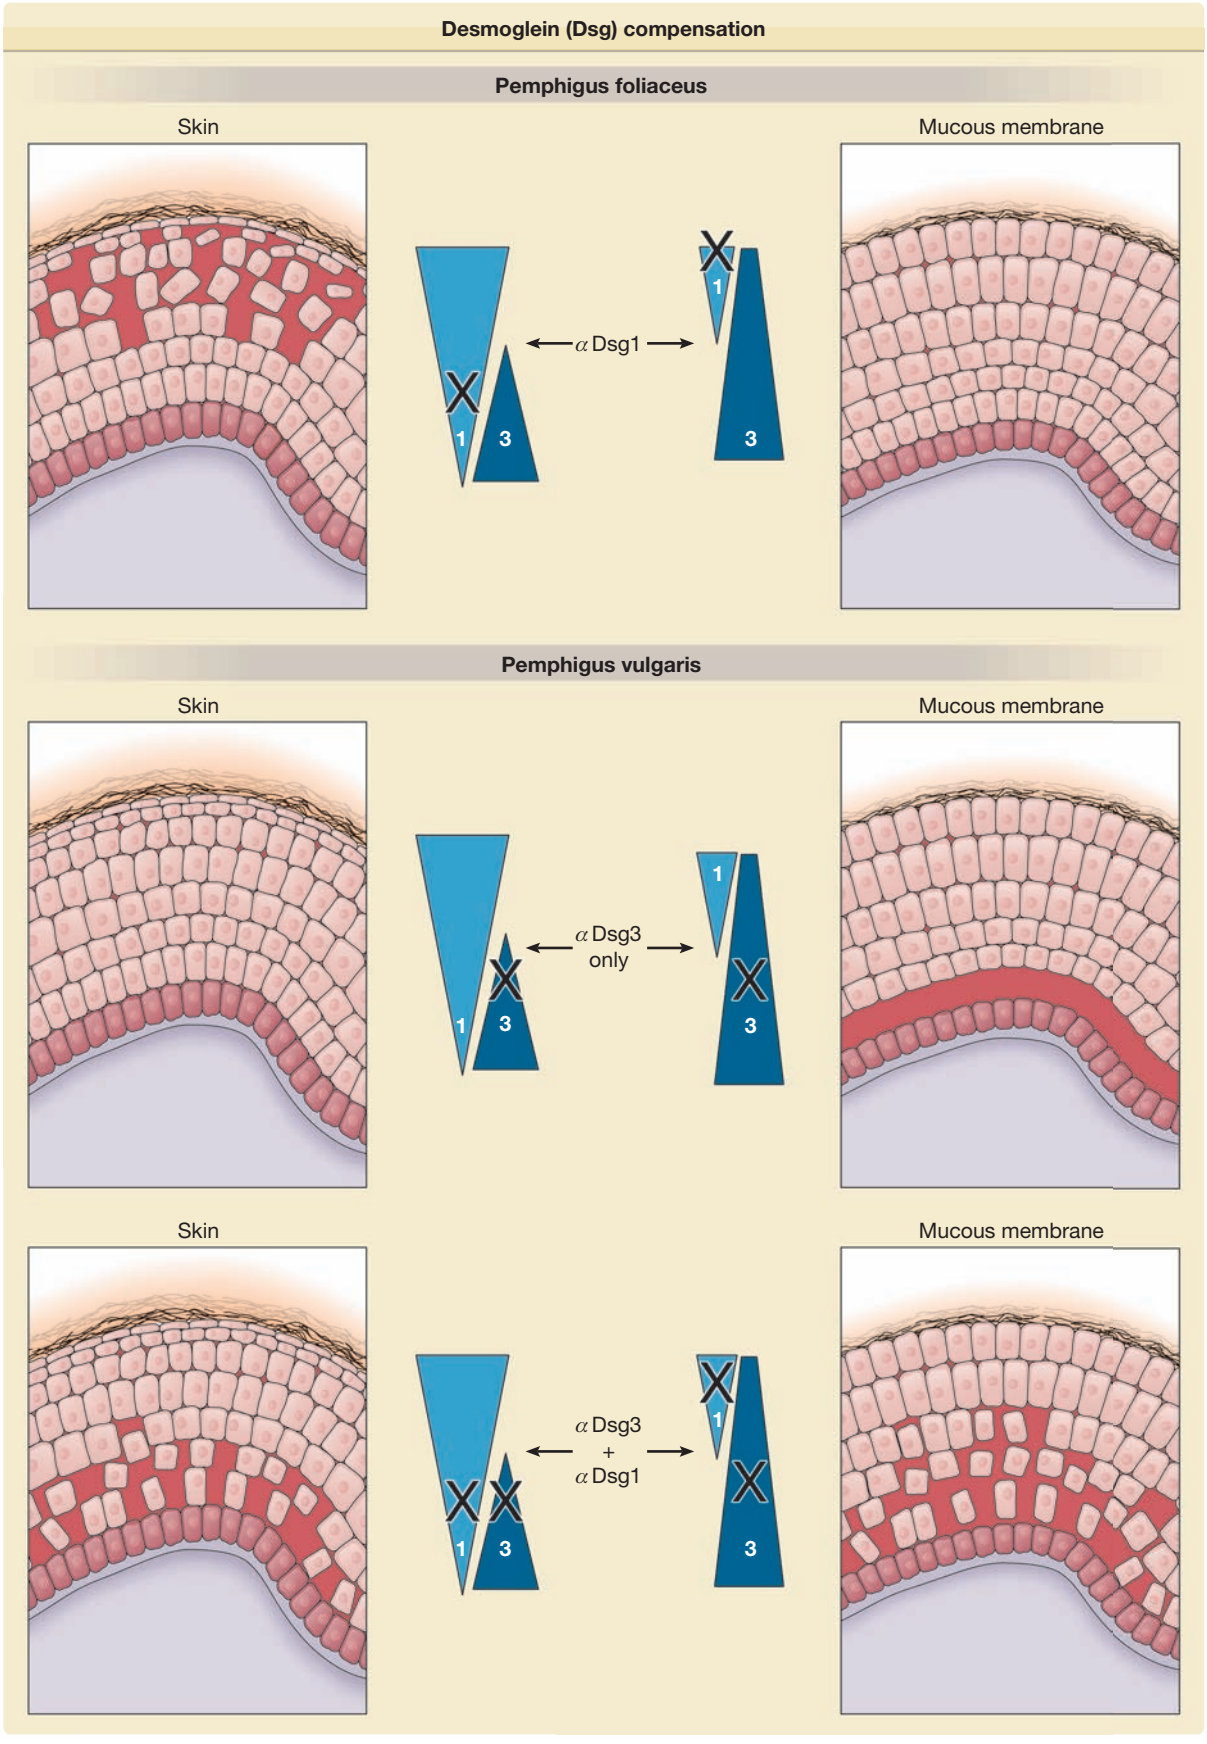

Figure 54-1 Desmoglein (Dsg) compensation. Triangles represent the distribution of Dsg1 and 3 in skin and mucous membranes. Anti-Dsg1 antibodies in pemphigus foliaceus cause acantholysis only in the superficial epidermis of skin. In the deep epidermis and in mucous membranes, Dsg3 compensates for antibody-induced loss of function of Dsg1. In early pemphigus vulgaris, antibodies are present only against Dsg3, which cause blisters only in the deep mucous membrane where Dsg3 is present without compensatory Dsg1. However, in mucocutaneous pemphigus, antibodies against both Dsg1 and Dsg3 are present, and blisters form in both mucous membrane and skin. The blister is deep probably because antibodies diffuse from the dermis and interfere first with the function of desmosomes at the base of the epidermis.

active lesions by pressure or mechanical shear force. This phenomenon is known as the *Nikolsky sign*.[96] This sign helps differentiate pemphigus from other blistering diseases of the skin such as pemphigoid (Box 54-1); however, similar findings can also be elicited in staphylococcal scalded skin syndrome, Stevens–Johnson syndrome, and toxic epidermal necrolysis.

VEGETATING LESIONS. In certain patients, erosions have a tendency to develop excessive granulation tissue and crusting, referred to as vegetating lesions (Fig. 54-4). This type of lesion tends to occur more frequently in intertriginous areas, in the scalp, or on the face (see Fig. 54-4A). Historically, patients presenting with vegetating lesions have been split out into different disease designations: *pemphigus vegetans of Hallopeau* and *pemphigus vegetans of Neumann*. However, the subsequent analysis of vegetating skin lesions by histology and immunofluorescence suggests that these cases are simply clinical variants of PV.[1,97] In the Hallopeau variant, vegetating and often pustular lesions are present from the outset of disease, are not preceded by bullae, and favor flexural regions (see Fig. 54-4B). Generally, the prognosis for these patients is thought to be better, with milder disease and a higher chance of remission compared to typical PV patients.[98] In patients with the Neumann variant, ordinary PV erosions heal with papillomatous formations, with prognosis related to the extent of disease activity. The vegetating type of response may also appear in certain lesions that tend to be resistant to therapy and remain for long periods of time in one place. Thus, vegetating lesions seem to be one reactive pattern of the skin to the autoimmune insult of PV.

Figure 54-3 Pemphigus vulgaris. Extensive erosions due to blistering. Almost the entire back is denuded. Note intact, flaccid blisters at the lower border of eroded lesions.

MUCOUS MEMBRANE LESIONS. The mucous membranes most often affected by PV are those of the oropharyngeal cavity (see Fig. 54-2B). As with cutaneous lesions, intact blisters are rare. Oropharyngeal erosions can be so painful that the patient is unable to eat or drink. The inability to eat or drink adequately may require inpatient hospitalization for disease control and intravenous fluid and nutrient repletion.

In the majority of patients, painful mucous membrane erosions are the presenting sign of PV and may be the only sign for an average of 5 months before skin lesions develop.[3] However, the presenting symptoms may vary; in a study from Croatia, painful oral lesions were the presenting symptom in 32% of patients.[20] Most of these patients progressed to a more generalized eruption in 5 months to 1 year; however, some had oral lesions for more than 5 years before generalization. On the other hand, in Tehran, 62% of patients presented with oral lesions only.[7] Skin involvement without mucous membrane involvement in PV is less common, accounting in one study for 11% of PV cases.[99]

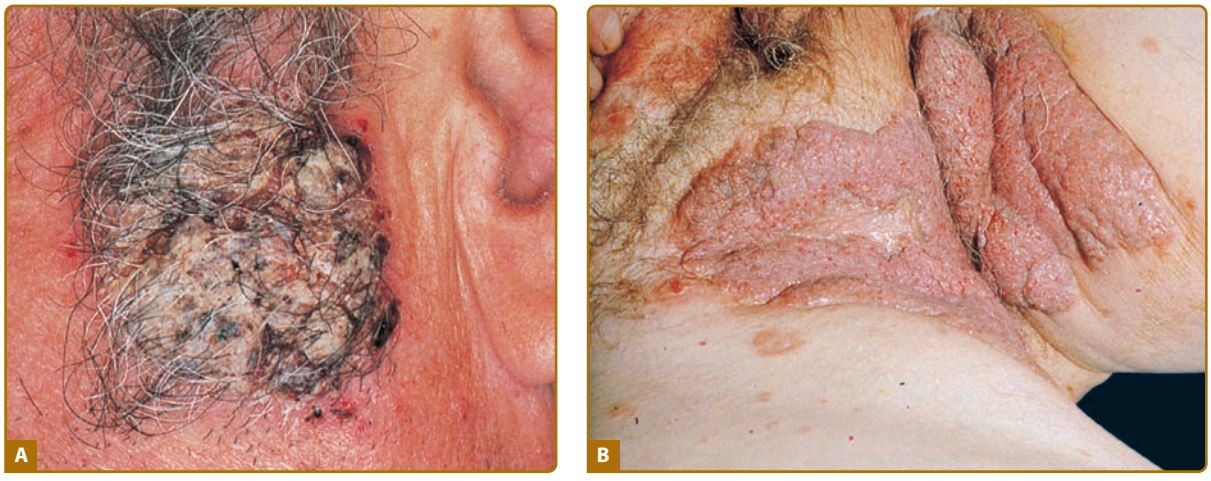

Figure 54-4 **A.** Crusted, vegetating lesions in pemphigus vulgaris. **B.** Extensive, vegetating granulomatous lesions in pemphigus vegetans.

Gastrointestinal tract involvement with PV has been described in the esophagus, stomach, duodenum, and anus, although only biopsies of the esophagus have been proven to be due to suprabasal acantholysis.[7,100,101] Involvement of other mucous membranes can also occur, including the vulvovaginal, nasal, laryngeal, and conjunctival mucosa.[102–106] In women, cervicovaginal lesions may be found in up to 51% of patients with active disease but these lesions may be asymptomatic. Even without obvious lesions, Pap smears may be positive in women with pemphigus and the acantholytic cells may be misinterpreted as indicative of cervical dysplasia.[107,108] There are rare case reports on corneal erosions in PV patients, but no histologic confirmation of acantholysis.[109]

PEMPHIGUS FOLIACEUS

CUTANEOUS LESIONS. The characteristic clinical lesions of PF are scaly, crusted erosions, often on an erythematous base. In more localized and early disease, these lesions are usually well demarcated and scattered in a seborrheic distribution, including the face, scalp, and upper trunk (Fig. 54-5A). The primary lesions of small flaccid blisters are typically not found. Disease may stay localized for years, or it may rapidly progress to generalized involvement, resulting in an exfoliative erythroderma (Fig. 54-5B). Like PV, PF may be exacerbated by ultraviolet radiation.[95,110,111] Patients with PF often complain of pain and burning in the skin lesions. In contrast to patients with PV, those with PF very rarely, if ever, have mucous membrane involvement, even with widespread disease.

The colloquial term for Brazilian endemic pemphigus, fogo selvagem (Portuguese for "wild fire"), takes into account many of the clinical aspects of this disease: the burning feeling of the skin, the exacerbation of disease by the sun, and the crusted lesions that make the patients appear as if they had been burned.

PEMPHIGUS ERYTHEMATOSUS. In 1926, Francis Senear and Barney Usher described eleven patients with features of a pemphigus–lupus erythematosus overlap (*Senear–Usher syndrome*).[112] Over the next several decades, debate over whether these patients had lupus erythematosus, pemphigus, seborrheic dermatitis, or features of all three disorders continued, with Senear concluding that the disease is best considered a variant of pemphigus, termed *pemphigus erythematosus*.[113]

Figure 54-5 Pemphigus foliaceus. **A.** Scaly, crusted lesions on upper back. **B.** Exfoliative erythroderma due to confluent lesions.

As these observations were made prior to the development of immunofluorescence testing for both pemphigus and lupus, the diagnosis was primarily based on the clinical presentation: crusted erosions in a seborrheic distribution, at times concurrent with more lupus-like discoid lesions with "carpet-tack" scale. Walter Lever noted that many patients initially categorized as pemphigus erythematosus went on to develop systemic lupus, or more widespread PF, or even PV, in some cases due to incorrect initial diagnosis. Therefore, rather than perpetuate the use of one term for different diseases, he proposed that pemphigus erythematosus be used to describe a localized form of PF with better prognosis.[1] After the development of immunofluorescence and antinuclear antibody testing for pemphigus and lupus, it was discovered that pemphigus erythematosus patients demonstrate immunologic overlap features; by definition all demonstrate the cell surface staining pattern classic for pemphigus, approximately 30% have positive antinuclear antibody titers, and 80% have positive lupus band tests, although the latter test is only positive in 20%–40% of biopsies on nonsun-exposed skin.[114] As most patients with pemphigus erythematosus do not develop systemic signs or symptoms of lupus, and some may progress from localized disease to generalized PF,[115] the diagnosis of pemphigus erythematosus is largely one of historic, rather than clinical, significance.

NEONATAL PEMPHIGUS

Infants born to mothers with PV may display clinical, histologic, and immunopathologic signs of PV.[47,116] The degree of involvement varies from none to severe enough to result in a stillbirth. If the infant survives, disease tends to remit as maternal antibody is catabolized. Mothers with PF may also transmit their autoantibodies to the fetus, but, as discussed in Section "Pathophysiology of Acantholysis," neonatal PF occurs only rarely.[117–119] Neonatal pemphigus should be distinguished from PV and PF that occur in childhood, which are similar to the autoimmune diseases seen in adults.[120]

DRUG-INDUCED PEMPHIGUS

Although there are sporadic case reports of pemphigus associated with the use of several different drugs, the association with penicillamine, and perhaps captopril, is the most significant.[121] The prevalence of pemphigus in penicillamine users is estimated to be approximately 7%. PF (including pemphigus erythematosus) is more common than PV in these penicillamine-treated patients, although either may occur. The findings of direct and indirect immunofluorescence are positive in most of these patients. Three patients with drug-induced PF and one with drug-induced PV have been shown to have autoantibodies to the same molecules involved in sporadic pemphigus, namely, desmoglein 1 and desmoglein 3, respectively.[122] Therefore, by immunofluorescence and immunochemical determinations, these patients with drug-induced pemphigus resemble those with sporadic disease.

Both penicillamine and captopril contain sulfhydryl groups that are postulated to interact with the sulfhydryl groups in desmoglein 1, 3, or both, thereby causing pemphigus either by directly interfering with these adhesion molecules or, more likely, by modifying them so that they become more antigenic. The use of these drugs may also lead to a more generalized dysregulation of the immune response, allowing production of other autoantibodies such as those resulting in myasthenia gravis. Most, but not all, patients with drug-induced pemphigus go into remission after they stop taking the offending drug.

Additionally, rare anecdotal reports have suggested the association of dietary intake and pemphigus, proposing the hypothesis that thiol-containing foods such as garlic, leeks, and onions may precipitate disease.[123,124] Some patients may note that certain foods aggravate oral lesions, but it is unlikely that dietary intervention alone will remit disease in most patients.

Interestingly, anecdotal case reports have reported improvement of PV with cigarette smoking,[125] as well as with the cholinergic agonists pyridostigmine, carbachol, and pilocarpine.[126,127] Studies suggest that activation of cholinergic receptors may regulate signaling pathways modulated by PV IgG, thereby affecting cell adhesion.[128] These results are intriguing given the clinical benefit of nicotine noted in other inflammatory diseases, such as ulcerative colitis.[129]

ASSOCIATED DISEASES

Myasthenia gravis, thymoma, or both have been associated with PV and PF.[130] Approximately one-half of associated pemphigus cases are vulgaris; one-half, foliaceus or erythematosus. Most of these data, however, were reported before the recognition of paraneoplastic pemphigus as a distinct entity. Therefore, although thymoma may clearly be associated with PV and PF, it may also be associated with paraneoplastic pemphigus (see Chapter 55). Myasthenia gravis is a tissue-specific autoantibody-mediated disease leading to skeletal muscle weakness. Early disease usually affects facial muscles, leading to symptoms of dysarthria, dysphagia, ptosis, or diplopia. Disease may then progress to affect the larger muscles of the trunk and extremities, with potential fatal complications from respiratory muscle involvement. Thymoma, in contrast, is typically asymptomatic in adults. In children, thymomas are more likely to be symptomatic with cough, chest pain, superior vena cava syndrome, dysphagia, and/or hoarseness from localized tumor encroachment.

Myasthenia gravis would be best evaluated by a neurologist, who can complete a full neurologic examination and may test for the presence of serum acetylcholine receptor autoantibodies. The course of myasthenia gravis and pemphigus appear to be independent of each other. Likewise, thymic abnormalities may either precede or follow the onset of pemphigus. Thymic abnormalities include benign or malignant thymoma and thymic hyperplasia. Posteroanterior

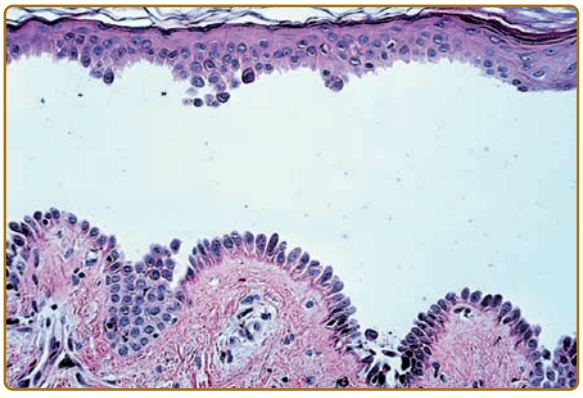

Figure 54-6 Histopathology of pemphigus vulgaris. Suprabasilar acantholysis. The row of tombstones.

and lateral chest radiographs with or without computerized tomography follow-up can detect most thymomas. Irradiation of the thymus or thymectomy, although clearly beneficial for myasthenia gravis, may not improve the pemphigus disease activity. Although this association is reported in at least 30 cases, the finding of thymoma or myasthenia gravis in a patient with PV or PF is still unusual.

LABORATORY TESTS

Diagnosis of pemphigus relies on skin biopsy of a fresh lesion for histology to determine the site of blister formation, as well as a confirmatory immunochemical study to document the presence of skin autoantibodies, either by direct immunofluorescence of perilesional skin, or indirect immunofluorescence or ELISA of patient serum.

HISTOLOGY

The characteristic histopathologic finding in PV is a suprabasal blister with acantholysis (Fig. 54-6). Just above the basal cell layer, epidermal cells lose their normal cell-to-cell contacts and form a blister. Often, a few rounded up (acantholytic) keratinocytes are in the blister cavity. The basal cells stay attached to the basement membrane, but may lose the contact with their neighbors; as a result, they may appear to be a "row of tombstones," symbolic of the potentially fatal prognosis of this disease. Usually, the upper epidermis (from one or two cell layers above the basal cells) remains intact, as these cells maintain their cell adhesion. Pemphigus vegetans shows not only suprabasilar acantholysis, but also papillomatosis of the dermal papillae and downward growth of epidermal stands into the dermis, with hyperkeratosis and scale-crust formation. In addition, pemphigus vegetans lesions may show intraepidermal abscesses composed of eosinophils and/or neutrophils.[131] Early PV lesions may show eosinophilic spongiosis.[132]

The histopathology of early blisters in PF patients demonstrates acantholysis (loss of cell-to-cell contact) just below the stratum corneum and in the granular layer (Fig. 54-7A). The stratum corneum is often lost from the surface of these lesions. The deeper epidermis, below the granular layer, remains intact. Another frequent finding is subcorneal pustules, with neutrophils and acantholytic epidermal cells in the blister cavity (Fig. 54-7B). Histologic findings in PF are often indistinguishable from those seen in bullous impetigo/staphylococcal scalded skin syndrome, because blisters in these latter diseases also result from dysfunction of desmoglein 1, in these cases due to proteolytic cleavage by staphylococcal exfoliative toxins.[31] Therefore, immunochemical studies are essential to confirm a diagnosis of PF, as these would be negative in staphylococcal-mediated skin blisters. The site of blister formation in pemphigus erythematosus is identical to PF. As in PV lesions, very early PF lesions may show eosinophilic spongiosis.[132]

IMMUNOFLUORESCENCE

The hallmark of pemphigus is the finding of IgG autoantibodies against the cell surface of keratinocytes. These autoantibodies were first discovered in patients' sera by indirect immunofluorescence techniques and soon thereafter were discovered by direct immunofluorescence of patients' skin.[133]

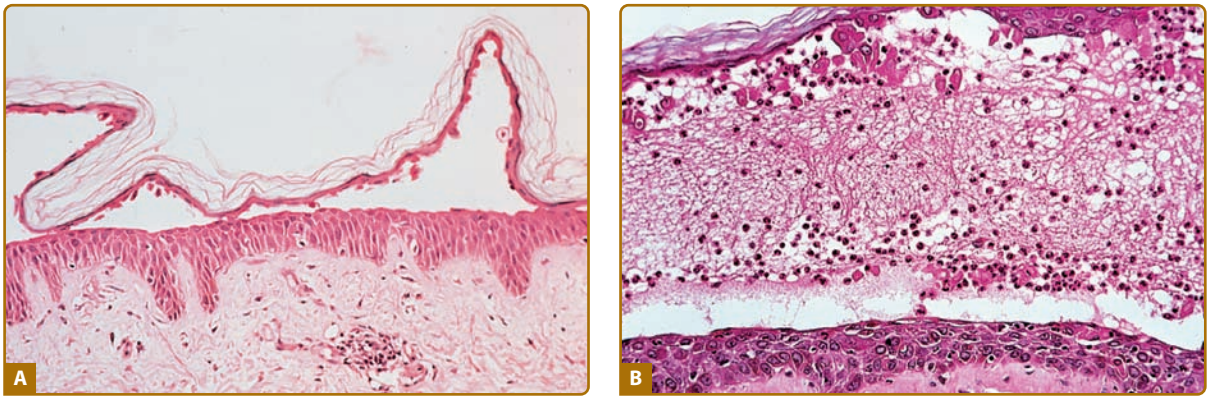

Figure 54-7 Histopathology of pemphigus foliaceus. **A.** Acantholysis in the granular layer. **B.** Subcorneal pustule with acantholysis.

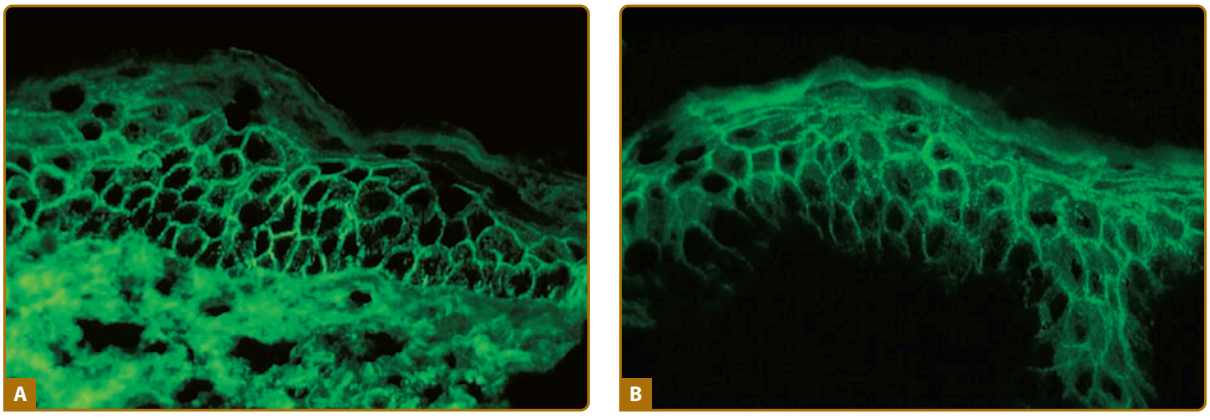

Figure 54-8 Immunofluorescence in pemphigus. **A.** Direct immunofluorescence for immunoglobulin G (IgG) of perilesional skin from a patient with pemphigus vulgaris. Note cell surface staining throughout the epidermis. **B.** Indirect immunofluorescence with the serum from a patient with pemphigus foliaceus on normal human skin. Note IgG on the cell surface throughout the epidermis.

DIRECT IMMUNOFLUORESCENCE. Essentially all patients with active PV or PF have a positive finding on a direct immunofluorescence study, which tests for IgG bound to the cell surface of keratinocytes in perilesional skin (Fig. 54-8A).[134] This is a nonquantitative test (either negative or positive). The diagnosis of pemphigus should be seriously questioned if the test result of direct immunofluorescence is negative. It is important that the biopsy for direct immunofluorescence be performed on normal-appearing perilesional skin, as the immune reactants can be difficult to detect in blistered inflamed epidermis (leading to a false negative result). In some cases of pemphigus erythematosus, IgG and C3 are deposited at the basement membrane zone of erythematous facial skin, in addition to the epidermal cell surface IgG, representing a positive lupus band test in addition to the typical pemphigus intercellular pattern.[135]

INDIRECT IMMUNOFLUORESCENCE. Indirect immunofluorescence is performed by incubating serial dilutions of patients' sera with epithelial substrates. It is reported as a semiquantitative titer (indicating the last dilution at which the serum demonstrates a positive cell surface staining pattern). The test is offered by most major national laboratories and can remain positive for weeks to months after healing of skin lesions, making it a good diagnostic test if a patient should present with no active skin lesions, for example, due to empiric treatment with prednisone by a referring physician. Depending on the substrate used for indirect immunofluorescence, more than 80% of patients with pemphigus have circulating antiepithelial cell surface IgG (Fig. 54-8B).[136] The substrate used to detect pemphigus antibody binding in indirect immunofluorescence greatly influences the sensitivity of the test. In general, monkey esophagus is more sensitive for detecting PV antibodies, and guinea pig esophagus or normal human skin is a superior substrate for detecting PF antibodies. Patients with early localized disease and those in remission are most likely to have negative findings on an indirect immunofluorescence test; for these patients the increased sensitivity of ELISA may help in diagnosis (see below).

Patients with PV and PF usually display similar direct and indirect immunofluorescence findings with IgG on the cell surface of epidermal cells throughout the epidermis, despite the different autoantigen profiles in these two diseases. Therefore, it is usually not possible to differentiate the two diseases by the pattern of immunofluorescence. There is a positive, but imperfect, correlation between the titer of circulating anticell surface antibody and the disease activity in PV and in PF.[137] Although this correlation may hold in general, and although patients in remission often show serologic remission with negative direct and indirect immunofluorescence findings,[138,139] disease activity in individual patients does not necessarily correlate with indirect immunofluorescence titer. Therefore, in the day-to-day management of these patients, following disease activity is more important than following antibody titer.

ENZYME-LINKED IMMUNOSORBENT ASSAY

For diagnosis of disease, antigen-specific ELISAs have been shown to be more sensitive and specific than immunofluorescence, and their titer correlates better than that of indirect immunofluorescence with disease activity.[35,140] Additionally, ELISAs are easier to perform and less subjective than immunofluorescence, and may replace the latter as the preferred first diagnostic test for pemphigus, although currently some major national laboratories do not offer desmoglein ELISA. These assays use desmogleins 1 and 3 bound to plates, which are then incubated with patient sera and developed with antihuman IgG reagents (Fig. 54-9). As an advantage over indirect immunofluorescence, ELISAs can help differentiate between PV and PF due to the different autoantigen profiles in these two diseases.[35,140,141,142] In most cases, ELISA is positive for desmoglein 3 (but not desmoglein 1) in mucosal PV, is

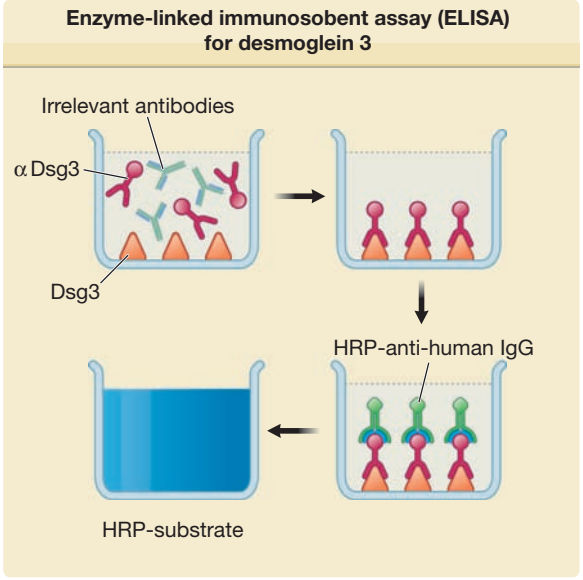

Figure 54-9 Enzyme-linked immunosorbent assay (ELISA) for desmoglein 3. Anti-Dsg3 antibodies (αDsg3) from pemphigus serum binds Dsg3 on the ELISA plate; irrelevant antibodies, that do not bind, are washed off. The plate is then incubated with horseradish peroxidase (HRP) conjugated antihuman IgG, which binds the anti-Dsg3 IgG that is on the plate. HRP is an enzyme that turns a clear substrate blue and the amount of color, read on spectrophotometer, correlates with the amount of pemphigus (i.e., anti-Dsg3) antibody in the patient's serum.

positive for both desmogleins 3 and 1 in PV with both mucosal and significant skin involvement, and is positive for only desmoglein 1 in PF. PV has rarely evolved into PF, and vice versa, as determined by clinical, histologic, and immunochemical criteria.[143–145] A small minority of PF patients may also demonstrate autoantibodies to desmoglein 3[146]; therefore, diagnosis should be made based on the clinical–serologic correlation. Additionally, some patients (e.g., those with bullous pemphigoid) may demonstrate a low level of antidesmoglein 3 autoantibodies,[140] which are detectable due to the high sensitivity of the ELISA. Therefore, a result in the indeterminate range should be interpreted carefully, as this may represent a true positive or a false negative, the latter presumably due to formation of nonpathogenic bystander autoantibodies after epidermal damage. As with indirect immunofluorescence, the correlation of ELISA index value with disease activity is not perfect. In making treatment decisions, a negative result on desmoglein ELISA is more helpful than a positive result, as a patient with the former is more likely to achieve remission off immunosuppressives, whereas a patient with the latter may or may not. In other words, disease activity is the mainstay for determining treatment.

PROGNOSIS AND CLINICAL COURSE

Before the advent of glucocorticoid therapy, PV was almost invariably fatal due to severe blistering of the skin and mucous membranes leading to malnutrition, dehydration, and sepsis. PF was fatal in approximately 60% of patients. PF was almost always fatal in elderly patients with concurrent medical problems; however, in other patients its prognosis, without therapy, was much better than PV.[147,148]

The systemic administration of glucocorticoids and the use of immunosuppressive therapy have dramatically improved the prognosis for patients with pemphigus; however, pemphigus is still a disease associated with a significant morbidity and mortality.[149,150] In the United States, the annual mortality rate from pemphigus (age-adjusted to the standard population) is estimated to be 0.023 deaths per 100,000.[151] A study in the United Kingdom showed that the risk of death in PV patients is 3.3 times greater than for controls.[9] Infection is often the cause of death, and by causing the immunosuppression necessary in the treatment of active disease, therapy is frequently a contributing factor.[152] With glucocorticoid and immunosuppressive therapy, the mortality (from disease or therapy) of PV patients followed from 4 to 10 years is approximately 10% or less, whereas that of PF is probably even less. In a study of 40 patients with PV, two patients (5%) died of sepsis and 17%, after an average of 18 months of therapy, went into a complete and long-lasting (>4 years, average, thought to be permanent) remission requiring no further therapy.[153] Another 37% of patients achieved remission but relapsed at times after therapy was stopped; most of these also eventually achieved long-lasting remissions. The remainder of patients required continual therapy. In a group of 159 patients with PV from Croatia, only approximately 12% went into long-term remission after therapy with glucocorticoids and immunosuppressives, but most relapsed.[20] In a study from Tehran of 1,206 pemphigus patients seen over 20 years, 6.2% of PV and 0.2% of PF patients died, mostly of septicemia; only 9.3% were in complete remission without therapy.[7] In some small studies, higher percentages of patients were reported to go into complete remission (see below). With the advent of rituximab therapy, complete remission in pemphigus may become more common.

TREATMENT

Despite the potentially fatal prognosis, there are currently no FDA-approved treatments. Approach to therapy of pemphigus varies widely, even among experts.[154] It is generally agreed that PV, even if initially limited in extent, should be treated at its onset, because it will ultimately generalize and the prognosis without therapy is very poor. In addition, it is probably easier to control early disease than widespread disease, and mortality may be higher if therapy is delayed.[155] Because PF may be localized for many years, and the prognosis without systemic therapy may be good, patients with this type of pemphigus do not necessarily require treatment with systemic therapy; the use of

topical corticosteroids may suffice. When the disease is active and widespread, however, the therapy for PF is, in general, similar to that for PV.

Recently, a consensus statement on disease definitions and endpoints was proposed by an international committee of pemphigus experts.[156] Additionally, clinical instruments have been developed for tracking disease activity.[157,158] The standardization of disease definitions and activity scoring will facilitate future clinical trials for pemphigus.

CORTICOSTEROIDS

The systemic administration of glucocorticoids, usually prednisone, is the mainstay of therapy for pemphigus. Before adjuvant immunosuppressive therapy was available, very high initial doses of prednisone (>2.0 mg/kg/day) were used for treatment, although such regimens have retrospectively been associated with significant morbidity and mortality from therapy.[152,159,160] In many patients the disease can be brought under control with a 0.5–1.0 mg/kg/day single daily dose, especially if used in combination with adjunctive immunosuppressive therapy, which is thought to result in fewer complications and decreased mortality as compared to higher dose glucocorticoid regimens.[161,162] For patients who do not initially respond or worsen, splitting the dose using a twice or three times daily schedule may achieve disease control. The full systemic dose of glucocorticoids has been defined in the consensus guidelines as 1.5 mg/kg/day of prednisone equivalent for 3 weeks. Therefore, patients whose total daily prednisone dose exceeds approximately 100 mg should be considered for adjunctive treatments, discussed below. Some experts still recommend controlling initial refractive disease with escalating doses of prednisone (increasing by 50% every 1 to 2 weeks until disease control or prohibitive side effects occur), with total daily doses as high as 240 mg.[148,163]

Once disease activity is controlled, tapering prednisone to as low a dose as possible should be the goal. Minimal therapy is defined as 10 mg daily of prednisone equivalent. Although there are no set guidelines, if disease activity can be fully controlled on minimal dose prednisone or lower, then glucocorticoid monotherapy may be feasible depending on the patient's other comorbidities and contraindications to alternative immunosuppressive agents. If patients have continued relapses with daily prednisone doses of 10 mg or higher, adjunctive immunosuppressive agents should be considered.

Interestingly, prednisone can control blistering within days, at a time when the autoantibody titer would be unchanged. A possible explanation is that prednisone may increase the synthesis of desmogleins or other cell adhesion molecules or change their posttranscriptional processing to prolong their half-life.[164] If pemphigus IgG depletes desmosomes of desmogleins, then prednisone could counteract this effect.

Topical corticosteroids may be used as monotherapy in mild forms of disease, or as adjunctive therapy to help heal new lesions. Patients with mucosal disease may benefit from the use of glucocorticoid elixirs as a swish and spit or dental trays to help apply class I corticosteroid gels or ointments to the gingiva. Additionally, class I–IV corticosteroids can be used as topical therapy to help resolve new blisters, even in patients on systemic glucocorticoids.

IMMUNOSUPPRESSIVE AGENTS

When greater than minimal doses of glucocorticoids are required for disease control, or if there are contraindications to oral glucocorticoids, other immunosuppressive agents are used for pemphigus therapy. In many cases, treatment regimens often begin with an immunosuppressive agent and prednisone simultaneously. Prospective randomized studies have shown that immunosuppressive agents such as mycophenolate mofetil, azathioprine, and cyclophosphamide have a steroid-sparing effect; retrospective studies suggest decreased mortality with use of adjuvants plus steroids compared to steroids alone.[147,165,166]

Because patients may die from complications of therapy, it is important to monitor all patients closely for potential side effects, such as blood count, liver and kidney laboratory abnormalities, gastrointestinal ulcer disease, high blood pressure, diabetes, glaucoma, cataracts, osteoporosis, and infection. The decision to use immunosuppressive agents, particularly in young patients, must also take into account the potential incidence of malignancies that might be associated with the long-term use of these drugs, as well as the risks of infertility (for cyclophosphamide) and teratogenicity (for mycophenolate mofetil, azathioprine, and cyclophosphamide, which are all pregnancy category D).

AZATHIOPRINE. Azathioprine has historically been considered as a first-line immunosuppressive agent for pemphigus, with clinical remission rates of approximately 50% in retrospective studies.[139,167] In a prospective randomized trial of high dose methylprednisolone (2.0 mg/kg/day) plus azathioprine (2.0 mg/kg/day), 72% of patients achieved clinical remission within a mean of 74 days, although 33% experienced significant adverse effects of therapy, including hyperglycemia, dizziness, abnormal liver enzyme tests, and infection.[165]

Azathioprine is a prodrug, which is converted to active mercaptopurine, thioguanine, and thioinosine metabolites, in part by thiopurine methyltransferase (TPMT), an enzyme whose levels can vary widely in the population. 89% of Caucasians demonstrate normal to high levels of TPMT, 11% are intermediate, and 0.3% are deficient for TPMT, the latter group representing those who do not tolerate azathioprine therapy.[168] Additionally, 1%–2% of Caucasians may have "super high" levels of TPMT, which is correlated with both treatment resistance as well as increased hepatotoxicity from excessive metabolite production.[169] Altogether, it is estimated that 5% of patients will be azathioprine intolerant, although the genotype–phenotype correlation is imperfect.[170]

In patients with normal TPMT levels, the consensus dosing regimen that defines treatment failure is 2.5 mg/kg/day for 12 weeks.[156] From a practical standpoint however, not all laboratories offer TPMT testing. Additionally, since patients with normal levels of TPMT may also experience azathioprine toxicity, it is reasonable to start all patients at a lower dose (e.g., 50–100 mg daily) and titrate upward until clinical remission, the target dose of 2.5 mg/kg/day, or unacceptable side effects result. Frequent blood and liver monitoring should continue, particularly over the first 8–12 weeks when delayed toxicity from the accumulation of metabolites may emerge.

MYCOPHENOLATE MOFETIL. Mycophenolate mofetil is also considered to be a first-line immunosuppressive agent for pemphigus. In 2006, the FDA granted orphan drug status to mycophenolate mofetil for the treatment of PV, thereby increasing the feasibility of a new drug approval. Typical doses range from 30–40 mg/kg/day dosed twice daily (2.0–3.0 g/day), although certain patients such as the elderly may achieve disease control with doses as low as 1.0 g/day.

In case series, mycophenolate mofetil has been shown to have a rapid effect in lowering pemphigus antibody titers and decreasing disease activity, even in patients whose disease is unresponsive to azathioprine.[171,172] A prospective randomized trial comparing methyprednisolone (2.0 mg/kg/day) with azathioprine (2.0 mg/kg/day) or mycophenolate mofetil (2.0 g/day) in pemphigus patients showed 72% in the azathioprine group and 95% in the mycophenolate mofetil group went in clinical remission in a mean of 74 and 91 days, respectively.[165] 19% of patients experienced significant side effects of mycophenolate mofetil therapy, compared to 33% in the azathioprine group. None of these differences was statistically significant. Another prospective randomized study indicated that azathioprine was significantly more effective than mycophenolate mofetil as a steroid sparing agent, although this study compared a full dose of azathioprine (2.5 mg/kg/day) to a partial dose of mycophenolate mofetil (2.0 g/day).[166] Caution with use of mycophenolate mofetil is warranted, as fatal infection and sepsis occurred in 2%–5% of transplant patients receiving mycophenolate mofetil, and increased risk of infection with or reactivation of cytomegalovirus, herpes zoster, atypical mycobacteria, tuberculosis, and John Cunningham (JC) virus (in progressive multifocal leukoencephalopathy) have been noted in postmarketing surveillance.[173] Interestingly, mycophenolate mofetil may offer protection against *Pneumocystis carinii* infection.[174]

CYCLOPHOSPHAMIDE. Cyclophosphamide, although more toxic than azathioprine or mycophenolate mofetil, is thought to be very effective in controlling severe disease, with one report of 19 of 23 patients with pemphigus achieving complete remission in a median time of 8.5 months.[175] A variety of small case series have evaluated different cyclophosphamide regimens for pemphigus, including daily oral therapy (1.1–2.5 mg/kg/day), daily oral therapy (50 mg) with intermittent high-dose intravenous dexamethasone and cyclophosphamide, and immunoablative intravenous cyclophosphamide.[167,175–179] All methods were effective in the short-term, although none were curative. Significant side effects, including hematuria, infection, and transitional cell carcinoma of the bladder, were observed with higher dose regimens, although one study using a lower daily dose of cyclophosphamide (1.1–1.5 mg/kg/day) did not report a significantly different safety profile compared with other immunosuppressive agents. Together with the risk of infertility, cyclophosphamide is not generally considered a first-line agent in the treatment of PV.

DAPSONE. In a case series and randomized double-blind trial, dapsone demonstrated a trend toward efficacy as a steroid-sparing drug in maintenance phase PV, although these results were not statistically significant.[180,181] Dapsone may be used in conjunction with other immunosuppressive agents, particularly rituximab (discussed below), where it offers the additional benefit of *Pneumocystis* pneumonia prophylaxis.

ADDITIONAL THERAPIES

There are additional therapies that can be used when the more standard treatments, discussed previously, are not effective.

RITUXIMAB. A very effective therapy for pemphigus that is refractory to more standard therapy is a monoclonal anti-CD20 antibody rituximab, approved for therapy of B-cell malignancies. In pemphigus patients, this monoclonal antibody presumably targets B cells, the precursors of antibody-producing plasma cells. The B cell also acts to process autoantigen and present it to T cells that provide "help" in stimulating the autoantibody response.[182] Rituximab is infused intravenously at a dose of 375 mg/m^2 once weekly for 4 weeks. Alternatively, the rheumatoid arthritis dosing regimen can be used (1,000 mg intravenously on day 1 and day 15). The course can be repeated in approximately 6 months for patients with more refractory disease, although a single cycle of rituximab has been shown to be highly effective, with 86% of patients experiencing complete remission lasting 34 months or greater.[183] Disease activity usually begins to remit within 1–2 months after the course of therapy. Some experts consider rituximab the therapy of choice for severe pemphigus uncontrolled by corticosteroids and azathioprine or mycophenolate mofetil or who have contraindications to corticosteroids.[183,184] However, fatal infections with rituximab therapy have been observed, including *Pneumocystis* pneumonia, reactivation of hepatitis B, and JC virus infection or reactivation causing progressive multifocal leukoencephalopathy.[185–188] Although these complications are rare, some experts recommend *Pneumocystis* prophylaxis for 1 year following rituximab infusion.

INTRAVENOUS IMMUNOGLOBULIN. Another method of decreasing serum autoantibodies is the intravenous use of γ-globulin (IVIg) in high doses. IVIg is thought to function by saturating circulating neonatal Fc receptor, thereby increasing catabolism of the patient's serum antibodies, which include the pathogenic autoantibodies.[189–191] It may be useful as adjuvant therapy in those pemphigus patients whose condition does not respond to more conventional therapy.[192,193] A multicenter, randomized, placebo-controlled, double blind study has confirmed its efficacy in pemphigus,[194] but it is expensive and probably requires continued infusions for maintenance of remission. There can also be significant side effects with this therapy, including stroke, deep venous thrombosis, and renal failure with sucrose-containing formulations.[195] Some centers will use IVIg to establish initial control of blistering in severely affected patients because it does not increase risk of infection as much as corticosteroids and immunosuppressants. IVIg has also been used in combination with rituximab,[196] although it is unclear whether the combination is safer or more effective compared to either alone.

PLASMAPHERESIS. Plasmapheresis is sometimes used for severe pemphigus, or for pemphigus that is unresponsive to a combination of prednisone and immunosuppressive agents. Although one controlled study found it to be ineffective,[197] other studies have found that it both reduces serum levels of pemphigus autoantibodies and controls disease activity.[198] Plasmapheresis plus intravenous pulse therapy with cyclophosphamide has been reported to result in remissions of PV.[199] For maximum effectiveness, it is probably necessary to perform plasmapheresis on patients taking immunosuppressive agents to prevent the antibody-rebound phenomenon that can follow the removal of IgG. Protein A immunoadsorption, which removes IgG selectively from plasma, has also been used.[200]

PULSED INTRAVENOUS HIGH-DOSE GLUCOCORTICOIDS. Intravenous, pulse administration of methylprednisolone, 250–1,000 mg given over approximately 3 hours daily for 4–5 consecutive days, can result in long-term remissions and decrease the total dose of glucocorticoids necessary to control disease.[201] Although the purpose of this therapy is to decrease the incidence of complications of long-term steroid use, it can result in all the usual glucocorticoid complications, as well as cardiac arrhythmias with sudden death, and its use is controversial.[202] Furthermore, a controlled trial found that adjuvant oral dexamethasone pulse therapy in addition to standard therapy with prednisolone and azathioprine for PV is not beneficial.[203] It may be that simply giving divided lower doses of prednisone could accomplish the same result with fewer side effects.

All in all, there has been a tremendous advance in the armamentarium of therapies for pemphigus since the time before the development of glucocorticoids when PV was a fatal disease. Thanks to these advances, the "row of tombstones" seen in the pathology of PV no longer alludes to its prognosis.

Chapter 55 :: Paraneoplastic Pemphigus

:: Grant J. Anhalt & Daniel Mimouni

PARANEOPLASTIC PEMPHIGUS AT A GLANCE

- Rare complication of malignancy, most commonly non-Hodgkin's lymphoma, chronic lymphocytic leukemia, or Castleman disease.
- Painful, erosive stomatitis and polymorphous cutaneous lesions that may be blistering and erosive (resembling erythema multiforme), morbilliform, or lichenoid.
- Serum autoantibodies directed against plakin proteins that are detected by indirect immunofluorescence against rodent bladder epithelium.
- High mortality rate, with death due to sepsis, complications of treatment, or bronchiolitis obliterans.
- No consistently effective therapy, but some success with the combined use of rituximab, systemic corticosteroids, and other immunosuppressive agents.

Paraneoplastic pemphigus (PNP) is an autoimmune disorder that is almost always linked to an underlying lymphoproliferative disorder. The following features define PNP:

1. Painful stomatitis and a polymorphous cutaneous eruption with lesions that may be blistering, lichenoid, or resemble erythema multiforme.
2. Histologic findings that reflect the variability of the cutaneous lesions, showing acantholysis, lichenoid, or interface change.
3. Direct immunofluorescence findings of immunoglobulin G (IgG) and complement deposition in the epidermal intercellular spaces and, often, granular/linear complement deposition along the epidermal basement membrane zone.
4. Serum autoantibodies that bind to the cell surface of skin and mucosae in a pattern typical of pemphigus, but in addition, bind to simple, columnar, and transitional epithelia.
5. The serum autoantibodies identify desmogleins 1 and 3, in addition to members of the plakin family of epithelial proteins, such as desmoplakins, envoplakin, and periplakin.[1]

Non-Hodgkin's lymphoma (NHL), chronic lymphocytic leukemia (CLL), and Castleman disease are the neoplasms most commonly associated with PNP. There is no regularly effective treatment. Most patients die from complications of the disease, including pulmonary involvement with respiratory failure.

EPIDEMIOLOGY

The incidence of PNP is unknown, although it is less common than pemphigus vulgaris or foliaceus (see Chapter 54). In an adverse events reporting analysis including 100,000 patients with known NHL and CLL, 12 were found to have PNP. Only three of them were identified by the reporting physician, and the remainder were identified only by retrospective data analysis, suggesting that the majority of cases of PNP are not being properly diagnosed. In this series, the most common misdiagnoses were erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis (TEN), and drug reaction.

ETIOLOGY AND PATHOGENESIS

In almost all cases, PNP is associated with a limited number of lymphoproliferative neoplasms. On the basis of 140 cases of PNP confirmed by immunoprecipitation findings of the characteristic autoantibody profile, the estimated frequencies of specific neoplasms are 44% NHL, 19% CLL, 16% Castleman disease (giant follicular hyperplasia), 8% thymoma (malignant and benign), 7% sarcomas that are retroperitoneal and often poorly differentiated, 4% Waldenström's macroglobulinemia, and in 2% the neoplasms were too poorly differentiated to categorize (Fig. 55-1). The

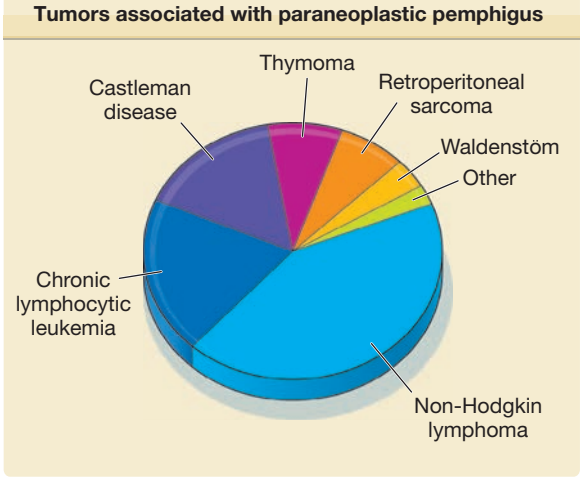

Figure 55-1 Tumors associated with paraneoplastic pemphigus.

disproportionate representation of Castleman disease is notable, given its overall rarity. In children with PNP, Castleman disease is almost always the underlying neoplasm.[2] Before the description of PNP, many cases of Castleman disease associated with atypical forms of pemphigus had been reported, and we suspect that most were PNP. A study of archived clinical material in one such case confirmed the presence of autoantibodies specific for PNP.

With very rare exceptions, more common cancers, such as adenocarcinomas of breast, bowel, and lung, or basal cell and squamous cell carcinoma of skin, have not been associated with PNP. There are a few reports of PNP and squamous cell carcinoma, but in most of them, the diagnosis was made with immunofluorescent techniques only, which have a significant false positive and false negative rate, and were not confirmed immunochemically, so the association remains unproven.

The mechanisms by which these tumors induce autoimmunity against epithelial proteins remain speculative. One hypothesis states that the tumors constitutively or anomalously express epithelial proteins. These proteins are targeted by the antitumor immune response that cross-reacts with normal constitutive epithelial proteins of the host. This mechanism occurs in several neurologic paraneoplastic syndromes.[3] This antitumor immune response may be initiated by reactivity against plakin proteins, and the antitumor immune response may cross-react with normal constitutive proteins of epithelia. However, to date, there are no data to support this hypothesis.

It is more likely that this autoimmune disease is a result of more complex interactions between the tumor cells, the immune system, and specific genetic background. In many autoimmune diseases, specific genetic predispositions have been found, and HLA studies performed on two different series of PNP patients revealed a significant predominance of HLA-class II DRB*03 and HLA-class I Cw*14 genes. It is interesting to note that these two HLA molecules are not those associated with development of pemphigus vulgaris, providing another argument to consider PNP as a distinct entity.[4,5]

There is evidence that dysregulated cytokine production by tumor cells drives the development of autoimmunity. Patients with PNP have evidence of markedly elevated levels of interleukin 6 (IL-6).[6] It has been observed that in a subset of cases of NHLs,[7] CLL, and Castleman tumors, the tumor cells secrete massive amounts of IL-6 in vitro. IL-6 is known to promote B-cell differentiation and to drive immunoglobulin production, and dysregulated IL-6 production has been implicated in certain autoimmune diseases. Castleman tumors are known to be associated with other autoimmune phenomena such as myasthenia gravis and autoimmune cytopenias, and these patients also have high serum levels of IL-6. Symptoms attributable to Castleman tumors are routinely reversed by complete excision of the affected node(s), and, coincidentally, serum IL-6 levels revert to normal. Administration of anti-IL-6 receptor monoclonal antibodies also effectively reverses systemic manifestations of Castleman disease and is currently being studied in clinical trials.[8]

It had also been proposed that the autoantibody may derive from the lymphoid tumor itself. Cultures of Castleman tumors have been shown to contain B cells that produce specific autoantibody.[9] However, Castleman tumors are unique in that they are not clonal neoplasms, and these studies showed the expansion of several immunologically active B-cell clones within the tumors. In Waldenström's macroglobulinemia, the autoantibody is polyclonal and IgG class, not IgM, and therefore, cannot be produced by the tumor cells.

Almost all patients with PNP have autoantibodies against desmogleins, demonstrable by enzyme-linked immunosorbent assay (ELISA), and when the desmoglein autoantibodies from these patients are affinity purified and injected into neonatal mice, acantholytic skin lesions are induced.[10] However, none of features of the disease that appear to be induced by cell-mediated autoimmunity are recreated by the immunoglobulin injections. No internal organs, like the lungs, are involved, and there are no findings of lymphocyte-mediated lichenoid or interface epithelial injury. This is another indication that humoral immunity alone reproduces features of acantholysis, but passive transfer of autoimmune cells from these patients may be necessary to induce the complete spectrum of the disease in animals.

CLINICAL FINDINGS

HISTORY

CUTANEOUS LESIONS. The most constant clinical feature of the disease is the presence of intractable stomatitis (Figs. 55-2A and 55-2B). It is the earliest presenting sign and the one feature that persists throughout the course of the disease, even after treatment and is extremely resistant to therapy. This finding is so consistent that in its absence, PNP should not be considered in the differential diagnosis.

This stomatitis consists of erosions and ulcerations that can affect all surfaces of the oropharynx. The lesions differ from those seen in pemphigus vulgaris in that they show more necrosis and lichenoid change. They also preferentially localize to the lateral borders of the tongue, and characteristically extend onto and involve the vermilion of the lips. Occasionally, oral lesions are the only manifestation of the disease.

The cutaneous lesions of PNP are quite variable, and different morphologies may occur in an individual patient according to the stage of the disease (see Fig. 55-2C and 55-2D). The initial patients reported with the syndrome had episodes of waves of blistering affecting the upper trunk, head and neck, and proximal extremities. These lesions consisted of blisters that ruptured easily, leaving erosions. The blisters on the extremities were sometimes quite tense, resembling those seen in bullous pemphigoid, or they had surrounding erythema, clinically resembling erythema multiforme (see Fig. 55-2D). On the upper chest and

Figure 55-2 **A.** Extensive erosions involving the vermillion of the lips in a patient presenting with paraneoplastic pemphigus and an occult lymphoma. The characteristic severe stomatitis, accompanied by polymorphous cutaneous lesions, is the most consistent feature of the disease. **B.** Painful ulcerations tend to localize to the lateral border of the tongue. **C.** Lesions of the trunk from the same patient pictured in **A.** Erythematous macules and papules coalesce and become erosive on the upper chest as the cutaneous lesions evolve. **D.** Lesions from the forearm of the same patient. These lesions clinically resemble erythema multiforme, but biopsy shows a mix of individual cell necrosis, interface change, and acantholysis.

back, confluent erosive lesions can develop, producing a picture resembling TEN. The similarity of the mucocutaneous features to erythema multiforme and TEN explains why this is the most common differential diagnosis for PNP. However, it is important to note that erythema multiforme and TEN are self-limited events that evolve and resolve over several weeks, whereas PNP is a relentlessly progressive and evolves continuously over months.

Cutaneous lichenoid eruptions are very common, and they may be the only cutaneous signs of the disease, or may develop in lesions that had previously been blistered. When cutaneous lichenoid lesions are present, severe stomatitis is also invariably present. In the chronic form of the disease and after treatment, this lichenoid eruption may predominate over blistering on the cutaneous surface. The common presence of both blisters and lichenoid lesions affecting the palms and the soles as well as the paronychial tissues helps to distinguish PNP from pemphigus vulgaris, in which acral and paronychial lesions are uncommon.

There are a small number of patients who appear to have PNP but who do not have demonstrable circulating autoantibodies.[11] These patients tend to have predominantly lichenoid skin and mucosal lesions, but behave in every other way like antibody-positive patients. They have the same underlying neoplasms, and frequently develop bronchiolitis obliterans. Because the definition of the disease relies so heavily on demonstration of the specific autoantibody markers, further study is required to determine the exact classification of what is presently termed the *lichenoid variant of PNP*.

The disease has also been identified in a horse and two dogs. In animal species, the disease is associated with the same neoplasms and has the same clinical outcomes.[12]

RELATED CLINICAL FINDINGS

PNP is the only form of pemphigus that involves nonstratified squamous epithelium. Approximately 30%–40% of cases develop pulmonary injury, often with a fatal outcome.[13] The earliest symptoms are progressive dyspnea associated initially with an absence of findings on chest radiography. Pulmonary function studies show airflow obstruction in large and small airways. Inflammation of the large airways evolves and is evidenced by endoscopic biopsy showing acantholysis of bronchial respiratory epithelium. Pulmonary function deteriorates in most cases despite immunosuppressive therapy, and radiologic, histologic, and functional changes characteristic of bronchiolitis obliterans develop.

LABORATORY TESTS

The key finding is the serologic identification of polyclonal IgG autoantibodies against plakin proteins and, in most cases, desmogleins 1 and 3. The plakins are a group of sequence-related proteins that form the intracellular plaque of desmosomes and hemidesmosomes, and mediate attachment of cytoskeletal intermediate filaments to transmembrane adhesion molecules such as the desmogleins (see Chapter 53). Autoantibodies against these proteins are the most characteristic surrogate markers for the disease. The pattern of antigens recognized by individual patients shows considerable variability, but the most characteristic and consistently recognized plakin antigens are envoplakin[14] and periplakin[15] (210 and 190 kDa, respectively; Fig. 55-3). The next most frequently detected are antibodies against desmoplakin I and desmoplakin II (250 and 210 kDa, respectively). Less commonly, patients recognize bullous pemphigoid Ag 1 (230 kDa), plectin (400 kDa), and plakoglobin (82 kDa). The identity and frequency of an antigen band at 170 kDa are not well defined. PNP patients may also have clinical and serologic evidence of other autoimmune phenomena such as myasthenia gravis and autoimmune cytopenias (see Fig. 55-3).

To screen for PNP autoantibodies, one can test for IgG autoantibodies by indirect immunofluorescence reactive with rodent urinary bladder epithelium. A positive result implies the presence of plakin autoantibodies; however, the sensitivity and specificity of this serologic test are only approximately 75% and 83%, respectively.[16] Recently, ELISA kits using recombinant proteins containing subdomains of envoplakin and periplakin have been developed and have demonstrated high sensitivity and specificity for the diagnosis of PNP.[17,18] More specific and sensitive tests, which are more time consuming, technically demanding, and of limited availability, include immunoblotting against epidermal cell extracts that can effectively detect antibodies against envoplakin, periplakin and desmoplakin, and immunoprecipitation, using radiolabeled keratinocyte extracts, which can detect antibodies against any of the plakin proteins.

The PNP autoantibody profile is more complex than that observed in pemphigus vulgaris or foliaceus, where there are autoantibodies produced only against the desmogleins. The humoral immunity in PNP may represent an example of epitope spreading in which patients develop autoantibodies against structurally related plakin proteins and structurally unrelated transmembrane cell surface proteins (the desmogleins) that are physically linked to the plakin proteins in the desmosome and hemidesmosome.

HISTOPATHOLOGY

The histopathology of PNP is distinctive from pemphigus vulgaris and foliaceus for two reasons. First, because the lesions can be clinically very polymorphous, there is substantial variability in the histologic findings.[19] Second, findings due to cell-mediated cytotoxicity are frequently observed.

Owing to the severe mucositis, many biopsies of oral lesions yield nonspecific changes of inflammation and ulceration. If one can biopsy perilesional epithelium, a lichenoid mucositis with variable degrees of individual cell necrosis and suprabasilar acantholysis can be observed.

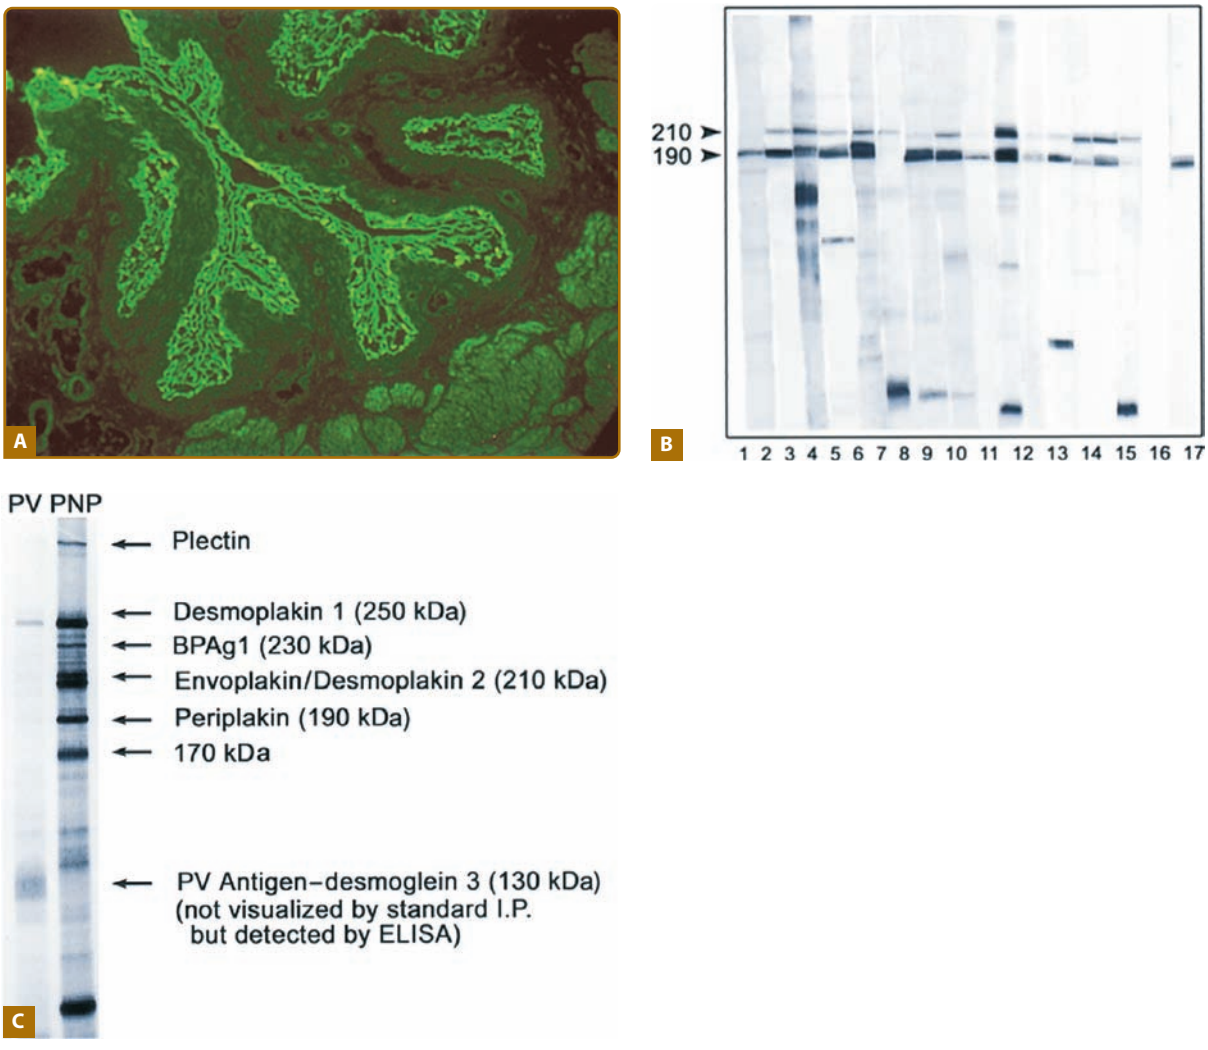

Figure 55-3 Diagnosis of paraneoplastic pemphigus (PNP) depends on the demonstration of antiplakin antibodies. **A.** This can be accomplished by indirect immunofluorescence of patient serum on rodent urinary bladder demonstrating binding of immunoglobulin G to the cell surface of transitional epithelial cells. A positive result implies the presence of antiplakin antibodies. This technique, although easily performed, has the lowest sensitivity and specificity. **B.** Immunoblotting against epidermal cell extracts is much more sensitive and specific. This shows detection of envoplakin (210 kDa) and/or periplakin (190 kDa) in 15 patients with PNP. Lane 16 is a normal control, and lane 17 shows a monoclonal antibody against periplakin. This technique uses denatured antigen extracts, so it does not reliably detect some of the PNP antigens, but antibodies against the most characteristic plakin antigens, envoplakin and periplakin, are easily detected. **C.** Immunoprecipitation using radiolabeled, nondenatured epidermal extracts and serum from a patient with PNP and pemphigus vulgaris (PV). In this case, the PNP patient's serum identifies all of the plakin antigens. Envoplakin and desmoplakin II migrate as a doublet at 210 kDa. This technique is the most sensitive and specific test for demonstration of antiplakin antibodies in PNP, but has limited availability. Although this technique readily detects the antiplakin antibodies, desmoglein 3 is not always efficiently identified, and this is best shown by using enzyme-linked immunosorbent assay (ELISA).

When evaluating biopsies from skin lesions, one must recognize that lesions with different clinical morphologies yield differing histologic findings. In noninflammatory cutaneous blisters, suprabasilar acantholysis is expected to be more prominent than the interface/lichenoid change (Fig. 55-4A). When erythematous macules and papules are sampled, interface and lichenoid dermatitis is predominant (see Figs. 55-4B and 55-4C). Lesions with a mixed clinical pattern also show mixed histologic features of concomitant suprabasilar acantholysis and interface/lichenoid dermatitis.

There is also observed variability of the interface and lichenoid dermatitis. The spectrum of changes can include: (1) individual keratinocyte necrosis with lymphocytic infiltration into the epidermis, reminiscent of that seen in erythema multiforme or graft-versus-host disease; (2) vacuolar interface change with sparse lymphocytic infiltrate of the basilar epithelium, resembling cutaneous lupus erythematosus or dermatomyositis; and (3) a thick lichenoid band along the dermal–epidermal junction similar to that seen in lichen planus. Although most of the specimens show a complex overlap of histologic patterns, there is a relatively good

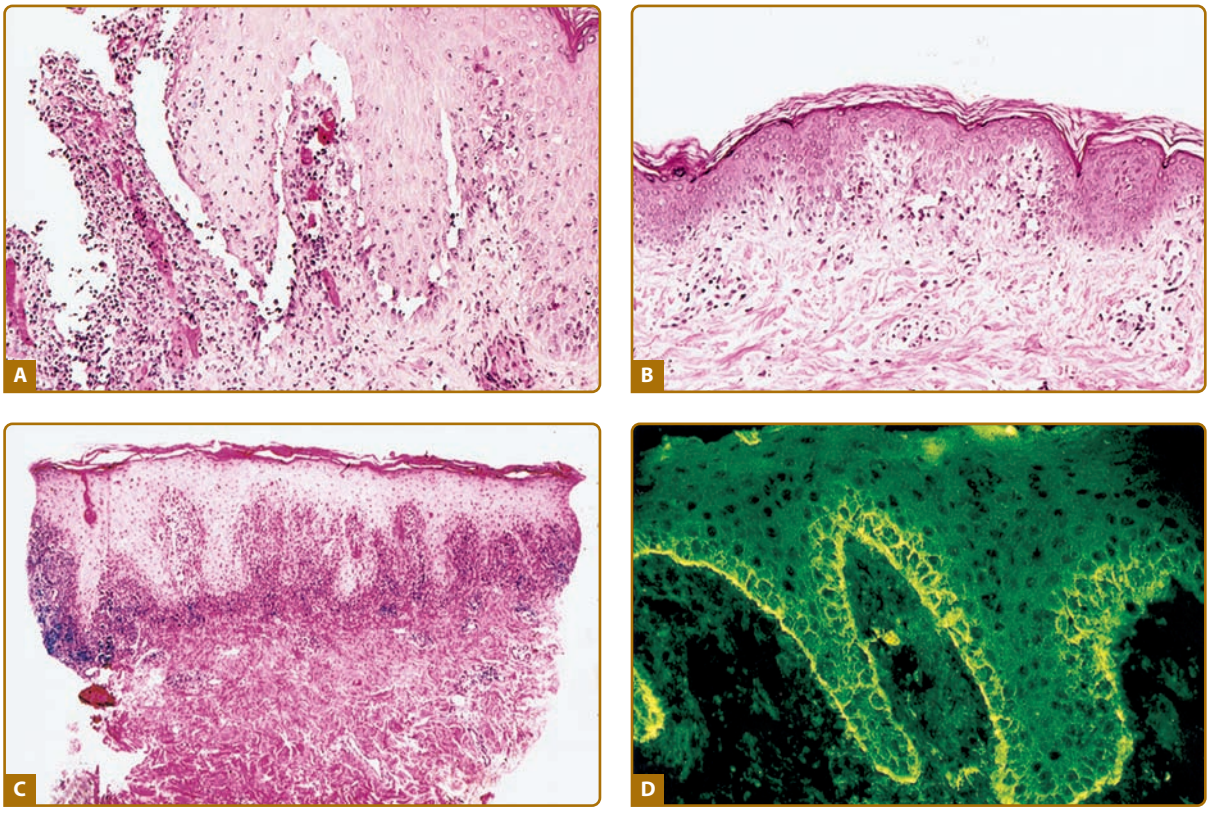

Figure 55-4 **A.** Histopathology of a blistering cutaneous lesion in paraneoplastic pemphigus. This demonstrates the characteristic presence of vacuolar interface change and suprabasilar acantholysis [Hematoxylin and eosin (H&E), 200×]. **B.** Macular and papular lesions may show just vacuolar interface change (H&E, 100×). **C.** Lichenoid lesions demonstrate lichenoid infiltrates on histologic examination (H&E, 40×). The presence of these varied histologic findings help differentiate paraneoplastic pemphigus from pemphigus vulgaris. **D.** Direct immunofluorescence can be negative in a significant number of cases, but when positive, the most characteristic changes are those of deposition of immunoglobulin G and complement components on both the surface of basilar and suprabasilar keratinocytes and along the epidermal basement membrane zone (Immunofluorescence with fluoresceinated anti-immunoglobulin G, 200×).

correlation between the clinical and the predominant histologic pattern.

The histopathologic variability of this disease may be related to the fact that it is a presumed antitumor immune response. If this speculation is correct, one would expect to observe a combination of both humoral and cell-mediated immunity that is aberrantly directed against normal epithelium. In such a setting, one would expect to see changes of the sort described in the previous paragraph. This degree of cell-mediated immunity is not seen in pemphigus vulgaris or foliaceus (see Chapter 54); hence the unique histopathologic features, and, presumably, the unique clinical features as well. The presence of T-cell-mediated epithelial cytotoxicity has been recently demonstrated in histologic studies.[20]

IMMUNOPATHOLOGY

Patients with PNP should have evidence of IgG autoantibodies bound to the cell surface of affected epithelium by direct immunofluorescence. However, false negatives are more common in PNP than in pemphigus vulgaris, and repeated biopsies may be necessary, as well as careful investigation of the adnexal structures which may be the only positive site.[21] In a minority of cases, one might also see a combination of both cell surface and basement membrane zone deposition of IgG and complement components, but the absence of this combined cell surface/basement membrane zone staining does not negate the diagnosis (see Fig. 55-4D).

SPECIAL TESTS

Approximately one-third of patients have an occult malignancy at the time they develop PNP. Neoplasms that would not be detected by routine complete blood count, serum chemistries, and physical examination are most likely to be intra-abdominal lymphoma, intrathoracic or retroperitoneal Castleman tumors, or retroperitoneal sarcomas. The most effective and efficient method for screening for these tumors is either computer-aided tomography or magnetic resonance imaging of the body from the neck to the base of the bladder. If available, Positron emission tomography/ computer tomography (PET/CT) using fluorodeoxyglucose (FDG) as a biologically active molecule can be more specific in the

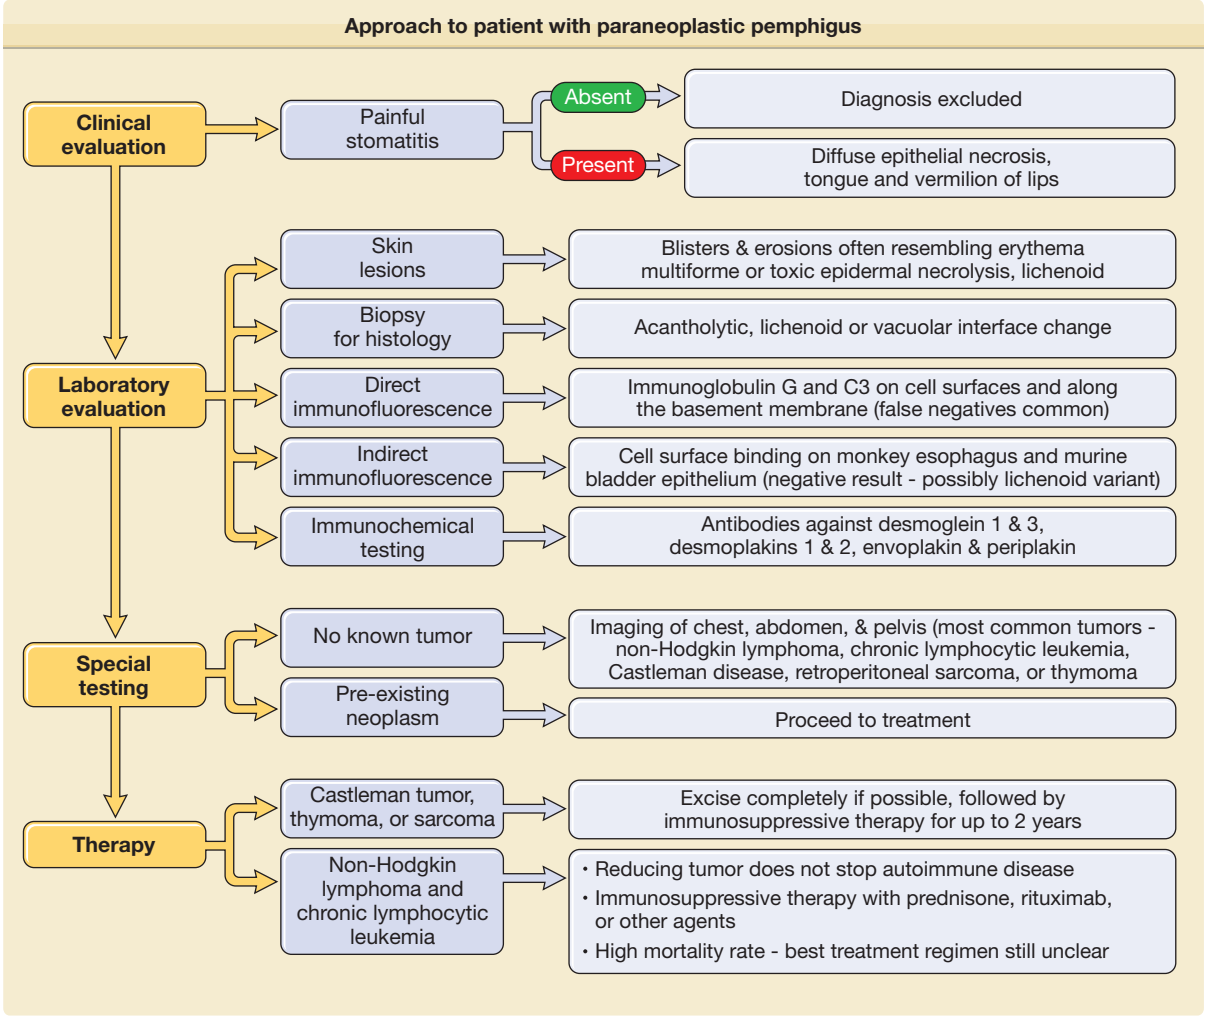

Figure 55-5 Approach to a patient with paraneoplastic pemphigus.

identification of an occult lymphoma. Other studies, such as endoscopy, are not required.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis can best be made if the algorithm shown in Fig. 55-5 is followed. The clinical differential diagnosis is summarized in Box 55-1.

PROGNOSIS AND CLINICAL COURSE

It is not known why PNP is so refractory to the type of immunosuppressive treatments that are usually effective in pemphigus vulgaris and other autoimmune diseases.

In those patients who do succumb, death has been attributed in individual cases to multiple factors,

BOX 55-1 DIFFERENTIAL DIAGNOSIS OF PARANEOPLASTIC PEMPHIGUS

- Oral lesions
  - Pemphigus vulgaris
  - Stevens–Johnson syndrome
  - Mucous membrane pemphigoid
  - Oral lichen planus
  - Chemotherapy-induced stomatitis
  - Major aphthous stomatitis
- Cutaneous lesions

  - Pemphigus vulgaris
  - Drug eruption
  - Lichen planus
  - Subepidermal blistering disorders

including sepsis, gastrointestinal bleeding, "multiorgan failure," and respiratory failure. Patients with autoimmune disease associated with B-cell neoplasms are known to have a high frequency of autoimmune cytopenias, and some fatal episodes of sepsis are suspected to have occurred because of sudden and unexplained neutropenia, possibly due to this mechanism. Respiratory failure is a common terminal event. The development of shortness of breath with obstructive disease progressing to bronchiolitis obliterans is a terminal complication in most cases. Because these patients have autoantibodies that react with desmoplakins, and because desmoplakins are present in respiratory epithelium, respiratory failure may be due to autoantibody-mediated injury to bronchial epithelium, with plugging of terminal bronchioles, resulting in airflow obstruction and ventilation/perfusion abnormalities. Additionally, direct damage to alveolar epithelium could cause a diffusion barrier and subsequent intractable hypoxia. One autopsy study showed an absence of autoantibodies and a marked infiltration of bronchioles with cytotoxic T cells in a patient who died from PNP and bronchiolitis obliterans. This shows that there may be similar complex humoral and cell-mediated autoimmune injury to the lung, similar to what is seen in the skin. The pulmonary injury does not respond well to medical treatment, and the development of shortness of breath and hypoxia in a patient with this syndrome is an ominous prognostic sign.

In patients with malignant neoplasms there is no definite correlation between tumor burden and the activity of the autoimmune syndrome. Treatment of the primary malignancy does not affect the activity of the autoimmune disease. It seems that once the process is initiated by the malignancy, the autoimmunity progresses independently. An example of the disconnect between tumor burden and autoimmunity is found in the case reported by Fullerton et al,[22] in which PNP occurred after successful autologous bone marrow transplantation for NHL. This patient was free of detectable tumor burden at the time of his death, but died from pulmonary injury secondary to PNP. It is notable that the patient underwent autologous bone marrow transplantation, and therefore received his own memory T cells, or possibly individual malignant lymphoid cells that were not detectable by routine autopsy methods.

TREATMENT

(See Box 55-2)

Individuals with benign or encapsulated tumors such as Castleman tumors or thymoma should have them surgically excised. If the entire lesion is removed, the disease generally improves substantially or goes into complete remission. The remission of the autoimmune disease may take 1–2 years after surgery, so continued immunosuppression during this period is required. The usual treatment involves combined use of prednisone and rituximab.[23] In pediatric cases with respiratory disease, the persistent autoimmunity immediately after surgery can cause ongoing pulmonary injury, and lung transplantation might be required for long-term survival.[24]

In patients with malignant neoplasms, there is no consensus regarding a therapeutic regimen that is consistently effective. Despite scattered individual reports of long-term survivors, almost all patients with NHL or CLL succumb in a period of 1 month to 2 years after diagnosis. Oral corticosteroids in a dose of 0.5–1.0 mg/kg produce partial improvement, but not complete resolution of lesions. Cutaneous lesions respond quickly to therapy, but the stomatitis is generally quite refractory to any treatment. Systemic corticosteroids and many other agents have been tried in individual cases, but none has proven to be particularly effective. Methods that have been tried and often failed include immunosuppression with cyclophosphamide, mycophenolate mofetil or azathioprine, gold, dapsone, plasmapheresis, and

BOX 55-2 TREATMENTS FOR PARANEOPLASTIC PEMPHIGUS

	DRUG	USUAL DOSE	OTHER DOSING
First line	Prednisone	0.5–1.0 mg/kg	Methylprednisolone, 1,000 mg IV daily × 3 days
	Rituximab	375 mg/m^2 IV weekly × 4 week, repeat every 6 months	1,000 mg IV weekly × 2 week
	Daclizumab	2 mg/kg IV weekly × 4 week, then every other week indefinitely	
	Basiliximab	20 mg IV on day 0 and day 4, repeat every 3–4 months	
Second line	Cyclosporine	5 mg/kg daily	
	Cyclophosphamide	2.5 mg/kg daily	
	Mycophenolate mofetil	1,000 mg PO bid	
	High-dose IV immunoglobulin	2 g/kg IV, repeat q 3–4 week	
	Plasmapheresis	Every other day for six total treatments	

photopheresis. A small number of patients have shown a good response to combination treatment directed at both humoral and cell-mediated autoimmunity. These patients received oral prednisone, rituximab, and daclizumab or basiliximab (both are nondepleting monoclonal antibody against CD25, the high affinity IL-2 receptor of T cells). This appears to be a less toxic way of downregulating both humoral and cell-mediated autoimmunity, with promising early results.

PREVENTION

There is no known intervention that may prevent the development of PNP in a patient with a known lymphoid malignancy. Although there has been individual case reports of PNP perhaps being triggered by certain drugs, radiation therapy, or cytokine administration, it is still not clear that any of these treatments triggered the autoimmune disease, and it appears more likely that the neoplasm itself triggers the autoimmunity.

Chapter 56 :: Bullous Pemphigoid

:: Donna A. Culton, Zhi Liu, & Luis A. Diaz

BULLOUS PEMPHIGOID AT A GLANCE

- Usually occurs in elderly patients.
- Yearly mortality varies from 6% to 40%.
- Pruritic urticarial lesions and tense large blisters. Oral mucous membrane erosions in minority of patients.
- Skin pathology shows subepidermal blisters with eosinophils.
- Direct immunofluorescence shows immunoglobulin (Ig) G and C3 at epidermal basement membrane of perilesional skin, indirect immunofluorescence shows IgG antibasement membrane autoantibodies in the serum.
- The autoantigens BPAg1e and the BP180 are proteins of the keratinocyte hemidesmosome, a basal cell–basement membrane adhesion structure.
- Therapy includes topical and systemic corticosteroids and immunosuppressives.

Bullous pemphigoid was originally classified as a unique disease with distinctive clinical and histologic features by Walter Lever in 1953.[1] Its separation from pemphigus was important, because at the time pemphigus vulgaris was often fatal, whereas bullous pemphigoid had a comparatively good prognosis. The separation of bullous pemphigoid from pemphigus was confirmed and fully justified by the characteristic immunopathologic features of these diseases described approximately 12 years later.[2,3]

EPIDEMIOLOGY

Bullous pemphigoid typically occurs in patients over 60 years of age, with a peak incidence in the 70s.[4] There are several reports of bullous pemphigoid in infants and children, although this is rare.[5–8] There is no known ethnic, racial, or sexual predilection for developing bullous pemphigoid. The incidence of bullous pemphigoid is estimated to be 7 per million per year in both France and Germany, and 14 per million per year in Scotland.[4,9–11] A recent large cohort study suggests that the incidence of bullous pemphigoid may be as high as 43 per million per year in the United Kingdom with incidence increasing over the last several years.[12]

ETIOLOGY AND PATHOGENESIS

IMMUNOPATHOLOGY

The hallmarks of bullous pemphigoid include the presence of subepidermal blisters, lesional and perilesional polymorphonuclear cell infiltrates in the upper dermis, and immunoglobulin (Ig) G autoantibodies and C3 bound to the dermal epidermal junction. Remarkable advances have been made in the last decades characterizing the antigens as hemidesmosomal components and developing an animal model that demonstrates the pathogenicity of bullous pemphigoid autoantibodies.

BULLOUS PEMPHIGOID ANTIGENS

Immunofluorescence (IF) techniques demonstrate that patients with bullous pemphigoid exhibit circulating and tissue-bound autoantibodies directed against antigens of the cutaneous basement membrane zone (BMZ).[3] Immunoelectron microscopy studies localize bullous pemphigoid antigens to the hemidesmosome, an organelle that is important in anchoring the basal cell to the underlying basement membrane.[13] These autoantibodies bind to both the intracellular plaque of the hemidesmosome and the extracellular face of the hemidesmosome. Bullous pemphigoid autoantibodies recognize two distinct antigens with molecular weights of 230 kDa and 180 kDa by immunoblot analysis of human skin extracts.[14] The 230-kDa molecule is termed BP230, BPAG1, or BPAG1e.[14–17] BPAG1e belongs to a gene family that includes desmoplakin I, a desmosomal plaque protein that is important in anchoring keratin intermediate filaments to the desmosome.[18,19] By immunoelectron microscopy BPAG1e is located in the intracellular plaque of the hemidesmosome, exactly where keratin intermediate filaments insert.[20] Analysis of BPAG1e-deficient mouse strains generated by transgenic knockout technology further demonstrates that the function of BPAG1e is to anchor keratin intermediate filaments to the hemidesmosome.[21] Mice lacking BPAG1e show fragility of basal cells due to collapse of the keratin filament network, but no epidermal–dermal adhesion defect. Interestingly, an alternatively spliced form of BPAG1e (termed BPAG1n) is expressed in neural tissue. BPAG1n stabilizes the cytoskeleton of sensory neurons,[22,23] just as BPAG1e stabilizes the cytoskeleton of epidermal cells. The lack of dermal–epidermal separation in the BPAG1e-null mice indicates that pathogenic autoantibodies in bullous pemphigoid do not act simply by inhibiting the function of BPAG1e.

The 180-kDa BP autoantigen is termed BP180, BPAG2, or type XVII collagen.[24–26] BP180 is a transmembrane protein with an intracellular amino-terminal domain and an extended carboxyl-terminal domain that spans the lamina lucida and projects into the lamina densa of the basement membrane.[27–31] Its cytoplasmic domain is located in the plaque of the hemidesmosome and its extracellular domain is linked to anchoring filaments.[32–34] The extracellular domain of BP180 contains a series of 15 collagen regions interrupted by 16 noncollagen sequence.[29] The NC16A subdomain, adjacent to the membrane-spanning region, harbors the major autoantibody-reactive epitopes.[35,36] These features make the BP180 antigen a prime target for pathogenic autoantibodies. As discussed in Section "Pathophysiology of Subepidermal Blistering," antibodies against the NC16A domain are capable of inducing subepidermal blisters in mice. Moreover, an enzyme-linked immunosorbent assay (ELISA) to measure antibodies against the BP180 NC16A domain is both sensitive and specific for a diagnosis of bullous pemphigoid[37–39] and its titers correlate with disease activity.[40] Further evidence that BP180 mediates dermal–epidermal adhesion comes from analysis of the gene defect in patients with the junctional subepidermal blistering disease, non-Herlitz junctional epidermolysis bullosa (JEB-nH), previously known as generalized atrophic benign epidermolysis bullosa. These patients have recessively inherited mutations in the *BP180* gene that result in a missing or dysfunctional protein.[41–43]

PATHOPHYSIOLOGY OF SUBEPIDERMAL BLISTERING

Bullous pemphigoid is an autoimmune inflammatory disease. The distinctive feature of bullous pemphigoid is the presence of circulating and tissue-bound autoantibodies against BP180 and BP230. Anti-BP180 autoantibodies of various immunoglobulin isotypes and IgG subclasses are present in bullous pemphigoid sera with IgG being predominant, followed by IgE.[44–46] Serum levels of anti-BP180-NC16A IgG and IgE correlate well with disease activity in bullous pemphigoid patients.[24,26,40] Inflammatory cells are present in the upper dermis and bullous cavity, including eosinophils (the predominant cell type), neutrophils, lymphocytes, and monocytes/macrophages. Both intact and degranulating eosinophils, neutrophils, and mast cells (MC) are found in the dermis.[47–50] Local activation of these cells may occur via the multiple inflammatory mediators present in the lesional skin and/or blister fluid.[51–59] Several proteinases are found in bullous pemphigoid blister fluid, including plasmin, collagenase, elastase, and MMP-9,[60–67] which may play a crucial role in subepidermal blister formation by their ability to degrade extracellular matrix proteins.

Both in vitro and in vivo data demonstrate that autoantibodies, particularly those against BP180, are pathogenic. In vitro studies using normal human skin sections indicate that bullous pemphigoid IgG is capable of generating dermal–epidermal separation in the presence of complement and leukocytes.[68,69] Early attempts to demonstrate the pathogenicity of patient autoantibodies by a passive transfer mouse model were unsuccessful because bullous pemphigoid anti-BP180-NC16A autoantibodies fail to cross-react with the murine BP180.[70] To overcome this difficulty, rabbit antibodies were raised against the epitope on mouse BP180. Passive transfer of these rabbit antibodies to neonatal mice induces blisters that resemble some key

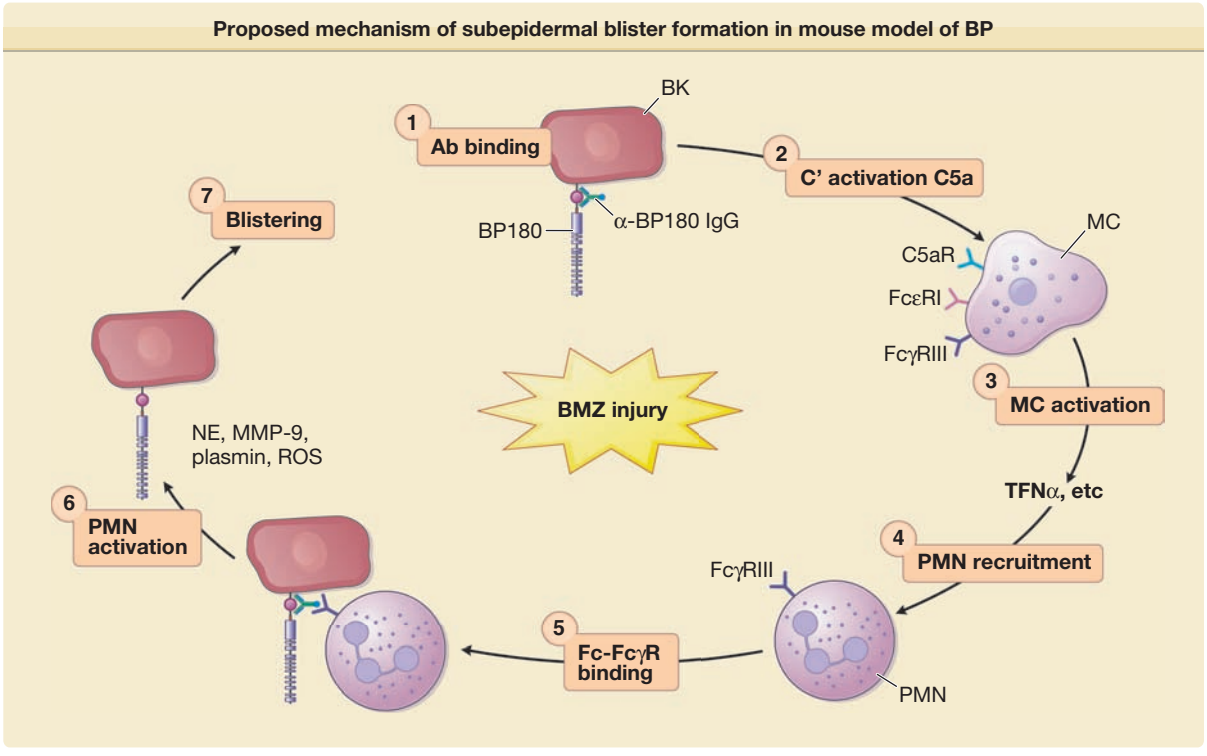

Figure 56-1 Proposed mechanism of subepidermal blister formation in mouse model of BP. Subepidermal blistering is an inflammatory process that involves the following steps: **1**, anti-BP180 IgG binds to the pathogenic epitope of BP180 antigen on the surface of basal keratinocytes (BK); **2**, the molecular interaction between BP180 antigen and anti-BP180 IgG activates the classical pathway of the complement system (C′); **3**, C′ activation products C3a and C5a cause mast cells (MC) to degranulate; **4**, TNF-α and other proinflammatory mediators released by MC recruit neutrophils (PMN); **5**, infiltrating PMNs bind to the BP180–anti-BP180 immune complex via the molecular interaction between Fcγ receptor III (FcγRIII) on neutrophils and the Fc domain of anti-BP180 IgG; **6**, the interaction between Fc and FcγRIII activates PMNs to release neutrophil elastase (NE), gelatinase B (MMP-9), plasminogen activators (PAs), and reactive oxygen species (ROS); **7**, Proteolytic enzymes and ROS work together to degrade BP180 and other extracellular matrix proteins, leading to subepidermal blistering.

features of human bullous pemphigoid, including in situ deposition of rabbit IgG and mouse C3 at the BMZ, dermal–epidermal separation, and an inflammatory cell infiltrate.[70] These studies demonstrate that experimental blistering in animals requires activation of the classical pathway of the complement system, mast cell degranulation, and neutrophil infiltration (Fig. 56-1).[71–75] A well-orchestrated proteolytic event occurs during the disease progression. Plasmin activates proenzyme MMP-9 and activated MMP-9 then degrades α1-proteinase inhibitor, the physiological inhibitor of neutrophil elastase. Unchecked neutrophil elastase degrades BP180 and other extracellular matrix components, resulting in dermal–epidermal junction separation.[76–79] To directly test the pathogenicity of anti-BP180 IgG autoantibodies from bullous pemphigoid patients, humanized BP180 mouse strains were generated, in which the human BP180 or NC16A domain replaces the murine BP180 or corresponding domain.[80,81] These humanized mice, upon injection with anti-BP180 IgG from bullous pemphigoid patients, develop subepidermal blisters.[80,81] Like the rabbit antimurine BP180 IgG-induced model, the humanized NC16A mouse model of bullous pemphigoid also requires complement, MC, and neutrophils (Fig. 56-2).[80]

IgE anti-BP180 autoantibodies may also play a role in blister formation. Human skin grafted onto immune-deficient mice injected with an IgE hybridoma to the extracellular portion of BP180 or total IgE from bullous pemphigoid patients' sera exhibit histological dermal–epidermal separation,[82,83] suggesting that anti-BP180 IgE antibodies may also participate in pathogenesis of bullous pemphigoid through activating MC and recruiting eosinophils.

Although animal model studies clearly show that an inflammatory cascade is triggered by BP180-specific antibodies and is essential for blister formation, direct interference of hemidesmosome-mediated cell–cell matrix adhesion by anti-BP180 autoantibodies may be another disease mechanism.[84] Involvement of anti-BP230 autoantibodies in bullous pemphigoid blistering is also implicated in some animal model studies,[85,86] but direct evidence in humans is lacking.

In addition to the humoral response, bullous pemphigoid patients also mount a cell mediated autoimmune response. Autoreactive T and B lymphocytes recognize BP180.[87–89] These studies suggest that bullous pemphigoid is a T- and B-cell-dependent and antibody-mediated skin autoimmune disease. As in most autoimmune diseases, the initial trigger for induction

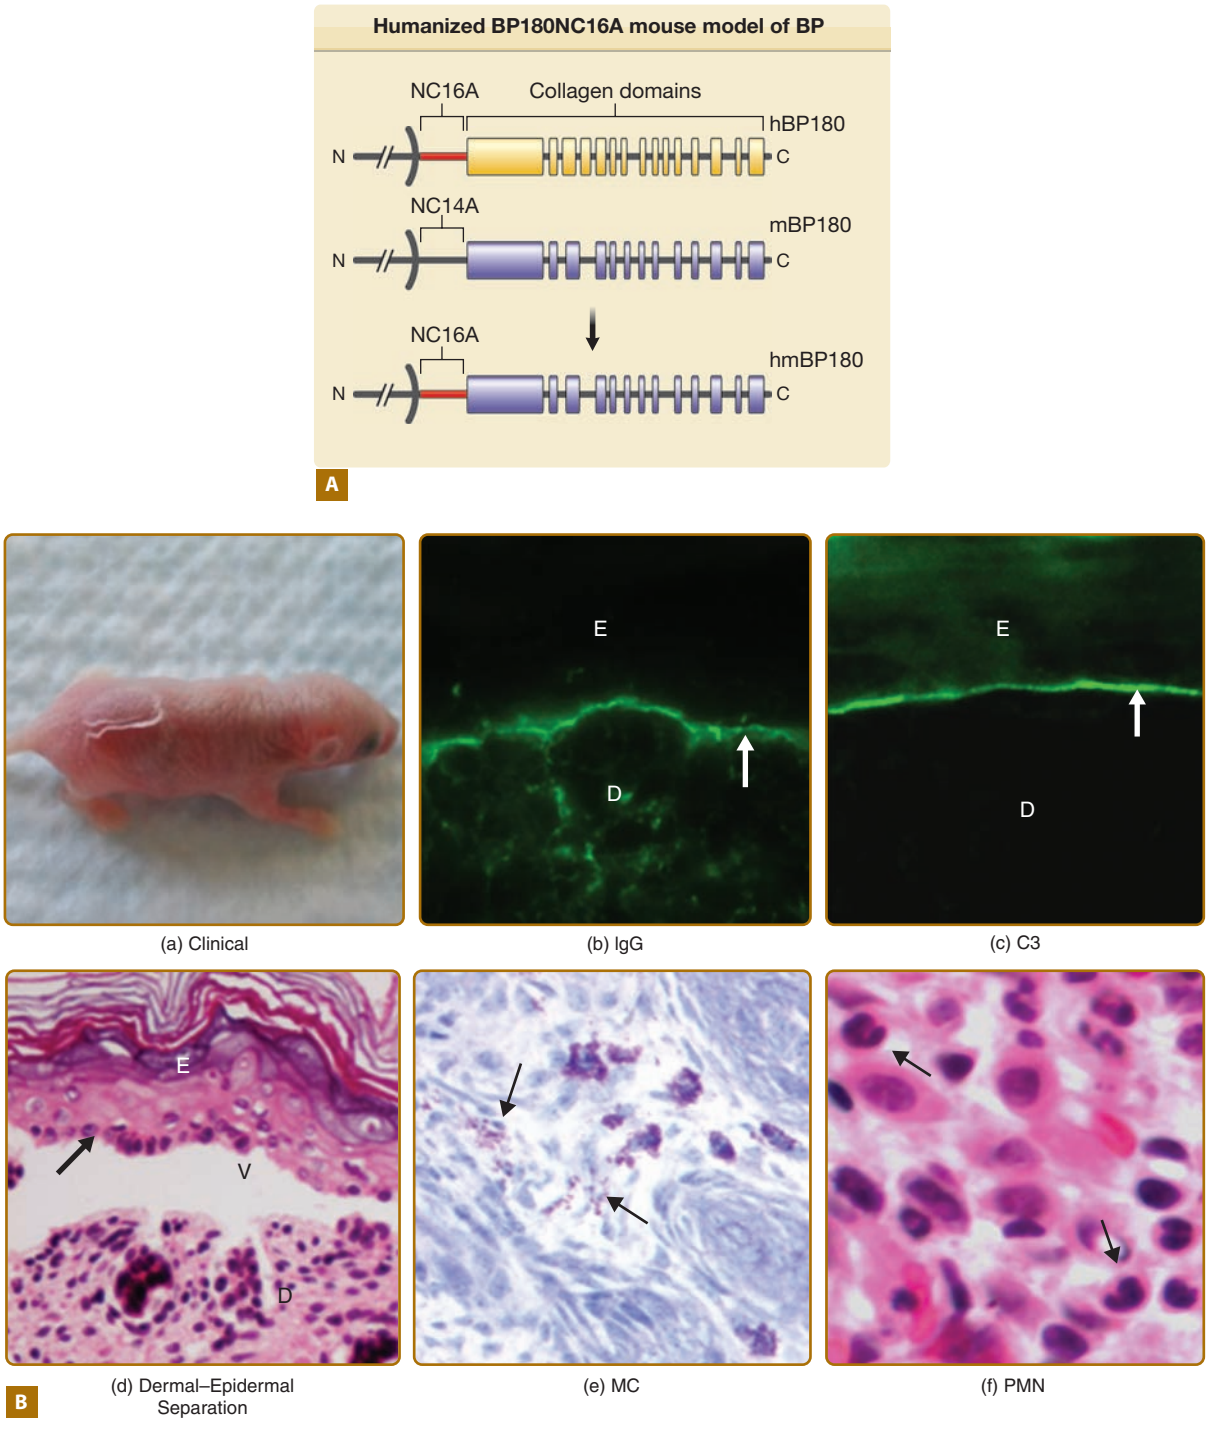

Figure 56-2 Humanized BP180NC16A mouse model of BP. **A.** Human BP180 (*top panel*) is a transmembrane protein of basal keratinocytes. It contains a single transmembrane domain. The extracellular region is consisted of 15 interrupted collagen domains (*yellow bars*) and 16 noncollagen domains (*black lines*). The NC16A domain (*red line*) harbors immunodominant epitopes recognized by BP autoantibodies. The extracellular region of mouse BP180 (*middle panel*) contains 13 collagen domains (*blue bars*) and 14 noncollagen domain (*black lines*). In humanized BP180NC16A mice, the mouse BP180NC14A domain was replaced by the human NC16A domain (*lower panel*). **B.** Neonatal NC16A mice injected i.d. with BP180NC16A-specific IgG autoantibodies developed clinical blistering (a). Direct IF showed BMZ deposition of human IgG (b) and murine C3 (c). Histological sections of lesional skin showed dermal–epidermal separation (d). Examination of toluidine blue-stained skin sections revealed degranulating mast cells (MC) (e). Hematoxylin/Eosin (H/E) staining showed infiltrating neutrophils (PMN) in the upper dermis (400× magnification) (f). E = epidermis; D = dermis; V = vesicle; arrows in panels b–d = basal keratinocytes.

of autoreactive lymphocytes and autoantibody production in bullous pemphigoid remains unknown.

Several other subepidermal blistering diseases also show autoimmune responses to BP180. These include pemphigoid gestationis (or herpes gestationis), cicatricial pemphigoid (or mucous membrane pemphigoid), linear IgA bullous dermatosis, and lichen planus pemphigoid.[90–100] It is possible that they may share some common immunopathological mechanisms with bullous pemphigoid.

CLINICAL FINDINGS

HISTORY

Most cases of bullous pemphigoid occur sporadically without any obvious precipitating factors. However, there are several reports in which bullous pemphigoid appears to be triggered by ultraviolet (UV) light, either UVB or following PUVA therapy, and radiation therapy.[101–103] Certain medications have also been associated with the development of bullous pemphigoid including penicillamine, efalizumab, etanercept, and furosemide.[104–109]

CUTANEOUS LESIONS

The classic form of bullous pemphigoid is characterized by large, tense blisters arising on normal skin or on an erythematous base (Fig. 56-3A).[110,111] These lesions are most commonly found on flexural surfaces, the lower abdomen, and thighs, although they may occur anywhere. The bullae are typically filled with serous fluid, but may be hemorrhagic. The Nikolsky and Asboe–Hansen signs are negative. Eroded skin from ruptured blisters usually heals spontaneously without scarring, although milia can sometimes occur. Once the lesions heal they leave hyperpigmented patches that may last for several months. Pruritus may be intense in some patients, but minimal in others.

Nonbullous lesions are the first manifestation of bullous pemphigoid in almost half of patients.[112] Often, urticarial type lesions precede the more classic tense bullae, and patients may present with these lesions early in the course of disease (Fig. 56-3B). The erythematous component in some bullous pemphigoid patients may appear eczematoid, serpiginous, or targetoid with erythema multiforme-like lesions.

Mucous membrane lesions occur in approximately 10% of patients and are almost always limited to the oral mucous membranes, particularly the buccal mucosa.[110,113–115] Intact oral mucosa blisters are rare, with erosions more commonly seen. The lesions heal without scarring and are fairly limited. Unlike erythema multiforme, the vermillion border of the lips is rarely involved. There are rare reports of esophageal involvement.[116,117] The presence of scarring is more suggestive of cicatricial pemphigoid as discussed in Chapter 57.

In addition to the more classic findings, unusual clinical presentations can be seen.[118] In these cases, the diagnosis is confirmed by IF and ELISA studies. For example, localized bullous pemphigoid often presents as tense bullae restricted to localized areas of involvement, most commonly on the lower legs.[119,120] Patients with localized disease have antibodies against the same pemphigoid antigens as patients with more generalized disease.[119–121] The lesions may remain localized for years or progress to generalized bullous pemphigoid. Childhood bullous pemphigoid often presents as localized disease with acral distribution being common.[5–8,122] Localized vulvar and perivulvar disease has also been described in young girls.[123,124] Other reports of localized bullous pemphigoid suggest that changes induced by radiation, trauma, or surgery (colostomy, urostomy, or skin graft donor site) at a particular site may precipitate disease in these areas.[125–133]

Other less common presentations include erythroderma, prurigo nodularis-like or vegetating lesions, and dyshidrotic dermatitis-like lesions. Again, the antibodies from these patients show typical IF localization and bind the pemphigoid antigens.[121,134–142]

Figure 56-3 Bullous pemphigoid. **A.** Large, tense bullae and erythematous patches studded of small vesicles on the thighs and lower legs. **B.** Urticarial lesions of bullous pemphigoid with overlying tense vesicles and bullae in the axilla.

In addition to atypical clinical presentations, bullous pemphigoid may also coexist with other cutaneous diseases. Lichen planus pemphigoides describes the coexistence of bullous pemphigoid and lichen planus with typical clinical, histologic, and immunopathologic features of both diseases.[143–146] Lichen planus pemphigoides more often presents in middle-aged patients (mean age of onset 35–45 years of age) and is more localized to the extremities with a less severe clinical course when compared to classic bullous pemphigoid. In rare instances, bullous pemphigoid has also been reported to coexist with pemphigus.[147–150]

DISEASE ASSOCIATIONS

Neurological disease is seen more frequently in bullous pemphigoid patients and it appears that patients with neurological disease (especially those over 80 years of age) have a significantly higher risk of developing bullous pemphigoid than those without neurological disease.[151–153] In rare instances, bullous pemphigoid may be seen in association with acquired hemophilia due to acquired Factor VIII inhibitor. Cutaneous clinical manifestations include ecchymoses, hematomas, and hemorrhagic bullae in addition to more systemic findings such as gastrointestinal bleeding.[154–156]

There have been many case reports of bullous pemphigoid associated with malignancy. However, case-control studies suggest that there is no increase, or a very small increase, in the frequency of malignancy in bullous pemphigoid patients compared with age-matched controls.[152,157–159] There may be an increased frequency of malignancy in bullous pemphigoid patients with negative indirect IF studies as compared with those with positive findings.[113,160] The perceived association may be explained by the fact that both bullous pemphigoid and malignancy occur more commonly in elderly patients. While a thorough review of systems and symptom-guided workup is indicated in patients with a new diagnosis of bullous pemphigoid, extensive screening for an asymptomatic malignancy is not warranted.

LABORATORY TESTS

The diagnosis of bullous pemphigoid is made based upon clinical, histologic, and IF features as described below. Other laboratory studies play a small supporting role. Approximately half of patients will have elevated total serum IgE levels, which often correlate with titers of bullous pemphigoid IgG autoantibodies by IF and pruritus.[51,161,162] Approximately one-half of patients have peripheral blood eosinophilia, which does not correlate with serum IgE levels.[162,163]

HISTOPATHOLOGY

Biopsy of an early small vesicle is diagnostic with histology revealing a subepidermal blister with a superficial dermal infiltrate consisting of eosinophils, neutrophils lymphocytes, and monocytes/macrophages (Fig. 56-4).[110] The infiltrate ranges from intense to sparse, but it characteristically contains some eosinophils, which may also be seen in the blister cavity. The blister roof is usually viable without evidence of necrosis. Histology of urticarial lesions may only show a superficial dermal infiltrate of lymphocytes, monocytes/macrophages, and eosinophils with papillary dermal edema. These urticarial lesions may also display degranulating eosinophils at the dermal–epidermal junction, with early separation of individual basal cells from the basement membrane and/or eosinophilic spongiosis.[164]

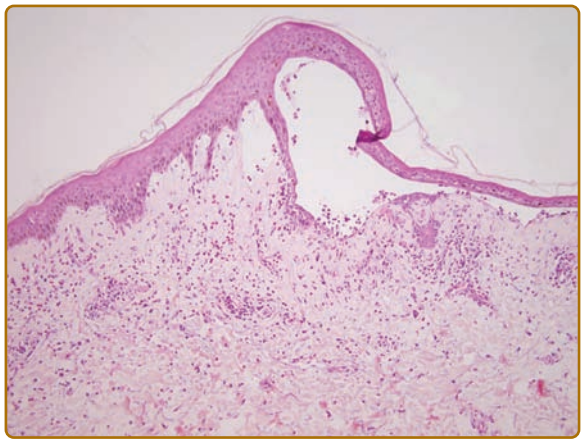

Figure 56-4 Histopathology of bullous pemphigoid. Subepidermal blister with an inflammatory cell infiltrate containing eosinophils in the superficial dermis (100× magnification).

ELECTRON MICROSCOPY

Ultrastructural studies demonstrate that early blister formation in bullous pemphigoid occurs in the lamina lucida, between the basal cell membrane and the lamina densa (Fig. 56-5A and 56-5B).[165] In areas of blister formation, there is loss of anchoring filaments and hemidesmosomes. Degranulation of eosinophils, neutrophils, and MC in the lesional/perilesional skin has also been observed by electron microscopy.[49]

SPECIAL TESTS

Direct IF of perilesional skin shows linear IgG (usually IgG1 and IgG4, although all IgG subclasses and IgE have been reported) and C3 along the basement membrane.[2,3,113,162,166] In approximately 70% of patients, there are circulating IgG and IgE autoantibodies that bind the BMZ on normal human skin or monkey esophagus by indirect IF.[45,113,162,163,166–169] Using 1 M NaCl split skin, which separates the epidermis from the dermis at the lamina lucida, an even higher percentage of patients will have detectable circulating anti-BMZ autoantibodies.[170,171] In addition to being more sensitive, the other

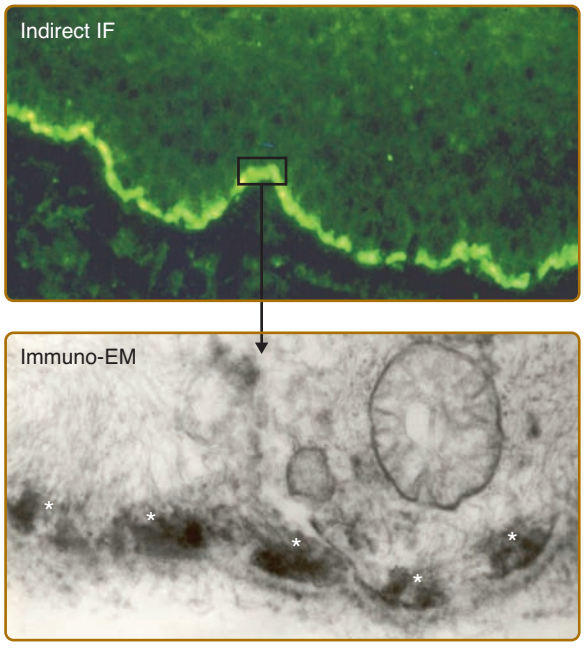

Figure 56-5 **A.** Indirect immunofluorescence of bullous pemphigoid serum shows a linear pattern of immunoglobulin G binding to the epidermal dermal junction of normal skin. **B.** Binding of bullous pemphigoid antibodies to human basal cell hemidesmosomes as described by Mutasim et al: *J Invest Dermatol* **84**:47-53, 1985. A small rectangle of linear indirect IF staining and the arrow depicts the immunolocalization of the reactive antibodies to the hemidesmosome (*white asterisks*).

advantage of the 1 M NaCl-split skin substrate is that bullous pemphigoid antibodies bind the roof of the artificially induced blister (i.e., the bottom of the basal cells). This finding differentiates bullous pemphigoid antibodies from epidermolysis bullosa acquisita (EBA) autoantibodies, which bind the base or the floor of the split skin (i.e., dermal side; Figs. 56-6A and 56-6B). In contrast to pemphigus, in bullous pemphigoid the indirect IF antibody titer does not usually correlate with disease extent or activity.[172]

Recently, ELISA techniques have proven to be useful in both clinical and research settings for the detection of circulating antigen specific IgG and IgE antibodies. Commercial kits are available for detection of both BP-180 (NC16A and total) and BP-230 IgG antibodies. A sensitivity of 89% and specificity of 98% when used with appropriate cutoff values are reported with these assays.[37] As many as 75% of patients also have antigen specific IgE with anti-BP180 and anti-BP230 IgE antibodies detectable by IF and ELISA.[44,46,168,173–176] Those patients with anti-BP180 IgE antibodies may have a more severe form of disease.[174] Antigen specific IgE antibodies may account for the early urticarial type lesions and likely play a role in recruiting eosinophils to skin lesions.[82,173]

Recent studies have shown that approximately 7% of the normal population has anti-BP180 antibodies detectable by ELISA in the absence of clinical and histologic features of disease without age or gender predilection. The predictive relevance of these circulating antibodies in healthy individuals is unknown as long-term follow-up is not available. However, this finding underscores the importance of using the ELISA in appropriate clinical settings and not as a screening tool in patients who lack other features of disease.[177]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for bullous pemphigoid includes other blistering diseases, such as linear IgA disease, dermatitis herpetiformis, erythema multiforme, EBA, and pemphigus. Histology and IF can easily distinguish bullous pemphigoid from these diseases (Box 56-1). Distinguishing bullous pemphigoid from EBA and cicatricial pemphigoid may be difficult as histology and direct IF may be identical.[115,178] EBA can usually be distinguished from bullous pemphi-

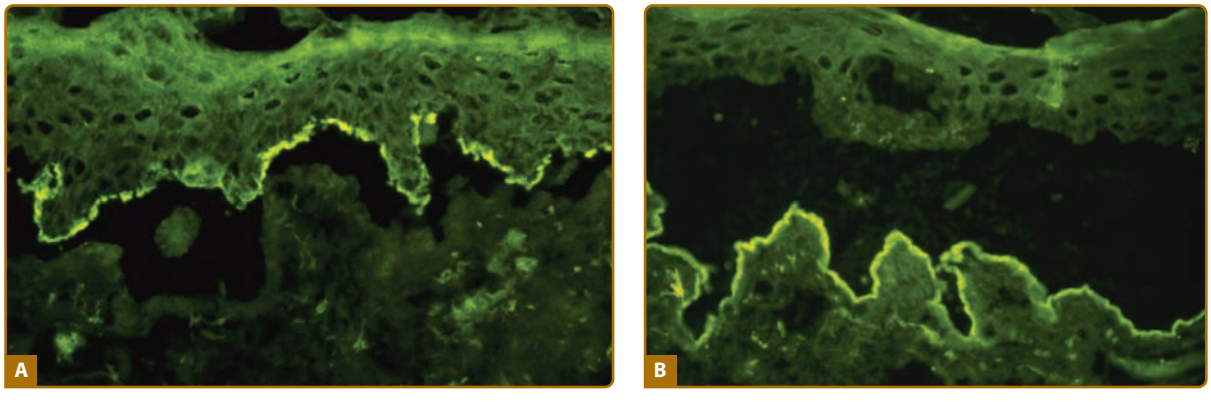

Figure 56-6 Indirect immunofluorescence on normal skin previously incubated in 1 M NaCl to induce a split through the lamina lucida of the dermal–epidermal junction. **A.** IgG antibodies from bullous pemphigoid serum binds to the roof of the artificial blister (hemidesmosomes). **B.** IgG antibodies from epidermolysis bullosa acquisita (EBA) serum binds to the floor of the split (collagen VII of anchoring fibers).

BOX 56-1 DIFFERENTIAL DIAGNOSIS OF BULLOUS PEMPHIGOID

SUBEPIDERMAL BLISTERING DISEASES WITH AUTOANTIBODIES

- Pemphigoid gestationis
- Cicatricial pemphigoid
- Epidermolysis bullosa acquisita (EBA)
- Linear immunoglobulin A disease
- Dermatitis herpetiformis
- Bullous lupus erythematosus, described as an EBA phenotype

SUBEPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES

- Erythema multiforme and toxic epidermal necrolysis
- Porphyria
- Epidermolysis bullosa (genodermatoses)

INTRAEPIDERMAL BLISTERING DISEASES WITH AUTOANTIBODIES

- Pemphigus

INTRAEPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES

- Allergic contact dermatitis (e.g., rhus dermatitis)
- Bullous impetigo, staphylococcal scalded-skin syndrome
- Friction blisters
- Hailey–Hailey disease
- Incontinentia pigmenti

goid by indirect or direct IF on salt-split skin as stated above.[179] Confirmation of EBA may be accomplished by ELISA assays using type VII collagen, the EBA antigen (discussed in Chapter 60). Immunoelectron microscopy also distinguishes these diseases because the IgG in EBA is below the lamina densa on the anchoring fibrils (type VII collagen), whereas the IgG in bullous pemphigoid is closely associated with the basal cell hemidesmosomes.[180]

As opposed to bullous pemphigoid, cicatricial pemphigoid usually presents with mucosal lesions predominantly, if not exclusively (see Chapter 57). Cicatricial pemphigoid is characterized by desquamative gingivitis as well as inflammation and scarring of conjunctiva. If there is blistering of the skin, it may be transient and may result in scarring. Large, tense blisters, which are characteristic of bullous pemphigoid, are usually not seen in cicatricial pemphigoid.

COMPLICATIONS

Complications in untreated patients include skin infection developing within denuded bullae, dehydration, electrolyte imbalance, and possibly death from sepsis.

PROGNOSIS/CLINICAL COURSE

Bullous pemphigoid is characterized by a waxing and waning course with occasional spontaneous remission in the absence of treatment. Localized disease often resolves spontaneously, but spontaneous remission can even occur in patients with more generalized disease. For example, prior to the availability of systemic corticosteroids, Lever reported that 8 of 30 adults with bullous pemphigoid went into remission after approximately 15 months (range, 3–38 months) of active disease.[110] In treated patients, the length of disease ranges from 9 weeks to 17 years with a median treatment period of 2 years and 50% remission rates in patients followed for at least 3 years.[181] Clinical remission with reversion of direct and indirect IF to negative has been noted in patients, even those with severe generalized disease, treated with oral corticosteroids alone or with azathioprine.[162,182] High ELISA titers and, to a lesser degree, positive direct IF at the time of therapy cessation has been associated with a high risk of relapse within the first year following cessation of therapy.[182] At least one of these tests should be performed before therapy is discontinued.

Old age, poor general health, and the presence of anti-BP180 antibodies have been associated with a poor prognosis.[183–186] Early mortality rates in untreated patients were reported to be 25%.[110] Newer studies have shown the 1-year mortality of patients with bullous pemphigoid to be between 19% and 40% in Europe, but lower (less than 6%–12%) in the United States.[12,183–185,187–190] The factors underlying this discrepancy in mortality rates between Europe and the United States are not clear. While mortality rates remain relatively low in the United States, recent studies have confirmed a slow steady increase in mortality over the last 24 years in the United States.[191]

TREATMENT

Treatment of bullous pemphigoid depends greatly on the extent of disease. Localized bullous pemphigoid often can be treated successfully with topical corticosteroids alone (Box 56-2).[162,166,192] Topical tacrolimus has also been reported to be useful in a few cases of localized pemphigoid.[192–196]

More extensive disease is usually treated with oral prednisone.[192,197,198] Despite the lack of randomized controlled trials, oral prednisone remains the mainstay of therapy. Some recent studies suggest that potent topical steroids, such as clobetasol propionate cream 0.05% applied twice daily, are also effective in both moderate and severe bullous pemphigoid and may be safer than oral prednisone.[189] Thus, these patients received a daily dose of 40 g of clobetasol propionate that was applied twice daily to the entire surface of the body until 15 days after control of the

disease had been attained. High-potency topical treatment did result in significant systemic absorption and therefore may act via local and systemic effects.[199] Such topical therapy can be expensive and difficult to apply, which may prove prohibitive in many patients.

In elderly patients, the complications of systemic glucocorticoid therapy (such as osteoporosis, diabetes, and immunosuppression) may be especially severe.[200] Therefore, it is important to try to minimize the total dose and duration of therapy with oral glucocorticoids. Starting doses of prednisone of 0.75–1.0 mg/kg/day or even less may be adequate for disease control.[201] In addition, immunosuppressive agents such as azathioprine, mycophenylate mofetil, and methotrexate (and less often cyclophosphamide) are often used in conjunction with prednisone for their potential steroid-sparing effects,[192,198,202–209] although very few controlled trials have addressed this common approach to therapy. High-dose "pulse" therapy with intravenous methylprednisolone also has been reported to be effective in rapidly controlling active blister formation in bullous pemphigoid.[210] Once the development of blisters has been arrested and the erythema has subsided, a careful tapering of the prednisone is recommended. A weekly lowering of 5 mg to reach 30 mg is commonly used. Lowering this dose must be done according to the clinical response of the patient. The majority of patients may be controlled with small amounts of prednisone and immunosuppressive drugs. Sulfones may be effective in a minority of patients. Dapsone and sulfapyridine have been reported to control disease activity in 15%–44% of bullous pemphigoid patients.[198,211–213]

Reports have described successful treatment of some bullous pemphigoid patients with tetracycline and nicotinamide or variations on this theme, such as erythromycin and nicotinamide or tetracycline alone.[214–216] In small numbers of patients, other therapies reported to be effective include plasmapheresis,[217] intravenous immunoglobulins,[218–220] methotrexate,[205,207,221] leflunomide,[222] and chlorambucil.[223]

Chapter 57 :: Cicatricial Pemphigoid

:: Kim B. Yancey

CICATRICIAL PEMPHIGOID AT A GLANCE

- A chronic autoimmune subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring.
- Lesions commonly involve the oral and ocular mucosae; other sites that may be involved include the nasopharyngeal, laryngeal, esophageal, genital, and rectal mucosae.
- A rare disorder, occurring in one person per million annually; females are affected 1.5–2.0 times as often as males.
- A progressive disorder that may result in serious complications (e.g., blindness, loss of the airway, esophageal stricture formation).
- Immunopathologic studies of perilesional mucosa and skin demonstrate in situ deposits of immunoreactants in epithelial basement membranes; circulating antibasement membrane autoantibodies are detected in sera of some but not all patients.
- A variety of different autoantigens are recognized by autoantibodies from patients, suggesting that cicatricial pemphigoid is not a single nosologic entity but rather a disease phenotype.

Cicatricial pemphigoid (alternate designation: mucous membrane pemphigoid) is a rare chronic autoimmune subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring of at least some sites of involvement.[1–6]

EPIDEMIOLOGY

Cicatricial pemphigoid has been estimated to occur in approximately 1 person per million annually; females are affected 1.5–2.0 times as often as males.[7–9] Cicatricial pemphigoid has a mean age of onset of the early to middle 60s.[9] Although there is no known racial or geographic predilection, the *HLADQB1*0301* allele has been shown to be significantly increased in frequency in patients with oral, ocular, and generalized bullous pemphigoid; amino acid residues at positions 57 and 71 to 77 of the DQB1 protein may represent a disease susceptibility marker.[1,10–14]

ETIOLOGY AND PATHOGENESIS

Autoantibodies directed against autoantigens in epidermal basement membrane are held responsible for the pathogenesis of cicatricial pemphigoid (Fig. 57-1).[15] A variety of different autoantigens are recognized by circulating autoantibodies from these patients.[1,16–31] These and other findings have led to the idea that cicatricial pemphigoid is not a single nosologic entity but rather a disease phenotype. Autoantigens recognized by immunoglobulin G (IgG) autoantibodies from patients with cicatricial pemphigoid are summarized in Table 57-1. While autoantibodies directed against some of these autoantigens have been shown to be pathogenic in vivo (Table 57-1), it is conceivable that other mechanisms may contribute to the pathogenesis of cicatricial pemphigoid. For example, recent studies have demonstrated high stromal expression of IL-13 in $CD3^+$ T cells from patients with ocular cicatricial pemphigoid and that these cells may contribute both profibrotic and proinflammatory stimuli to conjunctival fibroblasts.[39]

Bullous pemphigoid antigen 2 (BPAG2) appears to represent a major cicatricial pemphigoid autoantigen; other autoantigens of particular interest include laminin 332, integrin subunit β_4, integrin subunit α_6, type VII collagen, and bullous pemphigoid antigen 1. Other patients with cicatricial pemphigoid have IgA antibasement membrane autoantibodies (alone or in conjunction with IgG antibasement membrane autoantibodies); the best characterized IgA autoantigen linked to the cicatricial pemphigoid phenotype is bullous pemphigoid antigen 2.[1,40–42]

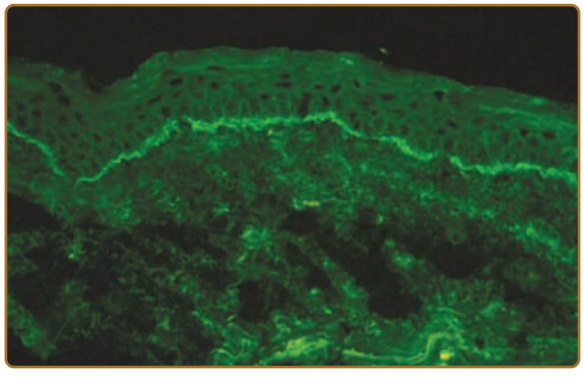

Figure 57-1 Direct immunofluorescence microscopy of normal-appearing perilesional skin from a patient with cicatricial pemphigoid shows continuous linear deposits of C3 in the epidermal basement membrane.

TABLE 57-1
Major Cicatricial Pemphigoid Autoantigens

Autoantigen	MW (kDa)	Location SSS/Ultra	Passive Transfer Studies
BPAG1	230	Epid/HD	
BPAG2	180	Epid/HD–af	IgG vs. the NC16A domain of BPAG2 creates subepid blisters in newborn mice that resemble those seen in patients with BP.[32,33]
Integrin β_4	~205	Epid/HD–af	
Integrin α_6	~120	Epid/HD–af	
Laminin 332	400–440	Derm/LL–LD interface	Exp IgG (intact IgG and Fab fragments alone) vs. laminin 332 create subepid blisters in newborn and adult mice that resemble those seen in patients with AECP.[34] Patient IgG creates subepid blisters in human skin grafts on immunodeficient adult mice that resemble those seen in patients with AECP.[35]
Type VII collagen	290	Derm/AF	Exp and patient IgG vs. the NC1 domain of type VII collagen create subepid blisters in adult mice that resemble those seen in patients with EBA.[36–38]

AECP = antiepiligrin cicatricial pemphigoid; AF = anchoring fibril; BP = bullous pemphigoid; BPAG1 = bullous pemphigoid antigen 1; BPAG2 = bullous pemphigoid antigen 2; Derm = dermal; EBA = epidermolysis bullosa acquisita; Epid = epidermal; Exp = experimental; HD = hemidesmosome; HD–af = hemidesmosome–anchoring filament complexes; IgG = immunoglobulin G; LL–LD interface = lamina lucida–lamina densa interface; Location SSS/Ultra = localization in 1 M NaCl-split skin/ultrastructural localization in epidermal basement membrane; MW (kDa) = molecular weight in kilodaltons; subepid = subepidermal.

CLINICAL FINDINGS

HISTORY

Patients typically describe the onset of painful, erosive, and/or blistering lesions on one or more mucosal surfaces. A few skin lesions on the upper body are also sometimes noted. Associated symptoms are site specific as detailed later.

MUCOSAL AND CUTANEOUS LESIONS

The mouth is the most frequent site of involvement in patients with cicatricial pemphigoid; it is often the first (and only) site affected. Lesions often involve the gingiva, buccal mucosa, and palate (Fig. 57-2); other sites such as the alveolar ridge, tongue, and lips are also susceptible.[9,43] A frequent oral manifestation is desquamative gingivitis. Other lesions may present as tense blisters that rupture easily or as mucosal erosions that form as a consequence of epithelial fragility. Lesions in the mouth may result in a delicate white pattern of reticulated scarring. In severe disease, adhesions may develop between the buccal mucosa and the alveolar process, around the uvula and tonsillar fossae, and between the tongue and the floor of the mouth. Gingival involvement can result in tissue loss and dental complications (e.g., caries, periodontal ligament damage, and loss of bone mass and teeth).

Ocular involvement in patients with cicatricial pemphigoid is common and may become sight threatening (Figs. 57-3 and 57-4). [44,45] Ocular lesions typically manifest as conjunctivitis that progresses insidiously to scarring. Early ocular disease can be quite subtle and nonspecific. Although disease is usually bilateral, it often begins unilaterally and progresses to both eyes within several years. Patients may complain of burning, dryness, or a foreign-body sensation in one or both eyes; frank blisters on conjunctival surfaces are rarely seen. Early disease is best appreciated by slit-lamp examination. Because disease may be localized to the upper tarsal conjunctiva, it may escape detection without eversion of the eyelids. Chronic ocular involvement can result in scarring characterized by shortened fornices, symblepharons (i.e., fibrous tracts between bulbar and palpebral conjunctival surfaces), and, in severe disease, ankyloblepharons (i.e., fibrous tracts fusing the

Figure 57-2 Denuded and inflamed sites on the oral mucosa are seen in association with sites of gingiva recession and loss.

Figure 57-3 The medial aspects of the lower conjunctival fornix and eyelid show shortening, fibrosis, and malaligned eyelashes.

Figure 57-5 Scalloped erosions and sites of denuded vulvar and vaginal mucosae.

superior and inferior palpebral conjunctivae with obliteration of the conjunctival sac). Conjunctival scarring also can cause entropion and trichiasis (i.e., in-turning of the eyelashes) that result in corneal irritation, superficial punctate keratinopathy, corneal neovascularization, corneal ulceration, and/or blindness. Additional ocular complications include scarring of the lacrimal ducts, decreased tear secretion, and loss of mucosal goblet cells leading to decreased tear mucus content and unstable tear films. It is very important for patients with suspected ocular involvement to be examined by an ophthalmologist, because early disease may be subtle, is only identified by slit-lamp examination, and can result in severe complications. Cicatricial pemphigoid may be limited to the eyes.

Other sites that may be affected by cicatricial pemphigoid include the nasopharyngeal, laryngeal, esophageal, and anogenital regions. Nasopharyngeal lesions can result in discharge, epistaxis, excessive crust formation, impaired airflow, chronic sinusitis, scarring, and tissue loss. Laryngeal involvement may present as hoarseness, sore throat, or loss of phonation. Chronic laryngeal erosions, edema, and scarring may result in supraglottic stenosis and airway compromise that eventually necessitates tracheostomy.[46] Esophageal involvement may result in stricture formation, dysphagia, odynophagia, weight loss, and/or aspiration. Moreover, it has been suggested that esophageal dysfunction and gastroesophageal reflux may elicit or exacerbate laryngeal disease and/or bronchospasm in such patients. Although involvement of the genital and/or rectal mucosae in patients with cicatricial pemphigoid is rare, it can be a source of substantial pain and morbidity (Fig. 57-5). Rare cases of urethral stricture, vaginal stenosis, and anal narrowing have developed as a consequence of this disease.

The skin is involved in 25%–35% of patients with cicatricial pemphigoid. The most frequently affected areas are the scalp, head, neck, and upper trunk (Fig. 57-6). Lesions typically consist of small vesicles or bullae situated on erythematous and/or urticarial bases. Lesions rupture easily and are often seen as small, crusted papules or plaques. The extent and number of

Figure 57-4 Ocular involvement has resulted in conjunctivitis, a shortened conjunctival fornix, and symblepharon formation.

Figure 57-6 The scalp displays scarring alopecia and a focal hemorrhagic crust as a consequence of involvement with cicatricial pemphigoid.

cutaneous lesions are generally small; lesions sometimes recur in the same areas.

RELATED PHYSICAL FINDINGS

SYSTEMIC ASSOCIATIONS. A cohort of 35 patients with antiepiligrin cicatricial pemphigoid (also called antilaminin 332 cicatricial pemphigoid) was shown to have an increased relative risk for cancer.[47,48] Ten patients in this cohort had solitary solid cancers (three lung, three gastric, two colon, two endometrial); eight patients developed cancer after the onset of cicatricial pemphigoid (six within a year, seven within 14 months). The time between blister onset and cancer diagnosis was approximately 14 months in nine of the ten patients. Eight patients in this cohort died as a consequence of their cancer. All deaths occurred within 21 months. This form of cicatricial pemphigoid appears to have a relative risk for malignancy that approximates that for adults with dermatomyositis; as is true for the latter, the risk for cancer appears to be particularly high in the first year of disease. Other patients with this form of cicatricial pemphigoid and cancer have been described more recently.[49–57] Interestingly, recent studies have suggested that the relative risk for cancer among patients with ocular or oral cicatricial pemphigoid and autoantibodies versus integrin subunit β_4 or integrin subunit α_6, respectively, may be reduced.[58,59]

BRUNSTING–PERRY PEMPHIGOID. In 1957, Brunsting and Perry described seven patients with locally recurrent and scarring subepidermal blistering lesions of the head or neck that for many years was thought to be a form of cicatricial pemphigoid.[60] Although these patients are typically elderly and demonstrate deposits of immunoreactants in epidermal basement membranes like other patients with cicatricial pemphigoid, Brunsting–Perry pemphigoid predominates in men and lacks mucous membrane involvement. More recently, patients with the same clinical, histologic, and immunopathologic features have been reported to have autoantibodies directed against type VII collagen (or rarely to bullous pemphigoid antigens).[3,61] Identification of similar patients with blister planes beneath the lamina densa further suggests that individuals with this phenotype usually have localized forms of epidermolysis bullosa acquisita.

LABORATORY TESTS

LIGHT MICROSCOPY

Although the findings of light microscopy studies of lesional skin or mucosa from patients with cicatricial pemphigoid often are nonspecific, they characteristically show a subepidermal blister and a dermal leukocytic infiltrate composed of lymphocytes and histiocytes as well as variable numbers of neutrophils and eosinophils.[2,3,62,63] Plasma cells often are seen in mucosal lesions, whereas eosinophils and neutrophils are seen most commonly in skin lesions. Biopsy specimens of older lesions may be relatively "cell poor" and show features that correlate with the noninflammatory character of such sites clinically. Light microscopy studies of older lesions often show fibroblast proliferation and lamellar fibrosis (i.e., fibrosis characterized by collagen bundles ordered parallel to the surface epithelium).

ELECTRON MICROSCOPY

Ultrastructural studies of lesional skin or mucosa from patients with cicatricial pemphigoid show that blisters typically develop within the lamina lucida and eventuate in partial or complete destruction of the basal lamina in older lesions.[62–66] A generally held impression is that blisters form below those of bullous pemphigoid, because scarring is more common in patients with this disease. Reports of patients with blisters in the sublamina densa region are thought to represent mucosa-predominant forms of epidermolysis bullosa acquisita.

IMMUNOFLUORESCENCE MICROSCOPY

Direct immunofluorescence microscopy of normal-appearing perilesional tissue from patients with cicatricial pemphigoid shows continuous deposits of immunoreactants in epithelial basement membranes.[5,66] The most commonly detected immunoreactants are IgG and C3 (see Fig. 57-1); the predominant subclass of these autoantibodies is IgG4.[67] IgA, IgM, and/or fibrin are found in some patients.[68] One study of skin and mucosal samples from ten patients found immunoreactants more commonly in perilesional mucosal biopsy specimens, which suggests that mucous membranes are the preferred biopsy site for direct immunofluorescence microscopy studies.[66] Splitting tissue samples with 1 M NaCl increases the sensitivity of direct immunofluorescence microscopy and facilitates identification of immunoreactants as well as their relative distribution within epithelial basement membranes.[69,70]

Indirect immunofluorescence microscopy studies using intact skin or mucosa often find low-titer IgG (and/or IgA) antibasement membrane autoantibodies in patients with cicatricial pemphigoid.[1,3,5,71] The use of 1 M NaCl-split skin as a test substrate in these studies substantially increases the detection of such autoantibodies.[27,72,73] In such studies, IgG (and/or IgA) binding is usually directed against the epidermal side of 1 M NaCl-split skin, although combined epidermal and dermal or exclusively dermal binding can occur. In fact, this heterogeneity in autoantibody binding patterns was one of the first clues that cicatricial pemphigoid is a disease phenotype that is associated with different autoantigens (see Table 57-1). Although some studies have suggested that the use of human mucosal tissue substrates increases the likelihood of detecting autoantibodies in patients with cicatricial pemphigoid, other studies have not obtained similar results.[6,66] Patients with both IgG and IgA antibasement membrane autoantibodies appear to have a worse prognosis

as defined by requirements for medications to control disease as well as overall clinical severity score.[33,35]

SPECIALIZED TESTS

Selected cases may require specialized immunochemical studies (e.g., immunoblot studies of keratinocyte or skin extracts, immunoprecipitation studies of biosynthetically radiolabeled keratinocytes) to identify the autoantigen targeted by patient antibasement membrane autoantibodies. Perilesional tissue from seronegative patients may be further characterized by immunoelectron microscopy studies to determine if in situ deposits of immunoreactants reside above or below the lamina densa of epidermal basement membrane.

DIFFERENTIAL DIAGNOSIS

The diagnosis of cicatricial pemphigoid is suggested when patients present with bullous or erosive lesions of mucous membranes and continuous deposits of immunoreactants are demonstrated in epithelial basement membranes of perilesional tissue. Distinguishing cicatricial pemphigoid from other autoimmune bullous diseases can be difficult and may require specialized immunopathologic studies and/or immunoelectron microscopy. Disorders that must be differentiated from cicatricial pemphigoid include lichen planus, erythema multiforme, lupus erythematosus, lichen sclerosus, and—in the case of ocular disease—cicatrizing or inflammatory conjunctivitis that results from long-term use of certain ophthalmologic preparations (e.g., pilocarpine, guanethidine, or ephedrine used in the treatment of glaucoma or idoxuridine used as an antiviral) or biologics that inhibit epidermal growth factor receptor tyrosine kinase (Box 57-1).[37,74] It also has been reported that some cases of ocular cicatricial pemphigoid develop after an acute episode of severe ocular inflammatory injury secondary to Stevens–Johnson syndrome[75] (see Chapter 40). Interestingly, the time between the appearance of Stevens–Johnson syndrome and the onset of ocular cicatricial pemphigoid in these patients can range from a few months to more than 30 years.

COMPLICATIONS

Site-specific complications of cicatricial pemphigoid were outlined earlier and are summarized in Table 57-2.

PROGNOSIS AND CLINICAL COURSE

Cicatricial pemphigoid is typically a chronic and progressive disorder, although involvement may be limited to a given anatomic site (e.g., the mouth, the conjunctivae) for many years. Cicatricial pemphigoid rarely goes into spontaneous remission; its treatment is largely determined by its severity and sites of involvement. Scarring can only be prevented in these patients; it cannot be reversed.

BOX 57-1 DIFFERENTIAL DIAGNOSIS OF CICATRICIAL PEMPHIGOID

Most Likely

- Pemphigus
  - Pemphigus vulgaris
  - Paraneoplastic pemphigus
- Other subepidermal immunobullous diseases
  - Epidermolysis bullosa acquisita
  - Bullous pemphigoid
  - Linear immunoglobulin A dermatosis
- Erythema multiforme
- Lupus erythematosus
- Lichen planus

Consider

- Drug-induced hypersensitivity reaction
- Lichen sclerosus (especially in the anogenital area)

Always Rule Out

- Pemphigus (specifically, pemphigus vulgaris, paraneoplastic pemphigus)
- Other subepidermal immunobullous diseases
- Erythema multiforme
- Lupus erythematosus
- Lichen planus

TREATMENT

The following overview (Box 57-2) is representative of most treatment regimens.[4,76–78]

Mild lesions of the oral mucosa and skin can often be treated effectively with topical glucocorticoids (or calcineurin inhibitors such as tacrolimus) in a gel or ointment base applied two to four times each day.[77,79,80] Blotting lesional sites dry with a soft disposable tissue can enhance the adherence and effectiveness of topical agents applied to lesional sites in the mouth. These agents are particularly effective before bed, because oral secretions diminish during sleep. Because it is difficult to maintain contact of topical agents with mucous membranes (and because lesions often are localized to the gingiva), customized delivery trays to occlude topical glucocorticoids over lesional sites in the mouth are also useful.[81] This approach also facilitates interactions with professionals who can manage other complications in these patients (e.g., dental complications). Mouthwash (dexamethasone 100 µg/mL, 5 mL per rinse) used in a "swish-and-spit" regimen for 5 minutes two to three times each day represents another approach for topical therapy. For oral disease resistant to topical glucocorticoids, these agents can (in some instances) be administered intralesionally. In addition to these measures, patients should follow a strict regimen of oral hygiene that includes regular brushing, flossing, and cleaning of teeth. Use of toothpastes and mouthwashes that lack sodium lauryl

TABLE 57-2
Potential Complications of Cicatricial Pemphigoid

Site	Potential Complications
Mouth	
Mucosa	Painful, erosive scarring lesions; adhesions between the buccal mucosa and the alveolar process; the uvula and the tonsillar fossae; the tongue and the floor of the mouth
Gingiva	Loss of gingival tissue, caries, periodontal ligament damage, loss of alveolar bone, loss of teeth
Eyes	
Conjunctivae	Painful, erosive conjunctivitis; foreign-body sensations; photophobia; scarring; shortened fornices; loss of goblet cells; decrease in tear mucus content, unstable tear film; symblepharons; ankyloblepharons
Eyelids	Ectropion, trichiasis, ankyloblepharons
Cornea	Corneal irritation, superficial punctate keratinopathy, corneal neovascularization, corneal ulcers, blindness
Tear ducts	Scarring, occlusion, secondary infection
Nose	Discharge, epistaxis, excessive crust formation, impaired airflow, recurrent and chronic sinusitis, scarring, tissue loss
Larynx	Hoarseness, impaired phonation, loss of voice, scarring, supraglottic stenosis, airway compromise, and loss
Esophagus	Dysphagia, odynophagia, impaired swallowing, aspiration, stricture formation, weight loss
Anogenital region	Painful erosions, stenosis, stricture, secondary infection

sulfate and alcohol, respectively, often facilitates patient compliance with such activities.

A number of reports have suggested that dapsone (50–200 mg by mouth daily) may be effective.[38,82] Others have found that cicatricial pemphigoid does not respond to this agent. Systemic glucocorticoids can be administered alone (e.g., 20–60 mg of prednisone by mouth each morning) or in combination with dapsone. Because of potentially severe complications, ocular, laryngeal, esophageal, and/or anogenital involvement requires aggressive management by teams of physicians familiar with specialized care of these organ systems. For mild or moderate ocular involvement, systemic glucocorticoids (e.g., 20–60 mg of prednisone by mouth each morning) alone or in conjunction with daily dapsone may be effective. Patients whose ocular disease is complicated by trichiasis may benefit from epilation, although this decision is best made by an

BOX 57-2 TREATMENTS FOR CICATRICIAL PEMPHIGOID

MILD INVOLVEMENT

Sites	***Local Care Measures***
Mouth	Topical corticosteroid (gels or ointments) bid/qid; topical corticosteroids under occlusion (e.g., dental trays); topical calcineurin inhibitors; intralesional corticosteroids
Nose	Irrigation with isotonic saline bid/tid; nasal lubricants; topical corticosteroids (e.g., via sprays, inhalers)
Anogenital region	Topical corticosteroids; topical calcineurin inhibitors
Skin	Topical corticosteroids; topical calcineurin inhibitors

MODERATE INVOLVEMENT

Sites	***Therapeutic Options***
Mouth, eyes, nose, larynx, esophagus, anogenital region	Local care measures outlined above plus dapsone 50–200 mg daily, prednisone 20–60 mg each morning, or both of these agents simultaneously

SEVERE INVOLVEMENT

Sites	***Therapeutic Options***
Mouth, eyes, nose, larynx, esophagus, anogenital region	Local care measures outlined above plus prednisone (1 mg/kg each morning), intravenous immunoglobulin (2 g/kg body weight over 2–3 days every 2–6 week for 4–6 months), or both of these agents simultaneously in conjunction with azathioprine (2–2.5 mg/kg/day), mycophenolate mofetil (1–2.5 g/day), cyclophosphamide (1–2 mg/kg/day), or rituximab (375 mg/m^2 weekly × 4 then every 4–6 months as needed, or 1000 mg on days 1 and 15 and then 500 mg at month 6).

ophthalmologist. For severe disease affecting the ocular, pharyngeal, or urogenital epithelia, a combination of systemic glucocorticoids and an additional immunosuppressive is indicated. In such cases, azathioprine (2.0–2.5 mg/kg/day), mycophenolate mofetil (1.0–2.5 g/day), or cyclophosphamide (1–2 mg/kg/day) are often used in conjunction with daily prednisone (1 mg/kg/day).[77,83–86] In this regimen, daily prednisone is tapered gradually over approximately 6 months, and the patient is maintained on the alternate agent alone for an additional 6–12 months. Such combined regimens have had success in halting the progression of severe ocular disease, limiting scarring, and producing long-term remissions. In an effort to avoid adverse effects and complications produced by prolonged treatment with immunosuppressive agents, some groups treat patients with intravenous immunoglobulin (i.e., intravenous immunoglobulin 2 g/kg of body weight administered over 2–3 days every 2–6 weeks for 4–6 months).[87–90] Another emerging trend in the management of patients with particularly severe disease is the use of biologic agents that antagonize tumor necrosis factor-α (e.g., etanercept, infliximab) or bind CD20 (rituximab).[91,92]

Involvement of the nasopharynx or esophagus potentially has severe complications and requires aggressive and specialized care. Nasal lesions often benefit from twice-daily irrigation of the nasal passages with saline or tap water as well as the use of topical emollients. Esophageal involvement requires medical management to avert dysphagia, pain, tissue loss, and secondary complications such as gastroesophageal dysfunction and reflux, stricture formation, aspiration, laryngeal irritation, or bronchospastic pulmonary disease. All patients with cicatricial pemphigoid require long-term follow-up because of the possibility for this chronic disease to relapse.

Chapter 58 :: Linear Immunoglobulin A Dermatosis and Chronic Bullous Disease of Childhood

:: Caroline L. Rao & Russell P. Hall III

LINEAR IMMUNOGLOBULIN A DERMATOSIS AT A GLANCE

- Rare blistering disease with onset typically after fourth decade of life.
- Linear band of immunoglobulin A at the dermal–epidermal basement membrane.
- Clinical presentations may mimic dermatitis herpetiformis, bullous pemphigoid, and cicatricial pemphigoid.
- May occur in association with many drugs, including vancomycin.
- May occur in association with inflammatory bowel diseases but only rarely associated with gluten sensitive enteropathy.
- Rarely seen in association with malignancy, specifically lymphoid.
- Histology shows subepidermal collection of neutrophils at the basement membrane, often collecting in papillary tips with subepidermal blisters.
- Most patients respond dramatically to treatment with dapsone; some require adjunctive systemic corticosteroids.
- Prognosis variable with both spontaneous remissions and long-standing disease.

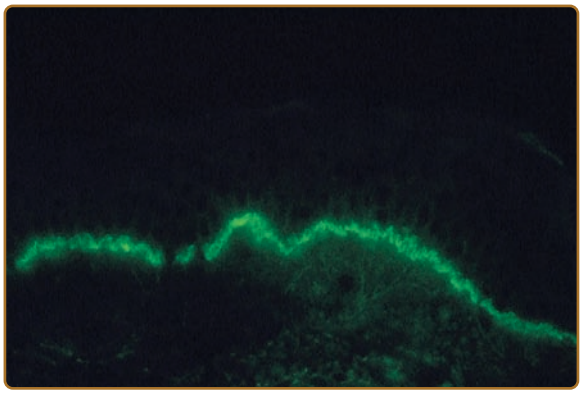

Figure 58-1 Direct immunofluorescence of normal-appearing perilesional skin from a patient with linear immunoglobulin A dermatosis. A homogeneous band of immunoglobulin A is present at the dermal–epidermal junction.

Linear immunoglobulin A (IgA) dermatosis is a rare immune-mediated blistering skin disease that is defined by the presence of homogeneous linear deposits of IgA at the cutaneous basement membrane (Fig. 58-1). Although in the original description of patients with linear IgA dermatosis it was considered to be a manifestation of dermatitis herpetiformis (DH), it has now been clearly separated from DH on the basis of its immunopathology, immunogenetics, and lack of consistent association with a gluten-sensitive enteropathy.[1–4] Patients with linear IgA dermatosis can present with lesions suggestive of epidermolysis bullosa acquisita (EBA), DH, bullous pemphigoid (BP), lichen planus, prurigo nodularis, or cicatricial pemphigoid.[1–6]

Drug-induced linear IgA was initially described in association with vancomycin and has subsequently been associated with a wide variety of drugs.[7–11] Drug-induced linear IgA has been found to differ somewhat from classic linear IgA in clinical presentation with a wider variety of clinical presentations including morbilliform, erythema multiforme like, and toxic epidermal necrolysis like.[7–14]

Chronic bullous disease of childhood (CBDC) is a rare blistering disease that occurs predominantly in children younger than 5 years of age and has an identical pattern of homogeneous linear IgA deposits at the epidermal basement membrane.[15,16] Recent studies have demonstrated that in some patients CBDC and linear IgA dermatosis represent different presentations of the same disease process.[17,18]

EPIDEMIOLOGY

Linear IgA dermatosis occurs most often after puberty, with most patients presenting after the fourth decade of life.[2,4,19] A slight predominance of females has been noted in several studies.[2,4,20] In contrast, CBDC presents most often before the age of 5 years.[20]As in patients with linear IgA dermatosis, there is a slight female predominance in patients with CBDC.[16,20]

Evaluation of the HLA association in patients with linear IgA dermatosis and CBDC has yielded conflicting results. Some investigators have found an increased frequency of the human histocompatibility antigen HLA-B8 in patients with linear IgA dermatosis, whereas others have found no increased frequency.[21–23] In CBDC, an increased frequency of HLA-B8 has been noted, with up to 76% of patients expressing HLA-B8.[20] Collier et al demonstrated an increased frequency of HLA-B8, -DR3, and -DQ2 in CBDC that was not seen in adults with linear IgA dermatosis.[21] These authors suggested that these haplotypes may have a role in earlier disease presentation. In addition, the *TNF2* allele was found with increased frequency in both adults and children with linear IgA disease when compared with unaffected subjects. There was, however, no increase seen in either adults or children when compared with HLA-DR3$^+$ controls.

CHRONIC BULLOUS DISEASE OF CHILDHOOD AT A GLANCE

- Rare blistering disorder of childhood presenting predominantly in children less than 5 years of age.
- Linear IgA at the dermal–epidermal basement membrane.
- Clinical presentation of tense bullae, often in perineum and perioral regions, giving a "cluster of jewels" appearance. New lesions sometimes appear around the periphery of previous lesions with a collarette of blisters.
- Histology shows subepidermal collection of neutrophils at the basement membrane, similar to linear IgA bullous dermatosis.
- Most patients respond dramatically to treatment with dapsone.
- Spontaneous remissions, often within 2 years, are frequent.

ETIOLOGY AND PATHOGENESIS: IMMUNOPATHOLOGY

Linear IgA dermatosis and CBDC are defined by the presence of a homogeneous linear band of IgA at the dermal–epidermal basement membrane zone. A minority of patients in both groups have additional deposits of other immunoreactants, most often IgG and occasionally the third component of complement (C3).[20] Because IgA is the predominant Ig of the secretory immune system, numerous investigators have attempted to determine if the IgA present in the skin of these patients is of mucosal origin. Characterization of the IgA subclass in the skin has revealed almost exclusively IgA1 and not the subclass most often associated

with mucosa, IgA2.[19,24,25] In addition, neither secretory piece nor J chain, both of which are present in secretory IgA, have been found in the IgA present in the skin of patients with linear IgA deposits.[26] Although these data have led to suggestions that the IgA is not of mucosal origin, the true origin of the IgA deposits in the skin of these patients is not known.

Initially it was thought that patients with linear IgA dermatosis and CBDC rarely had circulating IgA antibodies against the epidermal basement membrane. Indirect immunofluorescence, using 1 M NaCl-split normal human skin as a substrate, demonstrates that the majority of patients with CBDC have low-titer circulating antibodies against the epidermal side of the split skin.[19] Circulating low-titer IgA antibodies directed against the epidermal basement membrane also have been found in adults with linear IgA dermatosis.[20,27] Others have reported binding of IgA antibodies from some patients to the dermal side of normal human split skin, suggesting that more than one antigen may be the target for the IgA antibasement membrane antibodies.[27–29] Immunoelectron microscopic studies have been performed to determine the exact location of the IgA in the skin of patients with both linear IgA dermatosis and CBDC. Immunoelectron microscopy of the skin of patients with linear IgA deposits has revealed three distinct patterns of immunoreactants. In some patients with linear IgA dermatosis, the IgA deposits are found in the lamina lucida region of the basement membrane zone, similar to the location of immunoreactants present in the skin of patients with BP.[28,29] A second pattern of IgA deposition has been detected in which the IgA deposits are present at and below the lamina densa in a pattern similar to that seen in EBA.[28–30] Prost et al have described a third pattern of immunoreactants in some patients with linear IgA dermatosis in which the IgA deposits are found both above and below the lamina densa.[29] In a similar manner, immunoelectron microscopic studies of skin of patients with CBDC have shown the IgA immunoreactants to be in either the lamina lucida or a sublamina densa location.[17,30] These findings further support the probability that multiple antigens may be involved as the targets in both adults and children with linear IgA deposits in the skin. Horiguchi et al reviewed 213 cases of linear IgA in Japan and found a strong association between older age of onset and both IgG/IgA type and dermal binding. IgG was found in approximately 9% of patients with the infantile (CBDC) type whereas in adults (>16 years) IgG was found in 24% of patients. Interestingly, when comparing the different groups based on patterns of antigen binding (e.g., dermal vs. epidermal and IgA vs. IgG/A) no significant clinical differences were found.[31]

Although the relatively low titer of IgA antibodies against the basement membrane present in the sera of patients with both linear IgA dermatosis and CBDC has complicated the search for specific antigenic targets for the IgA, several investigators have made significant observations regarding the antigenic targets in these diseases. Zone et al studied sera from patients who had circulating IgA antibodies that bound to the epidermal side of 1 M NaCl-split normal human skin, as shown by indirect immunofluorescence.[32] They found that serum IgA from patients with either CBDC or linear IgA dermatosis bound to a 97-kDa protein. Immunoelectron microscopy revealed that the 97-kDa antigen is present in the lamina lucida, below the hemidesmosome of normal human skin, in a location similar to where the IgA is localized in patients with CBDC and linear IgA dermatosis.[33] Subsequently, Zone et al determined that the 97-kDa linear IgA bullous disease antigen is identical to a portion of the extracellular domain of the 180-kDa BP antigen (BPAG2 or collagen XVII), which is essential in anchoring basal keratinocytes to the epidermal basement membrane.[34] The BP antigen (BPAG2) consists of a 180-kDa transmembrane protein and 120-kDa portion that corresponds to the collagenous ectodomain. Roh et al and Schumann et al have reported that autoantibodies in patients with linear IgA dermatosis recognize the soluble 120-kDa ectodomain of type XVII collagen[35,36] The 120-kDa antigen target is not unique to linear IgA dermatosis because it is also the antigen targeted by autoantibodies in some patients with cicatricial pemphigoid and BP.[35,36] Furthermore, IgA antibodies and T cells from patients with linear IgA bullous dermatosis have been found to be directed against the NC-16A region of collagen type XVII, which is the same region against which the IgG and T cells from patients with BP are directed.[37,38] This may explain in part the overlap in clinical and histologic features of these conditions. Wojnarowska et al have identified another possible target antigen in patients with linear IgA dermatosis and CBDC using sera from patients in whom the IgA bound to the epidermal side of 1 M NaCl-split skin on routine indirect immunofluorescence. They found that IgA in the sera of some patients with these diseases bound to a 285-kDa protein (LAD 285) that was not the 230-kDa BP antigen or type VII collagen, the EBA antigen.[39]Allen and Wojnarowska have analyzed the sera of over 70 patients with both linear IgA dermatosis and CBDC and found that the predominant antigenic target in these patients is the BP180 antigen (collagen XVII), but that some patients react with multiple antigens including the BP230, LAD 285, and other yet to be identified proteins.[40] Ishtii et al described a patient with Linear IgA who had antibodies directed at the NC16a domain of BP180 without evidence of antibody formation to 120-kDa LAD 1.[41] In many patients, IgA appears to bind to several different antigenic targets, suggesting the possibility that there is epitope spreading. The clinical significance of these findings however, has not been established.[40]

CLINICAL FINDINGS

CUTANEOUS MANIFESTATIONS

The clinical manifestations of linear IgA dermatosis are heterogeneous and often indistinguishable from those seen in patients with DH.[2,4,20,42] Patients may present

Figure 58-2 Patient with linear immunoglobulin A dermatosis with crusted erosions, papules, and vesicles on the back and neck.

Figure 58-4 Patient with linear immunoglobulin A dermatosis with grouped urticarial papules on the back with scattered crusted erosions.

with combinations of annular or grouped papules, vesicles, and bullae (Figs. 58-2 and 58-3). Typically, these lesions are distributed symmetrically on extensor surfaces, including elbows, knees, and buttocks. Lesions most often are very pruritic, resulting in numerous crusted papules (Fig. 58-4). The clinical presentation can be difficult to distinguish from that seen in patients with DH. However, the degree of pruritus seen in patients with linear IgA dermatosis is variable and, in general, less severe than that seen in patients with DH. Some patients with linear IgA dermatosis present with larger bullae, in a pattern more consistent with that seen in patients with BP, or occasionally with cutaneous findings similar to those seen in patients with EBA.

Figure 58-3 Patient with linear immunoglobulin A dermatosis with annular erythematous plaques on the thighs.

Patients with drug-induced linear IgA bullous dermatosis have been reported with erythema multiforme-like findings and a toxic epidermal necrolysis-like presentation, with widespread bullae.[7,11,13] Localized palmar and morbilliform variants have also been described.[12,14] While vancomycin is most closely associated with the drug-induced linear IgA, a number of other medications have also been implicated including lithium, phenytoin, sulfamethoxazole/trimethoprim, furosemide, atorvastatin, captopril, and diclofenac.[13] In addition, a localized linear IgA in the setting of an acute contact dermatitis has been reported.[43] Recovery has been reported with discontinuation of the offending agent alone, but these patients may benefit from dapsone therapy (see Section "Treatment and Prognosis").[7,11,44]

The clinical presentation of CBDC is characterized most often by the development of tense bullae, often on an inflammatory base.[15] These lesions occur most frequently in the perineum and perioral region and often may occur in clusters, giving a "cluster of jewels" appearance (Figs. 58-5–58-7). New lesions sometimes appear around the periphery of previous lesions, with a resulting "collarette" of blisters. Patients often

Figure 58-5 Patient with chronic bullous disease of childhood. Tense bullae and crusted papules are present on the abdomen, with a clustering of bullae noted in the perineal region.

Figure 58-7 Extensive chronic bullous disease of childhood. Note tense and flaccid blisters without notable inflammation.

report significant pruritus and/or a burning of the skin with the development of skin lesions. Patients with CBDC often present with the acute development of large numbers of tense blisters, which may rupture and become secondarily infected. CBDC differs from linear IgA bullous dermatosis of adults in its typical clinical appearance, relative paucity of serious mucosal involvement, and good prognosis.[31]

Rarely, patients with linear IgA dermatosis may present with an acute febrile illness with arthritis, arthralgias, and generalized malaise.[45,46] The presence of multiple papules and vesicles in a patient with systemic signs and symptoms has led to the evaluation of these patients for systemic infections, including viral infections. Routine direct immunofluorescence, however, has revealed linear deposits of IgA, and these patients have responded to conventional therapy.

Figure 58-6 Chronic bullous disease of childhood. Tense blisters on erythematous bases in the pubic and inguinal areas.

MUCOSAL INVOLVEMENT

Mucosal involvement is an important clinical manifestation seen in patients with linear IgA dermatosis and CBDC. This involvement can range from largely asymptomatic oral ulcerations and erosions to severe oral disease alone as well as to severe conjunctival and oral disease typical of that seen in cicatricial pemphigoid.[20,47,48] Oral lesions may occur in up to 70% of patients with linear IgA disease.[20] Mucosal invasion with complication is less often seen in CBDC.[31] Although most patients with linear IgA dermatosis and mucosal involvement have significant cutaneous disease, cases have been reported in the literature in which the presenting and predominant clinical manifestations are lesions of the mucous membranes.[48,49] These patients may present with desquamative gingivitis and oral lesions consistent with those seen in patients with cicatricial pemphigoid (see Chapter 57). Patients also may present with conjunctival disease and scar formation typical of that seen in patients with cicatricial pemphigoid (see Chapter 57). Mucosal involvement also appears to be less prominent in patients with drug-induced linear IgA.[13] Patients with linear IgA bullous dermatosis have also been reported to present with severe laryngeal and pharyngeal involvement before the development of more typical cutaneous manifestitations.[50]

DISEASE ASSOCIATIONS

The similar clinical presentation of many patients with linear IgA disease to that seen in patients with DH led to the investigation of patients with linear IgA disease for an associated gluten-sensitive enteropathy. Although some investigators have found evidence of minimal inflammatory changes in the small bowel of patients with linear IgA disease, numerous investigators have been unable to show that the majority of patients with linear IgA disease have significant evidence of the villous atrophy characteristically seen in patients with DH.[3,51] In addition, the clinical manifestations of linear IgA disease have not been controlled by the use of a gluten-free diet.[52] Circulating autoantibodies against tissue transglutaminase, which occur in high frequency in patients with untreated gluten-sensitive enteropathy and DH, have not been found in most patients with linear IgA diseases.[53]

Other conditions have been reported in association with linear IgA disease. One example is ulcerative colitis (UC) and Crohn's disease, which can result in a clinical syndrome where the activity of both diseases is linked (i.e., as one disease flares, so does the other).[54,55] Paige and coworkers reviewed 70 patients with linear IgA bullous dermatosis and found 7.1% had associated UC. The extent and reason for this association has yet to be established. Perhaps, the abnormal mucosal IgA1 production seen in patients with UC may play a role.[55] In patients with CBDC, Horoguchi reported associated systemic disease in only 13 of 213 cases reviewed.[31] CBDC also has been reported in association with acute mononucleosis and *Paecilomyces* lung infection in the setting of chronic granulomatous disease.[56] The relationship between these conditions and CBDC has yet to be established.

The relatively acute onset of clinical, histologic, and immunopathologic findings consistent with linear IgA disease has been seen in patients who have been taking a variety of drugs, including vancomycin, lithium phenytoin, sulfamethoxazole/trimethoprim, furosemide, atorvastatin, captopril, and diclofenac.[7–9,13,44] Vancomycin is the most common drug that is associated with the development of linear IgA bullous dermatosis. Linear IgA dermatosis has similarly been described with interferon α2a and was temporally related to the influenza vaccine. While these may reflect an induction of a previously unrecognized autoimmune process, in both cases the eruption was self-limited, in contrast to classic linear IgA, which follows a chronic, waxing and waning course.[57,58] The mechanism of this interaction is not known; however, a small number of patients with vancomycin-induced linear IgA disease have been reported to have circulating IgA antibodies directed against the BP180, BP230, and LAD 285 antigens.[59,60] In one case of vancomycin-induced linear IgA bullous dermatosis, rechallenge with vancomycin in a gradual manner did not result in a recurrence of the eruption.[61]

Linear IgA disease also has been associated rarely with a variety of malignancies. Patients with linear IgA disease have been reported with both lymphoid and nonlymphoid malignancies.[62,63] Godfrey et al reported three cases of lymphoid malignancies in 70 patients with linear IgA disease followed for a mean of 8.5 years. This represented an increase over the predicted number of 0.2 cases in an age- and sex-matched population.[62] No increase in the rate of nonlymphoid malignancies was seen. These findings suggest a small risk of lymphoid malignancy in these patients. However, larger population-based studies need to be done to confirm these findings.

HISTOPATHOLOGY

Routine histopathology of an early lesion in patients with linear IgA dermatosis and CBDC reveals a subepidermal bulla with collections of neutrophils along the basement membrane, often accumulating at the papillary tips (Fig. 58-8). A mild lymphocytic infiltrate may be present around the superficial dermal blood vessels without any evidence of neutrophilic vasculitis. Occasionally, the inflammatory infiltrate is composed of eosinophils, but most frequently neutrophils are the major component of the subepidermal inflammation.[20,64,65] Electron microscopic examination of the blisters found in patients with both linear IgA dermatosis and CBDC has revealed that the blister forms either within the lamina lucida or in a sublamina densa location.[17,28] Most often the histopathology seen in linear IgA disease is difficult to distinguish from that seen in patients with DH. Smith et al[65] reported that patients with linear IgA disease tended to have fewer papillary microabscesses and a more diffuse infiltrate of neutrophils at the basement membrane zone. However, Blenkinsopp et al found no significant difference between the histopathology found in patients with linear IgA disease and those with DH.[64] In general, the histopathology of blisters in linear IgA disease, CBDC, and DH is virtually indistinguishable.

DIFFERENTIAL DIAGNOSIS

Linear IgA dermatosis often closely mimics the clinical pattern seen in patients with DH. Some patients may

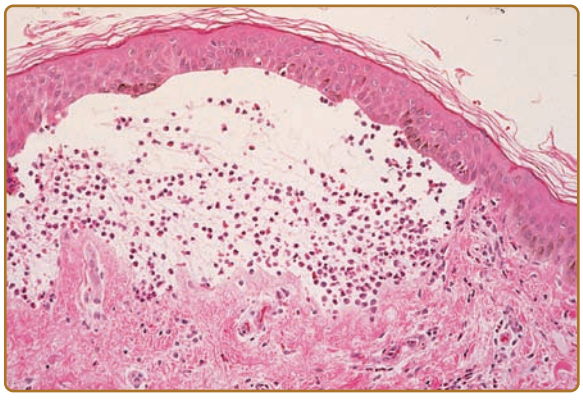

Figure 58-8 Histopathology of lesional skin from a patient with linear immunoglobulin A dermatosis showing a subepidermal blister filled with neutrophils. (Used with permission from Kim B. Yancey, MD.)

BOX 58-1 LINEAR IMMUNOGLOBULIN A BULLOUS DERMATOSIS DIFFERENTIAL DIAGNOSIS

- Dermatitis herpetiformis
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Bullous eruption of systemic lupus erythematosus
- Cicatricial pemphigoid
- Lichen planus
- Toxic epidermal necrolysis

have findings that resemble those seen in patients with BP, cicatricial pemphigoid, EBA, and, rarely, toxic epidermal necrolysis. In a similar manner, patients with CBDC must be differentiated from those with DH of childhood and childhood BP. The findings of linear IgA deposits at the basement membrane by direct immunofluorescence, most often in the absence of IgG and the C3, can distinguish this disease from BP, cicatricial pemphigoid, and EBA, whereas granular IgA deposits are found at the basement membrane in patients with DH (Box 58-1).

TREATMENT AND PROGNOSIS

Adults with linear IgA dermatosis have an unpredictable course.[4,20] Many patients have disease that continues for years, with few, if any, episodes of remission. Occasionally, patients may have a spontaneous remission with loss of clinical features of the disease and disappearance of the linear IgA deposits in the skin. Patients with severe mucosal disease, especially of the eyes, may have persistent problems with symblepharon formation and resulting structural problems with the eyelids and cornea, even after active blistering has remitted. Untreated ocular involvement can lead to cicatrix and loss of vision.[66]

Patients with linear IgA disease most often respond dramatically to dapsone or sulfapyridine. This response usually occurs within 24–48 hours, in a manner similar to that seen with DH; as such, it is not a helpful diagnostic sign for linear IgA disease.[2,4,20] Although most patients are well controlled with dapsone or sulfapyridine alone, some patients require low-dose prednisone therapy to suppress blister formation.[20] In patients who are unresponsive or intolerant of these medications, mycophenolate mofetil has been useful as a steroid-sparing agent.[67] Trimethoprim/sulfamethoxazole has been reported to be helpful when used in conjunction with other immunosuppressives.[68] The majority of patients with linear IgA disease cannot control their skin disease with a gluten-free diet.[52]

CBDC is most often a self-limited disease, with most children going into remission within 2 years of the onset of the disease.[15,16,20] Occasionally, the disease persists well into puberty but often is less severe than the initial eruption. Patients with CBDC respond in a similar dramatic fashion to dapsone or sulfapyridine.[15,16,20] Many children, however, require the addition of relatively small doses of prednisone to bring the disease under control.[15,16] Mycophenolate mofetil has been used as a steroid-sparing agent in isolated cases.[69] Intravenous immunoglobulins have also been proposed in the rare patient not responding to, or intolerant of, dapsone therapy.[70,71] Topical tacrolimus may also be a useful tool in minimizing systemic therapy.[72] Several case reports suggest that some patients with CBDC may respond to antibiotics, including sulfonamides, dicloxacillin, and erythromycin.[73,74] In one case series, seven children with linear IgA disease treated with flucloxacillin demonstrated improvement, with four achieving remission within 3 months.[75] However, spontaneous remission in these patients cannot be ruled out.

Chapter 59 :: Pemphigoid Gestationis (Herpes Gestationis)

:: Jeff K. Shornick

PEMPHIGOID GESTATIONIS AT A GLANCE

- Acute-onset, intensely pruritic, vesiculobullous eruption of pregnancy or the immediate postpartum period.
- Rare, occurring in roughly 1 in 50,000 pregnancies.
- Histopathology: dermal–epidermal separation with numerous eosinophils.
- Direct immunofluorescence: linear deposition of C3, with or without immunoglobulin (Ig) G, along the basement membrane zone of the epidermal fragment of salt-split skin.
- Enzyme-linked immunosorbent assay for pemphigoid gestationis antibody (BP180) commercially available.
- No significant maternal morbidity or mortality.
- Associated with a slight increase in premature and small-for-gestational-age births.

EPIDEMIOLOGY

Pemphigoid gestationis (PG) is the least common, yet best-characterized, dermatitis specific to pregnancy.[1] It classically presents as an intensely pruritic, urticarial rash during the later part of pregnancy or the immediate postpartum period, then rapidly progresses to a pemphigoid-like, vesiculobullous eruption. The rash may wax and wane during pregnancy, only to flare during labor and delivery. PG appears to be mediated by a specific immunoglobulin (Ig) G directed against the cutaneous basement membrane zone (BMZ).

PG occurs in approximately 1 in 50,000 pregnancies.[2,3] It is associated with HLA-DR3 and -DR4, and it appears likely that the incidence in various ethnic groups parallels the frequency of these genes in different populations.[4]

ETIOLOGY AND PATHOGENESIS

PG appears to be caused by an anti-BMZ antibody that induces C3 deposition along the dermal–epidermal junction. The PG autoantibody (formerly called HG factor) is an IgG that is infrequently found by direct immunofluorescence (IF), although indirect, complement-added IF reveals the circulating IgG in the majority of patients. In salt-split skin, staining remains with the epidermal fragment. An enzyme-linked immunosorbent assay (ELISA) for the PG antibody is commercially available, and when this highly sensitive test is used, antibody titers appear to correlate with disease activity.[5] The PG autoantibody appears to belong to the IgG1 subclass and fixes complement via the classical complement pathway.[6] T cells also show selective NC16A reactivity in PG, although their role in disease development remains to be elucidated.[7]

Nearly all patients with PG [and most patients with bullous pemphigoid (BP)] have demonstrable antibodies to BP180 (type XVII collagen), a 180-kDa transmembrane protein with its *N*-terminal end embedded within the intracellular component of the hemidesmosome and its *C*-terminal end located extracellularly (see Chapter 53). The extracellular section contains a series of 15 collagenous components alternating with 16 short, noncollagenous domains. The sixteenth noncollagenous segment closest to the plasma membrane of the basal keratinocyte is designated NC16A and contains the BP180 immunoreactive site.[8,9] The PG autoantibody is assumed to be pathogenic for several reasons: (1) It is found in essentially all patients. (2) In vitro, purified antibodies to BP180 cause chemoattraction to the dermal–epidermal junction with subsequent degranulation and dermal–epidermal separation.[10] (3) BP180 antibodies cause keratinocytes to lose cell adhesion in tissue culture.[11] (4) Rabbit antibodies to BP180 in animal models induce subepidermal blisters when infused into neonatal mice or hamsters.[12,13]

The BP180 protein differs significantly from the BP230 protein recognized by the majority of BP sera.[14,15] The 230-kDa protein is coded for on the short arm of chromosome 6.[16] Its complementary DNA (cDNA) has been sequenced[17] and codes for an intracellular protein[18] that shows considerable homology with desmoplakin I.[19] The 180-kDa protein is coded on the long arm of chromosome 10.[20] Its cDNA shows no homology with the 230-kDa cDNA but rather encodes a protein with two domains showing the primary structure of trihelical collagen.[21]

What initiates the production of autoantibody remains unclear, but because gestational pemphigoid is exclusively a disease of pregnancy, attention has focused on immunogenetics and the potential for cross-reactivity between placental tissue and skin.

Immunogenetic studies reveal an increase in HLA antigens DR3 or DR4, and curiously, nearly 50% of patients have the simultaneous presence of both.[22] The extended haplotype HLA-A1, B8, DR3 is known to be in linkage disequilibrium with a deletion of C4A (the C4 null allele or C4QO). Indeed, 90% of patients have either a C4AQO or a C4BQO.[23] However, whether the C4QO association is the primary genetic marker for PG

or the presence of a C4QO is even clinically relevant to complement function remains to be shown.

It is worth noting that patients with neither DR3 nor DR4 may have disease clinically indistinguishable from those with classic HLA findings; the presence of HLA-DR3, -DR4, or the concurrent presence of both is neither necessary nor sufficient to produce disease.[22]

Essentially, 100% of women with a history of PG have demonstrable anti-HLA antibodies.[24,25] Because the only source of disparate HLA antigens is typically the placenta (which is primarily of paternal origin), the universal finding of anti-HLA antibodies implies a high frequency of immunologic insult during gestation. Indeed, a slight increase in HLA-DR2 in the husbands of women with PG has been reported.[24] It has been suggested that immunologically primed women may simply react more strongly to tissue with disparate HLA antigens. Whether anti-HLA antibodies represent phenomenon or epiphenomenon remains to be clarified.

The autoantibody of gestational pemphigoid binds to amniotic basement membrane, a structure derived from fetal ectoderm and antigenically similar to skin.[26,27] Women with PG also show an increased expression of major histocompatibility complex class II antigens (DR, DP, DQ) within the villous stroma of chorionic villi but not skin.[28,29] Therefore, it has been proposed that PG is a disease initiated by the aberrant expression of major histocompatibility complex class II antigens (of paternal haplotype) within the placenta that serves to initiate an allogeneic response to placental BMZ, which then cross-reacts with skin.[30]

On the other hand, PG has also been reported in association with hydatidiform moles[31] and choriocarcinomas.[32] This is an intriguing clinical observation, because most hydatidiform moles are produced by a diploid contribution of paternal chromosomes and contain neither fetal tissue nor amnion. There are no case reports of a PG-like rash in males with choriocarcinoma. Unlike its counterpart in women, choriocarcinoma in males is strictly syngeneic tissue. Because choriocarcinoma in women is entirely derived from placental tissue (of paternal derivation), the suggestion is that the development of PG is somehow dependent on the state of partial allograph, not necessarily on the presence of amnion.

CLINICAL FINDINGS

PG is exclusively associated with pregnancy. It typically presents during late pregnancy with the abrupt onset of intensely pruritic urticarial lesions. Fifty percent of patients experience first onset on the abdomen, often within or immediately adjacent to the umbilicus. The other half present with typical lesions, but in an atypical distribution (extremities, palms, or soles). Rapid progression to a generalized, pemphigoid-like eruption, sparing only the face, mucous membranes, palms, and soles is the rule (although any site may be involved). Flares occur with delivery in approximately 75% of patients and may be dramatic. The explosive onset of blistering may occur within hours of delivery, either as a flare of preexisting disease or as presentation de novo. Up to one-quarter of patients initially present during the immediate postpartum period.

Newborns may be affected up to 10% of the time, but the disease is typically mild and self-limited. IF of newborn skin may yield positive findings despite a lack of clinically apparent disease, which suggests that more than C3 deposition alone is required to induce lesions.[33]

Because of clinical and IF similarities with BP, and because of the considerable confusion over the term *herpes gestationis* (particularly outside dermatology), most authors have accepted the revised terminology of PG.[34] However, there are several differences worth bearing in mind: (1) BP is a disease of the elderly and shows no gender bias. PG is exclusively associated with pregnancy. (2) PG shows a strong association with HLA-DR3, -DR4, and a C4 null allele. BP does not. (3) Indirect IF in BP yields positive results in the majority of patients, and the titer of anti-BMZ antibody is often high. The titer of anti-BMZ antibody in PG is usually so low that antibody cannot be detected without the use of complement-added or ELISA techniques. (4) The majority of BP sera react to an intracellular 230- to 240-kDa component of the hemidesmosome. Sera from most PG patients react to a 180-kDa transmembrane protein with a collagenous domain coded for on a different chromosome. Until such time as nosology is driven by pathologic mechanism instead of clinical observation, naming is likely to remain fungible.

CUTANEOUS LESIONS

The typical lesions of PG are urticarial or arcuate plaques that rapidly progress toward a mixed dermatitis, including tense, pemphigoid-like blisters (Figs. 59-1

Figure 59-1 Pemphigoid gestationis. Polymorphic lesions on dorsa of feet.

Figure 59-2 Pemphigoid gestationis. Erythematous urticarial and bullous lesions on the chest and shoulders.

and 59-2, and eFig. 59-2.1 in online edition). Blisters may arise within urticarial plaques or on otherwise normal-appearing skin. Pruritic urticarial papules and plaques of pregnancy (see Chapter 108) can show microvesiculation but not the tense, subepidermal blisters of PG.

RELATED PHYSICAL FINDINGS

PG is seen exclusively in women and only in the presence of pregnancy (or trophoblastic tissue). Any other setting is inconsistent with this diagnosis.

LABORATORY TESTS

Results of routine laboratory investigations are normal. Histopathology classically reveals a subepidermal vesicle with a perivascular infiltrate of lymphocytes and eosinophils (Fig. 59-3). Eosinophils may be lined up along the dermal–epidermal junction and typically fill the vesicular space. However, classic findings are seen only in the minority of cases. A nonspecific mixed cellular infiltrate containing a variable number of eosinophils is more common. The presence of eosinophils is the most constant histologic feature of PG.

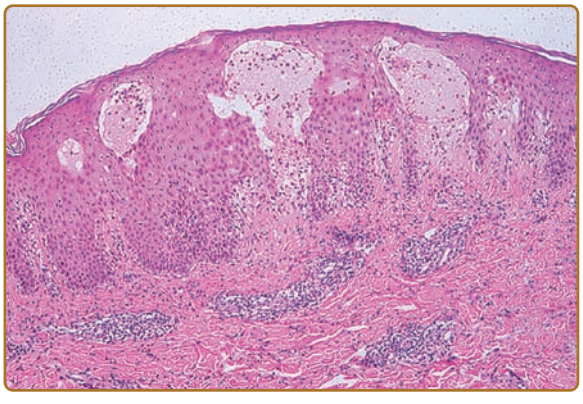

Figure 59-3 Pemphigoid gestationis. Subepidermal vesicle formation; dermal edema; infiltrate consisting of lymphocytes, histiocytes, eosinophils, and a few neutrophils; and focal basal cell necrosis. Note bulbous, teardrop-like vesicles.

SPECIAL TESTS

The sine qua non for a diagnosis of PG is the finding of C3, with or without IgG, in a linear band along the BMZ of perilesional skin (eFig. 59-3.1 in online edition). In salt-split skin specimens, antibody deposition is found along the bottom of the epidermal fragment, a finding similar to that seen in BP. Indirect IF only occasionally detects circulating IgG deposition. However, complement-added indirect IF reveals the circulating anti-BMZ IgG in nearly all patients. The PG ELISA now available may replace IF over time, though not all patients react with the BP180 antibody alone, and such a narrow focus may miss cases where the relevant antigen is outside the NC16A site.

Anti-BMZ antibody titers correlate with the extent and severity of disease, but only if ELISA tests are used.[5] There is no apparent correlation between HLA type and clinical activity.[22] An increased incidence of antithyroid antibodies has been documented in those with a history of PG, but clinically apparent thyroid dysfunction appears rare.[35] Antinuclear antibodies are not seen, and serum complement levels are normal.

DIFFERENTIAL DIAGNOSIS

Since early lesions of PG can be urticarial, the most frequent frustration is differentiating PG from pruritic urticarial papules and plaques of pregnancy, otherwise known as *polymorphous eruption of pregnancy* (see Chapter 108). PG usually progresses rapidly, which makes the clinical diagnosis apparent. Allergic contact dermatitis and drug eruptions might also be difficult to distinguish. Where doubt exists, IF (or ELISA) is the key to differentiation and is particularly relevant in helping patients plan for future pregnancies (Fig. 59-4 and Box 59-1).

COMPLICATIONS

No increase in maternal morbidity or mortality has been documented, although the impression of such remains from a review of published case reports. Cutaneous disease in the newborn is typically self-limited and rarely requires intervention. Although there is an increased risk of premature and small-for-gestational-age births,[33] there are no data to suggest that treatment with systemic corticosteroids alters the risk of premature delivery. That being the case, it is imperative that the risks of therapy be balanced against the severity of the symptoms.

Women with a history of PG appear to be at increased risk for the subsequent development of Graves disease.[35]

PROGNOSIS AND CLINICAL COURSE

The clinical presentation and course of disease may be extremely variable. Many patients experience spontaneous resolution during the later part of gestation

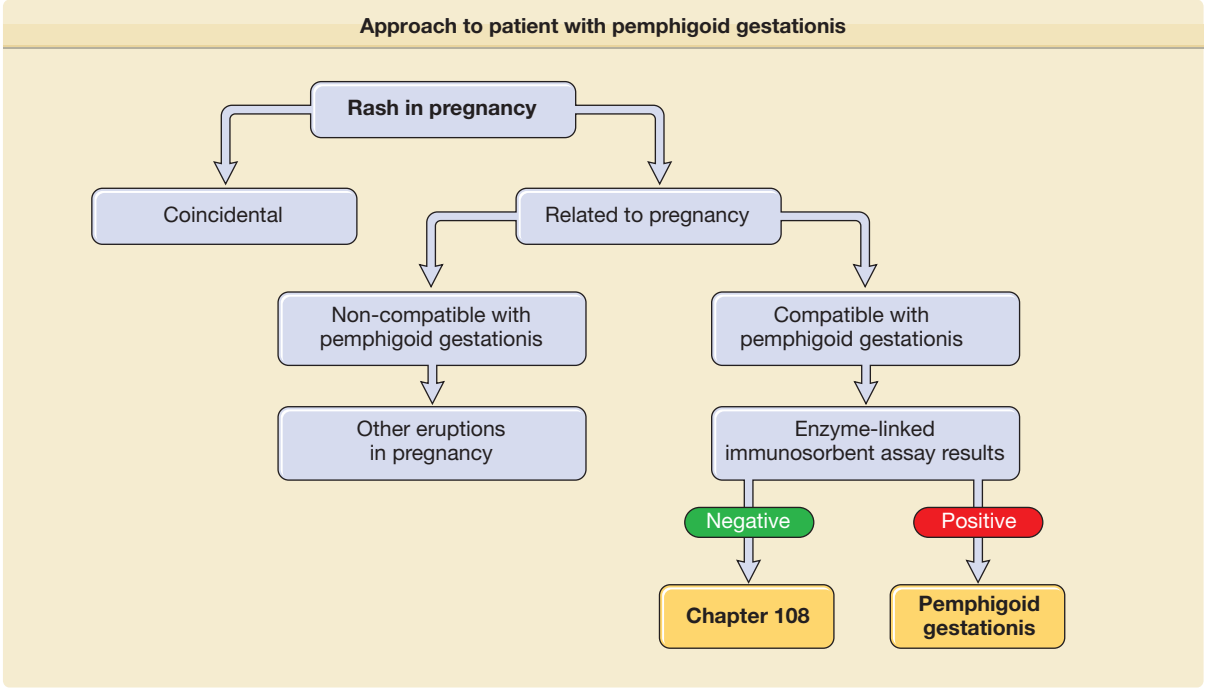

Figure 59-4 Approach to the patient with pemphigoid gestationis.

only to experience a flare, sometimes dramatically, at the time of delivery. Others develop relatively trivial urticarial lesions during one pregnancy, only to suffer characteristic blistering during a subsequent gestation. Still others develop classic disease during one pregnancy, then no disease during the next. The frequency of such "skip pregnancies" approximates 5% to 10%.[36] Recurrences associated with menstruation are common, particularly during the first several months after delivery, and flares during the subsequent use of oral contraceptives occur in at least 25% of patients.

BOX 59-1 DIFFERENTIAL DIAGNOSIS OF PEMPHIGOID GESTATIONIS

Most Likely
- Urticarial pemphigoid gestationis
- Pruritic urticarial papules and plaques of pregnancy
- Other eruptions of pregnancy (see Chapter 108)
- Contact dermatitis
- Drug eruption

Consider
- Urticaria
- Erythema multiforme
- Dermatitis herpetiformis

Rule Out
- Pemphigus vulgaris
- Varicella

Most disease remits spontaneously over weeks to months following delivery, although there are isolated reports of protracted postpartum involvement. It has often been said that once gestational pemphigoid develops, it tends to occur earlier and with greater severity during subsequent gestations, but there are no data to support this contention.

No clear pattern of paternal contribution, if there is one, has yet been elucidated. First onset during both primiparous and multiparous pregnancies has been reported, with and without a change in partners.

TREATMENT

Gestational pemphigoid is sufficiently rare that no controlled studies are available. Nonetheless, there is general consensus that treatment with topical corticosteroids and antihistamines is ineffective. Systemic corticosteroids remain the cornerstone of therapy. Most patients respond to 0.5 mg/kg of prednisone (prednisolone) daily. Maintenance therapy, generally at a lower dosage, may or may not be required throughout gestation. As noted earlier, many patients experience spontaneous disease regression during the third trimester, only to experience flare during parturition.

In individual cases, alternatives to corticosteroids (dapsone, pyridoxine, cyclosporine, rituxan) or adjuvants (gold, methotrexate, cyclophosphamide, plasmapheresis) have been tried. None, with the possible exception of cyclosporine, is useful prior to term, and the experience with each has been variable at best. There are obvious concerns with the use of any of these products during pregnancy.

PREVENTION

Only a small percentage of women who express DR3, DR4, or the combination of DR3 and DR4 ever develop PG, and the role of the paternal tissue in the development of disease (if any) is far from clear. With no predictive test available, prevention is not possible.

Those with a history of PG face the likelihood (but not the assurance) of recurrent involvement during subsequent gestations and are likely to develop symptoms during the use of oral contraceptives. Women who have experienced PG need not avoid additional pregnancies. However, they should be counseled that recurrent disease is the rule.

Chapter 60 :: Epidermolysis Bullosa Acquisita

:: David T. Woodley & Mei Chen

EPIDERMOLYSIS BULLOSA ACQUISITA AT A GLANCE

- Rare, autoimmune subepidermal bullous disease due to immunoglobulin (Ig) G autoantibodies to type VII collagen.
- Etiology is unknown.
- Skin fragility, subepidermal blisters, residual scarring, and milia formation. Common sites are trauma-prone areas such as hands, feet, elbows, knees, sacrum, nails, and mouth.
- Related features may include an underlying systemic disease such as inflammatory bowel disease. May have erosions of the mucosa and esophageal stenosis.
- Pathology shows subepidermal bulla, fibrosis, milia formation, and positive direct immunofluorescence for IgG deposits at the dermal–epidermal junction.
- Treatment options are limited and often difficult.

EPIDEMIOLOGY

Epidermolysis bullosa acquisita (EBA) is a sporadic autoimmune bullous disease of unknown etiology and with no gender, ethnic, or geographic predisposition. Although EBA does not have a Mendelian pattern type of inheritance, there may be some genetic predisposition to EBA and autoimmunity in African-Americans who live in the southeastern part of the United States.[1] African-American patients in the southeastern part of the United States who have either EBA or bullous systemic lupus erythematosus (SLE) have a high incidence of the HLA-DR2 phenotype. The calculated relative risk for EBA in HLA-DR2+ individuals is 13.1 in these patients. These results also suggest that EBA and bullous SLE are immunogenetically related and that either the *HLA-DR2* gene is involved with autoimmunity to anchoring fibril collagen or is some sort of a marker for some other gene that exists in linkage disequilibrium with it.[1]

ETIOLOGY AND PATHOGENESIS

EBA is a chronic, subepidermal blistering disease associated with autoimmunity to the collagen (type VII collagen) within anchoring fibril structures that are located at the dermal–epidermal junction (DEJ). Although the precise etiology of EBA is unknown, most of the evidence suggests an autoimmune etiology. The immunoglobulin (Ig) G autoantibodies to type VII collagen are associated with a paucity of normal-anchoring fibrils at the basement membrane zone (BMZ) separating the epidermis from the dermis and poor epidermal–dermal adherence. Although it is an acquired disease that usually begins in adulthood, it was placed in the category epidermolysis bullosa (EB) approximately 100 years ago because physicians were struck by how similar the clinical lesions of EBA were to those seen in children with hereditary dystrophic forms of EB. Direct immunofluorescence (DIF) of perilesional skin biopsies from EBA patients reveals IgG deposits at the DEJ.[2] EBA antibodies bind to type VII collagen within anchoring fibrils (see Chapter 53).[3,4]

Anchoring fibrils anchor the epidermis and its underlying BMZ to the papillary dermis. Patients with hereditary forms of dystrophic EB (see Chapter 62) and EBA have decreased numbers of anchoring fibrils in their DEJ. This paucity of anchoring fibrils is associated with two similar clinical phenotypes, EBA and dystrophic forms of hereditary EB, because both diseases are characterized by skin fragility, subepidermal blisters, milia formation, and scarring. Although both EBA and hereditary forms of dystrophic EB are etiologically unrelated in terms of their underlying pathogenesis, they share the common feature of decreased anchoring fibrils. In the case of dystrophic forms of hereditary EB, the cause of decreased or absent anchoring fibrils is a genetic defect in the gene that encodes for type VII collagen α chains that ultimately results in small, nonfunctional, or decreased anchoring fibrils.[5,6] The gene coding for type VII collagen is located on the short arm of chromosome 3, approximately 21 cm from zero.[7] The gene defects involved in hereditary forms of dystrophic EB have been identified at variable locations, but the severity of the disease appears to correlate with the degree of type VII collagen and anchoring fibril perturbations.[6] In EBA, the IgG autoantibodies binding to the type VII collagen α chains result in decreased anchoring fibrils, but the pathway leading to this reduction is unknown. It may be that type VII collagen α chains that are newly synthesized but decorated with EBA autoantibodies cannot form triple-helical structures and stable anchoring fibrils. Healed burn wounds that have been covered with cultured keratinocyte sheets also have decreased numbers of anchoring fibrils within the first year after transplantation, and this is associated with spontaneous blister formation, shortened suction blistering times, and skin fragility.[8] These observations provide indirect evidence that anchoring fibrils play a role in maintaining adherence between the epidermis and dermis.

The type VII collagen α chain has a molecular mass between 250 and 320 kDa, and the collagen consists of a homotrimer of three identical α chains (see Chapter 53). Each α chain consists of a large globular noncollagenous amino terminus called the *noncollagenous 1* (NC-1) *domain* that is approximately one-half the entire mass of the α chain. Next, there is a helical domain with typical glycine-X-Y repeats. At the carboxyl terminus is a second globular noncollagenous domain, NC-2, that is much smaller than NC-1.[9] Most EBA autoantibodies recognize four predominant antigenic epitopes within the NC-1 domain and do not recognize the helical or NC-2 domains.[10,11] There may be something intrinsically "antigenic" about the NC-1 domain because the available monoclonal antibodies that have been generated against type VII collagen specifically recognize only NC-1 subdomains.

A reduction in the number of anchoring fibrils is seen in lesional and perilesional skin of EBA patients, but the pathway leading to this reduction is unknown.

Several independent lines of evidence have implicated autoimmune responses as a key element in the pathogenesis of EBA. First, the pathogenic role of EBA antibodies is suggested by the observation that when patients with SLE develop autoantibodies to the EBA antigen, they develop widespread skin blisters and fall into a subset of SLE called *bullous SLE*.[12] This "experiment of nature" suggests that EBA autoantibodies are pathogenic and capable of inducing disadherence between the epidermis and dermis. Secondly, direct proof that EBA autoantibodies are pathogenic comes from recent passive transfer studies. We immunized rabbits and raised a high titer antiserum to the NC-1 domain of human type VII collagen. We injected this antibody into hairless immune competent mice, and the mice developed bullous skin disease with many of the features of EBA in humans.[13] The mice developed subepidermal blisters and lost nails on their feet. They also had circulating NC-1 antibodies in their blood and anti-NC-1 IgG antibody deposits at their DEJ. In addition, the mice had murine complement deposits at the DEJ induced by the autoantibody–antigen complex.[13] Another study by Sitaru and colleagues[14] showed that the injection of rabbit polyclonal antibodies to the NC-1 domain of mouse type VII collagen into mice also induced subepidermal skin blisters that were reminiscent of human EBA.[14] Further, we have also affinity purified human EBA autoantibodies against an NC-1 column and injected them into mice. The mice then developed clinical, histologic, immunologic, and ultrastructural features akin to human EBA.[15] Taken together, these successful passive transfer experiments and the observations with bullous SLE strongly suggest that EBA autoantibodies are "pathogenic" and capable of causing epidermal–dermal separation in skin.

In addition to a passive transfer animal model of EBA, Sitaru and colleagues[16] have established an active EBA animal model by immunizing certain strains of mice with fragments of the noncollagen domain (NC-1) of murine type VII collagen. In these animal models, activation of complement by the alternative pathway and NADPH oxidase for neutrophil action are required for the development of murine EBA.[17,18] The murine models of EBA with these requirements for components of inflammation may better reflect the inflammatory subsets of EBA than the classical noninflammatory mechanobullous EBA phenotype since it is known that not all EBA patients have complement-fixing antibodies or a pathology involving neutrophils. Alternatively, the murine model could reflect early processes in the development of all EBA that is later modulated in certain EBA patients by their intrinsic immune regulatory processes. The next advance in understanding the pathogenesis of EBA will be linking the pathogenic mechanistic steps involved in the disease with the patient's clinical phenotype of disease (see Section "Clinical Findings").

CLINICAL FINDINGS

(Fig. 60-1)

If a patient presents with bullae on the skin with no reasonable explanation despite a thorough history and physical examination, three tests should be done: (1) a skin biopsy for routine hematoxylin and eosin histology, (2) a second biopsy juxtaposed to a

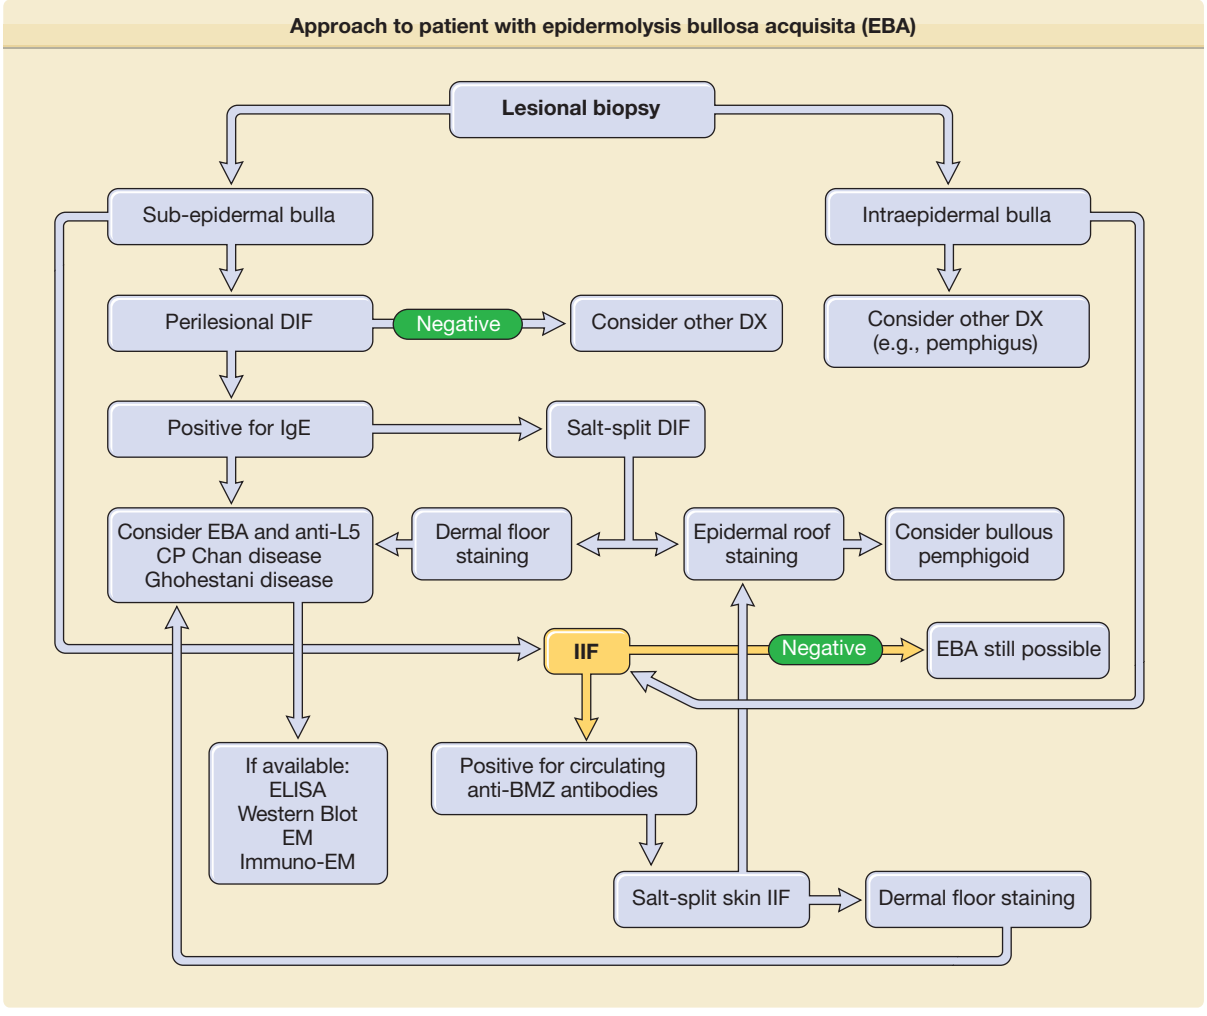

Figure 60-1 Approach to the patient with epidermolysis bullosa acquisita (EBA). BMZ = basement membrane zone; DIF = direct immunofluorescence; DX = diagnosis; ELISA = enzyme-linked immunosorbent assay; IgG = immunoglobulin G; IIF = indirect immunofluorescence.

lesion but on normal-appearing skin for DIF, and (3) a blood draw to test for antibodies against the BMZ and/or type VII collagen by indirect immunofluorescence (IIF) or enzyme-linked immunosorbent assay (ELISA).

HISTORY

CUTANEOUS LESIONS. The cutaneous lesions of EBA can be quite varied and can mimic other types of acquired autoimmune bullous diseases. The common denominator for patients with EBA is autoimmunity to type VII (anchoring fibril) collagen. Although the clinical spectrum of EBA is still being defined, there are at least five clinical presentations: (1) a classic presentation, (2) a bullous pemphigoid (BP)-like presentation, (3) a cicatricial pemphigoid (CP)-like presentation, (4) a presentation reminiscent of Brunsting–Perry pemphigoid with scarring lesions and a predominant head and neck distribution, and (5) a presentation reminiscent of linear IgA bullous dermatosis or chronic bullous disease of childhood.

CLASSIC PRESENTATION. The classic presentation (Figs. 60-2 and 60-3A) is of a noninflammatory bullous disease with an acral distribution that heals

Figure 60-2 Patient with epidermolysis bullosa acquisita who has severe blistering, erosions, scarring, and milia formation on trauma-prone areas of her skin. This is the classic presentation.

Figure 60-3 A. Classic presentation of epidermolysis bullosa acquisita with scarring and milia over trauma-prone areas of skin. **B.** Bullous pemphigoid-like presentation of epidermolysis bullosa acquisita with a widespread inflammatory vesiculobullous dermatosis. **C.** Cicatricial pemphigoid-like presentation of epidermolysis bullosa acquisita with a mucosa-centered bullous scarring eruption. **D.** Brunsting–Perry pemphigoid-like presentation of epidermolysis bullosa acquisita with bullous and scarring lesions predominantly on the head and neck.

with scarring and milia formation. This presentation is reminiscent of porphyria cutanea tarda (PCT; see Chapter 132) when it is mild and of the hereditary form of recessive dystrophic EB when it is severe (see Chapter 62). The classic form of EBA is thus a mechanobullous disease marked by skin fragility. These patients have erosions, tense blisters within noninflamed skin, and scars over trauma-prone surfaces such as the backs of the hands, knuckles, elbows, knees, sacral area, and toes (see Figs. 60-2, 60-3A, and 60-4). Some blisters may be hemorrhagic or develop scales, crusts, or erosions. The lesions heal with scarring and frequently with the formation of pearl-like milia cysts within the scarred areas (see Fig. 60-3A). Although this presentation may be reminiscent of PCT, these patients do not have other hallmarks of PCT, such as hirsutism, a photodistribution of the eruption, or scleroderma-like changes, and their urinary porphyrins are within normal limits. A scarring alopecia and some degree of nail dystrophy may be seen.

Although the disease is usually not as severe as that of patients with hereditary forms of recessive dystrophic EB, EBA patients with the classic form of the disease may have many of the same sequelae, such as scarring, loss of scalp hair, loss of nails, fibrosis of the hands and fingers, and esophageal stenosis.[19]

BULLOUS PEMPHIGOID-LIKE PRESENTATION

(See Chapter 56)

A second clinical presentation of EBA is of a widespread, inflammatory vesiculobullous eruption involving the trunk, central body, and skin folds in addition to the extremities.[20] The bullous lesions are tense and

Figure 60-4 An epidermolysis bullosa acquisita patient with involvement of the leg. Note bullae, erosions, and crusts.

surrounded by inflamed or even urticarial skin. Large areas of inflamed skin may be seen without any blisters and only erythema or urticarial plaques. These patients often complain of pruritus and do not demonstrate prominent skin fragility, scarring, or milia formation. This clinical constellation is more reminiscent of BP (see Figs. 60-3B and 60-4) than a mechanobullous disorder. Similar to BP, the distribution of the lesions may show an accentuation within flexural areas and skin folds.

CICATRICIAL PEMPHIGOID-LIKE PRESENTATION

(See Chapter 57)

Both the classic and BP-like forms of EBA may have involvement of mucosal surfaces. However, EBA also may present with such predominant mucosal involvement that the clinical appearance is reminiscent of CP (see Fig. 60-3C).[24] These patients usually have erosions and scars on the mucosal surfaces of the mouth, upper esophagus, conjunctiva, anus, or vagina with or without similar lesions on the glabrous skin.

BRUNSTING–PERRY PEMPHIGOID-LIKE PRESENTATION

(See Chapter 57)

Brunsting–Perry cicatricial BP is a chronic, recurrent vesiculobullous eruption localized to the head and neck and characterized by residual scars, subepidermal bullae, IgG deposits at the DEJ, and minimal or no mucosal involvement. However, the antigenic target for the IgG autoantibodies has not been defined. Nevertheless, a patient reported with this constellation of findings had IgG autoantibodies directed to anchoring fibrils below the lamina densa.[22] We have seen three additional patients with the features of Brunsting–Perry pemphigoid and autoantibodies directed to type VII collagen (unpublished observations). Therefore, it appears that EBA patients may present with a clinical phenotype of Brunsting–Perry pemphigoid (see Fig. 60-3D).

IMMUNOGLOBULIN A BULLOUS DERMATOSIS-LIKE PRESENTATION

(See Chapter 58)

IgA bullous dermatosis-like presentation of EBA is manifested by a subepidermal bullous eruption, a neutrophilic infiltrate, and linear IgA deposits at the BMZ when viewed by DIF. It may resemble linear IgA bullous dermatosis (LABD), dermatitis herpetiformis, or chronic bullous disease of childhood and may feature tense vesicles arranged in an annular fashion and involvement of mucous membranes.[23] The autoantibodies are usually IgA, IgG, or both.

The diagnosis of these subepidermal blistering cases with IgA antitype VII collagen antibodies showing linear IgA deposition at the BMZ is disputable. Some clinicians regard the patients as having purely LABD, whereas others regard them as having a subset of EBA. Further, the majority of EBA patients have low titer IgA antibodies in their blood directed against type VII collagen.

Childhood EBA is a rare disease. It has a variable presentation, including an LABD-like disease, a BP-like disease, and the classic mechanobullous EBA presentation. Although mucosal involvement is frequent and severe in childhood EBA, the overall prognosis is more favorable than in adult EBA.

INCIDENCE OF THE CLINICAL PRESENTATIONS OF EPIDERMOLYSIS BULLOSA ACQUISITA

According to the authors' experience, approximately 25% of patients with EBA may present with a BP-like clinical appearance. The disease of some of these patients eventually smolders into a more noninflammatory mechanobullous form. However, both the classic and BP-like forms of the disease may coexist in the same patient (Fig. 60-5). The clinical phenotype of EBA that is reminiscent of pure CP occurs in fewer than 10% of all EBA cases.

RELATED PHYSICAL FINDINGS

EBA patients may have many physical findings similar to patients with hereditary dystrophic EB due to gene defects in the type VII collagen gene. These include oral erosions, esophageal strictures, hypo- and hyper-

Figure 60-5 An epidermolysis bullosa acquisita patient demonstrating two presentations of the disease: the classic mechanobullous presentation with erosions, scarring, and milia over the elbows and the more inflammatory bullous pemphigoid-like lesions on her trunk.

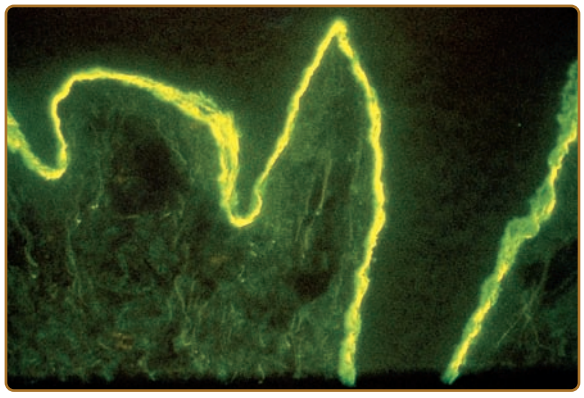

Figure 60-6 Direct immunofluorescence staining for immunoglobulin G deposits in perilesional skin of an epidermolysis bullosa acquisita patient. Note the dense deposits within the dermal–epidermal junction (the epidermis is on top in this section).

pigmentation skin mottling, nail loss, milia formation, scarring, and a degree of fibrosis of the hands.

A number of published reports suggest that EBA may be associated with various systemic diseases[24] such as inflammatory bowel disease, SLE, amyloidosis, thyroiditis, multiple endocrinopathy syndrome, rheumatoid arthritis, pulmonary fibrosis, chronic lymphocytic leukemia, thymoma, diabetes, multiple myeloma, and other diseases in which an autoimmune pathogenesis has been implicated. At the University of North Carolina, University of Stanford, University of Northwestern, and University of Southern California, with a combined experience of following over 62 EBA patients, it appears that inflammatory bowel disease is the systemic disease most frequently associated with EBA.

LABORATORY TESTS

HISTOPATHOLOGY

Routine histologic examination of lesional skin obtained from EBA patients shows a subepidermal blister and a clean separation between the epidermis and dermis. The degree of inflammatory infiltrate within the dermis usually reflects the degree of inflammation of the lesion observed by the clinician. Lesions that are reminiscent of recessive dystrophic EB or PCT usually have a notable scarcity of inflammatory cells within the dermis. Lesions that are clinically reminiscent of BP usually have significantly more inflammatory cells within the dermis, and these cells may be a mixture of lymphocytes, monocytes, neutrophils, and eosinophils. The histology of EBA skin specimens obtained from BP-like lesions may be difficult to distinguish from BP itself.

IMMUNOFLUORESCENCE

Patients with EBA have IgG deposits within the DEJ of their skin.[3,19] This is best detected by DIF of a biopsy specimen obtained from a perilesional site (Fig. 60-6). IgG is the predominant immunoglobulin class, but deposits of complement, IgA, IgM, factor B, and properdin also may be detected. The DIF staining demonstrates an intense linear fluorescent band at the DEJ. Yaoita et al[2] have suggested that a positive DIF and IgG deposits within the sublamina densa zone are necessary criteria for the diagnosis of EBA.

Patients with PCT, which may mimic EBA clinically, frequently have IgG and complement deposits at the DEJ similar to those of EBA patients (see Chapter 132). However, the DIF feature that distinguishes PCT from EBA is that PCT skin also demonstrates immune deposits around the dermal blood vessels.

Patients with EBA may have autoantibodies in their blood directed against the DEJ.[3] These antibodies can be detected by IIF of the patient's serum on a substrate of monkey or rabbit esophagus or human skin and stain the DEJ in a linear fashion that may be indistinguishable from BP sera.[15]

IMMUNOELECTRON MICROSCOPY

The localization of the immune deposits within the DEJ of the skin of EBA patients by immunoelectron microscopy is the "gold standard" for the diagnosis. As demonstrated by Nieboer et al[25] and Yaoita et al,[2] patients with EBA have immune deposits within the sublamina densa zone of the cutaneous BMZ. This localization is clearly distinct from the deposits in BP, which are higher up in the hemidesmosome area or lamina lucida area of the basement membrane. It is also distinct from CP, which has antigenic targets confined to the lamina lucida (see Chapters 56 and 57).

INDIRECT SALT-SPLIT SKIN IMMUNOFLUORESCENCE

When human skin is incubated in 1 M NaCl, the DEJ fractures cleanly through the lamina lucida zone. This

fracture places the BP antigen on the epidermal side of the split and all other basement membrane structures on the dermal side of the separation. Salt-split skin substrate can be used to distinguish EBA and BP sera.[3]

If the serum antibody is IgG and labels the epidermal roof, the patient does not have EBA and BP should be considered. If, on the other hand, the antibody labels the dermal side of the separation, the patient usually has either EBA or bullous SLE. The latter can be ruled out by other serology and by clinical criteria.

DIRECT SALT-SPLIT SKIN IMMUNOFLUORESCENCE

Perilesional skin incubated in cold 1 M NaCl is fractured through the DEJ, which effectively places the BP antigen (and any associated immune deposits) on the epidermal roof and the EBA antigen (and any associated immune deposits) on the dermal floor of the separation.[19] If the patient has EBA, immune deposits are detected on the dermal side of the separation by a routine DIF method using fluorescein-conjugated anti-human IgG.

WESTERN IMMUNOBLOTTING

Antibodies in EBA sera bind to a 290-kDa band in Western blots of human skin basement membrane proteins containing type VII collagen, whereas sera from all other primary blistering diseases do not.[3] This band is the α chain of type VII collagen. Often, a second band of 145 kDa is labeled with EBA antibodies. This band is the amino-terminal globular NC-1 domain of the type VII collagen α chain, which is rich in carbohydrate and contains the antigenic epitopes of EBA autoantibodies, bullous SLE autoantibodies, and monoclonal antibodies against type VII collagen.[10]

ENZYME-LINKED IMMUNOSORBENT ASSAY

Chen et al[26] have produced milligram quantities of recombinant, purified, posttranslationally modified NC-1 in stably transfected human cells and have used this NC-1 to develop an ELISA for autoantibody detection in EBA patients and in patients with bullous SLE. This new ELISA is more sensitive than immunofluorescence and Western blotting, and yet it is very specific for antibodies to type VII collagen.

DIFFERENTIAL DIAGNOSIS

(Box 60-1)

Because EBA has been described in infants and children, it is worth considering that a patient thought to have genetic dystrophic EB just might be a rare childhood patient with EBA. This can be ruled out by the antibody tests outlined in Section "Laboratory Tests." PCT can look clinically very much like classic EBA and can be ruled out by a urine or plasma test for uroporphyrins. Pseudo-PCT, usually caused by drugs such as nonsteroidal anti-inflammatory agents, can look similar to EBA with skin fragility, erosions, and blisters over trauma-prone areas, scarring, and milia formation. Nevertheless, the DIF appears different in that pseudo-PCT, like PCT, shows IgG deposits at both the BMZ at the DEJ and around dermal blood vessels (which are not stained in EBA).

The BP-like EBA can be eliminated by several methods listed above, but the first-line test would be indirect and direct salt-split immunofluorescence.

BOX 60-1 DIFFERENTIAL DIAGNOSIS OF EPIDERMOLYSIS BULLOSA ACQUISITA

Most Likely

- Porphyria cutanea tarda
- Pseudoporphyria cutanea tarda
- Bullous pemphigoid
- Cicatricial pemphigoid

Consider

- Linear immunoglobulin A bullous disease
- Brunsting–Perry pemphigoid
- Bullous systemic lupus erythematosus

DIAGNOSIS

The diagnostic criteria developed by Yaoita et al[2] for the diagnosis of EBA still stand. These criteria, with slightly updated modifications, are shown in Table 60-1.

Alternatives for the last item are indirect or direct salt-split skin immunofluorescence, Western blotting, and ELISA.

COMPLICATIONS

The complications caused by EBA include secondary skin infections, usually due to *Staphylococcus* or

TABLE 60-1
Diagnostic Criteria for Epidermolysis Bullosa Acquisita

- A bullous disorder within the clinical spectrum outlined earlier (see Section "Clinical Findings").
- No family history of a bullous disorder.
- Histology showing a subepidermal blister.
- Deposition of immunoglobulin G deposits within the dermal–epidermal junction (i.e., a positive direct immunofluorescence of perilesional skin).
- Immunoglobulin G deposits localized to the lower lamina densa and/or sublamina densa zone of the dermal–epidermal junction when perilesional skin is examined by direct immunoelectron microscopy.

Streptococcus, because the blisters and erosions compromise the skin's barrier. Scarring and milia formation are naturally occurring complications or sequelae of the deep blistering process. Severe EBA patients may develop significant fibrosis of the hands with decreased range of motion of the palm and digits. Because of wounds and fibrosis of the soles of the feet and toes, some EBA patients have difficulty walking. Many patients with EBA lose their fingernails. EBA patients with significant mucosal involvement may develop esophageal strictures and *even laryngeal scarring*.

TREATMENT

EBA usually responds poorly to treatment. Supportive therapy is warranted in all patients with EBA. This includes instruction in open wound care and strategies for avoiding trauma. Patients should be warned not to over wash or overuse hot water or harsh soaps and to avoid prolonged or vigorous rubbing of their skin with a washcloth or towel. In some patients, it appears that prolonged sun exposure may aggravate or promote new lesions on the dorsal hands and knuckles. Thus, avoidance of prolonged sun exposure and the use of sunscreens are helpful. The patient should be educated to recognize localized skin infections and to seek medical care and antibiotic therapy promptly when they occur.

EBA patients are often refractory to high doses of systemic glucocorticoids, azathioprine, methotrexate, and cyclophosphamide, especially when they have the classic mechanobullous form of the disease. These agents may be somewhat helpful in controlling EBA when it appears as an inflammatory BP-like disease. Some EBA patients improve on dapsone, especially when neutrophils are present in their dermal infiltrate.

Cyclosporine has been shown to be beneficial in EBA.[27] However, the long-term toxicity of this drug limits its use.

There are also independent reports of EBA patients responding to high doses of colchicine.[28] This is often used as a first-line drug because its side effects are relatively benign compared with other therapeutic choices. However, diarrhea is a common side effect of colchicine, which makes it difficult for many patients to achieve a high enough dose to control the disease. Moreover, because of this side effect, we are hesitant to use colchicine in EBA patients who also have inflammatory bowel disease. In addition, there are patients who do not respond to colchicine. Colchicine is a well-known microtubule inhibitor, but it also appears to have properties that have the potential to inhibit antigen presentation to T cells, which could downregulate autoimmunity.

Photopheresis has been used in Sézary syndrome, mycosis fungoides, and a variety of autoimmune bullous diseases (see Chapter 238). Photopheresis improves the clinical features of EBA and remarkably lengthens the suction blistering times of the patients, suggesting an improvement in their epidermal–dermal adherence.[29]

In addition to photopheresis, plasmapheresis and removal of the antibodies to type VII collagen in an EBA patient's plasma is useful for gaining control of EBA patients similar to pemphigus patients. Given that the autoantibodies are pathogenic, this is not surprising, but when plasmapheresis is performed it is necessary to have the patient also treated with a chemotherapy agent (such as azathiaprine, cyclophosphamide, mycotile mofelate, methotrexate).

Intravenous Ig has been used in dermatomyositis, an entity in which autoimmunity may play a role. Intravenous Ig has been reported to be effective in some patients with EBA.[30] The mechanism by which γ globulin may invoke a positive response in EBA is unknown.

The anti-TNF-α biologics (such as infliximab; see Chapter 234) and anti-CD antibodies against B cells have been tried in EBA with some success in limited open trials. Box 60-2 outlines treatment options in EBA that have some support in the medical literature.

Recently, anecdotal reports have also shown that, riuximab, a monoclonal antibody to the CD20 receptor on B lymphocytes is effective in treating recalcitrant patients with EBA.

BOX 60-2 TREATMENTS FOR EPIDERMOLYSIS BULLOSA ACQUISITA (EBA)

MEDICATION	DOSE RANGE
Colchicine[a]	0.6–3.0 mg/day
Cyclosporine A	6 mg/kg/day
Dapsone[b]	100–300 mg/day
Cytoxan	50–200 mg/day
Prednisone[c]	1.0–1.5 mg/kg
Intravenous immunoglobulin[d]	3 g/kg divided over 5 days
Infliximab	5 mg/kg at 0, 2, 4, and 6 week

[a]Must start with 0.4–0.6 mg/day and each 1–2 week double this dose as tolerated. When patient develops diarrhea, back off 1 tablet (0.4–0.6 mg).
[b]Begin at 25 mg/day and double each week after the complete blood count and liver function tests. Most patients need between 100–250 mg/day. Increasing the dose slowly helps the patient tolerate the anemia that develops (i.e., less orthostatic light-headedness, etc.). Expect a 1- to 2-g drop in the patient's hemoglobin on therapeutic doses.
[c]Usually does not help the classic, mechanobullous type of EBA with minimal inflammation. However, it may be somewhat helpful in the bullous pemphigoid-like type of EBA.
[d]Intravenous immunoglobulin is given over 4–5 days every month for 5 or 6 months to give it an adequate trial.

Chapter 61 :: Dermatitis Herpetiformis

:: Arash Ronaghy, Stephen I. Katz, & Russell P. Hall III

DERMATITIS HERPETIFORMIS AT A GLANCE

- Intensely itchy, chronic papulovesicular eruption distributed symmetrically on extensor surfaces.
- Characterized histologically by dermal papillary collections of neutrophils (microabscesses).
- Granular immunoglobulin (Ig) A deposits in normal-appearing skin are diagnostic for dermatitis herpetiformis.
- Most, if not all, dermatitis herpetiformis patients have an associated gluten-sensitive enteropathy.
- The rash responds rapidly to dapsone therapy and, in many patients, to strict adherence to a gluten-free diet.

EPIDEMIOLOGY

Dermatitis herpetiformis (DH) is characterized by an intensely itchy, chronic papulovesicular eruption that usually is distributed symmetrically on extensor surfaces. The disease can be clearly distinguished from other subepidermal blistering eruptions by histologic, immunologic, and gastrointestinal criteria. The prevalence of DH in various Caucasian populations varies between 10/100,000 and 39/100,000 persons.[1–3] Some reports suggests a 1.5:1 male to female ratio of DH patients. It may start at any age, including childhood; however, the second, third, and fourth decades are the most common. After presentation, DH persists indefinitely in most patients, although with varying severity. Two long-term studies of immunologically verified patients have suggested that the disease in approximately 10–12% of DH patients eventually remits.[4,5]

Patients with DH have an associated gluten-sensitive enteropathy (GSE) that is usually asymptomatic.

ETIOLOGY AND PATHOGENESIS

In 1884, Louis Duhring first described the clinical features and natural history of a polymorphous pruritic disorder that he called dermatitis herpetiformis; however, the critical elements in the pathogenesis of DH remained unknown until the 1960s.[6] In 1966, Marks et al first noted a gastrointestinal abnormality in patients with DH.[7] Shortly thereafter, it was shown that the lesion was reversible by avoidance of the dietary protein gluten.[8,9] Initially, the intestinal abnormality was thought to be present in 60%–75% of DH patients. However, this view has been modified in two ways. First, the diagnostic criteria for DH have been delineated more precisely, and second, it can be shown that certain patients without apparent gastrointestinal pathology can be "induced" to develop gastrointestinal lesions by subjecting them to a large gluten intake; such patients have been said to have latent celiac sprue.[10]

Thus, most patients with DH have a gastrointestinal abnormality similar (if not identical) to celiac disease, however minimal that may be when the patient is ingesting a normal gluten load. These studies have all confirmed that gluten, a protein found in wheat, barley, and rye, plays a critical role in the pathogenesis of DH. Oats, long thought to contain gluten and play a role in inducing DH lesions, have been shown to be devoid of toxicity in patients with DH.[11,12] As in celiac disease, there is an increased density of small bowel intraepithelial T cells with a γ/δ T-cell receptor in the jejunum of patients with DH.[13] The finding that T-cell lines from patients with DH produce significantly more interleukin 4 (IL-4) than those from patients with GSE and that gut biopsies from symptomatic patients with isolated GSE showed increased expression of interferon-γ suggests that different cytokine patterns may play a role in the varied clinical manifestations of these two diseases.[14,15] Systemic evidence of the gut mucosal immune response has also been found in the serum and the skin of patients with DH. Patients with DH on regular gluten-containing diets have been found to have increased serum IL-2 receptor levels and serum IL-8 levels, increased endothelial cell E-selectin expression in skin, and an increased expression of CD11b on circulating neutrophils.[16–18] These systemic manifestations of the gut mucosal immune response may play a role in creating the proinflammatory environment in the skin necessary for the development of skin lesions. The GSE seen in DH patients probably relates to the immunoglobulin (Ig) A deposits that are found in the skin of these patients, although a direct relationship has not been demonstrated. Patients with a clinical picture consistent with DH and partial IgA deficiency have been reported.[19]

In 1999, Dieterich et al identified antibodies to tissue transglutaminases (Tgases) in the sera from DH patients.[20] Distinguishing various types of Tgases enabled Sardy et al in 2002 to demonstrate that epidermal Tgase is the dominant autoantigen in DH.[21] This was confirmed by a study of nine DH patients by Donaldson et al demonstrating that the dermal deposits of epidermal Tgase colocalized with cutaneous deposits of IgA, in the papillary tips.[22] Because epidermal Tgases were strongly expressed in the upper epidermis, the authors suggested that in regions of trauma they may diffuse through the basement membrane after release from epidermal keratinocytes. Epidermal Tgases were also found in uninvolved skin at least 5 cm away from the lesion suggesting additional factors involved in the production of DH lesions.[22]

It is also known that patients with both GSE and DH have circulating IgA antibodies directed against Tgases.[20,23] There appears to be a predilection for these circulating IgA autoantibodies to bind to epidermal Tgase in DH, whereas the predilection is for autoantibodies to bind tissue Tgase in patients with isolated GSE.[21] The precise role of the circulating IgA antiepidermal Tgase in the development of skin lesions in patients with DH is not known. However, children with celiac disease have lower levels of circulating IgA antiepidermal Tgase when compared to adults with celiac disease, whereas levels of circulating IgA antibodies against tissue Tgase are not significantly different between children and adults with celiac disease.[24] This observation has led to the hypothesis that epitope spread over time results in the development of IgA antiepidermal Tgases and that this late onset of IgA antiepidermal Tgase antibodies may play a role in the typical development of DH in the second to third decade of life.[24]

The mechanism whereby the IgA antiepidermal Tgases bind to skin in patients with DH is not fully understood. One long-standing hypothesis has been that IgA-containing circulating immune complexes are responsible for the IgA deposits in DH skin. The recent discovery of IgA antiepidermal Tgase antibodies has led to the suggestion that IgA–epidermal Tgase immune complexes may be depositing in the skin of DH patients. However, only a minority of DH patients have been found to have IgA and epidermal tissue Tgase deposits colocalized in a perivascular pattern.[22,25] In addition, perivascular neutrophil deposits that are typically found with the perivascular deposition of immune complexes rarely occur in patients with DH.[26] These findings suggest an alternative hypothesis that IgA antiepidermal Tgase may directly bind in the skin to epidermal tissue Tgase. Direct antigen–antibody binding of IgA antiepidermal Tgases to skin also appears unlikely to represent the complete mechanism, since IgA deposits in DH skin cannot be removed using typical techniques for eluting antibody bound directly to antigen. It is possible that the IgA antiepidermal Tgases bind initially via antigen–antibody interactions and that ability of Tgases to cross-link proteins results in the IgA cross-linking to dermal proteins resulting in the stable, long-lasting IgA deposits seen in the skin of patients with DH. This hypothesis awaits confirmation.

Whether the IgA skin deposits play a role in the pathophysiology of blister formation is not known. The finding of IgA and complement in almost all skin sites, not only in lesional skin, makes one postulate that if IgA (either alone or as a part of an immune complex) does play a role, additional factors are still needed to explain the initiation of lesions. Takeuchi et al have demonstrated that minor trauma to skin results in increased expression of IL-8 and E-selectin, both of which may predispose to a neutrophilic inflammatory infiltrate.[27] These findings, coupled with the typical appearance of DH lesions on extensor surfaces at sites of trauma, suggest local cytokine/chemokine production after trauma may be one of the inciting factors of DH skin lesions. It may be that after the initial neutrophilic infiltrate binds to the cutaneous IgA, factors such as cytokines, chemokines, and proteases are released that both directly result in blister formation and induce basal keratinocytes to produce collagenases or stromelysin-1 that further contributes to the formation of blisters.[28,29] Other studies have suggested that T cells may play a role in the pathogenesis of the skin lesions; however, no specific T-cell responses to gluten have been detected.[30,31]

It has been known for some time that iodides, administered orally, can exacerbate or elicit eruptions of DH, and this has, in former times, been used for diagnostic

purposes. The availability of immunopathologic techniques for the detection of IgA deposits in skin has made such provocation tests obsolete.

The absence of animal models of DH, either naturally occurring or developed in the laboratory, has limited advances in our understanding of the pathogenesis of DH. Recently, Marietta and coworkers reported a new mouse model for DH. They reported an HLA-DQ8 transgenic nonobese diabetic mouse that when immunized with gluten developed neutrophilic skin lesions along with cutaneous deposits of IgA. In addition, withdrawal of dietary gluten resulted in resolution of the skin lesions.[32] Further investigation of this mouse model may provide important information regarding the pathogenesis of DH. Finally, there are a few case reports describing the onset of DH with such medication use as interferon, ribavirin, and gonadotropin-releasing hormone analog.[33,34]

CLINICAL FINDINGS

The primary lesion of DH is an erythematous papule, an urticaria-like plaque, or, most commonly, a vesicle (Figs. 61-1–61-3). Large bullae occur infrequently. Vesicles, especially if they occur on the palms, may be hemorrhagic. The continual appearance and disappearance of lesions may result in hyperpigmentation and hypopigmentation. Patients may present with only crusted lesions, and a thorough search may not reveal a primary lesion. The herpetiform (herpes-like) grouping of lesions is often present in some areas (see Figs. 61-1 and 61-3), but patients also may have many individual nongrouped lesions.

Figure 61-1 Dermatitis herpetiformis. Extensive eruption with grouped papules, vesicles, and crusts on the back.

Figure 61-2 Dermatitis herpetiformis. Papules, vesicles, and crusts on knees.

Symptoms vary considerably from the usually severe burning and itching in most patients to the almost complete lack of symptoms in a rare patient. Most patients usually can predict the eruption of a lesion as much as 8–12 hours before its appearance because of localized stinging, burning, or itching.

The usual symmetric distribution of lesions on elbows, knees, buttocks, shoulders, and sacral areas is seen in most patients at one time or another (see Figs. 61-1–61-4). Although these regions are affected most commonly, most patients have scalp lesions

Figure 61-3 Dermatitis herpetiformis. This patient has many firm-topped vesicles and bullae, some erosions, and residual hyperpigmentation. Some of the vesicles are arranged in an annular pattern.

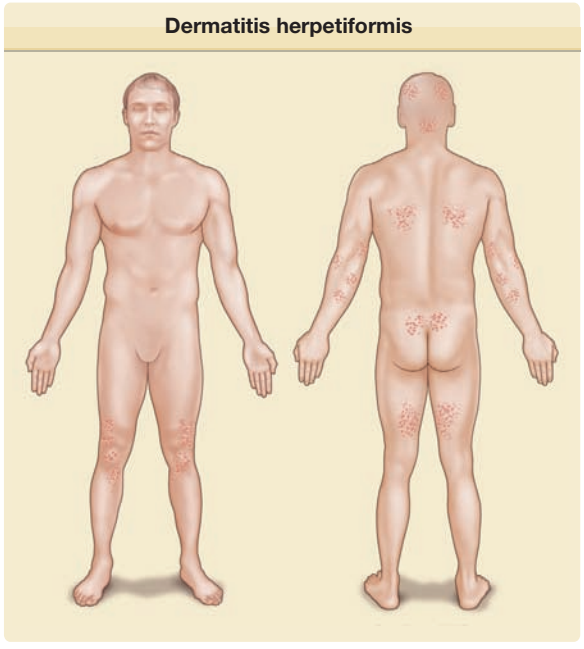

Figure 61-4 Dermatitis herpetiformis. Pattern of distribution.

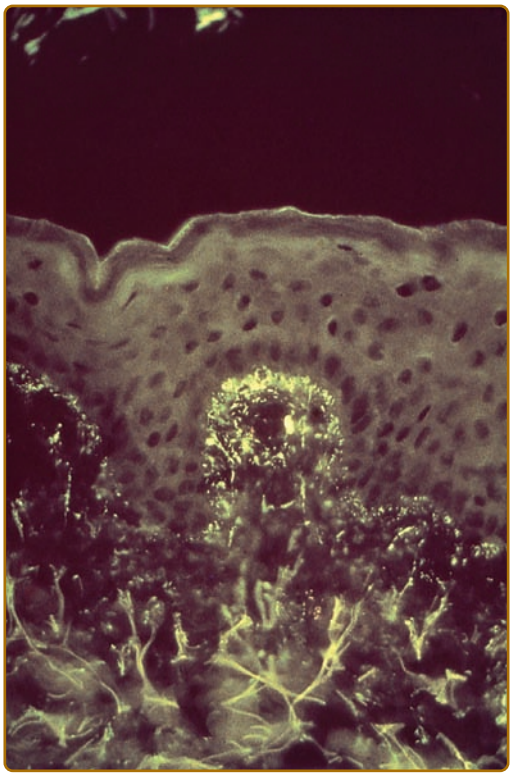

Figure 61-5 Dermatitis herpetiformis. Direct immunofluorescence showing granular dermal papillary deposits of immunoglobulin A.

and/or lesions in the posterior nuchal area. Another commonly affected area is the face and facial hairline. Mucous membrane lesions are uncommon, as are lesions on the palms and soles.

LABORATORY TESTS

IN VIVO–BOUND IMMUNOGLOBULIN A AND COMPLEMENT

After Cormane demonstrated that both perilesional and uninvolved skin of patients with DH contained granular Ig deposits located in dermal papillary tips, van der Meer found that the most regularly detected Ig class in DH skin was IgA (Fig. 61-5).[35,36] Although most patients have granular IgA deposits in their skin, recent studies have suggested that a distinct fibrillar pattern of IgA deposits can be found in some patients with DH.[37] The potential clinical significance of this difference is not known. For the most part IgA deposits have not been seen in the skin of patients with isolated GSE (celiac disease).[38] Recently, however, Cannistraci and coworkers have used confocal microscopy and reported faint colocalization of IgA and epidermal Tgases in the papillary dermis and in a perivascular distribution in the skin of patients with isolated GSE.[39] The significance of these findings in the pathogenesis of DH is not known.

Finding granular IgA deposits in normal-appearing skin is the most reliable criterion for the diagnosis of DH.[26,40] These IgA deposits are unaffected by treatment with drugs, but may decrease in intensity or disappear after long-term adherence to a gluten-free diet.[41,42] The IgA deposits are not uniformly intense throughout the skin and may be detected more easily in normal-appearing skin near active lesions.[43] In DH, other Igs sometimes are bound to the skin in the same areas as the IgA.[40] IgA deposits also may be seen in the skin of patients with bullous pemphigoid, scarring pemphigoid, Henoch–Schönlein purpura, and alcoholic liver disease, although in different patterns of distribution than those seen in DH.

Because of the IgA skin deposits and the association between DH and GSE (celiac disease), several groups have studied the IgA subclasses in DH. IgA1 is the predominant (or exclusive) subclass that has been identified in the skin of DH patients.[44,45] Most IgA1 is produced in the bone marrow, whereas most IgA2 is produced at mucosal sites. This does not negate the possibility that the IgA1 in skin may still be of mucosal origin because IgA1 is the predominant IgA subclass of IgA antibodies directed against dietary proteins produced in gut secretions in patients with DH. [46,47] Recently, Kantele et al reported a DH association with an increase in circulating IgA1-plasmoblasts with skin-homing receptors (CLA) as compared to those with IgA2.[48]

The third component of complement (C3) is frequently found in the same location as IgA. The presence of C3 in both perilesional and normal-appearing skin is not affected by treatment with dapsone (diaminodiphenyl sulfone), but C3 may not be detectable after treatment with a gluten-free diet.[42,49,50] C5 and components of the alternative complement pathway also may be seen in areas corresponding to the IgA deposits. The C5–C9 membrane attack complex, which

is formed as the terminal event in complement activation, is also seen in normal-appearing and perilesional skin of patients.[51]

The exact site of the IgA deposits in DH skin has been studied by immunoelectron microscopy. Early studies indicated that IgA is preferentially associated with bundles of microfibrils and with anchoring fibrils of the papillary dermis immediately below the basal lamina.[52,53] More recent studies, however, have indicated that some or almost all of the IgA deposits are related to nonfibrillar components of skin and other connective tissues.[53–55] There is also no agreement as to whether the IgA deposits in DH colocalize to fibrillin, a major component of the elastic microfibrillar bundles.[55,56]

SERUM STUDIES

Antireticulin antibodies of the IgA and IgG classes have been detected in the sera of 17%–93% of patients with DH and in higher percentages of patients with other diseases, especially celiac disease.[57] Thyroid microsomal antibodies and antinuclear antibodies also have been detected in increased frequency in the sera of patients with DH.[58,59] Putative immune complexes have been detected in the sera of 25%–40% of patients.[60,61]

Chorzelski et al have described an IgA antibody that binds to an intermyofibril substance (endomysium) of smooth muscle.[62] The nature of this antigen has been identified recently by the studies of Sardy et al, who showed that these IgA autoantibodies have specificity for Tgases, particularly epidermis-specific Tgases.[21] Although a majority of DH patients on gluten-containing diets have circulating antiepidermal Tgase antibodies, a significant number of patients do not.[24,63] Therefore, the presence of circulating antiepidermal Tgase antibodies should probably not be considered as a diagnostic test.

IMMUNOGENETIC FINDINGS

There is a marked increase in the incidence of certain major histocompatibility complex antigens in patients with DH. Worldwide studies have found that 77%–87% of DH patients have HLA-B8 (compared with 20%–30% of unaffected individuals).[64–66] In addition, the class II major histocompatibility complex antigens HLA-DR and -DQ are associated with DH even more frequently than is HLA-B8.[67,68] Park et al reported that more than 90% of patients expressed Te24, which was later shown to be similar to HLA-DQw2, and this finding has been confirmed by others.[69] Molecular studies indicate that susceptibility to DH is not associated with a unique HLA-DQw2 molecule.[70,71] Virtually all patients with DH have genes that encode the HLA-DQ (α1*0501, β1*02) or the HLA-DQ (α1*03, β1*0302) heterodimers, a pattern identical to that seen in celiac disease.[70,72] This strong association between susceptibility genes and DH and GSE is important clinically and pathophysiologically in that there is a strong concordance of these two diseases in monozygotic twins.[71] Furthermore, first-degree relatives of both DH and GSE patients are often (4%–5%) affected with one or the other of these diseases.[73]

Nonmajor histocompatibility complex susceptibility genes have been recently associated with DH. The *2 allele of the DNase-hypersensitivity region 1,2 of the Ig heavy chain regulatory region has been found with higher frequency in patients with DH.[74]

HISTOPATHOLOGY

The histology of an early skin lesion (clinically nonvesicular) is characterized by dermal papillary collections of neutrophils (microabscesses), neutrophilic fragments, varying numbers of eosinophils, fibrin, and, at times, separation of the papillary tips from the overlying epidermis (Fig. 61-6). In addition, in such early lesions, the upper and middle dermal blood vessels are surrounded by a lymphohistiocytic infiltrate as well as some neutrophils and an occasional eosinophil.[75,76] At times, early lesions may be difficult or impossible to differentiate from those of linear IgA disease (see Chapter 58), the bullous eruption of lupus erythematosus (see Chapter 155), bullous pemphigoid (see Chapter 56), or the neutrophil-rich form of epidermolysis bullosa acquisita (see Chapter 60). The histology of older lesions shows subepidermal

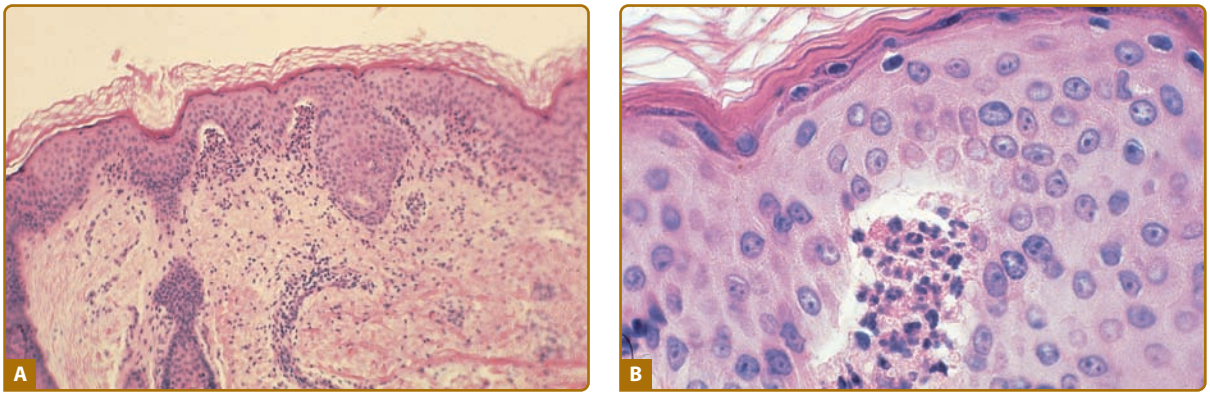

Figure 61-6 Dermatitis herpetiformis. Biopsy of an early lesion showing dermal papillary collections of neutrophils and eosinophils and subepidermal vesiculation at low (**A**) and high (**B**) magnification.

vesicles that may be impossible to differentiate from other subepidermal bullous eruptions, such as bullous pemphigoid, erythema multiforme, bullous drug eruption, and pemphigoid gestationis. Immunofluorescent localization and ultrastructural studies of the site of blister formation in DH have demonstrated that the blister forms above the lamina densa—within the lamina lucida. This is thought to occur because the lamina lucida is the most vulnerable component of the dermal–epidermal junction.[77,78]

ASSOCIATED PROBLEMS

GASTROINTESTINAL MANIFESTATIONS

It is now well accepted that most, if not all, DH patients have an associated gastrointestinal abnormality that is caused by gluten sensitivity.[18,9] The pathology of the GSE associated with DH and that in isolated GSE (GSE unassociated with DH) is essentially the same, although the lesion in the latter is usually much more severe; this applies to the epithelial cell derangement as well as to the character of the lymphoplasmacytic infiltrate. In addition, the distribution of the gastrointestinal lesion in the small intestine is, as a general rule, more widespread in celiac disease. The functional changes in the bowel and clinical sequelae encountered in the GSE associated with DH and those encountered in celiac disease are similar but again differ in degree, those in the latter being more severe. Thus, in DH one observes steatorrhea (20%–30% of patients), abnormal D-xylose absorption (10%–33% of patients), and occasional anemia secondary to iron or folate deficiency. In patients not taking dapsone or related drugs, the latter is usually due to malabsorption. Studies using elemental diets (see Section "Elemental and Other Diet Therapy") in the treatment of DH have questioned the critical role attributed to gluten in the pathogenesis of this disease. In addition to the small intestinal lesion, patients with DH have an increased incidence of achlorhydria and atrophic gastritis.[79,80] Reports of pernicious anemia and antibodies to gastric parietal cells are thus likely to be due to more than chance.

MALIGNANCY

Leonard et al have reported an increased frequency of malignancies, especially gastrointestinal lymphomas, and Collin et al have reported a significant increase in non-Hodgkin lymphomas in patients with DH.[81,82] A combined retrospective study from both these groups suggests a protective role for a gluten-free diet against gastrointestinal lymphomas.[83] Hervonen and coworkers reported that 1% of 1,104 patients with DH developed a lymphoma from 2 to 31 years after the diagnosis of DH.[84] Of interest, only two lymphomas were of the enteropathy-associated type, whereas eight were B-cell type lymphomas and one was unclassified. The patients with DH that developed lymphoma had adhered to a gluten-free diet less strictly than patients without lymphoma.[84] Recently, Viljamaa and coworkers reported on the rate of malignancies and mortality in patients with DH with a 30-year population-based study.[85] They reported no difference in overall malignancy rate in patients with DH from the general population; however, there was an increase in non-Hodgkin lymphomas. Of interest, the mortality rate for patients with DH was lower than in the general population. Lewis et al utilized the General Practice Research Database in the United Kingdom to study a cohort of 846 DH patients and 4,225 matched controls. They report no increased risk of malignancy in the DH patients. The authors suggest a population bias of hospitalized patients in previous smaller studies resulted in either differences in the degree of intestinal inflammation or unrelated illnesses increasing frequencies of malignancy in the DH patients[86] These most recent studies suggest that patients with DH may not have an increased risk of malignancy although further studies are needed.

OTHER DISEASES

In addition to celiac disease, atrophic gastritis, and pernicious anemia (see Section "Gastrointestinal Manifestations"), DH patients have a higher incidence of other autoimmune diseases such as thyroid disease, insulin-dependent diabetes, lupus erythematosus, Sjögren syndrome, and vitiligo.[58,87,88] This predilection for associated autoimmune diseases may be due to the high frequency of the 8.1 ancestral haplotype in these DH patients.[89]

Neurologic disease has been reported in patients with isolated celiac disease, including epilepsy, ataxia, opsoclonus-myoclonus, and dementia; however, confirmation of these findings awaits confirmation with large epidemiologic studies.[90] Some authors have proposed that patients with DH may be at higher risk for these neurologic complications due to long-standing ingestion of gluten; however, Wills and coworkers found no evidence of immune-mediated neurologic disease in their evaluation of patients with DH.[91,92]

Patients with untreated celiac disease have also been found to have an increased frequency of bone loss.[93] Patients with DH frequently continue on gluten-containing diets with a long-standing, albeit low grade, malabsorption. Di Stefano demonstrated a significantly reduced bone mineral density in patients with DH on gluten-containing diets.[94] However, recently Abuzakouk et al in a study of 25 DH patients did not find evidence of bone disease or any relation with bone mineral density and the severity of enteropathy.[95] The authors suggest that the discrepancy between their report and that of Di Stefano may be due to the fact that in the latter study the DH patients were newly diagnosed. These findings suggest that for now patients with DH should be followed closely and those on gluten-containing diets be screened for potential decrease in bone density. If decreased bone mineral density is found, patients should be encouraged to begin a gluten-free diet.

BOX 61-1 DIFFERENTIAL DIAGNOSIS OF DERMATITIS HERPETIFORMIS

Consider

- Eczema
- Atopic dermatitis
- Papular urticaria
- Neurotic excoriations
- Bullous pemphigoid
- Pemphigoid gestationis
- Linear immunoglobulin A dermatosis
- Atopic dermatitis

Rule Out

- Scabies

DIFFERENTIAL DIAGNOSIS

DH may be confused with numerous other conditions because of its pleomorphic manifestations and the occasional lack of diagnostic lesions (Box 61-1). Neurotic excoriations, eczema, papular urticaria, transient acantholytic dermatosis, pemphigoid, pemphigoid gestationis, erythema multiforme, and various other dermatoses can be differentiated easily on the basis of histologic and immunologic criteria. Linear IgA disease may be more difficult to differentiate clinically and histologically, but it is distinctive immunologically. A high index of suspicion is very helpful in that even in the absence of primary lesions, DH can be diagnosed based on the typical in vivo–bound granular IgA deposits in normal-appearing skin.

TREATMENT

SULFONES

Diaminodiphenyl sulfone (dapsone), sulfoxone (diasone—not available in the United States), and sulfapyridine provide prompt improvement in symptoms and signs of the disease. Symptoms may abate in as few as 3 hours or as long as a few days after the first pill is taken, and new lesions no longer erupt after 1–2 days of treatment. Exacerbations occur from hours to days after cessation of treatment. This response to therapy was, for a long time, the most important element in making a diagnosis. The preferred treatment for an adult is dapsone at an initial dosage of 100–150 mg/day (this usually can be taken once a day). An occasional patient may require 300–400 mg of dapsone for initial improvement. Patients should be instructed to take the minimal dose required to suppress signs and symptoms. Not all patients require daily treatment; in rare cases, 25 mg weekly is sufficient. Sulfapyridine, in a dosage of 1.0–1.5 g daily, is particularly useful in patients intolerant of dapsone, in elderly patients, and in those with cardiopulmonary problems. The pharmacology, mechanism(s) of action, adverse effects, and monitoring of dapsone are discussed in Chapter 225. It is important to know that nonsteroidal anti-inflammatory drugs often exacerbate DH, even in patients taking dapsone.[96]

GLUTEN-FREE DIET

EFFECT ON THE SMALL INTESTINE. There is no doubt that the intestinal lesion in DH responds to dietary gluten withdrawal. The time course of the response in adults with DH is the same as that in adults with celiac disease.

EFFECT ON THE SKIN DISEASE. Strict adherence to a gluten-free diet will, after variable periods of time (from 5 months to 1 year), reduce or completely eliminate the requirement for medication in most, but not all, patients. The most extensive early study by Fry et al has been confirmed by several groups.[97] However, it is only the very highly motivated patient who can adhere to the diet, which requires counseling by a dietitian who is very familiar with its use.

ELEMENTAL AND OTHER DIET THERAPY

Studies in small numbers of DH patients have indicated that elemental diets (composed of free amino acids, short-chain polysaccharides, and small amounts of triglycerides) can be very beneficial in alleviating the skin disease within a few weeks.[98,99] The beneficial effect on the skin disease may be achieved even if the patient ingests large amounts of gluten.[98] Unfortunately, elemental diets are difficult to tolerate for long periods. Interestingly, complete resolution of the skin lesions of DH has also been reported by adherence to the high-protein, unlimited fat, low-carbohydrate diet popularized as the "Atkins Diet."[100] Further studies are needed to confirm this report.

Chapter 62 :: Inherited Epidermolysis Bullosa

:: M. Peter Marinkovich

EPIDERMOLYSIS BULLOSA AT A GLANCE

- Family of inherited genodermatoses characterized by blistering in response to minor trauma
- Blistering level categories: simplex, junctional, and dystrophic subtypes
- Cutaneous involvement varies from localized to widespread blistering, depending on subtype
- Extracutaneous involvement varies from none to severely debilitating or lethal
- Oropharynx, trachea, esophagus, eyes, teeth, nails, hair can be involved, depending on subtype
- Diagnosis is made by immunofluorescent and/or electron microscopy followed by DNA analysis

INTRODUCTION

Inherited epidermolysis bullosa (EB), is a family of diseases, with the common feature of blistering in response to mild trauma. Patients with EB can show blistering in the form of small vesicles or larger bullae, which can occur on both the cutaneous surfaces as well as on the mucosal tissues. The fragility of the skin and mucosa and the traumatic production of painful blisters are what all EB cases share in common. However, the distribution of the involvement, the depth of blister formation, any associated extracutaneous involvement and the severity of the blistering process vary with the different EB subtypes and depend on the underlying heritable molecular defect. Different EB subtypes also vary in the way in which blistered areas heal. The wound repair responses are often abnormal and can eventuate into chronic erosions, hypertrophic granulation tissue, scarring, or even invasive carcinoma. While the milder EB subtypes are associated with a normal lifespan and little or no internal involvement, the most severe recessively inherited forms are mutilating, multiorgan disorders that threaten both the quality and length of life.

A number of early studies identified the major subtypes of EB. Studies of von Hebra[1–3] were the first to distinguish pemphigus from inherited blistering and the term epidermolysis bullosa hereditaria was first suggested by Koebner.[4] Hallopeau was the first to distinguish between simplex (nonscarring) and dystrophic (scarring) forms of the disease[5] while Weber[6] and Cockayne,[7] Dowling and Meara[8] and Koebner[4] each described unique forms of epidermolysis bullosa simplex. Hoffman,[9] Cockayne,[10] Touraine,[11] Pasini,[12] and Bart[13] provided much of the information about subtypes of dystrophic epidermolysis bullosa. Herlitz described epidermolysis bullosa letalis,[14] which was later found to be a part of the third major category of epidermolysis bullosa: the junctional form. The application of electron microscopy toward diagnosis of epidermolysis bullosa led to the studies of Pearson[15] and collaborators who classified the patients not only on the basis of clinical findings but also on the existence of ultrastructural changes. A comprehensive classification of epidermolysis bullosa based on a combination of ultrastructural and clinical findings was completed in an early landmark treatise by Gedde-Dahl.[16] Recent major advances have led to the identification of protein and genetic abnormalities in most types of epidermolysis bullosa patients. These studies have led to an improved understanding of the biological basis of epidermolysis bullosa and, finally, a classification of epidermolysis bullosa based on genetic/protein defects, which provides a rational approach to specific molecular therapy.

ETIOLOGY AND PATHOGENESIS

OVERVIEW

Epidermolysis bullosa arises from defects of attachment of basal keratinocytes to the underlying dermis.

These defects can arise from inside the keratinocyte plasma membrane or extracellularly in the dermal–epidermal basement membrane zone (BMZ). Many tissues such as the skin and cornea, which are subjected to external disruptive forces, contain a complex BMZ composed of a group of specialized components that combine together to form anchoring complexes (Fig. 62-1). At the most superior aspect of the BMZ, keratin-containing intermediate filaments of the basal cell cytoskeleton insert upon electron dense condensations of the basal cell plasma membrane termed hemidesmosomes. Anchoring filaments span the lamina lucida connecting hemidesmosomes with the lamina densa and anchoring filaments. At the most inferior aspect of the BMZ, collagen VII-containing anchoring fibrils extend from the lamina densa into the papillary dermis and combine with the lamina densa and anchoring plaques, trapping interstitial collagen fibrils. Thus, the cutaneous BMZ connects the extensive basal cell cytoskeletal network with the abundant network of interstitial collagen fibrils in the dermis.[17,18]

KERATIN FILAMENTS

Keratins are obligate heteropolymers that are composed of pairs of acidic and basic monomers. The keratin pair 5 and 14 assembles together to form the extensive intermediate filament network of the basal cell cytoskeleton.[19] Keratins contain a central α-helical rod with several nonhelical interruptions as well as nonhelical carboxyl and amino-terminal regions. The regions of highest conservation between the keratins are located on the ends of the keratin rod in the helix boundary motifs. Extensive mutagenesis studies suggest that helical regions near the ends of the central rod are important in keratin filament elongation, whereas the nonhelical domains may be important in forming lateral associations.[20]

HEMIDESMOSOMES

Hemidesmosomes contain intracellular proteins, including plectin and BP230. Plectin is a 500-kDa protein, which acts as an intermediate filament-binding protein. It is possible that plectin also interacts with microfilaments, as plectin contains a domain with similarity to the actin-binding domain of spectrin.[21,22] BP230, also known as BPAG1, is a 230-kDa protein which has homology both to desmoplakin[23] and to plectin. Several splicing variants of BP230 are of vital importance in the nervous system.[24–26] BP230 localizes to a region referred to as the inner plate on the cytoplasmic surface of the hemidesmosome and like plectin, functions in the connection between hemidesmosomes and intermediate filaments. BP230 negative transgenic mice lack a hemidesmosomal inner plate and the connection between hemidesmosomes and intermediate filaments is severed, creating a cytoplasmic zone of mechanical fragility just above the hemidesmosomes.

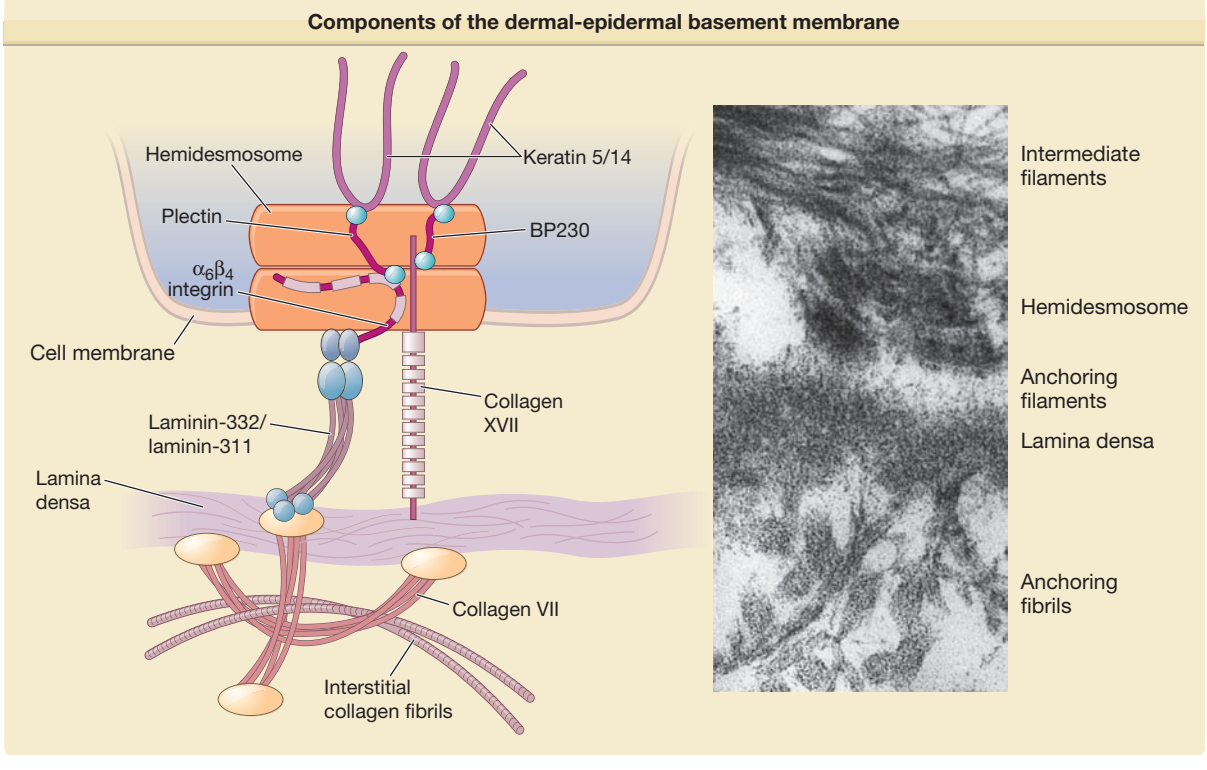

Figure 62-1 Schematic of the components of the dermal–epidermal basement membrane (*left*) compared with ultrastructural appearance of basement membrane morphological entities (*right*).

ANCHORING FILAMENTS

Hemidesmosomes also contain the transmembrane proteins collagen XVII (also termed BPAG2 and BP180)[27] and α6β4 integrin.[28] The cytoplasmic portions of these molecules make up part of the hemidesmosome dense plaque. The extracellular portions of these molecules make up portions of the anchoring filament that probably contribute to the structure known as the subbasal dense plate, which underlies hemidesmosomes in the lamina lucida region. β4 integrin only pairs with the α6 subunit, whereas the α6 subunit can combine either with the β4 integrin or with the β1 integrin. Both the α6β1 or α6β4 integrin combinations have been shown to act as receptors for laminins, but only α6β4 integrin acts as a specific receptor for laminin-332. α6β4 integrin plays a central role in organization of the hemidesmosome. The β4 integrin contains an especially large cytoplasmic domain, which functions in the interaction with other proteins of the hemidesmosomal plaque, including collagen XVII and plectin.[29] Skin from transgenic mice lacking β4 integrin is devoid of hemidesmosomes and shows severe deficits in cell adhesion.[30] Interactions between plectin and α6β4 integrin appear to be critical both in the assembly as well as the disassembly of hemidesmosomes.[31]

Collagen XVII (BPAG2, BP180) is a collagenous protein with a type II transmembrane orientation. Based on electron microscopy and cross-linking studies, collagen XVII assembles into a triple-helical homotrimer and contains three main regions: (1) an intracellular amino-terminal globular head, (2) a central rod, and (3) an extracellular flexible tail.[32] Collagen XVII associates with laminin-332 and α6β4 integrin in adhesion structures termed stable anchoring contacts. These stable anchoring contacts are formed by keratinocytes in vivo, and are thought to represent prehemidesmosomes.[33] The autoantigen in linear immunoglobulin (Ig) A bullous dermatosis, LAD-1[34,35] is a 120-kD protein which has been shown by peptide sequencing to be the cleaved exodomain of collagen XVII.[36] Collagen XVII undergoes processing in keratinocyte cultures and in skin through the action of sheddases, membrane-associated proteases that solubilize cell surface receptors.[37–39]

In addition to α6β4 integrin and collagen XVII, anchoring filaments contain the molecules laminin-332 and laminin-311. Like all members of the family of laminin proteins,[40–42] laminin-332 is a large heterotrimeric molecule, and contains α3, β3, and γ2 chains.[43,44] The first laminins to be described contained three short arms and one long arm, forming a cross shape as shown by rotary shadowing analysis. In contrast, laminin-332 contains truncations of each short arm.[45–47] Because of these short arm truncations, laminin-332 cannot self-polymerize with other laminins or bind to nidogen. Instead, laminin-332 forms a disulfide-bonded attachment to laminin-311,[48] the other known anchoring filament laminin[49] which contains α3, β1, and γ1 chains. Laminin-332 also undergoes processing of its γ2 and α3 chains.[50] While the rat laminin γ2 chain has been previously been shown to be processed by metalloproteinase-2[51] and membrane type metalloproteinase type 1,[52] the predominant site of cleavage by these enzymes is not conserved in human laminin-332.[53] Other studies have shown that processing of laminin γ2 chain takes place through a special class of proteins termed *C*-proteinases which also process *C*-terminal domains of procollagen molecules.[54] While one member of this class of proteins, bone morphogenic protein 1,[55] is capable of performing this action, a splice variant of bone morphogenic protein 1 (mammalian tolloid) is predominantly expressed in keratinocytes and fibroblasts and thus likely performs this function in the skin.[53] Mammalian tolloid also processes the laminin α3 chain,[53] although other enzymes such as plasmin,[56] matrix metalloproteinase 2[51] or membrane type matrix metalloproteinase 1[52] are also capable of this function. The γ2 chain short arm appears important in the assembly of laminin-332 into basement membrane.[57] The antigen recognized by mAb 19-DEJ-1[58] also localizes to anchoring filaments but its molecular identity remains unknown.

ANCHORING FIBRILS

Collagen VII is the major constituent of anchoring fibrils. Analysis of the deduced amino acid sequence of collagen VII[59] reveals the presence of a long central collagenous region characterized by repeating Gly-X-Y sequences that contains a number of noncollagenous interruptions, including a 39 amino acid noncollagenous segment in the center of the helix which corresponds to the "hinge region" predicted by biochemical studies.[60,61] These interruptions account for the flexibility of the collagen VII molecule, and explain its ability to loop around and entrap dermal matrix molecules, thus stabilizing the basement membrane to the underlying papillary dermis.[62] A 50 KDa component of anchoring fibrils has also been identified which appears to localize to the insertion sites of anchoring fibrils to the lamina densa.[63]

The 145-kDa *N*-terminal end of collagen VII contains the largest noncollagenous domain, which inserts onto the lamina densa and anchoring plaques. Collagen IV, the most abundant component of these structures, binds to the collagen VII NC-1 domain. A direct interaction between anchoring filaments and anchoring fibrils exists from a specific interaction between the anchoring filament component laminin-332 and the collagen VII NC-1 domain.[64,65] Collagen VII binds the β3 chain on laminin-332.[64,66–68] This appears to be a critical factor in the maintenance of dermal–epidermal cohesion. Like all collagens, collagen VII assembles into a triple helix. Only one gene and one chain of collagen VII, the α1 chain, have been identified, and thus collagen VII is a homotrimer. Collagen VII triple helices are joined together at their processed NC-2 globular domains to form antiparallel dimers.[62,69] Processing of the NC-2 domains takes place via the same family of *C*-proteinases (bone morphogenic protein 1 and/or mammalian tolloid) that are known to process laminin-332, a closely associated molecule. Anchoring fibrils may derive from lateral associations of collagen VII antiparallel dimers.

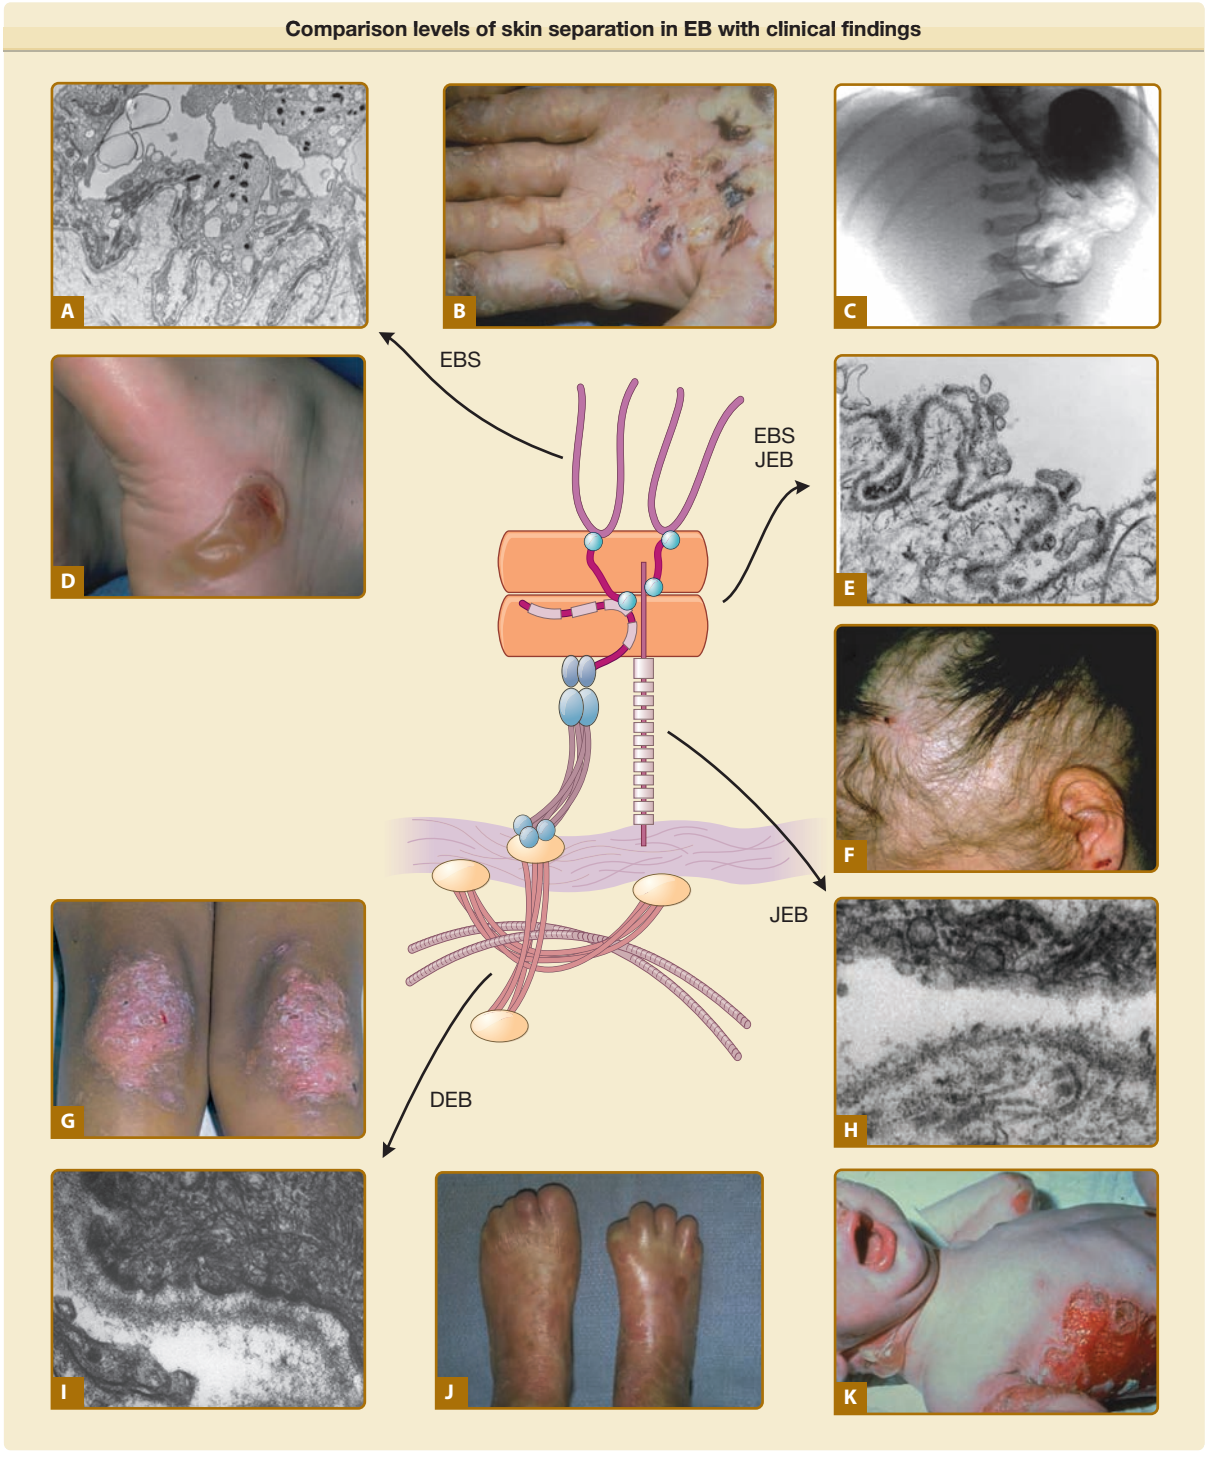

Figure 62-2 Comparison of levels of skin separation in EB with clinical findings. **A.** Transmission electron micrograph showing typical intraepidermal separation in EBS. **B.** Palmar hyperkeratosis and erosions in EB herpetiformis. **C.** Radiograph showing pyloric atresia associated with EB. **D.** Localized blister on heel in EBS Weber–Cockayne. **E.** Transmission electron micrograph showing typical separation at level of hemidesmosome in EB with pyloric atresia, alternatively classified as EBS or JEB. **F.** Nonscarring diffuse alopecia and scalp erosions in generalized atrophic benign epidermolysis bullosa. **G.** Localized dystrophic changes with milia in dominant DEB. **H.** Transmission electron microscopy showing typical intralamina lucida separation in JEB. **I.** Transmission electron microscopy showing typical sublamina densa separation in DEB. **J.** Pseudosyndactly in recessive DEB. **K.** Generalized blistering in Herlitz JEB. EBS = epidermolysis bullosa simplex; DEB = dystrophic epidermolysis bullosa; JEB = junctional epidermolysis bullosa.

CLINICAL FINDINGS

Epidermolysis bullosa has been traditionally classified according to the level of BMZ separation on transmission electron microscopy into simplex, junctional and dystrophic subtypes,[70] (Fig. 62-2). Although this ultrastructural "gold standard" for diagnostic grouping of EB has been electron microscopy, immunomapping of basement membrane antigens as viewed by indirect immunofluorescence can also be quite useful in distinguishing subtypes of EB as well as from other disorders in the differential (see Box 62-1) and is considerably less labor intensive. Within each of these groups there are several distinct types of EB based on clinical, genetic, histologic, and biochemical evaluation.[71] These findings are summarized below (Table 60-1).

BOX 62-1 DIFFERENTIAL DIAGNOSIS OF EPIDERMOLYSIS BULLOSA

Most Likely

- Pompholyx
- Insect bites
- Friction blisters
- Thermal burns
- Bullous impetigo

Consider

- Chronic bullous dermatosis of childhood (linear IgA disease)
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Bullous systemic lupus erythematosus
- Cicatricial pemphigoid
- Pemphigus vulgaris

Always Rule Out

- Stevens–Johnson syndrome
- Toxic epidermal necrolysis

EPIDERMOLYSIS BULLOSA SIMPLEX

Epidermolysis bullosa simplex (EBS) is a disease group characterized by intraepidermal blistering and most often is associated with keratin gene mutations. The disease phenotypes range from mild to severe among different subgroups.[72] The common EBS types are dominantly inherited and include Dowling–Meara (Herpetiformis) EBS, generalized (Koebner) EBS, and localized (Weber–Cockayne) EBS. There are several uncommon varieties that include EBS Ogna, EBS with muscular dystrophy, EBS with mottled pigmentation, EBS associated with *BP230/BPAG1* mutation, and a group of suprabasal EBS subtypes. EBS is not usually associated with growth retardation or anemia.

DOWLING–MEARA EBS. This subtype presents at birth, has a generalized distribution and is regarded

TABLE 62-1
Classification of Epidermolysis Bullosa

Level of Separation	Disease	Defect
Simplex	Generalized	KRT5/KRT14
Simplex	Dowling–Meara	KRT5/KRT14
Simplex	Localized	KRT5/KRT14
Simplex	Ogna	KRT5/KRT14/PLEC1
Simplex	Mottled pigmentation	KRT5/KRT14
Simplex	EB with muscular dystrophy	PLEC1
Simplex	Superficialis	KRT5/KRT14
Simplex	Ectodermal dysplasia-skin fragility	PKP1
Junctional[a]	EB with pyloric atresias	ITGB4/ITGA6/PLEC1
Junctional	Herlitz	LAMB3/LAMA3/LAMΓ2
Junctional	Non-Herlitz	LAMB3/LAMA3/LAMG2/COL17A1
Junctional	Localized	COL17A1
Dystrophic	Generalized dominant	COL7A1
Dystrophic	Localized dominant	COL7A1
Dystrophic	Recessive	COL7A1
Variable	Kindler syndrome	KIND1

[a]Alternatively classified as simplex.

Figure 62-3 Characteristic blister formation on trunk and arm in patient with Dowling–Meara EBS.

as the most severe of the EBS subtypes (Fig. 62-3). However, it differs from the Koebner variant in that the oral mucosa is more often involved, occasionally showing extensive erosions. Milium formation may sometimes occur in infancy in patients with this subtype; however, this postwound phenomenon usually resolves after infancy. The disease can often be associated with spontaneous appearance of grouped or "herpetiform" blisters. These occur on the trunk and proximal extremities and heal without scarring. It should be noted that this herpetiform pattern may not be seen when patients show a generalized blistering. Therefore, its absence should not be used as a basis to exclude this EB subtype. Dowling–Meara EBS often shows nail involvement, with shedding and regrowth with dystrophy or long nails with subungual hyperkeratosis. Hyperkeratosis of the palms and soles often develops beginning in early childhood and can progress to confluent keratoderma of the palms and soles. These can be quite painful and, occasionally, interference with ambulation has led to flexural contractures. Esophageal involvement in Dowling–Meara has occasionally been reported, and ranges ranging from erosions to pyloric atresia.[73] The upper respiratory tract can also be affected, including the laryngeal mucosa.[74] Natal teeth have been described.

GENERALIZED EBS. The other common form of generalized EBS is also known as the Koebner EBS. This subtype shows an onset of generalized blistering at birth or at latest during early infancy. The hands, feet, and extremities usually show the most involvement. Lesions often heal with postinflammatory hyper- or hypopigmentation. Atrophy and milia can occur, but are much less frequent than in Dowling–Meara EBS. Palmoplantar hyperkeratosis and erosions may be present (Fig. 62-4). Thickening of the soles is common, but often does not present until later childhood. The oral mucosa sometimes shows mild erosive activity but these usually improve with increasing age.

LOCALIZED EBS. This is the mildest form of EB and is often referred to as the Weber–Cockayne subtype of EBS (Fig. 62-5). This disease is the most common form

Figure 62-4 Widespread blistering in an infant with generalized EBS.

of EB and often presents during infancy or childhood. Occasionally, it presents in early adulthood, such as when blisters are noted following marching during military service. It is speculated that there are a number of undiagnosed cases of this form of EB, as it can be mild enough to escape reporting or detection during clinical visits. Hyperhidrosis of the palms and soles is a common association. Blisters can occasionally become secondarily infected. Postinflammatory pigmentary abnormalities occur with this variant, but milia and scarring as a rule are absent. Blistering activity usually follows areas of trauma, with hands and feet being the most common and the scalp being the least common. Mild oral erosions are present only rarely and usually

Figure 62-5 Trauma-induced blistering from clothing in patient with localized EBS.

resolve with increasing age. Nail involvement is rare with this EB subtype.

ADDITIONAL VARIANTS OF EBS

EBS of Ogna. Onset in infancy is common with seasonal blistering (summer) on the acral areas. Small hemorrhagic and serous blisters occur primarily on the extremities. Healing occurs without scarring. This disease was originally reported in patients from Norway. These patients also show a characteristic onychogryphosis of the great toenails.

EBS with Muscular Dystrophy. This rare clinical entity is an autosomal recessive disorder which consists of generalized blistering of the skin at birth or shortly thereafter. This is accompanied by a progressive muscular dystrophy.[75] It presents with generalized blistering similar to EBS of Koebner clinically. These patients have been shown to harbor mutations in the gene coding for HD1/plectin.[76–78] Mutations in plectin can also cause EB with pyloric atresia (see Junctional EB with Pyloric Atresia) and be difficult to distinguish clinically from disease resulting from integrin mutations.

EBS with Mottled Pigmentation. This form of EB, as its name implies, is characterized by mottled hyperpigmentation of the trunk and proximal extremities. Blistering tends to be mild, and begins at birth or early infancy. Pigmentary alterations appear reticulated and increase with advancing age, as blistering may improve. Mild oral mucosal involvement may be present in infancy. This progressive pigmentation is distinct from the large melanocytic nevi, which can be seen in all three EB types.[79]

Suprabasal EBS Subtypes. *EBS superficialis* is an uncommon form of EBS, named after the subcorneal separation that produces the blisters in this disease.[80] Erosions and crusts, rather than intact bullae, are usually seen in these patients, and heal with postinflammatory pigmentary changes. Despite the superficial cleavage plane, nail involvement. Atrophic scarring and milia have been observed in this disease.

Lethal acantholytic EBS[81] is a rare recessively inherited and lethal disorder characterized by generalized erosions at birth. As in the superficialis subtype, intact blisters are not normally seen, due to the very superficial level of epidermal separation, which appears sheet-like. Nails are dystrophic to absent. Complete alopecia, neonatal teeth, oral erosions, and respiratory involvement distinguish this disorder from other superficial EBS subtypes.

Ectodermal dysplasia skin fragility syndrome is another inherited disorder of suprabasilar epidermal separation, characterized by generalized erosions and sometimes superficial blisters at birth.[82] Alopecia is characteristic, as are palmoplantar keratoderma, painful fissures and nail dystrophy. Patients may sometimes demonstrate failure to thrive, cheilitis, hypohidrosis, and pruritus as well. Like the other superficial EBS subtypes, this disorder is associated with dystrophic nails.

MOLECULAR PATHOLOGY OF EBS. Most of the patients with EB simplex analyzed at the genetic level have been found to be associated with mutations of the genes coding for keratins 5 and 14.[20,72] The level of separation of the skin in these patients is at the midbasal cell, shown in Fig. 62-2A, associated with variable intermediate filament clumping. Hemidesmosomes and other BMZ structures are normal by electron microscopy. The majority of keratin gene mutations associated with epidermolysis bullosa simplex are dominantly inherited due to abnormalities in the multimeric assembly of keratin filaments. There is a smaller subset of patients with recessively inherited disease of varying severity.[83,84]

Mutations coding for the most highly conserved regions of keratins 5 and 14, the helix boundary domains,[85] correlate with the most severe form of EBS, the Dowling–Meara subtype, which exhibits intermediate filament clumping seen by transmission electron microscopy. On the other hand, milder types of disease, such as the Weber–Cockayne subtype, are associated with mutations coding for regions of keratins 5 and 14 that are less conserved. Mutations that code for a specific region of the amino-terminus of keratin 5 are present in patients having EBS with mottled pigmentation.[86] Although significance of this type of mutation and its association with pigmentary abnormalities remains unclear,[87,88] it has been suggested that the keratin 5 globular head domain is responsible for keratin filament insertion onto melanosomes. Recent studies have shown that some mutations of the keratin 5 gene may produce protein which is unstable under increased temperatures.[89] This could help to explain the well-observed exacerbation of some subtypes of EBS to warm temperatures.

The mutations associated with EBS with muscular dystrophy produce premature termination codons, splice site, or other mutations which result in lack of expression or defective expression of plectin.[90] Although the form of EB associated with plectin abnormalities is classified as simplex, it has an identical level of skin separation to that seen in junctional epidermolysis bullosa (JEB) with pyloric atresia. Specifically the separation is present just above the level of the hemidesmosome in the intracellular part of the BMZ. This separation of EBS with muscular dystrophy and JEB with pyloric atresia, diseases with identical levels of separation, into two distinct EB categories illustrates the limitations of the current EB classification system. Plectin defects, like α6β4 integrin defects, can also be associated with pyloric atresia.[90]

Plectin is normally expressed in a wide range of tissues, including muscle.[21] While the mechanism of muscular dystrophy in plectin-deficient patients is unknown, it has been observed that disorganization of muscle sarcomeres occurs in the absence of plectin. It is possible that absence of plectin's spectrin-like domain, which may normally interact with actin filaments in muscle, may be a key factor in the muscle pathology.[91] Interestingly, a case report of autosomal recessive EBS has been recently identified to be associated with both muscular dystrophy and pyloric atresia.[92] This case

was associated with homozygous premature termination codon mutations in the plectin gene causing a significant loss of plectin expression in the skin.[92]

Recently, another unique case of recessive dominant EBS has been identified, this one associated with null mutations of the dystonin gene coding for BP230/BPAG1.[93] Inherited blistering/skin fragility described with this defect was associated ultrastructurally by loss of hemidesmosomal inner dense plate and a concomitant reduction of other hemidesmosomal proteins, presumably by loss of BP230 stabilization. This patient's blistering was also accompanied by a neuropathy, which may be part of the inherited defect, since a splice variant of this molecule has a neural distribution.

The underlying molecular defect of ectodermal dysplasia skin fragility syndrome has been shown to be loss of function of the desmosomal protein plakophilin 1, encoded by PKP1.[94,95–100] Plakophilin is expressed mainly in suprabasilar keratinocytes and outer root sheath cells. Microscopic findings in this disease are usually intraepidermal acantholysis, located in the areas where plakophilin 1 is normally expressed.

JUNCTIONAL EB

All patients with JEB share the common histopathologic feature of blister formation within the lamina lucida of the BMZ due to defects of anchoring filaments located in the lamina lucida and superior lamina densa. This group of diseases is inherited in an autosomal recessive manner and there is considerable variation of the individual clinical phenotypes depending on the molecular defect. Three principal forms of JEB are most common. Herlitz disease, JEB gravis or lethal JEB are each used to describe patients presenting with the most severe and most common phenotype.[14,101]

HERLITZ JEB. Patients with Herlitz JEB, also known as JEB letalis, is one of the most severe EB subtypes and is lethal in most affected children during infancy or early childhood.[102] This disorder is characterized by generalized and often extensive blistering at birth (Fig. 62-6). Later during infancy, a distinctive perioricial granulation tissue begins to manifest, primarily around the mouth, eyes, and nares. The scalp, periauricular areas and, less frequently, locations outside of the head and neck may also be affected. This hypertrophic granulation tissue much less commonly occurs in nonlethal subtypes. Nails are usually severely affected and often are lost during infancy. The presence of nail involvement with periungual hypertrophic granulation tissue during the neonatal period can be a clue to this diagnosis. When nails are still present, they are usually dystrophic. Tooth enamel pitting is characteristic in both primary and secondary teeth, and can progress after tooth eruption. Oropharyngeal mucosal erosions are usually present and may be widespread. Erosions of all stratified squamous epithelial tissues, including nasal, conjunctival, esophageal, tracheal, laryngeal, rectal, and urethral mucosa can be affected. Associated systemic findings in severe cases are important factors in the lethality of this disease. Involvement of the large airways, including tracheolaryngeal stenosis or obstruction, is commonly associated with Herlitz JEB disease and hoarseness in early infancy is an ominous sign. There is a characteristic failure to thrive and growth retardation in this disease, often with a mixed anemia. Sepsis is a common and often lethal complication.

NON-HERLITZ JEB. (Figs. 62-7 and 62-8). Sometimes patients initially presenting with a Herlitz-like phenotype will survive infancy and clinically improve with age. These patients eventually prove to have a severity of blistering and oral erosions less than in the lethal form. In particular, a lack of significant hoarseness is regarded as a favorable prognostic sign, indicative of less severe internal disease manifestations. Scalp and nail lesions, as well as perioricial nonhealing erosions with exuberant granulation tissue are among the most common findings in these patients during childhood. Despite the lack of lethality in infancy, these patients nonetheless can have severe epithelial adhesion abnormalities. Tracheostomies or gastrostomy tubes may help in patient survival. The

Figure 62-6 Widespread blistering at birth in an infant with Herlitz JEB.

Figure 62-7 Perioricial erosions and hypertrohic granulation tissue in a patient with non-Herlitz JEB.

Figure 62-8 Loss of nails and skin atrophy a patient with non-Herlitz JEB/generalized atrophic benign EB.

nonlethal status of these patients distinguishes them from the Herlitz group and the terms nonlethal JEB or JEB mitis have been used in the past to describe these patients. They are much less common than Herlitz EB patients. There are other rare variants of nonlethal JEB that present with localized junctional blistering of the extremities or intertriginous areas.

Interestingly, the association of hypertrophic granulation tissue and laminin-332 defects has been noted in another group of patients with mutations of the laminin α3 (*LAMA3*) gene leading to a small truncation of the *N*-terminal IIIa domain of the laminin α3 chain. This disease, termed laryngo-onycho-cutaneous syndrome, is characterized by a triad of cutaneous erosions, nail dystrophy, and exuberant mucocutaneous granulation tissue, especially in the conjunctiva and larynx.[103] An experimental animal model of engineered laminin-332 deletions has been recently described which recapitulates this hypergranulation tissue phenotype.[104]

Generalized atrophic benign EB (GABEB) is a distinct subset of non-Herlitz JEB that also presents at birth with generalized cutaneous involvement.[105] Despite the widespread cutaneous blistering, there is a relative paucity of oral erosions or other mucosal disease. While enamel pitting is present, resulting in extensive dental caries, and nail dystrophy can often be severe, there is little other extracutaenous involvement noted in these patients. The blisters in these patients, which heal with a characteristic atrophic scarring, are debilitating and can be widespread, but nonetheless these patients generally have a normal lifespan. Blistering improves with age, growth is normal and anemia is uncommon. Some patients with this disease have undergone normal uncomplicated pregnancies and deliveries. One peculiar characteristic of these patients is a progressive alopecia of the scalp and terminal hairs elsewhere in the body. The hair loss starts to become severe after the onset of puberty. While patchy hair loss associated with atrophic scarring has been described, often the alopecia is quite diffuse and scarring is subtle or nonexistent.

LOCALIZED JEB. A very rare subtype of JEB is the localized variant, also known as minimus JEB. These patients generally show mild disease that can be accentuated in localized areas, most often the hands, feet and pretibial regions. Nails can sometimes be shed or become dystrophic, and enamel pitting can occur. Oral or nasal erosions can also occur; however, there is absence of any internal involvement. These patients generally have a favorable prognosis and a normal lifespan.

JEB WITH PYLORIC ATRESIA. These patients exhibit extreme mucosal and cutaneous fragility and may also have various urological abnormalities, including hydronephrosis, and nephritis, and rudimentary ears. Mutations of the genes coding for the β4 and α6 integrin are associated with EB[106] and in which pyloric atresia. Plectin mutations can also be associated with EB and pyloric atresia, although the the integrin mutations are more reliably associated with pyloric atresia. In these patients, hemidesmosomes are usually absent or rudimentary, and the level of separation is intraepidermal at the level of the hemidesmosome as seen in EBS with muscular dystrophy described above. The skin ultrastructure in patients with α6β4 defects is remarkably similar to the β4 integrin knockout mice described above; however, the mice do not show pyloric atresia. These studies illustrate well that there are limitations in the utility of animal models to study human epidermolysis bullosa. Most cases of this disease are quite severe and lethal in infancy, due to extensive extracutaneous epithelial sloughing, in addition to widespread blistering of the skin and mucosa. Rare nonlethal cases of this disease have been characterized which appear to result from a partial loss of function of β4 integrin.[107] Interestingly, nonlethal JEB can sometimes ameliorate itself through alterations in mRNA splicing.[108,109]

MOLECULAR PATHOLOGY OF JEB. JEB can be associated with mutations of the genes coding for any of the α3, β3, or γ2 subunits of laminin-332.[110,111] Absence of any of the three chains results in a lack of trimeric laminin-332 assembly and secretion, which results in a similar blistering phenotype. Patients with mutations of genes coding for the α3 or γ2 laminin subunits will still show normal expression of laminin-311, which contains α3, β1, and γ1 chains.[44] Therefore, positive linear BMZ staining of JEB skin for the α3 chain on immunofluorescence mapping studies with absent expression of the other chains is an indication of either a α3 or γ2 chain defect. Conversely, absence of α3 staining on immunofluorescence can be indicative of a mutation of the α3 gene. About 80% of laminin-332 mutations can be traced to one of two recurrent nonsense mutations in the *LAMB3* gene, making prenatal testing for laminin-332 lesions easier than other EB candidate genes.[112] In the Herlitz patients, all of the mutations so far detected have been those producing

premature termination codons, resulting in absence of expression of laminin-332. While Herlitz cases generally show a complete lack of expression of laminin-332, non-Herlitz patients with abnormal granulation tissue and significant mucosal involvement often show reduced expression of laminin-332. This is due to deletions or missense mutations that result in partial loss of laminin-332 function.[113–115] In some cases, spontaneous amelioration of blistering in severe junctional epidermolysis bullosa cases has taken place, leading to the expression of laminin-332.[109]

In the GABEB variant of non-Herlitz JEB, blistering occurs in the lamina lucida region and abnormalities of hemidesmosomes/anchoring filaments are usually present (Fig. 62-3). While laminin-332 mutations underlie a subset of GABEB patients, the majority of these patients have abnormalities of the hemidesmosomal protein collagen XVII (also known as BP180 or BPAG2). A number of mutations of the gene coding for collagen XVII have been described in GABEB patients, including premature termination codon mutations, missense mutations, splice site mutations, truncations, and a glycine substitution mutation.[111,116] While intralamina lucida/junctional skin separation has been shown in all patients with this disease, one patient was described with a cytoplasmic deletion of collagen XVII who showed intrabasal epidermal skin separation.[117] Localized junctional EB has been shown to be associated with COL17A1 mutations.[118]

Of interest, mosaic GABEB patients have been identified who demonstrate well-defined areas of blistering associated with absence of collagen XVII expression as well as areas of nonblistering skin associated with normal collagen XVII expression. Careful analysis of these patients' keratinocytes revealed reversion of one of the two alleles of the mutation, most likely due to a mitotic gene conversion involving nonreciprocal exchange of parental allele DNA.[119,120] It is possible that this phenomenon of mutational rescue of genes affecting recessive cases of EB is more widespread that currently reported and more careful examination of involved and uninvolved regions of EB skin undoubtedly will reveal more cases. Understanding how epidermolysis bullosa can undergo spontaneous molecular correction (revertant mosaicism) in these cases could help in the design of future molecular therapeutic strategies.

DYSTROPHIC EB

Dystrophic EB (DEB) is characterized by blisters that heal with scarring and milium formation. DEB can be inherited either in an autosomal recessive (RDEB) or dominant fashion (DDEB). One of the most important reasons to distinguish between these two subtypes is the increased prevalence of invasive squamous carcinoma associated primarily with the recessive form. Regardless of the mode of inheritance, DEB is derived from defects of the ultrastructural entity known as the anchoring fibril, which results in sublamina densa separation.

LOCALIZED DDEB. The localized subtype of dominant DDEB (sometimes called the Cockayne–Touraine of DDEB) can present at birth, but occasionally it is not appreciated until childhood. While generalized blistering can take place especially early in life, the blistering usually becomes localized to repetitively traumatized areas such as knees, sacrum, and acral surfaces (Fig. 62-9). These areas show a characteristic scarred, dystrophic appearance. Often the scarring is hypertrophic. Milia are common accompanying features of the healing process in these patients. Nail dystrophy or nail loss with atrophic scarring of the distal digits are common. Occasionally, nail abnormalities can be the only presenting abnormality in DDEB. Oral lesions are not common and teeth are usually unaffected. These patients have a good prognosis and a normal lifespan.

Figure 62-9 Localized trauma-induced blistering with secondary milia in a patient with dominant DEB.

GENERALIZED DDEB. The generalized form of DDEB (sometimes referred to as the Pasini subtype of DDEB) presents at birth with a generally more severe and widespread blistering phenotype compared to the localized subtype. Blisters in generalized DDEB heal with scarring plaques and milia, in a fashion similar to other DEB subtypes. In addition, this disease is sometimes distinguished by the spontaneous appearance of distinctive scar-like flesh colored papules on the trunk. These albopapuloid lesions are not pathognomonic, and can also be seen in other EB subtypes. As the patients get older the generalized blistering may eventually localize to the extremities. Patients often show dystrophic or absent nails. Oral erosions can often be present, but usually are not extensive, and enamel defects can be seen in some patients. A rare variant of self-remitting generalized DDEB, termed bullous dermolysis of the newborn, consists of generalized blistering that gradually recedes after infancy.[121]

RECESSIVE DEB. Recessive DEB (RDEB) can be quite variable in its severity. While the severe subtype is the most common, a localized form can occasionally be seen which has been termed RDEB mitis. Similar to localized DDEB, localized RDEB is usually confined to repetitively traumatized skin surfaces, most often in an acral distribution. Scarring and milium formation

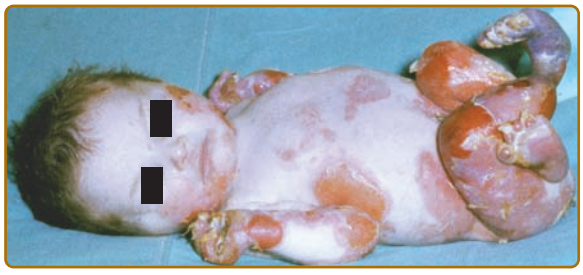

Figure 62-10 Widespread blistering with localized absence of skin at birth in a patient with recessive DEB.

accompany the healing of blisters. Mucosal involvement in localized RDEB, if present, is mild.

Severe RDEB, also known by the eponym the Hallopeau–Siemens, is a devastating disease (Fig. 62-10). This disease presents with generalized blistering at birth. Occasionally, there is extensive denudation of an entire region of skin at birth, often involving one of the limbs. This congenital absence of skin is sometimes termed Bart's syndrome, and has been described with all three major subtypes of EB. In RDEB, healing and blistering cycles occurring during infancy can lead to a progressive scarring which can become quite extensive. Pseudosyndactyly, resulting from a closure of the digits in a "mitten" of skin, is extremely common in this disease (Fig. 62-2J). Scarring can lead to flexion contracture of the hands, as well as the limbs. In contrast to the severe JEB patients, these patients do not show significant periorificial involvement. Instead, the scalp is the most commonly affected area on the head and neck of these patients. Alopecia is progressive, often without significant associated blistering.

The oropharynx can be extensively involved in both dominant and recessive DEB (Fig. 62-11) with generalized erosions evolving into a scarring which limits the movement of the tongue and narrows the opening of the oral cavity. The teeth can show significant enamel pitting, and caries can be extensive, leading to loss of teeth. Involvement of the trachea or larynx can lead to a narrowing of the airway, which can require intervention with a tracheostomy. Mucosal erosions of the esophagus can lead to stricture formation and webbing. The combination of oral lesions, dental caries, esophageal strictures, and increased caloric needs from extensive wound healing can lead these patients toward malnutrition and growth retardation. These patients usually have problems with anemia and may show a deficiency of iron absorption.

Figure 62-11 Oral erosions in a patient with dominant DEB.

In the past, most severe RDEB patients died in infancy of sepsis and other complications of extensive blistering. With improved nutritional, infection, and wound support, these patients now usually can survive into their teens or into adulthood. However, after puberty, another devastating complication, squamous cell carcinoma, can, and often does, appear. It is estimated that 50%–80% of HS-RDEB patients eventually develop these carcinomas and many of these die of metastatic disease. RDEB-associated carcinomas are distinct from other cutaneous squamous cell carcinomas in that they are extremely aggressive with strong tendencies for invasion and metastasis.

MOLECULAR PATHOLOGY OF DEB. Abnormalities of anchoring fibrils are present in DEB patients, ranging from subtle changes in some patients with dominant disease, to absence of anchoring fibrils in patients with RDEB. A sublamina densa plane of blister cleavage is present in all dystrophic blistering (Fig. 62-3). These observations correlate with immunofluorescent microscopic analysis of DEB patients, which demonstrates varying degrees of linear basement membrane staining in dominant patients and total absence of staining in severe recessive patients. In some patients, there is cytoplasmic retention of collagen VII in patient keratinocytes.[122]

Dystrophic EB has been shown to be associated in all cases thus far with mutations of the gene coding for collagen VII (*COL7A1*). In the recessive forms, mutations usually cause premature termination codons, leading to lack of collagen VII in tissue. It is known that mRNAs bearing premature stop codons show accelerated turnover.[123] In addition, truncated proteins that are not secreted or not assembled into anchoring fibrils may also show accelerated turnover. Either or both of these mechanisms can explain the lack of detectable collagen VII in the tissue of individuals with severe RDEB whose mutations lead to premature termination.[62,124,125] Recently, a revertant mosaicism phenotype has also been reported in RDEB.[126]

Generally, *COL7A1* mutations that do not cause premature termination codons produce less severe disease.[110,116] In particular, mutations which produce glycine substitutions of the triple helical region interfere with triple helical assembly of the collagen VII molecule. These types of mutations are present in many patients with milder dominant forms of this disease. In these patients, collagen VII molecules may not be able to assume the proper conformation needed to polymerize into anchoring fibrils. One subtype of DEB

associated with increased pruritus, EB pruriginosa, has also been associated with glycine mutations.[127] Other *COL7A1* mutations have been associated with impaired secretion of collagen VII, resulting in intracellular accumulation of this molecule. In one study, DEB patient mutations that involve the area of the gene coding for the collagen VII NC-2 domain were shown to interfere with NC-2 processing and the assembly of anchoring fibrils.[128]

KINDLER SYNDROME

New advances in our understanding of the molecular pathology of the skin have brought to light the underlying pathophysiology of a disease related to EB, Kindler syndrome. Kindler syndrome was first described by Theresa Kindler in 1954.[129] It is characterized by EB-like trauma-induced blistering at birth and during infancy, with atrophic changes during healing reminiscent of junctional or dystrophic EB.[130–136] However, in later childhood, the blistering usually subsides, and gives way to a progressive poikiloderma which distributes to sun-exposed areas. The poikiloderma may show areas of atrophy and hyperkeratosis, as well as hypopigmentation, hyperpigmentation, and telangiectasias. These patients often show photosensitivity. Nail changes and webbing of the toes and fingers are also sometimes present. Internal complications include oral inflammation, esophageal, or ureteral strictures and ectropion. Ultrastructurally, these patients show reduplication of the basement membrane, which is the most consistent feature seen. While there is often a sublamina densa split with anchoring fibril abnormalities, sometimes lamina lucida or intraepidermal separation can be seen associated with the blistering phenotype. Molecular investigation of this disease led to the discovery of a new epidermal protein, kindlin-1, which shows decreased expression by immunofluorescent microscopy in this disease. Kindlin-1 appears to have some homology to signaling proteins such as talin, which suggests a signaling function.[137] A number of mutations of the gene coding for kindlin-1, *KIND1*, have been described.[138–140] These include nonsense, frameshift, and splice site mutations which underlie the observed decrease in kindlin-1 expression in affected skin. Why the disease evolves from a blistering to a poikilodermatous phenotype and the exact function of kindlin-1 in epidermal homeostasis remain to be fully elucidated.

DIAGNOSIS

The first step toward making the diagnosis of EB begins with a thorough history and physical examination (Fig. 62-12). Useful historical information includes the age of onset of blistering and the presence of blistering in other family members. A review of gastrointestinal, respiratory, ocular, dental, bone, and genitourinary systems is important as is evaluation of general growth and development. Physical examination requires not only a complete skin exam, but a thorough evaluation of mucosal tissues, hair, nails, and teeth. Laboratory measurements of importance in the initial visit include evaluation for anemia, and for measures of nutrition, such as serum albumin.

Skin biopsy is another important diagnostic step. Routine histologic analysis cannot be used to diagnose EB but can be useful for excluding other causes of blistering. The dermal–epidermal BMZ is simply too small to be visualized by light microscopy. To differentiate levels of BMZ separation in skin biopsies, transmission electron microscopy (TEM), and/or indirect immunofluorescent microscopy (IDIF) must be used. While both TEM and IDIF will map the level of skin separation, each test can also provide additional unique diagnostic information, the utility of which depends on the clinical circumstances. For example, in dominant diseases such as EBS and DDEB, there is often not a detectable loss of antigens by IDIF, but ultrastructural abnormalities such as keratin filament clumping or anchoring filament abnormalities can still be seen by TEM. Conversely, in recessive disease, while TEM can detect ultrastructural abnormalities such as rudimentary hemidesmosomes, it cannot distinguish the loss of individual components of hemidesmosomes and other BMZ structures, as IDIF can.

The interior of blisters rapidly reepithelializes, which can obscure correct determination of blister levels. For this reason, it is critical to biopsy a blister that is as fresh as possible. One way to ensure a fresh blister is for the clinician to induce it in the office. This can be accomplished by gently rotating a pencil eraser over an intact area of patient's skin until separation of the epidermis from the dermis can be observed. When actually doing the biopsy, one should place the circular biopsy punch so that only 10% of the punch covers the visible blister with 90% covering intact skin. This is because it is helpful to have both intact and blistered skin on the same biopsy and extension of the blister is likely to occur either during the biopsy process or during shipping.

TEM has been used for decades for determining the level of blistering in EB subtypes. In addition to determining the level of blistering, ultrastructural entities can also be analyzed by TEM for characteristic alterations. For example, clumping of keratin intermediate filaments in basal keratinocyte cytoplasm is a pathognomonic finding for Dowling–Meara EBS. Rudimentary hemidesmosomes can be an important clue to the diagnosis of junctional EB. Absent or altered anchoring fibrils often occur in DEB subtypes especially the recessive forms.

IDDF microscopy has proved increasingly useful in recent years due to the availability of antibody panels directed against all the known EB antigens. In this technique, a panel of antibodies against known BMZ antigens is applied to frozen sections of blistered patient skin. The localization of the antigens to the epidermal or dermal portion of the blister indicates the level of skin separation in the BMZ. In EBS samples, for example, intracellular hemidesmosomal components such as BP230 and a lamina densa protein such as type IV collagen would each localize to the floor of the blister. In JEB cases, BP230 would localize to the roof of

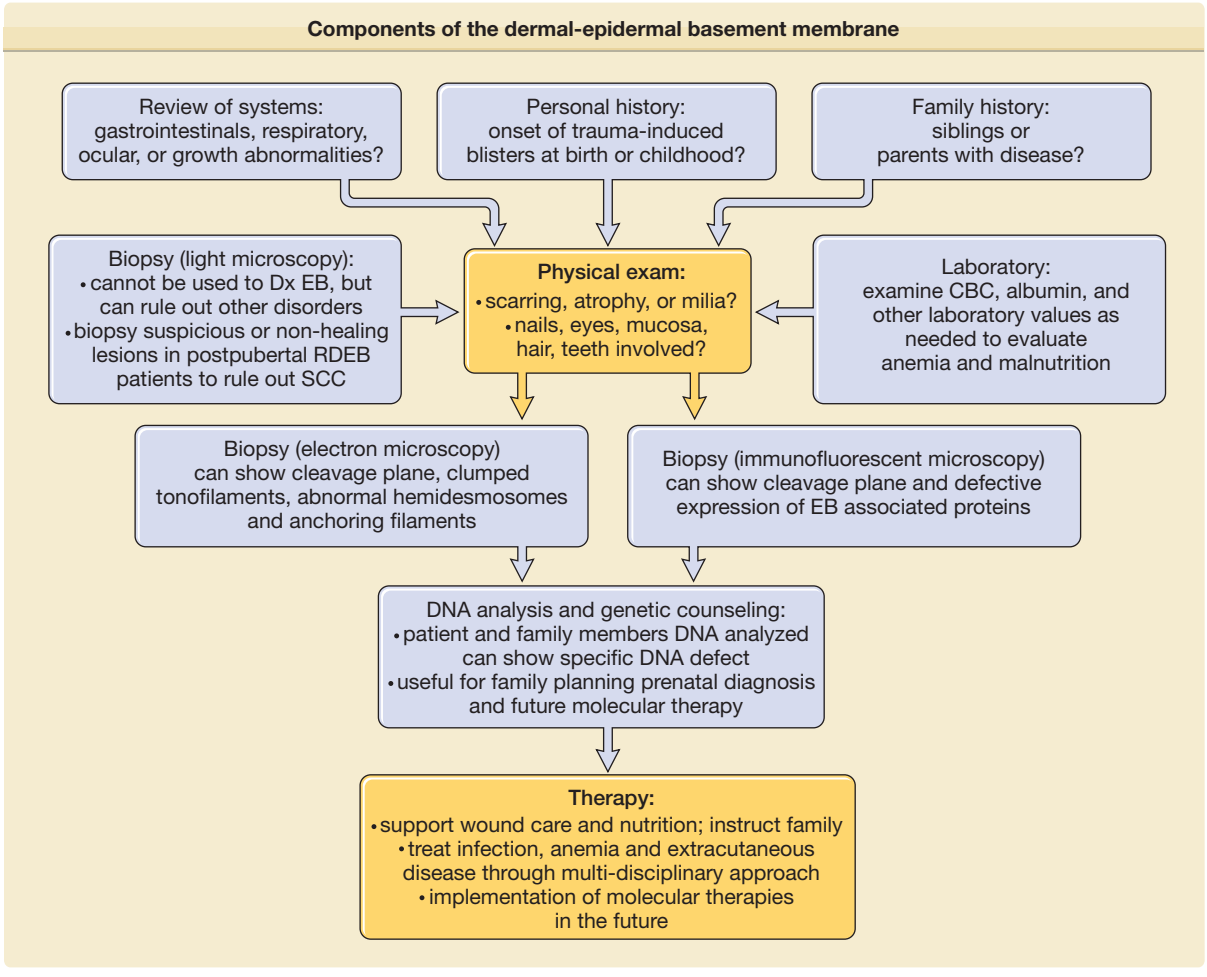

Figure 62-12 Approach to EB patients. A complete history, including family history and review of systems is essential. Physical exam can provide important clues, and laboratory values can help identify associated anemia and malnutrition. Electron microscopy and/or indirect immunofluorescent microscopy are required for diagnosis. DNA analysis is helpful for determining prognosis and family planning. Therapy is mainly supportive. Teaching and working with nursing staff and especially families is critical, as is interdisciplinary interactions with other specialties in the treatment of extracutaneous complications.

the blister while type IV collagen would localize to the floor. In DEB, collagen VII and BP230 would localize to the roof of the blister. The specific absence or presence of staining with a particular antibody in frozen sections of intact portions of patient skin gives important clues to the specific molecular defect. Samples that lack staining with antibodies specific to laminin-332 would further support a JEB diagnosis while a lack of staining for collagen VII would support a DEB diagnosis. Absence of staining for collagen XVII would support a non-Herlitz JEB/generalized atrophic benign EB diagnosis.

A complete panel of antibodies to support IDDF-based diagnosis of EB would include antibodies against laminin-332 (Herlitz and non-Herlitz JEB), as well as antibodies against BP230/BPAG1, BP180/collagen XVII (non-Herlitz JEB/generalized atrophic benign EB), collagen VII (RDEB), α6 and β4 integrins (JEB with pyloric atresia), plectin (EBS with muscular dystrophy), and keratins 5 and 14 (recessive EBS). Antibodies against the individual chains α3, γ2, and β3 chains of laminin-332 are especially helpful.

Its known that laminin-311 (which shares the same laminin α3 chain as laminin-332) is expressed in Herlitz JEB associated with null mutations of genes coding for β3 chain (*LAMB3*) and γ2 chain (*LAMC2*), but not in Herliz JEB associated with null mutations of the α3 chain gene (*LAMA3*).[44] Therefore, if laminin β3 and γ2 antibodies are negative and α3 antibody is positive, this could point the genetic analysis to examine the *LAMB3* and *LAMC2*. Conversely, if all three laminin-332 chains are absent by IDIF, this could point the genetic investigation toward *LAMA3*, saving time and effort in arriving at the final molecular diagnosis.

Gene mutation analysis has revolutionized our understanding of the EB family of diseases and is considered the ultimate final step in arriving at the molecular diagnosis in EB. Concurrent advances in our knowledge of the biochemical structure and supramolecular assembly of BMZ proteins have both facilitated

and complemented the molecular biology studies. Thus, EB patient diagnosis requires both clinical and molecular information. Blood samples or buccal swabs are taken from the patient as well as the parents and siblings for genetic analysis.

GENETIC COUNSELING

DNA mutation analyses can be extremely helpful to EB patients. The prognostic benefit to the patient can often be highly significant. For example, milder recessive DEB cases may have equivalent blistering activity compared to the more severe dominant cases, but their risk of invasive SCC is much greater. Through DNA diagnosis, these two groups can be distinguished, thereby identifying patients potentially at risk for invasive SCC.

Prenatal diagnosis of EB in affected families can be an extremely accurate technique, especially if the original proband has previously had mutational analysis or identification of the defective gene. Fetal skin biopsies and fetoscopy with their increased risk of pregnancy loss can now be avoided by analysis of either chorionic villus sampling as early as 8–10 weeks[141] or amniocentesis in the second trimester.[142] The development of highly informative intragenic and flanking polymorphic DNA markers in EB candidate genes together with rapid screening of genetic "hotspots" makes genetic screening of at risk pregnancies a viable option.[112,143] Coupling of the technique of in vitro fertilization with EB prenatal diagnosis, preimplantation diagnosis has now been successfully performed for EB cases.[144] Another promising area of prenatal diagnosis with potential future applications to EB is the detection and analysis of fetal cells in the maternal circulation.[145]

TREATMENT

Most therapy for epidermolysis bullosa is supportive. The regimen is tailored to the severity and extent of skin and systemic involvement and usually entails a combination of wound management, infection control, surgical management as needed, and nutritional support. Skin care and supportive care for other organ systems in certain EB subtypes is most optimally coordinated through a multidisciplinary approach. Comprehensive topical therapy is a mainstay of treatment in EB, with avoidance of trauma as a primary goal. Wound healing is impaired by endogenous factors, including foreign bodies, bacteria, nutritional deficiencies, anemia, and repeated trauma. Therefore, optimizing wound healing in EB patients involves control of all of these factors.[146]

SUPPORTIVE SKIN CARE

Extensive areas of denuded skin can result in the loss of the barrier provided by the stratum corneum. Subsequent microbial penetration can result in the accumulation of serum and moisture that further enhances bacterial propagation. The above factors combined with immunosuppressive therapy facilitate development of infections. Prevention of infection is obviously the preferred strategy.

A modified Dakin's solution (0.025% w/v sodium hypochlorite) can be helpful in reducing the bacterial load in patient skin. Soaking wounds in this solution for 20 minutes prior to dressing changes also helps to free adherent bandages that have dried onto the wound bed. After soaking, wounds can be dressed with mupirocin or other topical antibiotics, and covered with semiocclusive nonadhesive dressings. Tape causes further blistering and peeling of the skin; thus, it is essential to use self-adhering (clinging) gauze or self-adherent tape to hold nonadherent dressings in place.

For patients with generalized or localized subtypes of EBS, controlling exposure to heat may prove helpful in controlling blister formation. Advising patients to use soft, well-ventilated shoes is also recommended. Herlitz JEB patients, lacking functional laminin-332, an extracellular matrix protein shown to be involved in keratinocyte adhesion and migration, may have especially difficult problems with wound healing. For DEB patients, use of finger splinting or diligent hand wrapping and appropriate hand protection against trauma are helpful, especially following hand surgery (see below).

INFECTION

Management of skin infections is a critical part of EB patient care. Large areas of denuded skin provide an inadequate barrier to microbial penetration. Patients with severe EB subtypes such as recessive DEB may also have immunologic abnormalities including decreased lymphocyte production due to poor nutritional status that lower patients' resistance to infection. *Staphylococcus aureus* and *Streptococcus pyogenes* are common infectious agents. Gram-negative infections with *Pseudomonas aeruginosa* can also occur. Sepsis is a common cause of death in Herlitz JEB patients. Skin cultures and the use of the appropriate systemic antibiotics are indicated for wound infection. To prevent infections in chronic wounds, a regimen entailing regular whirlpool therapy followed by topical antibiotics is the preferred strategy. Rotation of topical antibiotics is also a helpful way to combat resistant bacteria.

SURGICAL TREATMENT

Among the EB patient population, those with the severe recessive DEB (Hallopeau–Siemens) variant are generally the most in need of surgical intervention.[147] Mitten pseudosyndactyly in these patients can be surgically released; however, this procedure may have to be repeated periodically due to the strong tendency of this condition to recur.[148–151] Splinting following surgery is essential to reducing recurrence of hand deformities. Surgery may also be used to correct limb, perioral, and perineal contracture deformities,

but a high rate of recurrence is common. Extra care must be taken to minimize trauma to oral mucosa in EB patients during intubation.

Application of allogeneic skin equivalents has recently demonstrated some promise in wound healing and improvement of quality of life[152] and thus represents an area of future investigation. While long-term benefit or persistence of allografted cells has not been demonstrated, this therapy nonetheless appears to a helpful short-term therapy to help chronic EB wounds to heal.

TUMORS

Squamous cell carcinoma often arises after puberty in patients with recessive DEB. SCC may arise in multiple primary sites, especially in nonhealing areas. Careful surveillance of nonhealing areas is of utmost importance since patients often die from metastatic disease, and the average survival rate after diagnosis of an RDEB-associated squamous cell carcinoma is 5 years. Surgical excision using either Mohs or non-Mohs approaches is an important first-line modality with radiation therapy limited by poor tumor response and impaired site healing.[153] Amputation is often used to control local spread of carcinomas detected on the limbs. Isotretinoin has been used for RDEB patients for chemoprevention of SCC. While it appears well tolerated, it is not clear whether in can increase the overall survival rate of these patients.[154] The epidermal growth factor receptor antagonist cetuximab has also been reported used in RDEB associated with advanced metastatic disease.[155] While the short-term results were positive in the one patient tested, published reports of long-term results and experience with wider groups of RDEB cancer patients are currently lacking.

CARE FOR EXTRACUTANEOUS INVOLVEMENT

GI MANAGEMENT. Esophageal lesions are often the most disabling complication found in recessive DEB and JEB of both the Herlitz and non-Herlitz varieties. Esophageal strictures usually respond to dilatation; however, recurrence of strictures after dilation is common.[156] Colonic interposition has proven effective in advanced cases. Gastrostomy tube insertion has been effective in providing nutrition to individuals with esophageal strictures.[157] Increased fluid and fiber intake and stool softeners may also be of value in EB patients who suffer from constipation.

EYE LESIONS. EBS patients, particularly those with the Dowling–Meara subtype can experience recurrent inflammation of the eyelid, with bullous lesions in the conjunctivae. Junctional EB patients and recessive DEB patients can experience corneal ulcerations with scarring, obliteration of tear ducts, and eyelid lesions.[158] Cicatricial conjunctivitis can also occur in recessive DEB patients. Corneal erosions are treated supportively with application of antibiotic ointments and use of cycloplegic agents to reduce ciliary spasms and provide comfort. Moisture chambers and ocular lubricants are also commonly used. Severely affected upper eyelids may be surgically managed with full-thickness skin grafting. Complete correction of any eye disorder in EB patients is difficult to achieve. Proper management of eye lesions in EB patients must include the assistance of an ophthalmologist to prevent serious visual compromise.[159]

OROPHARYNGEAL LESIONS. Good dental hygiene is essential for EB patients, and regular visits to the dentist are especially important. Enamel defects in JEB and DEB patients often lead to dental carries.[160,161] The softest brush available should be used for regular cleansing. Oral mucosal blistering may also accompany forms of JEB and DEB. Normal saline rinses are effective for gentle cleaning of the mucosal surfaces. Mouthwashes containing alcohol or other harsh agents should be avoided. Erosions and scarring involving the trachea and larynx with resultant narrowing of the airway. In patients with airway involvement, there is danger of pulmonary aspiration.[162]

NUTRITION AND ANEMIA COMPLICATIONS. Nutritional assessment and support can be critical in EB patients[163] for several reasons. Extensive cutaneous injury is associated with marked alterations in hemodynamic and metabolic responses, with increased caloric and protein requirements. Nutritional problems such as low selenium, iron overload, and chronic anemia in the setting of severe blistering may predispose the patient to severe internal complications. Congestive heart failure and cardiomyopathy are prime example of this. This uncommon but nonetheless severe and potentially fatal complication can occur both patients with RDEB or non-Herlitz JEB, becoming more frequent as patients get older.[164]

Oropharyngeal as well as gastrointestinal lesions provide the greatest overall threat to nutritional well-being. These include oral blistering, abnormal esophageal motility, strictures, dysphagia, diarrhea, malabsorption, and dental problems. Nutritional assessment must take into account the above factors in order to develop a supplemental regimen to replenish nutritional deficiencies. Patients are often unable to increase their food intake to balance this increased caloric need. For example, hypoplastic enamel formation in certain subtypes of EB such as GABEB may lead to tooth decay, mucosal blistering, and oral candidiasis. All of these potential complications may compromise patients' ability to eat. Extensive internal mucosal disadhesion in the gastrointestinal tract may cause abnormal GI motility, strictures, and diarrhea—complications that may lead to malabsorption of iron and other nutrients. Anemia of chronic disease can certainly affect all severe EB subtypes. Recessive DEB patients often show a particularly severe defect of iron absorption from the GI tract. In these patients, an iron deficient anemia can develop, which is not responsive to oral supplementation. For these patients, parenteral

iron can be helpful. Furthermore, if a lack of a reticulocyte response to iron supplementation is seen in iron deficient patients, it is helpful to assess the erythropoietin level and to treat with recombinant erythropoietin if necessary.[165] Transfusion is also useful in the treatment of anemia in EB, especially when symptoms require a rapid correction. Deficiencies of other trace minerals and other vitamins such as vitamin D, zinc have also been noted in severe RDEB patients.[166] Osteoporosis and fractures are also a frequent complication of RDEB patients, and bone scans, vitamin D and calcium supplementation may be helpful. Bisphosphonates can be useful in combating this problem.[167]

PSYCHOLOGICAL ASPECTS OF EPIDERMOLYSIS BULLOSA. Patients with EB, especially the severe subtypes, can be plagued with chronic pain and debilitation.[168–170] While many, despite extremely adverse conditions, seem to find a way to maintain a surprisingly positive outlook on life, others lapse into depression.[171,172] Severe epidermolysis bullosa patients can also create stress for their families and loved ones.[173] Thus, it is important to identify the warning signs of depression when they arise and to work in a mutidisciplinary approach with psychiatrists and clinical psychologists as needed. Supportive psychotherapy and patient support group meetings can help patients and their families in this regard. An additional source of support for patients and families include several important patient-based organizations that assist with education and support including Dystrophic Epidermolysis Bullosa Research Association and Epidermolysis Bullosa Medical Research Foundation.

SYSTEMIC THERAPIES

Systemic therapies are not effective in ameliorating the fundamental blistering tendencies in EB patients. Tetracycline and phenytoin have been used in the past for EB but are not currently indicated treatment.[174] Corticosteroids, either topical or systemic, have no beneficial long-term use in inherited EB.

MOLECULAR THERAPY FOR EPIDERMOLYSIS BULLOSA

A number of preclinical models have facilitated the study and development of therapy for epidermolysis bullosa. Some of these models utilize mouse genetic approaches to produce entirely murine tissue models.[175] These include transgenic mouse models with skin targeted expression of trans-dominant molecules including inducible disease phenotype models.[176] These include dominant-negative basal keratins in models of epidermolysis bullosa simplex. Murine knockout models have also been used, including knockout of basal keratin genes in a model of the same disorder and of the α6 and β4 integrins, laminin-332, and types XVII and VII collagens.[177–181] These targeted gene disruptions in mice have accurately recapitulated the blistering phenotype of the corresponding human disorders. These murine genetic models have been of great utility in clarifying our understanding of the pathogenesis of this group of disorders and in providing disease models for development of potential future therapies. Other animal models have also been shown to have the potential to study epidermolysis bullosa pathophysiology and therapy in a preclinical setting. Canine, murine, equine, and feline forms of a number of subtypes of epidermolysis bullosa show promise as preclinical models of molecular therapy.

In addition to such pure animal models, human skin/mouse chimeras have been generated in an attempt to produce true human tissue models of epidermolysis bullosa. These chimeras have either used full thickness grafting of EB patient skin or epidermis regenerated on skin composites and sheets from EB keratinocytes grown in culture.[182] Immune deficient SCID and nude mice readily accept such xenografts and the grafted EB skin retains the clinical and molecular characteristics of the patient donor. This immunodeficient mouse models can be extended to study injections of human cells or proteins as well. This approach has been reported for recessive dystrophic EB due to mutations in collagen VII and for benign junctional EB due to mutations in collagen XVII. Because human epidermis differs dramatically from mouse in tissue architecture, these in vivo models of human tissue in EB may be of special utility in development of models for gene therapy of these disorders.

Potential therapies for EB include protein and gene therapy. In the former case, the missing or defective protein is produced by recombinant methods and applied or injected directly to intact or blistered skin or given intravenously. Recent preclinical studies of collagen VII protein transfer into RDEB-derived skin equivalents have shown successful incorporation of this molecule into anchoring fibrils combined with clinical improvement of skin separation.[183] Collagen VII has a longer in vivo half-life than most molecules. This suggests that protein application or injection could take place at extended intervals, perhaps greater than 3 months, as persistence of exogenous collagen VII protein was detected in animal models at least this long.

In the case of gene therapy, delivery of genes targeted to restore normal protein expression is the goal.[184,185] Successful corrective gene delivery has recently been achieved in human EB tissue in the immune deficient model system described below for both laminin-332 and collagen XVII.[186,187] More recently both viral and nonviral methods of gene transfer have demonstrated successful expression of collagen VII in RDEB skin equivalents on immunodeficient mice[183,188–190] as well as in a canine animal model.[191]

The approach of retroviral ex vivo gene therapy using autologous keratinocytes was recently performed for one patient with junctional epidermolysis bullosa.[192] In this study, a patient with a missense mutation of laminin-332 was grafted with genetically corrected keratinocyte monolayers expressing wild type laminin-332. After over 1 year of post grafting follow up, grafts still showed positive expression of laminin-332 and resistance to blistering. Observations from this study suggested that proper selection of patient skin stem cells were an important part of the success of this study.

This latter study was the first to demonstrate that gene therapy for epidermolysis bullosa can be successfully performed in humans, and opens the door for many new clinical studies in other EB subtypes.

Dermal fibroblasts have long been appreciated as contributors of collagen VII to the dermal–epidermal basement membrane.[193] The technique of injecting collagen VII expressing fibroblasts have proven successful in restoring collagen VII expression and reversing the blistering phenotype in RDEB skin equivalents on immunodeficient mice[189,194] and in a mouse model of RDEB.[195] In addition, allogenic fibroblast-based approaches to the treatment of dystrophic EB have recently found their way into clinical trials, showing some success at delivering collagen VII to deficient RDEB patient skin.[196,197] Although profound immunosupression against a background of extensive skin erosions is not without significant risks, including sepsis and death, new advances in bone marrow transplantation of collagen VII expressing stem cells represents another novel and potentially effective route of cell-based molecular therapy for RDEB.[198–201]

COLLAGENS, ELASTIC FIBERS AND OTHER EXTRACELLULAR MATRIX PROTEINS OF THE DERMIS AT A GLANCE

- The extracellular matrix (ECM) is a complex network composed of a large number of components, which determines tissue stiffness, compliance, and resilience.
- ECM proteins (i.e., collagens, proteoglycans, glycoproteins) consist of structural domains with different biological functions.
- ECM signals control cell differentiation, polarity, migration, survival, and expression of specific genes.
- There are many ECM-associated heritable diseases. The molecular mechanisms responsible for the resulting phenotypes are often complex and involve several different cellular pathways.
- The dynamic balance between ECM synthesis and degradation is critical for many acquired disease processes, i.e., tumor invasion and metastasis, fibrosis, and inflammatory pathologies.

INTRODUCTION

The extracellular matrix (ECM) is a complex network of different components, responsible for determining and maintaining tissue architecture, and for mediating a number of important biological events. It is composed of a large number of diverse protein families, each constituted by many different individual members. These include the collagens, encoded by 42 different genes, elastin and associated microfibrillar proteins, fibronectin, proteoglycans, and many more molecules. (See Table 63-1.)

Although all of these proteins are genetically, structurally, and biologically diverse, a common denominator is that most of them have a modular structure, and they are composed of one, a few, or several copies of a limited set of individual structural modules, also called domains.[1] These can be combined in multiple ways giving rise to proteins as diverse as fibrillin and laminin (Fig. 63-1). Specific functions have been unraveled for some of these domains, for instance, interaction with other ECM proteins, cell adhesion-promoting activity, cytokine trapping, and regulation. Therefore, the ECM has a critical role for many cellular functions, including proliferation, survival, polarity, differentiation, expression of specific genes, and migration.[2–4] All different cell types, such as mesenchymal, epithelial, and endothelial cells, and also inflammatory and tumor cells, participate in the production of distinct ECM macromolecules, and are all influenced by interactions with these compounds. It is well established that the ECM determines the biophysical properties of connective tissues. More recently it became clear that, conversely, stiffness and compliance of connective tissues are important factors for the regulation of cellular functions.[5–8]

COLLAGENS

The proteins of the collagens family are the main structural components of the connective tissues and the major extracellular proteins of the human body. In human skin, collagens comprises approximately 80% of the dry weight of the dermis. The classical and first recognized physiologic role of collagens in the skin is to provide tensile properties that allow the skin to serve as a protective organ against external trauma. In addition, it is clear that collagens displays important

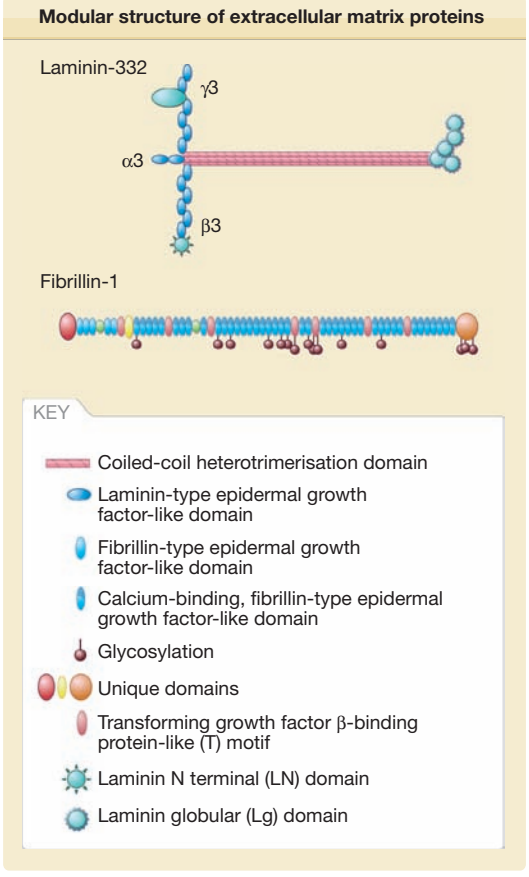

Figure 63-1 Modular structure of extracellular matrix (ECM) proteins. ECM proteins are composed by a few individual structural modules, such as fibrillin- and laminin-type epidermal-growth factor-like modules, von Willebrand factor A domain, follistatin-like and EF-hand Ca^{2+}-binding motif or coiled-coil oligomerization domains. These modules can be combined in multiple ways giving rise to proteins as diverse as fibrillin or laminin displayed here as examples. In addition, ECM proteins can be formed of a single polypeptide chain, as fibrillin, or of several polypeptide chains. For instance, laminin 332 is formed by three polypeptide chains, the a3, b3 and g2 chains.

biological properties regulating multiple cellular and tissue activities.

THE COLLAGENS TRIPLE HELIX

The bulk of collagens in dermis is deposited as large bundles of regularly oriented fibers composed of fibrils that are aligned in a parallel manner, which results in a pattern of cross-striations that can be visualized by electron microscopy (Fig. 63-2). The most prominent cross-striations appear as repeating bands spaced approximately 70 nm apart. The major component of these fibrils is type I collagens, the first identified member of the collagens family and the most abundant collagens in the dermis and most

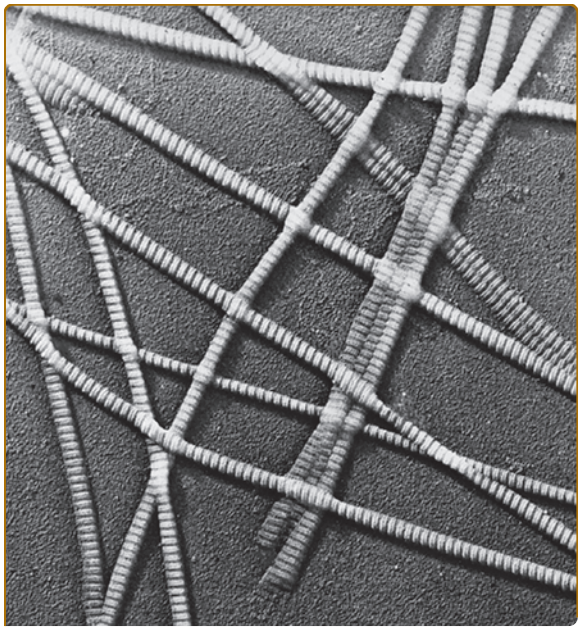

Figure 63-2 Electron micrograph of collagens fibers demonstrating the regular banding pattern at approximately 70-nm intervals (×45,000).

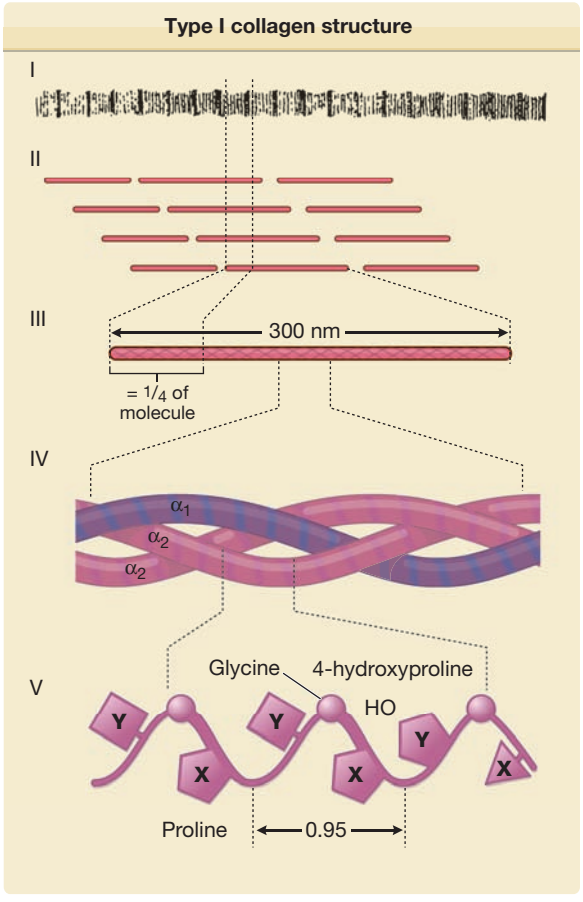

Figure 63-3 Schematic representation of the structure of type I collagens. The collagens fibers (I), which on electron microscopy demonstrate a repeating periodicity (see Fig. 63-2), are composed of individual collagens molecules aligned in a quarter-stagger arrangement (II). Each type I collagens molecule is an approximately 300-nm-long rod-like structure (III) consisting of three individual polypeptides, known as α chains, which are twisted around each other in a right-handed triple helix (IV). Each chain is composed of amino acids in a repeating Gly-X-Y sequence (V); as indicated, the X position is frequently occupied by a prolyl residue and the Y position is frequently occupied by a 4-hydroxyprolyl residue. The individual α chains have a left-handed helical secondary structure with a pitch of 0.95 nm. (From Uitto J et al: Collagens structure, function, and pathology. In: *Progress in Diseases of the Skin*, vol. 1, edited by R Fleischmajer. New York, Grune & Stratton, 1981, p. 103, with permission.)

other connective tissues.[9–11] The characteristic structural features of collagens were deduced from the study of type I collagens, which is therefore considered as the prototype of the collagens family.

The type I collagens molecule has an approximate molecular mass of 290 kDa and is composed of three polypeptide chains, each approximately 94 kDa. These three polypeptides, known as the α chains, are coiled around each other much like strands of rope, so that the collagens monomer has a triple-helical structure. This conformation gives the molecule a rigid, rod-like shape with approximate dimensions of 1.5 × 300 nm (see Fig. 63-3). The special structure of the collagens triple helix is largely explainable by the unusual amino acid composition of the α chains. Specifically, each α chain of type I collagens has approximately 1,000 amino acids, and glycine (Gly), the smallest amino acid, accounts for approximately one-third of the total number of amino acids, evenly distributed along the polypeptide. Consequently, the polypeptide chains of type I collagens can be described as repeating triplets represented as $(Gly\text{-}X\text{-}Y)_{333}$. Although the X and Y positions of the triplets can be occupied by any amino acid, they are often occupied by proline and hydroxyproline, respectively. These two amino acids account for approximately 22% of the total amino acid composition of type I collagens. The relatively high content of these amino acids and the characteristic distribution of glycine in every third position are necessary for the triple-helical conformation of the collagens molecule, and hydroxyproline plays a critical role in stabilizing the triple helix at body temperature. The triple-helical conformation defines the so-called collagenous domain, and it gives type I collagens many of its unique properties.[12] In particular, it is essential for assembly into fibrils. Mutations that affect the formation of the stable triple helix prevent collagens from forming fibers, which results in serious defects of connective tissue function and a spectrum of clinical phenotypes.[13–15]

GENETIC HETEROGENEITY OF COLLAGENS

Collagens comprises a family of closely related yet genetically distinct proteins. In the human genome, there are as many as 42 different genes encoding α chains with variable amino acid sequences. These α chains correspond to at least 28 different types of collagens, which have been assigned Roman numerals I to XXVIII (Table 63-2). These are subdivided into several subfamilies, mainly according to the length and number of collagenous and noncollagenous domains. In addition to well-characterized collagens, short triple-helical collagenous segments are present in other proteins, including acetyl cholinesterase, the C1q component of the complement system, gliomedin, pulmonary surfactant proteins, macrophage scavenger receptors, emilins (elastin microfibril interface-located glycoproteins), and ectodysplasin A, a product of the gene mutated in X-linked anhidrotic ectodermal dysplasia.[16] However, these proteins are not included in the collagens family because the collagenous domains are not a predominant part of the molecules, and the proteins do not function primarily as structural components of the ECM of connective tissue.

The genetically distinct collagens are distributed into several classes, mainly according to the length and number of triple-helical collagenous segments and noncollagenous domains present in the molecule, and on the basis of the architecture of their assembly in tissues (see Table 63-2). A classification and an overview of the major collagens types contributing to skin physiology and pathology are presented in the following paragraphs. Some collagens types are not discussed in detail because they do not appear to be

Red: The polypeptide is expressed in the dermis.
Green: The polypeptide is present at the dermal–epidermal junction (basement membrane).

present in the skin in significant quantities, or they do not seem to contribute to the physiologic properties of dermis, or because information is still lacking.

The first class groups the **fibril-forming collagens** types I, II, III, V, XI, XXIV, and XXVII. Except for collagens II, XXIV, and XXVII that were not detected in skin, all other fibril-forming collagens types are expressed in the dermis. These collagens types consist of a single 300-nm long collagenous domain, with very short nontriple-helical extensions (Fig. 63-4), and they assemble into relatively large fibrils.[11,12,17] **Type I collagens**, the most widely distributed and the most extensively characterized form of collagens, accounts for approximately 80% of the total collagens of adult human dermis. It is formed by two identical α chains, designated α1(I), and a third chain, called α2(I), that is clearly different in its amino acid composition. Thus, the chain composition of type I collagens is $[\alpha1(I)]_2\alpha2(I)$. **Type III collagens** represents approximately 10% of the total collagens in the adult human dermis.[18] It is composed of three identical α1(III) chains, distinguished from the chains of type I collagens by a relatively high content of hydroxyproline and glycine and the presence of one cysteine residue. Collagens types I and III form the relatively broad extracellular fibers that are primarily responsible for the tensile strength of the human dermis. Mutations in the type I and III collagens genes can result in connective tissue abnormalities in the skin and joints, among other tissues, in different forms of Ehlers–Danlos syndrome and fragility of bones in osteogenesis imperfecta.[13–15] **Type V collagens** forms a subfamily of similar interrelated collagens resulting from various assemblies of three different types of α chains, α1(V), α2(V), and α3(V). The predominant form in the skin is $[\alpha1(V)]_2\alpha2(V)$, where it represents less than 5% of the total collagens. In dermis, type V collagens is associated with major collagens fibers consisting of type I and III collagens, and type V collagens has been postulated to regulate the fiber diameter during fibrillogenesis. The importance of type V collagens has been demonstrated by the discovery of mutations in type V collagens genes in patients with classical autosomal dominant forms (types I and II) of Ehlers–Danlos syndrome.[19] It is of interest that a clinically similar, classical type of Ehlers–Danlos syndrome can be based on the absence of tenascin-X expression, which leads to an autosomal recessive form of the disease.[20] Tenascin-X is developmentally associated with collagens fibrillogenesis, and its absence could explain the presence of defective collagens fibers similar to those found in patients with mutations in type V collagens genes.

Another class comprises the **network-forming collagens** types IV, VIII, and X, which are, however, very different structurally (Fig. 63-4). **Type IV collagens** is a typical component of basement membranes, where it forms a lattice rather than the fibers characteristic of dermal collagens. Six different α (IV) chains exist, α1(IV) to α6(IV), and participate in the assembly of heterotrimers. In human skin, α1(IV) to α4(IV) chains are present in the basement membrane at the dermal–epidermal junction, with $[\alpha1(IV)]_2\alpha2(IV)$ being the predominant heterotrimer.[17,21] Type IV collagens chains contain imperfect Gly-X-Y triplets, a feature that confers flexibility to the triple-helical domain of the molecule. A noncollagenous globular domain at the amino-terminal part of the molecule mediates dimer formation, while a short segment at the carboxyl-terminal region of the molecule allows for tetramer assembly, altogether resulting in the so-called "chicken-wire" assembly network for collagens type IV.[17] Although

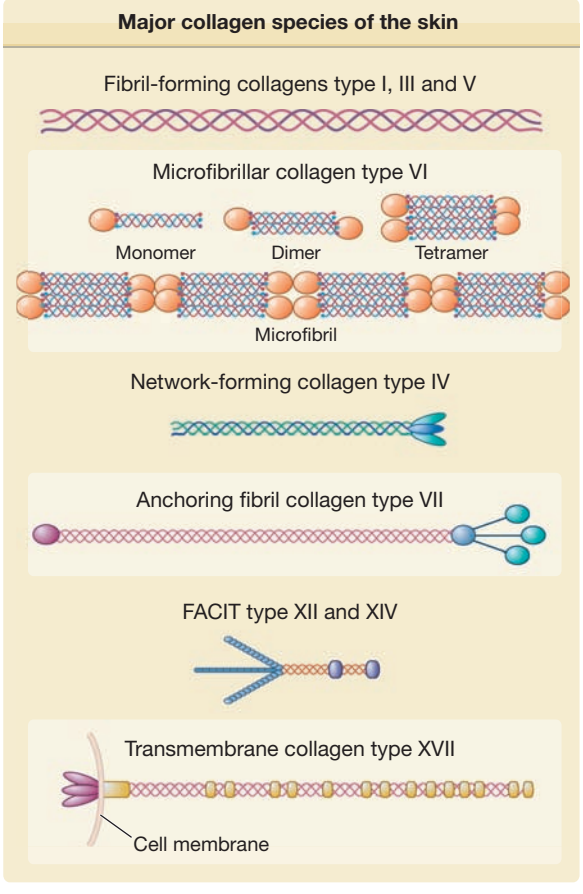

Figure 63-4 The major collagens species of the skin. According to several features, including length and number of collagenous and noncollagenous domains and supramolecular assemblies, the collagens molecules are grouped in different families. Type I, III, and V collagens have the characteristic rod-like structure and form the large collagens fibrils of the dermis. Type VI collagens molecules are arranged following a unique microfibrillar pattern of thin and long aggregates in the dermis. Also present in the dermal extracellular matrix are two FACITs (fibril-associated collagens with interrupted triple helices), type XII and XIV collagens associated to the large collagens fibrils formed by type I, III, and V collagens. Type IV collagens is ubiquitous of basement membranes where it forms large hexagonal networks. Two further collagens, type VII and type XVII, are specific of the dermal–epidermal junction, where type VII collagens is a component of the anchoring fibrils, while the ectodomain of transmembrane type XVII collagens is located in the anchoring filaments anchoring basal keratinocytes of the epidermis to the underlying basement membrane.

skin disorders associated with genetic mutations in type IV collagens have not been described, mutation in the *COL4A1* gene has been identified in a family with autosomal dominant porencephaly and infantile hemiparesis,[22] and mutations in the *COL4A5* gene result in Alport syndrome,[23] an X-linked renal disease. Furthermore, autoantibodies recognizing the collagens α3(IV) chain underlie Goodpasture syndrome,[23] and autoantibodies targeting the collagens α5(IV) chain are associated with a novel autoimmune disease characterized by subepidermal blisters and renal insufficiency.[24]

Two further collagens, **type VI collagens and type VII collagens**, are unique and each has its own distinct molecular structure and supramolecular assembly. Type VI collagens forms specific microfibrils in the dermis, while type VII collagens forms the anchoring fibrils of the dermal–epidermal junction. The microfibril-forming type VI collagens is relatively abundant in a variety of tissues, including skin. In humans, five distinct α chains—α1(VI), α2(VI), α3(VI), α5(VI), and α6(VI)[11]—have been identified (Table 63-2). The α1(VI), α2(VI), and α3(VI) chains fold into a triple-helical domain of approximately 100 nm in length, with globular domains at both ends (Fig. 63-4). The supramolecular assembly involves the formation of antiparallel dimers, then tetramers, which in turn align in rows, leading to relatively thin microfibrils, independently of the broad collagens fibers.[25,26] The microfibrils of type VI collagens may perform an anchoring function by stabilizing the assembly of the broad collagens fibers as well as basement membranes. Studies have now demonstrated that mutations in each of the three type VI collagens genes can lead to different forms of congenital muscular dystrophy, with multiple joint contractures, laxity of distal joints, and characteristic skin involvement.[27]

Type VII collagens, the major, if not the exclusive, component of the anchoring fibrils at the dermal–epidermal junction, has an unusually long triple-helical region of approximately 450 nm.[28] It has only one type of α chain, α1(VII), and the triple-helical collagenous domain is flanked by a large, nonhelical (noncollagenous) domain, NC-1, at the amino terminus and a shorter carboxyl-terminal nonhelical domain, NC-2 (Fig. 63-4). Type VII collagens molecules become organized into anchoring fibrils, which extend from the lower part of the lamina densa to the papillary dermis, through the formation of antiparallel dimers linked through their carboxyl-terminal ends. The large amino-terminal, noncollagenous domains of type VII collagens interact with type IV collagens and laminin 332 components of the dermal–epidermal basement membrane, and it has been suggested that most anchoring fibrils form U-shaped loops that entrap broad dermal collagens fibers consisting of type I and III collagens. Thus, alterations in the expression, structure, or molecular interactions of type VII with other basement membrane components could result in skin fragility. Such a situation is exemplified by dystrophic epidermolysis bullosa (DEB), a group of mechanobullous diseases characterized by blistering of the skin after minor trauma (see Chapter 62). In fact, distinct mutations in the type VII collagens gene, *COL7A1*, have been demonstrated in more than 500 families with different forms of DEB, and none of the families with DEB studied so far has revealed mutations in genes other than that encoding the α1(VII) polypeptide of type VII collagens.[29–31] Furthermore, type VII collagens serves as the autoantigen in the acquired form of epidermolysis bullosa, an autoimmune disorder with circulating antitype VII collagens antibodies (see Chapter 60).

A further class groups the *F*ibril-*A*ssociated Collagens with *I*nterrupted *T*riple helices, in short FACITs, including types IX, XII, XIV, XVI, XIX, XX, XXI, XXII, and XXVI.[11,32] An association with collagens fibers has been demonstrated for several of these collagens, hence the concept that they serve as important molecular bridges for the organization and stability of extracellular matrices. These collagens types form homotrimers with a relatively short triple-helical domain, and 2–4 noncollagenous domains (Fig. 63-4). In the skin, type XII and type XIV collagens associate with the large collagens fibrils of the dermis.

Type XV collagens and Type XVIII collagens are basement membrane-associated collagens. They have been called multiplexins because they contain multiple noncollagenous domains in their collagenous sequences.[33] Interest in these collagens stems from the fact that proteolysis liberates fragments endowed with functions different from those of the original intact molecules.[33,34]

Type XIII, XVII, XXIII, and XXV collagens are transmembrane proteins.[35] Their supramolecular assemblies remain unknown, and, except for types XIII and XVII, their presence in skin has not been established. **Type XVII collagens** (Fig. 63-4) is particularly important for skin physiology and pathology. It is a transmembrane protein anchored in the membrane of basal keratinocytes, with an intracellular domain and a large extracellular domain, or ectodomain, which is a component of the basement membrane at the dermal–epidermal junction. Immunoelectron microscopy has localized type XVII collagens to hemidesmosomes of basal keratinocytes and to the thin anchoring filaments originating from the hemidesmosomes and spanning the lamina lucida toward the lamina densa of the basement membrane.[36] The ectodomain of type XVII collagens consists of 15 collagenous domains with the characteristic repeating Gly-X-Y sequences that form triple helices. These collagenous domains are separated by noncollagenous segments of variable sizes, and consequently type XVII collagens is a protein characterized by alternating collagenous and noncollagenous segments.[37] The ectodomain colocalizes and interacts with laminin 332, also a component of anchoring filaments[36,38] (see also Chapter 53). Type XVII collagens was initially identified as the 180-kDa bullous pemphigoid antigen (*BPAG2*), which was recognized by circulating autoantibodies in the sera of patients with bullous pemphigoid or herpes gestationis.[39] The importance of the type XVII collagens was also shown by mutations in the corresponding gene *(COL17A1)* that underlie a nonlethal variant of junctional

epidermolysis bullosa, generalized atrophic benign epidermolysis bullosa (see Chapter 62). These patients have protracted, lifelong blistering of the skin, atrophic scarring, alopecia, and nail dystrophy.[37,40]

FROM COLLAGENS GENES TO SUPRAMOLECULAR ASSEMBLIES

The collagens genes, like most eukaryotic genes, are large, multiexon genes interrupted at several points by noncoding DNA sequences called *introns*.[41] For expression, the entire gene is transcribed into a high-molecular-weight precursor messenger RNA (mRNA), which undergoes posttranscriptional modifications, such as capping, polyadenylation, and intron splicing to yield a linear, uninterrupted coding sequence with 5′ and 3′ untranslated flanking regions. The mature mRNA is then transported into the cytoplasm and translated to the corresponding polypeptide. Thus, the eukaryotic gene coding for a protein is much larger than would be predicted from the amino acid sequences of the final protein.

With few exceptions, the collagens genes are widely scattered throughout the human genome (see Table 63-2). Knowledge of the precise chromosomal location of the genes coding for collagens in human skin has allowed identification of polymorphic markers within the genes and in the flanking DNA for use in genetic linkage studies. In addition, sophisticated mutation detection strategies, based on scanning of the genes, have led to identification of a large number of mutations in different collagens genes with characteristic phenotypic consequences.

Under physiologic conditions, fibril-forming collagens molecules spontaneously assemble into insoluble fibers.[17] This observation presented a logistic problem, because it was difficult to visualize how a collagens molecule could be synthesized inside the cell and then secreted into the extracellular space without premature assembly of the molecules into insoluble fibers. The solution to this problem was found in the demonstration that fibril-forming collagens, and some other collagens, is initially synthesized as a larger precursor molecule, procollagen, which is soluble under physiologic conditions.

The precursor polypeptides of procollagen, so-called *pre-proα chains*, are synthesized on the ribosomes of the rough endoplasmic reticulum in fibroblasts and related cells (Fig. 63-5). This initial translation product contains an amino-terminal signal (or leader) sequence rich in hydrophobic amino acids. This sequence serves as a signal for attachment of the ribosomes to the membranes of the rough endoplasmic reticulum and vectorial release of the nascent polypeptides into the cisternae of the rough endoplasmic reticulum. During the transmembrane transport of the polypeptides, the signal sequence is enzymatically removed in a reaction catalyzed by signal peptidase, and the polypeptides, termed *proα chains*, are released inside the lumen of the rough endoplasmic reticulum. For some collagens types, in particular the fibril-forming collagens, *proα chains* are larger than collagens α chains because they contain additional peptide sequences at both ends of the molecule.

POSTTRANSLATIONAL MODIFICATIONS OF POLYPEPTIDE CHAINS

After the assembly of amino acids into pre-proα chains on the ribosomes, the polypeptides undergo several modifications before the completed collagens molecules are deposited into extracellular fibers (Fig. 63-5). Most of these posttranslational modifications are catalyzed by specific enzymes (Table 63-3), and include (1) synthesis of hydroxyproline by hydroxylation of selected prolyl residues; (2) synthesis of hydroxylysine by hydroxylation of selected lysyl residues; (3) attachment of carbohydrates, galactose, or glucosylgalactose, onto certain hydroxylysyl residues; (4) chain association, disulfide bonding, and triple-helix formation; (5) proteolytic conversion of procollagens to collagens; and (6) fiber formation and cross-linking. Current evidence indicates that modification reactions (1)–(4) are intracellular events, whereas proteolytic conversion, fiber formation, and cross-linking probably take place extracellularly (see Fig. 63-5).

SYNTHESIS OF HYDROXYPROLINE, HYDROXYLYSINE, AND ATTACHMENT OF CARBOHYDRATES.

A characteristic feature of collagens is the presence of hydroxyproline and hydroxylysine residues.[9] Free hydroxyproline and hydroxylysine are not incorporated into nascent polypeptide chains, but result from the hydroxylation of prolyl and lysyl residues, respectively (Fig. 63-6). The hydroxylation reactions are catalyzed by enzymes belonging to the prolyl and lysyl hydroxylase families.[9,41–45] These enzymes require molecular oxygen, ferrous iron, α-ketoglutarate, and a reducing agent, such as ascorbate as cosubstrates or cofactors for the reactions (Fig. 63-6 and Table 63-3). Hydroxylation begins while the proα chains are growing on the ribosomes, and it is completed soon after the release of full-length polypeptide chains from the ribosomes (Fig. 63-7). The hydroxyproline in collagens is found in two isomeric forms, *trans*-3-hydroxy-L-proline, and the most abundant *trans*-4-hydroxy-L-proline. A critical amount of *trans*-4-hydroxy-L-proline is a prerequisite for the folding of α chains into the triple helix, the conformation required for secretion of procollagens molecules out of the cells. Because triple-helix formation takes place in the cisternae of the rough endoplasmic reticulum, and because prolyl hydroxylases do not hydroxylate prolyl residues if the collagens substrate is in a triple-helical conformation, hydroxyproline formation must be completed before the procollagens molecules leave this cellular compartment. Thus, in the absence of hydroxyproline, the critical triple-helical structure of collagens would not form under physiologic conditions, and no functional collagens fibers would appear in the extracellular space. Also, because prolyl hydroxylase requires a reducing agent, such as ascorbate, for its activity, ascorbic acid deficiency leads to a decreased formation of collagens fibers. This

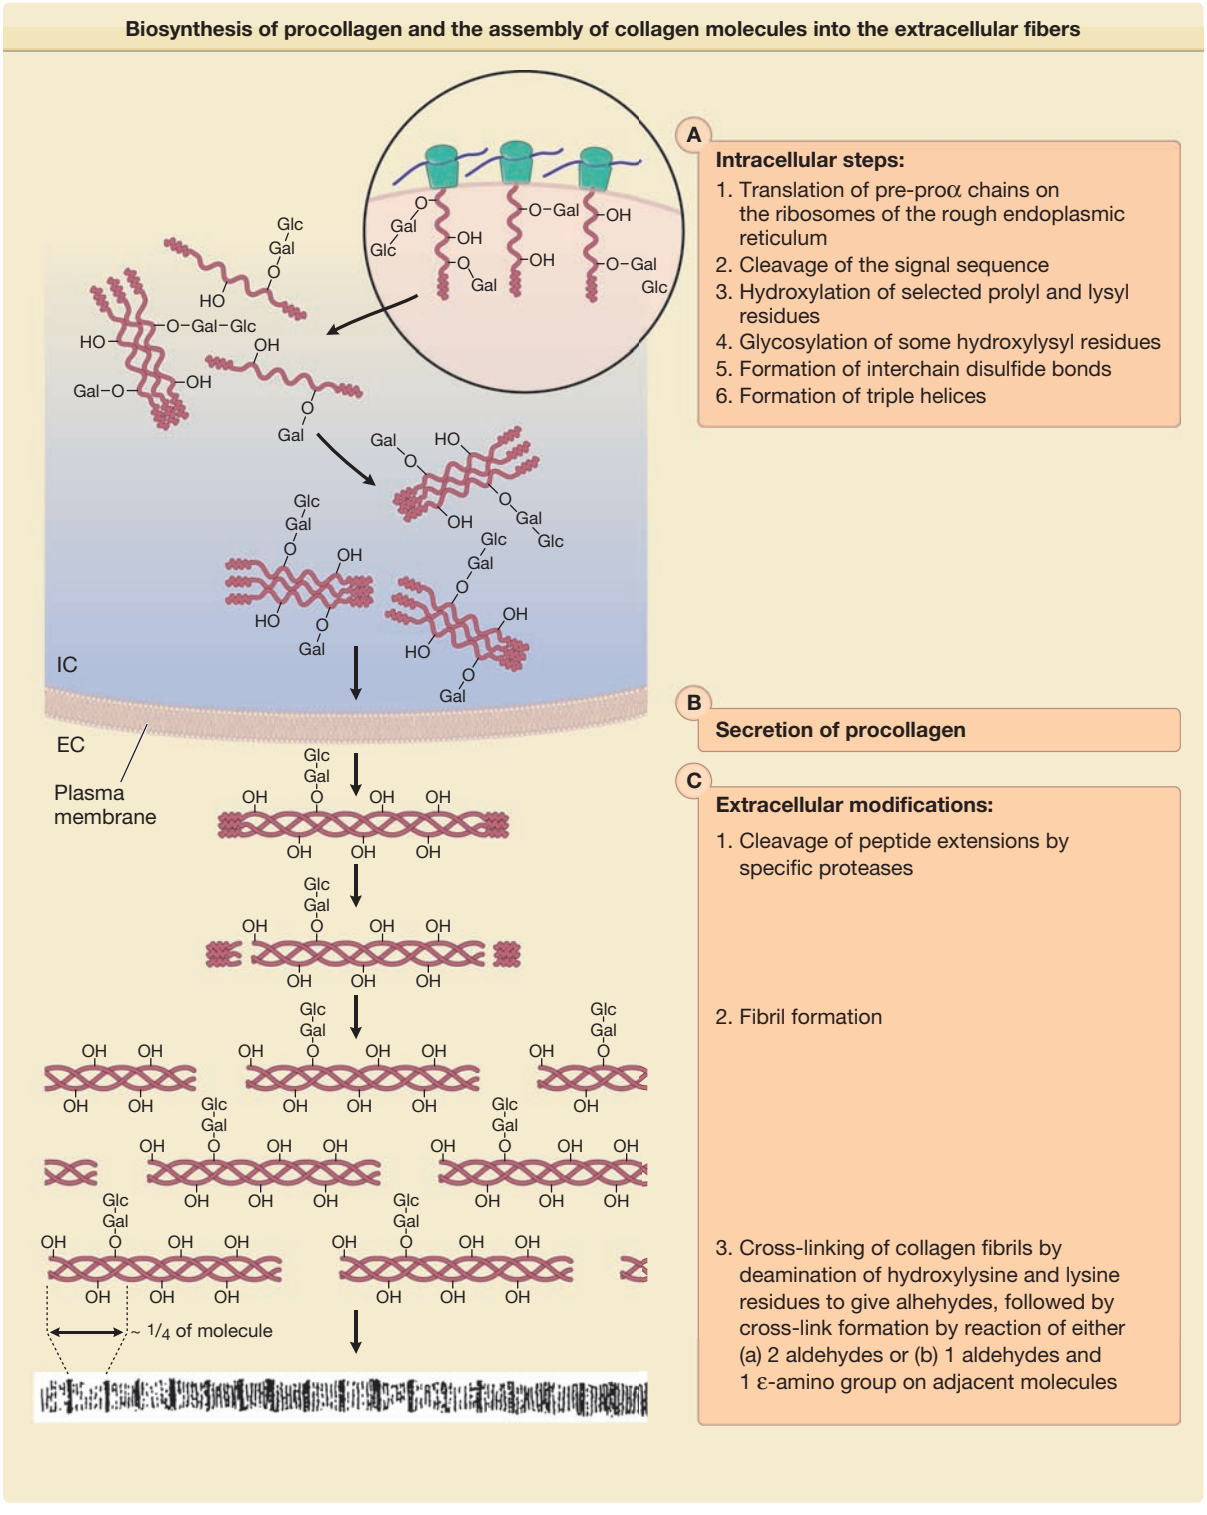

Figure 63-5 Biosynthesis of procollagens and the assembly of collagens molecules into the extracellular fibers. EC = extracellular; Glc-Gal = glucosylgalactose attached to a hydroxylysyl residue; IC = intracellular; mRNA = messenger RNA; –OH = hydroxyl group of hydroxyproline or hydroxylysine; RER = rough endoplasmic reticulum.

explains some of the clinical manifestations in scurvy, such as poor wound healing and decreased tensile strength of the connective tissues.[46] An analogous situation may exist in tissues with hypoxia, because molecular oxygen is a specific requirement for the formation of hydroxyl groups in hydroxyproline. Studies in animal models demonstrate that wound healing is relatively poor under hypobaric conditions, and in such situations the low oxygen levels may limit the synthesis of hydroxyproline.[47] This observation may also explain the

TABLE 63-3
Characteristics of Enzymes Participating in the Biosynthesis of Collagens

Enzyme[a]	Substrate	Product	Co-Factors and Co-Substrates
Signal peptidase	Nascent pre-proα chains	Proα chains	None known
Prolyl-4-hydroxylase	Prolyl residue in X-Pro-Gly sequence in proα chains[b]	4-Hydroxyproline	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Prolyl-3-hydroxylase	Prolyl residue in Pro-Hyp-Gly sequence in proα chains[b]	3-Hydroxyproline	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Lysyl hydroxylase	Lysyl residue in Lys-Gly, Lys-Ser, or Lys-Ala sequence in proα chains[b]	Hydroxylysine	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Collagens galactosyl transferase	Hydroxylysine in proα chains[b]	Gal-*O*-hydroxylysine	Mn^{2+}, UDP-galactose
Collagens glucosyl transferase	Galactosyl-*O*-hydroxylysine in proα chains[b]	Glc-Gal-*O*-hydroxylysine	Mn^{2+}, UDP-glucose
Protein disulfide isomerase[c]	Cysteine residues in the extensions of proα chains	S–S bonds stabilizing the correct protein conformation	Thiols
Procollagen *N*-proteinase (ADAMTS-2)	Procollagen or p_n-collagens	P_c-collagens or collagens[d]	Ca^{2+}
Procollagen *C*-proteinase	Procollagen p_c-collagens	P_n-collagens or collagens[d]	Ca^{2+}
Lysyl oxidases	Lysyl or hydroxylysyl residue in fibrillar collagens	Aldehyde derivatives of lysine or hydroxylysine	Cu^{2+}, O_2

ADAMTS = a disintegrin and metalloprotease with thrombospondin motifs; Ala = alanine; Gal = galactose; Glc = glucosyl; Gly = glycine; Hyp = hydroxyproline; Lys = lysine; p_c-collagens = collagens molecule with the *C*-terminal propeptide still attached whereas the *N*-propeptide has been removed; p_n-collagens= collagens molecule with the *N*-terminal propeptide still attached whereas the *C*-propeptide is cleaved off; Pro = proline; Ser = serine; UDP = uridine diphosphate.

[a]The action of these enzymes (with the exception of signal peptidase) is relatively specific to collagens; the complete sequences of procollagen synthesis and collagens degradation involve additional, less specific enzymes, such as those of transcription and translation.

[b]These reactions are terminated when the proα chains fold into the triple-helical conformation.

[c]It has not been established whether the formation of interchain disulfides in procollagen involves enzymatic catalysis, as occurs in some other proteins, or whether their synthesis takes place spontaneously.

[d]If intact procollagen is used as a substrate, partially modified products are formed; however, if the partially cleaved proteins (p_n-collagens, p_c-collagens) serve as substrates, collagens is produced.

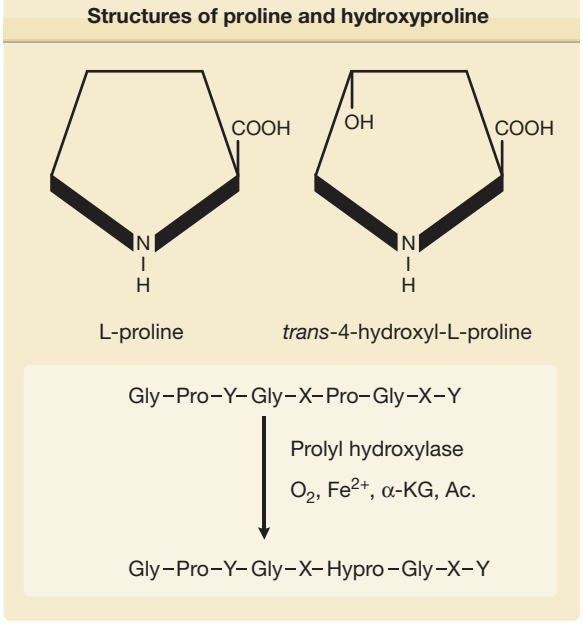

Figure 63-6 Structures of proline (Pro) and hydroxyproline (Hypro), and schematic representation of the enzymatic hydroxylation of prolyl residues in the Y position of the repeating Gly-X-Y sequence of collagens polypeptides. Ac = ascorbic acid; Gly = glycine; α-KG = α-ketoglutarate. (From Uitto J, Prockop DJ: Inhibition of collagens accumulation by proline analogs: The mechanism of their action. In: *Collagens Metabolism in the Liver*, edited by H Popper, K Becker. New York, Stratton Intercontinental, 1975, p. 139, with permission.)

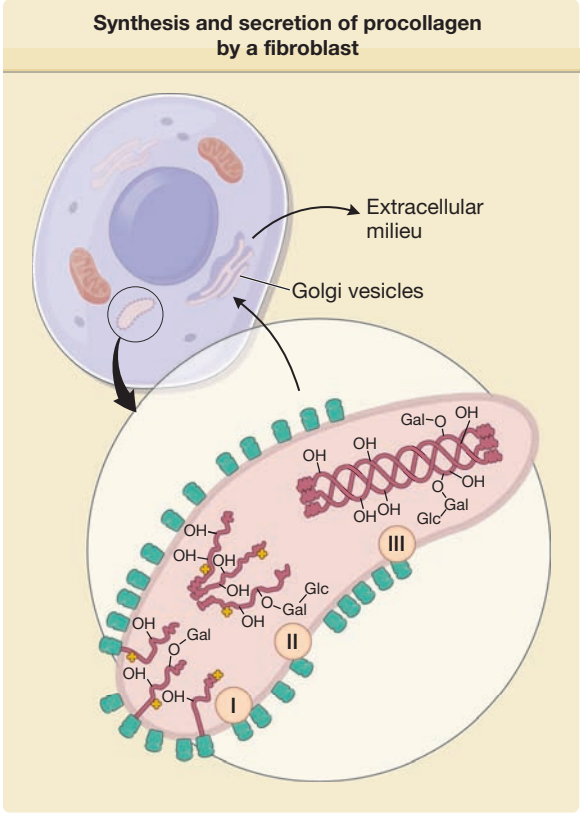

Figure 63-7 Representation of the synthesis and secretion of procollagen by a fibroblast. The enlarged area demonstrates events taking place in the rough endoplasmic reticulum of the cells during the synthesis of procollagen. In the first stage (I), the polypeptide chains of procollagen are synthesized on the membrane-bound ribosomes, and the nascent chains are fed into the cisternae of the rough endoplasmic reticulum. Hydroxylation of prolyl and lysyl residues and glycosylation of hydroxylysyl residues are initiated on the growing polypeptide chains, and these reactions are completed soon after the release of full-size chains from ribosomes (II). Three proα chains are linked together by the formation of interchain disulfide bonds, and the collagenous portions of the polypeptides assume a triple-helical conformation (III). The procollagen molecules are then transferred from the rough endoplasmic reticulum to Golgi vesicles and are secreted from these vesicles into the extracellular milieu. –OH = hydroxyl groups of hydroxyproline and hydroxylysine; –Gal = galactosyl residue attached to hydroxylysine; –Gal-Glc = glucosylgalactosyl residue attached to hydroxylysine in *O*-glycosidic linkage; the cloverleaf-like structures signify the hydroxylating and glycosylating enzymes. (After Prockop DJ et al: Intracellular steps in the biosynthesis of collagens. In: *Biochemistry of Collagens*, edited by GN Ramachandran, AH Reddi. New York, Plenum, 1976, p. 163, with permission.)

decreased healing tendency of wounds and ulcers in peripheral tissues that are anoxic due to relatively poor blood supply. It may also relate to the recent appreciation that prolyl hydroxylases are genuine oxygen sensors. In addition to the prolyl-4-hydroxylase playing a critical role in the hydroxylation of prolyl residues on nascent collagens polypeptide chains, there are additional prolyl-4-hydroxylase isoforms that are responsible for the hydroxylation of two proline residues that earmarks the α subunit of the hypoxia-inducible transcription factor (the master regulator of hypoxia-inducible genes) for proteasomal degradation.[44,48,49]

Lysyl hydroxylation is of critical importance because hydroxylysyl residues serve either as an attachment site for galactosyl and glucosylgalactosyl residues during the intracellular synthesis of procollagen, or to the formation of cross-links that stabilize the collagens matrix in the extracellular space.[9,45,50] The intracellular modification of lysyl residues is a sequential event, with first hydroxylation of lysyl residues, followed by the attachment of galactosyl residue to the hydroxyl group of hydroxylysine with an *O*-glycosidic bond and then a glucose moiety is attached to some of the galactosyl residues (see Figs. 63-5 and 63-7). Therefore, the synthesis of hydroxylysine is a prerequisite for the glycosylation of collagens (see Table 63-3). Three lysyl hydroxylase isoforms exist, and one of them, the lysyl-3-hydroxylase (LH3), displays three activities: (1) lysyl hydroxylase, (2) galactosyltransferase, and (3) glucosyltransfrase activities.[45] The glycosylation reactions use uridine diphosphate sugars as a source of the carbohydrate and require Mn^{2+} as a cofactor. In addition to the glycosylation of hydroxylysyl residues in the triple-helical portion of the molecule, the nonhelical extensions contain complex carbohydrates, consisting mainly of mannose. Deficiency of lysyl hydroxylase has been identified in patients with the scoliotic form (type VI) of Ehlers–Danlos syndrome, characterized by hyperextensible skin, loose-jointedness, severe kyphoscoliosis, and ocular fragility. A connective tissue disorder caused by mutations of the lysyl hydroxylase 3 gene has been recently identified in humans. The disorder is associated with abnormalities in several organs, including skin, and the phenotype has features that overlap with a number of known collagens disorders.[51]

CHAIN ASSOCIATION, DISULFIDE BONDING, AND TRIPLE-HELIX FORMATION

A critical step in the intracellular biosynthesis of procollagens is the association of three proα chains and subsequent folding of the collagens portion of the polypeptides into a triple helix (see Fig. 63-7). The noncollagenous peptide extensions on the individual proα chains assume globular conformations soon after their translation, and this conformation contains the specific information that directs the correct association of the three proα chains. Such a mechanism might explain the association of proα1 and proα2 chains in a proper 2:1 ratio during the synthesis of type I procollagen. It would also explain the rapid and efficient association of the proα chains and folding of the molecule into the triple helix. The association of the extensions at the carboxyl-terminal ends of the polypeptide chains appears to facilitate folding of the molecules into the triple helix, perhaps by providing a nucleation site from which the formation of the triple helix is propagated throughout the collagenous portion of the molecule.

CONVERSION OF PROCOLLAGENSS TO COLLAGENS

After secretion into the extracellular space, procollagens molecules are converted to collagens by limited proteolysis, which removes the extension peptides on the molecule.[52] The conversion of type I procollagens to collagens is catalyzed by two specific enzymes, (1) procollagens *N*-proteinase and (2) procollagens *C*-proteinase, that separately remove the amino-terminal and carboxyl-terminal extensions, respectively (see Table 63-3). Furthermore, the *N*-proteinase catalyzing the conversion of type III procollagens to collagens is a separate, specific enzyme.

The *N*-proteinase capable of cleaving type I procollagens belongs to the ADAMTS (a disintegrin and metalloprotease with thrombospondin motifs) family of extracellular proteases, and is called ADAMTS-2.[53] The activity of this enzyme is dependent on the native conformation of the amino-terminal propeptides in procollagen, because it does not catalyze the removal of the extension peptides from isolated proα chains. Furthermore, partially purified *N*-proteinase is inhibited by metal chelators, which suggests a requirement for divalent cations.

C-proteinase is required for the removal of the carboxyl-terminal extension from type I, II, III, and V procollagen, which allows the fully processed molecules to form functional fibers.[52] Cloning of type I procollagens *C*-proteinase revealed that it is identical to bone morphogenic protein-1, a metalloprotease implicated in pattern formation during development of diverse organisms and also capable of inducing ectopic bone formation.[54] The activity of *C*-proteinase/bone morphogenic protein-1 is stimulated by procollagens *C*-proteinase enhancers, glycoproteins that bind to the *C*-terminal propeptide of type I procollagen.[55] Thus, the conversion of procollagens to collagens is a complex, carefully controlled process, and lack of removal of either the amino- or the carboxyl-terminal extensions results in impaired tensile strength of collagens fibers in the skin. Specifically, deficiency in the removal of the amino-terminal propeptide of type I collagens in vivo causes dermatosparaxis, a disease of fragile skin, originally recognized in various animal species, and more recently recognized in humans.[56] Specifically, the human counterpart is the dermatosparaxis type of Ehlers–Danlos syndrome (type VIIc), caused by deficiency in *N*-proteinase activity. It should be noted that a disease with similar phenotype, the arthrochalasia type of Ehlers–Danlos syndrome (types VIIa and VIIb), can be caused by mutations in the type I collagens genes (*COL1A1* and *COL1A2*, respectively) at the cleavage site for the *N*-proteinase.[57]

COLLAGENS ASSEMBLY AND CROSS-LINKING

Collagens assembly is best defined for fibrillar collagens. After removal of the extension peptides in the extracellular space, the collagens molecules spontaneously align to form fibers. However, these fibers do not attain the necessary tensile strength until the molecules are linked together by specific covalent bonds known as cross-links.[58] The most common forms of cross-links in collagens are derived from lysine or hydroxylysine. The first step in the cross-linking of collagens is the enzymatic conversion of some of the lysyl and hydroxylysyl residues to the corresponding aldehyde derivatives by removal of the ε-amino groups (see Figs. 63-5 and 63-7). The aldehydes then form cross-links by two kinds of reactions. One reaction involves condensation of an aldehyde with an ε-amino group still present in another unmodified lysine or hydroxylysine to form a Schiff base-type of covalent cross-link. The second type of reaction is an aldol condensation between two aldehydes. In addition to these cross-links, collagens contains several more complex cross-links that also involve lysyl or hydroxylysyl residues. The lysine- and hydroxylysine-derived cross-links can be either intramolecular, occurring between two adjacent α chains in the same collagens molecule, or intermolecular, stabilizing the alignment of neighboring collagens molecules along microfibril structures.

The first step in collagens cross-linking, the oxidative deamination of certain lysyl and hydroxylysyl residues, is catalyzed by lysyl oxidase. This enzyme requires copper as a cofactor, and its activity is readily inhibited by nitriles, such as β-aminopropionitrile, which produce lathyrism in animals. Because the cross-links of collagens provide the tensile strength required in certain tissues, a defect in the formation of these covalent bonds can lead to a disturbance in connective tissue function. An example is occipital horn syndrome (previously known as *Ehlers–Danlos syndrome type IX*), which results from reduced lysyl oxidase activity (see Chapter 137). The primary defect resides in perturbed copper metabolism caused by mutations in a copper transport enzyme protein, an adenosine triphosphatase encoded by the gene *MNK-1* that is also involved in Menkes syndrome.[59] As a result, serum copper levels are reduced, which leads to reduced lysyl oxidase activity.

CONTROL OF COLLAGENS AND EXTRACELLULAR MATRIX PRODUCTION

A major question in ECM biology concerns the mechanisms that control the deposition of collagens and other ECM proteins in tissues. Such control must exist in vivo, because the consequences of uncontrolled ECM accumulation are demonstrated by diseases such as progressive systemic sclerosis (see Chapter 157) and various other fibrotic conditions.[60,61]

The accumulation of ECM in tissues can be controlled at several different levels of biosynthesis and degradation. Several observations suggest that an important control mechanism acts at the level of mRNA formation through regulation of the transcriptional activity of gene expression.[62,63] The transcriptional regulation of gene expression involves both *cis*-acting elements and *trans*-acting factors. The *cis*-acting elements are nucleotide sequences in the promoter region of the gene that serve as binding sites for *trans*-acting cellular proteins, which can upregulate or downregulate the transcriptional promoter activity. Some of the *trans*-acting factors are nuclear receptors,

such as the retinoic acid receptors (RAR and RXR)[49] that form a complex with the ligand (a retinoid) and then bind to the retinoic acid-responsive elements (RARE) in the target gene. Retinoids, such as all-*trans*-retinoic acid, modulate type I collagens gene expression both in vitro and in vivo.[64] In particular, quiescent nonproliferating cells can be stimulated by retinoic acid to activate collagens gene expression. This may have relevance to the elevated collagens synthesis observed in photodamaged dermis after topical application of all-*trans*-retinoic acid (see Chapter 109).

Diverse growth factors, cytokines, and chemokines are released into the extracellular space from different types of cells, such as fibroblasts, keratinocytes, and endothelial and inflammatory cells. By both paracrine and autocrine mechanisms these factors elicit intracellular signaling pathways acting on the transcriptional and/or translational levels. One of the most powerful regulators of collagens and ECM production is transforming growth factor β (TGF-β), a member of a family of growth factors involved in many physiological and pathological conditions.[65] Interestingly, TGF-β can induce the expression of other growth factors, in particular the expression of connective tissue growth factor in fibroblasts. Also, cytokines such as platelet-derived growth factor, interleukin-1 and -4, and chemokines, such as monocyte chemotactic protein-1 and -3, are thought to induce collagens production.[66]

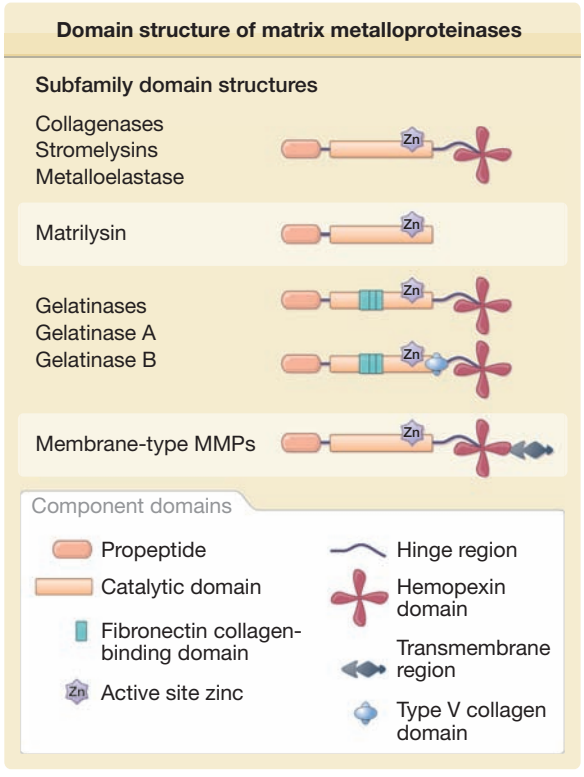

Figure 63-8 Domain structure of matrix metalloproteinases (MMPs).

DEGRADATION AND TURNOVER

In the extracellular space, most collagens form polymers described above, which in turn interact with other proteins of the ECM through multiple protein–protein interactions. It gives rise to large multimolecular assemblies and to the organization of the ECM proteins into specific networks.[17] In addition, many growth factors and cytokines specifically interact with ECM proteins, and they are therefore stored in the networks. There is a continuous remodeling of the multimolecular assemblies, at a rate that can be significantly enhanced during development, wound healing or in certain disease processes. This remodeling results in the release of a large variety of biologically active peptides, including growth factors.[34]

The remodeling of the ECM is a cooperative multistep process involving a variety of molecular pathways and mechanisms. The initial step depends on the presence of proteinases capable of initiating the degradation of the ECM proteins. These enzymes comprise the matrix metalloproteinase (MMP) family,[67–71] which includes collagenases, gelatinases, stromelysins, matrilysins, metalloelastase, enamelysin, and the membrane-type MMPs (Fig. 63-8 and Table 63-4). Interstitial collagenase (MMP-1) was the first enzyme of the MMP family to be discovered and was defined by its ability to break down triple-helical collagens that is resistant to most proteases.[72] Human skin collagenase was initially isolated in active form from the culture medium of skin explants and subsequently as a proenzyme from monolayer fibroblast cultures.[73] Other cell types present in skin, including keratinocytes, endothelial cells, monocytes, and macrophages, express an identical enzyme. Like the other MMPs, MMP-1 contains intrinsic zinc in the active site and requires calcium for its activity and thermostabilization.

MMP-1 degrades some of the collagens present in skin, such as types I, III, and VII, but not others like types IV and V.[74] At physiologic pH and temperature, the enzyme catalyzes a single cleavage three-quarter of the distance from the amino terminus in each of the three α chains comprising the triple-helical, native collagens monomer. Specifically, MMP-1 cleaves the α1(I) chain at a Gly-Ile (glycine-isoleucine) bond (residues 775 and 776) and the α2(I) chain at a Gly-Leu (glycine-leucine) bond in the homologous region. Ten other Gly-Ile or Gly-Leu bonds within the triple-helical domain of interstitial collagens are not cleaved, which suggests that the local conformation of the collagenase cleavage site is a major factor in determining substrate specificity. Indeed, MMP-1 catalyzes multiple cleavages in the denatured chains of all collagens types at Gly-Ile and Gly-Leu bonds. Thus, it appears that the triple-helical conformation of native collagens can drastically alter MMP-1 ability to catalyze cleavages that would be permissible from primary sequence consideration alone.

Human neutrophil interstitial collagenase (MMP-8) attacks collagens at the same site, as does human MMP-1, to produce the characteristic three-quarter/one-quarter collagens fragments. Human MMP-8 is highly homologous to MMP-1, but has a higher degree of glycosylation. It is not immediately secreted but is stored in neutrophil granules and released on stimulation. Although both fibroblast (MMP-1) and neutrophil (MMP-8) collagenases have similar affinities for type I and III collagens, fibroblast collagenase degrades soluble

TABLE 63-4
Matrix Metalloproteinases (MMPs)

Enzyme	MMP Number	Alternate Name	Proenzyme Molecular Weight	Known Matrix Substrates
Interstitial collagenase	MMP-1	Type I collagenase	52,000	Collagens I, II, III, VII, VIII, X, entactin, tenascin, aggrecan, denatured collagens, interleukin-1β, myelin basic protein, L-selectin
Neutrophil collagenase	MMP-8	—	75,000	Collagens I, II, III, V, VII, VIII, X, gelatin, aggrecan, fibronectin
Collagenase-3	MMP-13	—	52,000	Collagens I, II, IV, IX, X, XIV, aggrecan
Gelatinase A	MMP-2	72-kDa type IV collagenase	72,000	Denatured collagens, collagens IV, V, VII, X, XI, XIV; collagens I, species dependent; elastin; fibronectin; laminin; aggrecan; myelin basic protein
Gelatinase B	MMP-9	92-kDa type IV collagenase	92,000	Denatured collagens, collagens IV, V, VII, X, XIV, elastin, entactin, aggrecan, fibronectin, osteonectin, interleukin-1β, plasminogen, myelin basic protein
Stromelysin-1	MMP-3	Proteoglycanase	57,000	Proteoglycan core protein, laminin, fibronectin, collagens I, IV, V, IX, X, XI, gelatin, elastin, tenascin, aggrecan, myelin basic protein, entactin, decorin, osteonectin
Stromelysin-2	MMP-10	Transin-2	55,000	Proteoglycan core protein, collagens III, IV, V, laminin, fibronectin, elastin, aggrecan
Stromelysin-3	MMP-11	—	61,000	α1-proteinase inhibitor
Matrilysin	MMP-7	PUMP, matrilysin-1	28,000	Collagens IV, denatured collagens, laminin, fibronectin, elastin, aggrecan, tenascin, myelin basic protein
Matrilysin-2	MMP-26	Endometase	28,000	Gelatin, α1-proteinase inhibitor
Membrane-type MMP-1	MMP-14	MTI-MMP	63,000	Progelatinase A, denatured collagens, fibronectin, laminin, vitronectin, entactin, proteoglycans
Membrane-type MMP-2	MMP-15	MT2-MMP	72,000	Progelatinase A
Membrane-type MMP-3	MMP-16	MT3-MMP	64,000	Progelatinase A
Membrane-type MMP-4	MMP-17	MT4-MMP	70,000	Unknown
Membrane-type MMP-5	MMP-24	MT5-MMP	73,000	Progelatinase A
Membrane-type MMP-6	MMP-25	MT6-MMP	63,000	Unknown
Metalloelastase	MMP-12	—	54,000	Elastin, collagens IV, vitronectin, plasminogen, laminin, entactin, fibrinogen, fibrin, fibronectin

PUMP = punctuated metalloproteinase.

type III collagens with a higher turnover rate, whereas neutrophil collagenase degrades soluble type I collagens more rapidly. For both enzymes, the differences in specificity against monomeric collagens are largely abolished when the substrates are reconstituted into the insoluble fibrillar forms found in tissues.[75]

Important mechanistic information on collagens degradation has recently emerged, and specifically, it has been shown[75] that activated collagenase (MMP-1) moves processively on collagens fibrils in which the mechanism of movement is a biased diffusion with the biased component of the motion depending on the proteolysis of collagens and not on ATP hydrolysis. Most importantly, the closely related MMPs, MMP-2 (gelatinase) MMP-9, and the extracellular portion of the membrane-associated metalloproteinase MT1–MMP, can also diffuse on collagens fibrils. These studies also show that a collagenolytic MT1–MMP complex exists at the cell surface. The MT1–MMP complex anchored at the cell surface has profound implications concerning the generation of the forces required for cell locomotion, not only in the normal physiologic processes of tissue remodeling but also in pathologic processes, such as tumor invasion.

Collagenase-3 (MMP-13), first cloned from breast carcinoma, is homologous to rodent collagenase.[69] The purified recombinant enzyme cleaves triple-helical collagens, giving the characteristic three-quarter/one-quarter fragments. However, unlike interstitial and neutrophil collagenases, collagenase-3 acts five to ten times more rapidly on soluble type II collagens, a cartilage-specific collagens, than on types I and III. At physiologic temperature, the collagens cleavage products (i.e., the three-quarter/one-quarter fragments), which are initially triple helical, become soluble, are thermally unstable, and denature spontaneously, forming gelatin (denatured collagens). These denatured gelatin polypeptides are then susceptible to attack by other proteinases. Thus, the interstitial collagenases stand at a key point in connective tissue metabolism: they initiate the proteolytic events that result in the degradation of collagens and overall turnover of the extracellular matrices.

ELASTIN AND ASSOCIATED MICROFIBRILLAR PROTEINS

STRUCTURE AND DEVELOPMENT OF THE ELASTIC FIBERS

Elastic fibers form a network responsible for connective tissue elasticity and resilience specific of various organs.[76,77] The relative concentration of elastic fibers is highest in the aorta and arterial blood vessels and in the lungs, while in the skin they are only a minor component. Specifically, in sun-protected adult human skin, the elastin content is 1%–2% of the total dry weight of dermis.[78] In the papillary dermis, elastic fibers are present either as bundles of microfibrils (oxytalan fibers) or with small amounts of cross-linked elastin (elaunin fibers). In the reticular dermis, the elastic fibers consist primarily of elastin, and they are oriented horizontally in a network with vertical extensions to the papillary dermis in the form of oxytalan fibers. Examination of connective tissues by transmission electron microscopy has demonstrated that mature elastic fibers consist of two distinct components (Fig. 63-9). An amorphous, electron-lucent core consists primarily of elastin, surrounded by distinct electron-dense microfibrillar structures that have a regular diameter of 10–12 nm, and which is composed of a variety of microfibrillar proteins such as fibrillins and fibulins.

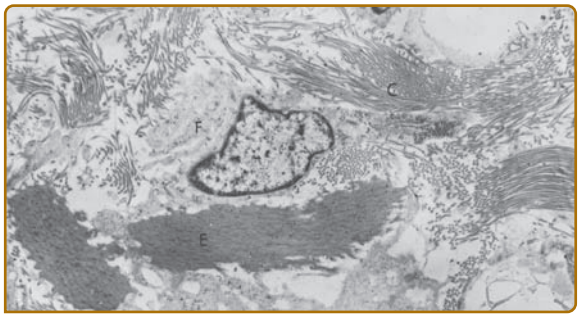

Figure 63-9 Transmission electron microscopy of human skin demonstrating a fibroblast (F) surrounded by elastic structures (E) and collagens fibers (C).

Elastin and the microfibrillar proteins exist in close association in various connective tissues; however, the relative proportions of these components vary during embryonic development. Elastic fibers that form during the first trimester of fetal development consist of bundles of microfibrils, which are thought to form a scaffold into which the elastin molecules will align while fetal age is increasing. Analysis of mature, fully developed elastic fibers suggests that elastin represents well over 90% of the total content of such fibers (see Fig. 63-9). However, it should be noted that skin as well as other tissues contain microfibrils devoid of elastin.

BIOLOGY OF THE ELASTIC FIBERS

Characterization of elastin was hindered for a long time by its extreme insolubility in mature animal tissues. However, it was discovered that this insolubility is attributable to the presence of complex covalent cross-links, known as *desmosines* (see Section "Fibrillogenesis and Cross-Linking of Elastin"), whose formation can be prevented by maintaining the animals on a copper-deficient diet or by feeding them lathyrogens, such as β-aminopropionitrile, which inhibit elastin and collagens cross-linking. Once the formation of the cross-links is prevented, a large fraction of newly synthesized elastin can be extracted from the tissues.[79]

Cloning of cDNAs corresponding to the human elastin mRNA, approximately 3.5 kilobases (kb) in size, has allowed elucidation of the entire primary sequence of tropoelastin[80–84] (Fig. 63-10). The basic molecular unit of elastin is a linear polypeptide, known as *tropoelastin*, that consists of approximately 800 amino acids with a molecular mass of around 70 kDa. Similar to collagens

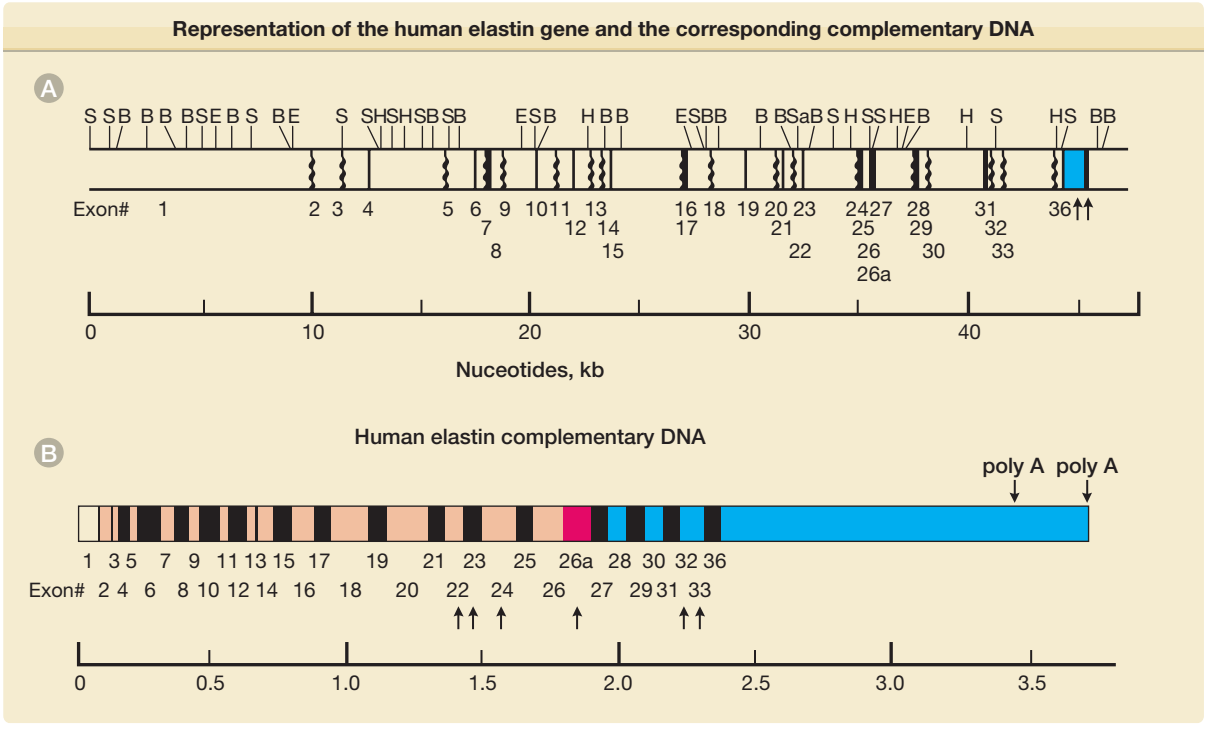

Figure 63-10 Representation of the human elastin gene (**A**) and the corresponding complementary DNA (cDNA) (**B**). **A.** The exons have been numbered starting from the 5′ end of the gene and correspond to those shown in the cDNA (see **B**). The presence of restriction endonuclease cleavage sites: BamHI (B), EcoRI (E), HindIII (H), and SacI (S) are noted on top. **B.** The cDNA, approximately 3.5 kilobases (kb) in size, is divided into separate exons that are numbered from 1 to 36 and drawn to scale. Note that the human elastin gene contains only 34 exons; however, to maintain a consistent numbering system between the bovine and human elastin genes, the last exon is designated as number 36; thus, the human gene is missing the counterparts of bovine exons 34 and 35. The arrows indicate the exons that have been shown to be subject to alternative splicing. The arrows with poly A indicate the polyadenylation sites. (From Uitto et al: Elastic fibers of the connective tissue. In: *Biochemistry and Physiology of Skin*, 2nd edition, edited by L Goldsmith. New York, Oxford University Press, 1991, with permission.)

type I, glycine accounts for about one-third of the amino acid residues in elastin; however, it is not evenly distributed as it is in a typical collagens sequence. Instead, the glycine residues are grouped in valine- and proline-rich regions, which are interspersed with alanine-rich sequences. Elastin also contains some hydroxyproline, but the relative content of this amino acid is considerably lower than that in collagens, and the values for hydroxyproline are variable. Elastin does not contain hydroxylysine or carbohydrate moieties covalently linked to the polypeptide chain.

A characteristic feature of elastic fibers is the presence of cross-links that covalently bind elastin polypeptide chains into a fiber network. The deduced amino acid sequence depicts alternating segments of cross-link domains, characterized by the presence of lysyl residues separated by two or three alanine residues, and hydrophobic domains. The two major cross-link compounds, desmosine and its isomer, isodesmosine, are structures that appear to be unique to elastin.[79] The content of desmosines in various elastin preparations has been shown to be fairly constant, approximately 1.5 residues per 1,000 amino acids. Consequently, assay of desmosine and isodesmosine can provide a quantitative measure of the elastin content in tissues.[79]

CONSTITUTIVE AND ALTERNATIVE SPLICING OF ELASTIN. The human elastin gene consists of 34 separate exons spanning a total of 45 kb of genomic DNA (see Fig. 63-10). The information stored in the DNA sequence is transcribed in the nucleus of the cells to a large mRNA precursor, which undergoes several posttranscriptional modifications, including splicing and polyadenylation. The processed molecules are then transported to the cytoplasm, where the functional mRNAs serve as templates for the synthesis of elastin polypeptides during translation. Several lines of evidence suggest that the rate of elastin biosynthesis is largely regulated by the abundance of the functional mRNA, and consequently, assay of elastin mRNA levels allows measurements of the rate of elastin biosynthesis in tissues and cells.

An early observation during the isolation of human elastin cDNAs was that several overlapping clones were identical, with the exception of short sequences that were absent in some clones but present in others.[81,83,84] Comparison of these sequences in the cDNAs with the corresponding genomic DNA segments indicated that the differences were due to alternative splicing of certain exons during posttranscriptional processing of the elastin pre-mRNA. In fact, at least six

exons in the human gene have been reported to be subject to alternative splicing, and several of the variant mRNAs are translated into protein. This mechanism can provide significant variation in the amino acid composition of individual elastin polypeptides and presumably in the function of the elastic fibers in different tissues. However, the developmental significance and tissue specificity of alternative splicing have not been elucidated in detail.

REGULATION OF ELASTIN GENE EXPRESSION. The elastin promoter contains a remarkable constellation of potential binding sites for transcriptional regulatory factors indicative of complex transcriptional regulation. These include multiple *Sp1* and *AP2* binding sites, putative glucocorticoid-responsive elements, and phorbol ester tumor promoter, 12-*O*-tetradecanoylphorbol and cyclic adenosine monophosphate-responsive elements. The absence of a TATA box in the promoter region suggests that there may be multiple sites of transcriptional initiation, and various molecular tests support this notion.[82] Functional analyses of the human elastin promoter segment have been carried out by constructing a panel of promoter-reporter gene (such as chloramphenicol acetyl transferase) constructs.[85] Use of these constructs in transient transfection of a variety of cultured cells, including human skin fibroblasts, indicated that the core promoter necessary for basal expression of the gene is contained within the region –128 to –1 (in reference to translation initiation site –1, +1), and the upstream sequences contain several upregulatory and downregulatory elements. Development of transgenic mice expressing the human elastin promoter has revealed that 5.2 kb of DNA flanking the human elastin gene contains the elements necessary for tissue-specific expression.[86] In addition to the 5′ upstream sequences, the first introns of both the bovine and human elastin genes contain regions of extremely strong sequence homology. Because it has been demonstrated that the first intron of three different collagens genes contains segments that act as enhancer elements of the promoter activity,[87] the strong conservation within intron 1 of the elastin gene suggests the possible presence of an enhancer in this gene as well.

CYTOKINE AND HORMONAL REGULATION OF ELASTIN SYNTHESIS. The presence of multiple *cis*-acting elements in the elastin promoter region suggests that elastin gene expression is subject to modulation at the transcriptional level by *trans*-acting factors. For example, previous studies have indicated that tumor necrosis factor-α decreases elastin mRNA abundance primarily by suppressing promoter activity.[88] In other studies, TGF-β has been shown to upregulate the abundance of human elastin mRNA by up to approximately 30-fold,[89] but evidence from transient transfection assays suggests that this upregulation is, at least in part, posttranscriptional. In fact, assay of elastin mRNA half-life suggests that TGF-β stabilizes the elastin mRNA, which leads to elevated steady-state levels. These observations collectively suggest that mediators released from inflammatory cells can modulate elastin gene expression, and such modulation may play a role in diseases characterized by altered accumulation of elastic fibers in tissues.

Vitamin D_3 also modulates elastin gene expression. Specifically, incubation of fibroblasts with vitamin D_3 results in an 80%–90% decrease in total accumulation of tropoelastin, accompanied by a parallel decrease in steady-state levels of the corresponding mRNA.[90] At the same time, insulin-like growth factor-1 enhances elastin gene expression at the transcriptional level.[91] Although there is preliminary evidence for modulation of elastin gene expression by selective growth factors and hormone-like substances, the precise details are largely unknown.

ELASTIN BIOSYNTHESIS. Elastin biosynthesis involves several specific steps necessary for the assembly of elastic fibers. Several studies show that smooth muscle cells in culture synthesize relatively large quantities of elastin, which suggests that they may be the major source of elastin in tissues rich in elastic fibers, such as vascular connective tissue.[92,93] The amount of elastin synthesized by cultured human skin fibroblasts is relatively small; nonetheless, fibroblasts may be the primary source of elastin in the dermis. After the completion of translation, newly synthesized polypeptides are translocated into the cisternae of the rough endoplasmic reticulum, and then transferred from the rough endoplasmic reticulum into the extracellular space. Several observations suggest that the secretion of elastin polypeptides is a process that involves the microtubules of the cells and that the molecules may be transferred out of the cells packaged in Golgi vacuoles or related vesicles.

FIBRILLOGENESIS AND CROSS-LINKING OF ELASTIN. The formation of desmosines occurs in the extracellular space, and the first step is the oxidative deamination of lysyl residues to corresponding aldehydes, known as *allysines*. This conversion is catalyzed by copper-requiring enzymes, lysyl oxidases.[94,95] The desmosines are formed by the fusion of three allysines and a fourth unmodified lysyl residue in two adjacent tropoelastin chains. Thus, the desmosines link the individual elastin polypeptides into an insoluble network.

Lysyl oxidases, a group of closely related enzymes, require copper and molecular oxygen as cofactors. It has been shown that the activity of lysyl oxidases is reduced with copper deficiency and that it is associated with a disorder of connective tissue.[96,97] In particular, the individual tropoelastin polypeptides remain soluble and the elastin-rich tissues are fragile.

DEGRADATION AND REMODELING OF ELASTIN. Although the metabolic turnover of elastin is very slow compared with that of proteins in general, a portion of the body's elastin is continuously degraded and may partly be replaced by newly synthesized fibers.[98] In addition, degradation of elastin is markedly increased in a variety of pathologic conditions.[99] Thus, the tissues containing elastin must contain proteolytic enzymes that are capable of degrading elastic fibers.

TABLE 63-5
Microfibrillar Component Proteins

Microfibrillar Protein	Characteristic Features	Human Chromosomal Locus
Fibrillins (FBNs)	350 kDa	
FBN1	Mutations in Marfan syndrome	15q15-q21
FBN2	Mutations in congenital contractural arachnodactyly	5q23-q31
FBN3		19p13.3–13.2
Latent TGF-β-binding proteins (LTBPs)	125–310 kDa	
LTBP1		2p22–24
LTBP2		14q22-q33
LTBP3		11q12
LTBP4		19q13.1–13.2
Fibulins (FBLNs)	60–240 kDa	
FBLN1		22q13.3
FBLN2		3p24-p25
FBLN3		2p16
FBLN4	Mutations in cutis laxa	11q13
FBLN5	Mutations in cutis laxa	14q32.1
Microfibril-associated glycoproteins (MAGPs)		
MAGP1	31 kDa; widely distributed in microfibrils	1p36.1-p35
MAGP2	25 kDa	12p12.3-p13.1
Microfibril-associated proteins (MFAPs)		
MFAP1	Very acidic	15q15-q21
MFAP2		1p36.1-p35
MFAP3		5q32-q33.2
MFAP4	Frequently deleted in Smith–Magenis syndrome	17p11.2
βig-h3		5q31
Lysyl oxidases (LOXs)		
LOX	Probably not structural components	5q23-q31
LOXL1		15q24-q25
LOXL2		8p21.3-p21.2
LOXL3		2p13
LOXL4		10q24
Emilins		
Emilin1 (gp115)		2p23
Emilin2		18p11.3

EGF = epidermal growth factor; TGF-β = transforming growth factor-β; βig-h3 = TGF-β-inducible gene h3.

Evidence for elastase, a specific elastolytic enzyme, was first obtained from study of the pancreas, and since then elastolytic enzymes have been detected in several other tissues, as well as in a variety of cell types, including polymorphonuclear leukocytes, monocytes/macrophages, and platelets.[100] However, elastases from different sources (pancreas vs. polymorphonuclear leukocytes) have different cleavage specificities, as shown by peptide mapping of degradation products.[101]

The classic elastases are serine proteases that degrade insoluble elastic fibers at neutral or slightly alkaline pH. The activity of these enzymes is inhibited by serum factors, such as α_1-antitrypsin and α_2-macroglobulin. In addition to the classic elastases, which are serine proteases, others were shown to be metalloenzymes requiring calcium for their activity. One such enzyme is secreted by macrophages isolated from human alveolar macrophage exudates.[102]

MICROFIBRILLAR PROTEINS

At the electron microscopic level, the microfibrils of the dermis appear in cross section as an outer electron-dense shell surrounding an inner lucid core, and in longitudinal section as a beaded chain, which suggests that they may be composed of more than one protein. Moreover, there is no immunoreactive elastin associated with microfibrils located close to the dermal–epidermal junction, but as microfibrils traverse the dermis, they are associated with an increasing amount of amorphous elastin. Because of their insolubility and apparent complexity, chemical characterization of the microfibrils has progressed slowly until recently. These structural proteins can now be divided into several groups based on their molecular characteristics. Table 63-5 lists these proteins and provides some distinguishing features, including their human chromosomal

localizations. These groups include several gene families that share common structural motifs.

THE FIBRILLINS. The largest, and perhaps the most important microfibrillar proteins for biology and pathology of the dermis, are the fibrillins, 350-kDa glycoproteins that form an integral part of the microfibril structure.[103,104] Electron microscopic images of human monomeric fibrillin synthesized by cultured fibroblasts show an extended flexible molecule, approximately 148-nm long and 2.2-nm wide. Multiple fibrillin molecules align in a parallel head-to-tail fashion to form microfibrils. Molecular cloning studies have so far identified three distinct homologous human genes, (1) *FBN1*, (2) *FBN2*, and (3) *FBN3*, encoding fibrillin-1, -2, and –3, respectively.[104] Analysis of the amino acid sequences deduced from cloned cDNAs showed that these proteins contain multiple repeats of a motif initially observed in epidermal growth factor (EGF) precursor molecule. These motifs have either six or eight conserved cysteines, and many of them contain a consensus sequence for calcium binding.[103,104] Such EGF-like motifs are quite frequent in ECM proteins, and occur as several copies in, for instance, laminins, fibulins, nidogens, agrin, perlecan, tenascins, and latent TGF-β-binding proteins (LTBPs). Besides important structural functions for tissue architecture, it is now clear that fibrillins regulate signaling events and control directly and indirectly cellular activities. Therefore, they play critical roles during development and disease processes.[105–107]

THE LATENT TRANSFORMING GROWTH FACTOR-β-BINDING PROTEINS. It is of interest that LTBPs contain EGF-like motifs similar to those found in fibrillins (Fig. 63-11 provides a comparison of the structures of fibrillins and LTBPs). TGF-β is always secreted as a latent complex with *L*atency-*A*ssociated *P*eptide (LAP) and this complex is bound to an LTBP (Fig. 63-12). To date, four distinct genes (*LTBP1* to *LTBP4*) have been identified, coding for LTBPs ranging in size from 125 to 310 kDa.[108,109] Although LTBPs may facilitate the secretion of TGF-β or association of the inactive complex to the cell surface where activation takes place, they are also found as free proteins associated with components of the ECM. Development of an *LTBP3* knockout mouse revealed craniofacial malformations, perturbed ossification, and development of osteosclerosis and osteoarthritis in the deficient animals. These observations were interpreted to mean that LTBP3 is important for the control of TGF-β action and, specifically, that LTBPs may modulate TGF-β bioavailability. Immunohistologic studies have localized LTBP1 to microfibrils in elastic fibers, which strongly suggests that one or more of the LTBPs may be a component of these fibrils. Furthermore, levels of LTBP1 are altered in a number of pathologic conditions, including solar elastosis.[110]

THE FIBULINS. The fibulins are a family of ECM glycoproteins that contain tandem EGF-like repeats similar to fibrillins and LTBPs, and a common carboxyl-terminal globular domain (see Fig. 63-11).

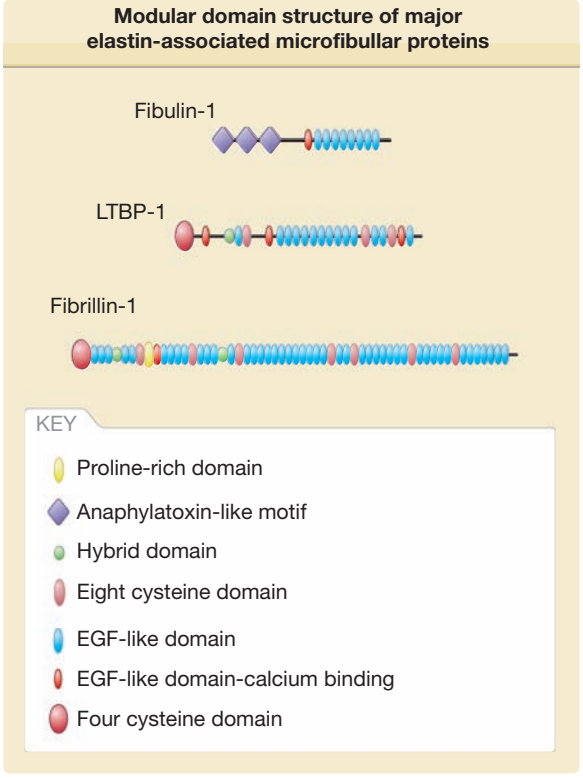

Figure 63-11 Modular domain structure of major elastin-associated microfibrillar proteins, including fibrillin (FBN), latent transforming growth factor-β-binding protein (LTBP), and fibulin (FBLN). The first member of each gene family is represented. The FBN, LTBP, and FBLN families are related because they share common protein motifs. (Adapted from Rosenbloom J, Abrams WR: Elastin and the microfibrillar apparatus. In: *Connective Tissue and Its Heritable Disorders*, 2nd edition, edited by RM Royce, B Steinmann. New York, Wiley-Liss, 2002.)

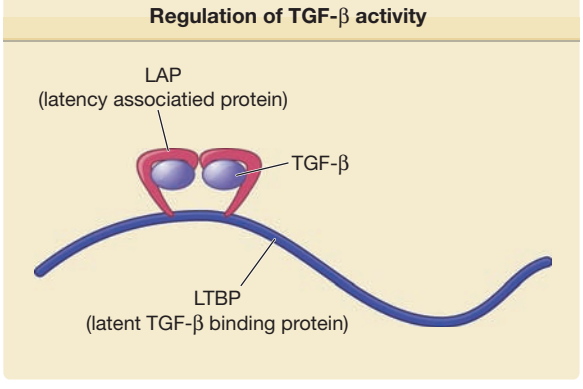

Figure 63-12 Regulation of TGF-β activity. TGF-β is synthesized and secreted in a latent, inactive form in a complex with the latency-associated peptide and the latent TGF-β-binding protein. Therefore, it can be stored in an inactive form in large ECM aggregates. Dissociation of the protein complex leads to activation of TGF-β and a rapid availability, depending on the biological requirements.

Molecular cloning has identified seven fibulin genes (see Table 63-5). Fibulins are widely distributed in connective tissues, including the skin, where they are located within the elastic fibers.[111,112] Fibulin-4- and fibulin-5-deficient mice, developed by targeted ablation of the corresponding genes, demonstrate marked reduction in elastogenesis. Fibulin-4-deficient mice have a severe phenotype that leads to perinatal death, primarily due to pulmonary and cardiovascular abnormalities.[113] Particularly interesting is the phenotype of fibulin-5 knockout mice, which show progressive laxity of skin in addition to vascular abnormalities and emphysematous lung changes.[114,115] The skin changes are reminiscent of those noted in patients with congenital cutis laxa. In fact, mutations in the *FBLN4* and *FBLN5* genes have been documented in some cases of cutis laxa.[116–118]

A number of other proteins unrelated to the fibrillins, LTBPs, and fibulins are constituents of the microfibrils. They include the lysyl oxidases,[94,95] interface proteins called emilins,[119] and several proteins[120] belonging to the families of *M*icrofibril-*A*ssociated *P*roteins (MAP) or microfibril-associated glycoproteins (see Table 63-5). Among the latter, microfibril-associated protein 1 is remarkable in that it is extremely acidic, with glutamic acid comprising 23% and aspartic acid 6% of the residues. The extremely acidic nature of the protein suggests that it may have an important function in the assembly of the very basic tropoelastin molecules. Finally, lysyl oxidases are critical for the cross-linking and stabilization of the elastic fiber structures.

PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

Historically, terms such as *ground substance* or *mucopolysaccharides* were used to describe proteoglycans because of their histologic appearance and their thick and mucinous nature when isolated. Because of these physical properties, proteoglycans were difficult to study. Our understanding of proteoglycans has markedly advanced as a result of increased information about their core proteins and the subsequent use of molecular tools to study the expression and function of both the protein core and glucosaminoglucan (GAG) components. Now, proteoglycans are recognized as a structurally unique and highly diverse group of macromolecules. The most distinguishing structural characteristic of proteoglycans is that they comprise both a core protein and covalently linked linear carbohydrate chains known as GAGs. Proteoglycans constitute an important portion of external cellular membranes and ECM of the skin. Their ability to bind proteins and alter protein–protein interactions or enzymatic activities has identified them as important determinants of cellular responsiveness in development, homeostasis, and disease. Because GAGs are highly polyanionic and bear a high charge density, they are a critical component of the skin, and together with the core proteins, they impart a unique set of functions that are critical to a large number of biologic processes.

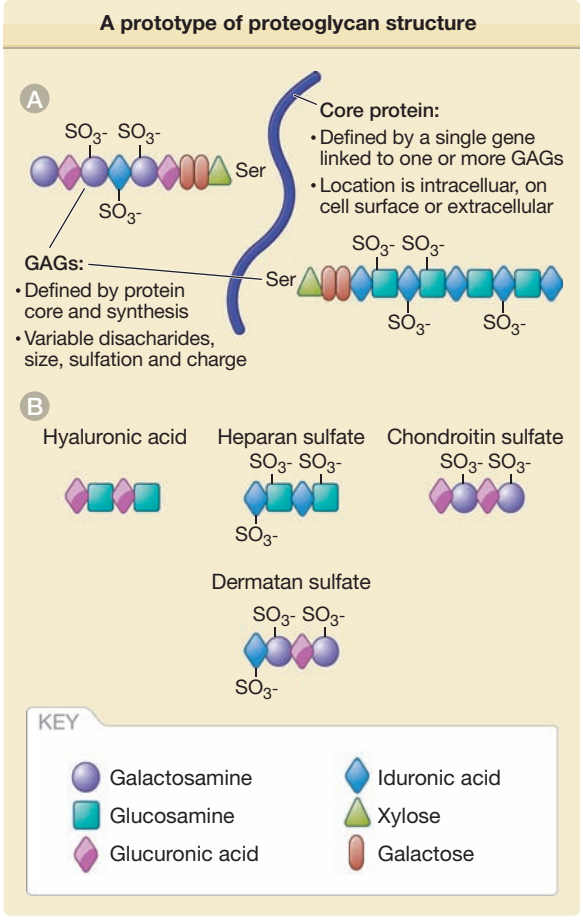

Figure 63-13 A. Prototype of proteoglycan structure. Core proteins may contain from 1 to 100 glycosaminoglycan (GAG) chains, depending on the core protein sequence. Two different GAG chains are shown: dermatan sulfate (*top left*) and heparan sulfate (*bottom right*). Sites of potential sulfation are indicated. Ser represents a serine amino acid residue in the core protein to which GAGs are attached. **B.** Disaccharide repeating units of GAGs shown as tetrasaccharides. Structures of heparan sulfate, dermatan sulfate, chondroitin sulfate A (chondroitin 4-sulfate)/C (chondroitin-6 sulfate), and hyaluronan are shown. Sulfation can vary in heparan sulfate and dermatan sulfate.

STRUCTURE AND SYNTHESIS OF PROTEOGLYCANS

The prototypical proteoglycan consists of a single core protein linked to one or more GAGs (Fig. 63-13). Each core protein has the capacity to accept a variety of GAG chains. Consequently, the nomenclature for proteoglycans is complicated in that individual molecules must be defined based on the core protein and the associated GAGs.

THE GLYCOSAMINOGLYCAN CHAINS

The GAG chains are defined based on the assembly of essential sugar residues.[121,122] These sugars are organized as disaccharide pairs that usually consist of an

acidic sugar that is either an iduronic acid or glucuronic acid alternating with a hexosamine that is either glucosamine or galactosamine. When the chains are assembled as disaccharides, the choice of sugars and the linkage between them is used to assign a name to the GAG chain. Thus, several terms are used to define GAGs (see Fig. 63-13), including *hyaluronic acid*, which contains a glucuronic acid alternating with *N*-acetylglucosamine-linked β1–3 and β1–4; *heparan sulfate*, containing iduronic or glucuronic acids alternating with *N*-acetylglucosamine-linked β1–4; *chondroitin sulfate*, containing glucuronic acid alternating with *N*-acetylgalactosamine-linked β1–3 and β1–4; and *keratan sulfate*, containing galactose alternating with *N*-acetylglucosamine-linked β1–4 and β1–3. A fifth general term used to describe GAGs, and of particular importance to cutaneous biology, is *dermatan sulfate*. This form of GAG (also known as *chondroitin sulfate B*) is similar to other chondroitin sulfates except that it contains a high proportion of iduronic acids in place of glucuronic acid and has more variable sulfation. Dermatan sulfate shares features of both chondroitin sulfate (*N*-acetylgalactosamine) and heparan sulfate (iduronate) (see Fig. 63-13).

The linear chains of linked disaccharide units in a GAG are highly variable in size, ranging from as few as ten disaccharides to several thousand. Thus, the mass of naturally occurring GAGs typically ranges between 5×10^3 Da and 5×10^7 Da for hyaluronic acid. Further variability is introduced into the GAG chain by epimerization reactions and sulfation reactions. The control of these reactions depends on the nature of the GAG, the core protein to which it may be attached, the cell type, and the cell environment. For example, the simplest GAG, hyaluronic acid, is never sulfated, whereas other GAGs can be sulfated to varying degree. The highly sulfated sugars tend to occur in specific regions of the GAG chain and are interspersed with areas of low sulfation. Such discrete domains of low or high sulfation are believed to determine the interactions between proteoglycans and GAGs and their many binding partners. The size, disaccharide composition, and sulfation are of critical importance in understanding GAGs. These parameters influence function and are the mechanism by which instructions are defined within the molecule. Thus, the linear GAG should be considered as a molecule containing information, just as information is encoded in a protein.[121,122]

Synthesis of GAGs (with the exception of hyaluronan) occurs in the Golgi apparatus, and the sequence information is determined by the activity and location of multiple specific enzymes along this pathway. Today, many of the enzymes that control heparan sulfate synthesis and those enzymes responsible for postsynthetic modifications have been identified and characterized. The sulfated GAGs are all synthesized on core proteins. The tetrasaccharide xylose–galactose–galactose–glucuronic acid is first assembled on the core protein by beginning with a xylosyltransferase that forms a linkage between xylose and a serine residue in the core protein. Subsequent elongation reactions that occur in the Golgi apparatus define the nature of the GAG chain. It is appreciated that part of the information necessary to direct synthesis of the GAG is encoded within the core protein sequence itself. The final product, core protein with attached GAG, defines the proteoglycan (see Fig. 63-13). Hyaluronan, the only GAG produced without attachment to a core protein, is synthesized by an enzyme complex at the plasma membrane and then extruded into the extracellular space.

THE VARIETY OF PROTEOGLYCAN CORE PROTEINS

For purposes of organization, it is useful to group proteoglycans according to their site of expression by the cell. Specific proteoglycan core proteins have been identified within the cell, attached to the cell surface, bound within the ECM, and released in soluble form (Table 63-6).

INTRACELLULAR PROTEOGLYCAN: SERGLYCIN. Serglycin is the best-known intracellular proteoglycan and is found within the secretory granules of hematopoietic cells, including mast cells, leukocytes, and eosinophils. The core protein is processed further to contain either heparan sulfate or chondroitin sulfate GAG. The heparan sulfate form is found in serosal mast cells and is a major source from which heparin is pharmacologically derived. The serglycin peptide core is composed primarily of tandem serine–glycine repeats and has an estimated mass of 16–18 kDa before GAG addition and 60–750 kDa after the addition of multiple heterogenous GAG chains.[123] Thus, serglycin is a unique proteoglycan because of its distinctive core protein sequence, and intracellular localization. In the skin, serglycin is found whenever mast cells or eosinophils enter the dermal stroma. On release, serglycin becomes a major source for the delivery of highly sulfated heparan sulfate GAG.

CELL SURFACE PROTEOGLYCANS: SYNDECANS AND GLYPICANS. Several cell surface proteoglycans are very interesting because they act at the interface between the plasma membrane and the extracellular environment. They are attached to the cell surface either by a phospholipid anchor (i.e., glypican family) or as membrane-spanning core proteins (i.e., syndecan family).

The glypicans share the glycophosphatidyl inositol anchorage mechanism and a unique cysteine motif that is likely to impart a compact tertiary structure to the proteoglycans. Consequently, glypicans can be visualized as a compact protein presenting GAG chains in close proximity to the outer surface of the plasma membrane. Six isoforms (glypican-1 to 6) have been described,[124–126] and expression of some glypicans may be altered in inflamed skin and chronic wounds.[127]

The syndecan core proteins consist of a short *C*-terminal cytoplasmic region, a transmembrane domain, and an extracellular region containing attachment sites for GAG chains. Unlike glypicans, syndecans span the plasma membrane and extend beyond the surface of the cell. In this way, syndecans are in a unique position to connect extracellular GAG to structures within the

TABLE 63-6
Core Proteins of Proteoglycans

Core Protein	Location	Usual GAG Component
Intracellular		
Serglycin	Mast cells, basophils	HS, CS
Cell surface		
Syndecan-1	Keratinocytes, other epithelia	HS, CS
Syndecan-2	Fibroblasts, endothelia, bone	HS
Syndecan-3	Neural cells, limbs	HS
Syndecan-4	Ubiquitous, lymphoid	HS, CS
NG-2	Neural, melanoma	CS
Glypican (GPC-1)	Brain, vascular endothelia	HS
Cerebroglycan (GPC-2)	Brain only	HS
OCI-5 (GPC-3)	Intestine and mesenchymal	HS
κ-glypican (GPC-4)	Kidney, brain	HS
Glypican-5 (GPC-5)	Brain, kidney, bone	HS
Glypican-6 (GPC-6)	Intestine, kidney, lung	HS
Epican	Keratinocytes	HS, CS, KS
Betaglycan	Fibroblasts, epithelia	HS
Endocan	Endothelia	DS
Thrombomodulin	Endothelia	DS
Extracellular matrix		
Aggrecan	Cartilage	KS, CS
Versican	Fibroblasts	CS, DS
Brevican	Brain	CS
Neurocan	Brain	CS
Phosphocan	Brain	CS, KS
Decorin	Fibroblasts, others	DS
Biglycan	Bone	DS
Epiphycan	Cartilage	DS
OIF	Cartilage	
Fibromodulin	Fibroblasts	KS
Lumican	Cornea	KS
Agrin	Brain	HS
Perlecan	Basement membranes	HS
Bamacan	Basement membranes	CS

CS = chondroitin sulfate; DS = dermatan sulfate; GAG = glycosaminoglycan; HS = heparan sulfate; KS = keratan sulfate; NG-2 = NG2 proteoglycan; OIF = osteoinductive factor.

cytoplasm.[124,126] The intracellular domain endows syndecans to participate in several signal transduction pathways, including the protein kinase C pathway.[127–129] Syndecan transcripts and proteins are expressed in distinct patterns during development and in mature tissues.[130] Syndecan-1 is particularly abundant on keratinocytes and can vary the nature of attached GAG chains as keratinocytes differentiate.[131] During wound repair, syndecan-1 and syndecan-4 are highly induced in the dermis and granulation tissue.[132] Deletion of syndecan-4 from mice decreases the rate of wound repair.[133] During malignant transformation, syndecan-1 expression decreases in the epidermis,[134] and expression can alter malignant behavior in select cell types.[135] Thus, syndecans have received particular attention as proteoglycans that modify cell function. Because syndecans and other proteoglycans can contain more than one GAG species, either simultaneously or under different cellular circumstances, GAG expression provides another mechanism of regulation in addition to protein expression.

LARGE AGGREGATING EXTRACELLULAR MATRIX PROTEOGLYCANS: AGGRECAN AND VERSICAN. Aggrecan, a large proteoglycan found in cartilage, has a core protein containing a region with over 100 serine–glycine dipeptides that serve as attachment sites for up to 130 GAG chains. As many as 100 aggrecan molecules can bind to a single hyaluronic acid molecule. Thus, the overall proteoglycan aggregate (from which the name *aggrecan* is derived) can have a mass near 200,000 kDa.[135]

In the skin, fibroblasts produce large aggregating proteoglycans similar to aggrecan, the best known being versican.[135,136] The core protein of versican contains attachment sites for 12–15 GAG chains, which are primarily chondroitin sulfate or dermatan sulfate. Versican, like aggrecan, binds hyaluronic acid, which enables it to form large aggregates. In skin, versican has been identified in the dermis (fibroblasts) and epidermis (keratinocytes) and demonstrates selective upregulation in response to TGF-β.[137] Thus, the size, distribution, and abundance of versican in the skin

suggest that it is an important molecule in the regulation of the behavior of the skin.

SMALL EXTRACELLULAR MATRIX PROTEOGLYCANS: DECORIN. Several genes encoding smaller ECM proteoglycans have been identified. One family is characterized by a leucine-rich repeat motif. The prototype of this family is decorin, an approximately 36-kDa secreted proteoglycan.[125,135,136] Decorin is a ubiquitous component of connective tissues and it is found in abundance in skin. The decorin core protein has a single dermatan sulfate chain covalently bound to a serine residue at amino acid position 4 and, like many other proteoglycans, also has *N*-linked oligosaccharides. Thus, after GAG addition, decorin can have a mass of 80 kDa. Decorin received its name from observations that this molecule closely associates with collagens fibrils and can be seen to "decorate" the fibrils in vivo. This interaction is attributed to the ability of the decorin core protein to directly bind to collagens type I.[138] The single GAG chain of decorin also binds to tenascin-X, another ECM protein that colocalizes with collagens fibrils in connective tissues.[139] These binding interactions contribute to collagens fibril formation and influence function. Interestingly, similar phenotypes showing abnormal collagens morphology are seen in a patient deficient in tenascin-X and in the murine decorin knockout model.[140]

FUNCTION OF PROTEOGLYCANS

To understand how proteoglycans function in the skin it is essential to appreciate the basics of their organization: (1) proteoglycans are part protein and part GAG; (2) GAGs are heterogeneous but encode specific information; (3) proteoglycan core proteins are expressed in different cellular compartments; and (4) proteoglycan expression and GAG composition vary according to cellular context. These characteristics are important, because many proteoglycan functions depend on their ability to bind other molecules in the environment, and because both the core protein and GAG chains may be mediating or influencing molecular interactions. Similar GAGs can be attached to diverse core proteins. This ability to interchange GAGs among cores adds complexity to the study of proteoglycan function, and in many cases, proteoglycan properties are defined by the GAG chains. It implies that certain genes encoding different core proteins to which similar GAGs are attached may have a similar function. The list of molecules to which the major skin proteoglycans heparan sulfate and dermatan sulfate bind is quite extensive (Table 63-7). Therefore, several functions for proteoglycans have been proposed that include the particular biologic system in which the ligand is involved.

Some of the most compelling experimental evidence for the functions of heparan and dermatan sulfate proteoglycans identifies the ability to bind several growth factors, cytokines, and components of the ECM.[141] For instance, heparan sulfate is required for the function of growth factors such as several members of the fibroblast growth factor family,[142,143] hepatocyte growth fac-

tor/scatter factor,[144] and vascular endothelial growth factor.[145] In this model, the heparan sulfate proteoglycan is found either at the cell surface or in a soluble form. The molecules then assemble to form a ternary complex at the cell surface between the growth factor, its specific high-affinity signaling receptor, and the proteoglycan.[146] Only after this ternary complex is formed does the cell receive the growth factor signal to begin to proliferate, differentiate, or migrate. Heparan sulfate-dependent growth factors, such as members of the fibroblast growth factor family, are induced in healing wounds and influence the wound repair process through the stimulation of keratinocyte proliferation, fibroblast growth, and angiogenesis. Because dermatan sulfate is the predominant GAG in wound fluid and because it can bind a variety of growth factors, cytokines, and ECM proteins, further study of this GAG and the proteoglycans it comprises promises to be an exciting area for future investigation.

In addition to binding to growth factors, heparan sulfate proteoglycans play an important role in adhesion to the ECM. In the current model, cell surface proteoglycans, in conjunction with other matrix-binding molecules such as the integrins, help the cell adhere to the ECM.[124,126] Furthermore, the formation of these focal adhesions requires heparan sulfate and the subsequent activation of protein kinase C by a domain in the syndecan-4 core protein cytoplasmic tail. In this setting, both the extracellular GAG and intracellular core protein of the proteoglycan have demonstrable signaling function.[128,129]

Other proteoglycans also interact with ECM molecules. Chondroitin sulfate and dermatan sulfate bind fibronectin and laminin. As mentioned earlier, decorin, to which dermatan sulfate is typically attached, is known to associate primarily with type I collagens via its core protein.[138] In mice, selective disruption of the decorin gene leads to abnormal collagens morphology and increased skin fragility.[140] Thus, through targeted disruption of the gene in the mouse, the function of decorin as a stabilizer of collagens fibrils has been directly confirmed.

The function of the large ECM proteoglycans in skin is thought to relate primarily to the physical properties inherent in their large mass and charge density. Hyaluronan has been studied extensively from this perspective because of its extreme hydrophilicity and viscosity in dilute solution. As discussed earlier, hyaluronic acid is pure GAG and is synthesized extracellularly without a core protein. The genes for human hyaluronan synthase have been cloned and identified.[147] The expression of hyaluronan is developmentally regulated in skin and changes during wound repair. It has been proposed that the physicochemical properties of hyaluronan serve to expand the matrix and thus aid cell movements. Other physical properties attributed to GAG and large proteoglycan complexes, such as those formed with versican or basement membrane proteoglycans, include their ability to act as anionic filters and elastic cushions and their function in salt and water balance. In fetal skin, the high relative content of hyaluronan has been associated with the ability of fetal skin to heal without scar.

CELLULAR RECEPTORS FOR PROTEINS OF THE EXTRACELLULAR MATRIX

Many components of the ECM regulate cellular behavior directly and indirectly. An indirect mechanism is provided by the modulation and control of the activity of cytokines, growth factors, and chemokines by proteins in the ECM. A direct and most important mechanism relies on the control of cellular activities through adhesive interactions between cell surface receptors and ECM proteins (Fig. 63-14). Several classes of cell surface receptors have been identified, such as the syndecans,[124,126] DDRs (*D*iscoidin *D*omain *R*eceptors),[148] and integrins.[10,149–152] The latter are noncovalently linked heterodimers of one α and one β subunits. Integrins have a short cytoplasmic domain (except for the 1,000 residue-long intracellular domain of the integrin β4 subunit expressed by keratinocytes), a single stretch transmembrane domain, and a large extracellular domain interacting with specific proteins of the ECM or with counter-receptor present on the surface of circulating cells, including microbial proteins. In human, 18 α and 8 β subunits have been characterized, assembling into 24 different combinations. The integrin cytoplasmic domain lacks enzymatic activity; however, by associating with multiple proteins into signaling platforms,

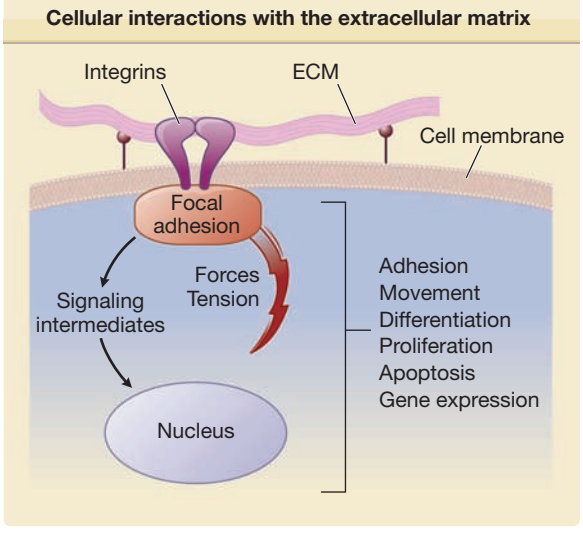

Figure 63-14 Cellular interactions with the extracellular matrix (ECM). The main cellular receptors for ECM constituents are the integrins. They consist of one α and one β subunits noncovalently associated. Together, the large extracellular domains of both subunits provide a binding site for specific ECM ligands. The short intracellular portions of the subunits are devoid of enzymatic activity and recruitment of cytoskeleton-associating and adaptor proteins is required for signal transduction and transmission of forces, both outside-in and inside-out. Through outside-in signaling, the ECM regulates many cellular functions, like adhesion, movement, survival, differentiation, and expression of specific genes. Inside-out transmission of forces is thought to be important for organization of the ECM architecture.

they activate diverse molecular pathways.[151,152] Adhesive interactions between integrins and ECM proteins control many cellular functions, such as migration, survival, differentiation, contraction, transmission of forces, and expression of specific genes.[149,150] Expression of a distinct set of integrins on the cell surface determines specificity, range, and versatility of the interactions with ECM proteins. For instance, fibroblasts express, among others, integrins with the property to interact with native fibril-forming collagens, fibronectin, and vitronectin.[10] In addition, the repertoire of integrins expressed by a given cell type may adapt to the differentiation stage during development and to specific physiological and pathological features of the microenvironment, such as wound healing, aging, inflammation, and fibrosis.[153] Integrins are also expressed by inflammatory cells and control their migration and targeting to specific sites of inflammation.[154] Finally, it has been suggested that integrins cross talk or act in synergy with growth factors, cytokines, and cognate receptors.[155] Together, the many facets of integrins endow these proteins with crucial roles in various physiological and pathological processes such as fibrosis, tissue repair, and carcinoma progression.

DISEASES OF THE DERMAL EXTRACELLULAR MATRIX

The many components of the ECM in the dermal compartment of the skin have an elaborate biosynthesis, maturation, and turnover, often a complex structure, and they are assembled into exquisitely complex networks. Therefore, it is not surprising that many diseases exist due to disturbances in the genetic expression, structure, homeostasis, and assemblies of ECM proteins.

Based on our understanding of the molecular biology and the metabolism of the ECM components, it is now possible to identify discrete points at which defects could occur. These can be located at different levels (Box 63-1). Many mutations in the genes coding for ECM proteins or in the enzymes involved in their posttranslational modifications or their supramolecular assemblies into defined networks have been identified as outlined in preceding paragraphs.

ECM deposition and assembly into insoluble and complex polymers are tightly controlled mechanisms, which undergo substantial variations during development, tissue remodeling, repair, ageing, wound healing, or fibrosis. Several ECM proteins are also targets for circulating antibodies, leading to autoimmune diseases. Most interesting for dermatology are the autoimmune blistering diseases that are discussed in detail in other chapters. There is also accumulating evidence that many ECM proteins manifest regulatory functions, which can be disturbed and lead to disease processes.

BOX 63-1 MOLECULAR MECHANISMS OF EXTRACELLULAR MATRIX-ASSOCIATED DISEASES

- Mutations in genes coding for
  - extracellular matrix (ECM) components
  - enzymes required for posttranslational modifications of ECM components
  - proteins required for folding/assembly of ECM proteins
  - enzymes required for ECM maturation, deposition, turnover, degradation
- Development of autoimmunity (blistering diseases, Goodpasture, etc.)
- Altered regulatory functions of the ECM

CUTANEOUS COLLAGENS DISEASES

The term *collagens disease* implies that a clinical condition involves an abnormality in the structure, synthesis, or degradation of collagens. This term is frequently used to characterize a clinically heterogeneous group of inflammatory diseases, including lupus erythematosus, scleroderma, and dermatomyositis. In the classic nomenclature, the use of the term *collagens disease* for these conditions was based on morphologic changes, known as *fibrinoid degeneration*, that have been interpreted to represent changes in collagens fibers. However, there is currently no evidence for a primary defect in collagens in these diseases. On the basis of available biochemical evidence, scleroderma is the only clinical condition among the classic collagens diseases that involves dysregulation of collagens metabolism (see also Chapter 157).

Collagens is an unusual protein in many respects, and its structure and metabolism involve a number of special features that are critical for deposition of normal collagens fibers. In a primary collagens disease, such a defect could be an inherited abnormality in the structure of the collagens or procollagens or in the enzymes participating in the biosynthesis and degradation of collagens. Indeed, there are many diseases in which a basic biochemical defect in collagens has been described, and several heritable connective tissue diseases with cutaneous involvement are now known to result from specific molecular defects in collagens genes (see Chapter 137). Many of these diseases involve insertions, deletions, or single-base substitutions in the genes that alter the primary structure of the protein.[9,13,14] In several acquired diseases, the regulation of collagens gene expression is disturbed, which leads to altered deposition of collagens in tissues. The diversity of collagens pathology is exemplified by Ehlers–Danlos syndrome and fibrotic skin diseases (see Chapters 137 and 157). Ehlers–Danlos syndrome comprises a group of phenotypically similar conditions that frequently result from abnormalities in the structure of collagens or in enzymes modifying collagens molecules.[19,20,56,57] In contrast, the fibrotic skin diseases exemplify conditions with altered regulation of collagens gene expression that leads to excessive accumulation of collagens in tissues.[61]

PATHOLOGY OF THE ELASTIC FIBERS IN CUTANEOUS DISEASES

Several heritable and acquired connective tissue diseases have been shown to be associated with aberrations in the elastic fibers, including pseudoxanthoma elasticum, cutis laxa, and the Buschke–Ollendorff syndrome (Table 63-8; see Chapter 137). In addition, clinically distinct entities with phenotypes closely resembling pseudoxanthoma elasticum (e.g., elastoderma) or cutis laxa (e.g., wrinkly skin syndrome) can be recognized.

There has been significant progress recently in identifying and understanding the molecular mechanisms associated with mutations in the fibrillin genes.[156] Heterozygous mutations that affect the structure or lead to a reduced synthesis are the cause of the Marfan syndrome. This disease is clinically characterized by abnormalities and disturbances in the ocular, skeletal, and cardiovascular systems. The patients display a thin skin, with extensive striae distensae; some, however, also have contractures. A careful analysis of mouse models with similar molecular defects revealed that the mutations in the fibrillin gene are associated with increased TGF-β signaling. Interestingly, the phenotype presenting with development of a mitral valve prolapse in this mice could be reverted or delayed by addition of TGF-β neutralizing antibodies. These data indicate that fibrillin-1 is likely to be involved in the tight regulation of TGF-β activity. In a clinical study, application of angiotensin II inhibitors to patients with Marfan syndrome consistently and significantly slowed the progression of aortic root dilatation.[157]

DISEASES DUE TO ABNORMAL PROTEOGLYCAN METABOLISM

Multiple cutaneous disorders are associated with abnormal proteoglycan synthesis or deposition. A deficiency of decorin core protein has been described as the cause of a variant form of Ehlers–Danlos syndrome. Even infectious diseases are influenced by proteoglycan expression. A good example is provided by the decorin-deficient mice, which are rather resistant to infection with *Borrelia burgdorferi*. Presumably, the resistance is caused by a partial dependence of the organism on decorin for binding in the dermis.[158] During aging, the composition of GAG in the skin undergoes marked changes and it has been proposed that the decrease in hyaluronic acid explains diminished skin turgor.[159,160] Retinoids also modify this response.[161] In keloids, hyaluronic acid synthesis is elevated.[162] Thyroid hormone also has a marked effect on the synthesis of proteoglycans and GAGs. The manifestation of this response is seen in thyroid dermopathy (Chapter 151), in which the mucinous material deposited is predominantly hyaluronic acid and chondroitin sulfate. Other pathologic skin conditions, including pseudoxanthoma elasticum, scleroderma, psoriasis, a variant form of Ehlers–Danlos syndrome, lichen myxedematosus, and ultraviolet B-irradiated skin, have also been reported to be characterized by abnormal amounts of proteoglycans. These associations do not imply that abnormal proteoglycan metabolism is responsible for these disorders, but they suggest that much of the pathophysiology of skin disease can be influenced by the function of cutaneous proteoglycans.

EMERGING DISEASE MECHANISMS

Mutations in the genes coding for key ECM proteins often lead to functional consequences, which are associated with severe clinical symptoms. Although structural alterations can certainly explain a number of symptoms, it is clear that not all pleiotropic clinical alterations are directly and solely due to the abnormalities in protein structure. Evidence is now accumulating that induction of endoplasmic reticulum stress represents an additional mechanism explaining some of the deleterious effects resulting from mutations in the genes needed for the elaboration of ECM proteins.[22,163–165] For instance, the accumulation of misfolded or unfolded mutant polypeptides in the endoplasmic reticulum induces the so-called "unfolded protein response."[166–168] It results in detrimental processes of diverse severity, ranging from increased protein targeting to the proteasome for destruction, autophagy, general reduction in protein synthesis including that of the abnormal protein, to complete cellular dysfunction with apoptosis of the cells (Fig. 63-15). Such a deleterious outcome has been demonstrated for mutations in several ECM genes, often

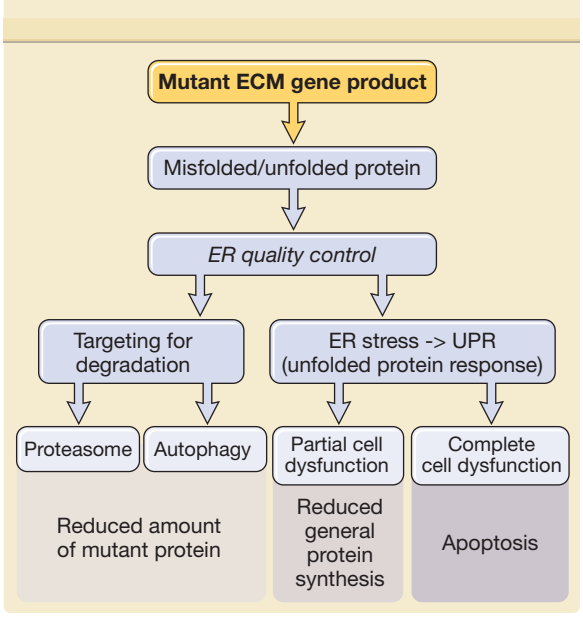

Figure 63-15 The endoplasmic reticulum stress as a mechanism inducing a deleterious function of the extracellular matrix (ECM). Misfolded ECM polypeptide chains harboring mutations, or excess of unfolded polypeptides, are either targeted for degradation or their accumulation within the endoplasmic reticulum induces the unfolded protein response, leading to partial or complete cell dysfunction and apoptosis.

TABLE 63-8
Clinical Features, Histopathology, Inheritance, Associated Biochemical Findings, and Predisposing Clinical Conditions in Cutaneous Diseases with Elastic Fiber Abnormalities[a]

Disease	Inheritance	Clinical Manifestations	Skin Histopathologic Findings	Biochemical Findings[b] Related to Elastic Fibers and Predisposing Clinical Conditions
Pseudoxanthoma elasticum	AR, sporadic[c]	Yellowish papules coalescing into plaques Inelastic skin Cardiovascular and ocular abnormalities	Accumulation of pleomorphic and calcified elastic fibers in the middermis	Deposition of calcium apatite crystals, excessive accumulation of glycosaminoglycans on elastic fibers; D-penicillamine treatment; mutations in the *ABCC6* gene
Buschke–Ollendorff syndrome	AD	Dermatofibrosis lenticularis disseminata and osteopoikilosis	Accumulation of interlacing elastic fibers in the dermis	Increased desmosine content in the skin; mutations in *LEMD3*
Cutis laxa	AR, AD, or NH	Loose, sagging, inelastic skin Pulmonary emphysema Tortuosity of aorta Urinary and gastrointestinal tract diverticuli	Fragmentation and loss of elastic fibers	Decreased desmosine content and reduced elastin mRNA levels; increased elastase activity in some cases; D-penicillamine treatment, inflammatory and urticarial skin lesions (e.g., drug reaction); mutations in the *ELN*, *EBLN4FBLN4*, or *FBLN5*, *LTBP4*, or *PYCR15* gene in limited cases
DeBarsy syndrome	AR	Cutis laxa-like skin changes Mental retardation Dwarfism	Rudimentary, fragmented elastic fibers	Reduced elastin mRNA levels
Wrinkly skin syndrome	AR	Decreased elastic recoil of the skin Increased number of palmar and plantar creases	Decreased number and length of elastic fibers	—
Middermal elastolysis	NH	Fine wrinkling of the skin, primarily in exposed areas	Fragmentation and loss of elastin in the middermis	Inflammatory; sun exposure
Anetoderma	NH	Localized areas of atrophic, sac-like lesions	Loss and fragmentation of elastic fibers in the dermis	Reduced desmosine content in the lesions; often secondary to inflammatory lesions
Elastosis perforans serpiginosa	NH	Hyperkeratotic papules, commonly on the face and neck	Accumulation and transepidermal elimination of elastic fibers	D-penicillamine-induced abnormalities in elastin cross-linking
Elastoderma	Unknown	Loose and sagging skin with loss of recoil	Accumulation of pleomorphic elastotic material without calcification in the mid and lower dermis and the subcutaneous tissue	—
Isolated elastomas	NH	Dermal papules or nodules	Accumulation of thick elastic fibers in the dermis	—
Elastofibroma dorsi	NH	Deep subcutaneous tumor, usually on subscapular area	Accumulation of globular elastic structures encased in collagenous meshwork	Trauma on the lesional area
Actinic elastosis	NH	Thickening and furrowing of the skin	Accumulation of irregularly thickened elastic fibers in upper dermis	Long-term sun exposure
Marfan syndrome	AD	Skeletal, ocular, and cardiovascular abnormalities Hyperextensible skin Striae distensae	Fragmentation of the elastic structures in the aorta	Mutations in the *FBN1* gene
Congenital contractural arachnodactyly	AD	Camptodactyly and joint contractures		Mutations in the *FBN2* gene
Williams syndrome	AD	Supravalvular aortic stenosis Velvety skin Dysmorphic facies	Disruption of smooth muscle and matrix relationship affecting blood vessels	Allelic deletion of the *ELN* gene; contiguous gene deletion syndrome

AD = autosomal dominant; AR = autosomal recessive; NH = not a heritable disease; mRNA = messenger RNA.
[a]Most of these conditions represent a group of diseases with clinical, genetic, and biochemical heterogeneity.
[b]The biochemical abnormalities have been demonstrated in only a limited number of patients in each group, and it is not known whether the biochemical changes are the same in each patient with any given disease.
[c]Rare cases with a distinct acquired form of pseudoxanthoma elasticum have been described.

resulting in severe clinical subsets of osteogenesis imperfecta or some inheritable cartilage diseases. However, it remains to be seen whether these mechanisms could play a much broader role and apply to other inherited or acquired disorders of the ECM.

Chapter 64 :: Morphea

:: Stephanie Saxton-Daniels & Heidi T. Jacobe

MORPHEA AT A GLANCE

- Occurs in children and adults.
  - Linear subtype predominates in children.
  - Circumscribed and generalized predominate in adults.
- A self-limited or chronically relapsing autoimmune disorder targeting the skin with the following major features:
  - Inflammatory, sclerotic, atrophic phases.
  - Thickened sclerotic skin.
  - Systemic disease including arthritis and neurological disorders.
- Differentiated from scleroderma by lack of acrosclerosis/sclerodactyly.
- Complications may cause significant irreversible cosmetic and functional impairment including the following:
  - Atrophy of dermis, fat, and subcutaneous structures.
  - Contracture.
  - Limb length discrepancy.
  - Bony abnormalities.
- Treatment based on the following:
  - Disease subtype.
  - Depth of involvement.
  - Stage (inflammatory, sclerotic, atrophic).
  - Potential for complications.

BOX 64-1 DIFFERENTIAL DIAGNOSIS OF MORPHEA

Most Likely

- Scleroderma (systemic sclerosis)
- Lipodermatosclerosis
- Eosinophilic fasciitis
- Trauma-induced fat necrosis (intramuscular injections)
- Nephrogenic systemic fibrosis
- Chronic graft-versus-host disease

Consider

- Lichen sclerosus
- Pretibial myxedema
- Connective tissue nevi
- Morpheaform basal cell carcinoma
- Chemical mediated sclerosing skin conditions (toxic oil syndrome, rapeseed oil, etc.)
- Lyme disease (acrodermatitis atrophicans)
- Phenylketonuria
- Scleromyxedema, scleroderma chronica, pretibial myxedema
- POEMS syndrome

Always Rule Out

- Carcinoma of the breast metastatic to skin (carcinoma en cuirase)
- Porphyria cutanea tarda

POEMS = *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes.

Morphea is a chronic autoimmune disease characterized by sclerosis of the skin. The term "localized scleroderma" is also used in an attempt to highlight the systemic features of morphea. This causes confusion with systemic sclerosis (scleroderma) often resulting in unnecessary evaluation and anxiety. It is the opinion of the authors this term should be avoided. Morphea itself has a spectrum of manifestations ranging from skin only to multiple organ involvement. Of note, organ involvement in morphea is distinctly different from systemic sclerosis (Box 64-1).

EPIDEMIOLOGY

Morphea has an estimated incidence of 2.7 per 100,000 with a female:male ratio of 2 to 3:1.[1] Morphea is more common in Caucasians.[2–5] The relative frequency of the different subtypes varies between studies. This is likely due to use of different classification systems. Twenty to thirty percent of morphea begins in childhood, but it can occur at any age.[2–5] Linear morphea is the most common pediatric subtype (although all subtypes occur at any age).[1,2,6] Twenty-five to eighty-seven percent of pediatric cases are linear morphea, with limb or trunk involvement in approximately 70%–80% and en coup de sabre (ECDS) or progressive facial hemiatrophy (PHA; formerly described as Parry–Rhomberg) in 22%–30%.[1,2,4,5,7,8] In adults, circumscribed and generalized subtypes predominate. Deep morphea/morphea profunda is uncommon in both adults and children with a frequency of 2%–4%.[1,2,4,7,8]

Periods of disease activity vary from 3 to 6 years, but reactivation after periods of remission occurs in 20%.[2,8] (eFig. 64-0.1 in online edition). Others have a chronic course persisting for decades. The prognostic markers for recurrent or chronic disease have yet to be determined.

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of morphea is poorly understood. Most pathologic events ascribed to morphea are extrapolated from studies in systemic sclerosis (assuming the two disorders arise from the same etiology). Morphea probably arises from a genetic background that increases disease susceptibility, combined with other causative factors (infectious, environmental exposures) that modulate disease expression.

Like many autoimmune connective tissue diseases, morphea is likely a complex genetic disease. Familial clustering is rarely seen,[5,9,10] and morphea is also associated with higher than expected rates of familial autoimmune disorders.[5,11,12]

Although there are no definitive associations, development of morphea lesions has been linked to local tissue trauma including radiation (eFig. 64-0.2 in online edition), surgery, insect bites, and intramuscular injections.[13] Although controversial, infectious agents have also been linked to lesion development.

Increasing amounts of evidence support autoimmune-mediated inflammation early in the course of morphea.[14] Early morphea lesions are characterized by the influx of large amounts of mononuclear lymphocytes (usually activated T lymphocytes), plasma cells, and eosinophils.[15] This is likely the result of autoimmunity, as there is widespread autoimmune reactivity in morphea patients (elevated ANAs, cytokines, and adhesion molecules).[5,12,16] Morphea patients also have concomitant autoimmune disease at higher expected frequency than a healthy population.[5,11]

Vessel damage and upregulation of adhesion molecules (ICAM-1, VCAM 1, and E-selectin) occur related to the inflammatory cell infiltrate which facilitates local monocyte recruitment.[17] These adhesion molecules are upregulated by cytokines classically associated with a Th2 immune response (Il-4, Il-1, and TNFs). Cytokines found in the sera and skin of morphea patients in increased concentration include IL-4, IL-6, and IL-8.[18] These cytokines (especially IL-4) upregulate TGF-β, initiating a cascade of events resulting in increased production of collagen and other extracellular matrix components via induction of connective tissue growth factor, platelet-derived growth factor, and matrix metalloproteinases. These cytokines and growth factors inhibit interferon-γ (a suppressor of collagen synthesis and Th1-related cytokine). Chimerism or nonself cells may play a role in the pathogenesis of morphea by initiating a local inflammatory reaction.[19]

CLINICAL FINDINGS

Morphea is currently divided into five subtypes (Table 64-1).[20] Superficial or deep disease (involving subcutis, fascia, or below) may occur with any subtype. Morphea lesions may also occur with overlying lichen sclerosus change (Fig. 64-1).

CUTANEOUS LESIONS

STAGES OF CUTANEOUS LESIONS. (Fig. 64-2). Morphea begins as erythematous plaques or patches, sometimes with a reticulated appearance. Later hypopigmented sclerotic plaques develop at the center of the lesion, surrounded by an erythematous or violaceous border (inflammatory stage) (Fig. 64-2A). Pain and/or itching can precede the initial skin findings. Sclerosis develops centrally, which turns into a shiny white color, as lesions expand with surrounding hyperpigmentation (sclerotic stage). There is loss of hair follicles, producing alopecia. Over months to years, the sclerotic plaque softens and becomes atrophic with hypo- or hyperpigmentation (atrophic stage) (Fig. 64-2B). The atrophic stage is associated with cigarette paper wrinkling (papillary dermis), cliff drop (dermal), or deep indentions (subcutis or deeper).

TABLE 64-1
Proposed Classification of Morphea Subtypes

Morphea Subtype	Modifiers	Clinical
Circumscribed	Superficial Deep	Single or multiple oval/round lesions limited to epidermis and dermis Single or multiple oval/round lesions involving subcutaneous tissue, fascia, or muscle.
Linear	Trunk/Limbs Head	Linear lesions involving possible primary site of involvement in subcutaneous tissue without involvement of skin, dermis, subcutaneous tissue, muscle, or bone En coup de sabre, progressive facial hemiatrophy, linear lesions of the face (may involve underlying bone)
Generalized 1. Coalescent plaque		More than or equal to four plaques in at least two of seven anatomic sites (head–neck, right/left upper extremity, right/left lower extremity, anterior/posterior trunk); isomorphic pattern: coalescent plaques inframammary fold, waistline, lower abdomen, proximal thighs; symmetric pattern: symmetric plaques circumferential around breasts, umbilicus, arms, and legs
2. Pansclerotic		Circumferential involvement of majority of body surface area (sparing fingertips and toes), affecting skin, subcutaneous tissue, muscle or bone; no internal organ involvement
3. Mixed		Combination of any above subtype: e.g., linear-circumscribed

Adapted from Laxer RM, Zulian F: Localized scleroderma. *Curr Opin Rheumatol* **18**:606-613, 2006.

CIRCUMSCRIBED MORPHEA.

Circumscribed morphea represents oval to round lesions undergoing the stages of activity described in the previous section that are not diffuse enough to meet criteria for generalized disease (Table 64-1). Patients with circumscribed morphea should be closely followed, as both linear and generalized morphea may begin with circumscribed lesions.

Atrophroderma of Pasini and Pierini are thought to be the residua of plaque-type morphea. The borders of the atrophoderma lesions have a "cliff-drop" appearance resembling "burnt-out" morphea lesions.

GENERALIZED MORPHEA.

Generalized morphea is characterized by more than or equal to four lesions on at least two of seven different anatomic sites. There are likely three variants of generalized morphea: (1) isomorphic, (2) symmetric, and (3) pansclerotic (Table 64-1; Figs. 64-3 and 64-4).[21,22] In direct contrast to systemic scleroderma, generalized morphea does not

Figure 64-4 Pansclerotic morphea: sclerosis encompassing majority of body surface area (**A**), characteristically sparing the fingertips (**B**). (Reproduced with permission from: Jacobe H: Morphea (localized scleroderma) in adults. In: *UpToDate*, edited by DS Basow. Waltham, MA, UpToDate, 2011. Copyright © 2011 UpToDate, Inc. Figure 64-5 **A.** Multiple linear lesions involving trunk and extremities. **B.** En coup de sabre. **C.** Multiple hyperpigmented linear morphea lesions on the face. (Reproduced with permission from: Jacobe H: Morphea (localized scleroderma) in adults. In: *UpToDate*, edited by DS Basow. Waltham, MA, UpToDate, 2011. Copyright © 2011 UpToDate, Inc. For more information visit www.uptodate.com.)

present with acrosclerosis or sclerodactyly. Instead, lesions frequently begin on the trunk and spread acrally, sparing the fingers and toes (Fig. 64-4).

LINEAR MORPHEA. Linear morphea usually affects the extremities and face, but it can occur on the trunk (where it is often misclassified as circumscribed) (Table 64-1, Fig. 64-5A). The presence of multiple linear lesions is not uncommon. A recent study suggests that linear morphea may follow Blaschko's lines.[23] Linear morphea may involve the dermis, subcutaneous tissue, muscle, or even underlying bone, causing significant deformities. Bone marrow inflammation has also been reported.[24,25] ECDS "cut of the sword" may present as an atrophic band linear plaque on the forehead (Fig. 64-5B), extending to the scalp (where cicatricial alopecia occurs), brow, nose, and lip. Other linear lesions on the head and neck present on the temple or chin, and are generally hyperpigmented atrophic plaques (Fig. 64-5C). PHF is characterized by a slowly progressive, unilateral atrophy of skin, soft tissues, muscles, and/or bony structures. The atrophy may be accompanied by classic linear morphea lesions on the face or elsewhere.

DEEP MORPHEA. Deep morphea, or morphea profunda, involves the deep dermis, subcutaneous tissue, fascia, and muscle. Plaques are poorly circumscribed

Figure 64-6 Morphea profunda: involved areas have "cobblestone" appearance with subcutaneous atrophy. (Reproduced with permission from Jacobe H: Morphea (localized scleroderma) in adults. In: *UpToDate*, edited by DS Basow. Waltham, MA, UpToDate, 2011. Copyright © 2011 UpToDate, Inc. For more information visit www.uptodate.com.)

and symmetrical (Fig. 64-6). The skin feels thickened and bound down to the underlying fascia and muscle. A "groove sign" (depression) may be present at the site of tendons and ligaments. Deep morphea lesions may underlie any clinical subtype of morphea, particularly linear and generalized, or occur alone.

EF, or Shulman syndrome, is a related disorder presenting with rapid onset of symmetric areas of pain and edema, usually on the extremities. EF may occur with cutaneous induration similar to morphea, or remain without skin involvement.

RELATED PHYSICAL FINDINGS

Extracutaneous manifestations develop in 22%–56% of morphea patients.[1,4,5,7,8,26] Articular and muscular (eFig. 64-6.1 in online edition) involvement (arthritis, myalgias, neuropathies, and carpal tunnel syndrome) is the most common finding (12%) and can occur unrelated to skin lesions.[11,27] Cutaneous disease itself produces limited range of motion, limb length discrepancy, joint deformity, and contracture (45%–56% linear morphea). Patients with lesions crossing joint lines are most at risk.[8,26] ECDS is associated with neurologic and ocular complications (3.6%) including seizures, headaches, adnexal abnormalities (eyelids, eyelashes), uveitis, and episcleritis.[11,27,28] Facial morphea may produce dental malocclusion, altered dentition, and atrophy of the tongue and salivary glands. Another possible finding is Raynaud phenomenon, although more strongly associated with systemic sclerosis.[5]

LABORATORY ABNORMALITIES

SERUM AUTOANTIBODIES. Autoantibodies reported in patients with morphea include ANA, anti-single-stranded DNA, antidouble-stranded DNA, antihistone, antitopoisomerase IIα, antiphospholipid, anticentromere, anti-Scl-70, and rheumatoid factor (MMP-1).[5,16,26,29–34] The clinical and prognostic significance of these autoantibodies remains unclear. ANA occur in 39%–80% of patients and are more common in patients with linear or generalized disease.[5,8,16,26]

OTHER SERUM ABNORMALITIES. Peripheral eosinophilia, hypergammaglobulinemia, and increased ESR/CRP may occur with active disease of any type, but particularly deep morphea (may correlate with disease activity).

IMAGING STUDIES

MRI provides a complete assessment of the extent of disease, including depth of involvement and disease activity.[25] This is especially helpful when deep involvement is suspected. It is also possible to evaluate the response to treatment, although not currently routine practice.

Ultrasonography (US) is a sensitive tool to evaluate or monitor tissue thickness, loss of subcutaneous fat and muscle, or other architectural alterations. Disease activity can be correlated with the detection of hyperemia and echogenicity.[35] Discussion with the radiologist performing the MRI or US studies is crucial to adequately detect and evaluate change related to the morphea.

COMPLICATIONS

Children with morphea can have significant morbidity related to morphea, including effects on growth, function, and quality of life (fewer studies exist in adults). Muscle weakness may occur in affected extremities or face. Behavioral changes, learning disabilities, and seizure (sometimes preceding cutaneous lesions)[36,37] have been reported in children with (and without) facial involvement. In addition, disfigurement and physical symptoms (fatigue, pain, itch) associated with morphea affect psychosocial development and play a substantial role in the quality of life for patients with morphea.

Panscleroticmorphea has been associated with an increased risk of squamous cell carcinoma due to chronic ulcers. The resulting sclerosis of the skin can cause significant contracture, and produces restrictive pulmonary defects and dysphagia. Circumferential sclerosis of the arms or legs may also produce compartment syndrome, bullae, and ulcers.

Morphea may coexist with other autoimmune diseases (systemic lupus erythematosis, vitiligo, primary biliary sclerosis, autoimmune hepatitis, Hashitmoto's thyroiditis, and myasthenia gravis).[38–43] In particular, generalized morphea has been associated with an increased rate of autoimmune disease.[5]

PROGNOSIS AND CLINICAL COURSE

Although morphea causes functional and aesthetic impairment, it is rarely life-threatening. Morphea may be self-limited, but frequently has a remitting relapsing or chronic course producing significant disease burden over time.[12] (eFig. 64-0.1 in online edition)

EVALUATION AND TREATMENT

OVERVIEW

The natural history of morphea is poorly understood. At least some cases undergo spontaneous remission after a few years of activity. However, even when spontaneous remission occurs, residual damage created by active disease remains. In addition, new evidence suggests at least a subset of morphea patients have continued disease activity over many years, ultimately leading to extensive disease burden and related morbidity.[12] Despite the large number of reported treatments, no consistent recommendations exist for therapy. This section aims to provide evidence-based algorithm for the rational evaluation and management of morphea patients (Figs. 64-7A and 64-7B).

PATIENT EVALUATION

In determining which therapy is appropriate, the following must be considered:

- ***Disease Activity and Damage*:** Existing studies indicate that early, active disease is most responsive to any therapy.[44] Indicators of active disease include development of new lesions or extension of existing lesions (photographs are critical), erythema and/or induration of the advancing edge of the lesion, patient reported symptoms such as itch or tingling. Disease damage (reversible or irreversible) includes pigmentary change, induration of the lesion center (controversial), atrophy (dermal, subcutaneous, muscle), contracture, limb length discrepancy, and scarring alopecia. Disease damage is much more difficult to treat and therapy should be aimed at preventing disease damage. Further, patients with

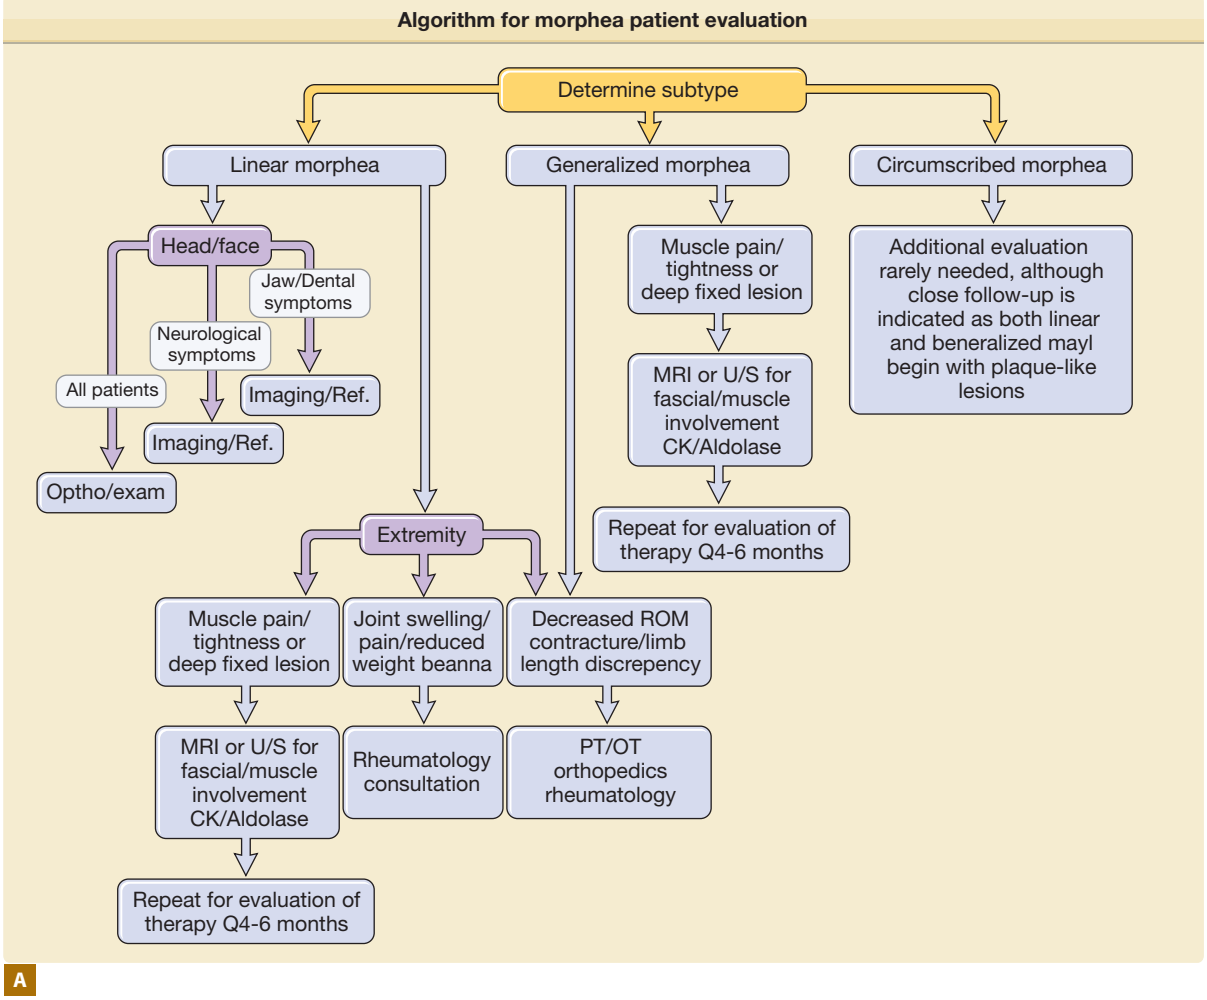

Figure 64-7 **A.** Algorithm for the evaluation of patients with morphea. (*continued*)

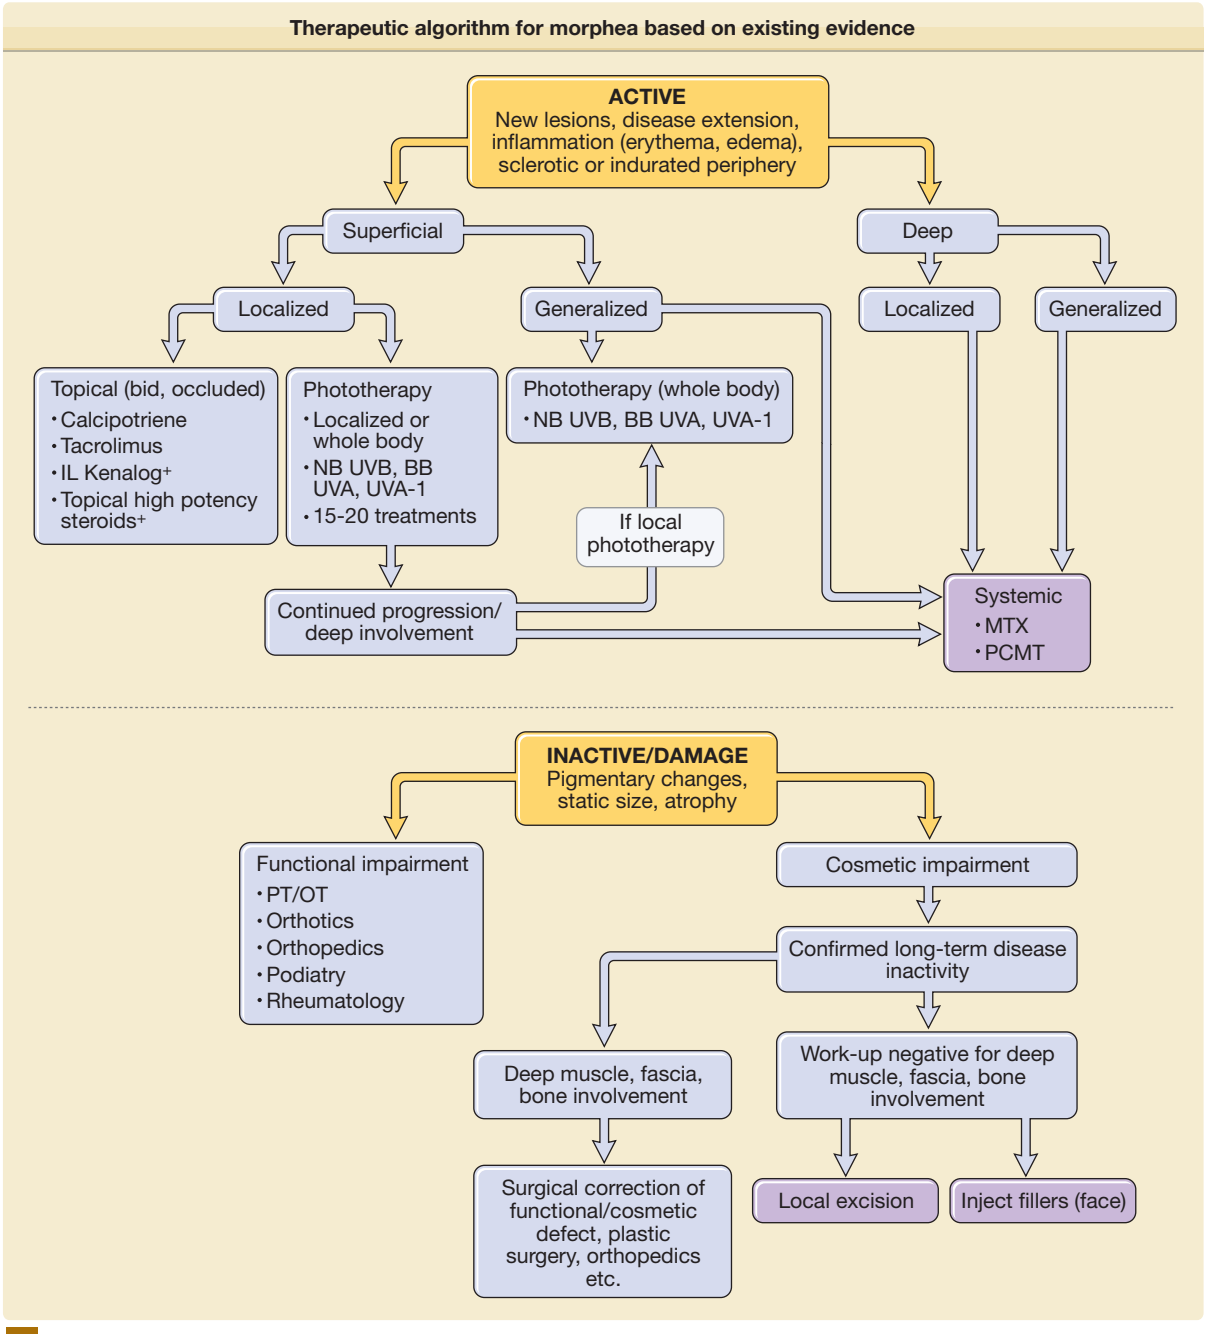

B

Figure 64-7 (*continued*) **B.** Therapeutic algorithm for morphea based on existing evidence. Superficial involvement is defined by histological evidence of papillary dermal involvement. Deep involvement is defined as sclerosis or inflammation of the deep dermis, subcutis, fascia, or muscle. Histological examination and/or MRI are encouraged to evaluate lesions for depth of involvement and, likewise, determine appropriate treatment as well as evaluation of therapeutic efficacy. *There is very little evidence for any therapy addressing disease damage in morphea. The risk of disease reactivation is also unknown, but possible with the use of invasive procedures. Therefore, surgery and the like should only be undertaken after prolonged inactivity of disease. †There is no evidence for efficacy in the literature. (Reproduced with permission from Jacobe H: Morphea (localized scleroderma) in adults. In: *UpToDate*, edited by DS Basow. Waltham, MA, UpToDate, 2011. Copyright © 2011 UpToDate, Inc. For more information visit www.uptodate.com.)

active disease at risk for significant damage (facial lesions, PFH, lesions crossing joint lines, large BSA involvement, rapid progression) likely need aggressive therapy (phototherapy and/or systemic immunosuppresives).

- ***Depth of Involvement*:** Morphea involving the superficial to middermis would logically be amenable to topical therapy or phototherapy; however, involvement of the deep dermis and beyond should be treated systemically. Deep involvement can occur in all subtypes of morphea, but is especially prominent among linear and some generalized patients.
- ***Disease Progression*:** Many generalized and linear morphea patients are initially diagnosed with circumscribed morphea, but progress to have much more extensive disease.[12] Therefore, patients who initially present with 1–3 plaques (which may be amenable to localized therapy) should be closely followed. If these patients progress, therapy should then be aimed at preventing further progression (i.e., phototherapy or systemic therapy).
- ***Systemic Involvement*:** Systemic involvement is usually an indication for systemic immunosuppressive therapy.
- ***Disease Subtype*:** Patients with linear and generalized (particularly those with rapid onset of confluent plaques) are likely at risk for severe, extensive disease and should be treated aggressively either with phototherapy or systemic immunosuppressives depending on the depth of involvement.

ROLE OF HISTOLOGY AND LABORATORY TESTING

The diagnosis of morphea is usually made by the clinical appearance of the lesions. Histological examination may aid therapeutic decision-making because it is sometimes difficult to determine the degree of activity or depth of involvement by clinical examination alone. Biopsy of the advancing edge of a lesion may provide insight into both (eFig. 64-6.2 in online edition). Biopsies should be taken from the inflammatory or indurated border or sclerotic center (indicate on pathology requisition) and include fat. For lesions with minimal clinical change, biopsy of site-matched unaffected skin is helpful. Although a large number of laboratory-based assessments are reported to reflect disease activity and prognosis in morphea, there are no widely accepted biomarkers for morphea. Consequently, laboratory-based tests are not recommended for evaluation morphea in the absence of specific signs and symptoms indicating the need for further assessment. Assessment via MRI and ultrasound is becoming increasingly useful for determination of lesion activity and depth and should be considered when deep morphea is present or suspected.

SPECIFIC TREATMENTS

See Table 64-2.

TABLE 64-2
Morphea Therapy

Treatment	Level of Evidence[a]
BB UVA	1, 2
UVA-1	1, 2
Calcitriol, oral (inefficacy 1)	1, 2
IFN-γ (inefficacy 1)	1
PUVA bath	2
PUVA cream	2

PHOTOTHERAPY. Phototherapy has the greatest evidence for efficacy (level 1, randomized controlled trials: broadband ultraviolet (UV) A, narrowband (NB) UVB, and UVA 1; level 2: PUVA systemic and topical).[45–50] NB UVB should be considered for lesions affecting the superficial dermis (relatively thin on palpation or with sclerosis and inflammation in the papillary and superficial reticular dermis). UVA-based therapies are more appropriate for deeper dermal lesions due to greater depth of penetration. UVA-1 in particular has evidence for normalization of dermal collagen and effect on inflammation in morphea so is appropriate for both inflammatory and sclerotic disease.[45] In the absence of access to UVA-1 phototherapy, use of broadband UVA is also supported by the literature.[50] Disease is expected to improve (progression halted and erythema improved) after 10–20 treatments and most trials stopped after 20–30 treatments. Evidence suggests that patients continue to improve after cessation of therapy, and some authors recommend using a greater number of treatments[30–50] for further therapeutic benefit. Uncontrolled trials demonstrated increased benefit with medium to high dose UVA-1

versus low dose, but controlled trials were less convincing. Optimum dose and regimen for UVA-1 phototherapy has yet to be determined. Phototherapy is likely ineffective for deep involvement (subcutis, fascia, muscle), and therefore should not be considered as primary therapy.

VITAMIN D DERIVATIVES. Only one study provides level-1 evidence on the effect of vitamin D derivatives in morphea, and it showed no difference between oral calcitriol and placebo.[51] In fact, placebo and treatment groups improved equally. The authors also point out that the study was underpowered by their own calculations, making definitive conclusions regarding the efficacy of oral calcitriol difficult. The efficacy of topical vitamin D derivatives has been explored via uncontrolled trials and case reports[52] (level-2 evidence) and showed improvement in most or all patients, albeit over several months of therapy (an interval in which lesions might improve independent of therapy). Importantly, calciprotriene was applied under occlusion in these studies.

IMMUNOMODULATORS

Methotrexate With or Without Corticosteroids. The use of methotrexate (monotherapy) and methotrexate combined with systemic corticosteroids is effective based on level-2 evidence.[28,44,53–55] Optimum dose and route, indications for addition of corticosteroids, and duration of therapy have not been determined. In most studies with combined therapy, corticosteroids are used for induction therapy either orally or via intravenous pulse (IVMP 30 mg/kg/day for 3 days per month or 1 mg/kg/day prednisone) over the first 3 months. Methotrexate is used as steroid sparing agent and started simultaneously (0.6 mg/kg/week in children or 15–25 mg/week in adults) and maintained for a prolonged period (1–2 years). Most study participants responded in a mean of 2–5 months. The best responders were all early in their disease course. Importantly, relapse was noted frequently after cessation of therapy, underscoring that therapy likely only suppresses disease activity.

Other Immunomodulators. Level-2 evidence suggests the use of occluded topical tacrolimus 0.1% ointment might be effective for active, inflammatory superficial plaque-type morphea.[56] Recent case series utilizing oral mycophenolate mofetil indicate potential utility in patients refractory to methotrexate or sensitive to corticosteroid side effects.[57] Case reports on the use of oral cyclosporine, bosentan, infliximab, and topical imiquimod have also reported some efficacy, but more definitive studies are lacking.

ANTIMICROBIALS. Despite the widespread use of antimicrobials in morphea (antibiotics and hydroxychloroquine), no published clinical trials exist.[58] Literature supporting the use of antimalarials is limited to a case series in which two patients improved with hydroxychloroquine (while simultaneously receiving oral steroids and methotrexate).[59] In a retrospective review, 7/11 patients continued to have active disease 3–153 months after starting hydroxychloroquine.[4] At this time, the use of these agents in severe morphea is likely not indicated pending more definitive evidence of efficacy.

LACK OF EVIDENCE. The most commonly used treatment for morphea, topical steroids, shows no evidence for efficacy in the literature. There are also no studies investigating the use of intralesional steroids. In the hands of the authors, intralesional steroids have been extremely effective in treating circumscribed plaques or as an adjuvant for recalcitrant areas in patients receiving phototherapy or systemic treatment. Current evidence does not support the use of penicillamine or interferon-γ.[60]

ADJUNCTIVE THERAPY. A significant number of morphea patients suffer irreversible sequelae. When these patients come to medical attention, they may no longer have disease activity, but rather damage from the past or a mixture of active disease and damage. Consequently, every morphea patient should be examined for the presence of limitation in range of motion, contracture, limb length discrepancy, or other functional impairment. In these cases, consultation with rheumatology, physical/occupational therapy, physical medicine and rehabilitation, plastic surgery, orthopedics, and oral maxillofacial surgery is highly recommended to maximize cosmesis, function, and minimize further damage.

Chapter 65 :: Lichen Sclerosus

:: Ulrich R. Hengge

LICHEN SCLEROSUS AT A GLANCE

- Infrequent chronic inflammatory dermatosis with anogenital and extragenital manifestations.
- Preferentially affects women in the fifth or sixth decade of life and children younger than the age of 10 years; gender ratio 5:1 female–male.
- Antibodies to extracellular matrix protein-1 and T cells with receptor rearrangement point to an autoimmune pathogenesis.
- Anogenital manifestations cause severe discomfort (pruritus, dyspareunia, dysuria, and painful defecation) and present with polygonal papules and porcelain-white plaques, erosions, and various degrees of sclerosis.
- Vulvar lichen sclerosus is associated with an increased risk of squamous cell carcinoma; the role of human papillomavirus infection or prior radiotherapy remains to be elucidated.
- Potent topical corticosteroids and skin care are the most successful therapeutics; calcineurin antagonists have also recently demonstrated benefit.
- Interdisciplinary management is essential for long-term control.

Lichen sclerosus (LS) is a chronic inflammatory dermatosis of the anogenital area that affects quality of life due to the severe itching. LS may also present with extragenital manifestations that are generally nonpruritic. Of note, vulvar disease seems to have an increased risk of squamous cell carcinoma, but the role of additional cofactors (e.g., human papillomavirus infection or prior radiotherapy) has not been defined.

EPIDEMIOLOGY

The incidence of LS has not been precisely determined. It has been estimated to be in the order of 14 per 100,000 persons per year.[1] LS is more prevalent in females, accounting for a 5:1 gender ratio. It preferentially affects women in the fifth or sixth decade of life and children younger than the age of 10 years.[1,2] Up to 15% of LS cases occur in children, particularly in girls, and one study reported a prevalence of 1 in 900 premenarchal girls.[3] A 0.07% incidence in males has recently been determined in a study of 153,432 male soldiers.[4] Among blacks and Hispanics, the incidence in this group was 1.06%, whereas the incidence was only 0.051% in white soldiers.[4] LS seems to be a prominent cause of phimosis; in one study, 14% of adolescent boys had LS, whereas 40% of phimosis cases in adult men were associated with LS.[5] Similarly, a recent study of foreskins examined after therapeutic circumcision for phimosis confirmed many cases of unrecognized LS.[6] As genital LS in males is almost exclusively seen in uncircumcised men, the rate of circumcision in a given population has a strong impact on the occurrence of the disease.

ETIOLOGY AND PATHOGENESIS

The cause of LS is unknown. While a genetic predisposition has generally not been found,[7] a recent observational cohort study reported a high rate of familial LS cases.[8] Of 1,052 females with LS, 126 (12%) had a positive family history of LS. Vulvar cancer was significantly increased in those patients with a family history of LS compared with those without (4.1% vs. 1.2%).[8] This report proposes a likely genetic component in the etiology of LS. Evidence for the presumed infectious cause, such as acid-fast rods, spirochetes, or *Borrelia*, has not been found.[7] Serologic and clinical evidence of thyroid disease, alopecia areata, pernicious anemia, and vitiligo suggested an association with LS. Extragenital LS is commonly seen in association with plaque-type morphea, and some authors have suggested a common pathomechanism. Recently, low-titer autoantibodies against the extracellular matrix protein-1 (ECM-1) and collagen XVII have been identified in 67% of LS.[9,10] ECM-1 (see Chapter 137) may be involved in basement membrane and interstitial collagenous fiber assembly and growth-factor binding,[11] and may also regulate blood vessel function.[12] In addition, antibodies to the basement membrane protein bp180 have been detected in childhood vulval LS lesions in four of nine children analyzed.[13] All antibodies were IgG-type. There was no clinical and family history of autoimmune diseases or autoantibodies in the children studied. Local irritation also seems to play a role in some cases. The disturbed function of fibroblasts with increased production of collagen has been demonstrated in LS.[14,15]

CLINICAL FINDINGS

CUTANEOUS LESIONS

Polygonal papules and porcelain-white plaques with atrophic fragile skin, fissures, telangiectasias, purpura, erythema, erosions, and different degrees of sclerosis are present in the anogenital area (Figs. 65-1A–65-1F);

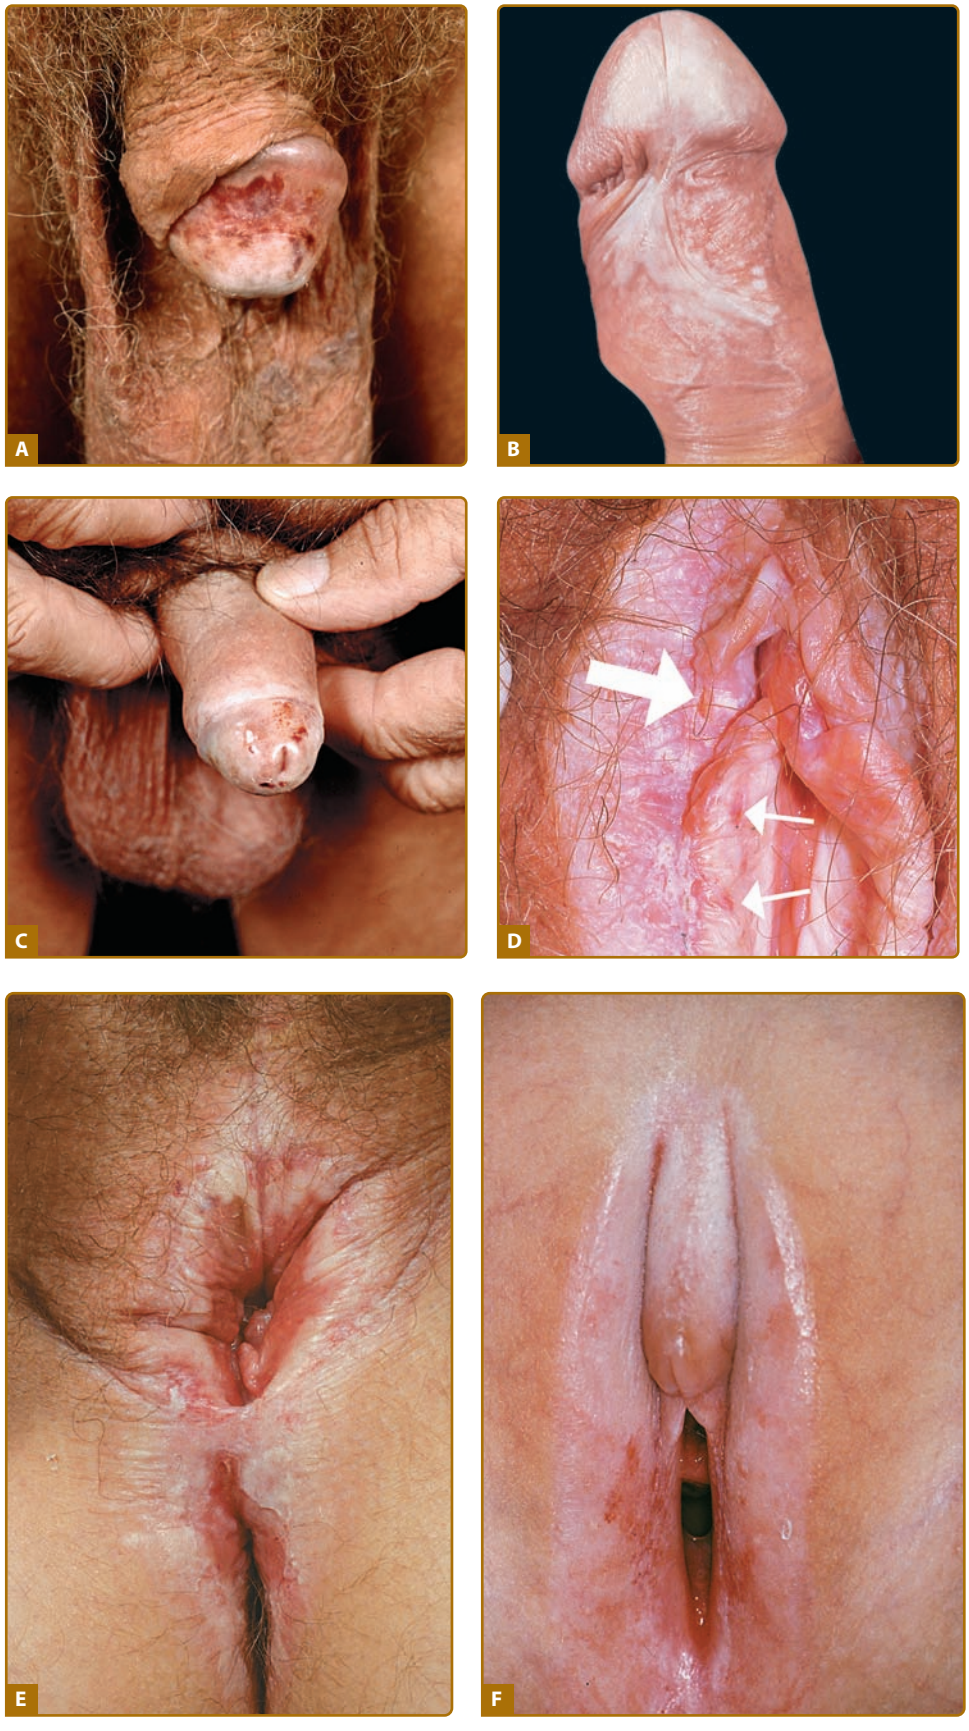

Figure 65-1 **A.** Early sclerosis and significant hemorrhage on the glans in early lichen sclerosus. **B.** Sclerosis of the frenulum and increased vulnerability with bleeding upon sexual intercourse. **C.** Significant sclerosis of the glans and conglutination with the preputium in advanced lichen sclerosus. Note narrowing of the urethral orifice and hemorrhage. **D.** In addition to the well-demarcated white vulvar plaque that is classic for lichen sclerosus, the waxy and crinkled texture, purpura (*small arrows*), and erosions (*large arrow*) are diagnostic. **E.** Sclerotic vulva with disappearance of the smaller labia and shrinkage of the introitus. Significant erythema and erosions are seen on the vulva and the anus in a figure-8 configuration. The patient complained of severe pruritus and dyspareunia. **F.** Erosive, sclerotic vulva in an 8-year-old girl.

Figure 65-2 Extragenital lichen sclerosus with confluent whitish papules and plaques on the skin over the thoracic and lumbar spine.

often the classical figure-8 pattern of the vulva and anus may be observed (see Fig. 65-1E). Blisters (occasionally hemorrhagic) may develop when the lichenoid infiltrate separates epidermis from the sclerotic dermis. The size of LS lesions may vary from a few millimeters to large portions of the trunk. Anogenital LS frequently causes intractable itching and soreness, dyspareunia, dysuria, discomfort with defecation, or genital bleeding and, with time, may lead to destructive scarring (see Fig. 65-1F). Gradual obliteration or synechiae of the labia minora and clitoris, as well as stenosis of the introitus, may also result (see Chapter 78). Male genital LS is usually confined to the glans penis, prepuce, or foreskin remnants (see Fig. 65-1A–65-1C). Penile shaft involvement is less common, whereas scrotal involvement is rare. Many male genital LS cases are simply diagnosed as phimosis. In severe cases, erections may become painful (see Chapter 77). Extragenital manifestations typically affect the thigh, the neck, trunk and lips; lesions are usually asymptomatic (Fig. 65-2). A recent clinical histopathological study has revealed 27 adult cases with lip involvement.[16] Clinical presentation consisted of asymptomatic vitiligo-like lesions in 70% with a variable degree of dermal sclerosis confined to the papillary layer. This was in contrast to genital LS lesions that showed both papillary and reticular dermal sclerosis in the majority of cases. Therefore, the vitiligo-like LS needs to be added to this spectrum of oral lichenoid lesions.

RELATED PHYSICAL FINDINGS

Except for the association with autoimmune thyroid disease, alopecia areata, pernicious anemia, morphea, and vitiligo, which should be ruled out, no additional related findings have been reported. In particular, genital infections by herpes simplex virus or *Candida* do not seem to be increased in LS patients.

LABORATORY TESTS

HISTOPATHOLOGY

Classical LS shows an atrophic epidermis and a lichenoid infiltrate at the dermal–epidermal junction.[17] Papillary edema is usually seen in early LS, but is gradually replaced by fibrosis with homogenization of acid mucopolysaccharides as the lesion matures (Fig. 65-3). The lymphocytic infiltrate in LS contains abundant T cells, B cells, and antigen-presenting dendritic cells that are major histocompatibility complex class II$^+$, CD8$^+$, and CD57$^+$.[18,19] A monoclonal T-cell receptor γ-chain rearrangement has alluded to the existence of an LS antigen, potentially the ECM-1 protein, which is also recognized by the recently described autoantibodies.[8,20] Epidermal hyperplasia and/or dysplasia associated with LS on vulvar specimens are associated with an increased risk of malignant transformation, especially in conjunction with infection by high-risk papillomaviruses.

SPECIAL TESTS

Imaging studies are only needed in special situations (e.g., urinary obstruction secondary to stenosing genital LS). High-resolution ultrasound is occasionally used to document the depth of sclerosis.

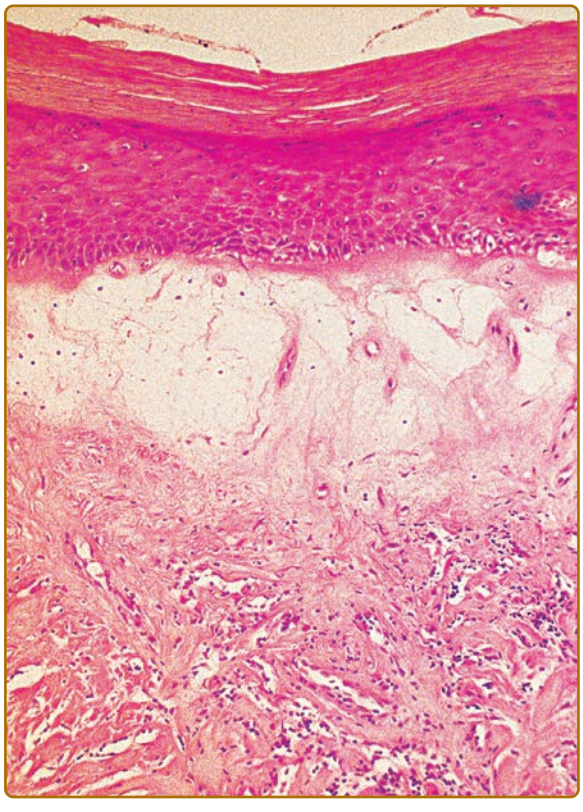

Figure 65-3 Hyperkeratotic epithelium without rete ledges and basal degeneration of keratinocytes. Collagen fibers are homogenized in the papillary dermis, and a lichenoid lymphocytic infiltrate is present. The dermal vessels are dilated.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A skin punch biopsy of a mature lesion will confirm the diagnosis if the diagnosis is not obvious by clinical examination. ECM-1 autoantibodies may be detected by specialized laboratories; a commercial enzyme-linked immunosorbent assay (ELISA) has recently become available.[21] Despite the described association with autoimmune diseases, an autoimmune workup (e.g., antinuclear antibody, parietal cell antibody, vitamin B_{12} levels, thyroid function tests) is not generally recommended due to their relatively low occurrence.[22] For the same reason, *Borrelia* antibody titers should not be analyzed, as they are not associated with LS.[23] To exclude squamous cell carcinoma, repetitive biopsies may be indicated.

The differential diagnosis of LS and localized scleroderma (morphea) may be difficult (Box 65-1; see Fig. 65-2). Clinically, morphea may be confused with extragenital LS. Morphea represents a circumscribed connective tissue disease with a number of different presentations. Typical early plaque-type lesions show a lilac ring with progressive central induration and whitening and peripheral hyperpigmentation (see Chapter 64). Histologically, early morphea presents as a dense lymphocytic, superficial, and deep perivascular infiltrate with degeneration of collagen fibers. In later stages, inflammation is replaced by dermal fibrosis much like the changes seen in LS. Patients have been described with lesions typical of both plaque-type morphea and the chalky white, atrophic plaques of LS, suggesting that morphea and LS may share a common pathomechanism.[24] Antinuclear antibodies may be positive in either morphea or LS.

Constipation is a common complication in children with anogenital LS.[25] The associated purpura and discoloration often raise concern about child abuse, especially if LS is not recognized (see Chapter 106). LS in children has occasionally been associated with a perineal pyramidal protrusion, a common lesion that can be confused with condyloma and is also associated with constipation. This association further (erroneously) increases the suspicion of sexual abuse.[26,27] It should be noted, however, that LS and child abuse may coexist[28] and that some cases of LS have been linked with trauma of the anogenital region (see Chapter 106). See Box 65-2 for pitfalls in the diagnosis of LS.

BOX 65-1 DIFFERENTIAL DIAGNOSIS OF LICHEN SCLEROSUS

GENITAL MANIFESTATIONS

Consider

- Balanitis plasmacellularis (Zoon disease)
- Child abuse (sexual)
- Complications of dermatologic laser surgery
- Contact dermatitis, including excessive genital hygiene
- Lichen planus
- Lichen simplex chronicus
- Vitiligo

Rule Out

- Cicatricial (scarring) pemphigoid
- Erythroplasia of Queyrat (Bowen disease)
- Leukoplakia
- Squamous cell carcinoma
- Paget disease

EXTRAGENITAL MANIFESTATIONS

Consider

- Anetoderma
- Atrophoderma of Pasini and Pierini
- Idiopathic guttate hypomelanosis
- Lipoid proteinosis (mild forms, see Chapter 137)
- Lichen nitidus
- Lichen planus
- Morphea
- Pinta
- Tinea versicolor

Rule Out

- Discoid lupus erythematosus
- Graft-versus-host disease (scleroderma-like)
- Extramammary Paget disease
- Squamous cell carcinoma

BOX 65-2 PITFALLS IN THE DIAGNOSIS OF LICHEN SCLEROSUS

- Wrong/incomplete diagnosis in the case of squamous cell carcinoma
- Lichen sclerosus, especially when bullous, hemorrhagic, or erosive; may be confused with child abuse
- Inappropriate surveillance for steroid adverse effects
- Irritant dermatitis due to overwashing of the anogenital area may imitate lichen sclerosus and facilitate the occurrence of contact dermatitis

COMPLICATIONS

Besides dyspareunia, urinary obstruction, constipation, secondary infection related to ulceration, and steroid use, squamous cell carcinoma represents the main complication in females (Fig. 65-4). The lifetime risk of developing squamous cell cancer as a complication of long-standing LS has been estimated in the order of 4%–6%.[1,29] Age, long duration of LS, human papillomavirus infection, and

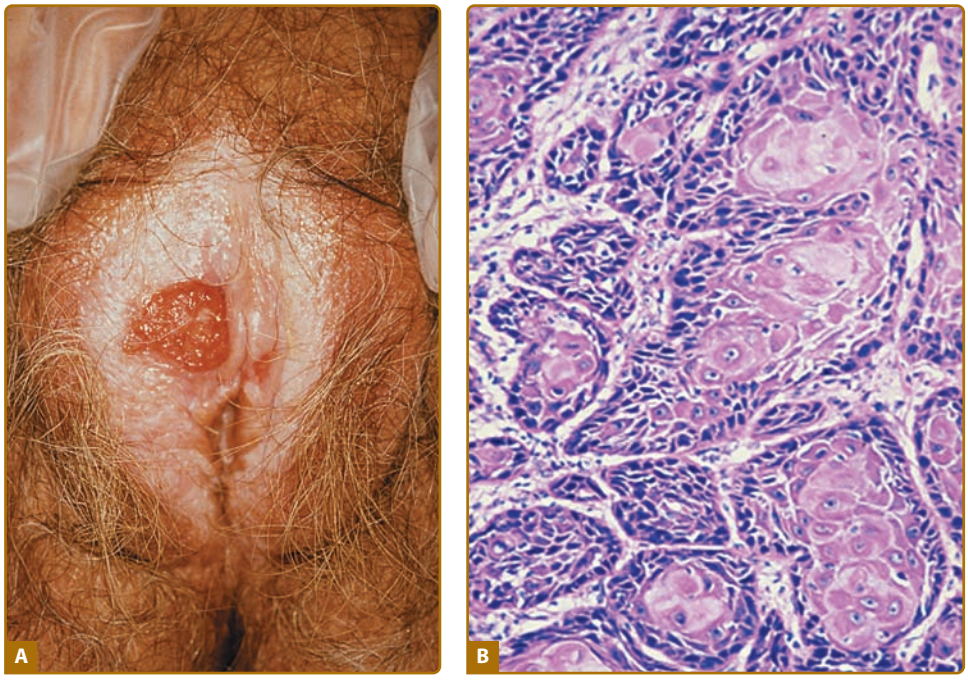

Figure 65-4 **A.** A 1.5-cm, sharply demarcated ulcer of long-standing lichen sclerosus on the right major labium. **B.** Histology reveals squamous cell carcinoma.

evidence of hyperplastic changes represent significant risk factors.[30,31] In males, painful erections and urinary obstruction represent the most frequent complications.

PROGNOSIS AND CLINICAL COURSE

The prognosis of LS is good for most anogenital cases, especially for those in prepubertal children that may resolve spontaneously or may be healed after treatment with ultrapotent topical steroids.[32] However, a recent study reported that childhood onset vulvar LS does not resolve at puberty.[33] The authors prospectively studied 12 cases, of which nine patients, who still had active LS at puberty, continued to require maintenance therapy after menarche. Six of the 12 experienced significant disturbance of the vulvar architecture. Therefore, prepubertal LS does not necessarily resolve at puberty. A further case series reported the efficacy of topical clobetasol propionate 0.05% in childhood LS.[34] Nine of 15 young girls suffered from a relapse about 1 year following the first clearing of the lesions. The authors also concluded that early aggressive treatment with ultrapotent corticosteroids enables the best clinical course of childhood LS.[34] The disease is usually self-limiting, but requires treatment due to the severity of patient discomfort. Recalcitrant chronic LS causing erosions and progressive scarring may result in severe sexual dysfunction. Cosmetic improvement for extragenital cases and for chronic atrophic genital disease is rather poor.

TREATMENT

Various attempts to treat LS have been undertaken. The single most effective treatment of LS is ultrapotent topical corticosteroids such as clobetasol.[20,32–43] However, there is no systematic trial to support this common practice. Due to corticosteroid adverse effects, the treatment period with ultrapotent steroids should be limited, generally to 4–6 weeks. Treatment should be continued, when necessary, with less potent corticosteroids or calcineurin inhibitors (see below).

Case series using topical tacrolimus and pimecrolimus have shown clinical effectiveness.[44–48] Although many of the effects of topical tacrolimus parallel those of corticosteroids,[49] adverse effects such as atrophy, telangiectasias, and pigment changes do not occur. A recent multicenter, phase II trial has assessed the safety and efficacy of twice-daily application of tacrolimus ointment 0.1% in 84 patients (49 women, 32 men, and 3 girls) with longstanding LS (mean duration, 5.8 years), with a follow-up period of 18 months.[50] Clearance of active LS was reached by 42.9% of patients, with at least 50% improvement in an additional 34.3% of patients. However, the duration of treatment to achieve an optimal response was up to 24 weeks.

Systemic therapy with retinoids, including isotretinoin, etretinate, and acitretin and oral tacrolimus, have been useful in small trials. Systemic antibiotics against borreliosis and penicillamine have not proved effective.

Destructive surgical therapies, such as cryotherapy,[51] the tissue-vaporizing carbon dioxide lasers, and nonablative lasers such as the pulsed dye and

Erb:YAG lasers, have been reported to work in LS but should only be used with caution. More recently, PUVA and UVA1 treatment have shown some promising success in LS. Vulvectomy should be limited to cases in which squamous cell carcinoma has been detected.[52–54]

Female LS patients should be particularly monitored for any sign of secondary genital malignancy. Prepubertal LS in girls may resolve spontaneously; however, some of these patients may eventually suffer from vulvodynia in adulthood. In case of LS-associated dyspareunia that interferes with sexual activity, the use of topical anesthetics should be considered.

Circumcision will generally resolve male genital LS and the associated phimosis, although potent topical steroids may obviate the need for surgery. Asymptomatic extragenital LS usually requires no treatment other than cover makeup in selected cases.

PREVENTION

No truly preventive measures of LS have been reported. An interdisciplinary management is essential for the long-term control of LS. Specialists from gynecology, urology, pediatrics, and psychosomatic medicine should be involved in patient care and collaborate to prevent significant complications, including the monitoring for squamous cell cancer and corticosteroid adverse events. It has also been helpful to circulate information via patient organizations for LS.

Chapter 66 :: Dermal Hypertrophies and Benign Fibroblastic/Myofibroblastic Tumors

:: Christine J. Ko

DERMAL HYPERTROPHIES AND BENIGN FIBROBLASTIC/MYOFIBROBLASTIC TUMORS AT A GLANCE

- Common benign dermal fibrous lesions include hypertrophic scar, keloid, dermatofibroma, and acrochordon.
- Certain benign tumors with a prominent dermal connective tissue component (e.g., angiofibroma, fibrofolliculoma/trichodiscoma, acrochordon-like lesions, and connective tissue nevi) may be associated with genetic disorders.
- Some dermal hypertrophies and tumors (e.g., desmoid tumor, infantile fibromatosis, infantile myofibromatosis) can at times be aggressive with high rates of recurrence.
- Other entities that present in infancy and childhood include fibrous hamartoma of infancy, fibromatosis colli, infantile digital fibromatosis, calcifying aponeurotic fibroma, juvenile hyaline fibromatosis, and infantile systemic hyalinosis.
- Other entities that primarily affect adults include adult fibromatoses (palmoplantar, penile, knuckle pads), pachydermodactyly, reactive lesions (nodular fasciitis, elastofibroma), solitary lesions (acquired digital fibrokeratoma, dermatomyofibroma, pleomorphic fibroma, collagenous fibroma, myofibroma, solitary fibrous tumor), and clinically distinctive hypertrophies (cutis verticis gyrata, pachydermoperiostitis, cerebriform fibrous proliferation).

TABLE 66-1
Fibroblastic/Myofibroblastic Tumors of Infancy and Childhood

Skin Involvement	Entity	Typical Site(s)
Often solitary	Infantile digital fibromatosis Myofibroma Calcifying aponeurotic fibroma Plantar fibromatosis Infantile fibromatosis Fibrous hamartoma of infancy Fibromatosis colli Cranial fasciitis	Digits Head/neck Palms/soles Soles None Upper arm/trunk Clavicle area Head/neck
Often multiple	Juvenile hyaline fibromatosis	Ears/face and other sites
Often multiple with visceral involvement	Infantile systemic hyalinosis Infantile myofibromatosis	Ears/face and other sites None

Dermal hypertrophies and benign fibrous tumors are quite common. Some of the entities described have characteristic clinical presentations and histopathologic features. Many primarily present in infancy and childhood (Table 66-1). A unifying histologic feature of hypertrophic scars and most of the rarer entities described is the presence of myofibroblasts, contractile spindle cells that express smooth muscle actin but not desmin (Table 66-2). Malignant fibrous tumors of the dermis are discussed in Chapter 125.

HYPERTROPHIC SCARS AND KELOIDS

Keloids and hypertrophic scars are related clinical lesions.[1] These lesions present at sites of prior dermal injury and wound repair. They often occur after local skin trauma (e.g. laceration, tattoo, burn, injection, ear piercing, vaccination, or surgery) or inflammatory skin disorders (e.g. acne, bites, or infections). There may be growth of keloids during pregnancy.[2] The predisposition to keloids in darker skin[3] and reports of a familial, autosomal dominant inheritance[4] suggest genetic influences. Hypertrophic scars and keloids show differences morphologically and histologically (Table 66-3),[5,6] suggesting differences in pathogenesis. There also is an apparent association with melanin pigment, as albino and vitiliginous skin do not form keloids.[7] Multiple keloids may also be associated with a genetic syndrome (Table 66-4).

Keloids appear as well-circumscribed pink to purple or hyperpigmented firm nodules (Fig. 66-1) or plaques. The surface of keloids is usually smooth, but can be nodular and borders are often smooth, but can be irregular (Table 66-3). The surface and borders of hypertrophic scars are always smooth and regular. There is a predilection for developing keloids at sites of increased tension, such as the shoulders, sternum, mandible, and arms. Keloids also commonly affect the earlobes. Keloids and hypertrophic scars are often painful, hyperesthetic, or pruritic. Ulceration can occur. Multiple keloids are common, but several rare entities may be considered in the clinical differential diagnosis (see Box 66-1).[8–11] Histopathologically, keloids are composed of thick, haphazard, eosinophilic, collagen bundles. Hypertrophic scars are more cellular with myofibroblasts either in disorganized whorls or sometimes oriented parallel to the epidermis.

Although the exact mechanism of keloid formation is still unclear,[12–19] TGF-beta and its signaling pathway are important (see Table 66-5).[12] Hypertrophic scars are associated with HLA-DRB16.[20] In most studies, keloids

[a]May occur spontaneously.

and scars show the same biochemical and pathologic abnormalities. Keloids express increased levels of the gli-1 protein, an oncogene product also present in neoplasms such as basal cell carcinoma.[21] Collagen synthesis and collagenase activity are increased in both keloids and hypertrophic scars. α1-Globulin (a collagenase inhibitor usually not present in normal scars) may contribute to increased collagen deposits. Hypertrophic scars have decreased levels of the profibrotic agent tumor necrosis factor.[22] Keloids contain tenascin C, a protein associated with inflammation and wound healing.[23] Fibroblasts from keloid-prone patients have altered cytokine patterns[24] and increased sensitivity to transforming growth factor- β1 (TGF- β1),[25] TGF-β2,[26]

platelet-derived growth factor, and epidermal growth factor.[27] Carbon dioxide laser treatment reduces TGF-β1 levels in keloids.[28] At least, part of the fibroblast stimulation may be secondary to infiltration of the scar by activated T cells.[29] Also, there seem to be decreased

levels of apoptosis, as shown by terminal transferase dUTP nick end labeling (TUNEL) assays and increased Bcl-2 and p53 expression in keloid-associated fibroblasts.[30]

The treatment of hypertrophic scars and keloids differs slightly.[7,31] Hypertrophic scars tend to be more responsive than keloids and generally flatten with time. Although injection of hypertrophic scars and keloids with intralesional steroids is a first-line treatment in many cases, depending on the situation (e.g. a wound previously infected, a wound across lines of tension or a joint), hypertrophic scars may respond quite well to surgery as an initial treatment. Surgery alone is generally not recommended for keloids, as they often recur as larger lesions. An exception to this may be keloids on the earlobes.[32] An algorithm for treatment is outlined in Treatment Box 66-2.

DERMATOFIBROMA (FIBROUS HISTIOCYTOMA, SCLEROSING HEMANGIOMA)

Dermatofibroma is a common, benign tumor that has a predilection for the lower legs of women. Any age may be affected, but typically dermatofibromas appear in the 20s and 30s. Dermatofibromas may be solitary or multiple and eruptive (see Box 66-3).[33] Trauma, such as secondary to insect bites, has been thought to induce some lesions, suggesting a reactive/reparative process. The recent demonstration of clonal X-inactivation in some cases of dermatofibroma supports a neoplastic nature.[34,35]

Usually asymptomatic, they occasionally are pruritic or painful. Some tumors grow very rapidly, whereas others remain static for many years. Characteristically, a dermatofibroma is firm, measuring from 0.5 mm to 1 cm in diameter, and lateral compression produces a dimple-like depression in the skin. The surface may be shiny or keratotic, and the color is variable, often brown but sometimes pink, red, tan, or flesh colored (Fig. 66-2A).

Histologically, the epidermis is usually hyperplastic and hyperpigmented. There may be follicular or sebaceous induction. The dermis has fascicles or haphazardly arranged collections of spindle cells that lack atypia in most cases (see Figs. 66-2B and 66-2C). The

BOX 66-2 FOR HYPERTROPHIC SCARS AND KELOIDS

	HYPERTROPHIC SCARS	KELOIDS

[a]Some authors consider 15 to be a cutoff.

BOX 66-4 ATYPICAL,[a] CELLULAR, DEEP, AND INDETERMINATE FIBROUS HISTIOCYTOMAS

Clinical Features

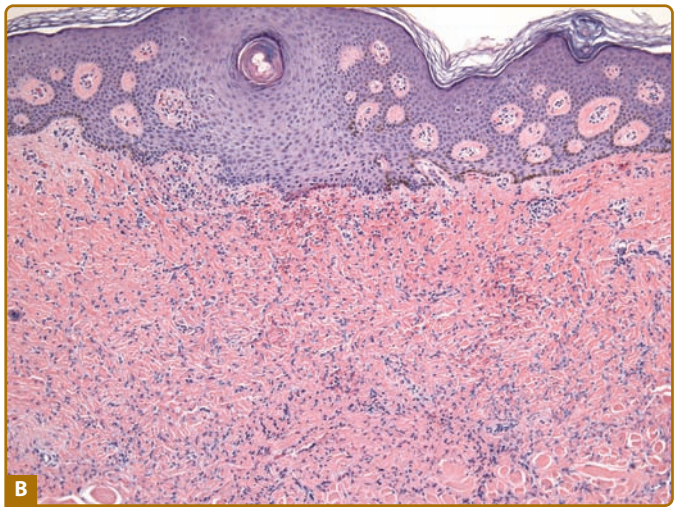
- Often >2 cm in size
- Sometimes facial
- Any age, but some predilection for young adults
- Often recur after incomplete excision
- Rare potential for metastasis

Histologic Features

- Background of dermatofibroma/fibrous histiocytoma
- Variable areas of atypical cells, high cellularity
- May extend deeply into subcutaneous, sometimes in a honeycomb pattern
- May stain with CD34

[a]Occasionally overlaps with aneurysmal variant.

edges of the lesion are poorly defined with individual cells hugging collagen bundles ("collagen entrapment"). Mitotic figures may be present, but atypical forms are not a feature. Dermatofibromas are generally factor XIIIa-positive[36] and CD34$^-$.[37] There are many histologic variants of dermatofibroma, most without clinical significance. Exceptions are in Box 66-4.



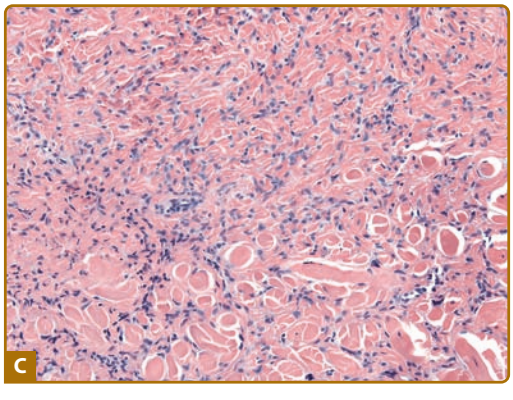


Figure 66-2 **A.** Dermatofibroma on the right thigh of a young man. **B** and **C.** Haphazardly arranged spindle cells in the dermis. The lesion edge is poorly defined with spindle cells infiltrating between thickened collagen fibers [(hematoxylin and eosin 100× magnification (**B**); 200× magnification (**C**)].

Figure 66-3 Soft fibromas or skin tags on the neck overlying acanthosis nigricans.

No treatment is necessary unless symptomatic. A common reason for removal is repeated trauma to the dermatofibroma, often secondary to shaving the lower legs. Cryosurgery may be helpful in flattening out the dermatofibroma but usually is not curative. Lesions termed "atypical," "cellular," "deep," and/or "indeterminate" are generally best treated with complete excision, particularly if clinical size is >2 cm (see Box 66-4).[38–44]

ACROCHORDON (FIBROEPITHELIAL POLYP, SKIN TAG, SOFT FIBROMA)

Acrochordons are pedunculated papules or tumors that are most commonly located on the eyelids, neck, axillae, and groin. There is a familial disposition, and acrochordons are more commonly seen in obese individuals, sometimes overlying acanthosis nigricans (Fig. 66-3). Acrochordon-like clinical lesions may be a feature of a genetic syndrome, although histologically there are differences (see Table 66-4).[45,46] Histologically, an acrochordon is a polypoid lesion with a central collagenous core. Adnexal structures are generally absent. Although usually asymptomatic, lesions can become irritated or necrotic. Patients often request removal for cosmetic reasons.

FIBROUS PAPULE (ANGIOFIBROMA)

A fibrous papule is a common papule on the lower portion of the nose or the central face. It usually presents in adulthood. Multiple lesions are a feature of certain genetic syndromes (see Table 66-4),[47–51] but occasionally may be seen in patients with no other stigmata of a genetic disorder.[52] The fibrous papule is small (2–5 mm), nontender, flesh colored (sometimes pink or slightly hyperpigmented), firm, and dome shaped. It must be differentiated from an early, nodular, basal cell carcinoma, and biopsy may be necessary. Unlike a basal cell carcinoma, it rarely bleeds and stays relatively stable in its smaller size. Histologically, the dermis shows fibrosis with stellate fibroblasts and dilated vessels. Identical histology is seen in pearly penile papules and periungual fibromas (Koenen's tumors) (see Chapter 140). No treatment is necessary, and a simple shave or punch excision is usually curative.

FIBROFOLLICULOMA/ TRICHODISCOMA

Fibrofolliculomas/trichodiscomas are 2- to 4-mm, dome-shaped, yellowish to skin-colored papules located on the head, neck, and upper trunk; multiple lesions may be associated with Birt–Hogg–Dubé syndrome (see Table 66-4).[45]

CONNECTIVE TISSUE NEVUS/ COLLAGENOMA/ELASTOMA

These hamartomas can be divided into familial, those associated with genetic disease (see Table 66-4),[47,50,53–57] and other isolated variants. Connective tissue nevi present as asymptomatic, flesh-colored to yellow–brown papules or plaques that may be solitary or grouped, linear, or irregular in distribution (Fig. 66-4).[58] The overlying epidermis is usually smooth. Histologically, connective tissue nevi show a normal epidermis overlying collagen in the lower dermis. The collagen may be subtly increased, thickened, or oriented vertically to the epidermis, and muscin may be increased. Elastic fibers may also be increased (elastoma).

Familial cutaneous collagenoma is an autosomal dominantly inherited condition of multiple, often papular connective tissue nevi usually appearing postpuberty on the trunk and upper extremities.[59,60] There

Figure 66-4 Cutaneous collagenoma, a connective tissue nevus involving almost the entire back.

may be associated systemic abnormalities such as progressive cardiomyopathy.

DESMOID TUMOR (AGGRESSIVE FIBROMATOSIS)

Desmoid tumors, also known as *deep* or *aggressive fibromatoses*, are a type of fibromatosis. All types (extra-abdominal, abdominal wall, intra-abdominal) may be induced by trauma (Fig. 66-5). Mutations have been found in the adenomatous polyposis coli (APC) gene (*5q21*).[61] Hormonal influences (e.g., pregnancy) are implicated in abdominal wall tumors.[62] Tumors associated with Gardner/Familial adenomatous polyposis (FAP) (see Table 66-4)[63] are often intra-abdominal,[64] may be more aggressive and surgically unresectable, and are associated with a 10% mortality.[65] Extra-abdominal tumors are deep-seated, often located in the area of the shoulder and pelvic girdle, chest wall, or head and neck.[66] Although surgery is widely accepted as first-line treatment,[67] complete surgical excision is difficult to achieve, and recurrences are common. Intra-abdominal tumors, particularly those associated with Gardner/FAP, may be best treated, if symptomatic, with radiation or chemotherapy.[68]

Figure 66-5 Desmoid tumors involving upper chest and epigastric region. These represent recurrences after multiple surgical interventions. This patient also had intra-abdominal desmoid tumors.

INFANTILE FIBROMATOSIS (LIPOFIBROMATOSIS, PEDIATRIC DESMOID TUMOR)

Infantile fibromatosis presents as a rapidly growing nodule on the head and neck, shoulder/upper arm, or thigh; generally before age 2. The lipofibromatosis variant has a predilection for the hands and feet.[69] Histologically, the tumor may have an immature mesenchymal pattern, variable amounts of adipose tissue,[69] or a desmoid tumor-like pattern. Local recurrence is common, but surgery is the treatment of choice.[70,71]

INFANTILE MYOFIBROMATOSIS

Infantile myofibromatosis generally presents before age 2, with many cases being congenital.[72,73] Multiple nodules involving the skin and other organs (gastrointestinal, kidney, lung, heart) are seen, with mortality approaching 75%.[73] Prognosis is generally excellent if only a solitary nodule (then termed *myofibroma*, see below) or multiple nodules limited to the skin are seen. For multiorgan involvement, treatment with surgical resection, chemotherapy and radiotherapy have been described.

Histologic diagnosis relies on the identification of two separate components—a fascicular myofibroblastic pattern at the periphery with a hemangiopericytoma-like pattern in the center. In the past, many cases were considered to be infantile or childhood hemangiopericytomas. Mitotic figures, vascular invasion, and tumor necrosis can be found, but do not predict malignant transformation.[74] Biopsy of these lesions, especially in infants and young children, is important to ensure that the lesions do not represent congenital infantile fibrosarcoma. Histopathologic examination as well as cytogenetic and molecular pathology studies will distinguish myofibromas (chromosome 8 abnormalities) from congenital infantile fibrosarcomas (translocation between chromosomes 12 and 15—*ETV6* and *NTRK3* genes).[75]

FIBROUS HAMARTOMA OF INFANCY

Fibrous hamartoma of infancy is a rare benign tumor that presents before age 2 (up to 25% congenital)[76,77] as a solitary, painless, rapidly growing, flesh-colored, ill-defined, subcutaneous nodule, or plaque. There is a male predominance. The most common locations are the axillary region, upper arm, upper trunk, inguinal region, and external genital region.[76,77] These lesions rarely present with overlying skin changes such as hypertrichosis, alteration in pigmentation, and eccrine gland hyperplasia.[77] Histologic features are characteristic, with an organoid pattern of fibrous trabeculae, myxoid areas with spindle cells, and adipose tissue.[76,78] The treatment of choice is complete excision.[73] An aggressive approach should be avoided because the overall prognosis is excellent.[79]

Figure 66-6 **A.** Well-defined pink nodules of infantile digital fibromatosis in a 9-month-old patient. **B.** The patient at age 2.5 years, with spontaneous resolution of the nodules. (Used with permission from Richard J. Antaya, MD.)

FIBROMATOSIS COLLI (STERNOCLEIDOMASTOID TUMOR OF INFANCY)

Fibromatosis colli is an often self-limiting, rapidly growing tumor, presenting in the first few weeks of life. It is characterized by a benign proliferation of fibroblasts in the lower one-third of the sternocleidomastoid muscle, rarely bilateral, and occasionally associated with torticollis or facial asymmetry.[80] The tumor often resolves within the first year of life.[80] Fine-needle aspiration is the preferred technique for diagnosis.[81,82]

INFANTILE DIGITAL FIBROMATOSIS

Infantile digital fibromatosis is a rare form of superficial juvenile fibromatosis presenting as (an) asymptomatic, flesh-colored, firm nodule(s) on the fingers and toes (tending to spare the thumb or hallux) (Fig. 66-6A), primarily in infants and less commonly in children. One-third of cases are congenital.[83] Histologically, poorly circumscribed, interlacing bundles of myofibroblasts are observed. The pathognomonic finding is eosinophilic, perinuclear inclusion bodies composed of actin filaments, which stain red with Masson trichrome stain and purple with phosphotungstic acid-hematoxylin.[84] Multiple clinically similar tumors, but without inclusion bodies on histopathologic examination, are associated with brachydactyly and facial dyspigmentation.[85] Despite the observation of spontaneous regression over years (Fig. 66-6B) and a high recurrence rate after excision, surgical intervention is common because deformities of the digit and contractures can occur with larger lesions.[83]

CALCIFYING APONEUROTIC FIBROMA

Calcifying aponeurotic fibroma is an uncommon, benign fibrous tumor. It is most commonly found on the palms and soles of male children and young adults (peak incidence between the ages of 8 and 14).[86,87] However, it can present in any area that is closely related to aponeuroses.[86] It is a very slow growing, deep-seated firm proliferation that presents as an asymptomatic infiltrative soft tissue mass, usually measuring less than 3 cm in diameter.[86] If symptomatic, surgical excision may be performed, although there is a 50% local recurrence rate. Local recurrence is more common in children younger than 5 years of age.[86]

On histopathologic examination, it is an ill-defined, poorly circumscribed tumor composed of spindled fibroblasts surrounding central calcified foci. The lesion typically is organized into nodules, with central hyalinization and incipient calcification surrounded by a palisade of chondrocyte-like cells. Less cellular areas contain spindled fibroblastic cells between coalescing calcified nodules. Osteoclastic giant cells may border the calcific deposits. These lesions may demonstrate actin and CD99 and S100 proteins with immunostaining.

JUVENILE HYALINE FIBROMATOSIS/INFANTILE SYSTEMIC HYALINOSIS

Juvenile hyaline fibromatosis (JHF) is a rare, autosomal recessive condition secondary to a defect on chromosome 4q21 associated with the locus of the capillary morphogenesis gene-2 (CMG2).[88] From infancy, subcutaneous, pearly papules and firm, large nodules that progressively enlarge and may ulcerate appear on the nose, chin, ears, scalp, hands (Fig. 66-7), back, and knees.[89] Histologically, cells with perinuclear vacuoles are seen in a hyalinized and chondroid stroma. Patients tend to have gingival hypertrophy, which can result in periodontal disease and caries. Progressive joint contractures, osteolysis, and muscular weakness can result in severe debilitation.

Preliminary genotype–phenotype analyses suggest that abrogation of binding by von Willebrand's factor type A domain of CMG2 results in severe disease

Figure 66-7 Juvenile hyaline fibromatosis. Tumors involving the hand. Both hands were affected.

typical of infantile systemic hyalinosis (ISH), whereas in-frame mutations affecting the highly conserved cytoplasmic domain result in a milder phenotype.[90] Although the fibrous skin lesions, joint contractures, gingival hypertrophy, and osteolysis are shared with JHF, the manifestations of ISH are present within the first months of life and often at birth.[91] Patients may also show diffusely thickened skin, hyperpigmented plaques on bony prominences, visceral involvement, frequent infections, and persistent diarrhea with failure to thrive, leading to death during infancy. The histologic and ultrastructural appearance of biopsied lesional skin resembles that of JHF.

Currently, no widely accepted effective treatment exists for JHF or ISH. Surgical excision is often not feasible due to the number and size of the tumors, and anesthesia can be complicated because of the oral and dental issues.

PALMOPLANTAR FIBROMATOSES

Dupuytren contracture (palmar fibromatosis) is characterized by progressive fibrosis of the palmar fascia, most commonly presenting as one or more nodules over the fourth and fifth metacarpal head. Nodules become cords, and joint contractures and flexion deformities of the fingers may follow.[92] Significant risk factors for development of Dupuytren contracture include old age, male sex, white northern European ancestry, family history, seizures, alcohol-induced liver disease, trauma, smoking, and diabetes mellitus.[93–95] This condition rarely occurs before age 30 and is very rare in children.[93] Concurrent plantar disease, knuckle pads, and/or keloids may be seen.[93,96]

Histologically, there are uniform, spindled fibroblasts separated by collagen.[93] Surgical correction may be the treatment of choice of progressive disease.[92] Recurrence is more common in patients with greater initial deformity, but less common if good surgical correction is achieved and postoperative rehabilitation provided.[97]

Ledderhose disease is characterized by plantar fibrosis especially over nonweight-bearing areas of the sole and has similar features to Dupuytren disease histologically.[93,96] Contractures are uncommon.[96,98] Typically adults are affected, but children can manifest disease.[93] These lesions may be treated with surgical excision.

PEYRONIE DISEASE (PENILE FIBROMATOSIS)

Fibrosis of the dorso-lateral penis, resulting in curvature of the penis and erectile dysfunction, is termed *Peyronie disease*. Risk factors include genetic predisposition, trauma to the penis, smoking, alcohol consumption, and history of diabetes or hypercholesterolemia.[99,100] Over several years, patients may have stabilization and rarely spontaneous regression of the disorder.[101] Conservative management is often recommended.[102] Surgery is reserved for those with compromised sexual function or disabling deformity.[101,103]

KNUCKLE PADS

Knuckle pads are circumscribed, thickened plaques over the dorsal aspects of the interphalangeal joints. Many patients have coexisting palmar, plantar, or penile fibromatosis.[93] Histologically, these lesions are very similar to Dupuytren disease. False knuckle pads are due to repetitive mechanical trauma.

PACHYDERMODACTYLY

Pachydermodactyly is a rare form of benign digital fibromatosis consisting of symmetric, painless, circumscribed swelling of the proximal interphalangeal joints of the fingers, often sparing the thumb.[104] It primarily affects adolescent males. Some consider this a variant of knuckle pads. It may be associated with tuberous sclerosis, atrophia maculosa varioliformis cutis (noninflammatory pitted scarring, usually on the face) and carpal tunnel syndrome. Histologically there is hyperkeratosis, acanthosis, and increased dermal fibrosis.

NODULAR FASCIITIS

Nodular fasciitis is a benign, self-limiting proliferation of fibroblasts of uncertain etiology that often follows trauma, observed most frequently on the upper extremity.[105] Although it is seen most commonly in young adults, it can occur at any age, without racial or sex predilection. It presents as a rapidly growing, painful mass (generally less than 2 cm) in the subcutis, fascia, or muscle. Cranial fasciitis is the most common variant in children and involves the head and neck. Histologically, nodular fasciitis presents as a poorly demarcated nodule in the subcutis, fascia, or dermis that is composed of spindled "tissue-culture"-like

fibroblasts and myofibroblasts in a loose, myxoid, highly vascular stroma that resembles granulation tissue. These lesions often have associated hemorrhage. Mitotic figures are present, but atypia and nuclear polymorphism are not seen. Despite the possibility of spontaneous involution, excision is the treatment of choice, with recurrences being rare.

ELASTOFIBROMA (ELASTOFIBROMA DORSI)

Elastofibroma is a rarely diagnosed, benign, fibroproliferative, soft-tissue tumor that occurs predominantly in the periscapular region of middle-aged to elderly women.[106] Many patients have bilateral involvement. Although the exact etiology is unknown, it is suspected that chronic subclinical microtrauma may lead to reactive hyperplasia of elastic fibers, with consequently increased production of fibrous tissue. Clinically, this tumor presents as a poorly circumscribed, firm, mobile mass; typically, the lesions are concealed with retraction and protuberant with protraction of the shoulders. More than 50% of patients are asymptomatic and present with a painless swelling. Magnetic resonance imaging often shows a characteristic layering of fibrous tissue and adipose tissue.[107] Typical histologic findings are thickened collagen and chenille-like elastic fibers admixed with adipose tissue.

ACQUIRED DIGITAL FIBROKERATOMA (ACRAL FIBROKERATOMA)

This lesion is a keratotic papule acquired in adulthood, often on the digits or occasionally the palms/soles (Fig. 66-8).[108] Histologically, there is overlying hyperkeratosis with abundant dermal collagen that is perpendicular to the epidermis in the papillary dermis.

Figure 66-8 Acquired digital fibrokeratoma. A hyperkeratotic papule with a collarette on the palm, a slightly unusual location.

DERMATOMYOFIBROMA

This is a 1–2 cm, ill-defined, indurated plaque, most commonly seen in young women on the shoulder or upper arm.[109,110] Histologically, in the deep dermis, there are fascicles of slender spindle cells parallel to the epidermis, with sparing of adnexal structures.

PLEOMORPHIC FIBROMA

Pleomorphic fibromas are usually solitary and appear in middle-aged to older individuals. They are generally nondescript, slow-growing, dome-shaped, or polypoid lesions with a predilection for the extremities.[111] Clinical behavior is benign; histologically, a polypoid lesion with a collagenous core has multinucleated cells and scattered large cells with atypical nuclei. Even with incomplete removal, recurrence is uncommon.

COLLAGENOUS FIBROMA (DESMOPLASTIC FIBROBLASTOMA)

Collagenous fibroma usually presents in the fifth to sixth decades with a 5:1 male–female ratio.[112] It is a benign tumor that appears as a slow-growing, painless, mobile mass (1–20 cm) located in the subcutaneous tissue or just deep to skeletal muscle. This tumor has a predilection for the upper arm and shoulder; but may also occur on the posterior neck, upper back, lower extremities, hand, abdominal wall, and hip joint. Histologically, the tumor has an infiltrative appearance into fascia or skeletal muscle and is composed of bland stellate and spindle-shaped fibroblasts and myofibroblasts in a collagenous matrix.

MYOFIBROMA

All ages may be affected by myofibroma. This is a tumor that some consider of vascular origin[113] that is similar histologically to the tumors of infantile myofibromatosis.[72,73] When solitary or multiple in the skin, the prognosis is excellent, with spontaneous regression in some cases.[72] These tumors have a wide distribution, but are often on the extremities in adults (Fig. 66-9), and are painless.[73] Histologic findings are diagnostic, commonly with multiple nodules or poorly circumscribed fascicles of spindle cells that express smooth muscle actin intermixed with thick collagen, sometimes with peripheral cells having a pericytic appearance.

SOLITARY FIBROUS TUMOR

Solitary fibrous tumor is a tumor once thought to only involve the pleural cavity but now known to be a rare

Figure 66-9 Myofibroma. A somewhat ill-defined, focally firm and focally spongy, pink to flesh-colored tumor (with smaller nodules within it) on the ankle. This asymptomatic lesion had been present since at least age 9 and had been growing slowly over the last 15 years.

soft tissue tumor.[114] It usually behaves nonaggressively. Histologically, there are dilated vessels, sometimes staghorn (some consider solitary fibrous tumor and hemangiopericytoma to be part of a spectrum), with interspersed spindle cells that are arranged in a "patternless" pattern. Cells are $CD34^+$. Malignant tumors have been described and should be ruled out when there is increased cellularity, pleomorphism, or mitoses.

CUTIS VERTICIS GYRATA

This rare condition presents on the scalp, often at puberty, and when primary, affects males more commonly. The scalp appears folded, with furrows running anteriorly to posteriorly. Primary disease is idiopathic or associated with neuropsychiatric disorders.[115–117] Histologically, the areas of folded scalp appear normal. Cutis verticis gyrata may also be seen secondarily in association with a variety of inflammatory or neoplastic diseases (see Table 66-4 and Box 66-5).[115] Clues for secondary involvement include early onset of disease (sometimes congenital), asymmetric disease, and disordered furrows that are not oriented anterior to posterior.[115] If the face and acral sites are involved, pachydermoperiostitis should be considered.

BOX 66-5 CONDITIONS ASSOCIATED WITH CUTIS VERTICIS GYRATA

Neuropsychiatric (e.g., schizophrenia, mental retardation, seizures)
Genetic syndromes (see Table 66-4)
Inflammatory (e.g., eczema, psoriasis, folliculitis, impetigo, erysipelas)
Local neoplasms (e.g., congenital melanocytic nevus, neurofibroma, fibroma, hamartoma)
Systemic illness (e.g., myxedema, acromegaly, amyloidosis, syphilis, leukemia, acanthosis nigricans, insulin resistance syndrome)

PACHYDERMOPERIOSTITIS

Pachydermoperiostosis (primary hypertrophic osteoarthropathy) is a rare genetic syndrome with most cases having autosomal dominant transmission.[118] At puberty, there is progressive enlargement of the joints due to pachydermia, periostosis, and clubbing. Other features include thickened skin on the face and scalp (resembling cutis verticis gyrata), palmoplantar hyperhidrosis, and acro-osteolysis. Arthralgias can be quite debilitating. Disease progresses for 5–20 years before stabilizing. Primary hypertrophic osteoarthropathy should be distinguished from secondary hypertrophic osteoarthropathy, which is generally secondary to pulmonary or cardiac disease.

CEREBRIFORM FIBROUS PROLIFERATION

In patients with Proteus syndrome, the soles (and sometimes the palms) have cerebriform overgrowth with gigantism. There is increased dermal fibrosis.

Chapter 67 :: Anetoderma and Other Atrophic Disorders of the Skin

:: Catherine Maari & Julie Powell

ANETODERMA AT A GLANCE

- Circumscribed 1- to 2-cm areas of flaccid skin that may be elevated, macular, or depressed.
- Often circumscribed sac-like protrusions.
- Primary or secondary to a preceding dermatosis in the same location.
- Association with antiphospholipid syndrome.
- Pathology consists of loss of elastic tissue in the dermis.

ANETODERMA

EPIDEMIOLOGY

The lesions in anetoderma usually occur in young adults between the ages of 15 and 30 years and more frequently in women than men. Anetoderma is rare, but the incidence is unknown. Several hundred cases have been reported.[1–4]

PATHOGENESIS

The pathogenesis of anetoderma is unknown. The key defect is damage to the dermal elastic fibers. Anetoderma may be considered to be unusual scars, because scars also have decreased elastic tissue. The loss of dermal elastin could be the result of an impaired turnover of elastin caused by either increased destruction or decreased synthesis of elastic fibers.

CLINICAL FINDINGS

All types of anetoderma are characterized by a circumscribed loss of normal skin elasticity. The characteristic lesions are flaccid circumscribed areas of slack skin with the impression of loss of dermal substance forming depressions, wrinkling, or sac-like protrusions (Fig. 67-1). These atrophic, skin-colored, or blue–white lesions are 5–30 mm in diameter. The number varies from a few to hundreds. The skin surface can be wrinkled, thinned, and often depigmented, and a central depression may be seen. Coalescence of smaller lesions can give rise to larger herniations. The examining finger sinks without resistance into a distinct pit with sharp borders as if into a hernia ring (buttonhole sign). The protrusion reappears as soon as the pressure from the finger is removed.[4]

The most common sites for these asymptomatic lesions are the chest, back, neck, and upper extremities. They usually develop in young adults, and new lesions often continue to form for many years as the older lesions fail to resolve.

Primary anetoderma occurs when there is no underlying associated skin disease (i.e., it arises on clinically normal skin). It is historically subdivided into two types: (1) those with preceding inflammatory lesions, mainly erythema (the Jadassohn–Pellizzari type), and (2) those without preceding inflammatory lesions (the Schweninger–Buzzi type). This classification is only of historical interest, because the two types of lesions can coexist in the same patient; the prognosis and the histopathology are also the same.[4]

True secondary anetoderma implies that the characteristic atrophic lesion has appeared in the exact same site as a previous specific pathology; the most common causes are probably acne and varicella. Numerous and heterogeneous dermatoses have been associated with secondary anetoderma, namely syphilis, Lyme disease, molluscum contagiosum, pilomatricomas, juvenile xanthogranuloma, xanthomas, granuloma annulare, leprosy, discoid lupus, sarcoidosis, and lichen planus, to mention only a few. Anetoderma has also been described in premature infants and, in some cases, it may have been related to the use of cutaneous monitoring leads or adhesives.[5] Both types may be associated with an underlying disease, mainly antiphospholipid syndrome[6] and human immunodeficiency virus. Although most cases are sporadic, rare cases of familial anetoderma have been recently described and are usually not associated with preexisting lesions.[7]

PATHOLOGY

In routinely stained sections, the collagen fibers within the dermis of affected skin appear normal. Perivascular lymphocytes are often present in all types of anetoderma and do not correlate with clinical inflammatory findings.[8]

The predominant defect as revealed by elastic tissue stains is a focal partial or complete loss of elastic tissue in the papillary and/or midreticular dermis. There are usually some residual abnormal, irregular, and fragmented elastic fibers (Fig. 67-2).[9] Presumably, the weakening of the elastic network leads to flaccidity and herniation. Direct immunofluorescence sometimes shows linear or granular deposits of immunoglobulins and complement along the dermal–epidermal junction or around the dermal blood vessels in affected skin.[10]

Figure 67-1 Anetoderma. Primary anetoderma. **A.** Multiple, sharply defined, depressed lesions that look punched out in the supraclavicular region. **B.** Soft, sac-like protrusions on the back. When depressed, there is the buttonhole phenomenon. This is the same patient as in **A**.

Electron microscopy demonstrates that the elastic fibers are fragmented and irregular in appearance and occasionally can be engulfed by macrophages.

DIFFERENTIAL DIAGNOSIS

Anetoderma must be differentiated from other disorders of elastic tissue as well as atrophies of the connective tissue (Box 67-1).

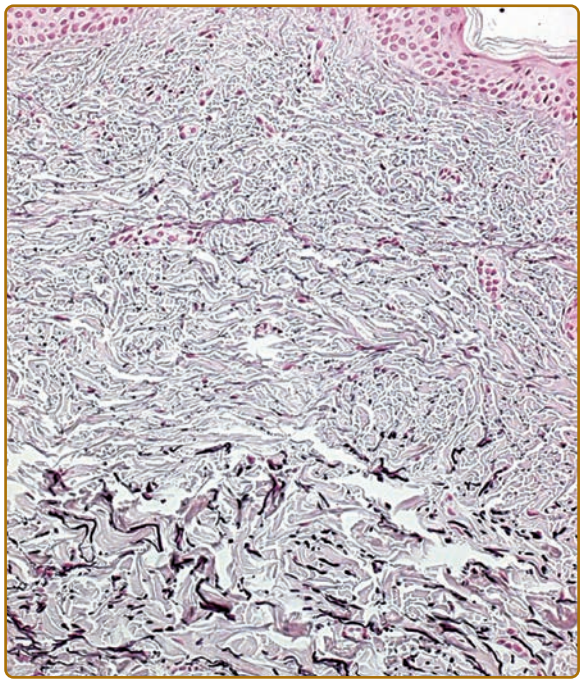

Figure 67-2 Anetoderma. Pathology shows decrease of elastic fibers in the papillary and reticular dermis (Weigert's stain). (Used with permission from Victor Kokta, MD.)

Keloids form nodules that are much firmer on palpation. A history of trauma is often elicited, and the pathology is very distinct.

Glucocorticoid-induced atrophy occurs most commonly over the triceps or buttocks at sites where injections are usually given. Clinically, the lesions resemble atrophoderma. History is obviously most helpful in making the diagnosis. On histopathology, polarization may show the steroid crystals in the dermis.

Nevus lipomatosus superficialis of Hoffman and Zurhelle presents as a clustered group of soft, skin-colored to yellow nodules usually on the lower trunk and buttocks and present since birth. Histology shows ectopic mature lipocytes located in the dermis.

Papular elastorrhexis is an acquired disorder characterized by white, firm nonfollicular papules measuring 1–3 mm, evenly scattered on the chest, abdomen, and back. It usually appears in adolescence or early adulthood. The pathology demonstrates focal degeneration of elastic fibers and normal collagen. There are no associated extracutaneous abnormalities. This is believed by some authors to be a variant of connective tissue nevi[11] or an abortive form of the Buschke–Ollendorff

BOX 67-1 DIFFERENTIAL DIAGNOSIS OF PRIMARY ANETODERMA

ELEVATED	DEPRESSED
Secondary anetoderma	Secondary anetoderma

Keloids	Acne scars
Nevus lipomatosus superficialis	
Papular elastorrhexis	
Connective tissue nevi	

syndrome,[12] whereas others think that these represent papular acne scars.[13] They are differentiated from anetoderma by being firm noncompressible lesions.

Middermal elastolysis (MDE) usually consists of larger areas with diffuse wrinkling without herniation and with elastolysis limited to the middermis (See below).

TREATMENT

There is no regularly effective treatment. In secondary anetoderma, appropriate treatment of the inflammatory underlying condition might prevent new lesions. In patients with limited lesions that are cosmetically objectionable, surgical excision may be useful. Various therapeutic modalities have been tried but with no improvement of existing atrophic lesions, including intralesional injections of triamcinolone and systemic administration of aspirin, dapsone, phenytoin, penicillin G (benzylpenicillin), and vitamin E. Some authors have reported improvement with hydroxychloroquine.

OTHER ATROPHIC DISORDERS OF THE SKIN

MIDDERMAL ELASTOLYSIS

MDE is a rare acquired disorder of elastic tissue. It is characterized by patches and plaques of diffuse, fine, wrinkled skin, most often located on the trunk, neck, and arms. In 1977, Shelley and Wood reported the first case of "wrinkles due to idiopathic loss of middermal elastic tissue."[14] Since then, fewer than 100 cases have been reported. The vast majority of patients are Caucasian women between the ages of 30 and 50 years.[15,16]

PATHOGENESIS. The pathogenesis of this acquired elastic tissue degeneration is still unknown. Ultraviolet (UV) exposure has been postulated to be a major contributing factor in the degeneration of elastic fibers,[17] including narrowband UVB.[18] Other possible mechanisms include defects in the synthesis of elastic fibers, autoimmunity against elastic fibers, and damage to elastic fibers through the release of elastase by inflammatory cells or fibroblasts. More recent data suggest that inflammatory processes and an altered balance between matrix metalloproteinase and tissue inhibitor of metalloproteinases are possibly involved in the pathogenesis of MDE.[19]

CLINICAL FEATURES. MDE is characterized by asymptomatic, well-demarcated, or diffuse areas of fine wrinkling (Fig. 67-3A). Rarely, erythematous patches, telangiectasias, or a reticular variant can be seen. Discrete perifollicular papules can be seen in some cases, leaving the hair follicle itself as an indented center. Lesions are typically found on the trunk, neck, and upper extremities. They are chronic and give the skin a prematurely aged appearance. There is usually no history of a preceding inflammatory dermatosis, but some patients report mild-to-moderate erythema. There is no associated systemic involvement.

HISTOPATHOLOGY. The pathology shows a normal epidermis and, occasionally, a mild perivascular infiltrate in the dermis. The characteristic histology is seen on elastic tissue stains and reveals a selective band-like loss of elastic fibers in the middermis (see Fig. 67-3B). There is preservation of normal elastic tissue in the superficial papillary dermis above, in the reticular dermis below, and along adjacent hair follicles. Electron microscopy studies have shown phagocytosis of normal as well as degenerated elastic fiber tissue by macrophages.[20]

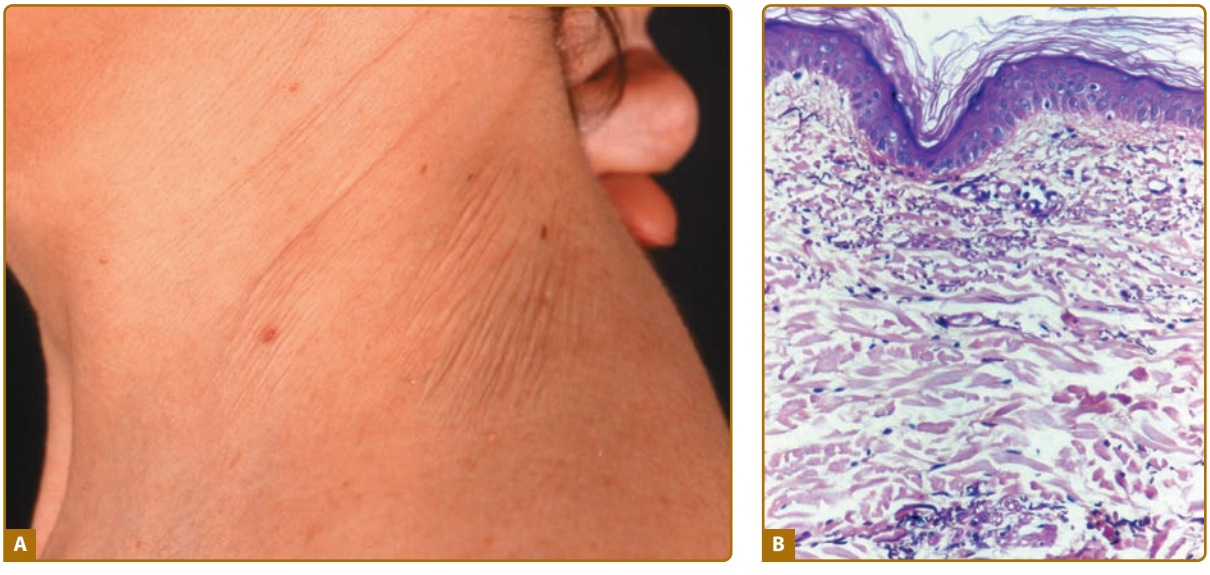

Figure 67-3 Middermal elastolysis. **A.** Well-circumscribed area of fine wrinkling on the neck of a middle-aged woman. (Used with permission from Richard Dubuc, MD.) **B.** Histology of middermal elastolysis. Note selective loss of elastic fibers in the middermis. Normal elastic tissue is preserved in the superficial papillary dermis and in the reticular dermis (Weigert's stain). (Used with permission from Danielle Bouffard, MD.)

DIFFERENTIAL DIAGNOSIS. MDE must be differentiated from the other common disorders of elastic tissue.

Solar elastosis differs by its onset in an older age group, location in only sun-exposed areas, yellowish color, and coarser wrinkling, as well as by hyperplasia and abnormalities of elastic fibers and basophilic degeneration of the collagen in the papillary dermis.

Anetoderma is characterized clinically by smaller soft macules and papules instead of diffuse wrinkling, and histologically by elastolysis that can occur in any layer of the dermis.

Perifollicular elastolysis differs by a selective and almost complete loss of elastic fibers surrounding hair follicles compared with preservation of elastic fibers around follicles in MDE. Elastase-producing *Staphylococcus epidermidis* was found in the hair follicles and is the presumed etiology of this condition.[21]

Postinflammatory elastolysis and cutis laxa were originally described in young girls of African descent. An inflammatory phase, consisting of indurated plaques or urticaria, malaise, and fever, preceded the diffuse wrinkling, atrophy, and severe disfigurement. Insect bites may be the trigger for the initial inflammatory lesions.[22]

TREATMENT

There is no known effective treatment for MDE. Sunscreens, colchicine, and topical retinoic acid have been tried without good success.[15,16]

STRIAE

(See Chapters 108 and 151)

Striae are very common and usually develop between the ages of 5 and 50 years.

They occur about twice as frequently in women as in men. They commonly develop during puberty, with an overall incidence of 25%–35%,[23,24] or during pregnancy, with an incidence of 77%.[25]

The factors leading to the development of striae have not been fully elucidated. Striae distensae are the results of breaks in the connective tissue, resulting in dermal atrophy. Many factors, including hormones (particularly corticosteroids), mechanical stress, and genetic predisposition, appear to play a role.

During puberty, striae appear in areas where there is a rapid increase in size. In girls, the most common sites are the breasts, thighs, hips, and buttocks, whereas in boys, they are seen on the shoulders, lumbosacral region, and thighs. Other less common sites include the abdomen, upper arms, neck, and axillae.

Striae distensae are a common finding on the abdomen, and less so on the breasts and thighs, of pregnant women, especially during the last trimester. They are more common in younger primigravidas than in older pregnant women and are associated with larger weight gain and with babies of higher birth weight. Striae gravidarum can be associated with a higher risk of lacerations during vaginal delivery.[26]

CLINICAL FINDINGS. Striae are usually multiple, symmetric, well-defined linear atrophic lesions that follow the lines of cleavage. Initially, striae appear as red-to-violaceous elevated lines (striae rubra) (see Fig. 107-3). Over time, the color gradually fades, and the lesions become atrophic, with the skin surface exhibiting a fine, white, wrinkled appearance (striae alba).[24] The striae can measure several centimeters in length and a few millimeters to a few centimeters in width. The striae associated with systemic corticosteroid therapy and Cushing syndrome can be larger and more widely distributed.

HISTOPATHOLOGY. Histologic findings show a decrease in dermal thickness and in collagen in the upper dermis. The collagen bundles are thinned and lie parallel to the epidermis, but they are also arranged transversely to the direction of the striae. Alterations in elastic fibers are variable, but dermal elastin can be fragmented, and specific elastin staining can demonstrate a marked reduction in visible elastin content compared with adjacent normal dermis.[27] There is absence of both hair follicles and other appendages.

DIFFERENTIAL DIAGNOSIS. The diagnosis of striae distensae is usually simple, but the differential diagnosis does include linear focal elastosis (elastotic striae) that was first described by Burket et al in 1989.[28] Linear focal elastosis is characterized by rows of yellow palpable striae-like bands on the lower back. Unlike striae, the lesions are raised and yellow rather than depressed and white. Elderly men are most commonly affected, although cases in teenagers have been described. Linear focal elastosis is probably not an uncommon condition. Histologically, there is a focal increase in the number of elongated or fragmented elastic fibers and a thickened dermis. It is postulated that linear focal elastosis may represent an excessive regenerative process of elastic fibers and could be thought of as a keloidal repair of striae distensae.[29]

TREATMENT. Striae distensae have no medical consequences, but they are frequently distressing to those affected. As stretch marks tend to regress spontaneously to some degree over time, the usefulness of treatments that have been tried without case controls is difficult to assess. Topical treatments that have shown some improvement of early stage striae are: tretinoin 0.1% cream,[30] a combination of 0.05% tretinoin/20% glycolic acid, or 10% L-ascorbic acid/20% glycolic acid.[31] Several lasers have been used in treating striae: the 585-nm pulsed-dye laser has been demonstrated to be of some efficacy in improving the appearance of striae rubra but has no effect on stria alba[32]; improvement in the leukoderma of the striae alba was noted with 308-nm excimer laser but maintenance treatment is required to sustain the cosmetic benefit.[33] The long-term future of treatment strategies is encouraging with the advance in laser technologies.

IDIOPATHIC ATROPHODERMA OF PASINI AND PIERINI

EPIDEMIOLOGY AND PATHOGENESIS. Idiopathic atrophoderma of Pasini and Pierini is a form of dermal atrophy that presents as one or several sharply demarcated depressed patches with no outpouching, usually on the back of adolescents or young adults.[34] Whether atrophoderma is a nonsclerotic, primarily atrophic variant of morphea or a separate distinct entity is still debated.[35–39] Its relationship to morphea is favored by its striking clinical and histologic similarities to the atrophy seen at sites of regressing plaques of morphea. Antibodies to *Borrelia burgdorferi* have been reported.[37] Typical lesions of morphea, lichen sclerosus, and atrophoderma have been observed to occur simultaneously in the same patient but in different areas, supporting the view that these conditions are related. In a series of 139 patients, 17% had white induration in the central portions of their atrophic lesions, and 22% had superficial plaques of morphea coexisting in areas outside of their atrophic foci.[35] However, to some, the different course and outcome of atrophoderma of Pierini and Pasini as compared with morphea justifies preservation of a distinct name.

This disorder is more frequently encountered in women than in men, with a ratio of 6:1. It usually starts insidiously in young individuals in the second or third decades of life. A congenital case was recently reported.[40] The lesions usually occur on the trunk, especially on the back and lumbosacral region, followed in frequency by the chest, arms, and abdomen.[37] The distribution is often symmetric and bilateral.

The lesions are single or multiple and usually round or ovoid, ranging in size from a few centimeters to patches covering large areas of the trunk (Fig. 67-4). They are usually asymptomatic and lack inflammation. When lesions coalesce, they can form large, irregular, brown patches but can be hypopigmented.[41] The surface of the skin is normal in appearance, and there is no skin induration or sclerosis.

Figure 67-4 Atrophoderma of Pasini and Pierini. Brownish depressed lesions on the lower back.

The borders or edges of these lesions are sharply defined, and they are usually described as abrupt, "cliff drop" borders ranging from 1 to 8 mm in depth, although they can have a gradual slant.[34] These depressed patches are characteristic and give the impression of inverted plateaus, or, if multiple lesions are present, they can have the appearance of Swiss cheese. They are even more apparent when present on the back because the dermis is thicker in this area. The skin surrounding the patches is normal in appearance, and there is no erythema or lilac ring as in morphea.

COURSE. The course of this benign disease is progressive, and lesions can continue to appear for decades before reaching a standstill. Transformation to generalized morphea has not been observed.

HISTOPATHOLOGY. The histologic picture is generally not diagnostic. The epidermis is usually normal or slightly atrophic. Collagen bundles in the mid- and reticular dermis show varying degrees of homogenization and clumping. Dermal thickness is eventually reduced when compared with adjacent normal skin.[38] Some irregular clumping and loss of elastic fibers were described in earlier case reports,[34] but in most series, no abnormality was seen with elastic tissue stains[35,37]; therefore, this is not of diagnostic value. The appendages are usually preserved. If sclerodermatous changes appear in preexisting patches, the histology reveals varying degrees of collagen sclerosis resembling morphea.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis is to be made with active lesions of morphea that usually present as indurated, often hyperpigmented plaques with a characteristic peripheral lilac rim.

THERAPY. No treatment has been proved effective. Dramatic response to oral hydroxychloroquine was recently reported in one patient.[42]

FOLLICULAR ATROPHODERMA

Follicular atrophoderma refers to dimple-like depressions at the follicular orifices. It can occur as an isolated defect of limited extent, in association with a variety of disorders in which hair follicles are plugged with keratin, or with rare genodermatoses.[43,44]

Distinctive ice-pick depressions around hair follicles can be seen most commonly on the back of the hands or feet and on the cheeks. These pitted scars can present at birth or early in life. A family history may be present. Follicular atrophoderma occurs in the conditions described in the following sections.

ATROPHODERMA VERMICULATUM. Atrophoderma vermiculatum is a term that applies when the lesions are found exclusively on the cheeks. It is a

Figure 67-5 Atrophoderma vermiculatum. Multiple, small, pitted scars on the cheek of a young girl.

Figure 67-6 Ulerythema ophryogenes. Erythematous follicular papules and scarring alopecia of the eyebrow.

condition that can either occur sporadically, be inherited as an autosomal dominant disorder, be part of a group of related diseases including keratosis pilaris atrophicans, or be associated with various syndromes.

Multiple inflammatory symmetric papules on the cheeks, presumably centered around hair follicles, may precede the atrophic lesions. These papules then go on to develop pitted, atrophic, and depressed scars in a reticulated or honeycomb pattern (Fig. 67-5). These lesions can extend to the forehead and preauricular regions. This condition usually has its onset in childhood or, less often, around puberty. Men and women seem to be affected equally.[45] It usually has a slow progressive course.

Keratosis Pilaris Atrophicans. Keratosis pilaris atrophicans[46] can include atrophoderma vermiculatum but also a group of closely related disorders that includes keratosis follicularis spinulosa decalvans and ulerythema ophryogenes. These conditions are characterized by keratotic follicular papules, variable degrees of inflammation, and secondary atrophic scarring. Keratosis follicularis spinulosa decalvans begins in infancy with keratotic follicular papules over the malar area and progresses to involve the eyebrows, scalp, and extremities, with scarring alopecia. This condition is inherited in an X-linked recessive fashion in some patients. Ulerythema ophryogenes (or keratosis pilaris atrophicans faciei) differs from atrophoderma vermiculatum by affecting primarily the lateral portion of the eyebrows (ophryogenes) with erythema, follicular papules, and alopecia (Fig. 67-6).

The underlying pathologic defect in these disorders appears to be abnormal follicular hyperkeratinization of the upper third of the hair shaft leading to obstruction of the growing hair and production of chronic inflammation. The end result of this process is scarring below that level. Histopathology is usually not very helpful and shows dilated follicles, sometimes associated with plugging, inflammation, and sclerosis of dermal collagen.

Associated Syndromes. The various syndromes that include atrophoderma vermiculatum are the Rombo syndrome (milia, telangiectasias, basal cell carcinomas, hypotrichosis, acral cyanosis, and, rarely, trichoepitheliomas), Nicolau–Balus syndrome (syringomas and milia), Tuzun syndrome (scrotal tongue), and finally the Braun–Falco–Marghescu syndrome (palmoplantar hyperkeratosis and keratosis pilaris).

Therapy. These disorders are mainly a cosmetic but vexing problem. Various topical treatments, including emollients, corticosteroids, tretinoin, and keratolytics, have shown no consistent benefit. Systemic isotretinoin has been shown to stop progression and to induce remission in some cases.[46] Dermabrasion as well as carbon dioxide and 585-nm pulsed-dye lasers are other options to improve the appearance of the atrophic scars.[47]

BAZEX–DUPRÉ–CHRISTOL SYNDROME (OMIM #301845).

Bazex–Dupré–Christol syndrome is characterized by follicular atrophoderma, milia, multiple basal cell carcinomas, hypotrichosis, and localized hypohidrosis.[48–50] The follicular atrophoderma described as multiple ice-pick marks or patulous follicles can be found most commonly on the dorsa of the hands. It is inherited in an X-linked dominant fashion, and the gene has been linked to Xq24–q27.[48] Subsequently reported findings include facial hyperpigmentation, hair shaft dystrophy, and multiple genital trichoepitheliomas.

CONRADI–HÜNERMANN–HAPPLE SYNDROME (X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA, CDPX2, OMIM #302960)).

Conradi–Hünermann syndrome is an X-linked dominant disorder that occurs only in girls

because it is usually lethal in hemizygous males. The underlying molecular defect consists of mutations in the emopamil-binding protein gene at Xp11.23-p11.22.[50] The clinical manifestations include an ichthyosiform scaling erythroderma patterned along the lines of Blaschko that usually resolves during the first year of life and is replaced by bands of follicular atrophoderma.[43] Hyperpigmentation, cataracts, scarring alopecia, saddle-nose deformity, asymmetric limb reduction defects, and stippled calcifications of the epiphyses can be seen. Ichthyosis with keratotic follicular plugs containing dystrophic calcification in newborns are distinctive histopathologic features.[51]

OTHER ATROPHIES OF THE CONNECTIVE TISSUE

Many systemic conditions [scleroderma (see Chapter 157), lupus erythematosus (see Chapter 155), dermatomyositis (see Chapter 156)], and genodermatoses (poikiloderma congenitale, dyskeratosis congenita, Cockayne syndrome, Hallermann–Streiff syndrome) have skin atrophy as an associated finding and are described in other chapters.

Chapter 68 :: Ainhum and Pseudoainhum

:: Robert T. Brodell & Stephen E. Helms

AINHUM AND PSEUDOAINHUM ARE SYNDROMES RELATED TO EXTERNAL CONSTRICTING BANDS

- Constricting bands are classified as ainhum and pseudoainhum.
- Ainhum is defined by a constricting band around a digit and is most common in tropic and subtropic latitudes occurring around the fifth toe or toes of people accustomed to walking barefoot.
- Pseudoainhum constrictions clinically mimic ainhum and are much more common in the developed world. It may be caused by (1) amniotic bands; (2) constrictions associated with keratotic disorders or those associated with infections or trauma; and (3) constriction by external forces such as hairs and threads.
- Autoamputation can result from ainhum and pseudoainhum.
- Treatment can simply be the removal of foreign strands wrapped around a digit or limb or surgical intervention in more advanced cases (Z-plasty or amputation).

AINHUM AND PSEUDOAINHUM

Constricting bands are classified as ainhum and pseudoainhum. *Ainhum* describes the development of constricting bands around toes in underdeveloped countries of Africa and may ultimately result in autoamputation. In the African Yorub language, ainhum means "to saw" or "file" and in the Brazilian patois, it means "fissure." In the remainder of the world, constricting bands that mimic ainhum are termed *pseudoainhum*.

EPIDEMIOLOGY

Ainhum (dactylolysis spontanea) is traditionally a disease of middle-aged African males accustomed to going barefoot.[1] In the tropic and subtropic climates, its incidence has been reported as between 0.015% and 2% of the population.[2] This same condition is rarely seen throughout the rest of the world. Occasional isolated cases were reported in the United Kingdom and North America.[1,3] Pseudoainhum of all types is very rare.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of ainhum has not been clearly elucidated. Chronic trauma, infection, hyperkeratosis,

decreased vascular supply, and impaired sensation may produce excessive fibroplasia in a susceptible host.[4] Dent et al described impaired blood supply to the foot proximal to the groove at the plantar digital junction. Poor perfusion was the result of attenuation of the posterior tibial artery and absence of the plantar arterial arch leading to abnormal healing following mechanical trauma. Ainhum has also been blamed on rotational stress applied to the bare, mechanically unstable foot.[5]

There are three pathophysiological categories of pseudoainhum: (1) congenital constricting bands are caused by the umbilical cord; (2) constriction by external forces, such as hairs or threads, which are generally factitial; and (3) constricting bands secondary to other diseases. These may be hereditary or nonhereditary. Hereditary causes include pachyonychia congenita, Mal de Meleda, mutilating keratoderma,[6] lamellar ichthyosis,[7] and psoriasis.[8–10] Nonhereditary diseases include vascular anomalies as seen in Raynaud disease, diabetes mellitus, linear scleroderma, systemic sclerosis. Sensory changes associated with leprosy, tertiary syphilis, syringomyelia, and spinal cord tumors as well as trauma resulting in scar formation from burns, frostbite, and physical trauma can also cause constricting bands to form. When associated with chronic trauma and infection of the extremities, the pathophysiology may be identical to true ainhum.

CLINICAL FINDINGS

Ainhum usually affects the fifth toe; it may be unilateral, but 75% of the cases are bilateral. One or more digits can be involved. All toes can be involved, even the great toe.[11] In early lesions, a groove or sulcus appears at the plantar junction of the toe and the sole. As this sulcus deepens, edema develops distally and roentgenographic examination shows resorption of the underlying bone and ultimately autoamputation.[12]

Congenital constricting bands (Streeter bands) usually involve more than one part of the body (Fig. 68-1) and frequently encircle large structures such as limbs or even the trunk. They persist throughout life and interfere with normal growth of the involved segment unless surgically treated[13] (Fig. 68-2). Autoamputation can occur. More than 50% of cases are associated with other congenital anomalies usually syndactyly or clubfoot when constricting bands are found on the feet.[14]

Factitious pseudoainhum may prove to be a most challenging diagnosis. Strands of hair, fibers, or threads are intentionally wrapped around digits or other body parts such as a nipple or penis. This phenomenon is most commonly encountered in children, but can occur in mentally ill adults.[15] Because of soft-tissue swelling, the ligating band may not be visible and the true cause of the condition may not be immediately recognized.[15]

Acquired constricting bands are associated with a variety of medical and dermatological conditions. In general, pseudoainhum is more likely to involve any

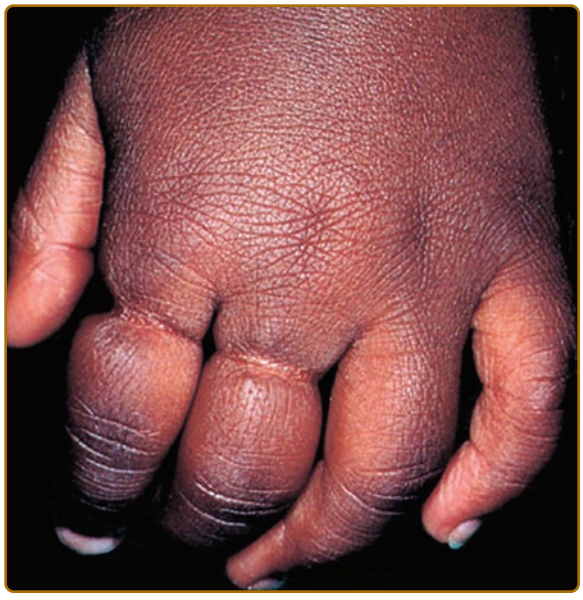

Figure 68-1 Congenital constricting bands about two digits. No etiology was identified.

of the toes or even the hands (Fig. 68-3; eFig. 68-3.1 in online edition). In children, when chronic dermatophyte infection is identified and appropriately treated, complete reversal of the constriction may occur. Severe hyperkeratosis as occurs with Vohwinkel syndrome (keratoderma hereditarium mutilans)[6,16] may show constricting bands due to palmar and plantar hyperkeratoses as well as starfish-like and linear keratoses.

Figure 68-2 Pseudoainhum (congenital constricting band) of the leg in an infant. (Used with permission from Ilona Frieden, MD.)

Figure 68-3 Pseudoainhum of hand with autoamputation due to amniotic bands. (Used with permission from Ilona Frieden, MD.)

The pathology of ainhum and pseudoainhum are similar with fibrotic bands resembling scar tissue.[4,12] The bands in ainhum usually extend deep into the subcutaneous layers and may impinge upon underlying skeletal and vascular structures. Additionally, moderate inflammation and epidermal or verrucous hyperplasia may be present. In pseudoainhum the bands tend to be more superficial. Also, in pseudoainhum there may be histologic clues to the associated disorder, such as dermatophytosis, foreign bodies, or distinct patterns of keratinization.

COMPLICATIONS

The constricting bands of both ainhum and pseudoainhum ultimately produce a dangling, twisted digit, which can become gangrenous or infected. When this tenuous connection produces necrosis, autoamputation occurs.

PROGNOSIS AND CLINICAL COURSE

Diseases caused by constricting bands proceed slowly and often painfully over many years eventuating in autoamputation in severe cases.

TREATMENT

Surgery is the mainstay of therapy and early intervention is important. In most cases of ainhum, prompt amputation may allow the patient to escape pain and infection. Early cases of ainhum or pseudoainhum may respond to conservative plastic repair with a Z-plasty or similar relaxing closure by avoiding further disease progression and damage to underlying structures.[12]

Impending amputation i n Vohwinkel syndrome can sometimes be aborted by therapy with oral etretinate.[16] When chronic fungal or bacterial infections or psoriasis are diagnosed in the early phase of band formation, treatment may reverse the threat to the digit (eFig. 68-3.2 in online edition). Other predisposing causes of underlying diseases should be treated aggressively in the hope of forestalling progression. For example, a case of infantile psoriasis with pseudoainhum was successfully treated with narrowband UVB phototherapy and pimecrolimus.[17]

PREVENTION

Ainhum is rarely seen in people who are protected by wearing shoes. Congenital pseudoainhum cannot be prevented. Psychological counseling may prevent recurrences of pseudoainhum in patients with factitial disease. Control of the underlying disease process may delay progression or prevent recurrence in pseudoainhum of the acquired type.

Chapter 69 :: Acquired Perforating Disorders

:: Julia S. Minocha & Bethanee J. Schlosser

ACQUIRED PERFORATING DISORDERS AT A GLANCE

- Acquired perforating disorders represent a group of separately identified cutaneous disorders that occur most often in the setting of chronic renal disease or diabetes mellitus.
- The previously recognized Kyrle's disease (KD), acquired elastosis perforans serpiginosa (AEPS), acquired reactive perforating collagenosis (ARPC), and perforating folliculitis (PF) are now classified under the umbrella term of acquired perforating dermatosis.
- Lesions present as umbilicated papules and/or nodules with a central keratotic plug or crust distributed preferentially on extensor surfaces of the extremities.
- Histopathological examination of lesional skin demonstrates invagination of the epidermis with extrusion of dermal material (collagen, elastin, and/or fibrin) through the cup-shaped epidermal depression.
- Treatment is challenging with no universally effective therapy, and patients often exhibit a chronic course.

INTRODUCTION

Acquired perforating disorders represent a group of separately identified cutaneous disorders that occur in adult patients, most often in the setting of chronic kidney disease (CKD) or diabetes mellitus (DM).[1] Kyrle's disease (KD), acquired elastosis perforans serpiginosa (AEPS), acquired reactive perforating collagenosis (ARPC), and perforating folliculitis (PF) were previously considered distinct disorders.[2–5] Given their shared clinical and histopathological characteristics, these four disorders are now classified under the umbrella term of acquired perforating dermatosis (APD).[1] APD is characterized clinically by the presence of umbilicated papules and/or nodules with a central keratotic plug or crust and histologically by the transepidermal extrusion of dermal components (collagen, elastin, and/or fibrin).[6] Although some cases may exhibit clinical and histological characteristics that typify one of the four classically recognized disorders, use of the comprehensive term APD is encouraged.

EPIDEMIOLOGY

Kyrle, in 1916, first described KD in a young diabetic woman and termed it hyperkeratosis follicularis et parafollicularis in cutem penetrans.[5] In 1953, Lutz published the initial description of elastosis perforans serpiginosa (EPS) as keratosis follicularis serpiginosa.[7] The first case of AEPS associated with CKD was identified in 1986 by Schamroth, Kellen, and Grieve.[2] Mehregan, Schwartz, and Livingood reported the earliest description of reactive perforating collagenosis (RPC) in 1967, and the first case associated with DM was recognized by Poliak et al in 1982.[3,8] PF was originally described by Mehregan and Coskey in 1968.[4] In 1989, Rapini, Heber, and Drucker recognized the common clinical and histopathologic characteristics of these disorders and introduced the term acquired perforating dermatosis.[1] Various terminology has been used in the literature to refer to APD (Table 69-1).

APD occurs worldwide without gender predilection.[17] The most common systemic diseases associated with APD are CKD and DM. APD has been documented in 4.5%–10% of hemodialysis patients in North America and in 11% of a dialysis population (both hemodialysis and peritoneal dialysis) in Great Britain.[17,18] APD has also occurred in patients with CKD who are not undergoing dialysis as well as those who have received renal transplants. The most common cause of CKD among APD patients is diabetic nephropathy.[18] Table 69-2 lists less commonly reported associated conditions. APD has rarely been associated with the use of certain therapeutics, including tumor necrosis factor-α inhibitors, indinavir, and sorafenib.[44–46] A predominance of blacks among hemodialysis patients with APD has been reported in one study, but not confirmed in others.[11] AEPS is well recognized as a potential adverse effect of prolonged D-penicillamine therapy.[47] AEPS has also been reported in patients with CKD in the absence of penicillamine exposure or other associations.[2]

ETIOLOGY AND PATHOGENESIS

The precise etiology and pathogenesis of APD are unknown. APD pathology likely involves a complex interaction between the epithelium, connective tissue, and inflammatory mediators. Superficial trauma to the epidermis may be the primary inciting factor in susceptible patients.[8] Predisposing conditions include vasculopathy/angiopathy (related to DM), microdeposition of exogenous materials within the dermis (including calcium salts and silicon, pertinent to the increased frequency of APD in dialysis patients), and epidermal or dermal change related to metabolic derangements including vitamin A deficiency.[13,18,43,48,49]

TABLE 69-1
Synonyms for Acquired Perforating Dermatosis

Acquired reactive perforating collagenosis[9]
Hyperkeratosis follicularis et parafollicularis in cutem penetrans[5]
Hyperkeratosis penetrans[10]
Keratosis follicularis serpiginosa[7]
Kyrle's disease[11]
Kyrle-like lesions[12]
Perforating disorder[13]
Perforating folliculitis[8]
Perforating folliculitis of hemodialysis[14]
Reactive perforating collagenosis of diabetes mellitus (DM) and renal failure[15]
Uremic follicular hyperkeratosis[16]

Given APD's common association with CKD, scratching due to chronic pruritus has been thought to lead to microtrauma and subsequent transepidermal elimination of dermal components. Koebnerization, predominant localization to trauma-prone areas, and resolution of APD lesions with discontinuation of manipulation/trauma support this mechanism.[6] Diabetic vasculopathy has been proposed as an additional predisposing factor for APD in DM patients by creating a relatively hypoxic environment in which trauma from scratching causes dermal necrosis. The finding of PAS-positive thickening of vessel walls in the upper dermis of diabetic patients with APD[48,50] supports this hypothesis, but has not been noted in all studies.[6,51] Imbalances in fibronectin, transforming growth factor-β3 (TGF-β3), and matrix metalloproteinases in APD lesions have also been demonstrated; these molecules are essential to normal epithelial differentiation and wound healing, and their aberration may predispose to the development of APD lesions.[48,51,52] In AEPS, it is hypothesized that penicillamine alters dermal elastic fibers in affected patients.[53] Elastic fiber abnormalities, including "bramble bush-appearing" fibers of variable thickness and increased numbers of fibers in the papillary and reticular dermis, have been described in patients with penicillamine-induced AEPS.[54]

TABLE 69-2
Conditions Associated with Acquired Perforating Dermatosis

Common Associations
Chronic kidney disease
Diabetes mellitus (insulin-dependent and noninsulin-dependent)
Scabies[19,20]

Rare Associations
Acquired immunodeficiency syndrome (AIDS)[21,22]
Arthropod bites[23,24]
Atopic dermatitis[25]
Cutaneous cytomegalovirus infection[26]
Hyperparathyroidism[9]
Liver diseases (hepatitis C, hepatitis B, steatohepatitis, primary biliary cirrhosis)[6,27]
Lupus vulgaris[28]
Myelodysplastic syndrome[29]
Malignancy (Hodgkin lymphoma, mixed histiocytic–lymphocytic lymphoma, hepatocellular carcinoma, pancreatic carcinoma, prostate carcinoma, papillary thyroid carcinoma)[30–37]
Mikulicz's disease[38]
Neurodermatitis[9]
Poland syndrome[39]
Primary sclerosing cholangitis[40]
Pulmonary aspergillosis[41]
Pulmonary fibrosis[25]
Salt water application[13]
Thyroid disease (hypothyroidism, sick euthyroid syndrome, Hashimoto thyroiditis)[9,27,42]
Vitamin A deficiency[43]

CLINICAL FINDINGS

HISTORY

Most patients report lesional pruritus, ranging from mild-to-severe and intractable, of skin lesions. Lesions may also be painful.[6]

CUTANEOUS LESIONS

APD characteristically manifests as round, umbilicated, skin-colored, erythematous or hyperpigmented papules and nodules with a central crust or keratotic plug, predominantly involving the extensor surfaces of the extremities and the trunk (Fig. 69-1). Lesions less commonly involve the face or scalp. In rare cases, purple annular plaques or pustules mixed with papules have been observed. Some lesions may be follicular (PF) (Fig. 69-2). AEPS lesions exhibit papules in a serpiginous configuration, often with central atrophy, and typically occurring on the neck, trunk, and extremities (Fig. 69-3). Scratching can lead to koebnerization with linear umbilicated papules arising in excoriated skin.

Figure 69-1 Acquired perforating dermatosis. Multiple, round, hyperpigmented papules, each with a central keratotic plug, distributed on the extensor aspects of the hand and wrist in a patient with chronic kidney disease.

Figure 69-2 Perforating folliculitis. Multiple follicular, erythematous, firm papules with variable central crusting.

RELATED PHYSICAL FINDINGS

Although most common in patients receiving hemodialysis, especially for diabetic nephropathy,[18] APD has also been seen in CKD patients without hemodialysis or who have undergone renal transplantation. Table 69-2 lists medical conditions that are less often associated with APD.

HISTOPATHOLOGY

The diagnosis of APD is based on clinical and histopathologic findings. Folliculitis and prurigo nodularis may occur concomitantly, especially in patients with CKD; multiple biopsies should be taken if lesions show different clinical morphologies. APD is characterized histologically by transepidermal elimination of dermal material through an epidermal invagination, which may be follicular or perifollicular. Lesions typically demonstrate a central keratotic plug with crusting or hyperkeratosis; parakeratosis is variable. Within the dermis surrounding the perforation, there is often a focal inflammatory infiltrate with neutrophils predominating in early lesions and lymphocytes, macrophages, or multinucleated giant cells present in older lesions.

Figure 69-3 Acquired elastosis perforans serpiginosa in a patient taking penicillamine for Wilson's disease. Annular plaque with variably crusted erythematous papules at the periphery and central cribriform scarring.

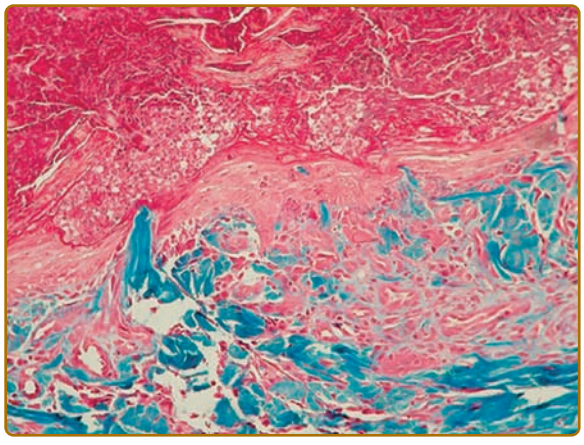

Figure 69-4 Reactive perforating collagenosis. Collagen bundles can be seen crossing from the reticular dermis through the epidermis into an epidermal depression containing necrotic debris. (Hematoxylin and eosin stain.)

The four initially identified acquired perforating disorders [(1) RPC, (2) AEPS, (3) KD, and (4) PF] were classically differentiated histopathologically on the basis of the nature of the eliminated dermal material. In RPC, collagen bundles are detected within the plug (Fig. 69-4); in AEPS, elastic fibers are instead noted (Fig. 69-5). In KD, amorphous dermal material and/or keratin comprise the extruded material. PF is characterized by perforation of the follicular epithelium by degenerating collagen and extracellular matrix (Fig. 69-6). Clear identification of the eliminated material may be impossible and, in addition, multiple substances (i.e., collagen and elastic fibers) may be simultaneously detected, reinforcing the clinical and histopathologic overlap within APD.

LABORATORY TESTS

Laboratory evaluation for comorbidities should include fasting blood glucose, glucose tolerance test, serum creatinine, glomerular filtration rate or creatinine clearance, serum uric acid, liver function tests, and thyroid function tests. A comprehensive past medical history and review of systems should be obtained. Additional diagnostic testing for associated conditions (Table 69-2) should be performed as indicated.

DIFFERENTIAL DIAGNOSIS

(Box 69-1)

The differential diagnosis of APD is broad and includes both infectious and inflammatory disorders, including those that koebnerize (Box 69-1). APD can be especially difficult to differentiate from prurigo nodularis. Perforating pseudoxanthoma elasticum should be distinguished from AEPS.

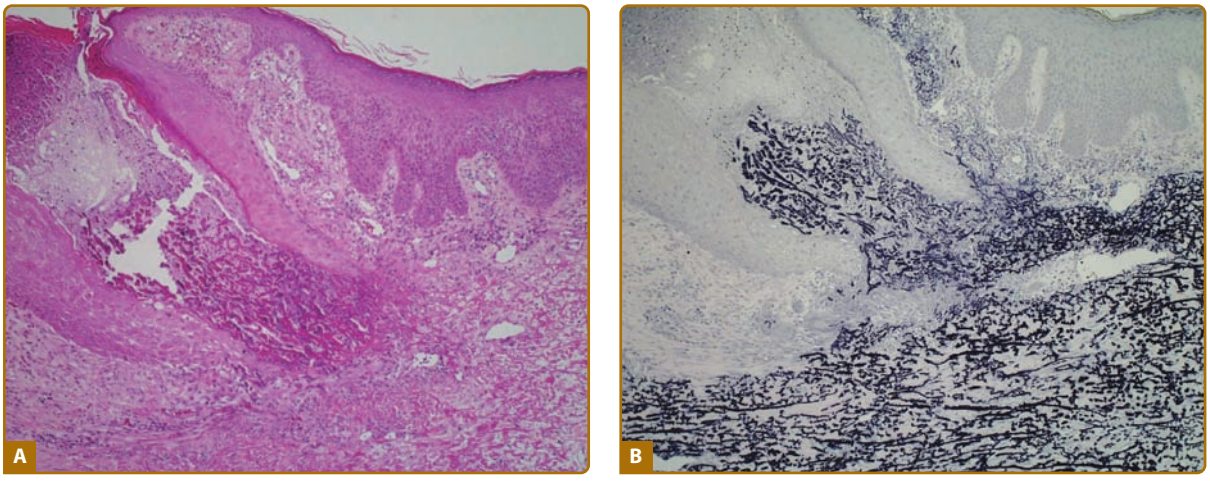

Figure 69-5 Acquired elastosis perforans serpiginosa. **A.** Dilated follicular structure with transepidermal elimination of densely eosinophilic elongated bundles. (Hematoxylin and eosin stain.) **B.** Transepidermally eliminated elongated bundles are elastin fibers (elastin stain).

COMPLICATIONS

Most complications that occur in patients with APD arise from underlying systemic illnesses. However, patients should be monitored for secondary infection (bacterial, fungal, and viral) as well as parasitic infestation. In an attempt to relieve the associated pruritus, patients may apply products to their skin that may result in irritant or allergic contact dermatitis. In darker skinned patients with more excoriations, postinflammatory pigmentary alteration and scarring can be significant.

PROGNOSIS

The prognosis of APD is heavily linked to the presence of underlying diseases. Some studies have shown that APD may improve with successful treatment of the underlying illness.[25] Most cases of APD continue for years unless treated.

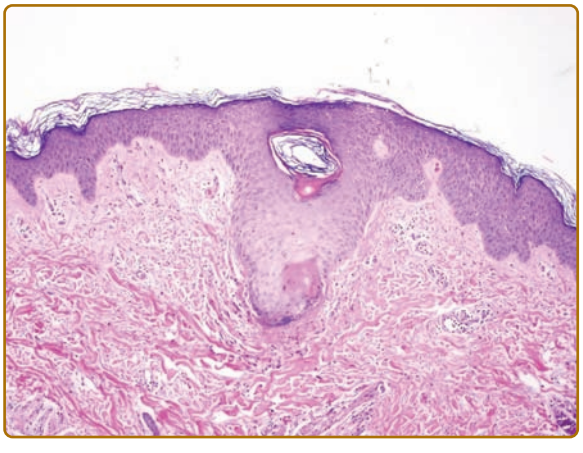

Figure 69-6 Perforating folliculitis. Dilated follicular unit exhibits necrosis and disruption of the epithelium.

TREATMENT

Treatment of APD is difficult. Table 69-3 details the therapeutic options that have been described in the literature to date. There have not been any well-designed clinical trials of APD, and current treatment strategies are based largely on anecdotal reports. In patients with CKD, improvement in APD lesions has been reported after changing the type of dialysis tubing or modification of the dialysis procedure.[18] In a few cases, APD has resolved following renal transplantation.[17,14,80] The most commonly employed treatments for APD include topical and oral retinoids, topical and intradermal

BOX 69-1 DIFFERENTIAL DIAGNOSIS OF ACQUIRED PERFORATING DERMATOSIS

- Actinic granuloma (annular elastolytic giant cell granuloma)
- Arthropod bites
- Discoid lupus erythematous
- Flegel disease (hyperkeratosis follicularis perstans)
- Folliculitis (bacterial, yeast)
- Keratosis follicularis (Darier disease)
- Keratosis pilaris
- Lichen planus
- Multiple keratoacanthomas (Ferguson–Smith familial keratoacanthomas, Grzybowski eruptive keratoacanthomas)
- Perforating granuloma annulare
- Perforating periumbilical calcific elastosis
- Perforating pseudoxanthoma elasticum
- Porokeratosis
- Prurigo nodularis
- Psoriasis
- Sarcoidosis
- Scabies

TABLE 69-3
Treatment of Acquired Perforating Dermatosis

Treatment	Action	Dosing
Topical Therapies		
Retinoic acid[a]	Retinoid	0.025% gel[55]
Tretinoin[a]	Retinoid	0.1% cream one to three times daily[56,57]
Tazarotene[a]	Retinoid	0.1% gel daily[58]
Beclomethasone[a]	Corticosteroid	0.1% cream[17]
Triamcinolone acetonide[a]	Corticosteroid	10 mg/mL intralesional injection[17]
Imiquimod	Immune response modifier	Daily for 6 weeks then three times per week for 4 weeks[59]
Phenol	Antipruritic	0.5% phenol with 10% glycerin in sorbolene cream[60]
Capsaicin	Capsaicinoid	0.025%–0.075% ointment
Systemic Therapies		
Isotretinoin[b]	Retinoid	Isotretinoin 0.5 mg/kg/day[61,62]
Acitretin[b]	Retinoid	25–30 mg/day [60,63]
Prednisolone	Corticosteroid	30 mg daily[64]
Allopurinol[b]	Xanthine oxidase inhibitor	100 mg daily[65,66]
Doxycycline	Antibiotic	100 mg daily[20,67,68]
Metronidazole	Antibiotic	500 mg twice daily[69]
Clindamycin	Antibiotic	300 mg three times daily[70]
Hydroxychloroquine	Antimalarial	200 mg daily[71]
Physical Modalities		
UVB[a]	Phototherapy	MED for 2 minutes every other day with increments of 30 seconds for 2–4 weeks[72]
NUVB[a]	Phototherapy	Three times a week for 2–3 months[60] 400 mJ/cm^2 increased to 1,500 mJ/cm^2, two to three times per week, 10–15 exposures[73]
PUVA[b74]	Phototherapy	Four times per week for total of 326 J/cm^2[75]
Liquid nitrogen	Cryotherapy	10 seconds, on five occasions over 4 months, one occasion 3 months later[76]
Carbon dioxide laser	Laser	Five lesional passes at 300 J (pattern 5, size 7, density 7), followed by three resurfacing passes at 300 J (pattern 2, size 8, density 5), power of 80 W[77]
TENS	Other	1 hour daily for 3 weeks[78]
Surgical debridement[70,79]		

UVB = ultraviolet B; NUVB = narrowband ultraviolet B; PUVA = psoralen and ultraviolet A; TENS = transcutaneous electrical nerve stimulation.
[a]First-line therapy.
[b]Second-line therapy.

corticosteroids, and UVB phototherapy. Phototherapy has been shown to be effective for uremic pruritus and therefore may be particularly beneficial for patients with CKD by reducing koebnerization.[73] Several authors have reported improvement in APD following treatment with allopurinol in cases of elevated or normal uric acid levels.[73] Currently available therapeutic options may not provide complete resolution of APD lesions or associated symptoms.

SECTION 10

Disorders of Subcutaneous Tissue

Chapter 70 :: Panniculitis

:: Iris K. Aronson, Patricia M. Fishman, & Sophie M. Worobec

INTRODUCTION

Inflammation in subcutaneous fat often poses a diagnostic problem for clinician and pathologist alike, since the clinical and histopathological findings in the various inflammatory disorders of adipose tissue (AT) have overlapping features. Specificity in diagnosis is potentially difficult since similar clinical presentations are sometimes associated with disparate histopathological features. Diagnostic problems may also relate to the corollary observation that a range of clinical presentations may have similar histopathologic findings.

There is no universally accepted classification of panniculitis, but from the point of view of many pathologists, a useful classification begins by dividing panniculitis into septal and lobular forms, "septal" signifying inflammation confined predominantly to the septa, and "lobular" indicating inflammation predominantly involving the fat lobule itself. The septal form has been most classically associated with erythema nodosum (EN) and the lobular form with all or most other types of panniculitides. But even this beginning point has not been proven adequate since lobular granulomatous panniculitis may be seen in clinically classic EN,[1] and lobular panniculitides may have mixed lobular and septal inflammation.[2] This classification has been expanded by making note of the presence or absence of vasculitis in the septa or lobules,[3] by the composition of the inflammatory infiltrate, and by additional specific features when present (Fig. 70-1).

Since diverse clinical conditions may be expressed by similar histopathologic features, and the spectrum of histopathologic features in EN and other panniculitides may be variable,[4] it may not be possible to make a specific diagnosis of panniculitis based on histopathology alone. This necessitates correlation with clinical features, including location of lesions, systemic symptoms, laboratory findings, and etiological factors. A significant aid to success in the diagnosis of inflammation in AT is obtaining a tissue sample that will adequately represent the histopathologic changes in the lesion. This can only be done with large excisional biopsies, as small punch biopsies are unlikely to obtain adequate AT, and the inflammatory infiltrate can be missed. An additional consideration is that inflammation in AT is not a static process, and as samples taken at different stages of an evolving lesion will present with different histopathologic features, more than one biopsy may be necessary to come to a conclusive diagnosis.

Under the best of circumstances, with optimal histopathologic sampling and clinical correlation, there may be no specific etiology for many inflammatory reactions in AT. But even with a specific diagnosis or etiology, underlying questions remain. Why were the inflammatory cells accumulating in the AT? What were they doing there?

ADIPOSE TISSUE REGIONAL DIFFERENCES

One of the characteristics of certain types of panniculitides is the preferential localization, such as the pretibial areas for EN, the calf for erythema induratum (EI), and the upper arms, shoulders, and face for lupus panniculitis. Location of panniculitis is a helpful adjunct for differential diagnosis of inflammation in AT and the question of why that occurs may be traced to the origin of the adipocyte regions from different areas of the mesoderm and the varying gene expression in different fat depots.[25] The differences in gene expression between fat depots are large, up to 1,000-fold, and appear to be intrinsic, autonomous, and independent of the tissue microenvironment.[25] Different AT depots may also contain variable percentage of adipocytes of different developmental origins,[25] including brown AT (BAT) that has been observed to be present in white AT depots.[25,26]

The role of AT in innate immunity, inflammation, adaptive immunity, and energy homeostasis places the adipocyte itself centrally in the inflammatory disorders that affect it. The presence of adipocyte transmembrane PRRs, TLRs, and cytosolic PRRs, NLRs, and RLRs and receptors for interaction with macrophages and lymphocytes, as well as production and secretion of multiple cytokines and adipokines reflect the role of

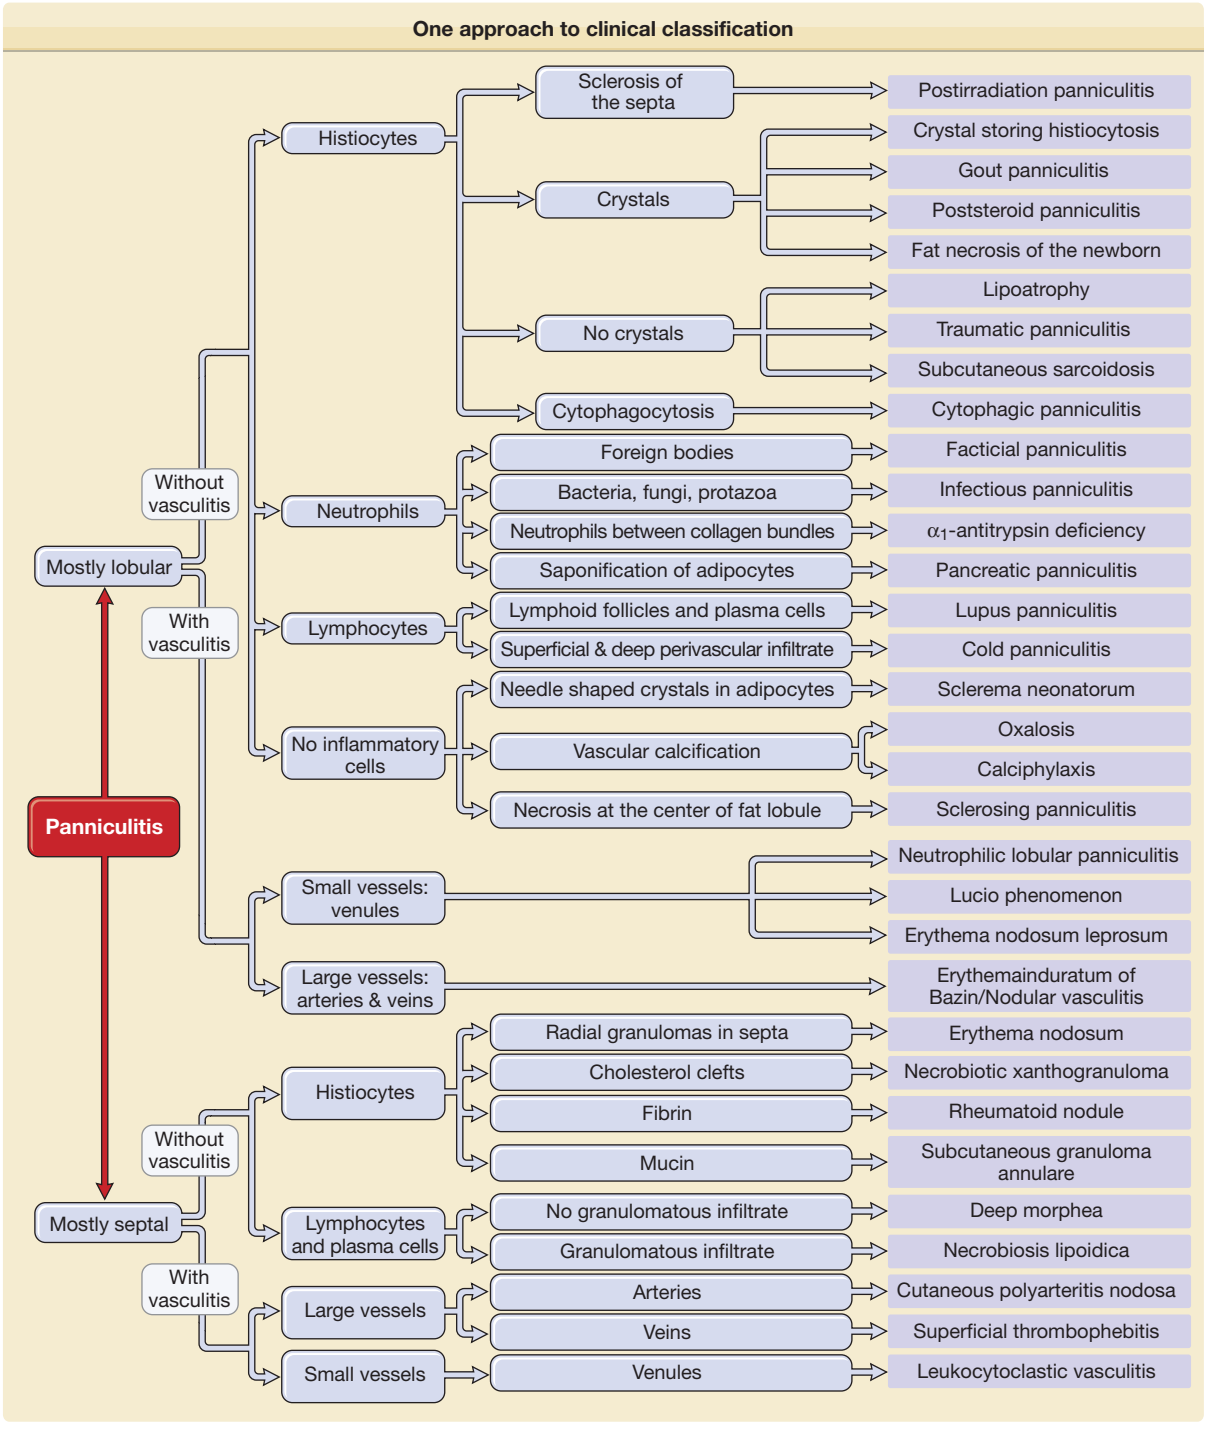

Figure 70-1 Approach to the patient with panniculitis.

the adipocyte in protecting the host from infectious disease and other environmental dangers. The complex interweaving of the adipocyte's role in such numerous and varied spheres may lead to complications should there be a genetic or acquired functional abnormality and/or molecular perturbations, and this may in some instances result in the inflammatory process known as panniculitis.

NODULAR LESIONS OF THE LEGS

Nodular lesions of the legs may represent EN, EI, nodular vasculitis (NV), cutaneous polyarteritis nodosa, or nodules related to vascular disorders. Diagnosis of these disorders often presents difficulties because their clinical manifestations as well as histopathological findings

may overlap. In order to diagnose lesions of the leg, one needs information on the typical as well as unusual manifestations of each disorder, the associated diseases and conditions, and the histopathological presentation.

ERYTHEMA NODOSUM

ERYTHEMA NODOSUM AT A GLANCE

Clinical

- Symmetric, tender, erythematous, warm nodules, and plaques on the anterior aspects of the lower extremities. May become confluent.
- Acute onset; no ulceration or scarring; more common in women.
- Fever, fatigue, arthralgias, arthritis, headache common.
- Lasts from 3–6 weeks, with new lesions appearing for up to 6 weeks.

Histopathology

- Mostly septal panniculitis without vasculitis.
- Thickened septa with inflammatory cells.
- Neutrophils in early lesions and histiocytes and Miescher granulomas in late-stage lesions.

Treatment

- Treatment of the associated disorder.
- Bed rest, aspirin, nonsteroidal anti-inflammatory drugs.
- Systemic corticosteroids are rarely indicated.

EPIDEMIOLOGY. EN may occur in both genders, at any age from childhood to 70 years of age, but is more common in young women in the second to fourth decades of life.[27] There is no gender difference in childhood cases. Prevalence varies from 2.4 per ten thousand population to 52 per million population, and in patient population from 0.38% to 0.5% of patients seen in clinics in Spain and England, respectively.[28,29]

ETIOLOGY AND PATHOGENESIS. EN is a panniculitis that has been reported in association with infections (bacteria, viruses, fungi, and protozoa), medications (antibiotics, oral contraceptives, halides), malignancies (most often leukemias or lymphomas), autoimmune diseases, and other inflammatory disorders, especially sarcoidosis and inflammatory bowel disease (see eTables 70-0.1 and 70-0.2 in online edition). Geographical variations in infectious etiology occur, but streptococcal upper respiratory infections are the most common infectious etiologic factors and the most common causes in childhood.[30] Tuberculosis was a common etiology in the past, and though less frequent now, must always be excluded. Half of all EN cases are idiopathic, without specific etiology, even though in many a viral cause may be suspected.[30]

EN is considered to be a hypersensitivity reaction to the various etiologic factors, but the pathophysiological mechanism of the disorder is not yet understood. Early studies have shown the presence of IFNγ and IL-2, activation of leukocytes, [31] and upregulation of various adhesion molecules,[32,33] and genetic polymorphism in TNF-α promoter, MIF (macrophage migration inhibitory factor), or RANTES (regulated upon activation, normal T-cell expressed, and secreted).[34–36] More recent information identifies AT as an immune organ and adipocytes as cells of the innate immune system, with primary responsibilities and capabilities of activating inflammatory systems and the adaptive immune system to destroy pathogens[37] (see Section "Introduction"). Historically, the primary function of the adipocyte was thought to be protective. However, excessive adipocyte production and secretion of multiple proinflammatory adipokines and adipocytokines is associated with obesity, cardiovascular disease, hypertension, and diabetes.[37] In contrast, the inflammatory reaction of EN is associated with a more limited coccidiomycosis infection[38] and with a less severe and shorter duration of sarcoidosis,[38] especially in those carrying the HLA-DRB1*03-positive leukocyte antigen,[39] which belongs to the "8.1 ancestral haplotype" genes associated with a wide range of immunopathologic diseases.[40] Therefore, it is possible that, especially in AT, certain genetic mutations associated with enhanced inflammatory reactions may confer resistance to certain pathogens, and this may explain the observation that EN, whether in association with coccidiomycosis or sarcoidosis, may be protective against disease dissemination.[38,39]

CLINICAL FEATURES. EN most commonly presents with an acute onset of tender, painful, erythematous, warm nodules and plaques on the anterior and at times the lateral aspect of both lower legs and ankles (Fig. 70-2). Other sites may also be involved, including forearms, thighs, and rarely the trunk or even the face, especially in children.[41,42] The nodules may persist a few days or weeks, may become confluent, and evolve from an erythematous or purple-like hue to a bruise-like pigmentation called erythema contusiforme if hemorrhage is present in the AT. The eruption usually lasts from 3 to 6 weeks, with new lesions appearing for up to 6 weeks, but it may persist longer and may recur.[42] The lesions do not ulcerate, and they resolve without atrophy or scarring.

Systemic symptoms such as fever, fatigue, malaise, arthralgia, arthritis, and headache are common. Abdominal pain, vomiting, diarrhea, and cough are less frequent.[30,42] Ocular manifestations may accompany the cutaneous lesions.[42] Tonsillitis/pharyngitis/upper respiratory infection (URI) preceded the onset in 20%–30% in two series[29,30] and prodromal symptoms may appear 1–3 weeks prior to lesional onset, at which time symptoms may become exacerbated.[43]

Figure 70-2 Erythema nodosum. Erythematous nodules located mainly on the anterior of the legs.

Laboratory abnormalities may include a high ESR, positive throat culture, or high ASO titer in those with a streptococcal etiology and leukocytosis. A positive PPD must be evaluated in the context of prevalence of tuberculosis in the geographical area. Chest X-ray will rule out pulmonary infectious or noninfectious disease (sarcoidosis), and serology or culture for various infectious diseases as well as other testing may be warranted in the appropriate setting (see eTables 70-0.1 and 70-0.2 in online edition).

HISTOPATHOLOGY. Histopathologically, EN is considered the prototype of septal panniculitis, although lobular inflammation may additionally be present. The composition of the inflammatory infiltrate varies according to lesional age, with the earliest lesions demonstrating septal edema, extravasated red blood cells, and scattered neutrophils. More fully developed lesions of EN show widening of the septa and early fibrosis, along with a septal infiltrate that includes lymphocytes, histiocytes, neutrophils, and eosinophils.[27,42,44] There may be extension of the infiltrate into adjacent fat lobules, but centrilobular necrosis of adipocytes is not seen.[27,41,42] Late-stage lesions show widened and fibrotic septa, often containing granulomas (Fig. 70-3A). The fibrosis and inflammation may encroach upon and partially efface fat lobules. Occasionally, predominantly polymorphonuclear cells may be present in typical EN,[45] but this is considered to be part of the early phase of inflammation.[27,41,42]

Miescher's granuloma, a discrete micronodular aggregate of small histiocytes around a central stellate cleft[27,42] (Fig. 70-3B), is considered characteristic of early EN by some, but is not universally found in EN,[41,44] and has been described in other types of panniculitis.[41] The picture of Miescher's granuloma also evolves, as in later-stage lesions, some aggregates of larger histiocytes and multinucleated giant cells retain a central cleft. An overlying superficial and deep perivascular dermal infiltrate is frequently present in EN.[41] Lipomembranous changes have been described in late stages of EN.[27,42] Although by definition, vasculitis is characteristically absent in EN, thrombophlebitis has been emphasized by some as a feature in early EN,[1] and medium vessel arteritis may rarely occur.[4]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis includes cellulitis, infection-induced panniculitis, acute lipodermatosclerosis (LDS), EI/NV, which tends to appear on the calves and ulcerate, other vasculitides which must be differentiated histopathologically, and pancreatic panniculitis, which may occur anywhere on the leg, ulcerate and drain, and which is accompanied by an increase in serum lipase and amylase.

TREATMENT. Treatment of EN primarily focuses on treatment or removal of the etiologic factor. Suspected medications should be discontinued, underlying infections sought and treated if possible, and associated

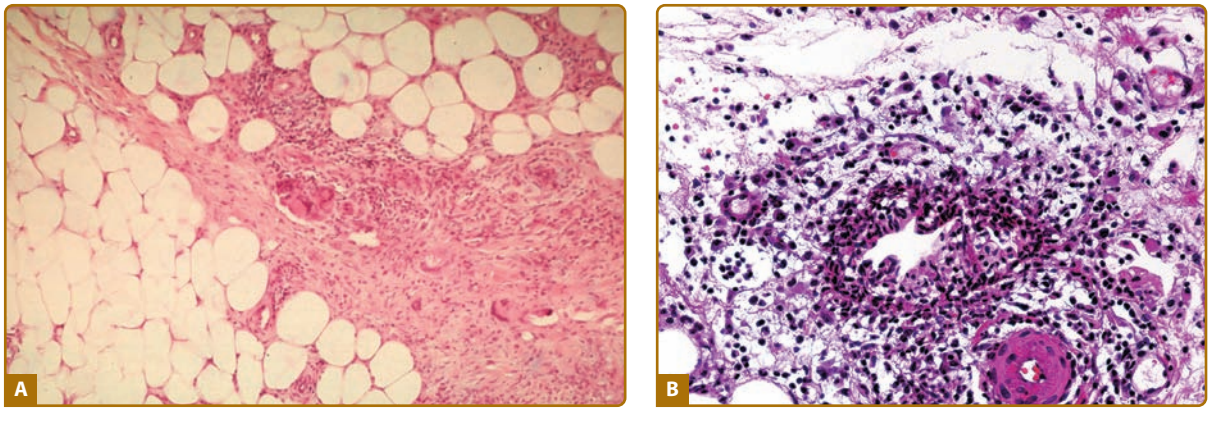

Figure 70-3 Erythema nodosum. **A.** Widened septa with inflammatory infiltrate including multinucleated giant cells. **B.** High magnification of a Miescher's granulomas shows a discrete micronodular aggregate of small histiocytes around a central stellate cleft.

inflammatory disorders or malignancies sought and appropriately treated. The disorder may persist for months before remission, and recurrence is possible, especially if the etiology is unknown.[46] Additional management options include bed rest and leg elevation, aspirin, nonsteroidal anti-inflammatory agents (avoided with IBD). Supersaturated potassium iodide solution (SSKI), 2–10 drops (1 drops = 0.03 mL = 30 mg) three times per day in water or orange juice has been useful, but individuals with thyroid disorders and on certain medications may be at risk for hypothyroidism and goiter as well as toxicity reactions of high potassium involving the heart and lungs.[47] SSKI is contraindicated in pregnancy. Other medications that have been used to treat EN include colchicine (especially for Behcet's disease),[48] corticosteroids (rarely used, especially since an underlying infection must be ruled out), etanercept,[49] and infliximab for IBD-associated EN.[50]

ERYTHEMA INDURATUM AND NODULAR VASCULITIS

EPIDEMIOLOGY AND CLINICAL FINDINGS.

EI is an inflammatory panniculitis, most commonly presenting with ulcerated nodules on the calves, and frequently associated with MTB infection. A similar disorder, without ulceration appearing in calves and other lower extremity sites was subsequently described without MTB association and was called NV. However, with patients presenting with different features in either the same flare or in preceding or subsequent flares, multiple studies have concluded that the clinical and pathological features of the two nodular leg syndromes are so similar that it is impossible to separate them.[51–54] Therefore, at this time the terms are most often used interchangeably. But some still prefer to use EI to denote the MTB-associated panniculitis, and NV for those without MTB association despite the otherwise identical features, to emphasize the need for antituberculosis therapy in the former cases.[55]

EI/NV is seen most commonly in young to middle-aged women, presenting as recurrent erythematous to violaceous nodules and deep plaques on the lower legs that may be tender, or only tender to pressure[52] (Fig. 70-4). Some lesions may heal without scarring, but often ulceration leads to scarring.[52] Surface changes include crusting of the ulcers and a surrounding collarette of scale (Fig. 70-5). The histology is shown in Fig. 70-6. The posterior leg calf region is the most frequent location, but lesions may also appear in the anterolateral areas of the legs, the feet, thighs, and rarely the arms and face.[51] EI lesions develop more frequently during winter, and EI is commonly associated with obesity and venous insufficiency of varying degree and manifestation.[52]

COURSE.

EI/NV can have a protracted course with recurrent episodes over years.[52,53] Patients with EI/NV are for the most part in fairly good health, except for the associated diseases, without the symptoms usually associated with EN. There has been one case report of membranous glomerulonephritis associated with EI/NV[72] and one case of painful peripheral neuropathy in an initially MTB skin test negative patient who was later found to have MTB-positive culture of cervical lymph node.[73]

TREATMENT.

In patients with positive MTB cultures, positive skin test or Quantiferon gold test for MTB, treatment with triple agent antituberculosis therapy is indicated. Patients with hepatitis B or C should

ERYTHEMA INDURATUM OF BAZIN/ NODULAR VASCULITIS AT A GLANCE

Clinical

- Erythematous subcutaneous nodules and plaques of lower legs; common on calves, but also on anterolateral legs, feet, and thighs; rarely elsewhere.
- Commonly associated with venous insufficiency; more frequent in middle-aged women.
- Often, ulceration and scarring, especially on the calves.
- Chronic course.
- Infectious etiology including bacterial [especially *Mycobacterium tuberculosis* (MTB)], fungal, protozoal, and viral should be sought.

Histopathology

- Mostly lobular or mixed lobular and septal panniculitis with vasculitis in 90%.
- Extensive necrosis of the adipocytes in the center of the fat lobule.
- Variable inflammatory infiltrate in the fat lobule: neutrophils in early lesions and epithelioid histiocytes and multinucleated giant cells in fully developed lesions.
- Vasculitis of the small veins and venules of the fat lobule.

Treatment

- With positive MTB microbiological, serological or Mantoux tests, or when MTB DNA is demonstrated: a full course of antituberculosis triple-agent therapy. If other infection proven or suspect: treat specific infection.
- In other cases: potassium iodide, other anti-inflammatory drugs, supporting bandages, support hose, leg elevation, bed rest.

Figure 70-4 Erythema induratum. Erythematous to brown and bluish nodules with ulceration on calves.

receive appropriate intervention for that disorder. Other infectious etiologies including fungi, parasites, and viruses should be sought and treated, if present. Medications that may have incited EI should be discontinued.

Anti-inflammatory treatments that have been used in EI/NV not associated with MBT include super saturated potassium iodide (SSKI), nonsteroidal anti-inflammatory agents (NSAIDS), colchicine, antimalarials, corticosteroids,[55] gold[74] as well as bed rest or leg elevation, and treatment of venous insufficiency with compression and pentoxifylline. Other treatments that have been used include tetracycline and mycophenolate mofetil.[75] If immunosuppressive agents are used, continued monitoring for possible infectious etiology is recommended.

LIPODERMATOSCLEROSIS

LDS (synonyms: sclerosing panniculitis, hypodermitis sclerodermiformis, chronic panniculitis with lipomembranous changes, sclerotic atrophic cellulitis, venous stasis panniculitis) is a form of sclerosing panniculitis involving the lower legs.

EPIDEMIOLOGY

LDS is the most common form of panniculitis, seen by clinicians far more frequently than EN, which has the next highest incidence. LDS occurs in association with venous insufficiency, mostly in overweight women over the age of 40.[76,77] In a review of 97 patients with LDS, 87% were female with a mean age at diagnosis of 62 years; 85% of patients were overweight (BMI >30); and 66% were obese (BMI >34).[78] Comorbidities included hypertension (41% of patients), thyroid disease (29%), diabetes mellitus (21%), prior history of lower extremity cellulitis (23%), deep vein thrombosis

Figure 70-5 **A.** and **B.** Erythema induratum with surrounding collarette of scale.

LIPODERMATOSCLEROSIS AT A GLANCE

Clinical

- Indurated plaques of wood-like consistency on the lower legs, acute and chronic changes, pain frequent.
- Chronic venous insufficiency, higher than normal BMI, female gender, arterial hypertension, arterial ischemia, episodes of thrombophlebitis.
- Pulmonary hypertension in patients with systemic sclerosis and sclerosing panniculitis.

Histopathology

- Background of stasis changes; mostly lobular panniculitis without vasculitis.
- Ischemic necrosis at the center of fat lobule.
- Thickened and fibrotic septa and atrophy of the subcutaneous fat, with marked fibrosis and sclerosis in late-stage severe cases.
- Frequent membranocystic changes.

Treatment

- Compression stockings, ultrasound therapy, pentoxifylline.
- Successful response to anabolic steroids in some cases.

(19%), psychiatric illness (13%), peripheral neuropathy (8%), and atherosclerosis obliterans (5%).[78] Due in part to its placement in the ICD9 classification under "Venous insufficiency with inflammation," and its designation by various medical names (see list of synonyms for LDS above), precise data for prevalence of LDS are not available. With increasing rates of obesity in the United States and the aging of the baby boomer generation, a corresponding increase in incidence and prevalence of LDS will likely follow.

ETIOLOGY AND PATHOGENESIS

Most patients with LDS are female and also have in common venous hypertension and a higher than normal BMI. Additional associated features that have been sought as pathogenetic factors in LDS include the following: elevated hydrostatic pressure-induced increased vascular permeability secondary to down-regulation of tight junctions[79,80] with extravascular diffusion of fibrin[78]; microthrombi[81]; abnormalities in protein S and protein C[82]; hypoxia[83]; damage to endothelial cells by inflammatory cells[84]; upregulation of intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), leukocyte function-associated antigen 1 (LFA-1), platelet- and endothelial-derived factors[85]; and inflammation with wound healing and local collagen stimulation leading to fibrosis and further vascular and lymphatic damage.[78] The fibrosis is accompanied by increased transforming growth factor-β 1 (TGF-β1) gene and protein expression[86] as well as an increase in procollagen type 1 gene expression.[87]

Hypoxia in AT induces chronic inflammation with macrophage infiltration and inflammatory cytokine expression.[88] The adipocyte plays a significant role in extracellular tissue remodeling. For this task, the adipocyte produces multiple matrix metalloproteinases (MMPs) as well as tissue inhibitors of metalloproteinases (TIMPs) and other tissue proteases needed during tissue remodeling,[89] all of which may significantly contribute to the tissue remodeling seen in LDS. Recent studies have linked expansion of AT (as seen in obesity) to resultant hypoxia, causing an increase in hypoxia-inducible factor 1α (HIF1α) expression.[90] This stimulates multiple extracellular factors, including

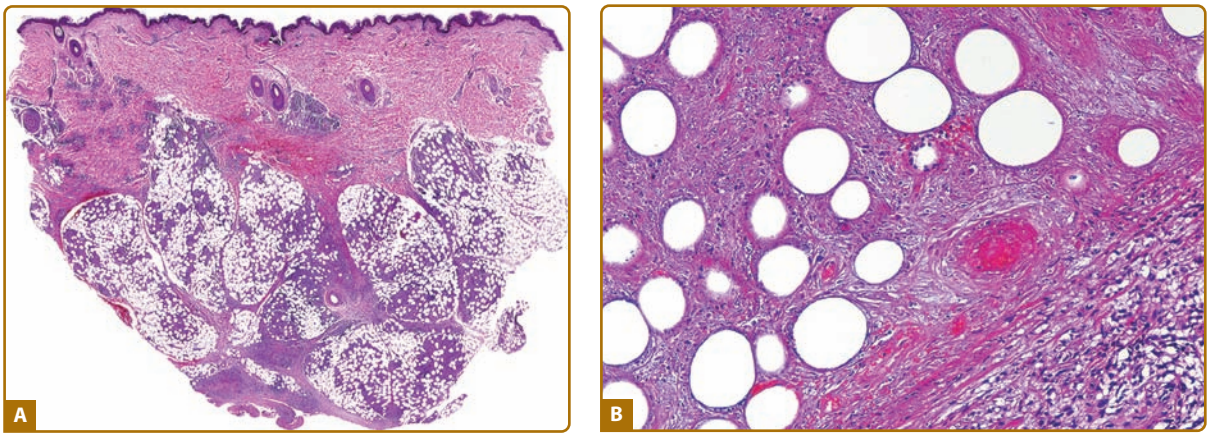

Figure 70-6 Erythema induratum-nodular vasculitis. **A.** Histopathology: scanning power shows a mostly lobular panniculitis. **B.** Higher magnification: extensive adipocyte necrosis and vascular damage-necrotizing vasculitis of small venules in the fat lobule.

collagen I and III, as well as other components involved in remodeling the extracellular matrix, leading to fibrosis as the end result.[91]

A theory regarding an infectious pathogenesis of LDS was advocated by Cantwell and colleagues, who reported the presence of unusual acid-fast bacteria that could not be grown in culture in biopsies of several patients with LDS.[92] This 1979 article dealt with the controversial issue of pleomorphic, nonrod-shaped, acid-fast bacteria being responsible for disease. It is widely accepted that other infections associated with repeated episodes of cellulitis cause lymphatic damage and subsequent changes in the AT.[77] Particularly in the light of more recent discoveries that adipocytes are cells of the innate immune system and possible reservoirs of infectious organisms of all types, the role of infection as a contributing factor to LDS should be reconsidered and explored, perhaps in an analogous manner to that of the process leading to evidence of MTB DNA and dormant MTB in AT of the legs in EI.[58,67]

CLINICAL FINDING'S

LDS has an acute inflammatory stage and a chronic fibrotic stage with a spectrum of intermediate[77] and overlapping presentations. In patients presenting with the acute form (Fig. 70-7A), very painful, poorly demarcated, cellulitis-like erythematous plaques to purple somewhat edematous indurated plaques or nodules are seen on the lower legs, most commonly on the lower anteromedial calf area.[77,93] Scaling may be present in some. The pain can be so intense that patients may not even tolerate a sheet while in bed. In this stage, patients are frequently diagnosed as having EN, cellulitis, or thrombophlebitis,[77,93] and compression may not be tolerated. The acute form may last a few months or even a year.[93] Although patients in this acute phase may present without obvious signs of venous disease,[77] vascular studies show venous insufficiency in the majority.[93] In the remaining group of LDS patients with normal venous studies, most have a high BMI, and given that obesity is usually associated with inactivity, these patients may not exert enough calf muscle contraction to maintain normal venous pressure in the lower extremities[78]; also, obesity is frequently associated with arterial hypertension.

The chronic form of LDS may or may not be preceded by a clinically obvious acute form.[77] Chronic LDS features indurated to sclerotic, depressed, hyperpigmented skin (Fig. 70-7B). These findings occur on the lower portion of the lower leg, predominantly but not limited to the medial aspect, or in a stocking distribution. This is described as having an "inverted champagne bottle" or a "bowling pin" appearance.[76,77,93]

Although some patients may not describe associated pain or tenderness,[93] pain is the most frequent symptom reported by others.[78] Most of the patients are obese or overweight and have hypertension and evidence of venous abnormalities, but only rarely obstruction.[78] Unilateral involvement is seen in 55%, localized plaque in 51%, and ulceration in 13% of cases[78] (Fig. 70-8). Dermatosclerosis in patients with systemic sclerosis has

Figure 70-7 Chronic lipodermatosclerosis (LDS). **A.** Sclerotic hyperpigmented skin on medial lower leg. **B.** Superimposed acute on chronic lipodermatosclerosis with ulceration.

Figure 70-8 Chronic lipodermatosclerosis with champagne bottle/bowling pin deformity.

been associated with pulmonary infarction and hypertension secondary to leg thrombi.[94]

Diagnostic tests to evaluate peripheral vascular disease should include ankle brachial index for arterial evaluation. Also indicated are venous tests: Dopplers to detect thrombi as well as color duplex sonography to detect direction of flow and presence of venous reflux.[93] If the clinical findings are characteristic, biopsy of LDS is usually discouraged, due to the high incidence of subsequent development of ulcers at the biopsy site.[77] But if necessary for diagnosis, a thin elliptical excision from the margin of an erythematous and indurated area, closed primarily with sutures, is recommended.[77]

DERMATOPATHOLOGY

Histopathologic findings reflect the evolution of the disease. Dermal stasis changes are present at any stage, and these include a variable degree of proliferation of capillaries and venules, small thick-walled blood vessels, extravasated erythrocytes, hemosiderin-laden macrophages, lymphohistiocytic inflammation, and fibrosis.[53,95]

In the subcutis, early lesions of LDS show a sparse infiltrate of lymphocytes in the septa, accompanied by central lobular ischemic fat necrosis; the latter is recognized by the presence of pale-staining, small anucleate adipocytes. Capillary congestion is also observed within fat lobules; this may be accompanied by endothelial cell necrosis, thrombosis, red cell extravasation, and hemosiderin deposition.[53,95] Septal fibrosis and small foci of lipomembranous fat necrosis and fat microcysts have also been described to occur in acute lesions.[95] In lipomembranous or membranocystic change, small pseudocystic spaces are formed within necrotic fat. The spaces are lined by a hyaline eosinophilic material believed to be the residue of disintegrated adipocytes and their interaction with macrophages.[96] This distinctive membranous lining is highlighted by periodic acid-Schiff (PAS) staining and may present an arabesque pattern, with intricate undulating papillary and crenulated projections into the cystic spaces. However, membranocystic changes are not exclusive to LDS and may be found in any type of panniculitis.[53,97]

With progression of LDS, the spectrum of histopathologic changes encompasses increasing degrees of membranocystic fat necrosis, septal fibrosis, and thickening; an inflammatory infiltrate comprising lymphocytes, histiocytes, and foamy macrophages; and partial to extensive atrophy of fat lobules.[53,77,95] Advanced lesions show septal sclerosis most prominently, with marked atrophy of fat lobules secondary to lipophagic fat necrosis, accompanied by microcystic and lipomembranous change and a marked reduction in inflammation.[53,95] The most severe LDS shows marked fibrosis and sclerosis in the AT layer with little inflammation.[77] In late stages, with fibrous thickening of the lower dermis and replacement of the subcutis by sclerosis, a punch biopsy of involved skin may not produce any subcutaneous fat.[98]

TREATMENT

Compression therapy is the major universally recommended treatment for LDS.[77,78] Higher compression gradient (30–40 mm Hg) may be more effective, but lower class compression (15–20 mm Hg or 20–30 mm Hg) may be associated with higher rate of compliance, especially in the elderly, and has been shown to be effective in decreasing edema.[99] One mechanism by which compression improves venous return and decreases edema is via tightening of vascular tight junctions, significantly elevating expression of tight junction proteins and inhibiting permeability of fluid into the perivascular tissue, thereby preventing progression of venous insufficiency.[79,80] Stockings must be worn all day and not removed until bedtime, since even a few days without compression may lead to recurrence of the edema and inflammation.[99]

Stanazolol has been shown to be effective in LDS, with decrease in pain, erythema, and induration.[77,100] Patients tolerated the treatment well, but potential side effects of this treatment include hepatotoxicity, and this may preclude its widespread use. In the United States, this drug is no longer distributed. Other anabolic steroids such as oxandrolone and danazol have also been used.[101,102] Pentoxifylline has been successfully used in LDS cases with and without associated ulceration. A Cochrane Database System review of 12 trials involving 864 patients in 2007 concluded the drug was a useful adjunct to compression for treating venous ulcers and may be effective in the absence of compression.[103] Other treatments for chronic venous insufficiency include horse chestnut seed extract,[104,105] oxerutin,[106,107] and flavonoid fraction.[108]

Ultrasound therapy was reported in two studies as being successful in reducing and even resolving hardness, tenderness, and erythema.[109,110] Readily available through physical therapy departments, it is a simple and safe treatment of a painful and refractory condition and may be used along with Grade-2 compression therapy.[109,110]

PREVENTION

Since being overweight and obese are common conditions among affected patients, efforts to reduce weight are prudent.

INFECTION-INDUCED PANNICULITIS

INFECTIOUS PANNICULITIS AT A GLANCE

Clinical

- Caused by wide variety of infectious agents, including bacteria, fungi, parasites, and viruses.
- AT may serve as reservoir for various infections.
- Due to primary inoculation or hematogenous spead; patients may be immunosuppressed.
- Erythematous plaques, nodules, abscesses, ulcers with purulent discharge.

Histopathology

- Suppurative granulomas within fat lobule.
- In primary cutaneous infections, epicenter of inflammation is superficial dermis; in secondary infections, epicenter is deep reticular dermis and subcutaneous fat.
- Special stains, cultures, and serologic studies necessary for detection of microorganisms.

Treatment

- Appropriate antimicrobial therapy selected according to susceptibility tests.

EPIDEMIOLOGY

Infection-induced panniculitis (Infectious panniculitis, infective panniculitis) is panniculitis directly caused by an infectious agent.[62] AT infection can be due to bacteria, mycobacteria, fungi, protozoa, and viruses.[53,62,111] Primary infections produced by direct inoculation at a wound site (injury, surgical procedure, catheter, injection, acupuncture) usually result in a single lesion which may enlarge and spread locally.[53,62,111] Secondary infections caused by sepsis and hematogenous spread may manifest as single or multiple lesions.[53,62,111] In immunosuppressed patients, microorganisms may be numerous and identified on routine histopathology or special stains. In immunocompetent patients, microorganisms may be sparse and not seen on either routine histopathology or special stains, requiring positive cultures or serological studies for identification.[53,62,111] Recent reports of infectious etiologies in association with various autoimmune disorders include *Staphylococcus aureus* panniculitis with juvenile dermatomyositis (DM),[112] *Mycobacterium*- and *Histoplasma*-associated panniculitis with rheumatoid arthritis,[113,114] and diffuse fusariosis with acute lymphobastic leukemia (ALL).[115]

CLINICAL FINDINGS

The clinical appearance of infectious panniculitis varies from fluctuant- or abscess-type lesions with purulent discharge and ulcerations to nonspecific erythematous firm nonfluctuant subcutaneous plaques and nodules, purpuric plaques, and EN-type lesions.[62,111,129] Deep nodules or plaques may not always appear fluctuant, and pustules, fluctuant papules, and ulcers can be superimposed on top of the nodules.[111] The most common sites of infection are the legs and feet, but upper extremities, trunk, and face may also be involved.[62,111] Immunosuppression of varying etiology is the most frequent, but not universal, association.[53,62,111] Immunosuppression is associated with more widespread abscess-type lesions containing nontuberculous mycobacteria, whereas in immunocompetent patients, granulomas are more commonly seen.[111,130] Fungal infections occur in the following clinical settings: (1) localized environmentally injected panniculitis of mycetoma, chromoblastomycosis, and sprorotrichosis; or (2) panniculitis associated with systemic disseminated fungal infection that may be seen in individuals with normal immune functions, or with opportunistic fungal infection seen in immune compromised individuals.[111,129] Clinical features vary with the setting, the infective organism and the underlying state of the individual's immunocompetence or immunosuppression.[111,129]

HISTOPATHOLOGY

Evaluation of panniculitis for infections should include histopathologic studies with special stains for all types of organisms as well as culture and sensitivity testing of biopsy material. In the immunosuppressed patient, microorganisms may be numerous and more readily identified, but in immunocompetent patients, microorganisms may not be seen on either routine histopathology or special stains, requiring positive cultures or serological studies for identification.[53,62,111] The anti-Bacille Calmette-Guérin (BCG) polyclonal antibody immunostain cross-reacts with many bacteria, mycobacteria, and fungi with minimal background staining and is advocated as a good screening tool for detection of microorganisms in paraffin-embedded tissue specimens when conventional stains are negative.[53,111,131] Molecular PCR techniques have been utilized with mycobacterium infections.[56–58,122] Histopathologic features may vary with the organism and its virulence, the host immune status, and the duration of the lesion at time of biopsy.[62] Classified by some as a mostly lobular panniculitis,[53] infection-induced panniculitis often presents a mixed septal and lobular pattern, and a predominantly septal, EN-like neutrophilic panniculitis has also been reported to occur in cases of bacterial as well as fungal etiology.[62] The superficial dermis is the

epicenter of inflammation in infections acquired by direct inoculation or by an indwelling catheter, in contrast to more deeply seated infections secondary to hematogenous spread involving the deep reticular dermis and subcutaneous fat.[53]

Generally, in a typical case, the subcutaneous fat contains a dense infiltrate of neutrophils and some admixed lymphocytes and macrophages, often with extension into the overlying dermis and with abscess formation a common finding.[62,111] Patterson et al additionally noted distinctive subcutaneous features in the majority of 15 reported cases of infection-induced panniculitis of bacterial, atypical mycobacterial and fungal origin, independent of the particular causative microorganism. These features included hemorrhage, vascular proliferation, foci of basophilic necrosis, and sweat gland necrosis. Overlying changes such as parakeratosis, acanthosis, and spongiosis were seen in all cases in which the epidermis was available for examination. All 15 cases also had dermal findings, most commonly upper dermal edema, a diffuse and perivascular inflammatory infiltrate, often with prominent neutrophils, proliferation of thick-walled vessels, and focal or diffuse hemorrhage.[62] With observation of any of these enumerated features, special stains for bacteria, mycobacteria, and fungi are imperative, and additional immunohistochemistry or PCR amplification techniques may be necessary.

Other histopathologic changes may point toward a more particular etiology. Suppurative granulomas formed by epithelioid histiocytes surrounding aggregated neutrophils may occur in panniculitis caused by atypical mycobacteria.[53] Caseating granulomas, though rarely seen, raise suspicion for tuberculous panniculitis.[111] A case of panniculitis secondary to CMV has been reported as a mostly septal panniculitis with many CMV inclusions contained within endothelial cells.[132]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis includes α_1-antitrypsin (α_1AT) panniculitis, pancreatic panniculitis, traumatic, and factitial panniculitis. It is important to recall that presence of one of the above diagnostic types of panniculitis does not exclude infection, as in the case of α_1AT panniculitis associated with lymph node histoplasmosis.[133]

TREATMENT

Treatment will vary and depend on the suspected or known organisms and their cultures and sensitivities. In cases involving bacteria such as MTB and parasites such as *T. cruzi*, their known capability to remain dormant in AT necessitates the use, for adequate treatment durations, of appropriate antibiotics, selected for their abilities to affect nonreplicating organisms.[67,121]

α_1-ANTITRYPSIN PANNICULITIS

α_1-ANTITRYPSIN-DEFICIENCY PANNICULITIS AT A GLANCE

Clinical

- ZZ-, MZ-, MS-, and SS-phenotype-associated panniculitis rare, with higher percentage (>60%) in ZZ cases; low levels of α_1-antitrypsin are associated with emphysema, hepatitis, cirrhosis, vasculitis, and angioedema.
- Subcutaneous nodules mostly located on the lower abdomen, buttocks, and proximal extremities.
- Frequent ulceration and isomorphic phenomenon.

Histopathology

- Mostly lobular panniculitis without vasculitis.
- Necrosis of fat lobules with a dense inflammatory infiltrate of neutrophils.
- Splaying of neutrophils between collagen bundles of deep reticular dermis.
- Large areas of normal fat adjacent to necrotic adipocytes.

Treatment

- Dapsone, doxycycline.
- Homozygous ZZ patients with severe forms of the disease: supplemental intravenous infusion of exogenous α_1-proteinase inhibitor concentrate or α_1-antitrypsin produced by genetic engineering; liver transplantation.

ETIOLOGY AND PATHOGENESIS

α_1AT is a glycoprotein that accounts for 90% of the total serum serine protease inhibitor capacity in humans.[134] It is produced and secreted mainly by hepatocytes, but also in small amounts by monocytes/macrophages and neutrophils,[135–137] and is known to inhibit trypsin, chymotrypsin, leukocyte elastase, kallikrein, collagenase, plasmin, and thrombin among other proteases.[134] α_1AT may also help regulate protease stimulated activation of lymphocytes, phagocytosis by macrophages and neutrophils, and complement activation.[138–141] It is an acute phase reactant, increased in times of stress.

α_1AT deficiency is inherited as a codominant disorder, and more than 100 alleles have been identified.[142,143] The α_1AT phenotypes are classified according to gel

Figure 70-9 α_1-Antitrypsin deficiency associated panniculitis. **A.** Fluctuant abscess type appearance. **B.** Discharge of oily material.

electrophoresis migration/mobility as F (fast), M (medium), S (slow), and Z (very slow), but null variants that do not produce any α_1AT and patients may have dysfunctional α_1AT with normal levels.[144] Homozygous MM, the most common phenotype, is associated with normal levels of α_1AT, whereas those homozygous for ZZ have low levels at 10%–15% of normal, and those heterozygous for S or Z allele have levels in between. MS heterozygous individuals may have low normal serum levels.[145] Due to the complex nature of these proteins, combination protein levels, or phenotyping and genotyping, have been recommended.[144] Estimated prevalence of α_1AT deficiency in Caucasians is 1 per 3,000–5,000 in the United States, with incidence in Caucasian newborns similar to that of cystic fibrosis.[144]

CLINICAL FINDINGS

α_1AT deficiency is most commonly associated with pulmonary and hepatic disease, leading to chronic obstructive pulmonary disease (COPD), hepatic cirrhosis, or hepatocellular carcinoma[144]; the ZZ genotype is at highest risk. There is no association of the null variant with hepatic disease, as it is the accumulation of polymerized α_1AT in the liver that induces damage, and accumulation does not occur in this variant.[144] The exact mechanism of injury is still controversial.[144]

Panniculitis uncommonly occurs in α_1AT deficiency. Less than 50 cases have been reported[146,147] in ZZ, MZ, MS, and SS phenotypes, with higher percentage (>60%) of ZZ cases as well as higher incidence in women (65%).[146] Presenting in an age range from childhood (infancy) to the elderly, panniculitis is most frequently seen between ages 30 and 60.[146,148] Patients present with painful erythematous nodules and plaques, but early lesions may have a cellulitic or fluctuant abscess-type appearance (Fig. 70-9A). Lesions may ulcerate and discharge an oily material or serosanguineous discharge[9] (Fig. 70-9B) and resolve with atrophic scars.[53] The lesions appear most commonly on the lower trunk (buttocks) (Fig. 70-10) and proximal extremities, but lower legs and other sites may be affected.[53,146,150] As trauma or excessive activity may precede the onset of lesions in a third of patients,[53,146] debridement is discouraged.[53] α_1AT panniculitis has occurred in patients with such conditions as hypothyroidism, mixed connective tissue disease, lymphoproliferative disorders, and infections, including a focus of histoplasmosis in a lymph node.[133,149] Therefore, the presence of α_1AT deficiency in association with panniculitis should not

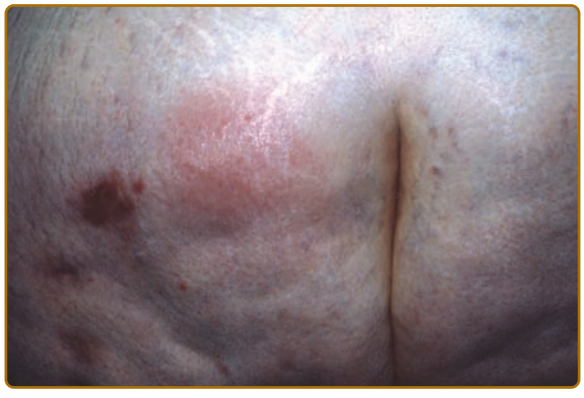

Figure 70-10 α_1-Antitrypsin deficiency associated panniculitis. Nodular lesion on the buttock.

preclude a search for infection or other underlying medical problems such as autoimmune disorders, malignancies, or infections, since they may coexist. Cutaneous and subcutaneous necrosis can develop rapidly. Extensive involvement with α_1AT panniculitis can be life threatening, and fatal cases have been reported.[148,151,152] Erythrophagocytosis was noted in the biopsy of one of the patients with fatal panniculitis.[153]

Possible mechanisms leading to the development of α_1AT panniculitis include lack of interference with the various proteases that lead to activation of lymphocytes, macrophages, complement, and lysis and destruction of connective tissue at sites of inflammation. Trauma to adipocytes may result in their activation, with release of the various adipokines and cytokines that are chemotactic to inflammatory cells, whose released proteases are unopposed due to absence of the α_1AT, leading to severe damage in involved tissue.[154,155] Animal models of soft tissue injury show elevated levels of IL-6 and MCP-1 and increased systemic inflammatory mediators.[154]

PATHOLOGY

Histopathologic findings vary with the age and type of lesion biopsied. Early in their development, nodular lesions may reveal edema and degeneration of adipocytes, with ruptured and collapsed cell membranes and a perivascular mononuclear infiltrate.[153] Also reported at this stage is a mild infiltrate of neutrophils and macrophages in septa and lobules, with foci of early necrosis of subcutaneous fat. This may be accompanied by splaying of neutrophils between collagen bundles throughout the overlying reticular dermis, considered an early and distinctive diagnostic clue.[156] More advanced lesions have masses of neutrophils and histiocytes associated with necrosis and replacement of fat lobules (Figs. 70-11A and 70-11B). A focal pattern of involvement is another distinguishing feature that may be appreciated, manifested by large areas of normal fat in immediate proximity to necrotic septa and fat lobules.[157] Liquefactive necrosis and dissolution of dermal collagen may be accompanied by ulceration, and degeneration of elastic tissue may lead to septal destruction and the appearance of "floating" necrotic fat lobules.[149,158] A rare occurrence is an exclusively septal pattern of mixed inflammatory infiltrate with a predominance of neutrophils.[146,158] Neutrophils and necrotic adipocytes are less prevalent in late stage lesions, with replacement by lymphocytes, foamy histiocytes, and variable amount of fibrosis within fat lobules.[149,159]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of α_1AT panniculitis includes other panniculitides that may ulcerate and drain such as the spectrum of infections, factitial disease, EI, and pancreatic panniculitis. Subcutaneous Sweet syndrome, rheumatoid arthritis, and myelodysplasia-associated neutrophilic panniculitis do not usually drain and ulcerate.[160,161]

TREATMENT

Many medications have been used in the treatment of α_1AT deficiency panniculitis including colchicine, antimalarials, steroids, immunosuppressive agents, cytotoxic agents, dapsone, doxycyline, plasma infusion and plasma exchange, intravenous α_1AT replacement therapy, and liver transplantation.[148,150,162–167] Steroids, immunosuppressives, and cytotoxic agents were the least successful treatment options. Doxycycline and especially dapsone were very helpful in mild to moderate cases, but severe panniculitis required A1P replacement therapy.[148,149,159,167] Panniculitis resolved with liver transplantation,[168] and panniculitis acquired after liver transplantation was successfully treated with retransplantation.[169]

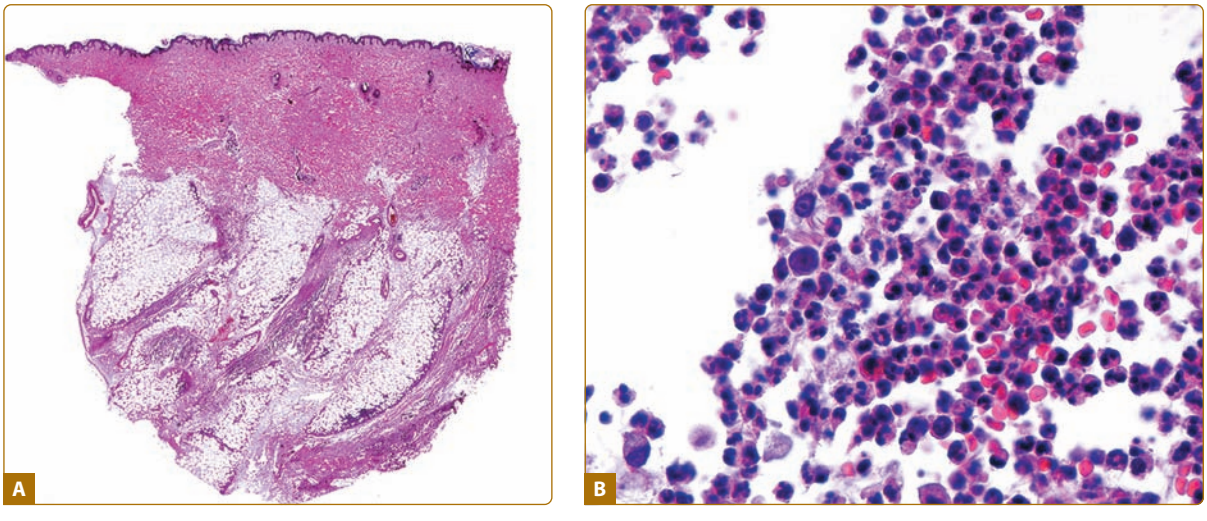

Figure 70-11 α_1-Antitrypsin panniculitis. **A.** Scanning power shows a mostly lobular panniculitis. **B.** Dense inflammatory infiltrate of neutrophils in the fat lobule.

PANCREATIC PANNICULITIS

PANCREATIC PANNICULITIS AT A GLANCE

Clinical

- Erythematous subcutaneous nodules that often ulcerate spontaneously.
- Lower extremities (around ankles and knees) are most frequent sites of involvement.
- Regression of pancreatitis-associated cutaneous lesions, but those associated with pancreatic carcinoma tend to persist; may be fatal.

Histopathology

- Mostly lobular panniculitis without vasculitis.
- Intense necrosis of adipocytes at center of fat lobule.
- Ghost adipocytes with finely granular and basophilic intracytoplasmic material.

Treatment

- Treatment of the underlying pancreatic disease, ocreotide, plasmapheresis.

EPIDEMIOLOGY

Panniculitis in association with pancreatic disease is a rare occurrence, developing in 2%–3% of all patients with pancreatic disorders and appearing in the setting of acute or chronic pancreatitis, pancreatic carcinoma, or pancreatic pseudocysts.[170–172] Although pancreatitis is most commonly due to alcohol abuse, cholelithiasis, or pancreatic calculi, medications and viral infections are also known etiologic factors.[173,174] The cutaneous panniculitis may precede the diagnosis of the associated pancreatic disease by weeks to months in up to 45% of patients.[170,173] Mono- or oligoarticular arthritis secondary to periarticular fat necrosis may be present in over half of patients.[170] This triad of pancreatic disease, panniculitis, and polyarthritis may occur with either pancreatitis or pancreatic carcinoma.[175] and is seen in less than 1% of pancreatitis patients[172]; joint disease may precede the diagnosis of pancreatic disorder.[175] Abdominal symptoms may be mild or absent.[175] Pancreatic panniculitis may also be seen in association with pancreatitis following renal or pancreas renal transplant,[176,177] with SLE,[178] and with hemophagocytic syndrome (HPS).[179] Panniculitis associated with pancreatic disease may be fatal,[170,172,180] with a mortality rate of up to 24% in one series[175] and mortality rates of 100% in those with pancreatic carcinoma and 42% of 19 patients with pancreatitis in another series.[181]

ETIOLOGY AND PATHOGENESIS

Pancreatic panniculitis has generally been attributed to release of pancreatic enzymes such as lipase, amylase, and trypsin into the circulation, promoting vascular permeability, leading to release of fatty acids from adipocytes and subsequent fat necrosis.[172,182] However, there are reports of normal serum levels of pancreatic enzymes in association with typical pancreatic panniculitis.[170] Additionally, incubation of normal AT with amylase and lipase and with pancreatitis patient serum high in those enzymes failed to induce fat necrosis in vitro,[183] leading to suggestions that other mechanisms may be involved in the development of pancreatic panniculitis. Since many of the lesions appear on lower legs, these mechanisms may include venous hypertension, but likely also involve adipocyte generated cytokines and adipokines related to effects of high levels of free fatty acids[170]; resistin and leptin have been shown to be potential markers of extrapancreatic fat necrosis.[184]

CLINICAL FINDINGS

The cutaneous lesions appear most frequently on the lower legs, especially the periarticular areas,[170] but are also found on the arms, thighs, and trunk.[170] Lesions often appear in crops, although single nodule pancreatic panniculitis also occurs.[185] The lesions are ill-defined erythematous to red–brown edematous tender nodules, which in mild cases may involute and resolve with atrophic hyperpigmented scars,[170] may have central "softer" areas or may become fluctuant, abscess-like, and drain oily material similar to lesions of α_1AT deficiency panniculitis (Fig. 70-12A).[170]

Extracutaneous manifestations include periarticular fat necrosis with concomitant arthritis,[170] painful medullary fat necrosis in bone,[172] and pleural effusions and serositis.[172,181] The presence of pleural effusions, alone or with arthritis, is associated with a high mortality rate.[181] Eosinophilia may be seen in both pancreatitis- and pancreatic malignancy-associated pannicultis,[181] and a pancreatic tumor in association with panniculitis, polyarthritis, and eosinophilia (Schmid's triad) imparts a poor prognosis.[186]

HISTOPATHOLOGY

Fully developed lesions of pancreatic panniculitis demonstrate lobular fat necrosis with distinctive qualities (Fig. 70-12B). Adipocytes lose their nuclei but maintain peripheral outlines, forming characteristic "ghost cells" (Fig. 70-12C). With saponification, calcification occurs, producing fine granular basophilic deposits within and around individual necrotic adipocytes. The ghost cells are frequently aggregated in small clusters at the center of fat lobules, with a peripheral inflammatory infiltrate of neutrophils.[53] In older lesions, necrosis and ghost cells are less evident, replaced by foamy histiocytes, multinucleated giant cells, lymphocytes, and eventually, fibrosis.[53,98] Of note,

Figure 70-12 Pancreatic panniculitis **A.** Clinical features: erythematous subcutaneous nodules that ulcerate and exude an oily material. **B.** Scanning power shows a mostly lobular panniculitis with adipocyte necrosis at the center of the fat lobule. **C.** Higher magnification shows ghost adipocytes, necrotic adipocytes without nuclei and with cytoplasmic fine granular basophilic material due to calcification.

pancreatic panniculitis has been reported to originate as a septal inflammatory process similar to EN in its earliest manifestation,[187] and findings mimicking pancreatic panniculitis have been documented at the site of subcutaneous interferon β injections in the course of treatment of multiple sclerosis.[188]

Treatment is supportive and directed at the underlying pancreatic disorder. Since patients may not have abdominal symptoms, pancreatic panniculitis should be considered in the differential diagnosis of any panniculitis. Resolution of the lesions occurs with specific surgical treatment appropriate to the underlying disorder.[173,175,189] Ocreotide, a somatostatin analog, and plasmapheresis have also been associated with resolution of pancreatic panniculitis.[190,191]

LUPUS PANNICULITIS [LUPUS ERYTHEMATOSUS PANNICULITIS (LEP), LUPUS PROFUNDUS, SUBCUTANEOUS LUPUS ERYTHEMATOSUS]

EPIDEMIOLOGY

Lupus erythematosus panniculitis (LEP) is a rare variant of lupus erythematosus (LE), which primarily affects the subcutaneous AT.[192,193] LEP may appear as the sole manifestation of LE or may occur prior to or

LUPUS PANNICULITIS AT A GLANCE

Clinical

- Erythematous nodules on face, shoulders, upper arms, scalp, chest, buttocks; rarely on lower extremities.
- Persistent areas of lipoatrophy in regressed lesions.

Histopathology

- Mostly lobular panniculitis without vasculitis (lymphocytic vasculitis occasionally).
- Lobular lymphocytic infiltrate, with plasma cells in many cases, eosinophils sometimes.
- Lymphoid follicles with germinal centers often.
- Sclerotic collagen bundles within septa.
- Hyaline necrosis and atrophy of entire fat lobule in late-stage lesions.
- Interface changes of discoid lupus erythematosus in 20%–30% of cases (changes at the dermal–epidermal interface may also rarely accompany subcutaneous panniculitis-like T-cell lymphoma).

Treatment

- Antimalarials, thalidomide.
- If active and severely inflamed, short oral courses of corticosteroids.
- Dapsone, cyclosporine, methotrexate, intravenous immunoglobulin, and rituximab.

after the onset of discoid lupus erythematosus (DLE) or systemic lupus erythematosus (SLE).[194,195] The incidence of SLE in patients with LEP has been reported to range from 10% to 41%, with the highest incidence seen in a Japanese series of 44 cases[193,195,196]; LEP occurs in only 1%–5% of patients with SLE.[192,193] Although rare, LEP occurs worldwide, more frequently among women than men, with a female to male ratio of about 4:1.[193,195,197] LEP is most common between the ages of 30 and 60, but may rarely be seen in childhood or even as neonatal lupus.[53,193,194,198] When present in association with SLE, LEP tends to occur in SLE cases of lesser severity.[195,197] There are a few case reports of LEP in more than one family member, or of family members with SLE unaccompanied by LEP.[192,193] Patients with LEP may also have other autoimmune disorders such as Sjögren's syndrome and rheumatoid arthritis.[192,193]

ETIOLOGY AND PATHOGENESIS

While a complete understanding of why LEP develops is still lacking, the innate immune system has been recently recognized to play a significant role in the development of SLE. Adipocytes are important cells of the innate immune system and function in pathogen recognition, activation of adaptive immunity, and as a reservoir for various microbes. All TLRs are expressed in AT. Adipocytes themselves express TLR1, 2, 3, 4, and 6, whereas TLR5, 7, 8, 9, and 10 are expressed on the nonadipocyte stromovascular fraction of AT.[199] The reasons for "lupus panniculitis" may vary from genetic polymorphism of TLRs leading to inappropriate activation of innate immune systems (especially of the type 1 interferon system),[200] to inappropriate interactions of adipocytes with inflammatory cells, to immune responsiveness against microbial and nonmicrobial antigens within AT. The localization of LEP to specific fat depots may be a clue to the functions of those adipocytes, or to a specific genetic aberration, or to the type of lymphocytes that are attracted to those AT depots.

In SLE, TLR7 and TLR9 recognize RNA and DNA patterns, respectively, and appear to provide a mechanism for recognition of self-DNA or self-RNA, with subsequent activation of the adaptive immune system and production of autoantibodies to nucleic acids and proteins bound to nucleic acids.[201–205] Inhibitors of TLR7 and TLR9 can prevent disease in mouse models of autoimmunity,[203] although deletion of TLR9 may enhance disease in some experimental models.[206] Both receptors have been suggested as therapeutic targets.[203,205,206] Genetic variations in TLR9 receptor has been shown to predispose to SLE in a Japanese series[207] and regression of SLE was seen in a patient who developed an acquired TLR7 and TLR9 defect and antibody deficiency.[208] SLE occurs much more commonly in women, and both TLR7 and TLR8 are encoded on the X chromosome, adding another layer of disease association.[209] In addition, hydroxychloroquine, the most common treatment for all variants of SLE and LEP, has been shown to block intracellular TLRs in vitro.[210]

CLINICAL FINDINGS

LEP lesions may be tender and painful and usually appear on the upper arms (lateral aspect), shoulders, face, scalp, hips, buttocks, breasts, and rarely on the lower extremities (Fig. 70-13).[193–195] Orbital/ocular involvement may present with periorbital edema.[211,212] The lesions are deep subcutaneous nodules without any surface changes, or with surface changes including erythema and DLE features such as atrophy, hyperkeratosis, hyper- or hypopigmentation, telangiectasia, follicular plugging, and focal ulceration and necrosis.[193,194] The shoulder and arm sites are frequently associated with surface DLE lesions.[193] Incidence of ulceration varies from <7% (of 44 Japanese cases).[195] to 28% of 40 US cases.[197] Individual lesions may enlarge

Figure 70-13 Lupus panniculitis. **A.** Atrophic upper arm lesion with superficial hyperpigmentation. **B.** With superimposed discoid lupus erythematosus and ulceration.

and/or coalesce to involve large areas with atrophy.[193] Areas of ongoing indurated panniculitis may coexist with DLE, subcutaneous atrophy, and bizarre scar formation.[193] LEP resolves with depressed lipoatrophic areas that may involve much of the upper arms, shoulder, or buttock.[193,194] Facial involvement may result in noticeably atrophic malar areas with severe cosmetic alterations. LEP is a chronic inflammatory disorder with yearly or periodic flares or long remissions.[193] Lesions may appear at sites of trauma, including injections and surgical sites.[193,194] Average disease duration is 6 years, with a range of less than 1 year to 38 years.[197]

Serological findings may be normal[194] or abnormal.[193,195] Patients without associated SLE may have low positive ANA titers and those with SLE tend to have higher positive titers.[195] C4 deficiency may be found.[194,213] Other laboratory findings in some patients may include rheumatoid factor, false positive Venereal Disease Research Laboratory (VDRL), specific ANAs, leucopenia, anemia, or thrombocytopenia.[193]

HISTOPATHOLOGY

Findings may vary, with features of DLE in about 20%–30% of cases. These features include vacuolar alteration of the basal cell layer, thickened basement membrane,[53,193,195] mucin deposition between dermal collagen bundles,[53,193,195] and a superficial and deep perivascular inflammatory infiltrate of lymphocytes.[53] Findings of basement membrane thickening or liquefaction degeneration and/or pigment incontinence may be noted in significant percentages of LEP patients without clinical epidermal changes.[195] The AT shows a mostly lobular or mixed lobular and septal panniculitis, with lymphocytes, often with formation of lymphoid follicles (some with germinal centers), variable hyaline fat necrosis,[53,195] hyalinized, and sclerotic septal collagen bundles associated with an interstitial infiltrate of lymphocytes and plasma cells[53]; occasional lymphocytic vasculitis in small blood vessels of fat lobules, presence of eosinophils in the inflammatory infiltrate in some cases,[53] and membranocystic changes in some late stage lesions.[53] Calcification and/or fibrin thrombi may also be noted in 10% of cases.[195]

In cases with only AT involvement and without other features specific for DLE or SLE, differentiation from subcutaneous T-cell lymphoma, although essential, can be very difficult. There are reports of a spectrum of subcutaneous lymphoid dyscrasias, with lesions originally diagnosed as LEP progressing to indeterminate lymphocytic lobular panniculitis and eventuating in a subsequent diagnosis of subcutaneous panniculitis-like T-cell lymphoma (SPTL).[214] There may also be epidermal involvement in SPTL,[215–217] making the distinction even more difficult; in two cases initially thought to be LEP, one with subcutaneous leg nodules demonstrating

biopsy changes of interface vacuolar alteration and mucin deposition,[218] and the other with vacuolar interface changes,[219] the final diagnosis was fatal SPTL. Multiple wedge biopsies may be necessary to differentiate the αβ TCR-SPTL (SPTL-AB) or the more ominous γδ TCR (SPTL-GD) subcutaneous lymphoma from benign LEP.[214,216,217] Hemophagocytocytic syndrome has been reported in SLE with panniculitis,[220] but is more common in patients with SPTL-AB and SPTL-GD.[216]

Direct immunofluorescence biopsies are very helpful in the diagnosis of LEP, with positive findings in almost all SLE-associated LEP, and a high percentage of positive findings in LEP alone.[193,195] Blood vessel deposition of immunoglobulins and complement varies.[193,195] In those cases in which the histopathology does not provide a specific diagnosis, immunofluorescence biopsies may demonstrate the essential features for diagnosis.[193]

Immunhistochemical studies of LEP show a predominance of lymphocytes, with both αβT helper ($CD4^+$) and cytotoxic ($CD8^+$) lymphocytes mixed with ($CD20^+$) B cells and plasma cells.[196]

Polyclonal findings are seen upon analysis of the TCR-γ gene,[196] although there are additional reports that LEP can also show clonality, respond to antimalarials or corticosteroids, and not progress to clinical lymphoma, suggesting that some cases of LEP may represent an abortive lymphoid dyscrasia.[221]

In one study of biopsies from six patients with active LEP, high levels of type I interferon marker MxA were found in the epidermis and infiltrate of inflamed LEP lesions, along with numerous $CD123^+$ cells with plasmacytoid morphology and expression of interferon inducible protein (IP10)/CXCL10. Sixty to ninety percent of the infiltrating cells in the lobular infiltrates comprised cytotoxic $CXCR3^+$ lymphocytes expressing granzyme B and Tia1, leading to the conclusion that a type 1 interferon-driven immune response was present in active LEP lesions.[222]

In addition to SPTL, the differential diagnosis of LEP includes panniculitis associated with DM or morphea, as well as other panniculitides that may occur in patients with SLE such as pancreatic panniculitis and EN.

TREATMENT

Treatment is challenging and difficult, and there are no easily verifiable assessment tools to judge response to therapy other than clinical assessment of erythema, induration, and tenderness.[223] Antimalarials are usually the first-line treatment for LEP[193,194,197,224] and may be the only medications needed.[193,224] When monotherapy with hydroxychloroquine is ineffective, combination with quinacrine has been used successfully.[194,225] Antimalarials have a lesser effect in smokers,[226–228] requiring at least 3 months to show effectiveness.[194] Antimalarials interfere with inflammatory cytokines[229] as well as TLRs.[210] The effect of cigarette smoking on antimalarial treatment in LE still needs to be better defined, since cigarette smoke may both attenuate and enhance different aspects of the immune system and, in the airways, is considered able to suppress innate immune response to infections.[230,231]

Corticosteroids are effective and useful if the disease is active and severe.[193,195,232] Corticosteroids may be used short term during the period of antimalarial initiation, but long-term use is generally avoided due to the chronic nature of LEP. Intralesional steroids are not recommended currently since they are traumatic and may induce atrophy. Other treatments include dapsone,[233] thalidomide,[223,234] cyclosporine,[235] methotrexate,[236] intravenous immunoglobulin (IVIG)[236] and rituximab.[237]

OTHER CONNECTIVE TISSUE DISEASE-ASSOCIATED PANNICULITIS

PANNICULITIS ASSOCIATED WITH DERMATOMYOSITIS AT A GLANCE

Clinical

- Erythematous painful nodules and plaques on the arms, buttocks, thighs, and abdomen.

Histopathology

- Mostly lobular or mixed septal and lobular panniculitis.
- Lobular lymphocytic and plasma cell infiltrate, hyaline sclerosis of septal collagen bundles, progressive fibrosis of fat lobules.
- Calcification in 25% of cases may have vacuolar alteration at dermal–epidermal junction; membranocystic change may be present in late-stage lesions.

Treatment

- Same as for dermatomyositis.

EPIDEMIOLOGY

Clinical signs of panniculitis in association with DM are very rare, despite histopathological findings of focal nonspecific panniculitis in 9% (5/55) of biopsy specimens from patients with Diabetes Mellitus (DM).[193,238] In a 2009 literature review of clinical panniculitis with nodular and plaque lesions in DM patients, 24 cases were identified, including six in children.[239]

CLINICAL FINDINGS

Panniculitis associated with DM presents as painful indurated erythematous nodules and plaques on the arms, buttocks, thighs, and abdomen; these may ulcerate and result in lipoatrophy.[240,241] The nodules and plaques usually present in association with the characteristic cutaneous manifestations of DM. They are rarely the sole manifestation.[53,242] Juvenile DM is also known to result in lipoatrophy without preceding clinical panniculitis lesions.

HISTOPATHOLOGY

Histopathological features are similar to those of lupus panniculitis,[53] consisting of a mostly lobular panniculitis, or mixed lobular and septal panniculitis, with lymphocytic and plasma cell infiltrates, hyaline sclerosis and fibrosis of septal collagen bundles, progressive replacement of the fat by fibrosis, and calcification in 25% of cases.[53,193,239] Lesions may be associated with vacuolar alteration of the dermal–epidermal junction, and late features may include membranocystic change.[53] Dermal findings include mucin deposition or edema with perivascular lymphocytic inflammation.[243]

DIFFERENTIAL DIAGNOSIS

The main differential diagnoses are cellulitis, infection-associated panniculitis, and lupus panniculitis, which can be distinguished by a combination of clinical, laboratory, and histological findings.

CLINICAL COURSE

The panniculitis may precede, occur with, or appear late in the disease course,[240] and subsides and flares with the overall DM activity.[244] Infection can cause worsening of the panniculitis. Three patients have had infection associated with the panniculitis, two with *S. aureus* [including an immunosuppressed adolescent with both methicillin-resistant *S. aureus* (MRSA) and *Acinetobacter baumanii*] and one with *Mycobacterium chelonae*.[239] Membranocystic changes indicated a worse prognosis.[239]

TREATMENT

As in therapy for DM, treatment for DM-associated panniculitis consists of corticosteroids alone,[239] or corticosteroids and methotrexate,[242,244] or other immunosuppressive therapies such as azathioprine, cyclosporine, or IVIG.[240] Response of panniculitis in juvenile DM to hydroxychloroquine has been variable.[245] Patients with cutaneous calcification may benefit from treatment with IVIG.[246] Infection should be aggressively sought and identified prior to increasing immunosuppressive therapy; concurrent infection may require antibiotic therapy and reduction in immunosuppression.[239]

Panniculitis may also occur in patients with morphea (see Chapter 64) or systemic sclerosis (see Chapter 157).

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

CYTOPHAGIC HISTIOCYTIC PANNICULITIS AT A GLANCE

Clinical findings

- Subcutaneous erythematous to violaceous plaques and nodules on extremities, trunk, less frequently elsewhere; lesions ulcerate.
- Fever, hepatosplenomegaly, two or more cytopenias; hemocytophagocytosis in bone marrow, lymph nodes, liver, or CNS.
- Hypertriglyceridemia, ferritin >500 mg/L; increased soluble CD25, CD163 levels.
- Low or absent NK cell activity, fibrinogen levels.
- Rapidly fatal disease course; intermittent remissions and exacerbations prior to death; or nonfatal acute or intermittent course.

Histopathological findings

- Mostly lobular panniculitis without vasculitis.
- Histiocytes and mature lymphocytes within fat lobules.
- "Bean-bag" cells: macrophages that contain intact or fragmented erythrocytes, leukocytes or platelets within their cytoplasm; may be focal, hard to find.
- Necrosis of adipocytes.

Treatment

- Immunosuppressive therapy: glucocorticosteroids, in combination with cyclosporine or etoposide, combined chemotherapeutic medications, anakinra; supportive care; search for associated malignancies and infections.

SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

EPIDEMIOLOGY

Subcutaneous fat necrosis of the newborn (SCFN) is a rare panniculitis that occurs in the first few weeks of

SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN AT A GLANCE

Clinical

- Circumscribed, red to violaceous, subcutaneous nodules, or plaques with predilection for buttocks, shoulders, cheeks, and thighs.
- Hypercalcemia in some cases, even presenting much later than acute episode; rarely, hypertriglyceridemia, hypoglycemia, thrombocytopenia, anemia.

Histopathology

- Mostly lobular panniculitis without vasculitis.
- Dense inflammatory infiltrate of lymphocytes, histiocytes, lipophages, and multinucleated giant cells.
- Needle-shaped clefts, often in radial array, within cytoplasm of histiocytes and multinucleated giant cells.

Treatment

- Nodules and plaques usually resolve spontaneously.
- Monitor for hypercalcemia for 6 months following onset, treat if hypercalcemia develops.

life. It presents in full-term newborns with a preceding history of perinatal problems, including meconium aspiration, asphyxia, hypothermia (e.g., for cardiac surgery or ice pack application for supraventricular tachycardia), hypoxemia, seizures, sepsis, preeclampsia, factors requiring cesarean section, forceps delivery, severe neonatal anemia, maternal cocaine use, and/or failure to thrive.[279–287] SCFN may be complicated by hypercalcemia, and rarely, by hypertriglyceridemia, hypoglycemia, thrombocytopenia, and anemia.[282–284]

ETIOLOGY AND PATHOGENESIS

The cause in not known, but hypothermia or hypoxia is presumed to be involved. Possible explanations have included a biochemical defect in the composition or metabolism of neonatal fat, leading to crystallization, fat necrosis, and subsequent inflammation after cold stress.[283,288] The hypercalcemia may be related to increased levels of 25-hydroxyvitamin D3–1α hydroxylase within the granulomatous infiltrate of lesions.[289] Another explanation takes into account the presence of BAT in neonates along with its main function, which is to rapidly convert fat stores to heat under conditions of cold stress.[290] BAT is widely distributed in the early years of life. At its maximal size relative to body weight at birth, when nonshivering heat generation is most needed, the presence and function of BAT relates to the immaturity of the heat regulating mechanism, providing the young with a "thermogenic jacket."[25,290] The BAT cells leak hydrogen ions across the inner membrane of the mitochondria to generate heat instead of creating ATP for other metabolic processes.[291] The mechanism is complex, and uses uncoupling protein isoform 1 (UCP1), found specifically in BAT, cytosolic fatty acids, and Ca^{2+} ions.[292]

CLINICAL FINDINGS

Lesions are sharply demarcated, erythematous to violaceous, firm, indurated nodules, or plaques located on the back, shoulders, arms, buttocks, thighs, or face, but usually not on the anterior trunk[279,283] (Fig. 70-15A). In one case, MRI findings consistent with fat necrosis were seen in the abdominal wall as well as in the fat surrounding the liver, spleen, and a kidney.[293] The subcutaneous nodules range in size from several millimeters to up to 11 cm in greatest dimension,[280,294] may be single or multiple, and may be of irregular shape, although usually well defined.[280] Rarely, fluctuant nodules may drain an oily or chalky white material.[294] Lesions are not warm to touch[280] and may vary from entirely painless[280] to those requiring morphine for control of pain.[284]

HISTOPATHOLOGY

Characteristically, SCFN is a mostly lobular panniculitis (Fig. 70-15B), with focal necrosis of the fat lobule and a dense inflammatory infiltrate of lymphocytes, histiocytes, and foreign body giant cells; a few eosinophils may insinuate between the fat cells. Many adipocytes retain their cellular outlines, but contain fine eosinophilic strands and granules as well as needle-shaped clefts in radial array[53,98,283,295] (Fig. 70-15C). On frozen section, these clefts are occupied by doubly refractile crystals, representing triglycerides. Similar clefts and crystals may also be seen within the cytoplasm of the multinucleated giant cells.[53,98,282,295] Late stage lesions may demonstrate fibrosis and calcified areas within fat lobules; the latter may also be seen radiographically.[53,280]

DIFFERENTIAL DIAGNOSIS

Differential diagnoses include cellulitis, erysipelas, and cold panniculitis (if cold-induced).[285,286] In contrast to SCFN, the histopathology of cold panniculitis does not feature the presence of needle-shaped clefts within the subcutaneous AT.[286] Other childhood panniculitides with the histologic finding of needle-shaped clefts in subcutaneous fat include sclerema neonatorum, which manifests with diffuse skin hardening in stressed infants,[296] and poststeroid

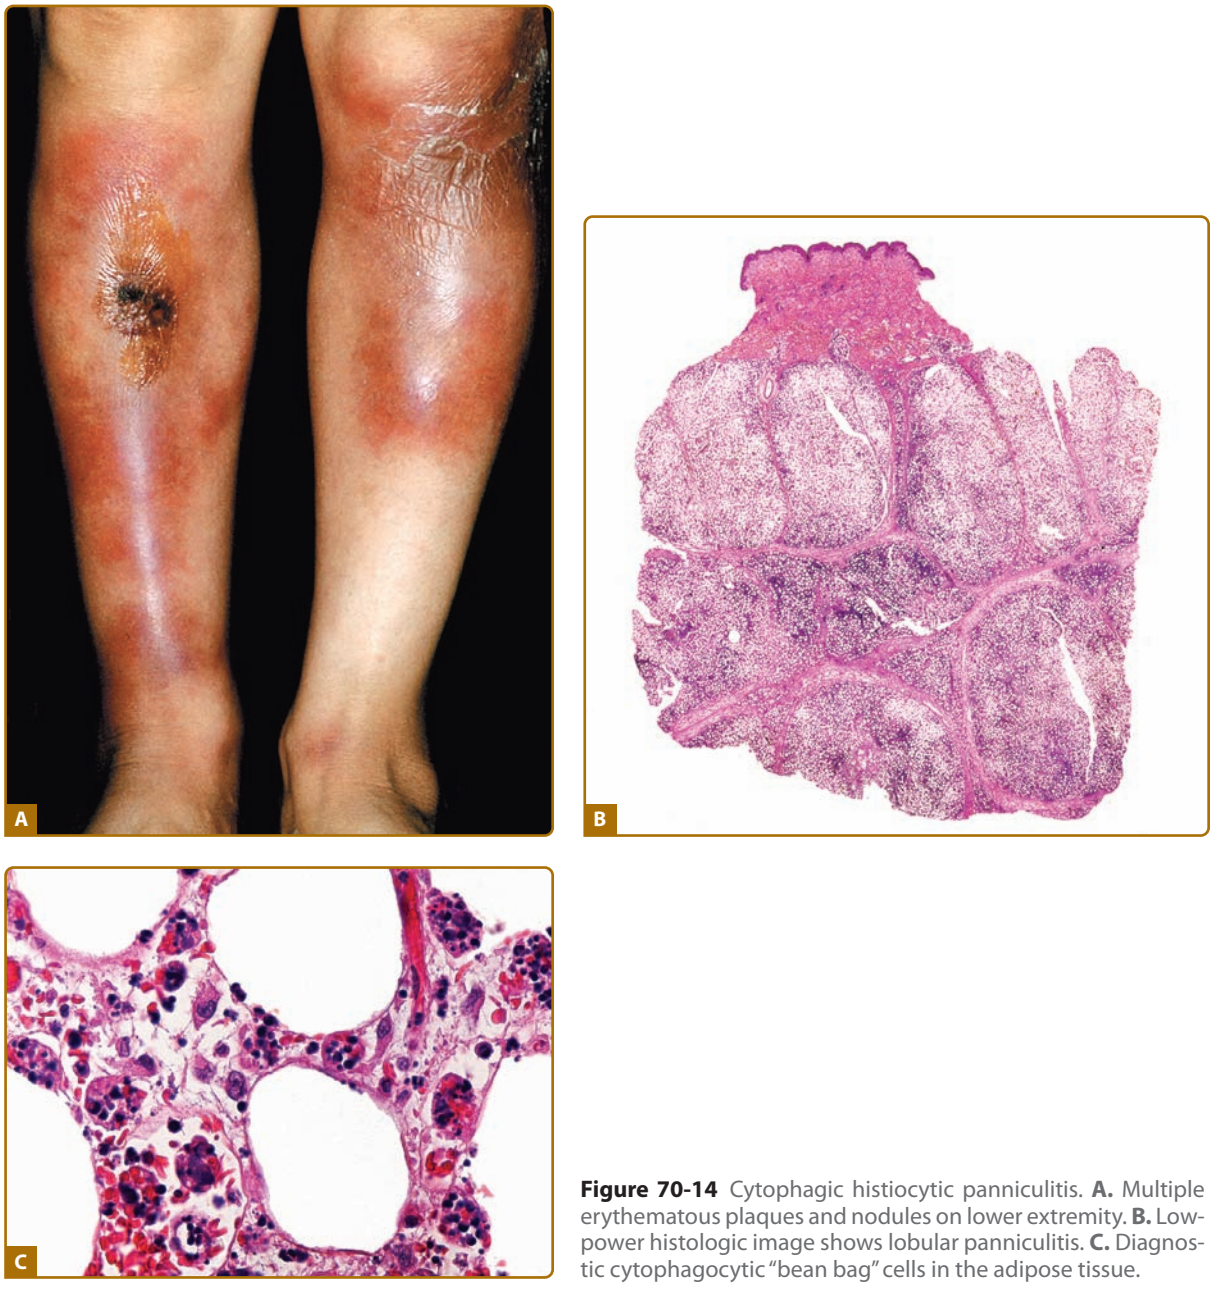

Figure 70-14 Cytophagic histiocytic panniculitis. **A.** Multiple erythematous plaques and nodules on lower extremity. **B.** Low-power histologic image shows lobular panniculitis. **C.** Diagnostic cytophagocytic "bean bag" cells in the adipose tissue.

panniculitis.[297–299] Only one infant with the clinical findings of both the diffuse hardening of the skin of sclerema and the violaceous nodules of SCFN has been described.[300] Poststeroid panniculitis occurs in children, usually within 10 days (range, 1–40 days) after rapid cessation of high-dose systemic corticosteroid therapy.[297,298]

CLINICAL COURSE

SCFN is usually a benign process with an uncomplicated course and excellent prognosis. Lesions regress in a few weeks to 6 months, with some eventuating in atrophy.[283,284,293] However, there are several metabolic complications that may occur during and even after resolution of the panniculitis.[283] These include hypercalcemia,[280,282,284,293,294] thrombocytopenia,[282,283] hypertriglyceridemia, which appears to be related to the fat necrosis[283,284] and anemia.[283] Hypercalcemia may be asymptomatic and uncomplicated,[281,284] or may become symptomatic, with failure to thrive, irritability, fever, vomiting, hypotonia, seizures, polyuria and polydypsia, and even death.[280,294] Soft tissue calcification may occur and resolve without evidence of hypercalcemia,[280] or calcium may deposit in the kidneys and cardiovascular system.[282–284] The hypercalcemia may have a delayed onset up to 6 months after appearance of the skin lesions; therefore, serial monitoring of serum calcium levels is necessary.[283,284]

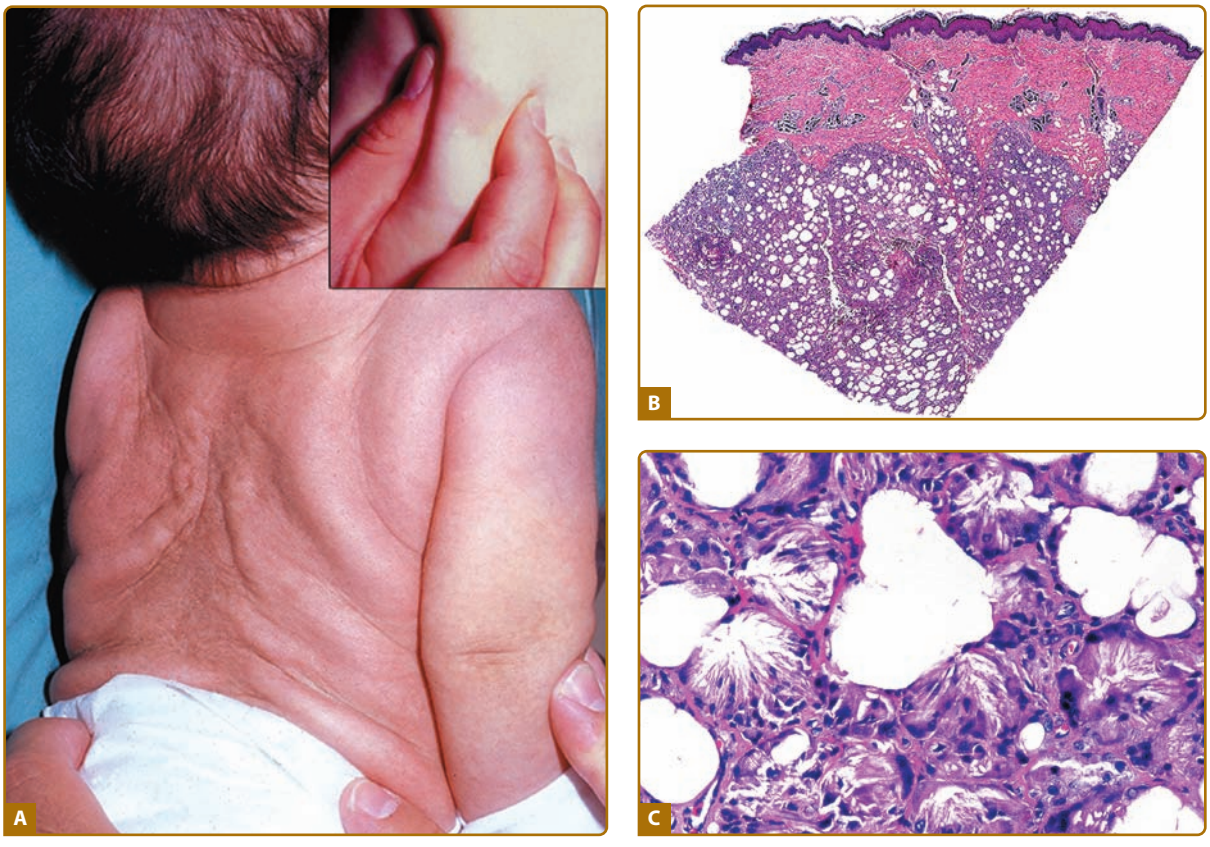

Figure 70-15 Subcutaneous fat necrosis of the newborn. **A.** Circumscribed indurated subcutaneous nodules on the back. **B.** Scanning power shows mostly lobular panniculitis. **C.** Higher magnification shows narrow needle-shaped clefts of adipocytes, histiocytes, and multinucleated giant cells.

TREATMENT

SCFN nodules resolve spontaneously, and treatment should be conservative in most cases, except for fluctuant lesions that may benefit from aspiration to prevent rupture, infections, necrosis, and scarring.[282,283] Serum calcium should be monitored with serial calcium determinations. If hypercalcemia is present, management by a pediatric endocrinologist will include hydration, use of the calcium wasting diuretic furosemide, and a low calcium and vitamin D diet.[283,294] The diuretics that increase calcium excretion may also induce dehydration, requiring careful monitoring. If these measures are insufficient to control hypercalcemia, systemic glucocorticoids are used, as they interfere with vitamin D metabolism and inhibit active vitamin D production by the macrophages in the inflamed AT[279,283,294]; however, nephrocalcinosis may still develop in spite of response to systemic steroids.[301] First and second generation bisphosphonates, including etidronate,[302,303] clodronate,[304] and pamidronate,[305] have been used to treat hypercalcemia in SCFN. However, nephrocalcinosis may develop, despite a rapid response to pamidronate.[306] The degree and duration of hypercalcemia and hypercalciuria may be the important factor in development of nephrocalcinosis; this calls for close early monitoring and recognition of hypercalcemia, since rapid therapeutic intervention to lower serum and urine calcium may be the best treatment modality for prevention of dystrophic calcification.[306]

COLD PANNICULITIS

COLD PANNICULITIS AT A GLANCE

Clinical

- Circumscribed, red to violaceous, subcutaneous nodules or plaques on the face and thighs, and rarely of the scrotal fat in prepubertal boys.
- Follows exposure to cold weather, popsicles, ice packs, and swimming in cold ocean water.

Histopathology

- Mostly lobular panniculitis (lymphohistiocytic or mixed infiltrate) without vasculitis.
- Perivascular lymphohistiocytic infiltrate involving blood vessels at dermosubcutaneous junction and within overlying dermis.
- Findings similar to those seen in perniosis.

Treatment

- Avoid direct ice placement on skin, mucous membranes.
- Spontaneous resolution within 3 months.

FACTITIAL PANNICULITIS

FACTITIAL PANNICULITIS AT A GLANCE

Clinical

- Erythematous nodules with disparate location or appearance in patients with personality aberrations.
- Subcutaneous implantation range from medications, cosmetic fillers, oils, food to human waste.

Histopathology

- Mostly lobular panniculitis without vasculitis.
- Suppurative granuloma involving the fat lobule; requires cultures for various organisms.
- Polarization of the slide may identify the refractile foreign material.
- Panniculitis morphology, such as histiocyte characteristic inclusions, or cystic spaces with foreign substances may vary with type of injected material.

Treatment

- Psychiatric treatment for self-inflicted factitial panniculitis.
- Supportive care and interference with injection of responsible agents.
- In panniculitis induced by cosmetic fillers, intralesional steroids, and often the implanted material must be surgically excised.

Factitial panniculitis is a reaction in AT induced by external factors, usually injection of foreign materials. This may be iatrogenic due to injection of medications or cosmetic fillers, or secondary to cupping and acupuncture,[320] or other means of trauma (accidental or deliberate). Factitial panniculitis is also associated with self-induced injections of various substances due to psychiatric disorder. History obtained from patients of injections of therapeutic agents or cosmetic fillers aids the diagnosis. Self-inflicted factitial panniculitis due to substances that may not necessarily leave a recognizable clinical or histopathologic footprint may be difficult to diagnose and requires a high index of suspicion.[53,320–322] Factitial lesions present a spectrum of clinical findings, from papules and nodules to erosions or ulcerations with perfect round or angulated appearance[322] (Fig. 70-16). Lesions due to blunt trauma will often be ecchymotic, show organized hematomas and hemosiderin deposits.[322] Injections of various oily substances will lead to foreign body reactions with foamy histiocytes and pseudocystic spaces.[53,322] Injection of medication and various other substances such as acids, milk, mustard, acids, alkalis, infected/contaminated materials, urine, and feces have been reported.[53,322] Early lesional histopathology is usually predominantly neutrophilic, and later may show a granulomatous infiltrate.[53,234] Due to the presence of macrophages and lymphocytes in AT, as well as the adipocyte's role as an innate immune cell producing multiple cytokines, materials injected into AT are treated as a foreign agent, with an inflammatory immune response with or without associated fat necrosis.[53,234] Patients with self-induced factitial panniculitis suffer from mental illness and require psychiatric care.[53,234] If iatrogenic, the causative action must cease. Surgical excision of the injected materials may be necessary.[320,322]

Chapter 71 :: Lipodystrophy

:: Abhimanyu Garg

LIPODYSTROPHY AT A GLANCE

- Lipodystrophies are genetic or acquired disorders characterized by selective loss of body fat. The extent of fat loss determines the severity of associated metabolic complications such as diabetes mellitus, hypertriglyceridemia, hepatic steatosis, and acanthosis nigricans.
- Four loci have been identified for the autosomal recessive congenital generalized lipodystrophy (CGL), namely, (1) *AGPAT2*, (2) *BSCL2*, (3) *CAV1*, and (4) *PTRF*.
- Four loci have been identified for autosomal dominant familial partial lipodystrophy (FPL), namely, (1) *LMNA*, (2) *PPARG*, (3) *AKT2*, and (4) *PLIN1*.
- *CIDEC* is the locus for autosomal recessive *FPL*, and *LMNA* and *ZMPSTE24* are loci for autosomal recessive mandibuloacral dysplasia-associated lipodystrophy.
- Molecular basis of many rare forms of genetic lipodystrophies remains to be elucidated.
- The most prevalent variety of lipodystrophy develops after prolonged duration of protease inhibitor containing highly active antiretroviral therapy in HIV-infected patients.
- The acquired generalized lipodystrophy and acquired partial lipodystrophy are mainly autoimmune in origin.
- Localized lipodystrophies occur due to drug or vaccine injections, pressure, panniculitis, and other unknown reasons.
- The current management includes cosmetic surgery and early identification and treatment of metabolic and other complications.

Lipodystrophies are a heterogeneous group of disorders characterized by selective loss of adipose tissue.[1] The extent of fat loss varies, with some patients losing fat from small areas (localized lipodystrophy), whereas others may have more extensive fat loss, for example, involving the extremities (partial lipodystrophy) or the entire body (generalized lipodystrophy). Depending upon the extent of fat loss, patients may be predisposed to develop complications associated with insulin resistance such as, diabetes mellitus, dyslipidemia, hepatic steatosis, acanthosis nigricans, polycystic ovarian disease, and coronary heart disease.[2,3] There are two main types of lipodystrophies: (1) genetic and (2) acquired. A detailed classification of various types of lipodystrophies is given in Table 71-1.

GENETIC LIPODYSTROPHIES

In the last decade or so, considerable progress has been made in elucidation of the molecular basis of many types of genetic lipodystrophies. In general, mutations in genes involved in adipocyte differentiation, triglyceride synthesis, lipid droplet formation, and adipocyte survival have been reported to cause lipodystrophies.

EPIDEMIOLOGY

Although the genetic lipodystrophies are rare, recent advances such as improved definition of the phenotypes and elucidation of the molecular defects, have led to increased recognition of these syndromes. Overall, based on literature reports of less than 1,000 patients, the estimated prevalence of genetic lipodystrophies may be less than 1 in a million. The autosomal recessive, congenital generalized lipodystrophy (CGL) has been reported in fewer than 300 patients, with clustering of patients reported from Lebanon and Brazil where there is increased prevalence of consanguinity. The autosomal dominant, familial partial lipodystrophy (FPL) of the Dunnigan variety due to *LMNA* mutations is the most common with ~500 patients being reported; autosomal dominant, FPL due to *PPARG* mutations with ~30 patients; autosomal

   c. Drug-induced
   d. Centrifugal
   e. Idiopathic

recessive, mandibuloacral dysplasia (MAD) due to *LMNA* mutations in ~30 patients and due to *ZMPSTE24* mutations in eight patients. Affected females are recognized easily and thus are reported more often than males.

CONGENITAL GENERALIZED LIPODYSTROPHY (CGL, BERARDINELLI–SEIP SYNDROME)

ETIOLOGY AND PATHOGENESIS. This autosomal recessive disorder can be recognized at birth or soon thereafter due to near total lack of body fat. Genome-wide linkage analysis with positional cloning strategy and candidate gene approach have led to the identification of four genetic loci for CGL: (1) 1-acylglycerol-3-phosphate-*O*-acyltransferase 2 (*AGPAT2*) gene on chromosome 9q34,[4,5] (2) Berardinelli–Seip congenital lipodystrophy 2 (*BSCL2*) gene on chromosome 11q13,[6] (3) caveolin 1 (*CAV1*) gene on chromosome 7q31,[7] and (4) polymerase I and transcript release factor (*PTRF*) on chromosome 17q21.[8] AGPAT2 is a critical enzyme involved in the biosynthesis of triglycerides and phospholipids from glycerol-3-phosphate and is expressed highly in the adipose tissue.[9] The *BSCL2*-encoded protein, seipin, plays a role in lipid droplet formation and may also be involved in adipocyte differentiation.[10–12] Caveolin 1 is an integral component of caveolae, specialized microdomains seen in abundance on adipocyte membranes. Caveolin 1 binds fatty acids and translocates them to lipid droplets. *PTRF* is involved in biogenesis of caveolae and regulates expression of caveolins 1 and 3.[8]

CLINICAL FINDINGS. Patients with CGL present with near total loss of body fat, marked muscularity, prominent subcutaneous veins, acromegaloid features, acanthosis nigricans, hepatomegaly, and umbilical prominence or hernia (Fig. 71-1A, Table 71-2). During childhood, they have a voracious appetite, and accelerated linear growth. Females usually have hirsutism, clitoromegaly, oligoamenorrhea, and polycystic ovaries. Only a few women have had successful pregnancies. Fertility is normal in men. Some of them develop hypertrophic cardiomyopathy, mild mental retardation, and focal lytic lesions in the appendicular bones after puberty.[13–15] Metabolic abnormalities related to insulin resistance, such as diabetes mellitus, hyperlipidemia, and hepatic steatosis, may manifest at a young age and are often difficult to control. Patients with *BSCL2* mutations lack mechanical fat located in the retro-orbital region, palm, sole, and in periarticular regions as well as metabolically active adipose tissue located in the subcutaneous (sc), intra-abdominal, intrathoracic, and other areas as compared to those with *AGPAT2*, *CAV1*, and *PTRF* mutations where mechanical fat is preserved.[7,16] The only reported patient with *CAV1* mutation also had short stature and presumed vitamin D resistance.[7] Only 21 patients with *PTRF* mutations have been reported and they have congenital myopathy, increased creatine kinase levels, percussion-induced myoedema, pyloric stenosis, cardiac rhythm disturbances including prolonged QT interval, exercise-induced ventricular tachycardia, and atlantoaxial instability.[8,17,18] Patients of Lebanese origin harbor homozygous c.659delGTATC mutation in *BSCL2*, whereas those of African origin nearly always have either homozygous or compound heterozygous c.IVS4–2A>G mutation in *AGPAT2* gene.[5,6,13]

Figure 71-1 Clinical features of patients with various types of lipodystrophies. **A.** Anterior view of a 33-year-old Hispanic female with congenital generalized lipodystrophy (also known as Berardinelli–Seip congenital lipodystrophy), type 1 due to homozygous c.IVS4–2A>G mutation in *AGPAT2* gene. The patient had generalized loss of sc fat with acanthosis nigricans in the axillae and neck. She has umbilical prominence and acromegaloid features (enlarged mandible, hands, and feet). **B.** Anterior view of a 27-year-old Native American Hispanic female with familial partial lipodystrophy of the Dunnigan variety due to heterozygous p.Arg482Trp mutation in *LMNA* gene. She had marked loss of sc fat from the limbs and anterior truncal region. The breasts were atrophic. She had increased sc fat deposits in the face, anterior neck, and vulvar regions. **C.** Anterior view of an 8-year-old German boy with acquired generalized lipodystrophy. He had severe generalized loss of sc fat with marked acanthosis nigricans in the neck, axillae, and groin. **D.** Anterior view of a 39-year-old Caucasian female with acquired partial lipodystrophy (Barraquer–Simons syndrome). She had marked loss of sc fat from the face, neck, upper extremities, and chest, but had lipodystrophy on localized regions on anterior thighs. She had increased sc fat deposition in the lower extremities. **E.** Lateral view of a 53-year-old Caucasian male infected with human immunodeficiency (HIV) virus with highly active antiretroviral therapy-induced lipodystrophy. He had marked loss of sc fat from the face and limbs, but had increased sc fat deposition in the neck region anteriorly and posteriorly showing buffalo hump. Abdomen was protuberant due to excess intra-abdominal fat. He had been on protease inhibitor-containing antiretroviral therapy for more than 8 years.

FAMILIAL PARTIAL LIPODYSTROPHY (FPL)

ETIOLOGY AND PATHOGENESIS. FPL is an autosomal dominant disorder characterized by fat loss from the limbs with variable fat loss from the trunk and increased sc fat deposition in nonlipodystrophic regions (Fig. 71-1B). It results from heterozygous missense mutations in one of the four genes: (1) lamin A/C (*LMNA*) on chromosome 1q21–22,[19–22] an integral component of nuclear lamina; (2) peroxisome proliferator-activated receptor γ (*PPARG*) on chromosome 3p25,[23–25] a key transcription factor involved in adipocyte differentiation; (3) v-AKT murine thymoma oncogene homolog 2 (*AKT2*) on chromosome 19q13,[26] involved in downstream insulin signaling; and (4) perilipin 1 (*PLIN1*) on chromosome 15q26, a key component of lipid droplets.[27] Adipocyte loss in patients with *LMNA* mutations may be due to disruption of nuclear envelope function and integrity resulting in premature cell death.

CLINICAL FINDINGS. Patients with FPL have normal body fat distribution during early childhood, but around the time of puberty, sc fat from the extremities and trunk is progressively lost (Fig. 71-1B). The face, neck, and intra-abdominal region are spared, and often excess fat accumulates there.[28,29] Affected men are often more difficult to diagnose clinically, as many normal men are also quite muscular. Women are more severely affected metabolically.[30] Some patients with mutations in amino-terminal region of lamin A/C also develop myopathy, cardiomyopathy, and conduction system abnormalities indicative of a multisystem dystrophy.[31] On the other hand, others with mutations in the extreme C-terminal region of lamin A may have mild lipodystrophy.[32]

TABLE 71-2
Clinical Features of Various Types of Congenital Generalized Lipodystrophy (CGL)

	Subtype of CGL			
Characteristic	**CGL1**	**CGL2**	**CGL3**	**CGL4**
Gene	*AGPAT2*	*BSCL2*	*CAV1*	*PTRF*
Loss of metabolically active adipose tissue	+++	+++	++	++
Loss of mechanical adipose tissue	–	+	–	–
Bone marrow fat	–	–	+	+
Lytic bone lesions	++	+	–	–
Mild mental retardation	–	+	–	–
Cardiomyopathy	–	+	–	+
Echocardiogram	Normal	Abnormal	Normal	Normal
Catecholaminergic polymorphic ventricular tachycardia (CPVT)	–	–	–	+
Prolonged QT interval	–	–	–	+
Sudden death	–	–	–	+
Congenital pyloric stenosis	–	–	–	+
Atlantoaxial instability	–	–	–	+
Acanthosis nigricans	+++	+++	++	+/–
Hepatomegaly	+	+	+	+
Congenital myopathy	–	–	–	+
Diabetes mellitus	+	+	+	–
Hypertriglyceridemia	+	+	+	+
Hypocalcemia	–	–	+	–
Hyperinsulinemia	+	+	+	+

Nearly 30 patients with FPL due to heterozygous mutations in *PPARG* gene have been reported so far. They have more marked fat loss from the extremities, especially from distal regions, but the fat from the face, neck, and truncal area is spared. There is increased prevalence of hypertension among the affected subjects. Four subjects from a single family with diabetes and insulin resistance were reported to harbor a heterozygous mutation in *AKT2* gene. The female proband had lipodystrophy of the limbs although detailed studies of body fat distribution were not performed. Recently, five FPL patients were reported to harbor *PLIN1* mutations.[27]

MANDIBULOACRAL DYSPLASIA (MAD) ASSOCIATED LIPODYSTROPHY

ETIOLOGY AND PATHOGENESIS. Mutations in *LMNA* and zinc metalloproteinase (*ZMPSTE24*) on chromosome 1p34 also result in autosomal recessive, MAD-associated lipodystrophies.[33,34] *ZMPSTE24* is involved in posttranslational proteolytic processing of prelamin A to mature lamin A and its deficiency can result in accumulation of prelamin A in cells which is supposed to cause toxicity.

CLINICAL FINDINGS. Patients with MAD have characteristic skeletal abnormalities including hypoplasia of the mandible and clavicles, acroosteolysis, cutaneous atrophy, progeroid features such as thin beaked nose, hair loss, thin skin with prominent superficial vasculature and mottled hyperpigmentation, delayed dentition and closure of cranial sutures, joint stiffness, and lipodystrophy.[35,36] Those with *ZMPSTE24* mutations develop clinical manifestations earlier in life, are premature at birth, and can develop focal segmental glomerulosclerosis and calcified skin nodules.[37,38]

OTHER TYPES

ETIOLOGY AND PATHOGENESIS. Recently, a single patient with autosomal recessive, FPL phenotype was found to harbor a homozygous missense mutation in cell death-inducing DNA fragmentation

factor a-like effector c (*CIDEC*) gene on chromosome 3p25, involved in lipid droplet formation.[39] The histopathology of the sc adipose tissue of the patient revealed multilocular, small lipid droplets in adipocytes. Heterozygous *LMNA* mutations can also cause variable amount of fat loss in patients with atypical progeroid syndrome[40] and generalized loss of sc fat in Hutchinson–Gilford progeria syndrome.[41] Another distinct autosomal recessive autoinflammatory lipodystrophy syndrome with a spectrum of disease manifestations (see JMP and CANDLE syndromes below) results from mutations in proteasome subunit, beta-type, 8 (*PSMB8*).[42,43,44a,44b] *PSMB8* encodes the β5i subunit of the immunoproteasome involved in proteolytic cleavage of immunogenic epitopes presented by major histocompatibility complex, class I molecules.[44c] The molecular genetic basis of many other genetic lipodystrophy syndromes remains unclear (Table 71-1).

CLINICAL FINDINGS. We recently reported a novel autosomal recessive syndrome with mandibular hypoplasia, deafness, progeroid features (MDP)-associated lipodystrophy.[45] All males with MDP had undescended testes and were hypogonadal. One adult female showed lack of breast development. The molecular basis of this syndrome remains unclear. *PSMB8* mutations present as a spectrum of clinical manifestations ranging from onset during the first months of life[46] to later during childhood.[47] Early features are recurrent fevers, annular violaceous plaques, poor weight and height gain, persistent violaceous eyelid swelling, hepatomegaly, arthralgias variable muscle atrophy, and progressive lipodystrophy.[46] Histopathologic examination of lesional skin shows atypical mononuclear infiltrates of myeloid lineage and mature neutrophils, and laboratory abnormalities include chronic anemia, elevated acute-phase reactants, and raised liver enzymes with a cytokine profile showing high levels of IP-1, MCP-1, IL-6, and IL-1Ra, consistent with an IFN signaling signature.[43] This presentation has been called CANDLE syndrome (Chronic Atypical Neutrophilic Dermatosis with Lipodystrophy and Elevated temperature).[46] Older individuals with *PSMB8* mutations show joint contractures, muscle atrophy, microcytic anemia, and panniculitis-induced (JMP) childhood-onset lipodystrophy.[47] Other features of JMP syndrome include hypergammaglobulinemia, elevated erythrocyte sedimentation rate, hepatosplenomegaly, and calcification of basal ganglia.[42,44a,44b,47] Other rare syndromes of lipodystrophy include SHORT syndrome, which is characterized by the constellation of *S*hort stature, *H*yperextensibility or inguinal hernia, *O*cular depression, *R*ieger anomaly, and *T*eething delay.[48,49] This syndrome is reported to have autosomal recessive as well as dominant inheritance patterns and fat loss is usually confined to the face, upper extremities, and trunk, and sometimes the buttocks.[48,49] The autosomal recessive, neonatal progeroid (Weidemann–Rautenstrauch) syndrome presents with generalized loss of body fat and muscle mass and progeroid appearance at birth.[50]

ACQUIRED LIPODYSTROPHIES

Despite recognition of acquired lipodystrophies for more than a century, progress in understanding underlying pathogenetic mechanisms has been slow.

EPIDEMIOLOGY

Acquired partial lipodystrophy was recognized approximately 125 years ago and only ~250 cases of various ethnicities with male-to-female ratio of 1:4 have been reported.[51] Acquired generalized lipodystrophy has been reported in less than 100 cases, mostly Caucasians with a male-to-female ratio of 1:3.[52] The most common type at present is highly active antiretroviral therapy [containing protease inhibitors (PIs)]-induced lipodystrophy in human immunodeficiency virus (HIV)-infected patients, which is estimated to be affecting more than 100,000 patients in the United States and many more in other countries.[53]

ACQUIRED PARTIAL LIPODYSTROPHY (APL, BARRAQUER–SIMONS SYNDROME)

ETIOLOGY AND PATHOGENESIS. The exact pathogenesis of sc fat loss remains unclear but there is strong evidence of autoimmune-mediated adipocyte loss as more than 80% of the patients have low levels of complement 3 (C3) and presence of a circulating immunoglobulin (Ig) G, C3-nephritic factor that blocks degradation of the enzyme C3 convertase.[51] Loss of fat could be due to C3-nephritic factor-induced lysis of adipocytes expressing factor D.[54]

CLINICAL FINDINGS. Acquired partial lipodystrophy develops in most patients before age 15. Patients lose sc fat gradually in a symmetric fashion starting with the face and then spreading downwards. Most of them present with fat loss from the face, neck, upper extremities, and trunk with sparing of sc abdominal fat and lower extremities (Fig. 71-1C). Approximately, 20% of the patients develop mesangiocapillary (membranoproliferative) glomerulonephritis, and some develop drusen.[51] Usually, patients do not develop metabolic complications.

ACQUIRED GENERALIZED LIPODYSTROPHY (AGL, LAWRENCE SYNDROME)

ETIOLOGY AND PATHOGENESIS. The exact mechanisms of fat loss are not known. In approximately 25% of patients, sc fat loss occurs following development of sc inflammatory nodules that on biopsy reveal panniculitis.[52] These lesions initially result in localized fat loss followed by generalized loss of fat. Another 25% of the patients have associated autoimmune diseases such as juvenile dermatomyositis.[52] In the

remaining patients with the idiopathic variety, multiple unknown mechanisms are likely involved.[52] Patients with the panniculitis-associated variety have less severe fat loss and metabolic complications than seen in other types.

CLINICAL FINDINGS. Acquired generalized lipodystrophies present with variable amount of sc fat loss usually during childhood. Although many patients have generalized loss of fat, some areas are spared in some of them (Fig. 71-1D). Usually, intra-abdominal or bone marrow fat is spared.[52] However, patients develop extremely severe hepatic steatosis and fibrosis, diabetes, and hypertriglyceridemia, which are difficult to manage.

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY (HAART)-INDUCED LIPODYSTROPHY IN HIV-INFECTED PATIENTS

ETIOLOGY AND PATHOGENESIS. Drugs such as HIV-1 PIs and nucleoside analogs are implicated in causing lipodystrophy in HIV-infected patients. Many, but not all, PIs may induce lipodystrophy by inhibiting ZMPSTE24, resulting in accumulation of prelamin A.[55] Other mechanisms may include PI-induced alteration of expression of key transcription factors involved in lipogenesis and adipocyte differentiation, such as, sterol regulatory element-binding protein 1c, and PPARG.[56] PIs also reduce glucose transporter 4 expression, which may be a mechanism for inducing insulin resistance.[57] Nucleoside analogs, especially zidovudine and stavudine, may induce fat loss by inhibiting polymerase-γ, a mitochondrial enzyme involved in replication of mitochondrial DNA.[58] Since most patients receive multiple antiretroviral drugs together, the individual effects of PIs or nucleoside reverse transcriptase inhibitors (NRTIs) on the phenotype are not clear.

CLINICAL FINDINGS. Patients infected with HIV usually lose sc fat from the face, trunk, and extremities 2 years or more after receiving PI-containing HAART (Fig. 71-1E; Figs. 71-2A and 71-2B). Fat loss from the face can be so severe as to result in an emaciated appearance. Some of them develop buffalo hump, double chin, and also gain intra-abdominal fat. The fat loss progressively gets worse with ongoing HAART therapy and does not reverse on discontinuation of PIs. Some cases develop diabetes mellitus and many develop combined hyperlipidemia that can predispose the patients to coronary heart disease.[59]

LOCALIZED LIPODYSTROPHY

ETIOLOGY AND PATHOGENESIS. This can occur due to sc injection of various drugs, panniculitis, pressure, and other mechanisms.[2]

CLINICAL FINDINGS. Localized lipodystrophies present with sc fat loss from a focal region resulting in a dimple or a crater with overlying skin usually unaffected. In some patients, large contiguous or anatomically distinct areas on any region of the body may be involved.[2]

APPROACH TO PATIENT ALGORITHM

Lipodystrophies should be strongly suspected in "lean or nonobese" patients who present with premature onset of diabetes, hypertriglyceridemia, hepatic steatosis, acanthosis nigricans, and polycystic ovarian syndrome. These patients should be examined carefully for evidence of loss of sc fat especially from the hips and thighs, as well as excess sc fat deposition in various anatomic regions. For those presenting with generalized lipodystrophy during childhood, pictures at birth should be evaluated for evidence of fat loss. If lipodystrophy phenotype is discovered at or shortly after birth, CGL should be considered; otherwise, the patient may have acquired lipodystrophy.

HISTORY

Patients should be asked about the age of onset and progression of lipodystrophy and other associated manifestations. Taking a detailed family history, including the history of consanguinity, is very important to understand the mode of inheritance of genetic lipodystrophies. Associated autoimmune diseases, especially juvenile dermatomyositis, should be considered in patients with acquired lipodystrophies. Those with localized lipodystrophies should be asked about local injections, trauma, pressure, or other insults. A detailed history of duration and type of antiretroviral therapy should be obtained from HIV-infected patients with lipodystrophy.

CUTANEOUS LESIONS

The most common cutaneous lesion seen in patients with lipodystrophies is acanthosis nigricans in the axillae, groins, neck, and sometimes even on the knuckles, Achilles tendons, and trunk (Figs. 71-3A and 71-3B). Many patients develop clitoromegaly and hirsutism due to associated polycystic ovarian syndrome. Freckles have been noted in a patient with atypical progeroid syndrome (Fig. 71-3C). Thin beaked nose with loss of the scalp, eyebrow, and axillary hair with cutaneous atrophy and mottled hyperpigmentation can be seen in patients with progeroid syndromes and MAD (Fig. 71-3D) along with acroosteolysis (Fig. 71-3E).[35,40,41] Rare patients with MAD develop shiny, taut, atrophic skin with a tendency to breakdown. Eruptive, tuberous, and planar xanthomas are also commonly seen in patients with extreme hypertriglyceridemia (Figs. 71-3F and 71-3G). Loss of sc fat from the soles can result in plantar calluses. Subcutaneous nodules with overlying erythema may be seen in patients with panniculitis.

Figure 71-2 **A.** Highly active antiretroviral therapy-induced lipodystrophy in a patient with human immunodeficiency virus (HIV) infection-associated lipodystrophy in a patient receiving highly active antiretroviral therapy. Loss of buccal fat results in prominence of the zygomatic arch **B.** Highly active antiretroviral therapy-induced lipodystrophy with loss of subcutaneous fat from the lateral buttock and deposit in the trunk, causing an increased waist–hip ratio.

LABORATORY TESTS

Laboratory testing depends upon the type of lipodystrophy. Except for patients with localized lipodystrophies, a serum chemistry profile for glucose, lipids, liver enzymes, and uric acid should be obtained. Measurement of fasting and postprandial serum glucose and insulin during an oral glucose tolerance test can provide some estimate of insulin resistance. Serum leptin measurements are not diagnostic, but can help guide treatment decisions as far as investigational human recombinant leptin replacement therapy is concerned. Serum leptin and adiponectin levels are very low in patients with generalized lipodystrophies.[60] Patients with acquired partial lipodystrophy should be tested for serum C3 and C3-nephritic factor and annually checked for proteinuria. Radiographs can show presence of lytic lesions in appendicular bones in patients with CGL and skeletal defects in those with MAD. Skin biopsy is useful for patients with localized lipodystrophy or panniculitis-associated varieties.

SPECIAL TESTS (INCLUDING IMAGING STUDIES)

Distinction between various types of lipodystrophies can be made by physical examination and supported by anthropometry, including measurement of skinfold thickness with calipers at various sites. For in-depth phenotyping of body fat distribution, dual energy X-ray absorptiometry, and a whole body T-1 weighted magnetic resonance imaging can be conducted. For those genetic lipodystrophies whose molecular basis is known, various commercial and research laboratories offer genetic testing. Prenatal genetic testing is also feasible. FPL patients and CGL, type 4 patients who are predisposed to cardiomyopathy should undergo electrocardiography and Holter monitoring to detect arrhythmias and echocardiography to assess cardiac function.

DIFFERENTIAL DIAGNOSIS

The most important differential diagnosis of generalized lipodystrophies is with conditions presenting with severe weight loss, such as, malnutrition, famine, starvation, anorexia nervosa, uncontrolled diabetes mellitus, thyrotoxicosis, adrenocortical insufficiency, cancer cachexia, HIV-associated wasting, diencephalic syndrome and chronic infections. For partial lipodystrophies, distinction should be made with Cushing syndrome, generalized and truncal obesity, and multiple symmetric lipomatosis (Madelung disease). Patients with MAD and progeroid syndromes-associated lipodystrophies should be differentiated from those with Werner syndrome and leprechaunism (Donahue syndrome).

Figure 71-3 Dermatologic manifestations seen in patients with lipodystrophies. **A.** Acanthosis nigricans (brownish discoloration with thickening of the skin) in the axilla and anterior neck in an 8-year-old Caucasian boy with acquired generalized lipodystrophy. **B.** Acanthosis nigricans in the perineum and medial parts of the proximal thighs in a 37-year-old female with familial partial lipodystrophy (FPL). Multiple, small skin tags accompany increased pigmentation and thick skin. **C.** Multiple, slightly hyperpigmented flat plaques (freckles) in a 7-year-old boy with atypical progeroid syndrome due to heterozygous p.Cys588Arg mutation in *LMNA* gene. **D.** Loss of hair from the posterior scalp region in a 5-year-old girl with severe mandibuloacral dysplasia (MAD) due to homozygous p.Arg527Cys mutation in *LMNA* gene. She had narrow shoulders due to clavicular hypoplasia. **E.** Acroosteolysis in a 20-year-old Hispanic woman with MAD due to homozygous p.Arg527His mutation in *LMNA* gene. The terminal digits appear short and bulbous due to resorption of the terminal phalanges. The skin on the dorsum of the hand is atrophic, especially over the proximal interphalangeal and metacarpophalangeal joints. **F.** Tuberous xanthomas over the middle finger of a 45-year-old Caucasian patient with severe hyperlipidemia associated with FPL of the Dunnigan variety due to heterozygous p.Arg482Gln mutation in *LMNA* gene. **G.** Planar xanthomas on the sole of the patient described in F. (Panel C reproduced with permission from Garg A et al: Atypical progeroid syndrome due to heterozygous missense *LMNA* mutations. *J Clin Endocrinol Metab* **94**:4971-4983, 2009. Copyright 2009, The Endocrine Society. Panel G reproduced with permission from Simha V, Garg A: Lipodystrophy: lessons in lipid and energy metabolism. *Current Opin Lipidol* **17**:162-169, 2006. Wolters Kluwer/Lippincott Williams & Wilkins.)

COMPLICATIONS

Some patients develop extreme hypertriglyceridemia and chylomicronemia, which result in acute pancreatitis and even death. Long-term complications of diabetes such as nephropathy, neuropathy, and retinopathy are frequently seen. Many patients develop coronary heart disease and other atherosclerotic vascular complications.[30,61] Hepatic steatosis can lead to cirrhosis, necessitating liver transplantation. Sudden death has been reported during childhood in CGL, type 4, likely due to arrhythmias.[17] Some patients with APL and membranoproliferative glomerulonephritis may require kidney transplantation.[51] Patients with Hutchinson–Gilford progeria syndrome die of acute myocardial infarction or cerebrovascular accidents during teenage years.[62] Some patients with atypical progeroid syndrome and FPL, Dunnigan develop cardiomyopathy with valvular dysfunction, congestive heart failure, and arrhythmias requiring pacemaker implantation.[31,40] Two adult patients with MAD due to *ZMPSTE24* mutations have died of renal failure due to focal segmental glomerulosclerosis.[37]

PROGNOSIS/CLINICAL COURSE

The prognosis is dependent upon the type of lipodystrophy. Most of the published cases of CGL have been children and thus there is lack of data about their prog-

nosis. In our experience, some have died of complications of acute pancreatitis, cirrhosis, or developed end-stage renal disease, requiring renal transplantation, and blindness due to diabetic retinopathy. Patients with FPL are also predisposed to metabolic complications and die of atherosclerotic vascular and coronary heart disease or cardiomyopathy and rhythm disturbances. Some patients with MAD have reportedly died during childhood and some died later in the 3rd and 4th decades of complications of renal failure.[37,63] Patients with AGL suffer severe metabolic complications. Patients with APL and membranoproliferative glomerulonephritis develop renal failure, but others have normal life span as do those with localized lipodystrophy. HIV-infected patients with lipodystrophy are predisposed to developing coronary heart disease.

TREATMENT

Treatment of various types of lipodystrophies is quite challenging. There is no specific treatment available to reverse the loss of body fat. The mainstay of treatment includes cosmetic surgery and management of complications. Patients with partial lipodystrophies can undergo autologous adipose tissue transplantation or implantation of dermal fillers such as hyaluronic acid, calcium hydroxylapatite, silicone, polyacrylamide gels, or poly-L-lactic acid.[64] Unwanted excess adipose tissue can be surgically excised or removed by liposuction. Those with CGL can undergo reconstructive facial surgery including fascial grafts from thighs, free flaps from anterolateral thigh, anterior abdomen, or temporalis muscle.[1] Support of the parents is critical for preventing unwanted stress and psychological sequelae in children affected with lipodystrophies.

All patients are advised to consume low-fat diets. These diets can improve chylomicronemia in patients with extreme hypertriglyceridemia. However, high carbohydrate intake may also raise very low-density lipoprotein triglyceride concentrations. Increased physical activity should be encouraged to mitigate insulin resistance and its complications except in those with FPL who have cardiomyopathy. Lytic bone lesions in appendicular bones in patients with CGL usually do not pose an increased risk of fractures.

There are no well-controlled trials available to guide treatment decisions about how to manage metabolic complications. For severe hypertriglyceridemia, an extremely low-fat diet along with fibrates and n-3 polyunsaturated fatty acids should be used. Statins can be added if required. Any form of estrogen therapy should be avoided, as it can pose the risk of severe hypertriglyceridemia-induced acute pancreatitis. Diabetes should be managed initially with metformin. Thiazolidinediones should be used with caution in patients with partial lipodystrophies as they can potentially increase unwanted fat deposition in nonlipodystrophic regions.[65] Although thiazolidinediones can be useful in FPL patients with *PPARG* mutations, the data on their efficacy are equivocal.[66] If hyperglycemia persists despite using various combinations of oral antidiabetic drugs, insulin therapy should be initiated. For those with extreme insulin resistance, U-500 insulin should be used. No specific therapy is available at this time for hepatic steatosis. Although, subcutaneous metreleptin replacement therapy has been shown to improve diabetes control, hepatic steatosis, and hypertriglyceridemia in markedly hypoleptinemic patients with generalized lipodystrophies,[67,68] its effects in patients with FPL so far have been equivocal.[69] Metreleptin therapy is investigational and not approved by the Food and Drug Administration of US. Switching PIs and NRTIs strongly associated with lipodystrophy to other regimen may improve dyslipidemia and insulin resistance in HIV-infected patients with lipodystrophy; however, loss of sc fat may not improve.[70]

PREVENTION

With the discovery of the molecular genetic basis of many types of inherited lipodystrophies, prenatal diagnosis can be offered for those families with an affected child. Premarital genetic counseling can be provided to those with high prevalence of consanguinity and CGL such as those from Lebanon and certain regions of Brazil. If the newer HAART regimen (not including PIs) are proven not to be associated with lipodystrophy and are deemed to be efficacious and safe, we may be able to prevent development of lipodystrophy in HIV-infected patients.

SECTION 11

Disorders of Melanocytes

Chapter 72 :: Biology of Melanocytes

:: Hee-Young Park & Mina Yaar

BIOLOGY OF MELANOCYTES AT A GLANCE

- Melanoblasts
  - derive from the neural crest. Their migration/survival in the epidermis is influenced by numerous factors.
- Melanocytes
  - populate the epidermis, hair follicle, eye, cochlea, and meninges.
  - synthesize melanin, an indole derivative of 3,4 di-hydroxy-phenylalanine (DOPA) that is stored in melanosomes.
  - are influenced by endocrine, paracrine, and autocrine factors and by ultraviolet (UV) irradiation.
- Melanosomes
  - display four maturation stages.
  - contain structural matrix proteins, melanogenic enzymes, pH-maintaining proteins, and free-radical scavengers.
  - are transported to melanocyte dendrite tips and transferred to epidermal keratinocytes.
  - in skin, absorb UV radiation and protect against photodamage.

EMBRYONIC DEVELOPMENT

Melanocytes are pigment-producing cells that originate from the dorsal portions of the closing neural tube in vertebrate embryos[1] (eFig. 72-0.1 in online edition). They derive from pluripotent neural crest cells that differentiate into numerous cell lineages including neurons, glia, smooth muscle, craniofacial bone, cartiledge, and melanocytes.[2,3] Progenitor melanoblasts migrate dorsolaterally between the mesodermal and ectodermal layers to reach their final destinations in the hair follicles and the skin as well as inner ear cochlea, choroids, ciliary body, and iris.[2,4] Pigment-producing cells can be found in fetal epidermis as early as the 50th day of gestation.

Melanoblast migration and differentiation into melanocytes are influenced by a number of signaling molecules produced by neighboring cells. These include Wnt, endothelin (ET)-3, bone morphogenetic proteins (BMPs), steel factor (SF) (stem cell factor, c-Kit ligand), and hepatocyte growth factor (HGF/scatter factor).[5–10] By interacting with their specific cell surface receptors, these molecules induce intracellular and intranuclear signaling to influence gene transcription and protein synthesis. Genetic defects in some of these molecules are associated with human genetic diseases: ETs (Waardenburg syndrome and Hirschsprung disease) and c-Kit and stell factor with piebaldism. Detailed discussion of each signaling molecule is available online.

SITE-SPECIFIC MELANOCYTES

MELANOCYTE STEM CELLS

Generally, stem cells are defined by their undifferentiated state and their capacity to develop into several differentiated cell types. They are quiescent, slow-cycling cells that frequently are found in niches where they are surrounded by differentiated cells that affect their behavior through the secretion of cytokines and growth factors.[29,30]

Melanocyte stem cells reside in the hair follicle bulge (Fig. 72-1). They express TRP-2 as well as the neural crest stem cell intermediate filament nestin in addition to other neural crest stem cell markers including the transcription factors Sox10 and Pax5 that participate in the regulation of microphthalmia-associated transcription factor (MITF) and TRP-2. Melanocyte stem cells can leave the bulge region and migrate/differentiate in the epidermis or the hair follicle.

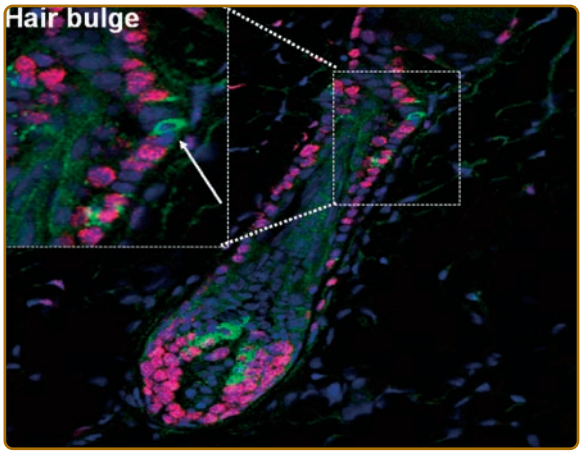

Figure 72-1 Melanocyte stem cells in the hair follicle bulge. A stem cell melanocyte is shown in the hair follicle bulge, indicated by an *arrow* in the high-power insert. These cells stain positive for TRP-2 (*green fluorescence*), an early marker of commitment to the melanocyte lineage, but are negative for the proliferation marker Ki-67 (*red fluorescence*) that characterizes melanocytes migrating down the follicle to the dermal papilla during the anagen phase of the hair cycle. (From Botchkareva NV et al: SCF/c-kit signaling is required for cyclic regeneration of the hair pigmentation unit. *FASEB J* **15**:645, 2001, with permission.)

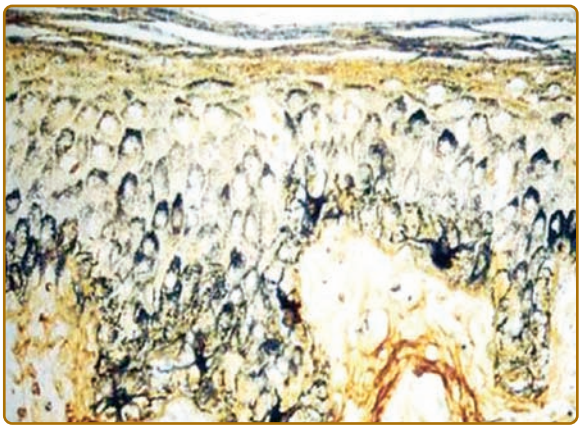

Figure 72-2 Melanosomes are organized into supranuclear "caps" within keratinocytes. Note melanized dendritic melanocytes and adjacent keratinocytes with the supranuclear "caps." (From Byers HR et al: Role of cytoplasmic dynein in perinuclear aggregation of phagocytosed melanosomes and supranuclear melanin cap formation in human keratinocytes. *J Invest Dermatol* **121**:813, 2003, with permission.)

CUTANEOUS MELANOCYTES

The largest number of melanocytes are present in the skin and hair follicles. While in most furred mammals melanocytes are found only in the hair follicle, in humans, melanocytes are also present in interfollicular epidermis, specifically in the basal layer.[28] There is approximately one melanocyte per five or six basal keratinocytes. Melanocytes synthesize melanin, a pigmented polymer that is stored in cytosolic organelles called melanosomes that are transferred to keratinocytes through melanocyte dendritic processes (Fig. 72-2). As keratinocytes are continuously being desquamated, there is a constant need for synthesis and transfer of melanosomes from melanocytes to keratinocytes in order to maintain cutaneous pigmentation.

The term "epidermal melanin unit" describes a single epidermal melanocyte surrounded by several epidermal keratinocytes[31] (Fig. 72-3). Interestingly, signals from keratinocytes substantially regulate epidermal melanocyte survival, dendricity, melanogenesis and the expression of cell surface receptors[32] (see below). Most keratinocyte-derived signals are induced by ultraviolet (UV) irradiation.

Melanocyte density/mm^2 ranges from approximately 550 to >1,200 with the highest concentrations found in the genitalia and face.[33,34] Melanocyte density is the same in individuals of different racial backgrounds,[34] and thus cutaneous pigmentation does not depend on melanocyte number, but rather upon melanogenic activity within the melanocyte, the proportion of mature melanosomes, and/or their transfer and distribution within the keratinocytes.[35] Indeed, in light-skinned individuals, melanosomes are smaller and are present in clusters within the keratinocytes, while in ethnic groups with darker complexion, melanosomes are larger, darker, and are individually dispersed within the keratinocytes.[36]

HAIR FOLLICLE MELANOCYTES

In contrast with interfollicular epidermal melanocytes, the follicular melanin unit undergoes cyclic modifications in coordination with the hair cycle (Fig. 72-4). Melanocytes are located in the proximal hair bulb during anagen and there is a ratio of 1:5 between melanocytes and keratinocytes and 1:1 between melanocytes and basal layer keratinocytes.[37] Melanocytes proliferate, migrate, and undergo maturation during early to mid anagen. Melanogenesis and melanin transfer to keratinocytes occurs throughout anagen. Melanocytes eventually apoptose during late catagen. In mice, melanocyte proliferation and differentiation during anagen depends on c-Kit expression by melanocytes and SF synthesis by keratinocytes.[38]

Similar to their role in the epidermis, in hair, melanocytes transfer melanin to differentiated keratinocytes that ultimately form the hair shaft. They thus determine hair color by the amount of melanin transferred, as well as by the ratio of eumelanin (black–brown) to pheomelanin (red–yellow) (see below).[39]

In hair, melanin does not appear to have a protective effect, since UV irradiation does not reach the hair follicle. Still, in furry animals hair color plays an important role in camouflage, mimicry, and social communication.[40] It is also speculated that melanocytes restrain keratinocyte proliferation, affect calcium homeostasis, and protect against reactive oxygen species (ROS) during the rapid proliferation and differentiation of the hair follicle.[37]

MELANIZATION

The major differentiated function of melanocytes is to synthesize melanin in specialized organelles within the melanocytes, the melanosomes, and to transfer melanosomes to neighboring keratinocytes in order to provide protection from UV irradiation (Fig. 72-5). Melanogenesis, the synthesis and distribution of melanin in the epidermis, involves several steps: transcription of proteins required for melanogenesis; melanosome biogenesis; sorting of melanogenic proteins into the melanosomes; transport of melanosomes to the tips of melanocyte dendrites and transfer of melanosomes to keratinocytes. Disruption in any of these events results in hypopigmentation.

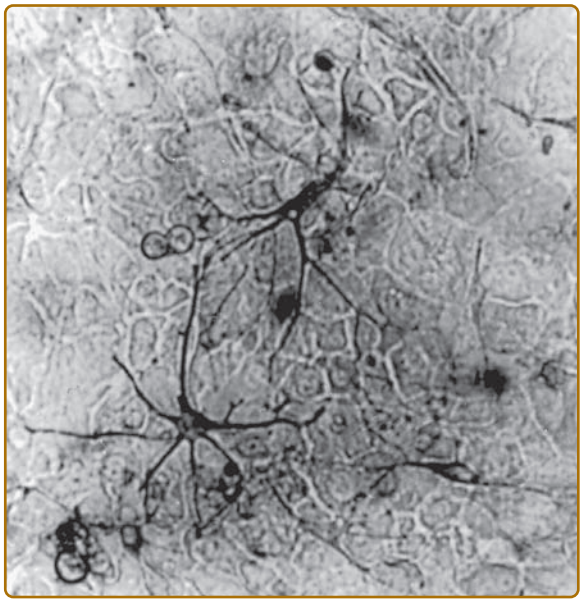

Figure 72-5 Melanocytes cultured on keratinocytes. Light micrograph showing dendritic melanocytes from a black donor loaded with melanin and adjacent pigmented keratinocytes due to transfer of melanosomes.

MELANOSOMES

MELANOSOME BIOGENESIS

The melanosome is a unique membrane-bound organelle in which melanin biosynthesis takes place. Because melanosomes contain enzymes and other proteins also

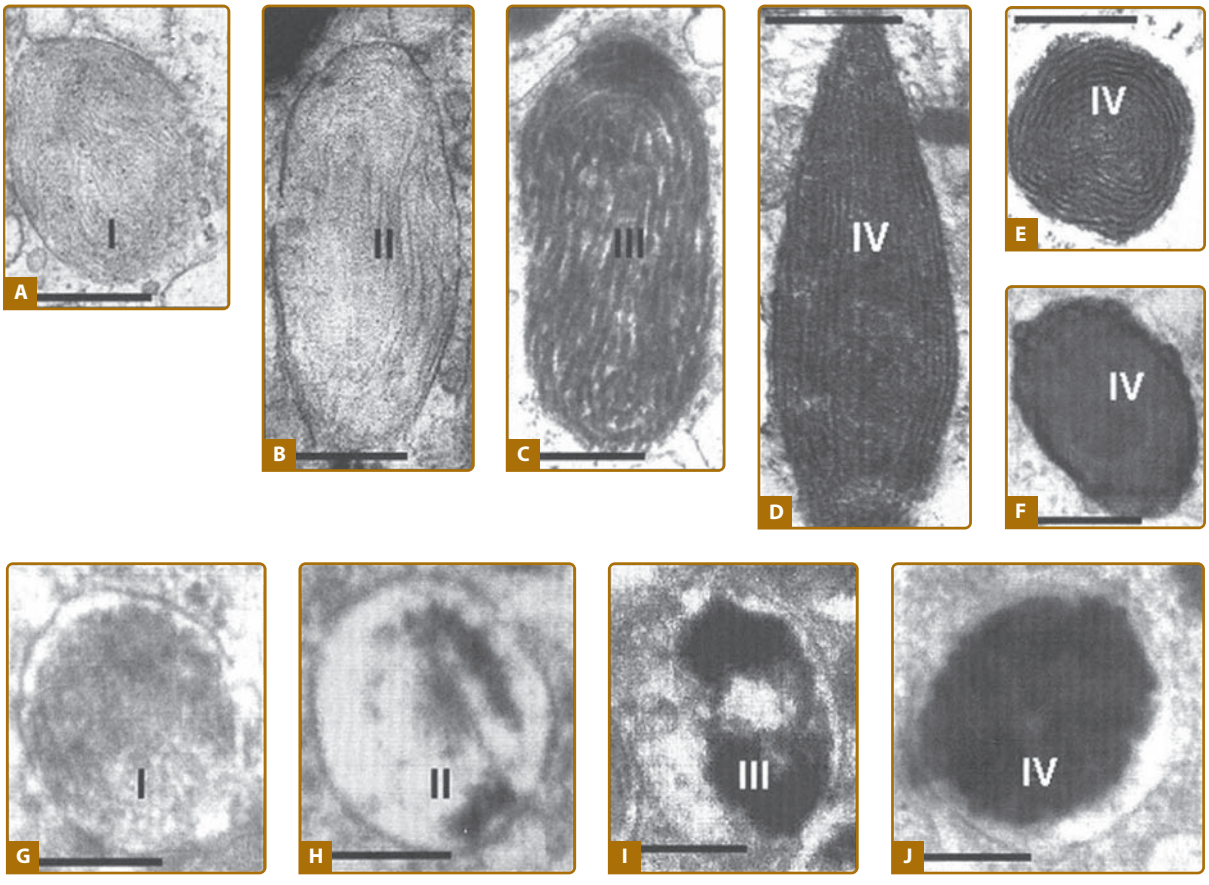

Figure 72-6 Melanosome biogenesis. Electron microscopy of eumelanosome (**A–F**) and of pheomelanosome (**G–J**) development. I, II, III, and IV in **A–J** represent the different maturation stages of melanosomes. [Scale bars are as follows (in µm): a = 0.20; b = 0.23; c = 0.24; d = 0.22; e = 0.20; f = 0.35; h = 0.26; i = 0.26; j = 0.30; k = 0.5.] (From Slominski A et al: Melanin pigmentation in mammalian skin and its hormonal regulation. *Physiol Rev* **84**:1155, 2004, with permission from the American Physiological Society.)

present in lysosomes, they are thought to represent a modified version of the latter. Proteins common to both organelles include the lysosome-associated membrane proteins (LAMPs) that participate in autophagy and regulation of intravesicular pH,[56] as well as acid phophatase, a marker enzyme for lysosomes.[56] Also like lysosomes, melanosomes can endocytose receptors that are targeted for degradation.[56]

Depending on the type of melanin synthesized, melanosomes can be divided into eumelanosomes and pheomelanosomes (Fig. 72-6). Eumelanosomes are large (~0.9 × 0.3 µm), elliptical in shape and contain a highly structured fibrillar glycoprotein matrix required for eumelanin synthesis.[40] Pheomelanosomes are smaller (~0.7 µm in diameter), spherical in shape and their glycoprotein matrix appears disorganized and loose[40] Although both eumelanosomes and pheomelanosomes may be present within a single melanocyte,[57] once committed, they do not change.[58]

Melanosomes display four maturation stages (Fig. 72-6). Stage I melanosomes or premelanosomes likely develop from the endoplasmic reticulum (ER).[40] They have an amorphous matrix and display internal vesicles that form as a result of membrane invagination. Premelanosomes already contain the glycoprotein Pmel17 (gp100) but it requires further processing to become a component of the final fibrillar matrix.[59] Stage II eumelanosomes have organized structured fibrillar matrix, but no active melanin synthesis, whereas in stage II pheomelanosomes melanin synthesis already takes place. Although no active melanogenesis takes place in stage II eumelanosomes, they already contain the enzyme tyrosinase. Deposition of melanin on the fibrillar matrix is found in stage III eumelanosomes, while stage IV eumelanosomes are fully melanized and their internal matrix is masked by melanin deposits.[60,61]

MELANOGENIC PROTEINS

The timely and organized sorting of melanogenic enzymes and structural proteins to melanosomes is an integral part of melanosomal maturation. Melanosome proteins express sorting signals at their amino-terminus and these direct them into the ER and eventually into the melanosomes.[40,60,61]

ENZYMES

Tyrosinase. Tyrosinase is present in plants, insects, amphibians, and mammals. It was initially identified in the early 1900s in mushroom extracts and was subsequently isolated and purified in 1949 from murine

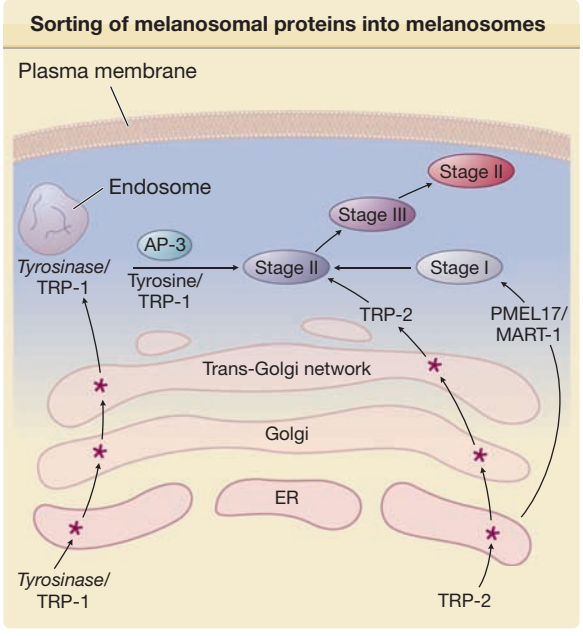

Figure 72-7 Sorting of melanosomal proteins into melanosomes. Tyrosinase and tyrosinase-related protein-1 (TRP-1) are initially synthesized in the endoplasmic reticulum (ER) and, after additional maturation steps (*) in the Golgi and trans-Golgi network, are packaged in endosomes as a complex. TRP-2 follows similar maturation steps. Melanosomes originate in the ER as stage I already containing the melanosomal proteins PMEL17 and MART-1. They then mature to stage II melanosomes and fuse with tyrosinase/TRP-1 in a process directed by the adaptor protein 3 (AP-3). Melanosomes become progressively darker as melanin biosynthesis takes place.

melanoma cells.[62] Mouse and human *tyrosinase* genes are 60–70 kb, and 50 kb long, respectively. The murine *tyrosinase* gene maps to chromosome 7, whereas human *tyrosinase* gene maps to chromosome 11. The human *tyrosinase* gene is composed of five exons and four introns,[63] and tyrosinase mRNA is approximately 2 kb long (genebank access number NM_000372).

Tyrosinase is synthesized in the ER as a precursor protein whose nascent chain is processed in the Golgi complex where sialic acid and neutral sugars are added to the peptide via *N*- and *O*-glycosidic linkages through a process called glycosylation[64] (Fig. 72-7). At least four forms of tyrosinase, all differing with regards to their degree of glycosylation, have been identified. The glycolsylation steps have been shown to be important for proper association of tyrosinase with melanosomes, as well as for its activity.[64] Following the glycosylation steps, mature tyrosinase is folded in the ER, a step required for appropriate trafficking/sorting of tyrosinase into the Golgi apparatus and ultimately into endosomes and finally into melanosomes. A strict control mechanism guarantees the elimination of defective tyrosinase.

Within the melanosome, tyrosinase spans melanosomal outer membrane (eFig. 72-7.1 in online edition). It has three domains: (1) an inner melanosomal domain, (2) a melanosomal transmembrane domain, (3) and a cytoplasmic domain. The inner domain that contains the catalytic region is approximately 90% of the protein. It is followed by a short transmembrane domain, and a cytoplasmic domain composed of approximately 30 amino acids.[65] Histidine residues present in the inner (catalytic) portion of tyrosinase bind copper (Cu) ions and the latter are required for tyrosinase activity.

The biological function of the tyrosinase cytoplasmic domain was not known for a long time. In a mouse model where the entire cytoplasmic domain is missing, tyrosinase protein is inserted into the cellular plasma membrane instead of into the melanosomal membrane, suggesting that tyrosinase cytoplasmic domain is required for proper trafficking of tyrosinase into melanosomes. Indeed, it was found that the motif EXXQPLL (glutamic acid-X-X-glutamine-proline-leucine-leucine, where "X" stands for any amino acid) in the cytoplasmic domain is responsible for tyrosinase trafficking into the melanosomes.[66] In addition, protein kinase C-β (PKC-β) (see below) must phosphorylate two serine residues on this cytoplasmic domain to activate tyrosinase,[65] and in the absence of those phosphorylation events pigmentation does not occur.

Tyrosinase mutations including missense, nonsense frameshift, and deletion mutations that lead to inactivation of the enzyme are found in oculocutaneous albinism type I (see Chapter 73 and Albinism database: http://albinism-db.med.unm.edu/). Such mutations may affect tyrosinase glycosylation interfering with enzyme maturation, or may involve Cu-binding sites disrupting tyrosinase activity or premature termination of tyrosinase protein that causes truncation of cytoplasmic domain.[64]

Tyrosinase-Related Proteins. Two tyrosinase-related proteins, (1) TRP-1 and (2) TRP-2, play important roles in melanogenesis.[67–69] They are structurally related to tyrosinase and share ~40% amino acid homology. Also, similar to tyrosinase, TRP-1 and TRP-2 are glycoproteins located within the melanosomes and span the melanosomal membrane.[70] The conserved nucleotide and amino acid sequences among these three melanogenic enzymes suggest that they originated from a common ancestral gene.[71,72] Mutations of TRP-1 and TRP-2 in mice after coat color ("brown" and "slaty" mice, respectively) and polymorphisms of these gene products are implicated in lighter hair and skin color in European population studies. Their functions are incompletely understood, but the proteins complex with tyrosinase and may stablilize it.

Protein Kinase C-β. PKC constitutes a family of at least 12 isoforms[86] among that PKC-β has been shown to be involved in regulating tyrosinase activity.[87] The mechanisms through which PKC mediates a wide range of membrane generated signals and their relevance to melanocyte biology are further discussed below (see Section "Signaling Pathways Regulating Melanocyte Functions"). PKC-β phosphorylates serine residues on the cytoplasmic domain of tyrosinase, thus activating tyrosinase.[88] Still, the means by which PKC-β-mediated phosphorylation of tyrosinase leads to the enzyme activation is not well elucidated. It has been suggested that phosphorylation of tyrosinase causes a

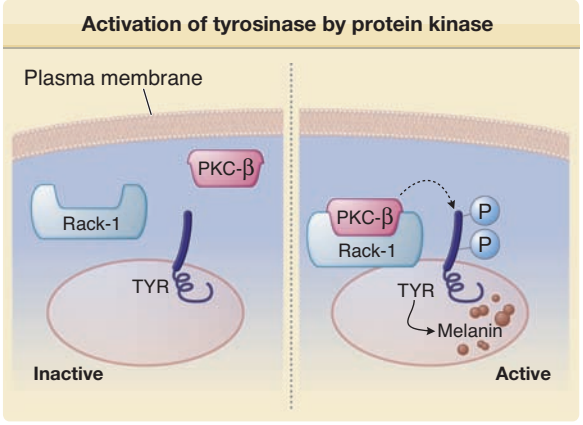

Figure 72-8 Activation of tyrosinase by protein kinase C-β (PKC-β). Under baseline conditions, there is no activation of PKC-β, and tyrosinase (TYR) is not phosphorylated. Activated PKC-β binds receptors for activated C-kinase-I (RACK-I), the complex translocates to the melanosome, and phosphorylates serine residues on the cytoplasmic tail of tyrosinase. Tyrosinase phosphorylation activates the enzyme to catalyze melanin biosynthesis.

complex to form between tyrosinase and TRP-1,[89] an event known to stabilize tyrosinase and increase its enzymatic activity.[79]

In melanocytes, activated PKC-β is associated with melanosomes and the enzyme is found in close proximity to the melanosomal membrane.[88] While structural differences among PKC isoforms may contribute to their associations with particular subcellular fractions, receptors for activated C-kinase (RACK), unique for each PKC isoform, primarily determine the translocation of specific PKC isoforms to specific cellular compartments to activate its target on the membrane[90–92] (Fig. 72-8). RACK-I is the PKC-β partner,[90] and in human melanocytes, the activated PKC-β/RACK-I complex translocates to the melanosome membrane to allow tyrosinase phosphorylation (Fig. 72-8)[93]

STRUCTURAL PROTEINS.

Fibrillar matrix proteins within the melanosomes are required for proper deposition of melanin. Pmel17 and MART-1 are two such melanosomal structural matrix proteins.

Pmel17. Pmel17, also known as gp100 and the silver locus product, is a glycoprotein recognized by the antibodies HMB45, HMB50, and NKI-β.[94] It plays a critical role in fibril matrix formation within eumelanosomes.[59,95] Pmel17 transcription is induced by α-MSH through MITF and it is synthesized as a precursor protein in the ER and the protein undergoes glycosylation and eventual cleavage (Fig. 72-7). After its synthesis, Pmel17 is transported to stage I melanosomes to form a fibrillar structure that is the backbone of eumelanosome matrix,[94] contributes to melanosome ellipsoid shape and promotes melanin polymerization.[94] Melanosomes lacking Pmel17 cannot transit to stage II and have no active melanogenesis.[96] It has been suggested that loss of functional Pmel17 results in melanin cytotoxicity, perhaps through leakage of melanin intermediates from abnormal melanosomes into the cytosol.[94,97] However, there are no known hypopigmentary disorders in humans linked to mutations of *Pmel17*.

MART-1/Melan A. MART-1, also known as Melan A, is a membrane-associated protein[98] that is present in stage I and stage II melanosomes and forms a complex with Pmel17 (Fig. 72-7). MART-1 affects the expression, stability, trafficking, and processing of Pmel17 within the melanosomes.[98] To date, no hypopigmented phenotypes associated with nonfunctional MART-1 have been identified.

TRANSPORT PROTEINS

Heterotetrameric Adaptor Protein Complexes. Sorting of membrane-associated proteins including tyrosinase, TRP-1, TRP-2, and Pmel17 and directing them to the appropriate cytosolic organelles is facilitated by heterodimeric adapter protein complexes (APs).[99,100] AP-3 and possibly also AP-1 facilitate tyrosinase transport from endosomes to melanosomes[101] (Fig. 72-7). Patients with Hermansky–Pudlak syndrome—an autosomal recessive disorder of oculocutaneous albinism, platelet dysfunction, and pulmonary disease (see Chapter 73)—have defects in specific subunits of the AP-3 adaptor protein complex and as a result display several anomalies associated with cellular transport of molecules.[102] Studies suggest that a molecule of the kinesin family, microtubule-associated motor proteins, is involved in endosomal sorting and positioning of melanosomal proteins via interaction with AP-1.[103,104]

P-Protein. The P-protein (pink-eyed dilution) is a transmembrane protein with 12 membrane-spanning domains whose sequence is homologous to that of other transmembrane transport proteins, including anion transporters[97,105,106] thought to function as a transport protein.[107] Studies have identified the protein as an ATP-associated proton pump responsible for maintaining acidic environment within the melanosomes.[108] Other proposed functions of P-protein include stabilizing the tyrosinase/TRP-1/TRP-2 complex and/or transporting tyrosine into the melanosomes.[105] Individuals lacking functional P-protein display oculocutaneous albinism type 2, largely due to improper melanosomal pH.[108–110] Also, Angelman and Prader–Willi syndromes display deletion mutations that include the P-locus on chromosome 15.

SLC24A5. SLC24A5 is a melanosomal protein whose structure and homology to cation exchange proteins suggests that it is a melanosome-associated cation exchanger.[111] Mutations in *slc24α5* in zebrafish lead to hypopigmentation of the organism.[111] The ancestral human homolog is expressed by darker complexioned individuals including Africans and Asians, while lighter complexioned Europeans tend to express a variant allele.[111]

SCAVENGER PROTEIN

Lysosome-Associated Membrane Proteins. LAMPs are linked to melanosome membranes and/or matrix. They are thought to protect melanosomal integrity by acting as scavengers of free radicals that

are produced during melanin biosynthesis.[112] Because LAMPs are also present in lysosomes, it is thought that melanosomes and lysosomes share a common ancestral origin.[112]

REGULATORY PROTEINS

Microphthalmia-Associated Transcription Factor

Gene and Protein. MITF, a basic-helix-loop-helix (bHLH) and leucine zipper transcription factor, has been termed the master gene for melanocyte survival and is a key factor regulating the transcription of the major melanogenic proteins, tyrosinase, TRP-1, TRP-2,[12] PKC-β[113] and MART-1.[114] In melanocytes, it is the MITF-M isoform that stimulates transcription of *tyrosinase* and *PKC-β*.[114] MITF binds to conserved consensus elements in gene promoters, specifically the M-(AGTCATGTGCT) and E- (CATGTG) boxes.[115] It can bind as a homodimer or a heterodimer with another related family member.[116] MITF appears to be a key regulator determining cell fate, as transfection of human MITF cDNA into mouse fibroblasts converts these cells into dendritic cells expressing melanocyte-specific genes.[117]

MITF comprises a family of nine isoforms: (1) MITF-M, (2) -A, (3) -B, (4) -H, (5) -C, (6) -D, (7) -E, (8) -J, and (9) -Mc.[118,119] MITF-M expression is highly specific for melanocytic cells.[120] Melanocytes express in addition other MITF isoforms specifically, MITF-A, -B, and, -E[114]The biologic role of other MITF isoforms in normal melanocytes is not known.

Regulation of MITF Activity and Expression. The activity and stability of MITF are modulated by phosphorylation of the protein. MITF activity is increased upon its phosphorylation by the mitogen-activated protein kinase-2 (MAP kinase-2), whose activity is in turn induced by binding of SF/kit/stem cell factor to c-Kit receptor[121] (Fig. 72-8). Phosphorylated MITF binds to another protein, p300/CBP, which belongs to a coactivator family of proteins and acts to enhance MITF transcriptional activity.[121,122] Another kinase that is activated by SF/c-Kit interaction is p90RSK that also phosphorylates MITF but at a different site from that phosphorylated by MAP kinase-2.[123] These phosphorylation events both activate MITF and at the same time decrease the stability of the protein, as phosphorylated MITF is targeted for degradation by proteosomes (eFig. 72-8.1A in online edition).[123,124]

The expression of MITF is under the control of several transcription factors, including Sox10 (mutated in Waardenburg's syndrome type 4, see Chapter 73) and Pax3. MITF expression is also controlled by the cAMP-response element binding protein (CREB) and Lef1 transcription factor that participates in Wnt-signaling. These transcription factors bind to specific sites within *MITF* promoter regions to induce MITF transcription.[116] The promoter region of the *MITF* gene contains a cAMP-response element (CRE) that interacts with CREB when the cAMP-dependent pathway is activated.[125,126] Therefore, cAMP-elevating agents like α-MSH induce the expression of MITF (eFig. 72-8.1B in online edition).

MITF Role in Melanocyte Proliferation and Survival. MITF promotes melanoycte survival by upregulating the expression of a major antiapoptotic protein BCl2.[127] It is frequently overexpressed or amplified in melanomas, contributing to their increased survival.[128–131] Mutations in *MITF* are found in the pigmentary disorder Waardenburg syndrome type 2[132](see Chapter 73).

A role for MITF in melanocyte proliferation has also been proposed, as under certain conditions, MITF induces the expression of the cell cycle-associated kinase Cdk2 that is involved in the progression of cells from G1 into S phase of the cell cycle.[133] MITF also suppresses the expression of p21, a protein that inhibits Cdk2 activation.[133,134] Conversely, under

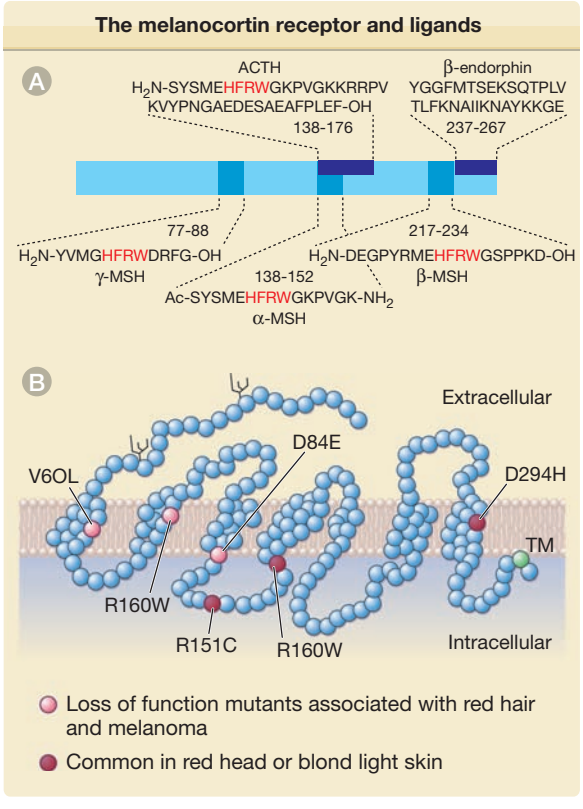

Figure 72-9 The melanocortin receptor (MCR) and its ligands. **A.** Structure of the proopiomelanocortin precursor. Standard abbreviations for amino acids are used. The synthetic superactive α-melanocyte-stimulating hormone (α-MSH) analogue [Nle^4 D-Phe^7]-α-MSH is modified by the exchange of methionine (M) with norleucine and L-phenylalanine (F) with D-phenylalanine. In *red* are critical amino acids required for binding to the MCR. **B.** Schematic representation of the human MC1R receptor. Each of the 318 amino acid residues in the polypeptide chain of the receptor is represented by an empty circle. Branched structures represent *N*-linked glycosylation sites. Reduced function mutants (*red circles*), variants common in red- or blond-haired and fair skinned individuals (*orange circles*), and the conserved *C*-terminal cysteine (*green circle*), the possible site for fatty acid acylation and anchoring to the plasma membrane, are indicated. Ac = acetylated; ACTH = adrenocorticotropic hormone; NH_2 = amidated; TM = transmembrane domain.

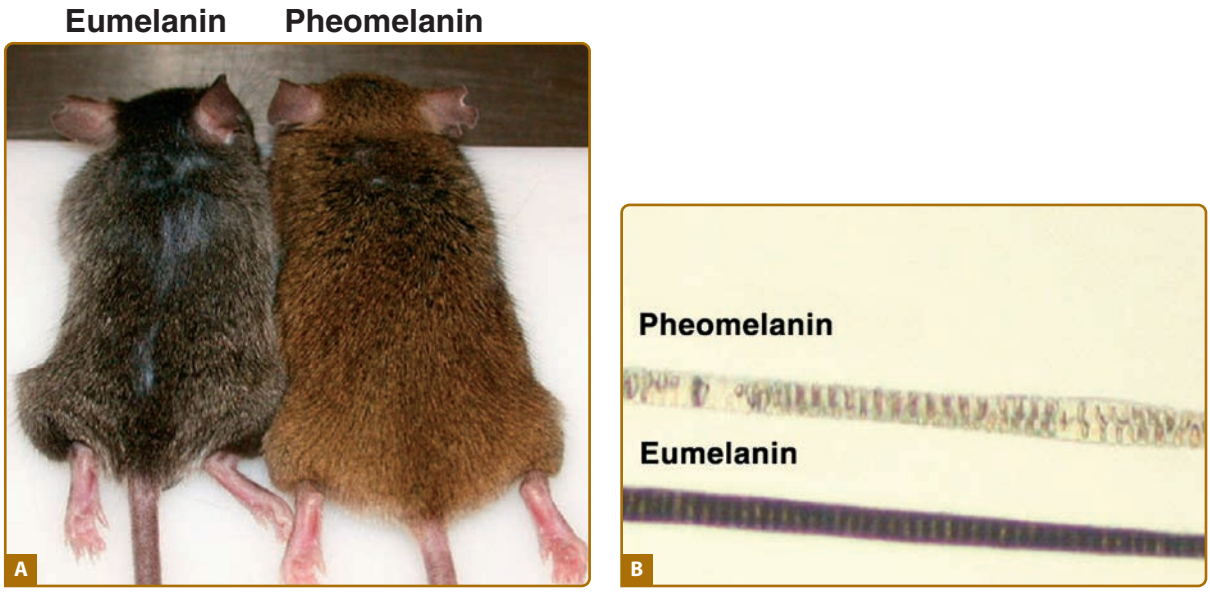

Figure 72-10 Eumelanin and pheomelanin presentation in mice. **A.** Two mice with different coat colors are shown. The one on the left displays brown/black coat color due to eumelanin, and the one on the right displays red/yellow coat color due to pheomelanin. **B.** Representative hair shafts of these mice. (From Sharov et al: Bone morphogenic protein (BMP) signaling controls hair pigmentation by means of cross-talk with the melanocortin receptor 1 pathway. *PNAS* **102**:93, 2004, with permission.)

different conditions, MITF can induce p21 expression and it can also stimulate the expression of $p16^{INK4a}$, a protein that inhibits the activation of kinases required for progression through the cell cycle, thus promoting cell cycle arrest.[135,136] Because MITF cooperates with other transcription factors to induce its effects, it is to be expected that these transcription factors would influence MITF activity, resulting in either stimulation or inhibition of melanocyte proliferation.

Mice bearing null mutations of *MITF* display loss of melanocytes, deafness and failure of differentiation of retinal pigment epithelium.[12]

Melanocortin 1 Receptor. Melanocortin receptors (MCRs) comprise a family of five related receptors (MC1R, MC2R, MC3R, MC4R, and MC5R). Each has seven transmembrane domains and they belong to the G-protein-coupled receptor superfamily.[137] MC3R and MC4R are mainly found in the central nervous system, are absent in melanocytes,[138] and are thought to control energy intake. MC2R is expressed in the adrenal cortex and MC5R is expressed in peripheral adipocytes.[139] MC1R is expressed in a number of cells such as endothelial cells, fibroblasts,[140] and keratinocytes,[140] but the highest expression is found in melanocytes.[140]

α-MSH and adrenocorticotropic hormone (ACTH), a 39 amino acid proopiomelanocortin-derived peptide that contains the α-MSH sequence (Fig. 72-9A),[141–143] activate MC1R (Fig. 72-9B) Receptor–ligand interaction leads to G-protein-dependent activation of the enzyme adenylate cyclase followed by increased intracellular cAMP level[141] inducing MITF transcription and upregulating the level of melanogenic proteins including tyrosinase[40] promoting the synthesis of brown/black eumelanin.[141] Agouti, a protein expressed in both humans and mice, whose expression in mice leads to yellow coat color, antagonizes α-MSH by competitive binding to MC1R. It thus blocks adenylate cyclase activation[144–146] and favors pheomelanin over eumelanin synthesis (Fig. 72-10). However, the role of agouti in human pigmentation is poorly documented.

Polymorphisms within the *MC1R* gene are largely responsible for the different skin/hair color among different racial groups.[147] At least 30 MC1R variants have been identified and nine of them display loss of function[148,149] (Fig. 72-9B), not being able to induce intracellular cAMP production in response to α-MSH despite adequate receptor/ligand binding. Other MC1R variants have reduced affinity for α-MSH.[148,149] Three MC1R variants, each with only a single amino acid substitution, have been associated with red/yellow hair and fair skin[150] of Northern Europeans and Australians.[151–156] Mice expressing a loss-of-function MC1R variant receptor also fail to respond to UV irradiation with increased pigmentation despite an increased level of epidermal α-MSH,[157] but do tan if provided forskolin, a chemical enhancer of pigmentation that bypasses the receptor to directly increase cAMP, demonstrating that the intracellular melanogenic pathway is functional in such individuals.[155]

MELANIN BIOSYNTHESIS

Two types of melanins are synthesized within melanosomes: (1) eumelanin and (2) pheomelanin.[158] Eumelanin is dark, brown–black, and insoluble, whereas pheomelanin is light, red–yellow sulfur-containing, and soluble.[158] Melanins are indole derivatives of 3,4 di-hydroxy-phenylalanine (DOPA) and they are

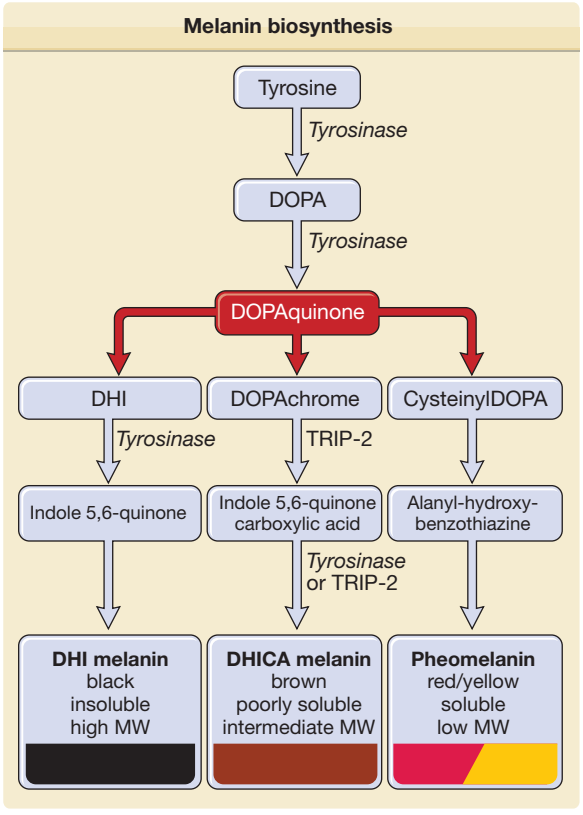

Figure 72-11 Melanin biosynthesis. Melanin biosynthesis begins with the amino acid tyrosine that is converted to DOPA (3,4-dihydroxyphenylalanine) in the rate-limiting step of melanin biosynthesis catalyzed by tyrosinase. DOPA is subsequently converted to DOPAquinone by the same enzyme. DHI (5,6-dihydroxyindole) and DHICA (5,6-dihydroxyindole-2-carboxylic acid) are then formed to produce either black or brown eumelanin. Alternatively, through incorporation of glutathione or cysteine, DOPAquinone can form pheomelanin. MW = molecular weight; TRP = tyrosinase-related protein.

formed in melanosomes through a series of oxidative steps[159] (Fig. 72-11). Melanosomal pH affects the activity of the melanogenic enzymes and influences melanin polymerization.

The synthesis of both types of melanin involves the rate-limiting catalytic step in which the amino acid tyrosine is oxidized by the enzyme tyrosinase (also called tyrosine oxidase, DOPA oxidase, monophenol, DOPA: oxygen oxidoreductase) to DOPA, a first step in a reaction known as the Raper–Mason pathway[160] (Fig. 72-11). Conversion of tyrosine to DOPA is thought to be the critical rate-limiting step in melanogenesis, as inhibition of this reaction blocks melanin synthesis.[161] In both reactions, DOPA acts as a cofactor and also as a substrate for tyrosinase. Although the exact interaction between tyrosinase and its substrates is not completely understood, in vitro kinetic studies suggest that distinct sites mediate tyrosinase binding to tyrosine and to DOPA, and that binding to DOPA causes a conformational change in tyrosinase, resulting in increased affinity for both tyrosine and DOPA.

DOPA is oxidized into DOPAquinone,[162] DOPAquinone is further converted to DOPAchrome and DOPAchrome can be converted to 5,6-dihydroxyindole (DHI) or to 5,6-dihydroxyindole-2-carboxylic acid (DHICA). The latter reaction is catalyzed by the enzyme DOPAchrome tautomeras or TRP-2. The level of brown versus black eumelanin appears to correlate with DHI/DHICA ratio, with a higher ratio leading to the formation of black eumelanin and a lower ratio to brown eumelanin.[163] DOPAquinone can also combine with glutathione or cyteine to form cysteinylDOPA, which then becomes the yellow/red, soluble, low-molecular-weight pheomelanin.[163] Interestingly, tyrosinase also catalyzes a more distant step in melanin biosynthesis, namely DHI conversion to indole-5,6-quinone. In mice, the enzyme TRP-1 (also called DHICA oxidase) converts DHICA to indole-5,6-quinone carboxylic acid. However, the TRP-1 role in human melanin biosynthesis is not well established.

The main function of melanin is to provide protection against UV-induced DNA damage by absorbing and scattering UV radiation (280–400 nm). Accordingly, energy absorption by melanin is maximal in this portion of the electromagnetic spectrum, and decreases gradually across the visible light spectrum. UV absorbed by melanin is converted into heat, a less toxic form of energy.[164] Still, in vitro studies conducted by several investigators suggest that melanin's capacity to act as a sunscreen is limited and that melanin, when incorporated into a cream and spread over the skin, absorbs only 50%–75% of incident sunlight. Naturally, it is possible that in vivo, by virtue of localizing above the nucleus, melanin in melanosomes achieves a higher level of protection.

Melanin intermediates as well as melanin itself can also be harmful to the cell because, depending on their molecular weight and polymerization state, they can promote UVA (320–400 nm)-induced DNA damage, most likely through the generation of ROS.[165] It has been suggested that the increased incidence of UV-induced melanomas in light-skinned, red-hair individuals is not only due to decreased ability of pheomelanin to protect against UV-induced DNA damage, but may also be due to mutagenic capacity of pheomelanin and possibly other melanin intermediates as a result of their pro-oxidant capacity.[166]

MELANOCYTE DENDRITES

Melanocyte dendrites are branching protoplasmic processes that interact with keratinocytes. Actin is a major structural component of melanocyte dendrites, and actin filament disruption leads to dendrite loss.[167] Cocultures of keratinocytes and melanocytes demonstrate that keratinocyte-derived factors play a role in melanocyte dendricity.[168] These factors include ET-1, nerve growth factor (NGF), α-MSH, ACTH, prostaglandins (PGs) E_2 and $F_{2\alpha}$[168] and β-endorphin.[169] Integrins, receptors that mediate actin-extracellular matrix contact are likely to play a role in dendrite formation as well.[170]

Another group of proteins, the Rho family, also plays a role in melanocyte dendrite formation. Rho proteins become active when they bind GTP and inactive when binding GDP.[171,172] It appears that when Rho is activated, dendrites retract; while when its family member Rac is activated, dendrites form.[172] Indeed, it is currently assumed that by increasing cAMP levels, α-MSH inhibits Rho, enhancing melanocyte dendricity. Thus, the equilibrium between Rho and Rac appears to be an important factor influencing melanocyte dendricity.

MELANOSOME TRANSPORT

WITHIN MELANOCYTES

Melanosomes are transferred from their site of origin in melanocyte perikaryon to the tips of melanocyte dendrites. Melanosome transport takes place on microtubules that are arranged parallel to the long axis of the dendrite and is controlled by two classes of microtubule-associated motor proteins: (1) kinesins[173–175] and (2) cytoplasmic dyneins[176–180] (Fig. 72-12). Both motor proteins act as short cross-bridge structures connecting the organelle to the microtubules.

Centrifugal, anterograde organelle movement is mediated primarily by kinesin, whereas centripetal movement is controlled by cytoplasmic dynein. Studies examining melanosomal transport suggest that their microtubule-dependent movement is bidirectional,[181] consistent with a cooperative forward and backward pull of kinesin[173] and dynein,[176] respectively. For melanosomes with net centrifugal movement, the bidirectional movement appears to terminate with myosin-Va (encoded by dilute locus)-dependent melanosomal capture in the actin-rich periphery of the dendrite (Fig. 72-12).[181]

Additional proteins that participate in melanosome transport include Rab27a (encoded by *ashen* locus) that mediates myosin-Va binding to melanosomes through another linker protein-melanophilin (encoded by *leaden* locus) (Fig. 72-12).[182] In the absence of myosin-Va, melanosomes do not collect in dendrite tips.

Mutations in any of the above gene products results in decreased cutaneous pigmentation. Griscelli syndrome, a rare autosomal recessive disorder in which individuals display dilute skin and hair color, is the result of mutations of *myosin-Vα*, *Rab27α*, or *melanophilin*[182] (see Chapter 73). *Myosin-Vα* and *Rab27α* are closely located on chromosome 15.[183–186] Because myosin-Va is also expressed in the brain, mutations of this gene may also cause neurological abnormalities. Rab27a also plays a role in immuno-regulation and individuals with mutations of this gene display abnormalities of the immune system. Mutations of *melanophilin* result only in the distinctive hypopigmentation that characterizes the syndrome.[186]

Melanosome transport across melanocyte dendrites

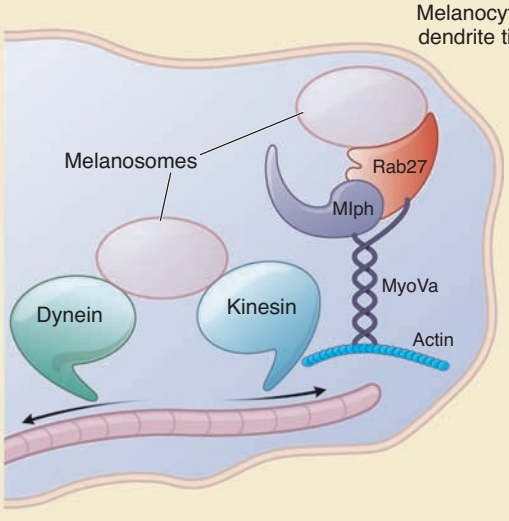

Figure 72-12 Schematic diagram of melanosome transport across melanocyte dendrites. Melanosomes move bidirectionally along melanocyte dendrites. They are attached to microtubules through the motor proteins kinesin (anterograde) and dynein (retrograde). At the tip of the dendrite, melanosomes are captured in the actin-rich periphery. Myosin-Va (MyoVa) mediates melanosome binding to actin through the linker proteins Rab27a and melanophilin (Mlph).

TO KERATINOCYTES

Transfer of melanosomes from melanocytes to neighboring keratinocytes is a critical step in normal pigmentation. Studies suggest several ways for melanosomal transfer, including exocytosis, cytophagocytosis, fusion of plasma membranes, and transfer by membrane vesicles.[187]

The exocytosis pathway of melanosomal transfer involves fusion of the melanosomal membrane with the melanocyte plasma membrane, melanosome release into the intercellular space and phagocytosis by surrounding keratinocytes. Cytophagocytosis is a term indicating the phagocytosis of a live cell or a portion of it. With regard to keratinocytes, they cytophagocytose the tip of a melanocyte dendrite, which then fuses with lysosomes inside the keratinocyte, is transported to a supranuclear location where the phagolysosome membranes break up releasing the melanosomes. Fusion of keratinocyte and melanocyte plasma membranes creates a space through which melanosomes are transferred from the melanocyte to the keratinocyte. Indeed, high-resolution photography shows the presence of filopodia—slender, filliform, pointed cytoplasmic projections at the tip of melanocyte dendrites.[188] These filopodia adhere and fuse with keratinocyte plasma membrane prior to melanosome transfer. Another way of melanosomal transfer involves shedding of melanosome-filled vesicles followed by phagocytosis of these vesicles by keratinocytes, or their fusion with keratinocyte plasma membrane.

The molecular and cellular mechanisms involved in melanosome phagocytosis have been partially elucidated. It appears that keratinocytes express a

seven-transmembrane G-protein coupled receptor called protease activated receptor-2 (PAR-2). PAR-2 is activated when serine proteases cleave the extracellular portion of the receptor, exposing a new segment that acts as a tethered (attached) ligand.[189,190] Activation of PAR-2 increases keratinocyte phagocytic activity.[189,190]

Interestingly, and consistent with its role in melanosome phagocytosis, UV induces the activity and expression of PAR-2.[191] UV effect on PAR-2 activity and expression is more pronounced in individuals with skin phototypes II and III than in those with skin phototype I.[191] Keratinocyte growth factor receptor has also been implicated in enhancing phagocytosis of melanosmes by keratinocytes.[192]

REGULATION OF MELANOCYTE FUNCTION

Melanocyte behavior in skin is largely influenced by signals from neighboring keratinocytes as well as autocrine signals and environmental factors such as UV irradiation (also see Section "UV Irradiation and Melanocytes"). The synthesis and secretion of most keratinocyte-derived factors is increased by UV irradiation, but it is also evident that UV can directly stimulate melanocyte dendricity and melanin production.[171,193] Melanocytes receive both positive and negative paracrine signals that modulate their proliferation and differentiated function.

MELANOGENIC STIMULATORS

PROOPIOMELANOCORTIN AND DERIVED PEPTIDES. It is well documented that MSH and ACTH are potent stimulators of melanogenesis. They belong to a family of peptides derived from the precursor proopiomelanocortin (POMC) that is synthesized, in addition to the pituitary gland, also by epidermal keratinocytes. Interestingly, POMC expression in keratinocytes is induced by UV, phorbol esters, and interleukins.[194,195] In rodents, α-MSH stimulates melanogenesis and favors eumelanin over pheomelanin production, but systemic administration of α-MSH, β-MSH, and ACTH to people increases skin pigmentation predominantly in sun-exposed areas.[196,197] However, in certain disease conditions characterized by abnormally high levels of ACTH, such as Addison disease[198] or Nelson's syndrome[199] (ACTH secreting pituitary adenoma), more generalized hyperpigmentation of the skin has been observed.[200]

Aside from its effect on melanogenic proteins and eumelanin synthesis, α-MSH was also reported to enhance the repair of UV-induced DNA damage in melanocytes, specifically the repair of pyrimidine dimers, and also to reduce the level of UV-induced hydrogen peroxide in the cell.[201] In addition, α-MSH was shown to regulate melanosomal pH.[202] These data suggest a role for POMC-derived peptides beyond merely stimulating melanogenesis.

ENDOTHELIN-1. ET-1 appears to play a role in mature melanocytes, inducing melanogenesis by activating tyrosinase and increasing TRP-1 levels.[203,204] ET-1 also leads to melanocyte proliferation[203,204] and promotes dendrite formation.[205] Cultured keratinocytes synthesize and secrete ET-1,[204–206] and UV irradiation stimulates ET-1 production by keratinocytes.[204,205] ET-1 can also cooperate synergistically with other growth factors/cytokines to further influence melanocyte function.

ET-1 upregulates MC1R level and increases MC1R affinity for α-MSH.[207,208] Similar to α-MSH, ET-1 displays photoprotective effects on melanocytes, enhancing thymine dimer repair, decreasing the level of UV-induced hydrogen peroxide, and inducing the level of antiapoptotic proteins.[201,209]

STEEL FACTOR (SF). Like other keratinocyte-derived factors, SF is induced by UV-irradiation, and in guinea pigs, anti-Kit antibodies block UV-induced tanning. SF can also act synergistically with other cytokines such as IL-3, IL-6, IL-7, IL-9, and granulocyte-macrophage-colony stimulating factor to regulate UV-induced melanogenesis and melanocyte survival.[210,211]

INFLAMMATORY MEDIATORS. Several inflammatory mediators can affect skin pigmentation. PGs—arachidonic acid-derived metabolites, and leukotrienes—lipid compounds related to PGs, both mediators of inflammatory responses, affect melanocyte function. Their level is elevated in sunburned skin[212] and in a variety of inflammatory dermatoses, including atopic dermatitis[213] (see Chapter 14) and psoriasis[214] (see Chapter 18).

Human melanocytes express several PG receptors including the receptors for PGE_2 and $PGF_{2\alpha}$.[215,216] Indeed, $PGF_{2\alpha}$ stimulates melanocyte dendrite formation and activates tyrosinase,[215,216] and UV irradiation upregulates the level of PG receptors on melanocytes.[215,216] Similarly, leukotrienes B_4 and C_4 increase melanin synthesis and stimulate melanocyte proliferation and motility.[217] Interestingly, melanocytes also contribute to cutaneous inflammatory responses, as they synthesize and release IL-8 when stimulated by the proinflammatory cytokines IL-1 and TNF-α.[218]

Melanocytes also respond to histamine released by mast cells during cutaneous inflammation. Histamine binds H_1 and H_2 receptors to induce melanocyte dendricity and upregulate tyrosinase level.[219,220] These effects are decreased when melanocytes are pretreated with the H_2 receptor antagonist famotidine.[220]

NEUROTROPHINS. Neurotrophins (NTs) are a family of molecules that enhance neuronal survival in the central and peripheral nervous systems. They include NGF,[221] NT-3,[222–224] NT-4,[225] and brain-derived neurotrophic factor.[226,227] Melanocytes express the low-affinity receptor common to all NTs, $p75^{NTR}$,[228] as well as the high-affinity receptors for NGF (TrkA) and NT3 (TrkC).[229] Keratinocyte-derived NGF, whose expression is upregulated by UV irradiation, is chemotactic for melanocytes and

induces their dendricity.[230] Both NGF and NT-3, the latter expressed by dermal fibroblasts, increase melanocyte survival. Specifically, after UV irradiation, NGF supplementation increases the level of the antiapoptotic Bcl-2 protein, reducing melanocyte apoptotic cell death.[231,232] Thus, in addition to other keratinocyte-derived cytokines, NGF may help preserve the population of cutaneous melanocytes that would otherwise be depleted by UV damage.

BASIC FIBROBLAST GROWTH FACTOR. Basic fibroblast growth factor (bFGF), named for its ability to stimulate the growth of fibroblasts, was one of the first identified melanocyte mitogens.[233,234] It is produced by keratinocytes, but lacks a secretory signal and hence is presumed to affect melanocytes through cell–cell contact. It binds tyrosine kinase transmembrane receptors to induce its mitogenic effect in the presence of cAMP elevating factors. Like other keratinocyte-derived cytokines, it is upregulated in response to UV irradiation.[234,235] Keratinocyte growth factor, another member of the FGF family of proteins, has been shown to promote melanosome transfer from melanocytes to keratinocytes.[192]

NITRIC OXIDE. Nitric oxide (NO) is a diffusible free radical displaying pleiotropic bioregulatory effects in diverse cells and tissues.[236,237] Melanocytes and keratinocytes produce NO in response to inflammatory cytokines,[238–241] and NO production in keratinocytes is induced by UV irradiation.[242] NO increases tyrosinase activity and melanogenesis[242] and is thus an autocrine as well as paracrine molecule that affects melanocyte behavior in skin.

CATECHOLAMINES. Catecholamines are a group of signaling molecules, primarily functioning as neurotransmitters and as endocrine hormones.[243] Catecholamines bind either α_1-adrenergic receptors (AR) or β_2-AR and can induce melanogenesis through PKC-β or cAMP-dependent pathways.[169,244]

MELANOGENIC INHIBITORS

Numerous reports have suggested the existence of endogenous melanogenic inhibitors,[245,246] but only few specific molecules have been identified. One group of inhibitors includes sphingolipids, a class of membrane-associated lipids[247] that act as signal transducers. Sphingolipids were shown to decrease melanogenesis, at least in part by enhancing MITF degradation via ubiquitin-meditated pathways.[248,249] Another melanogenic inhibitor, BMP-4, downregulates tyrosinase expression in melanocytes,[250] also in part via its effects on MITF.[251] Interestingly, physiologic doses of UV irradiation, a potent melanogenic stimulator, decrease the expression of BMP receptors on melanocytes,[250] presumably eliminating its inhibition during UV-induced tanning. Mice that transgenically overexpress the physiologic BMP antagonist noggin have a darker coat color than wild-type mice and their hairs have a higher eumelanin to pheomelanin ratio.[252]

SIGNALING PATHWAYS REGULATING MELANOCYTE FUNCTION

Growth factors, cytokines, hormones, and other ligands for receptors expressed on melanocytes exert their biologic effect by interacting with their specific cell surface receptors, generating a signaling cascade involving activation or inhibition of protein kinases and leading to distinct patterns of protein phosphorylation. Two types of kinases participate in cellular signaling: (1) serine/threonine kinases and (2) tyrosine kinases that by definition phosphorylate serine and/or threonine residues and tyrosine residues, respectively, on their specific target proteins. This section reviews the major signaling pathways that affect melanocyte behavior in skin.

cAMP/PKA-DEPENDENT PATHWAY

cAMP, one of the first identified intracellular second messengers, plays a key role in diverse biological functions such as cellular metabolism, growth, and differentiation.[253,254] It also mediates α-MSH effect[255] and was one of the first recognized regulators of mammalian pigmentation[256] The intracellular level of cAMP is upregulated by a membrane-associate enzyme called adenylate cyclase that is activated upon receptor–ligand interaction in receptors that are coupled to GTP-binding proteins like MC1R[257] (eFigs. 72-8.1 and 72-12.1 in online edition). cAMP is also elevated by reagents such as choleragen or isobutylmethylxanthine. Providing melanocytes with dibutyryl cAMP, a cAMP analog, increases the intracellular level of cAMP and induces signaling that leads to melanogenesis.[258]

cAMP-dependent protein kinase (PKA) mediates most of the biologic actions of cAMP.[257] PKA is a serine/threonine kinase consisting of two regulatory subunits and two catalytic subunits.[257] It exists in the cytosol in an inactive form and binding of cAMP to its regulatory subunits releases the catalytic subunits, activating the enzyme.[257] PKA phosphorylates the cAMP responsive element-binding protein (CREB) that binds its DNA consensus sequence CRE in the MITF promoter to induce MITF transcription (eFig. 72-8.1 in online edition). cAMP elevation also affects other target genes by increasing or decreasing their transcription[259] (eFig. 72-12.1 in online edition). In vitro, PKA effect can be antagonized by the inhibitor PKI that acts as a pseudosubstrate for the catalytic subunit of PKA and thus prevents it from phosphorylating its endogenous substrates.[260]

PKC-DEPENDENT PATHWAY

PKC is a serine/threonine kinase involved in diverse cellular functions, including growth, transformation, and differentiation.[261] PKC resides as an inactive enzyme in the cytoplasm, and it is activated by diacylglycerol (DAG), a component cleaved from the plasma membrane when cell surface receptors interact with

their ligands. DAG can also be released from the membrane by UV irradiation (eFig. 72-12.1 in online edition). DAG induces PKC translocation to membranes where the latter is activated[261] to induce phosphorylation of serine/theonine residues on target proteins like tyrosinase. Phorbol esters mimic DAG action and initially activate PKC.[261] However, within 24 hours the entire cellular reserves of PKC are depleted, and when melanocytes are treated with phorbol esters they can no longer signal through PKC.[87]

The critical role of PKC in melanogenesis was first suggested by the observation that addition of DAG, the endogenous activator of PKC, to cultured human melanocytes rapidly increased total melanin content,[262] and this increase was blocked by a PKC inhibitor.[262] Moreover, topical application of DAG to guinea pig skin increased epidermal melanin content.[263]

The expression of the 12 PKC isoforms varies among different tissues.[86] Each isoform is thought to carry out a distinct biological function. Human melanocytes express PKC-α, -β, -ε, -δ, and -ς[264,265] and the PKC-β isoform is specifically involved in regulating tyrosinase activity (see above). ET-1 and histamine also utilize the PKC-dependent pathway (in addition to cAMP-dependent pathway) to exert their regulatory effects on melanocyte function.[266,267]

RECEPTOR TYROSINE KINASES

Melanocytes express several distinct tyrosine kinase receptors that bind BMP, bFGF, HGF, and c-Kit ligand. Receptor–ligand interaction activates an intracellular tyrosine kinase domain on the receptor, phosphorylating the receptor and subsequently activating a series of kinases called mitogen-activated protein (MAP) kinases, or other intracellular signaling molecules (eFig. 72-12.1 in online edition). Through a chain reaction involving phosphorylation of proteins like MITF, the signals are transferred to the nucleus to activate or suppress the transcription of genes that participate in melanocyte proliferation, melanogenesis, and/or survival.

β_2- AND α_1-ADRENERGIC RECEPTORS

Studies suggest that pathways that increase intracellular cAMP are also involved in regulation of melanogenesis. POMC-deficient mice (POMC $^{-/-}$) that lack melanocortin ligands still display normal black coat color.[269] Histological and electron paramagnetic resonance spectrometry of the hair follicles showed normal structure and eumelanin pigmentation.[269] This study suggests that either MC1R has adequate basal activity to induce pigmentation or that pathways that do not involve melanocortin can also induce melanogenesis. Indeed, melanocytes express both β_2-AR and α_1-AR, respectively.[270,244] α_1-AR interacts with melanocyte derived-norepinephrine and increases the level of DAG[169,244] inducing melanogenesis in a PKC-β-dependent pathway. Also, keratinocytes produce epinephrine, which then binds to β_2-AR expressed on melanocytes and increases the level of cAMP, leading to melanin synthesis.[244] Therefore, numerous pathways may act in tandem to regulate melanogenesis.

UV IRRADIATION AND MELANOCYTES

TANNING RESPONSE

Melanocyte survival, proliferation, and differentiated function are influenced by environmental factors, the most important of which is UV irradiation. UV irradiation induces tanning, the so-called facultative skin color, an increase above baseline or constitutive skin pigmentation that provides protection against future UV irradiation.[271] Tanning is divided into immediate tanning and delayed tanning.

IMMEDIATE TANNING. Immediate tanning or immediate pigment darkening occurs within 5–10 minutes of exposure and fades within minutes to days depending on the UV dose and the complexion of the individual (Fig. 72-13B). As summarized in Table 72-1, immediate tanning does not provide photoprotection and does not increase epidermal melanin level.[272] It is primarily produced by UVA irradiation, although visible light can also induce immediate tanning.[273] Immediate tanning is only visible in darker individuals, and it is thought to represent melanosomal relocation from the perikaryon to melanocyte dendrites.[274]

DELAYED TANNING. Delayed tanning, summarized in Table 72-1 and shown in Figure 72-13A, occurs within 3–4 days after UV exposure.[271,272] UV is arbitrarily divided into UVC (100–280 nm), UVB (280–320 nm), and UVA (320–400 nm). The UVC portion of the spectrum is generally not present in terrestrial sunlight because it is absorbed by the atmospheric ozone layer. Delayed tanning is affected by both UVB and UVA. The action spectrum that produces delayed tanning is the same as for UV-induced erythema (sunburn), with UVB wavelengths far more effective than UVA.[264] Especially in darker skinned individuals, suberythemogemic UV doses may be effective as well. Delayed tanning peaks between 10 days and 3–4 weeks depending on the absorbed UV dose and the individual's skin type, then fades gradually over a few weeks. Histologically, there are increased epidermal melanocytes, melanocyte dendriticity, and melanosome transfer to keratinocytes with greater melanization of individual melanosomes.[272,274] Overall, total epidermal melanin is increased, providing additional photoprotection from UV irradiation.

DIRECT AND INDIRECT EFFECTS OF UV IRRADIATION

UV irradiation affects melanization, melanocyte proliferation and survival both directly and indirectly through its effect on keratinocytes, inducing the synthesis and secretion of paracrine keratinocyte factors.

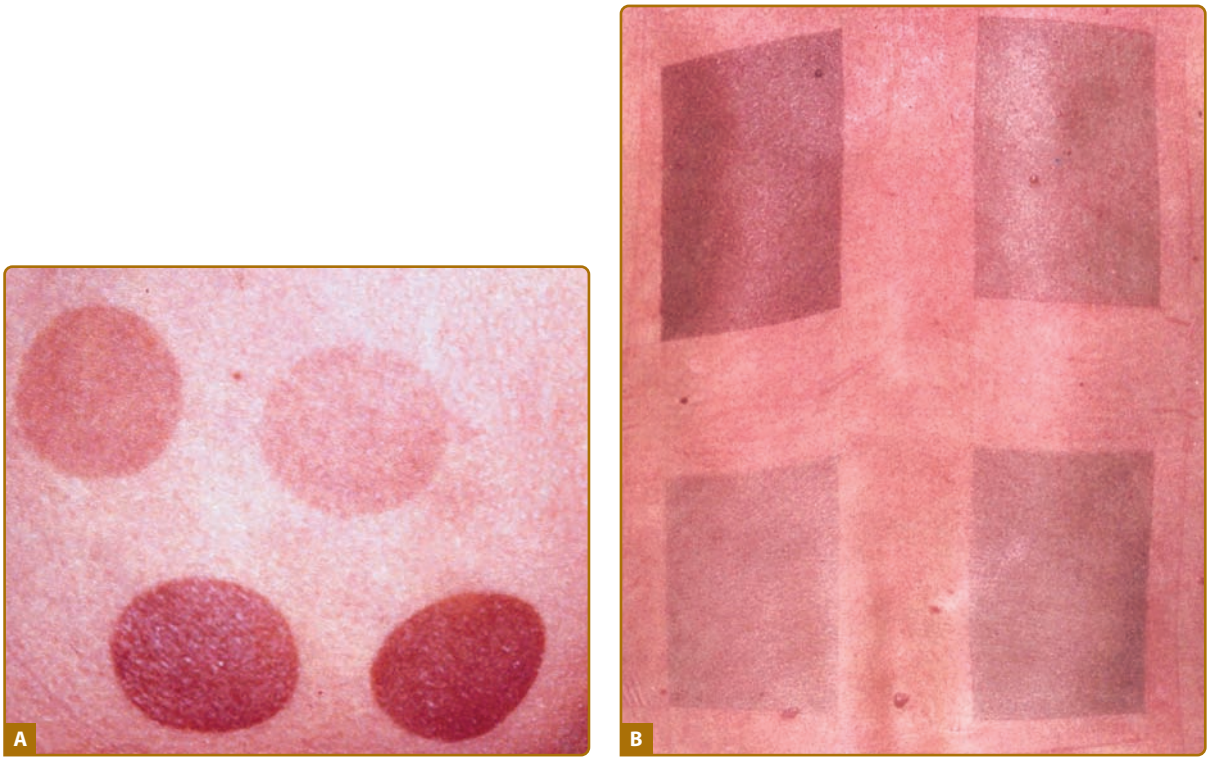

Figure 72-13 **A.** Delayed tanning. Four template test sites in a phototype III individual were exposed to repeated erythemogenic doses of ultraviolet B (UVB) (+UVA) delivered in 24-hour intervals, and the photograph was taken 10 days after the last exposure. The tan in the more heavily pigmented test sites persisted for 2 months. **B.** Immediate tanning in a phototype III individual. Four template test sites were exposed to various doses of UVA, and the photograph was taken 2 hours after the end of exposure. After 48 hours, the tan had almost completely faded.

DIRECT EFFECTS. UV irradiation triggers several biological reactions through its interaction with cellular chromophores that absorb photons. Photochemical reactions affect proliferation, survival, and the differentiated function of melanocytes. Most UVA effects are assumed to be the result of oxidative damage mediated through UVA absorption by cellular chromophores like melanin precursors that act as photosensitizers leading to the generation of ROS and free radicals.[275] UVB irradiation is directly absorbed by cellular DNA, leading

TABLE 72-1
Immediate Tanning versus Delayed Tanning

	Immediate	Delayed
Onset	Minutes	3–4 days
Peak intensity	Minutes to few hours	10–28 days
Fading	Within 24 hours	Weeks
Mechanism	Redistribution of melanosomes	↑Keratinocyte-derived melanogenic cytokines ↑Tyrosinase level and activity ↑Melanin synthesis ↑Melanocyte dendriticity ↑Melanosome number ↑Melanosome transfer ↑Melanocyte proliferation
Photoprotection	Unchanged	Increased
Change in skin color	Undetectable in fair skin Subtle in darker skin	Obvious in most light-skinned and all dark-skinned individuals

to the formation of DNA lesions, mainly cyclobutane dimers and pyrimidine (6–4) pyrimidone photoproducts.[276] DNA damage repair systems are activated, at least in part through the tumor suppressor p53 protein. It has been shown that plasma membrane lipids are also affected by UV irradiation to release DAG,[277] which then activates PKC-β to stimulate melanogenesis by activating tyrosinase (see above).

INDIRECT EFFECTS. Key keratinocyte paracrine factors induced by UV irradiation and their effects on melanocytes are summarized in eTable 72-1.1 in online edition. These factors can act alone and/or synergistically to modulate melanocyte function. Interestingly, UV irradiation also induces the level of TNF-α and IL-1, cytokines that inhibit melanogenesis, suggesting a fine-tuned epidermal equilibrium between melanogenic stimulators and inhibitors after UV irradiation, with the final outcome of increased melanogenesis and melanocyte proliferation.

THE ROLE OF DNA DAMAGE IN MELANOGENESIS

Interestingly, the action spectrum for tanning is virtually the same as that for the formation of thymine dimers,[278,279] and UV-induced melanogenesis can be augmented in pigment cells by treatment with T4 endonuclease V,[276] an enzyme that acts exclusively to enhance the repair of UV-induced DNA damage. Moreover, treatment of melanocytes with agents that act exclusively by damaging DNA, unlike UV that has multiple cellular targets, also stimulates melanogenesis.[280]

A central role for DNA damage and/or its repair in stimulating melanogenesis is further suggested by the fact that p53, a tumor-suppressor protein and transcription factor termed the Guardian of the Genome, when activated, upregulates the level of tyrosinase mRNA and protein, enhancing melanogenesis.[281–284] Thus, tanning may be viewed as part of a p53-mediated DNA damage adaptive response that protects the skin during subsequent exposure to UV irradiation.

p53 IN UV-INDUCED MELANOGENESIS. A central role for DNA damage and/or its repair in stimulating melanogenesis is further supported by the fact that the tumor-suppressor protein p53, when activated, upregulates the level of tyrosinase mRNA and protein, enhancing melanogenesis.[281–285] In p53 knockout mice, it was observed that UV irradiation of the ears (that contain interfollicular melanocytes) minimally stimulates melanogenesis, compared to the far greater "tanning" response in p53 wild-type mice.[282] These findings were expanded by Cui et al,[286] who found a p53 consensus sequence in the POMC gene promoter, thus establishing a continuous signaling pathway from UV-induced DNA damage to the final tanning response. It was shown in mice keratinocytes that following UV irradiation p53 activation stimulates POMC transcription, thereby increasing the release of POMC-derived α-MSH, a key physiologic inducer of melanogenesis. Keratinocyte-derived α-MSH then stimulates MC1R on melanocytes, resulting in increased production of eumelanin.[286]

It has also been shown that p53 transcriptionally upregulates the hepatocyte nuclear factor-1α (HNF-1α) that is a transcription factor for tyrosinase.[287] Thus, even in keratinocyte absence, UV directly activates p53 and HNF-1α in melanocytes to increase tyrosinase transcription. Furthermore, UV is known to increase H_2O_2 that activates p53.[288] Thus, tanning may be viewed as part of a p53-mediated DNA damage adaptive response aimed at protecting the skin from subsequent UV irradiation.[282,283,289]

MELANOCYTE AGING AND PHOTOAGING

Epidermal melanocyte aging is affected by both genetic and environmental factors. With aging, there is a decrease in the density of epidermal melanocytes (number per unit area of skin surface), approximately 10% per decade.[290] However, the number of DOPA-positive melanocytes is greater in chronically sun-exposed skin than in sun-protected skin,[290] possibly due to melanocyte proliferation after sun exposure and/or UV-induced keratinocyte-derived paracrine factors. Melanocyte loss is especially notable in hair follicles with age, with total loss of melanocytes in approximately half of all scalp follicles by middle age.[37] Hair graying (depigmentation) occurs over the entire body but is usually first noted on the scalp, perhaps because of the long anagen (growth) cycle and resulting requirement for melanocyte proliferation and sustained high level of melanogenesis.

In vitro melanocytes derived from older individuals show decreased proliferative capacity compared to those derived from younger individuals. Also, with aging in vitro, there is a general increase in the levels of total melanin as well as in the level differentiation-associated proteins such as MITF, TRP-1, and TRP-2[291,292] and decrease in the level of proliferation-associated proteins such as cyclin D1 and E.[291,292]

Chapter 73 :: Albinism and Other Genetic Disorders of Pigmentation

:: Thomas J. Hornyak

ALBINISM AND CONGENITAL DISORDERS OF PIGMENTATION AT A GLANCE

- Worldwide occurrence
- Albinism is usually inherited as a recessive trait, but other congenital disorders of pigmentation are usually inherited as dominant traits. There can be marked differences in penetrance.
- Clinical features of albinism may include lightly pigmented or nonpigmented skin and silvery-white or light hair color.
- Ocular nystagmus and reduced visual acuity are important features of albinism that distinguish albinism from other congenital disorders of pigmentation.
- Clinical features of congenital disorders of pigmentation include patches of white hair (poliosis), variations in iris color, and depigmented patches of white skin.
- The presence of ocular nystagmus is useful for distinguishing albinism from congenital disorders of pigmentation.
- Albino skin contains melanocytes with reduced or absent DOPA-positivity. Depigmented patches in congenital disorders of pigmentation lack melanocytes.

EPIDEMIOLOGY

EPIDEMIOLOGY OF ALBINISM

Oculocutaneous albinism (OCA) is the most common inherited disorder of generalized hypopigmentation, with an estimated frequency of 1 in 20,000 in most populations. Four different types of OCA have been described. OCA1 and OCA2 are the most frequent types and account for approximately 40% and 50%, respectively, of OCA worldwide. OCA2 occurs in approximately 1 in 30,000 to 1 in 36,000 Caucasians and 1 in 10,000 to 1 in 17,000 blacks in the United States,[1–3] but is reported at higher frequencies ranging from 1 in 1,400 to 1 in 7,000 in Sub-Saharan Africa[4,5] and even as high as 1 in 170 individuals in the Kuna population of the Panama coast.[6] OCA3 and OCA4 are far less frequent, although the rufous OCA phenotype, described later, associated with OCA3 in South African blacks has been reported at an incidence of approximately 1/8,500,[7] while OCA4 accounts for 27% of all cases of OCA in Japan.[8]

Hermansky–Pudlak syndrome (HPS) is rare except in the Caribbean island of Puerto Rico, particularly in the northwestern region where the majority of patients are found, with an incidence of 1 in 1,800.[9] Chediak–Higashi syndrome is also quite rare.

BOX 73-1 DIFFERENTIAL DIAGNOSIS OF ALBINISM

- OCA types 1–4
- Hermansky–Pudlak syndrome
- Griscelli syndrome
- Chediak–Higashi syndrome
- Ocular albinism
- Currently unclassified types of albinism
- Tietz syndrome
- Vitiligo (extensive)
- Ziprkowski–Margolis syndrome (X-linked albinism–deafness syndrome)
- Cross (Cross–McCusick–Breen) syndrome (oculocerebral syndrome with hypopigmentation)

TABLE 73-1
Characteristics of Albinism

Disease	Chromosome	Gene Locus	Protein [Biogenesis of Lysosome-Related Organelles Complex (BLOC)]	Distinguishing Signs
Oculocutaneous albinism type 1	11q21	*TYR*	Tyrosinase/TYR	Type 1A—no pigment Type 1B—some pigment
Oculocutaneous albinism type 2	15q11.2-q12	*P*	Pink protein/P	Some pigmentation apparent; nevi and freckles possible
Oculocutaneous albinism type 3	9p23	*TYRP1*	Tyrosinase-related protein-1/TYRP1	Similar to OCA2 phenotype. Includes rufous (red) albinism phenotype.
Oculocutaneous albinism type 4	5p	*MATP*	Membrane-associated transporter protein/MATP	Similar to OCA2 phenotype. Most common in individuals with Asian biogeographic ancestry.
Hermansky–Pudlak syndromes				
Type 1	10q24	*HPS1*	HPS1 (BLOC-3)	Pulmonary fibrosis associated; absent platelet dense granules is a hallmark of all types of HPS
Type 2	15q15	*AP3B1*	β-3 subunit of adaptor protein 3 complex/AP3B1	
Type 3	3q24	*HPS3*	HPS3 (BLOC-2)	
Type 4	22q11.2-q12.2	*HPS4*	HPS4; distant homology with yeast CCZ1 (BLOC-3)	Pulmonary fibrosis associated
Type 5	11p14	*HPS5*	HPS5 (BLOC-2)	
Type 6	10q24.32	*HPS6*	HPS6 (BLOC-2)	
Type 7	6p22.3	*DTNBP1*	Dysbindin (BLOC-1)	
Type 8	?	*BLOC1S3*	BLOC1S3 (BLOC-1)	
Chediak–Higashi syndrome	1q43	*LYST*	Lysosome trafficking/LYST	Giant peroxidase-positive lysosomal granules in neutrophils

EPIDEMIOLOGY OF CONGENITAL DISORDERS OF PIGMENTATION

Waardenburg syndrome (WS) is probably less frequent than OCA. The highest reported incidence is 1/20,000 in Kenya, although most estimates of its incidence in the Netherlands where it was originally reported are in the range of 1/40,000. The incidence of WS with deafness is lower, ranging between 1/50,000 and 1/212,000. WS has been described occurring in a range of frequencies in the congenitally deaf, ranging from 0.9%–2.8% to 2%–5% in different reports. The incidence of piebaldism is estimated to be less than 1/20,000.[10,11]

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES

Awareness of the biologic basis of the distinction between congenital disorders of pigmentation, which are disorders of melanocyte development, and the varieties of albinism, which are disorders of melanocyte differentiation, is important for fully understanding their clinical manifestations. Albinism results from the dysfunction of a normal complement of pigment cells, which results in complete or partial loss of cutaneous pigmentation. The forms of albinism, including the subtypes of OCA as well as albinism syndromes with systemic manifestations, result either from enzymatic defects in the biosynthesis of melanin, from melanosomal defects that interfere with melanin formation, or from problems in the intracellular transport and localization of proteins essential for melanin biosynthesis (Table 73-1; see Chapter 72). Congenital disorders of pigmentation usually result from mutations in genes critical for melanocyte development during embryogenesis. These disorders can also be associated with other systemic problems because of the requirement for these gene products in the development of cell types other than melanocytes. More accurate descriptors of these disorders could be *congenital* (or *genetic*)

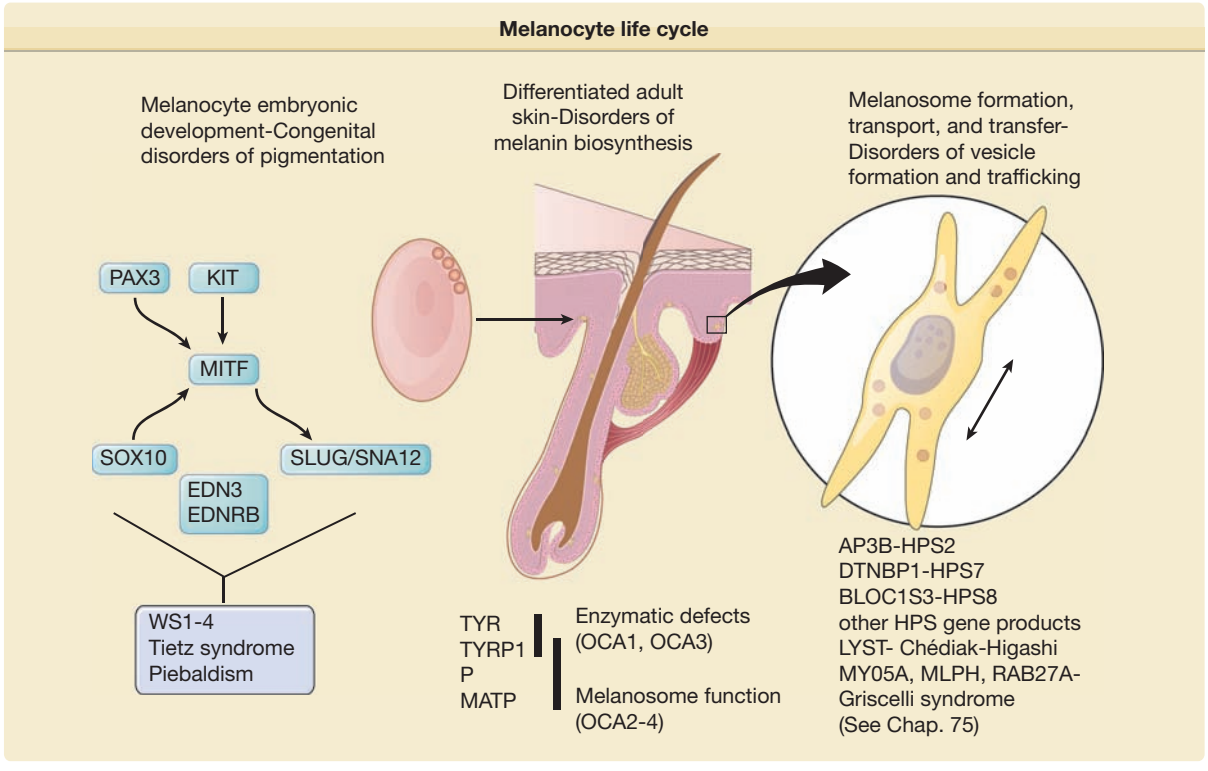

Figure 73-1 Schematic diagram illustrating the steps of the melanocyte life cycle, from development through differentiation, where key genes, altered in the indicated genetic diseases, act to control the function of the melanocyte.

disorders of melanocyte differentiation and *congenital* (or *genetic*) *disorders of melanocyte development*, to reflecting the fact that both categories of conditions, albinism and developmental pigmentary syndromes, are generally inherited but result from different mechanisms of disease (Fig. 73-1).

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES OF ALBINISM

Although the pigmentary abnormalities associated with types of albinism can vary widely, common to all types of albinism is reduced visual acuity and ocular nystagmus, a result of misrouting of the optic nerve at the optic chiasm and foveal hypoplasia. This has been described not only in humans[12] but also in other albino mammals.[13] Experiments using the tyrosinase promoter to express both tyrosinase and tyrosine hydroxylase in albino transgenic mice suggest that the tyrosine hydroxylase activity of tyrosinase is particularly important for ensuring the proper routing of retinal projections at the optic chiasm during development.[14,15] The ocular manifestations of albinism can vary greatly, ranging from severe (20/400) to nearly undetectable, but is often close to 20/80.[16] They also include a reduction in iris pigment, a reduction in retinal pigment, and alternating strabismus.

OCULOCUTANEOUS ALBINISM TYPE 1.

OCA1 [Online Mendelian Inheritance in Man (OMIM) #203100] is caused by loss of function of the melanocytic enzyme tyrosinase resulting from mutations of the *TYR* gene.[17–19] Null mutations are associated with a total loss of function and no pigment formation (OCA1A), whereas "leaky" mutations result in an enzyme that retains some function and is associated with some pigment formation (OCA1B). OCA1 appears to be the most common type of albinism in non-Hispanic Caucasian patients.[20]

Analyses of DNA from individuals with OCA1A have shown a large number of different mutations in the *TYR* gene. These mutations include missense, nonsense, frameshift, splice site, and deletion mutations. Most individuals with OCA1 are compound heterozygotes with different mutant maternal and paternal alleles.[7] Missense mutations in the *TYR* gene are distributed among distinct regions of the coding sequence, which suggests that the encoded protein has multiple functional domains. Two of the clusters are in the copper-binding regions, with a third near the amino-terminus of the mature protein, in the extramelanosomal domain of tyrosinase shown to require phosphorylation for enzyme activation.[21,22] Clustering of mutations in discrete regions of the coding sequence is consistent with these regions' importance either for the melanogenic activity of tyrosinase or for functions related to its maturation or processing.[7,22] Missense mutations at the signal peptide cleavage site[23,24] implicate this cleavage event as an important step in the development of tyrosinase activity. Frameshift mutations near the *C*-terminus of the coding region[25,26] indicate that the cytoplasmic domain of tyrosinase is also important for full activity, possibly because of the presence of protein kinase C-β-dependent

Figure 73-2 OCA1A with no hair or skin pigment, demonstrating iris translucency.

Figure 73-3 OCA1B with golden blond scalp hair and tan.

phosphorylation sites that have been identified at its extreme *C*-terminus.[22]

All nonsense and frameshift mutations are associated with a complete loss of tyrosinase activity, presumably because of the subsequent production of a truncated protein. With missense mutations the picture is more complicated. A set of missense mutations that were associated with OCA1 patients accumulating pigment with age in either OCA1B or temperature-sensitive OCA (OCA1TS) patients[27] were shown to have residual enzymatic activity. Hence, it is likely that a subset of *TYR* missense mutations are responsible for the OCA1B and OCA1TS phenotypes because of the reduced, rather than absent, tyrosinase activity in their melanocytes.[7] However, other missense mutations resulting in the OCA1A and OCA1TS phenotypes result in defective intracellular processing of tyrosinase and retention of the mutant tyrosinase proteins in the endoplasmic reticulum, which suggests that some molecular variants of OCA1 represent an endoplasmic reticulum retention disease.[28–30] Thus, the residual enzymatic activity of a missense tyrosinase mutant cannot fully predict its phenotype, because other, presumably conformational, determinants of nascent mutant proteins may lead to their retention in the endoplasmic reticulum, block transport to the melanosome, and cause a more severe pigmentary phenotype.

In OCA1A, or the classic tyrosinase-negative OCA, there is a complete inability to synthesize melanin in skin, hair, and eyes, resulting in the characteristic "albino" phenotype. Affected individuals are born with white hair and skin and blue eyes, and there are no changes as they mature. The phenotype is the same in all ethnic groups and at all ages (Fig. 73-2). The hair may develop a slight yellow tint due to denaturing of the hair protein due to sun exposure and/or shampoo use. The irides are translucent, appear pink early in life, and often turn a gray–blue color with time. No pigmented lesions develop in the skin, although amelanotic nevi can be present. The architecture of skin and hair bulb melanocytes is normal. The melanosomes show a normal melanosomal membrane, and normal internal matrix formation is observed in stage 1 and 2 melanosomes.

The phenotype of OCA1B can range from minimal hair pigment to skin and hair pigmentation approaching the normal pigmentary phenotype for the individual's genetic composition and continental ancestry. Most individuals with OCA1B have very little or no pigment at birth and develop varying amounts of melanin in the hair and skin in the first or second decade of life (Fig. 73-3). In some cases the melanin develops within the first year. The hair color changes to light yellow, light blond, or golden blond first, as a result of residual pheomelanin synthesis, and eventually can turn dark blond or brown in adolescents and adults. The irides can develop light-tan or brown pigment, sometimes limited to the inner third of the iris, and iris pigment can be present on globe transillumination. However, some degree of iris translucency, as demonstrated by slit lamp examination, is usually present. Many individuals with OCA1B will tan with sun exposure, although it is more common to burn without tanning. Pigmented lesions (nevi, freckles, lentigines) develop in the skin of individuals who have developed pigmented hair and skin. In some patients, the moderate amount of residual tyrosinase activity can lead to near-normal cutaneous pigmentation, so that the clinician may overlook subtle cutaneous pigmentary abnormalities and render instead the mistaken diagnosis of ocular albinism (OA).

One variation of OCA1B is the temperature-sensitive phenotype. In this variation, scalp and axillary hair remain white or slightly yellow, but arm and leg hair pigments. The skin remains white and does not tan. The retention of melanin synthesis in the cooler areas of the body, such as the arms and legs, but not

the warmer areas, such as the trunk and the scalp, is associated with a temperature-sensitive mutation in tyrosinase, which loses activity above 35°C.[27] Similar tyrosinase mutations have been described in the Himalayan mouse[31] and in the Siamese cat with dark "points" at the tips of the ears and on the paws.[32]

OCULOCUTANEOUS ALBINISM TYPE 2.

Mutations of the *OCA2 (P)* gene, which maps to chromosome arm 15q, are responsible for OCA2 (OMIM #203200).[33] OCA2 occurs worldwide, though somewhat more frequently in the African, African-American, and certain Native American populations. Historically, affected individuals have benefited from limiting their sun exposure, especially in desert and equatorial climates. Interesting anthropological studies have described how various societies have differed in their treatment of members with OCA2. For example, the Cuna Indians of Panama actively forbade marriage between female and male albinos, and infanticide against albino infants was common in the early twentieth century. In contrast, no marriage discrimination was practiced in Hopi tribes, whose albinos were not expected to participate in farming activities requiring substantial exposure to sunlight.[34] From the standpoint of melanin synthesis, the defect in OCA2 appears to involve a reduction in eumelanin synthesis primarily, with less effect on pheomelanin synthesis. The predicted structure of the *OCA2* gene, a melanosomal protein, includes 12 transmembrane domains.[35,36] As expected, a number of mutations of the human *OCA2* gene are associated with human OCA2.[37,38]

In Sub-Saharan Africa, a single 2.7-kb deletion allele accounts for 60%–90% of mutant *OCA2* alleles and is associated with a common haplotype, suggesting a common founder.[5,38–40] It has been estimated that this single mutation is associated with 25%–50% of all mutant *OCA2* alleles in African-Americans.[5,38–44] However, other diverse mutant alleles have been described in this population and in Africans. The Brandywine, Maryland, isolate affects an inbred American population, originally located in a rural area east of Washington, DC, that has been studied extensively for its prevalence of albinism, dentinogenesis imperfecta, and other inherited recessive and dominant conditions, with mixed Caucasian, African, and possibly Native American ancestry.[45] In this population, 1 in 85 individuals has OCA2[45,46] and is homozygous for the 2.7-kb deletion allele of *OCA2*.[38] Thus, it is likely that this 2.7-kb deletion allele accounts for the distinct OCA2 phenotype in Africans and African-Americans.[47]

OCA2 also has been reported at relatively high frequencies ranging from 1 in 28 to 1 in 6,500 in specific Native American groups, including those populations in the southwest United States (Hopi population), southern Mexico, eastern Panama (Kuna population), and southwest Brazil.[34] In the Navajo population, a homozygous 122.5-kb deletion has been described in members with OCA2. This mutations results in the loss of exons 10 to 20 of *OCA2*, corresponding to a region containing seven of the transmembrane domains, and appears to be specific for OCA2 within the Navajo population.[48] On the other hand, OCA2 in the Kuna population is caused by a splice site mutation in intron 17 of *OCA2*.[49] Unlike the mutations in *TYR*, the missense mutations described to date in *OCA2* do not seem to cluster in any specific region.

Figure 73-4 OCA2 with yellow hair, white skin, and freckles in an African individual (classic tyrosinase-positive OCA phenotype).

Regarding *OCA2* gene product function, it has been shown that melanosomes from P protein-deficient melanocytes have an abnormal pH. Melanosomes in cultured melanocytes derived from wild-type mice are typically acidic, whereas melanosomes from P protein-deficient mice are nonacidic.[50] Hence, it is likely that the P protein regulates the pH of melanosomes, perhaps by functioning as an anion cotransporter in conjunction with a distinct proton pump on the melanosomal membrane. An alternate possibility is that the acidic conditions mediated by the P protein favor the normal biogenesis of melanosomes, including the correct targeting of other melanosomal proteins such as tyrosinase.[51] Single nucleotide polymorphisms in the first intron of *OCA2* are the major determinant of brown versus blue iris color,[52] and a germ line polymorphism of the *OCA2* gene is associated with favorable survival of estrogen receptor-negative breast cancer.[53] Conceivably this finding may be related to the previously reported enhanced sensitivity of cells overexpressing P protein to cytotoxic agents.[54]

In African and African-American individuals, there is a distinct OCA2 phenotype (Fig. 73-4). Hair is yellow at birth and remains so throughout life, although the color may turn darker. Hair color can turn lighter in older individuals, and this probably represents the normal graying with age. The skin is creamy white at birth and changes little with time. No generalized skin pigment is present, and no tan develops with sun exposure, but pigmented nevi, lentigines, and freckles often develop, since the cutaneous melanocytes in these individuals both remain susceptible to ultraviolet (UV)-induced changes early in life and retain some ability

to synthesize melanin later. The irides are blue–gray or light tan or brown. The development of lentigines or ephelides, well-demarcated pigmented patches usually on sun-exposed areas of the skin, may be evidence of a separate genetic susceptibility because these lesions only develop in some OCA2 families and not in others. The presence versus absence of ephelides is associated with a lower risk of skin cancer in South African albinos,[55] probably because the ability to produce ephelides by albinos in that environment also signifies a greater ability to produce pigment and thus demonstrate increased protection from UV radiation.

In Caucasian individuals with OCA2, the amount of hair pigment present at birth or developing with time varies from minimal in northern Europeans (particularly Scandinavians) to moderate in southern European or Mediterranean individuals. The hair can be very lightly pigmented at birth, having a light yellow or blond color, or more pigmented with a definite blond, golden blond, or even red color. The skin is creamy white and does not tan. The iris color is blue–gray or lightly pigmented, and the amount of translucency correlates with the development of iris pigment. With time, pigmented nevi and lentigines may develop, and freckles are seen in areas with repeated sun exposure. The hair in Caucasian individuals may slowly turn darker through the first two or more decades of life.

The normal delayed maturation of the pigment system and sparse hair early in life can make it difficult to recognize albinism early in northern European individuals. For all types of OCA in northern European families, the cutaneous hypopigmentation at birth or early in life is often similar to that of the parents and relatives, and the first concern is raised when it appears that the child is not tracking well or has developed nystagmus.

PRADER–WILLI AND ANGELMAN SYNDROMES.

Prader–Willi and Angelman syndromes often are associated with hypopigmentation.[57,58] The intragenic deletion encompassing one *P* allele in these patients[59,60] suggests that the observed pigmentary phenotype is related to OCA2 and the *P* gene, even if the details of this association are not fully understood.[47]

PRADER–WILLI AND ANGELMAN SYNDROMES

OCULOCUTANEOUS ALBINISM TYPE 3.

Mutations in the *TYRP1* gene result in OCA3 (OMIM #203290). The first described mutation was in an African-American newborn twin initially classified clinically as brown OCA. Mutation analysis revealed a single-base deletion at codon 368 producing a frameshift and premature stop codon in exon 6 and a slightly truncated TYRP1 molecule.[63] This mutation is shared by a substantial proportion of the rufous ("red") OCA population in southern Africa.[64] Rufous OCA is a distinct OCA phenotype in which the skin color is a mahogany brown with a slight reddish hue, and the hair color varies from deep mahogany to sandy red.[2,64] Additional OCA3-associated *TYRP1* mutations include a single-base substitution at codon 166, resulting in the alteration of a serine to a premature stop codon in exon 3 and a truncated TYRP1 molecule,[64] also identified in the rufous OCA population; and, in a Pakistani kindred, individuals homozygous for a distinct premature termination mutation.[65] A Caucasian male was compound heterozygous for a missense mutation in *TYRP1* located in the second copper-binding domain, inherited from the patient's mother, and a stop codon, which apparently occurred spontaneously.[66] Interestingly, the *p.S166X* mutation in TYRP1 previously associated with rufous OCA[64] was found to modify an OCA2 phenotype to a red-haired variant.[67]

OCA3 has presented with both the brown OCA and the rufous OCA phenotypes in the African and African-American populations. In the two cases of individuals with *OCA3* mutations only, not of African descent, the phenotype has been that of a tyrosinase-positive albinism, such as OCA1B or OCA2. As additional examples of OCA3 are characterized, genotype–phenotype correlation should become clearer.

PATHOGENESIS OF OCA3

HERMANSKY–PUDLAK SYNDROME.

Mutations in eight different genes to date have been associated with types of HPS.[70] Currently, our understanding about the function of their gene products varies greatly. However, a common theme is their functional involvement in trafficking cell type-specific products in cells containing lysosome-related organelles (LROs), including melanosomes in melanocytes.

HPS patients have OCA, with variable hypopigmentation of the skin, hair, and irides, and ocular abnormalities (see Fig. 73-5 and eFigs. 73-4.1, 73-5.1–73-5.3 in online edition). In addition, they lack platelet dense bodies and demonstrate a prolonged bleeding time, mucous membrane bleeding, a predisposition to epistaxis, easy bruising, and metromenorrhagia.[75] Whole-mount electron microscopy is used to provide a definitive determination of the absence of platelet dense bodies.[76]

The greatest clinical experience exists with patients with HPS1 (OMIM #604982), HPS3 (OMIM #606118), and HPS4 (OMIM #606118). Pulmonary fibrosis is a common and severe manifestation of HPS1 and HPS4, generally causing death between the fourth and sixth decades of life.[70,77] However, pulmonary fibrosis appears not to be associated with HPS3, which also features less severe pigmentary abnormalities.[78–80] Among HPS1 and HPS4 patients, a granulomatous colitis is associated, occurring in approximately 15%.[81,77] Ceroid lipofuscin, a complex lipid-protein material, has been reported to accumulate in the cells of HPS patients, predominantly those with HPS1.[75]

Mutations in distinct genes, rather than clinical phenotypes, define the various types of HPS. For example, more than two dozen distinct mutations have been found in *HPS1* that cause disease.[76–78] The most common, found in over 400 Puerto Rican individuals, is a 16-base pair (bp) frameshift duplication in exon 15.[79,80] Although the precise function of HPS1

Figure 73-5 Puerto Rican HPS1 patient. The patient died of pulmonary fibrosis.

protein is not yet known, HPS1 associates with HPS4 in the 200 kDa BLOC-3 (biogenesis of LROs complex-3) complex[81] and has also been found in association with HPS4 in a larger, 500-kDa complex in melanoma cells and fibroblasts.[82–84] In melanocytes cultured from the skin of HPS1 patients, the melanogenic enzymes TYR, TYRP1, and DCT/TYRP2 are found in large vesicular structures in the cell body and dendrites, instead of in the granular pattern typically associated with melanosomal localization,[85,86] suggesting a role in the control of protein trafficking to the melanosome. Mutations in *HPS4* have been described in 15 patients,[76] although its exact cellular role is not yet known. Functionally, the ATP-dependent pump MRP4 (ABCC4), normally localized to platelet granules and the plasma membrane, was found to be greatly reduced in HPS4 platelets.[87]

Mutations or deficiencies in the *AP3B1* gene, encoding the β_{3A} subunit of adaptor complex 3 (AP-3), one of the four known APs, cause HPS2 disease.[88] AP-3 interacts with tyrosinase, which is not targeted properly to melanosomes in *AP3B1*-deficient melanocytes. Hence, AP-3 protein is required for the trafficking of tyrosinase, and possibly other melanosomal proteins, from an intracellular site to melanosomes. Interestingly, the subcellular distribution of TYRP1 is unchanged in HPS2 melanocytes, suggesting that TYRP1 transport, in contrast to tyrosinase, is not entirely dependent upon the AP-3 mechanism.[89] The respiratory infections associated with HPS2 may be due to the abnormal movement of lytic granules in cytotoxic T lymphocytes (CTLs) to the immunologic synapse, leading to impairment of microbial killing.[90]

The most commonly described mutation in *HPS3* is a 3904-bp deletion mutation that includes the entire first exon, found in a Puerto Rican population, which is distinct from the *HPS1* Puerto Rican mutation.[72] In addition, a splice site mutation has been described in Ashkenazi Jews with HPS3 who are either homozygous for this mutation or compound heterozygous for this mutation and other, nonconserved mutations.[73] The HPS3 protein associates with the HPS5 and HPS6 proteins in the 340-kDa BLOC-2 complex.[91,92] Melanocytes from HPS3 patients exhibit defective localization of tyrosinase and TYRP1 in later stage melanosomes, whereas proteins normally incorporated into early-stage melanosomes, such as silver/Pmel17/gp100 and melan-a/MART1, are unaffected.[85,93] These melanocytes exhibited lower levels of melanin than control melanocytes, suggesting that the trafficking defect in tyrosinase, and perhaps also TYRP1, is responsible for the pigmentary dilution that can be observed in these patients.

GRISCELLI SYNDROME. Griscelli syndrome is discussed in Chapter 75.

CHEDIAK–HIGASHI SYNDROME CHS (OMIM #214500). CHS is a rare autosomal recessive disorder characterized by severe immunologic defects, hypopigmentation, bleeding tendency due to absent or reduced platelet dense bodies,[94] progressive neurologic dysfunction, and the presence of giant peroxidase-positive lysosomal granules in peripheral blood granulocytes.[95,96] Mutations in the *LYST* (lysosomal regulator trafficking) gene have been associated with Chediak–Higashi syndrome.[97] Although the precise role of the *LYST* product is not known, structural comparisons and inferences from the cell biology of *LYST* mutant cells suggest it may be important for membrane fusion during vesicular transport from the trans-Golgi network to late endosomes and multivesicular structures.[96,97]

Most patients with CHS have a severe form of the disease, childhood CHS,[98] with early onset of the so-called *accelerated phase*, characterized by fever, anemia, and neutropenia, including a lymphoproliferative syndrome with hemophagocytosis and benign infiltration of most tissues by activated T lymphocytes. This form of the disease is uniformly fatal unless patients undergo allogenic bone marrow transplantation. However, this treatment does not prevent future neurologic complications.[69] Ten percent to 15% of patients exhibit a much milder clinical disease, adult CHS,[98] surviving to adulthood but developing progressive and often fatal neurologic dysfunction in middle age. Very rare patients exhibit the intermediate adolescent CHS phenotype,[98] which presents with severe infections in early childhood but has a milder course by adolescence and no accelerated phase. Interestingly, mutation analysis of patients with the childhood, adolescent, and adult forms of CHS showed that patients with severe childhood CHS had only functionally null mutant *LYST* alleles, whereas patients with the adolescent and adult forms of CHS tended to exhibit missense mutant

alleles that likely encode *LYST* polypeptides with partial function. Furthermore, some patients with the CHS phenotype do not have *LYST* mutations detectable with established techniques.[98]

The hypopigmentation phenotype of CHS is variable and can be quite mild. Hair color is light brown to blond, and commonly has a silvery or metallic sheen.[96] Iris pigment is present, and nystagmus and photophobia may be present or absent. Histologic studies of the eye in CHS have shown reduced iris pigment, a marked reduction in retinal pigment granules, and infiltration of the choroid with reticuloendothelial cells.[99] Cutaneous hypopigmentation is probably a consequence of both the giant, hypopigmented melanosomes clustered around the nucleus within CHS melanocytes, and their inefficient transfer to keratinocytes.[100] Pigment granules in the hair shaft are large and have an irregular shape.[101]

The giant, peroxidase-positive lysosomal granules in neutrophils are a hallmark of the disease. These granules appear to inhibit neutrophil function, which along with neutropenia commonly observed is a likely determinant of the recurrent bacterial infections.[96] CHS natural killer (NK) cells have defective lytic granule secretion,[102] and defective cytotoxic T lymphocyte-associated antigen 4 function has been proposed as a potential mechanism for the accelerated, lymphoproliferative stage of the disease.[103] A reduced number of irregular platelet dense granules in CHS is responsible for the bleeding diathesis component.[69,96]

BOX 73-2 DIFFERENTIAL DIAGNOSIS OF CONGENITAL DISORDERS OF PIGMENTATION

- Waardenburg syndromes types 1–4
- Tietz syndrome
- Piebaldism
- Woolf's syndrome
- Generalized vitiligo
- Segmental vitiligo
- Vogt–Koyanagi–Harada syndrome
- Chemical leukoderma
- Tuberous sclerosis (hypopigmented macules and patches)
- Ziprkowski–Margolis syndrome (X-linked albinism–deafness syndrome)

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES OF CONGENITAL DISORDERS OF PIGMENTATION

WAARDENBURG SYNDROME. WS, described by the Dutch physician Petrus Waardenburg in 1951,[104] is the prototypic congenital disorder of pigmentation. Although it was originally described as a syndrome combining pigmentary defects of the hair (poliosis or white forelock) and iris, congenital deafness, and developmental craniofacial abnormalities, it was subsequently realized that additional phenotypic manifestations could be part of the same syndrome. Four types of WS, WS1 through WS4, have been described.[105–110] The discovery of molecular mutations accounting for the different types of WS has helped to explain its wide variety of manifestations as well as to illuminate the importance of specific genes for the development of different tissues and organs (Table 73-2). While practically all cases of WS1 and WS3 show mutated *PAX3*,[105,105,109,110] WS4 individuals either have homozygous mutations in *EDN3* (the endothelin-3 gene)[111–113] or *EDNRB* (the endothelin-B receptor gene)[114] or heterozygous mutations in *SOX10*.[115] On the other hand, WS2 appears to arise more heterogeneously, as a mutation in *MITF* has been shown in only a small fraction of WS2 patients.[107,108]

Waardenburg Syndrome Type 1. Individuals with WS1 (OMIM #193500) are usually heterozygous for mutations in *PAX3*; hence, WS1 is autosomal dominant in inheritance. Although many different mutations in *PAX3* have been associated with WS1, these mutations are thought either to be functionally

TABLE 73-2
Waardenburg and Tietz Syndrome Characteristics

Disorder	Clinical Signs	Mutated Gene(s)
Waardenburg syndrome (WS) type I	Hypopigmented patches, heterochromia irides, dystopia canthorum, sensorineural deafness (~75%)	*PAX3*
WS type II	Same as type I, but no dystopia canthorum	*MITF* *SNAI2/SLUG* (homozygous)
WS type III	Same as type I with limb abnormalities	*PAX3*
WS type IV	Same as type I with Hirschsprung's disease (congenital aganglionosis of the colon)	*EDN3* *EDNRB* *SOX10*
Tietz syndrome	Generalized hypopigmentation and sensorineural deafness	*MITF*

Figure 73-6 Waardenburg syndrome type 1. Note poliosis (white forelock) and dystopia canthorum (lateral displacement of the medial canthi of the eyes).

null alleles or to abrogate the interactions of PAX3 with DNA.[116]

Individuals with WS1 have pigmentation abnormalities associated with craniofacial abnormalities (see Fig. 73-6). Dystopia canthorum, which is lateral displacement of the medial canthi of the eyes, is the hallmark craniofacial defect found in virtually all cases of WS1. A broadening of the nasal root, the presence of hypoplastic alae nasi, and synophrys are other craniofacial abnormalities associated with WS1. Poliosis, such as the presence of a white forelock, is the most common pigmentation abnormality associated with WS1. Depigmented white spots on the skin occur less commonly, but are often located at the ventral midline reflecting the compromised migration of dysfunctional melanocyte precursors from their origin in the dorsal neural crest. Pigmentary abnormalities of the iris, including complete heterochromia irides (differently colored irises), partial heterochromia irides (variations of color within an iris), or hypoplastic blue irides, can also be associated with WS1. Premature graying may also be observed in WS1. Congenital deafness is present in 57% of cases.[117]

The importance of PAX3 for the expression of MITF,[118,119] with consequent effects upon melanocyte survival during development, is likely to account for the pigmentary defects of WS1. A role for *PAX3* in governing the development of neural crest derivatives that contribute to bony and cartilaginous structures of the face,[120] particularly those contributing to the formation of the frontal bone, explain the craniofacial anomalies observed in WS1. Sensorineural deafness, observed with incomplete penetrance in WS1, results from the variable failure of melanoblasts to migrate to or to survive in the stria vascularis in the lateral wall of the cochlea.[121,122]

Waardenburg Syndrome Type 2. Linkage analysis of families with WS2 (OMIM #193510, 608890, 600193, 606662) identifed the *MITF* locus as a candidate locus for the disease gene. At least nine different of mutations have been found in the coding region of the *MITF* gene in WS2 families.[107,123] However, *MITF* mutations account for only a minor portion (15%) of WS2 cases. A mutation in the transcription factor gene *SLUG/SNAI2* has also been associated with WS2,[124] as have heterozygous deletion mutations in *SOX10*,[125] but mutations in other, as yet undefined genes are likely to be implicated in the future. WS2 is inherited in an autosomal dominant pattern. Since most of the known MITF mutations in WS2 compromise the HLHZip region, thereby interfering with dimerization of mutant MITF with wild-type MITF,[126] the pigmentary developmental pathology in most cases of WS2 probably occurs through haploinsufficiency (reduced gene dosage, expression, or protein activity) rather than through dominant-negative effects.[123] Tietz syndrome, described later, is likely to result from dominant-negative effects of mutant MITF.

That mutations in MITF cause a subtype of WS is mechanistically attractive because of the crucial importance of MITF in melanocyte survival during development. An epistatic relationship exists between PAX3 and SOX10 and MITF in melanocyte development during embryogenesis. PAX3 and SOX10, as transcription factors, synergically transactivate MITF.[33,34] Since mutations of PAX3 and SOX10 also cause auditory-pigmentary symptoms in other types of WS, it is likely that failure of MITF transactivation is the main determinant of pigment cell developmental dysfunction in these other subtypes as well. SLUG/SNAI2, as a transcriptional target of MITF,[35] may act in the same pathway as an important downstream MITF effector in melanocytes whose activity is inhibited in SLUG-associated WS2.

Although all types of WS have skin, hair, and iris pigmentation anomalies and the possibility of hearing loss, WS2 is notable for featuring only these auditory-pigmentary symptoms. Diagnostic criteria for WS2 have previously been defined.[116] Individuals fulfilling two of the following four criteria, in the absence of dystopia canthorum, limb deformity, or Hirschsprung disease, should be counted as affected:

1. Congenital sensorineural hearing loss
2. Pigmentary disturbance of iris
   a. Complete heterochromia irides (two eyes of different color)
   b. Partial or segmental heterochromia (segments of blue or brown pigmentation in one or both eyes)
   c. Hypoplastic blue irides (characteristic brilliant blue, with thin iris stroma, in both eyes)
3. Pigmentary disturbance of the hair
   a. White forelock from birth or in teens
   b. Premature graying before age 30 years
4. A first- or second-degree relative with two or more of criteria 1–3

A survey of 124 cases of WS2 and 270 cases of WS1 revealed differences of phenotypic penetrance between WS2 and WS1: congenital sensorineural hearing loss occurred in 77% and 57%, respectively; heterochromia irides in 48% and 27%, respectively; hypoplastic blue

eye in 9% and 17%, respectively; white forelock in 9% and 17%, respectively; early graying in 23% and 26%, respectively; and white skin patches in 6% and 31%, respectively. The higher incidence of hearing loss in WS2 may be due to the difficulty of diagnosing WS2 in individuals without hearing loss. The hearing loss is congenital, sensorineural, and nonprogressive, showing marked variation between and within families. Among 81 WS2 cases in one series, 84% of patients reported bilateral hearing loss; 40% of patients noted profound loss, whether unilateral or bilateral.[117]

Waardenburg Syndrome Type 3. WS3 (OMIM #148820), also known as *Klein–Waardenburg syndrome*, is regarded as a variant of WS1. Most affected persons are heterozygous for a mutation in *PAX3*, although a few severely affected homozygotes have been described.[109] No specific mutations in *PAX3*, with the possible exception of a missense mutation at Asp47, have been correlated with the WS3 phenotype rather than the WS1 phenotype, although individuals with either homozygous or compound heterozygous mutations in *PAX3* may tend to exhibit a severe WS3 phenotype instead of WS1.[127] In addition to the features of WS1, WS3 patients have musculoskeletal abnormalities, manifested as limb contractures and hypoplasia of the limb musculature. The WS3 phenotype is consistent with the previously described role of PAX3 in the activation of transcription factors that govern muscle and limb development,[128] distinct from its role regulating development of neural crest derivatives.

Waardenburg Syndrome Type 4. WS4 (OMIM #277580), also known as *Shah–Waardenburg syndrome*, is caused by heterozygous mutations in the transcription factor gene *SOX10*, or by homozygous mutations in the gene encoding the peptide ligand endothelin-3, *EDN3*, or its receptor, *EDNRB*.[129] In addition to governing aspects of melanocyte development, these genes are important determinants of the development of the distal aspect of enteric nervous system cells, also neural crest derived, that innervate the distal part of the colon, which explains the association with Hirschsprung's disease or congenital aganglionosis of the colon. WS4 is the combination of the WS1 phenotype with Hirschsprung's disease.

TIETZ SYNDROME.

Tietz syndrome[130] (OMIM #103500) is a hypopigmentation–deafness syndrome resulting, like WS2, from mutations in *MITF.* Tietz syndrome has been described in three families to date. In each case, the mutation is found in the region of the *MITF* gene encoding the DNA-binding domain. In two cases,[131,132] an in-frame deletion mutation (*DelR217*) has been described, which affects the DNA-binding basic domain of MITF, leaving the dimerization HLHZip domain intact and functional. In these heterozygous Tietz syndrome individuals, it is likely that DelR217-MITF binds with wild-type MITF and interferes with the ability of the dimer to bind to DNA, a dominant-negative effect. Indeed, the identical mutation in mice[133] causing a semidominant phenotype, a phenotype that is incomplete in the heterozygous state, in vivo with a mild heterozygous spotting phenotype, but a prominent homozygous phenotype with early embryonic loss of all melanocyte precursors,[134] was shown to have a dominant-negative effect in vitro.[126] In addition, another mutation described in the family originally reported with the syndrome is predicted to exhibit an Asn210Lys substitution in the basic region.[135] The localization of this mutation to the DNA-binding region also suggests that it has dominant-negative effects.

Although sometimes regarded as a variant of WS2A (MITF-associated WS2),[136] Tietz syndrome individuals exhibit generalized cutaneous hypopigmentation similar to that found in OCA2, rather than distinct depigmented patches. Reduced melanosomes in keratinocytes found in one affected individual[132] may account for the generalized hypopigmentation that is observed. Affected individuals invariably exhibit profound hearing loss. Interestingly, a child with a deletion on chromosome arm 3p encompassing the entire *MITF* locus not only exhibits generalized hypopigmentation reminiscent of Tietz syndrome but also mild craniofacial anomalies and retention of some hearing function, as can be seen in types of WS.[137]

PIEBALDISM.

Piebaldism (OMIM #17280) is caused by mutations in the *KIT* proto-oncogene.[138] Stimulation of the KIT receptor tyrosine kinase by its ligand, stem cell factor (SCF)/KIT ligand, results in the phosphorylation of MITF and potentiation of MITF activity.[139] This relationship between the KIT receptor and MITF, as a final common effector of melanocyte survival during development, is likely to explain the developmental patchy loss of melanocytes occurring in human piebaldism when KIT receptor function is compromised.

Patients with piebaldism generally have depigmented patches on the ventral or lateral trunk and/or the mid-extremities, sparing the hands and feet. Poliosis is a common feature. The depigmented patches tend to be larger than those observed in WS. Typically, piebaldism is not associated with deafness, although piebaldism with deafness, otherwise referred to as Woolf syndrome, has been molecularly confirmed.[140]

DYSCHROMATOSIS SYMMETRICA HEREDITARIA.

Dyschromatosis symmetrica hereditaria (DSH; OMIM #127400), an autosomal dominant condition, was recently shown to be caused by mutations in *ADAR1*, formerly known as *DSRAD*, encoding adenosine deaminase acting on RNA 1, an RNA-editing enzyme.[141,142] It is not known how reduced activity of this enzyme results in pigmentary loss at acral sites. Patients exhibit speckled hypopigmentation, which is limited to the dorsa of the hands and feet.

COMPLICATIONS OF ALBINISM AND CONGENITAL DISORDERS OF PIGMENTATION

The complications of albinism revolve around the impact of the reduced visual acuity and hypopigmentation upon the affected individual. The primary medical complications are the early appearance of skin tumors in individuals with inadequate sun protection in equatorial climates. Delayed recognition and management of squamous cell carcinoma and melanoma in this setting can lead to metastasis and early death.

The complications of congenital disorders of pigmentation are more likely to relate to their associated manifestations, such as deafness or aganglionic megacolon, than the pigmentary loss.

PROGNOSIS/CLINICAL COURSE OF ALBINISM AND CONGENITAL DISORDERS OF PIGMENTATION

With the exception of individuals with OCA1A, patients with OCA can realize gradual pigmentation of the skin and hair over the course of their lives, and develop melanocytic nevi.

As long as the life-threatening aganglionic megacolon of WS4 is recognized at birth and corrected surgically, the prognosis of congenital disorders of pigmentation is favorable, with minor long-term health consequences. Spontaneous repigmentation of both the white forelock and white spots has been reported, as has contraction of the white spots.

MANAGEMENT OF ALBINISM AND CONGENITAL DISORDERS OF PIGMENTATION

All individuals with albinism should be under the care of an ophthalmologist and should have annual examinations until adult life. Most are hyperopic or myopic, and many have significant astigmatism; refractive correction aids in their visual attentiveness and performance.

Proper dermatologic care and protection from UV radiation of the sun and care by a dermatologist are strongly advised for individuals with OCA. Precautions include the use of sunscreens, hats, and long sleeves, as well as sun avoidance.

For HPS patients, topical control of bleeding can be achieved with thrombin and Gelfoam. In advance of dental procedures or biopsies, intravenous infusion of 1-desamino-8-D-arginine vasopressin can be used prophylactically.[69] The accelerated phase of CHS is managed initially with multimodal immunomodulatory therapy and maintenance cyclosporine followed by allogeneic hematopoietic cell transplantation.[143]

No treatment has been reported for the pigmentary loss associated with congenital disorders of pigmentation. However, melanocyte grafting, either with epidermal grafts or epidermal cell suspensions as used for the treatment of stable vitiligo,[144–146] might be an option to consider. Cochlear implants in the pediatric population with WS have led to positive outcomes.[147] It is important to recognize the hearing defect early so that proper management, including proper social and mental development and schooling, can be implemented.

Genetic counseling can help affected individuals assess their chances of transmitting the disorder to their progeny.

Chapter 74 :: Vitiligo

:: Stanca A. Birlea, Richard A. Spritz, & David A. Norris

VITILIGO AT A GLANCE

- The most frequent depigmenting disorder, affecting 0.3%–0.5% of the population worldwide
- An acquired disease involving multiple genes and nongenetic environmental factors
- Characterized by progressive autoimmune-mediated destruction of epidermal melanocytes
- Typical presentation: patches of white skin and hair
- Cause of physiological and social stigma among affected individuals
- Increased risk for other autoimmune diseases, unpredictable evolution and unsatisfactory therapeutic outcomes

EPIDEMIOLOGY

The prevalence of vitiligo is reasonably consistent among different populations: ~0.38% in Caucasians,[1] 0.34% in Afro-Caribbeans,[2] 0.46% in Indians,[3] though perhaps somewhat less frequent in Han Chinese, 0.093%.[4] Vitiligo appears to affect both genders equally, though women are overrepresented among patients seeking clinical care. Vitiligo can develop at any age,[5] with a mean age-of-onset in Caucasian patients of about 24 years.[6] The most common subtype, generalized vitiligo (GV), is an autoimmune disease that is associated with other autoimmune diseases in about 20%–30% of patients, most frequently autoimmune thyroid disease (Hashimoto's thyroiditis or Grave's disease), rheumatoid arthritis, psoriasis, type 1 diabetes (usually adult-onset), pernicious anemia, systemic lupus erythematosus, and Addison's disease.[7]

ETIOLOGY AND PATHOGENESIS

Vitiligo is a multifactorial, polygenic disorder, with a complex pathogenesis that is not yet well understood.[8] Of various theories of disease pathogenesis, the most accepted is that genetic and nongenetic factors interact to influence melanocyte function and survival, eventually leading to autoimmune destruction of melanocytes.[7] Other suggested explanations have included defects of melanocyte adhesion,[9] neurogenic damage,[10] biochemical damage,[11] autocytotoxicity,[12] and others.

GENETICS OF VITILIGO

Large-scale epidemiological surveys have shown that most cases of vitiligo occur sporadically, although about 15%–20% of patients have one or more affected first-degree relatives. Typically, familial aggregation of cases exhibits a non-Mendelian pattern suggestive of polygenic, multifactorial inheritance.[8] Concordance in monozygotic twins is 23%,[6] indicating that both genetic and nongenetic (presumably environmental) factors play major roles in disease pathogenesis.

Almost all studies of vitiligo genetics have focused on GV. Several genes involved in immune function, including loci in the MHC, *CTLA4*, *PTPN22*, *IL10*, *MBL2*, and *NALP1* (*NLRP1*), have been implicated in susceptibility to GV on the basis of genetic linkage or association studies.[7] A recent, very large genome-wide association (GWA) study of European Caucasian GV patients and families identified at least ten different loci that contribute to GV risk.[13] Seven of these GV susceptibility loci have also been associated with other autoimmune diseases [(1) *HLA* class I, (2) *HLA* class II, (3) *PTPN22*, (4) *LPP*, (5) *IL2RA*, (6) *UBASH3A*, and (7) *C1QTNF6*], two loci encode proteins involved in immune function [(1) *RERE* and (2) *GZMB*], and another locus, *TYR*, encodes tyrosinase, a key enzyme of melanin biosynthesis and the major GV autoantigen.

Segmental vitiligo (SV) appears to be genetically distinct from GV. Its generally sporadic occurrence and unilateral distribution have led to the suggestion that it might result from somatic mosaicism for de novo mutations,[14,15] perhaps in genes that are critical for melanoblast/melanocyte development or survival, although this hypothesis remains to be confirmed.

AUTOIMMUNE HYPOTHESIS

There is compelling biological evidence supporting an autoimmune basis for GV.[16] GV is epidemiologically associated with a number of other autoimmune diseases,[6,17] both in patients and in their close relatives, indicative of a heritable autoimmune diathesis. Humoral immunity was first implicated by the finding in some cases of circulating antimelanocyte autoantibodies[18] that target various melanocyte antigens, including tyrosinase, tyrosinase-related protein-1, dopachrome tautomerase, and others, and that have the capability to kill melanocytes in vitro[19] and in vivo.[20] Currently, these autoantibodies are thought to reflect secondary humoral responses to melanocyte

destruction rather than a primary cause of GV.[18] A greater role is attributed to the inflammatory infiltrate sometimes seen at the margins of active GV lesions, composed mainly of cytotoxic T lymphocytes. As these T cells express a type-1 cytokine profile and colocalize with epidermal melanocytes, it has been hypothesized that these cells are actively cytolytic toward remaining melanocytes, via the granzyme/perforin pathway.[21]

An immune mechanism has also been suggested to underlie chemical leukoderma.[22] The so-called "occupational vitiligo" may occur in individuals who encounter large doses of phenolic compounds, usually 4-tertiary butyl phenol (4-TBP) and other phenolic compounds that may be contained in cleaning solutions. Occupational vitiligo usually initially involves the hands and forearms (the site of contact with the inciting agent). At present, it is unclear whether these agents are directly toxic to melanocytes, or whether some individuals might be genetically susceptible to melanocyte injury from aliphatic phenolic derivatives, ultimately resulting in melanocyte death, release of antigenic intracellular proteins, loss of tolerance, and autoimmunity.

An immune mechanism has also been proposed for the vitiligo-like depigmentation, which can appear in the course of IL-2 immunotherapy-based treatments for cutaneous melanoma, possibly via the stimulatory effect of IL-2 on T cell growth and activation.[23–25] Some melanoma-associated antigens (e.g., MART-1, gp100, and tyrosinase) are expressed on normal melanocytes, suggesting that the occurrence of treatment-related vitiligo-like depigmentation in melanoma may involve cross-reaction of some antimelanoma immune responses with normal melanocytes.

BIOCHEMICAL HYPOTHESIS

There is some evidence that vitiligo is a disease of the entire epidermis, possibly involving biochemical abnormalities of both melanocytes and keratinocytes.[11] The specific morphological and functional abnormalities observed in vitiligo melanocytes and keratinocytes are thought to have a genetic background.[11] Ultrastructural abnormalities of keratinocytes from perilesional vitiligo skin have been related to impaired mitochondrial activity,[26] and are thought to affect the production of specific melanocyte growth factors and cytokines that regulate melanocyte survival.[11] An essential biochemical finding is elevated levels of H_2O_2 in affected regions of epidermis,[27] that may be caused in part by reduced enzymatic antioxidant capacity of keratinocytes and melanocytes.[11,19] A defective antioxidant defense may confer melanocytes an increased susceptibility both to immunologic cytotoxicity and to cytotoxicity induced by reactive oxygen species.[19]

CLINICAL FEATURES

The principal clinical manifestation of vitiligo is the appearance of acquired milk-white macules with fairly homogeneous depigmentation and well-defined

Figure 74-1 Vitiligo vulgaris in an adult.

borders. On the basis of the polymorphic distribution, extension, and number of white patches, vitiligo is classified into generalized (vulgaris, acrofacial, mixed), universalis, and localized (focal, segmental, and mucosal) types.[28] Vitiligo is also classified as segmental and nonsegmental types, on the basis of distinctive clinical features and natural histories.[29] According to this classification, non-SV includes all cases not classified as segmental, including localized, generalized, and acrofacial.

- Vitiligo vulgaris—multiple scattered lesions distributed in a more or less symmetrical pattern; the most common presentation of GV (Fig. 74-1).
- Acrofacial vitiligo—affects the distal end of fingers and facial orifices in a circumferential pattern; a subtype of GV (Fig. 74-2).

Figure 74-2 Acrofacial vitiligo.

Figure 74-3 Vitiligo universalis.

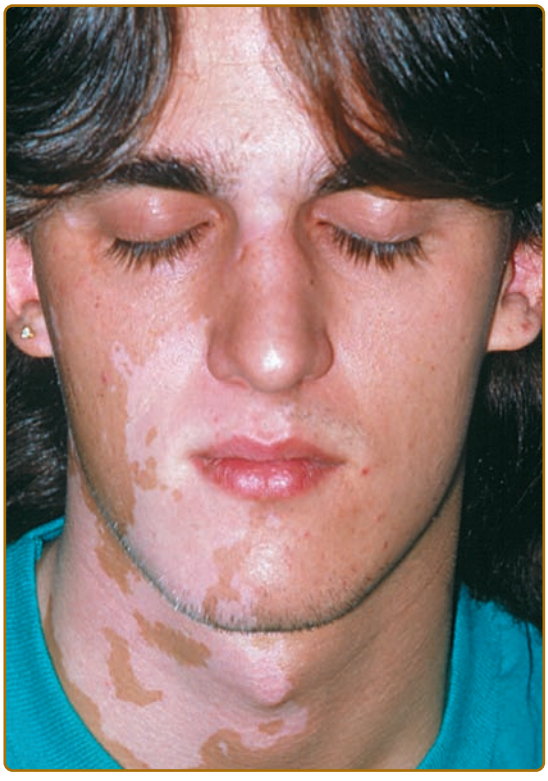

Figure 74-5 Segmental vitiligo of the face and neck.

- Mixed vitiligo—combination of acrofacial and vulgaris, or segmental and acrofacial types.
- Vitiligo universalis—complete or nearly complete depigmentation of the whole body (Fig. 74-3); the most severe form of GV.
- Focal vitiligo—characterized by the presence of one/few macule(s) in one area but not distributed in a segmental pattern (Fig. 74-4); considered a precursor form of GV.
- Mucosal vitiligo—a term reserved for depigmentation of mucous membrane alone.
- SV—characterized by macules having unilateral dermatomal distribution that do not cross the midline (Fig. 74-5). It generally affects young children and typically remains localized, the depigmented lesions persisting unchanged for many years.[30] The occurrence of concomitant other autoimmune diseases is uncommon, compared with GV.[29,31,32]

Vitiligo often demonstrates a predilection for sun-exposed regions, body folds, and periorificial areas, although any part of the body can be affected. Various precipitating factors have been suggested, including physical trauma to the skin, sunburn, psychological stress, inflammation, pregnancy, contraceptives, vitamin deficiency, and many others. However, at this time no specific environmental triggers have been proven.

Vitiligo may appear at sites of skin trauma (Koebner's phenomenon) (Fig. 74-6).

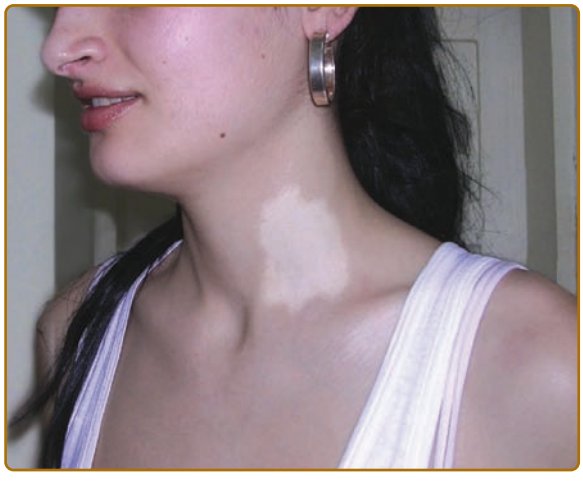

Figure 74-4 Focal vitiligo—unique macule of focal vitiligo.

Figure 74-6 Koebnerization under brassiere.

Figure 74-7 Leukotrichia. (Reprinted with permission from Falabella R: Vitiligo and the malanocyte reservoir. *Indian J Dermatol* **54**(4):313-318, 2009.)

Leukotrichia (depigmentation of hair within vitiligo macules (Fig. 74-7), can be quite variable (10%–60%), and is considered to indicate destruction of the melanocyte reservoir within the hair follicle, therefore, predicting a poor therapeutic response.[28] Premature graying of the hair has been described in up to 37% of patients with vitiligo,[28] although poor definition and quantitation of this feature makes this supposed clinical association uncertain.

SPECIFIC RARE CLINICAL PHENOTYPES

- Trichrome vitiligo is characterized by the presence of patches of intermediate hue (hypopigmentation) between the normal skin and the completely depigmented skin.
- Quadrichrome vitiligo is characterized by the presence of a fourth color (dark brown) at sites of perifollicular repigmentation. It is more often encountered in patients with darker skin phototypes.
- Pentachrome vitiligo—the occurrence of five shades of color: (1) white, (2) tan, (3) medium brown, (4) dark brown, and (5) black.
- Confetti vitiligo or vitiligo ponctué —tiny punctate-like depigmented macules on a hyperpigmented macule or on normal skin.
- Red vitiligo—the depigmented lesions have a raised erythematous border.
- Blue vitiligo—a blue–gray appearance of the skin, which corresponds histologically with the absence of epidermal melanocytes and presence of numerous dermal melanophages.

RELATED PHYSICAL FINDINGS

COMORBID ASSOCIATIONS

GV has been often associated with a variety of other conditions, principally autoimmune diseases.[33] The most prevalent associated autoimmune disease is autoimmune thyroid dysfunction, either hypothyroidism (Hashimoto's thyroiditis) or hyperthyroidism (Grave's disease). Other autoimmune diseases such as rheumatoid arthritis, psoriasis, type 1 diabetes mellitus (usually adult-onset), pernicious anemia, systemic lupus erythematosus, and Addison's disease also occur with increased frequency in patients with GV.[6,17] Most of these disorders, including GV, can occur in various combinations and constitute components of the APECED (APS1) and Schmidt (APS2) multiple autoimmune disease syndromes.

Vitiligo can also be part of the Vogt–Koyanagi–Harada (VKH) syndrome, a multiorgan disorder that affects pigmented structures, such as the eye, inner ear, meninges, and skin.[34] Several clinical and experimental studies have pointed to a role of cell-mediated immunity in VKH, particularly involving $CD4^+$ T cells and Th1 cytokines.[35,36]

Another very rare multiorgan disorder, Alezzandrini syndrome, associates facial skin depigmentation, poliosis, deafness, and unilateral tapetoretinal degeneration of the eye.[37] However, many investigators now believe that VKH and Alezzandrini's syndrome are merely different clinical expressions of the same fundamental disease.[38]

DEPIGMENTATION OTHER THAN VITILIGO

Skin depigmentation may occur in melanoma patients in three different clinical contexts[39]: partial depigmentation ("regression") of the tumor, leukoderma acquisitum centrifugum around the tumor, and vitiligo-like depigmentation, occurring at distant sites. Vitiligo-like depigmentation is thought to be a marker of the patient developing immunity against melanoma cells and to be an indicator of favorable prognosis, especially in advanced stages.[25]

The most common form of leukoderma acquisitum centrifugum appears around pigmented nevi (called halo nevi), and often progress to spontaneous disappearance of the nevus,[39] presumably via lymphocyte-mediated destruction of nevus cells.

DIAGNOSIS

The diagnosis of vitiligo is established principally on clinical grounds, which may include distribution and extent of lesions, and natural history of disease.[40]

LABORATORY. Given the association between vitiligo and other autoimmune diseases, several screening laboratory tests are helpful, including T4 and thyroid-stimulating hormone levels, antinuclear antibodies, and complete blood count. Clinicians should also consider testing for serum antithyroglobulin and antithyroid peroxidase antibodies, particularly when patients have signs and symptoms suggestive of thyroid disease.

HISTOLOGY. A skin biopsy is rarely necessary to confirm the diagnosis of vitiligo. Generally, histology shows an epidermis devoid of melanocytes in lesional areas,[41] and sometimes sparse dermal, perivascular, and perifollicular lymphocytic infiltrates at the margins of early vitiligo lesions and active lesions, consistent with cell-mediated immune processes destroying melanocytes in situ.[42] Some reports[42] have suggested that melanocytes may never be completely absent from the depigmented epidermis and that residual melanocytes maintain the capability of recovering functionality. Further studies are needed to clarify this highly debated issue with obvious therapeutic implications.

Differential diagnosis for vitiligo is presented in Box 74-1 and Box 74-2.[43,44]

BOX 74-1 DIFFERENTIAL DIAGNOSES FOR GENERALIZED VITILIGO

CONDITION	DISTINGUISHING FEATURES
Inherited Hypomelanoses	
Piebaldism	Stable and circumscribed white patches (with absence of melanocytes) affecting anterior body and limbs; white forelock; autosomal dominant.
Waardenburg's syndrome	White forelock, white skin macules, hypertelorism, deafness, ±Hirschsprung disease; multiple genes-autosomal dominant or recessive.
Tuberous sclerosis	Ash leaf hypopigmented macules, facial/periungual angiofibromas, shagreen patches; autosomal dominant.
Ito's hypomelanosis	Linear distribution, unilateral or bilateral pattern of hypopigmented macules; sporadic; chromosomal or genetic mosaicism.
Infectious Disorders	
Tinea versicolor	Hypopigmented lesions, beginning as reddish macules with fine scales upon scraping and seborrheic distribution. At mycologic examination: hyphae and spores.
Secondary syphilis	Depigmented round/oval patches (postinflammatory depigmentation) around the neck (necklace of Venus), trunk, limbs, or depigmented patches with peripheral reticular hyperpigmentation (primary lesion). Serological tests for treponemal infection are positive.
Leprosy (tuberculoid/borderline forms)	Depigmented patches with polymorphic presentation, usually accompanied by localized anesthesia; histology: compact skin granulomas.
Postinflammatory Hypopigmentation	
Discoid lupus erythematosus, scleroderma, lichen sclerosis et atrophicus, psoriasis	Patients have history of preexisting dermatosis.
Paramalignant Hypomelanoses	
Mycosis fungoides	Hypomelanotic macules or diffuse depigmentation especially in darker skin phototypes. Flat skin patch, plaque, and tumors. Histology: epidermal infiltrates with mononuclear cells.
Cutaneous melanoma	Halo depigmentation around or within the tumor.
Autoimmune reactions to advanced melanoma	Depigmentation at a distance from the tumor; the presence of tumor excludes typical vitiligo.
Idiopathic Disorders	
Idiopathic guttate hypomelanosis	Hypopigmented well circumscribed macules, sharply defined and small in size. They are slow progressive and nonconfluent. Histology indicates epidermal atrophy and reduction in melanin content.
Postinflammatory pigment loss	Postburn hypopigmentary lesions, shaped in the form of the burn. Hypopigmenting inflammatory reactions leave ill-defined, poorly circumscribed lesions. The history of preceding eruption/injury excludes vitiligo.
Toxin-Induced Depigmentation	
Drug-induced depigmentation	Vitiligo-like depigmentation generally caused by topical occupational exposure to phenolic–catecholic derivatives, often affecting the hands and forearms. Caused by use of systemic drugs (chloroquine, fluphenazine, physostigmine, imatinib, or topical imiquimod).

From Taïeb A, Picardo M: Clinical practice. Vitiligo. *N Engl J Med* **360**:160, 2009.

BOX 74-2 DIFFERENTIAL DIAGNOSES FOR LOCALIZED VITILIGO

NEVUS DEPIGMENTOSUS	Solitary hypopigmented macule well circumscribed with irregular borders, stable in size, solitary, most often present at birth.
NEVUS ANEMICUS	Hypochromic pale lesion with well-defined borders and irregular margins; often solitary, located on the trunk. Histology and electron microscopic examination reveal no abnormality in melanocytes or melanization.

CLINICAL COURSE AND PROGNOSIS

The clinical course of any given case of GV is unpredictable, but is typically gradually progressive and difficult to control with therapy. Sometimes lesions spread over time, whereas in other cases disease activity stops, persisting in stable status for a long period. Some clinical parameters such as a long duration of the disease, occurrence of Koebner's phenomenon, leukotrichia, and mucosal involvement have been suggested as indicators of relatively poor prognosis.[28]

TREATMENT

FUNDAMENTS OF VITILIGO THERAPY: MELANOCYTE REPOPULATION

The key principle of vitiligo therapy is facilitating repopulation of depigmented patches of the interfollicular epidermis with active melanocytes that are able to migrate, survive to repopulate the depigmented skin, and carry out melanin biosynthesis.[45] Repigmentation may occur spontaneously and may also be therapy-induced. Spontaneous repigmentation is unpredictable, often clinically insignificant, and tends to be cosmetically unacceptable.[46,47] It occurs in fewer than 50% of patients, most commonly in younger patients and in sun-exposed areas, where natural sunlight may act as an inducing agent.[48] In clinical practice, the most frequently encountered pattern of repigmentation is perifollicular (Fig. 74-8), though other patterns, such as marginal, diffuse, or combined also may occur.

The principal source of melanocytes involved in repopulation of vitiligo skin is most likely melanocyte precursors derived from the outer root sheath (ORS) or bulge area of the hair follicle.[49–51] A secondary potential reservoir may be located near lesional borders.

Figure 74-8 Follicular repigmentation in vitiligo after psoralen and ultraviolet A light therapy.

The middle and lower parts of the ORS are populated by L-3,4-dihydroxyphenylalanine (DOPA)-negative, amelanotic melanocytes,[49,50] which may be recruited from the ORS of the hair follicle in response to ultraviolet (UV), corticosteroids, or other stimuli. As a result, the number of melanocytes in the ORS of hair follicles increases significantly and some become active, suggesting that melanocyte precursors proliferate and at least some undergo maturation.[50] Activated ORS melanocytes acquire all of the structural and enzymatic proteins required for melanogenesis, proliferation and maturation as they migrate up the hair follicle into the nearby epidermis, where they spread centrifugally and form perifollicular pigment islands. They then become larger cells, with intense DOPA oxidase activity.

Vitiligo repigmentation is assessed in terms of the proportion of treated subjects in whom a specified degree of repigmentation is achieved; depending on the study, more than 50% or more than 75% repigmentation may be considered a good response.[52] Wood's lamp (UVA) examination is useful to monitor response to therapy. In the absence of epidermal melanin that otherwise absorbs most of the UVA light, more photons reach the dermis, where they are absorbed by collagen that then fluoresces and emits bright visible light. In contrast, visible wavelengths of ambient room light are less well absorbed by melanin in the normally pigmented epidermis than UVA wavelengths and do not produce fluorescence in the dermis. Hence, under Wood's light the vitiligo area appears brighter and the normal skin appears darker than when illuminated with ambient room light (Fig. 74-9).

THERAPEUTIC APPROACHES

Different treatment strategies (Box 74-3) have been designed to inhibit the immune response in vitiligo, thereby reducing melanocyte destruction, and also enhancing epidermal repopulation by melanocytes, both by stimulating recovery of damaged melanocytes in situ and by reactivating residual melanocytes or stimulating melanocyte in-migration from neighboring skin or hair follicles. However, at present it is not clearly understood to what extent treatments must suppress the autoimmune process versus stimulate

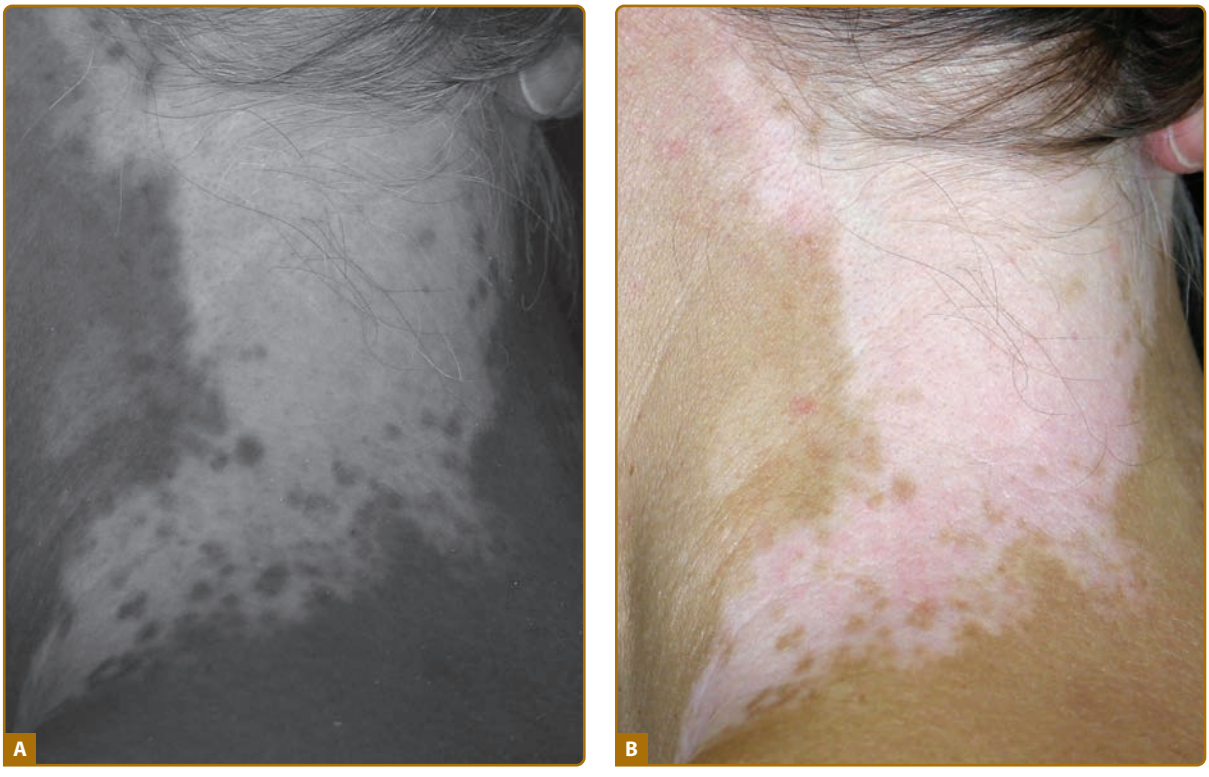

Figure 74-9 Wood's lamp examination. Wood's lamp provides bright reflection of white patches and enhanced details on intermediate pigment tones (**A**), as compared with white light (**B**). (Reprinted with permission from Taieb A, Picardo M: Vitiligo. *NEJM* **260**:160-169, 2009.)

melanocyte repopulation of the epidermis to provide maximum efficacy.

UV radiation therapy includes phototherapy with narrowband UVB (NB-UVB—311 nm) or broadband UVB (BB-UVB—290–320 nm), and photochemotherapy. UV therapy is thought to act as a skin immunomodulator, regulating the activity of inflammatory cytokines, depleting of Langerhans cells, modulating the activity of regulatory T cells, and polarizing the immune response toward the Th2 profile, thereby reducing or stabilizing the depigmentation process in vitiligo.[45] In addition, UV radiation coordinates several of the pathways via which melanogenic cytokines stimulate melanogenesis.[45] Furthermore, UV may also induce the release of epidermal factors that stimulate melanocyte proliferation and migration, although this speculation has not been substantiated in repigmenting vitiligo lesions. The release of several paracrine factors produced by UV-exposed keratinocytes[53] that regulate melanocyte functions is thought to be under p53 regulation,[54] although further studies are needed.

ULTRAVIOLET B NARROWBAND

Narrowband UV (NB-UVB) light, with peak emission at 311 nm, is considered the most effective and safest current therapy for vitiligo, and thus is currently the treatment of choice for patients with moderate-to-severe GV. Recent studies evaluating psoralen and UVA (PUVA) versus NB-UVB indicate that NB-UVB

BOX 74-3 TREATMENTS FOR VITILIGO

	TOPICAL	PHYSICAL	SYSTEMIC	SURGICAL
First line	Corticosteroids Calcineurin inhibitors	Ultraviolet B (narrowband) Systemic psoralen and ultraviolet A light (PUVA)		
Second line	Calcipotriol	Topical PUVA Excimer laser	Corticosteroids (pulse therapy)	Grafting Melanocyte transplant

produces higher repigmentation rates and better color matching).[55] NB-UVB has fewer short-term adverse reactions such as painful erythema and appears to have fewer long-term side effects such as epidermal thickening, atrophy, and photocarcinogenesis than PUVA.[56] Several clinical studies have reported high rates (≥75%) of repigmentation in at least 40% of patients treated with NB-UVB.[57–60]

The most commonly used NB-UVB protocol[43] involves twice-weekly administration of a fixed starting dose of 0.21 J/cm^2, increasing the dose by 20% at each session until the minimal erythema dose (the lowest dose that results in visible erythema on depigmented skin at 24 hours) has been reached. Approximately 9 months of therapy are required to achieve maximal repigmentation; at least 3 months of treatment are warranted before the condition can be classified as nonresponsive.

The most responsive sites are face, trunk, and limbs, and the least responsive sites are the hands and feet.

PHOTOCHEMOTHERAPY (PUVA)

Until recently, PUVA was considered the mainstay of therapy for patients with widespread vitiligo. PUVA consists of a combination of topical or oral 8-methoxypsoralen with UVA (320–400 nm) irradiation. The psoralen of choice, methoxsalen, is given in an oral dose of 0.4-mg/kg body weight, 1–2 hours prior to UVA exposure. For topical PUVA therapy, methoxsalen 0.1% is applied to areas of vitiligo 30–60 minutes before exposure to UV radiation. Topical PUVA is indicated in patients whose vitiligo involves less than 20% of the body surface area, and painful burns (phototoxicity reactions) are unfortunately difficult to avoid. Oral psoralens can be used for patients with more extensive involvement or in patients who do not respond to topical PUVA (see Chapter 237). After oral treatment, patients must wear UVA-blocking glasses, and it is also recommended they use broad-spectrum sunscreens and wear protective clothing. Patients with darker complexions tend to respond best to PUVA, possibly because they tolerate higher PUVA exposures.[61] Potential side effects of PUVA therapy are discussed in Chapter 237. PUVA is not recommended for use in children under the age of 12 years owing to the long-term delayed risks of cataract formation and skin cancer.

CORTICOSTEROIDS

TOPICAL CORTICOSTEROIDS

Topical corticosteroids represent the first-line therapy for localized vitiligo, and are highly recommended for facial or small lesions and for use in children. Advantages include ease of application, high compliance rate, and low cost. Compared with PUVA, which promotes a predominantly perifollicular pattern of repigmentation, topical corticosteroids result in more diffuse repigmentation, which occurs more quickly but is less stable.[62] Light and electron microscopy of skin biopsies from control and steroid-treated areas showed marked repopulation by functional melanocytes in the repigmented vitiliginous skin. In steroid repigmented areas melanocytes appeared dendritic and DOPA-positive, and unlike melanocytes in the pigment margins of untreated areas of vitiligo, contain many melanosomes of normal size and shape.[63] The current trend, based on the results of a large meta-analysis that included randomized controlled trials of 29 patient series, is that class 3 and 4 corticosteroids are the most effective for treatment for localized vitiligo.[52] Thus, localized lesions can be treated with a high-potency fluorinated corticosteroid (e.g., clobetasol propionate ointment, 0.05%) for 1–2 months. Treatment can be gradually tapered to a lower potency corticosteroid (e.g., hydrocortisone butyrate cream, 0.1%). Caution is necessary when using topical steroids on and around the eyelids, as their use can increase intraocular pressure and exacerbate glaucoma. Vitiligo recurrence after cessation of treatment and corticosteroid-induced side effects (i.e., skin atrophy, telangiectases, striae, and, rarely, contact dermatitis) are the limiting factors. Combination therapy (corticosteroids + UVB, corticosteroids + calcineurin inhibitors, corticosteroids + vitamin D analogs) may be beneficial in some cases, as two agents together may act synergistically on pigment restoration and on immune suppression, at lower individual doses, thus, potentially minimizing overall side effects.

SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids have been used in pulse therapy and for short periods to halt rapid spread of depigmentation in some cases of GV.[61]

CALCINEURIN INHIBITORS

Calcineurin inhibitors can be effective in vitiligo therapy because of their capacity to restore the altered cytokine network. Tacrolimus has been shown to inhibit T cell activation by downregulating transcription of genes encoding proinflammatory cytokines IL-2, IL-3, IL-4, IL-5, interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), and granulocyte-macrophage colony-stimulating factor (GM-CSF) in T cells.[64] In addition, a direct effect of tacrolimus on melanocyte growth and migration during repigmentation has been reported.[65] Topical calcineurin inhibitors (e.g., tacrolimus ointment 0.03%–0.1%, pimecrolimus ointment 1%) are generally preferred for treating localized vitiligo lesions of the face and neck,[43] and seem to be more effective in combination with UV radiation delivered by high-fluency UVB devices.[43] Although several reports have emphasized the advantages of calcineurin inhibitors (selective mode of action, absence of skin atrophy, and systemic absorption), additional studies of their effectiveness are needed, as well as more

information about possible risks of cutaneous and extracutaneous cancers.

TOPICAL VITAMIN D DERIVATIVES

Vitamin D analogs—calcipotriol ointment (0.005%) and tacalcitol ointment (20 µg/g)—restore pigmentation in vitiligo by inducing skin immunosuppression, which halts the local autoimmune process, and via direct activation of melanocytic precursors and melanogenic pathways.[66] Some studies report more efficient repigmentation when vitamin D analogs are used in combination therapy, probably because of more complex stimulation of the repopulation process, targeting both melanocyte growth (with corticotherapy or UV) and differentiation (with a vitamin D analog). Vitamin D derivatives are indicated for use in localized disease; benefits include lack of skin atrophy and their easy application. However, their role in vitiligo treatment remains controversial; whereas some studies have reported substantial benefit, others found vitamin D analogs ineffective.[45]

PSEUDOCATALASE

Pseudocatalase has been used to reconstitute deficient activity of catalase in vitiligo epidermis, degrading excessive H_2O_2 and allowing recovery of enzyme activities in vitiligo skin.[67] Pseudocatalase monotherapy or combination with NB-UVB has shown apparent efficacy in repigmentation and prevention of disease progression in uncontrolled trials,[68,69] while in other studies showed no substantial benefit.[70–72] Therefore, its effect in vitiligo needs further validation.

LASER THERAPY

UV B narrowband excimer laser (XeCl) and monochromatic excimer light (MEL) are currently used for treatment of localized vitiligo. These are similar to classical NB-UVB treatments, with the advantage of fewer side effects because only one lesion is treated at a time. These treatments produce optimal aesthetic results, with minor contrast between normal and affected skin.[56] The XeCl has laser-coherent emission of monochromatic rays, whereas the MEL device can generate and selectively deliver 308-nm UVB light. No data for cancer risk and other long-term side effects are available; therefore, caution is currently advised.[73]

SURGICAL TREATMENT

Autologous skin grafts are an option for repigmentation only in patients with stable vitiligo that is refractory or only partially responsive to medical treatment, and in general limited in extent (less than 3% of body-surface area).[43] The most frequent side effects are infection, postinflammatory hyperpigmentation, unaesthetic repigmentation, cobblestoning, and scarring.[55] UV-light therapy generally hastens and improves repigmentation when combined with surgical methods.

Autologous skin graft approaches can be categorized into five principal groups.[55] Of note, in the United States any procedure in which cells are manipulated (e.g., cultured) must be performed in a good manufacturing practices (GMP) facility.

NONCULTURED EPIDERMAL SUSPENSIONS

This technique is performed by grafting noncultured suspensions containing both keratinocytes and melanocytes[74,75] (eFigs. 74-9.1A and 74-9.1B in online edition); suspensions are obtained by 0.25% trypsin digestion of a thin piece of donor skin and are injected into blisters raised by liquid nitrogen freezing or seeded on recipient sites denuded by superficial dermabrasion. An advantage of this method is lack of scarring if recipient and donor sites are carefully manipulated.

THIN DERMAL–EPIDERMAL GRAFTS

Grafts are harvested at a depth of 0.1–0.3 mm, placed directly on recipient abraded areas next to each other, and are secured with surgical dressings under mild pressure for 1 week. Repigmentation occurs during the following weeks. Good results have been reported on dorsal hands and fingers.[76,77]

MINIGRAFTING

Minigrafting represents the most commonly used current surgical method for vitiligo repigmentation (eFigs. 74-9.2A and 74-9.2B in online edition). Multiple perforations are made on recipient sites using 1.0–1.2-mm punches 3–4 mm apart from each other. Next, minigrafts are harvested from the donor site using a similar punch and are transferred to recipient sites with fine forceps or a hypodermic needle.[78] Repigmentation occurs around each minigraft up to 2–5 mm by coalescence of spreading pigment. Good results are achieved in patients with refractory lip leukoderma, although the risk of cobblestoning seems to be high.[76,79] An advantage of this method is its simplicity.

EPIDERMAL GRAFTING

Grafts are harvested at negative pressure using different custom-made suction devices,[55] the preferred donor sites being the inner aspect of the thigh and the flexor aspect of the forearm.[80] Recipient sites are prepared by removing the epidermis using liquid nitrogen freezing or superficial dermabrasion[81] or laser ablation.[55] Epidermal grafts have been successfully used for lip vitiligo.[82] The

Figure 74-10 Treatment with MBEH. Response of disfiguring facial vitiligo to treatment with MBEH (**A**) before, (**B**) after 4 months, (**C**) after 6 months and (**D**) after 8 months.

main advantage is the absence of scarring in donor and recipient sites.

IN VITRO-CULTURED EPIDERMIS WITH MELANOCYTES AND MELANOCYTE SUSPENSIONS[55]

EPIDERMIS WITH MELANOCYTES. An epidermal suspension collected from a small donor skin sample is prepared by 0.25% trypsin digestion and seeded in culture flasks. After 3 weeks, epidermal sheets are harvested from the culture vessel and transplanted onto depigmented recipient sites previously denuded by liquid nitrogen freezing, superficial dermabrasion, lasers, or diatermo surgery. A hyaluronic artificial matrix for growing keratinocytes and melanocytes has also been used with success.[83]

MELANOCYTE SUSPENSIONS. In vitro-cultured melanocyte suspensions are obtained in a similar manner using specific and defined cultured media such as Ham's F12. During subculturing, pigment cells increase in number and may be transplanted onto denuded areas at a density of up to 100,000 melanocytes/cm^2. The suspension spreads onto recipient areas and is covered for a week, providing a good cellular take.[74,84] The large population of cells obtained from a small donor site represents a great advantage for treating extensive vitiligo areas in a single session.

MICROPIGMENTATION

Micropigmentation is useful for vitiligo lesions on mucous and mucocutaneous areas. It is accomplished by tattooing inert pigment granules into the dermis within collagen bundles and extracellularly at a depth of 1–2 mm, delivered by multiple electrically driven needles. Combinations of white, yellow, black, red, and brown pigments are used.[55]

DEPIGMENTATION

Some adult patients with extensive vitiligo may elect to undergo depigmentation of residual pigmented patches on facial and exposed areas. Depigmentation is achieved using 20% monobenzyl ether of hydroquinone (MBEH; monobenzone), which induces melanocyte loss via necrotic death without activating the caspase cascade or DNA fragmentation.[85] MBEH is first applied as a patch test for 48 hours to detect hypersensitivity. Subsequently, twice-daily applications for at least a year are followed by irreversible depigmentation[86] (Figs. 74-10A–D). Sunlight protection of depigmented skin is essential to prevent nonmelanoma skin cancers.[55]

We propose a treatment algorithm for vitiligo, considering the therapeutic approaches presented above (Fig. 74-11).

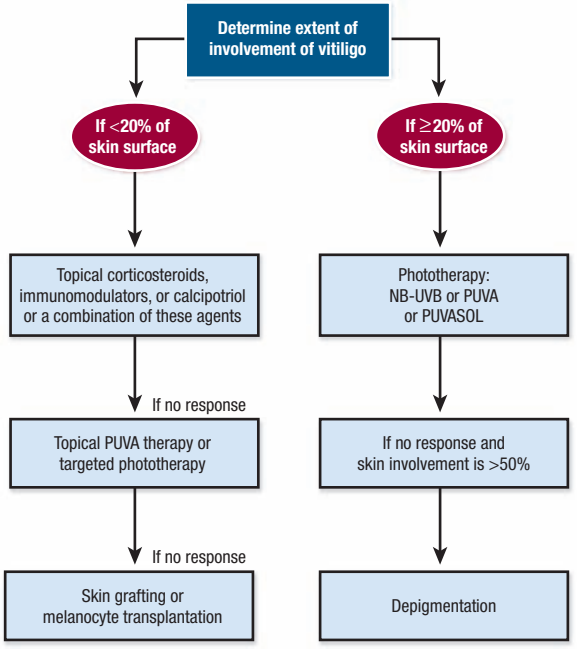

Figure 74-11 Treatment algorithm for vitiligo.

CAMOUFLAGE, SUN PROTECTION, AND PSYCHOLOGICAL SUPPORT

Use of cosmetic camouflage, on the face and other exposed areas, and clothing to conceal affected areas can improve the quality of life for patients with vitiligo. Modern camouflage dyes and creams are waterproof, and the wide range of color and shades available can enable patients to choose the most suitable ones for their own skin color (Figs. 74-12A and 74-12B).

Tanning should be avoided since it enhances the contrast of vitiligo lesions with normally pigmented skin. Moreover, sunscreens are needed to prevent sunburn of depigmented unprotected skin. However, this is somewhat problematic, as moderate sun exposure (heliotherapy) in many cases can induce epidermal repopulation with melanocytes. As well, it has been suggested that skin friction due to repeated application of sunscreen might exacerbate the disease,[43] although there is no evidence to support this hypothesis. Depigmented skin in vitiligo tends to show increased tolerance to UVB light over time (photoadaptation), with the extent of tolerance based in part on skin phototype, supposedly due to both pigmentary and nonpigmentary influences,[87] although the specific mechanism remains unknown.

Psychological support may be beneficial to some patients. Listening to patients' complaints and concerns and providing reassurance with advice about possible treatments and capacity for improvement is usually helpful for patients. Consider psychiatric evaluation for patients with marked low self-esteem and depression.

Figure 74-12 Cosmetic camouflage. Focal vitiligo of chin before (**A**) and after (**B**) application of cosmetic camouflage.

NONTRADITIONAL TREATMENTS

A wide range of nontraditional treatments have been suggested for vitiligo, and some may be considered as alternative approaches for patients who either failed or are unsuitable for the above therapies. The most commonly used include vitamin and nutritional supplements, immunomodulators, human placental extracts, khellin, and topical and systemic phenylalanine, among many others. There is no convincing evidence that any of these nontraditional treatments is effective.

PREVENTION

Patients, patient support groups, and purveyors of alternative medicines have developed extensive and diverse hypotheses regarding vitiligo causation and approaches to its prevention. At present, there is no compelling evidence that any approach to vitiligo prevention is effective. Moreover, there is currently no useful approach to identify individuals at high risk for developing vitiligo.

Chapter 75 :: Hypomelanoses and Hypermelanoses

:: Hilde Lapeere, Barbara Boone, Sofie De Schepper, Evelien Verhaeghe, Mireille Van Gele, Katia Ongenae, Nanja Van Geel, Jo Lambert, & Lieve Brochez

HYPOMELANOSES AND HYPERMELANOSES AT A GLANCE

- Pigmentation disorders confront the clinician with a sometimes complex differential diagnosis, but can be approached logically as follows:
  - Congenital or acquired
  - Isolated or part of a syndrome
  - Diffuse or circumscribed
  - Epidermal or dermal
  - With or without inflammation
- Altered skin pigmentation may be caused by the following factors:
  - Increased or decreased melanin
  - Abnormal melanin distribution
  - Decreased hemoglobin
  - Deposition of exogenous pigments

AN ALGORITHMIC APPROACH TO PIGMENTATION DISORDERS

Pigmentation disorders of the skin can either be hypomelanotic, hypermelanotic, or may present with a pattern of mixed hypo- and hypermelanosis. The diagnosis of these disorders can be quite challenging. An algorithmic approach based on clinical features and history of pigmentary disorders is used throughout this chapter and serves as a guide for the clinician' diagnosis and treatment (eFigs. 75-0.1 and 75-0.2 in online edition) (Table 75-1, eTable 75-1.1 in online edition).

HYPOMELANOSIS

Generalized hypopigmentation, including the various defects, classified as "albinism" has been discussed in Chapters 73 and 74. Localized forms of hypomelanosis can be related to defects in melanocyte precursor migration and disordered pigment transfer between melanocytes and keratinocytes, and as a result of postinflammatory changes.

CONGENITAL HYPOMELANOSIS

Some genetic disorders with reduced skin and hair pigmentation are caused by impaired melanocyte migration/differentiation or melanosome abnormalities.[1] Piebaldism, Waardenburg syndrome, and Tietze syndrome, characterized by a localized absence of melanocytes resulting in "white-patch" patterns, belong to the first group whereas oculocutaneous albinism (OCA), Griscelli syndrome (GS), Elejalde syndrome (ES), Chédiak–Higashi syndrome (CHS), and Hermansky–Pudlak syndrome (HPS) belong to the second group. OCA, CHS, and HPS are discussed in Chapter 73; GS and ES are discussed here. They are rare autosomal recessive disorders with abnormal biogenesis or transport of "lysosome-related organelles" (a group of specialized cytoplasmic organelles including melanosomes, platelet dense bodies, and lymphocyte lytic granules).[2] GS, ES, and CHS are termed "silvery hair syndromes" because hair of these patients has a particular silver–gray hue.[3]

GRISCELLI SYNDROME. Three types of GS [GS types I–III (GS1–3)] are known. The phenotype of the patients is characterized by various degrees of skin hypopigmentation and hair with a silvery shine (Fig. 75-1), usually lighter than in unaffected family members. Furthermore, neurological signs and symptoms and/or immunologic impairment with "accelerated phases" of uncontrolled lymphocyte and macrophage activation with lymphohistiocytic infiltration of the central nervous system (CNS) are associated.[4] This lymphoproliferative syndrome is similar to that observed in, for example, virus-associated hemophagocytic syndrome.[5]

Briefly, patients with GS type I (GS1) are characterized by primary and severe neurological symptoms

TABLE 75-1
Differential Diagnosis and Management of Dermal Melanocytosis

	Nevus of Ota	Nevus of Ito	Mongolian Spot	Nevus of Hori	Dermal Melanocyte Hamartoma
Epidemiology	▪ Mostly congenital ▪ Sporadic (rare familial cases) ▪ Asian and female predominance	▪ Mostly congenital ▪ Sporadic (rare familial cases) ▪ Asian and female predominance	▪ Congenital ▪ Often familial ▪ Asian, African, and Hispanic population with slight male predominance	▪ Acquired ▪ Familial or sporadic ▪ Asian and female predominance	▪ Congenital
Clinical presentation	▪ Blue to slate-gray mottled macular hyperpigmentation	▪ Blue to slate-gray mottled macular hyperpigmentation	▪ Uniform blue to slate-gray macular hyperpigmentation	▪ Brown–blue progressing to slate-gray mottled macular hyperpigmentation	▪ Mottled hyperpigmentation with small blue–gray macules in a diffuse pigmented patch
Distribution	▪ Trigeminal nerve	▪ Acromioclavicular nerve	▪ Lower back and sacrum	▪ Especially malar region of the cheek (also forehead, upper eyelids, temple)	▪ Dermatomal distribution
Histology	▪ Spindle-shaped melanocytes diffusely throughout the dermal layers. Sometimes more band-like melanocytic proliferation and stromal fibrotic reaction.	▪ Spindle-shaped melanocytes diffusely throughout the dermal layers. Sometimes more band-like melanocytic proliferation and stromal fibrotic reaction	▪ Spindle-shaped melanocytes diffusely throughout the dermal layers	▪ Dermal melanocytes in the upper and middermis	▪ Dermal melanocytes in the upper two-thirds of the dermis (including subpapillary layer)
Therapy	▪ Q-switched laser ▪ Cryotherapy ▪ Surgery	▪ Q-switched laser ▪ Cryotherapy ▪ Surgery	▪ Usually spontaneous regression during childhood	▪ Q-switched laser in combination with bleaching cream and chemical peels	▪ None
Associated features	▪ Rare malignant transformation	▪ No associated features of medical concern	▪ Possible association with inborn errors of metabolism	▪ No associated features of medical concern	▪ None

occurring early in life or even at birth without signs of an accelerated phase. These symptoms can include seizures, spasticity, psychomotor retardation, peripheral facial palsy, hemiparesis, encephalopathy, and hypotonia. CNS disorder is pertinent and never regresses with time.

Immunological and hematological manifestations are only observed in GS type II (GS2) and include: anemia, neutropenia, and lack of natural killer cell function, with development of an accelerated phase of the disease with fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia, and generalized lymphohistiocytic infiltrates of various organs, including the CNS. Onset of the accelerated phase seems to be associated with viral or bacterial infections. When a remission occurs, recurrent accelerated phases with increasing severity will be observed.

Neurological problems may also occur in GS2 patients and are related to lymphocyte infiltration of the CNS. Associated symptoms are, for example, hyperreflexia, seizures, signs of intracranial hypertension (e.g., vomiting), hypertonia, nystagmus, and ataxia. Psychomotor development is normal at onset, and regression of CNS signs, at least in part, can be observed during remission, although some sequelae may be irreversible. Skin hypopigmentation and silvery-grey hair in Griscelli patients are not caused by deficient melanosome biogenesis but by impaired intramelanocytic melanosome transport. Murine models with autosomal recessive mutations on the dilute (d), ashen (ash), and leaden (ln) locus present a phenotype close to that of their human GS counterparts.[6] These loci respectively encode three molecules, myosin Va, Rab27a, and melanophilin (Mlph) that act as a tripartite complex linking the melanosome to subcortical actin. When MYO5A (GS1), RAB27A (GS2), or MLPH (GS3) is mutated in human melanocytes, the tripartite complex fails to form and melanosomes can no longer be tethered near the plasma membrane for transfer to keratinocytes, leading to a pigmentary defect.[7]

Figure 75-1 A Griscelli patient with silvery gray eyebrows/eyelashes.

The prognosis for patients with GS is generally bad. They usually die in the first or second decade of their life if accelerated phases are not treated adequately. As for GS2 therapy, allogeneic bone marrow transplantation has appeared to be successful in some cases, especially when carried out at an early age.[8–11] Palliative therapy consists of suppressing the accelerated phases with immunosuppressive therapy (high-dose corticosteroids, cyclosporine) and chemotherapeutic agents (methotrexate, etoposide, cytosine arabinoside). For GS1 there is no therapy. Palliation consists of treating infections with antibiotics.[12]

The hematologic, immunologic, and neurologic findings in GS1–3 presumably relate to organelle transport difficulties in the respective organ systems.

ELEJALDE SYNDROME (OMIM #256710).

ES, also referred to as *neuroectodermal melanolysosomal disease*, is another autosomal recessive pigment mutation with silvery hair, pigment abnormalities, and severe CNS dysfunction[21,22] similar to those of GS1. ES patients do not manifest the hemophagocytic syndrome or immunological impairment associated with GS2.[23,24]

Certain patients with ES have clinical and histologic features suggestive of GS1, indicating that these are other cases of *MYO5A* mutations.[25,26] Further work will be required to define the molecular basis of ES and to group all patients with these rare disorders correctly.

ACQUIRED LOCALIZED HYPOMELANOSIS

PITYRIASIS VERSICOLOR.

(See Chapter 189). Pityriasis versicolor is characterized by slightly scaling macules that can either be hypopigmented, pink or salmon-colored, or hyperpigmented (Fig. 75-2); variants with red and black macules have also been described. The prevalence of pityriasis versicolor is very high in hot and humid climates.

This superficial mycosis is caused by *Malassezia* species of which *M. globosa*, *M. sympodialis*, and *M. Furfur* are most frequently identified in lesional scales. *M. Furfur* cultures produce a wide range of fluorochromes and pigments that appear to lead to depigmentation, high resistance to ultraviolet (UV)-induced tanning, and lack of inflammation observed in pityriasis versicolor.[27] In approximately one out of three patients, a yellow–green fluorescence is visible using Wood's light. It should be differentiated from the nonscaling depigmented lesions of vitiligo that frequently affect hands and feet, whereas pityriasis versicolor is mainly located on the trunk. The slightly scaling patches of pityriasis alba (PA) usually occur on the face and limbs and are nonfluorescent. Many local and systemic antifungal preparations are effective but relapses often occur.[28,29]

PIGMENTARY DEMARCATION LINES.

Originally described in Japanese patients as a line present on upper and lower extremities corresponding to a border of transition between the more deeply pigmented skin of the outer (dorsal) surfaces and the lighter inner (ventral) surfaces, the concept of

Figure 75-2 Pityriasis versicolor. **A.** Typical macules are round, very well circumscribed, have fine scale, and are off-white to tan colored. Typical distribution involves the upper back and upper chest. Involvement of the lower arms and legs and of the face is unusual. **B.** Confluent macules create scalloped borders. This is a characteristic pattern of macules of pityriasis versicolor.

Figure 75-3 Pigmentary demarcation line (Futcher line). These lines are often barely perceptible but common in darker skinned phototypes.

pigmentary demarcation lines was expanded to include five specific patterns, labeled A–E, with A: upper anterolateral arms, across pectoral area (Fig. 75-3), B: posteromedial portion of lower limb, C: vertical hypopigmented line in pre- and parasternal area, D: posteromedial area of spine, and E: bilateral aspect of chest, marking from midthird of clavicle to periareolar skin. In a population survey of black and white patients it was determined that these lines appeared in early childhood. They are present in the majority of female black adults, with types A and B being most prevalent. Seventy-five percent of black adult males had at least one type of pigmentary demarcation line, with type C the most prevalent. Fifteen percent of white female adults had at least one line, and 14% of black women saw type B lines appearing during pregnancy.[30] The lines of pigmentation are often called Futcher's lines in the United States.

The pathogenesis of pigmentary demarcation lines is uncertain. Some authors believe that these lines coincide with lines of Blaschko and are secondary to a form of pigmentary mosaicism. Others suggest that there is no true genetic difference but hypothesize that the difference between cells on the dark, posterior side versus the light, anterior side are due to the normal function of genes, such as the agouti locus.[31]

According to some reports, pigmentary demarcation lines do not follow lines of Blaschko but have a pattern similar to lines of Voigt, which separate dermatomes arising from nonconsecutive dorsal roots. The difference in melanogenesis would be explained by a strict territorial control by different homeobox genes during development.[32]

Figure 75-4 Pityriasis alba.

PITYRIASIS ALBA. PA is a common benign condition mainly affecting the head and neck region of preadolescent children. Although the disease is more noticed in darker skin types, there is no predilection for either sex or skin type. The etiology and pathogenesis remain poorly understood. PA is widely understood to represent mild atopic dermatitis. Unprotected sun exposure, frequent bathing, and hot baths are strongly related to the development of PA. Lower serum levels of copper, a cofactor for tyrosinase, could also play a role in the pathogenesis of this condition.

PA may present as a pink patch with an elevated border, fading after several weeks into a paler spot covered with powdery white scale (Fig. 75-4). The lesions progress to nonscaly hypopigmented macules persisting for months or years. The three stages may occur simultaneously.

Histologically, there is markedly reduced pigment in the epidermis of lesional skin, but no significant difference in melanocyte count was found between lesional and normal skin. Ultrastructurally, degenerative changes in melanocytes and a reduced number of melanosmes within keratinocytes were seen.[33] Extensive PA often also involves the inferior torso in a symmetric pattern. The lack of a preceding inflammatory phase and spongiosis differentiate extensive PA from the classic form. This particular form of PA may overlap with progressive macular hypomelanosis (PMH), a condition mainly described in young female adults, characterized by relapsing hypopigmented, nonscaling patches involving the back, particularly after summer.[34]

Pigmenting PA is a variant associating classic PA with a superficial dermatophyte infection, almost always affecting the face. It is clinically characterized by a bluish hyperpigmentation, attributed to melanin deposits in the dermis surrounded by a hypopigmented scaly area. One-third of patients have concurrent classic PA.

Differential diagnosis includes any localized form of hypopigmentation, especially inflammatory skin conditions associated with postinflammatory hypopigmentation, such as psoriasis, but also with fungal infection, nevus depigmentosus, nevus anemicus, tuberous sclerosis, mycosis fungoides (MF), or vitiligo.

The disease is self-limited and treatment is often not completely successful. Topical steroids and emollients are helpful. Topical tretinoin has also been used with success, but may be irritating. Extensive PA and pigmenting PA have also responded to UV therapy and oral antifungals, respectively. Supportive measures such as decreasing sun exposure, use of sunscreens, and reducing frequency and temperature of baths should be recommended.

The pathogenesis of pigment loss is unclear.[34–38]

SARCOIDOSIS. (See Chapter 152). Hypopigmentation is a rare manifestation of sarcoidosis. Hypopigmented macular lesions scattered over the trunk and extremities but also papular or nodular lesions may be present. The presence of noncaseating dermal granulomas, usually most evident in biopsies of indurated lesions, reinforce the diagnosis. A reduction in melanin content of the epidermis with preservation of melanocytes has been demonstrated.

The pathogenesis of pigment loss is unclear.[39–41]

SCLERODERMA. (See Chapter 157). Hypopigmentation has been described as a pigmentary change in morphea (localized scleroderma) (Fig. 75-5) and scleroderma (progressive systemic sclerosis). Localized hypopigmentation and/or hyperpigmentation are seen in areas of localized sclerosis. Focal depigmentation with perifollicular hyperpigmentation ("salt and pepper pigmentation") especially on upper trunk and extremities, mimicking vitiligo, is reported in up to 30% of patients with scleroderma. The coexistence of scleroderma/morphea and vitiligo has also been reported.[42–44]

LUPUS ERYTHEMATOSUS. (See Chapter 155). Pigment alterations are frequently seen in discoid lupus erythematosus. Hypopigmented patches result from interface dermatitis with destruction of the epidermal basal layer containing melanocytes. "Burned out" lesions are atrophic and depigmented and may be surrounded by hyperpigmentation. Cutaneous depigmentation is also reported in systemic lupus erythematosus, usually localized to inflammatory skin lesions. Biopsy specimens in depigmented skin feature degeneration of the basal layer with epidermal atrophy, a variable number of melanocytes, and pigmentary incontinence in the superficial dermis. The mechanism of hypopigmentation in lupus is not known but could be postinflammatory or cicatricial.

Vitiligo has also been reported in association with lupus erythematosus.[45] A shared genetic predisposition may explain the association of these two autoimmune disorders.[46]

MYCOSIS FUNGOIDES. (See Chapter 146). MF, the most common type of cutaneous T-cell lymphoma, is clinically characterized by three cutaneous phases: (1) the patch phase, (2) the plaque phase, and (3) the tumor phase. Several pigmentary changes have been described in MF.

In poikiloderma vasculare atrophicans, a variant of the patch stage, mottled pigmentation, atrophy and telangiectasia of the involved skin are observed. A mix of hyper- and hypopigmentation may remain after regression of the skin lesions following treatment.

Hypopigmented MF is an uncommon variant of this lymphoma. It mainly develops before the fourth decade, predominantly in juvenile-onset cases and in dark-skinned individuals, without sex predilection. Irregular hypopigmented patches with variably distinct borders are preferentially located on trunk and extremities. Erythema, scaling, and infiltration may be present. A central area of normal pigmentation may be observed. These lesions may also be associated with the more typical lesions of the three cutaneous phases. The hypopigmentation develops without preceding skin changes and occasionally complete depigmentation is observed.

Histopathologically, hypopigmented MF is characterized by minimal dermal involvement, lack of epidermal atrophy, and moderate to marked exocytosis. Pigment incontinence and decrease or absence of melanin may be observed. Infiltrating lymphocytes often have a T-suppressor cell $CD8^+$ phenotype, but a $CD4^+$ phenotype has also been reported.

Electron microscopy may disclose degenerative changes in melanocytes. Melanocytes may be incompletely melanized or occasionally reduced in number. The number of melanosomes within keratinocytes is normal or decreased and melanin-containing macrophages can be observed in the papillary dermis. T-cell receptor gene rearrangement analysis may help to confirm the diagnosis but is often negative, as in early stage MF.

The pathogenesis of hypopigmented MF is not clear. At least in cases showing a $CD8^+$ phenotype, hypopigmentation could be due to the melanocytotoxic effect of nonneoplastic $CD8^+$ lymphocytes, as hypothesized in vitiligo.

Hypopigmented MF responds well to treatment, particularly psoralen and UVA light (PUVA) or

Figure 75-5 Morphea. Note the discrete hyperpigmentation in the area of localized sclerosis.

narrowband UVB therapy. It has a relatively benign course, although recurrences are common. Hypopigmented MF should be distinguished from other causes of diffuse hypopigmentation, especially vitiligo, tinea versicolor, PA, or postinflammatory hypopigmentation.[47–51]

INFECTIONS

Treponematoses. (See Chapters 200 and 201). Nonvenereal treponematoses are currently endemic in parts of Central and South America, Africa, Asia, and the Pacific Islands and can be severely disfiguring. Depigmentation is seen in several stages of yaws, bejel, and pinta. When the primary lesion of yaws disappears, a typical depigmented and pitted scar remains. In the tertiary stage of bejel, gummatous nodules develop in the skin and in other organs. Most skin lesions regress, leaving depigmented, noncontracted scars. Pinta is the only treponematosis that only affects the skin and causes pigmentary abnormalities in the first, second, and third stages of the disease. The sentinel lesion of pinta may heal at the end of the primary stage, leaving a macular dyschromia. The secondary stage is characterized by the appearance of the so-called *pintids*, which are initially red but often turn brown, slate-blue, gray, or black. This stage can last several years, leading to a mix of depigmentation and hyperpigmented lesions. Generalized pigmentary abnormalities develop during the tertiary stage. A symmetrical pattern of vitiligo-like lesions and brown, gray or blue and black lesions is seen over bony prominences (Fig. 75-6).[52]

Onchocerciasis. (See Chapter 207). Several different skin manifestations can become apparent during the course of onchocerciasis. Onchocercal depigmentation or "leopard skin" is rarely associated with itch and is one of the most common skin manifestations of onchocerciasis. Hypopigmented patches with perifollicular spots of normally pigmented skin, typically occur symmetrically on the pretibial area of older people in endemic areas.[53] (Fig. 75-7).

Post-kala-Azar Dermal Leishmaniasis (PKDL). (See Chapter 206). Post-kala-azar dermal leishmaniasis develops in insufficiently treated kala-azar or visceral leishmaniasis, which is caused by *Leishmani. donovani*. Skin manifestations of PKDL are nodules and plaques, facial erythema, and hypopigmented macules. Nodules and plaques typically develop around the mouth and spread to the face, arms and chest, but the macules may occur more generalized over the whole body. Mild disease can resolve spontaneously, but severe forms require systemic treatment.[54,55]

Leprosy. (See Chapter 186). The presence of a hypopigmented lesion with reduced sensation is the hallmark of leprosy and is one of the diagnostic criteria (Fig. 75-8). Indeterminate leprosy, frequently the first manifestation of leprosy, is characterized by the presence of a few such lesions. Tuberculoid leprosy usually manifests as a limited number of well-defined,

Figure 75-6 Pinta. The hypomelanosis in pinta is a vitiligo-like hypomelanosis that occurs later in the disease and is associated with deep blue to slate-gray areas of hyperpigmentation.

depressed, hairless lesions occur that appear hypopigmented in black patients and erythematous in white patients.[56]

CHEMICAL AND PHARMACOLOGIC AGENTS.

The potential for chemicals to induce hypopigmentation was discovered in the first half of the twentieth century. Leukoderma was noticed in rubber workers exposed to

Figure 75-7 Onchocerciasis.

Figure 75-8 Leprosy. A characteristic off-white hypomelanotic and anesthetic macule.

the monobenzylether of hydroquinone (MBEH), a frequently used antioxidant in the rubber industry. Since then, depigmenting properties have been attributed to many chemicals and new therapeutic depigmenting agents have been developed.[57]

Occupational exposure to chemicals that have a destructive effect on melanocytes can result in chemical leukoderma. Agents such as *para*-tertiary butylphenol, *para*-tertiary butyl catechol, MBEH, and hydroquinone can cause permanent depigmentation. The depigmentation caused by chemicals is difficult to distinguish from idiopathic vitiligo. The former usually starts at the hands and forearms, presumptive sites of contact, but depigmentation at a distance is also possible (Fig. 75-9). Chemical leukoderma spreads by coalescence of small macules, whereas the sudden appearance of large patches with perifollicular sparing is more suggestive of vitiligo. Chemical leukoderma is very likely if several exposed workers develop depigmentation. However, not all exposed individuals develop leukoderma and it is hypothesized that the individual susceptibility is variable.[57,58]

Chemicals are also employed therapeutically or cosmetically to lighten skin color. There are three main mechanisms of action for bleaching agents. Some act before melanin is synthesized by inhibiting tyrosinase transcription and glycosylation. Other agents act during melanin synthesis by inhibiting enzymes such as tyrosinase or peroxidase or act as reducing agents or radical oxygen species scavengers. Finally, some agents act after melanin synthesis because they are responsible for tyrosinase degradation, inhibition of melanosome transfer, or acceleration of skin turnover, leading to depigmentation.[59]

MBEH was used as a lightening agent until its ability to cause total permanent and often confetti-like depigmentation became apparent. It should be used only to produce total depigmentation in patients with diffuse vitiligo. A formulation with 20% MBEH is usually prescribed for that purpose. Hydroquinone is one of the most popular depigmenting substances and is frequently used for the treatment of melasma in concentrations between 2% and 5%. Concentrations higher than 5% incur a risk of permanent depigmentation. Adverse effects are irritation, postinflammatory pigmentation, and exogenous ochronosis.[57,59–61]

PHYSICAL AGENTS. Heat, freezing, X-ray, ionizing radiation, UV irradiation, and laser light can cause hypopigmentation or permanent depigmentation by damaging melanocytes, leading to destruction or impaired function.[62]

LICHEN SCLEROSUS. (See Chapter 65). Lichen sclerosus typically presents as a pruritic erythematous patch in the early stage, evolving to a depigmented atrophic plaque with porcelain white appearance.

Mechanisms believed to play a role in this idiopathic leukoderma include decreased melanin production, blocked transfer of melanosomes to keratinocytes, and loss of melanocytes.

MELANOMA-ASSOCIATED LEUKODERMA. (See Chapter 124). Regression in a primary melanoma lesion typically causes a depigmented scar-like area within the lesion.

Melanoma-associated hypo- or depigmentation, also known as leukoderma acquisitum centrifugum, can occur around the primary melanoma or metastases or at distant sites. The latter is often called vitiligo, although the resemblance is limited. Whereas vitiligo depigmentation is usually symmetric and spreads centripetally to the trunk, melanoma-associated hypo- or depigmentation tends to be extensive, patchy, and asymmetric. The lesions may be mottled (hypomelanotic) or milk white (amelanotic). In most cases, leukoderma appears simultaneously with the finding of metastases. Histologic examination of lesions shows a decrease or complete absence of melanocytes. Macromelanocytes with stubby dendrites can also be observed. Melanoma with associated leukoderma may be associated with a better survival rate than comparably advanced lesions without epidermal pigment loss. Strong evidence suggests that melanoma-associated leukoderma results from host immune reaction against the malignancy, involving humoral and cellular mechanisms. Both passive and active immunotherapeutic strategies used in the treatment of melanoma have been associated with leukoderma (Fig. 75-10).[63,64]

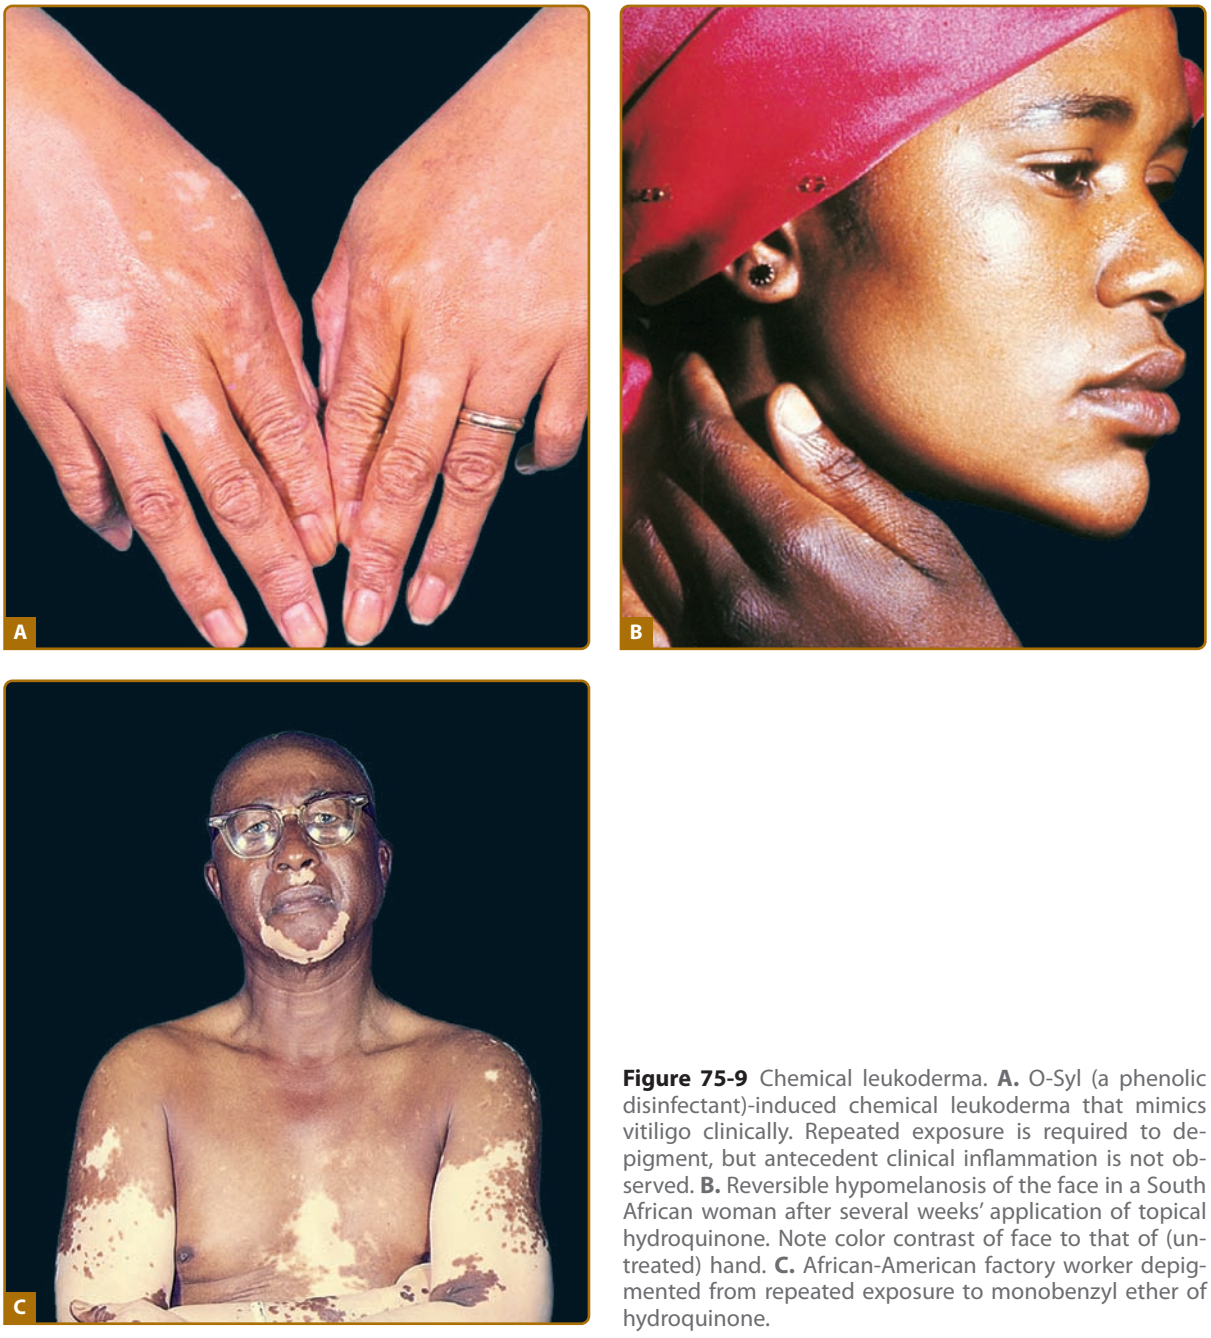

Figure 75-9 Chemical leukoderma. **A.** O-Syl (a phenolic disinfectant)-induced chemical leukoderma that mimics vitiligo clinically. Repeated exposure is required to depigment, but antecedent clinical inflammation is not observed. **B.** Reversible hypomelanosis of the face in a South African woman after several weeks' application of topical hydroquinone. Note color contrast of face to that of (untreated) hand. **C.** African-American factory worker depigmented from repeated exposure to monobenzyl ether of hydroquinone.

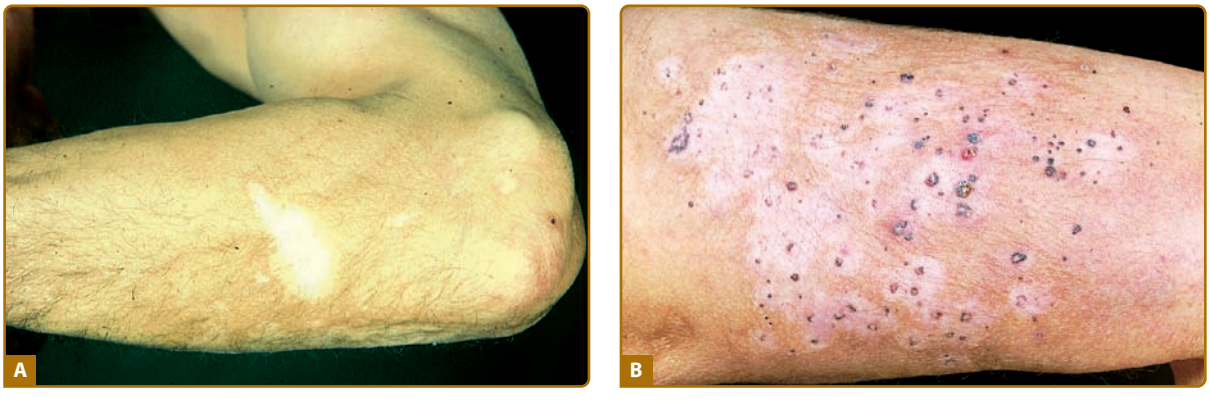

Figure 75-10 Melanoma-associated leukoderma. **A.** This hypomelanosis may resemble vitiligo clinically and be characterized by an absence of melanocytes. It may be associated with a favorable prognosis. **B.** These macules in a different patient developed after the patient developed metastases to the skin. They surround the individual metastases.

ACQUIRED DIFFUSE HYPOPIGMENTATION

Nutritional disorders and endocrinopathies mainly cause hyperpigmentation. Diseases such as copper deficiency, vitamin B_{12} deficiency, kwashiorkor, Addison disease, hyperthyroidism, and diabetes can also be associated with hypopigmentation, but are discussed under Section "Hypermelanosis" because hyperpigmentation is their main feature.

HYPOTHYROIDISM. (See Chapter 151). Hypothyroidism is frequently associated with cutaneous alterations. The skin is pale due to anemia and vasoconstriction. Yellowish discoloration of the palms, soles, and nasolabial folds is caused by an accumulation of carotene in the stratum corneum. The associated hypercarotinemia results from reduced capacity of the liver to convert β-carotene to vitamin A. Vitiligo has been associated with autoimmune hypothyroidism.[65–67]

HYPOPITUITARISM. Panhypopituitarism results from a variety of conditions that compromise the anterior pituitary. As a consequence, release of pituitary-derived factors including melanocyte-stimulating hormone (MSH), thyroid-stimulation hormone, adrenocorticotrophic hormone, luteinizing hormone, follicle-stimulating hormone, growth hormone, and vasopressin is decreased. Due to the reduction of circulatory pituitary hormones, production of cortisol, thyroxine, estrogens, and testosterone in target organs is lowered.

Patients suffering from panhypopituitarism look pale due to anemia and decreased cutaneous blood flow. As well, generalized hypopigmentation results from decreased adrenocorticotrophic and MSH that stimulate epidermal melanogenesis.[66]

HYPOGONADISM. Castrated human males are characteristically pale and their genital skin is not hyperpigmented as in normal men. An impaired tanning response to UV radiation has been described. Administration of testosterone makes the skin turn darker and restores the tanning response.[68]

SELENIUM DEFICIENCY. Loss of hair and skin pigmentation due to selenium deficiency has been described in children receiving long-term total parenteral nutrition. After selenium supplementation, skin and hair darken.[69]

COPPER DEFICIENCY. Acquired copper deficiency occurs in severely malnourished infants. Hypopigmentation of the hair is attributed to copper deficiency, presumably because tyrosinase is a copper-dependent enzyme, but as multiple nutritional deficiencies tend to coexist pathogenesis is difficult to confirm.[70]

IDIOPATHIC GUTTATE HYPOMELANOSIS. Idiopathic guttate hypomelanosis (IGH) is an acquired leukoderma, characterized by discrete, round, or oval porcelain-white macules of approximately 2–5-mm diameter, which increase in number with aging

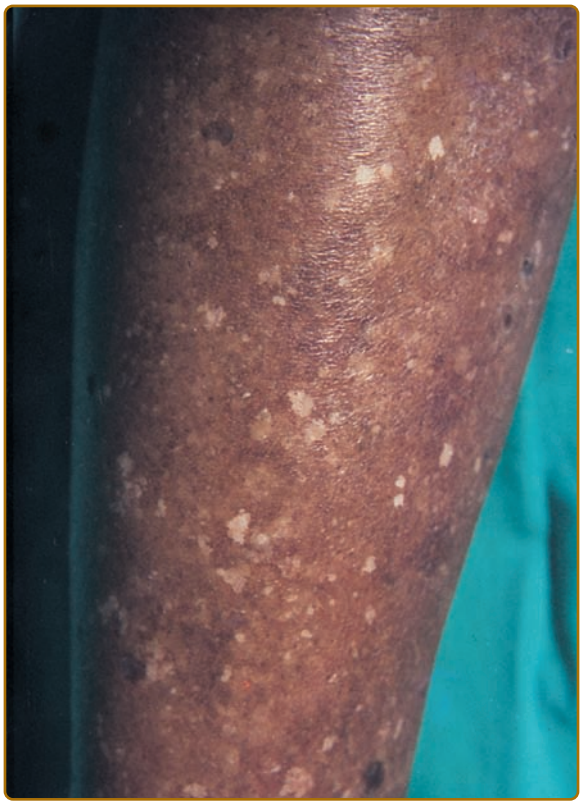

Figure 75-11 Idiopathic guttate hypomelanosis. Lesions on the leg of an African-American individual.

(Fig. 75-11). Any associated hairs often remain pigmented. Lesions are found in a photodistribution and tend to occur in chronically sun-damaged skin. They are often seen pretibially and on the forearms, although they may also arise on other sun-exposed areas, including the face, neck, and shoulders. IGH has been hypothesized to be UV-induced, although controversy exists. Some suggest that IGH may reflect the normal aging process.[71]

Histologically, IGH lesions are characterized by slight basket-weave hyperkeratosis with epidermal atrophy and flattening of the rete pegs. Lesions show a decrease in melanocytes and melanin content of the affected epidermis and pigment granules are irregularly distributed.

A variety of therapies with variable success are described, including cryotherapy, superficial dermabrasion, topical steroids, and topical retinoids.[72,73]

LEUKODERMA PUNCTATA. Leukoderma punctata was first described by the development of multiple punctiform hypopigmented and achromic spots after several months of PUVA treatment.[74] Later, similar cases were described after UVB therapy for psoriasis and after topical PUVA in one case of segmental vitiligo.[75]

Lesions are predominantly present on the extremities, upper back and chest. They are round or oval, sharply demarcated, and small (0.5–1.5 mm), without follicular distribution. Spontaneous reduction of the leukodermic lesions has been observed.[74]

It has been suggested that phototoxicity damage to keratinocytes and melanocytes is the etiologic factor. Leukoderma punctatum is suggested to be distinct from IGH on the basis of the clinical and histologic features. In IGH, lesions are larger and spontaneous resolution is not reported. Ultrastructurally, leukoderma punctata demonstrates slight-to-severe damage of keratinocytes and melanocytes not reported in IGH.

CANITIES. Hair graying or canities is a process of chronological aging and occurs regardless of gender or race.[76] The age of onset, which appears to be hereditary, is usually in the fourth decade. The average age for whites is mid-30s, for Asians late 30s, and for Africans mid-40s. Premature canities (before 20s or 30s) can be associated with pernicious anemia, hyper/hypothyroidism, osteopenia, and several rare syndromes like progeria and pangeria (Werner syndrome). Graying usually appears at the temples first, then the vertex, and, finally, the occiput. Beard and body hair are affected later. Gray hairs seem to be thicker and longer than normally pigmented hairs. The perception of "gray hair" derives in large part from the admixture of pigmented and white hair, but individual hair follicles can indeed exhibit pigment dilution or suboptimal melanocyte–cortical keratinocyte interactions during the graying process.[77–79] An acute episode of alopecia areata may result in a very sudden "overnight" graying (so-called *canities subita*) that is caused by the preferential loss of pigmented hair in this immune-mediated disorder.

HEMODIALYSIS. Chronic hemodialysis patients frequently show disorders of skin pigmentation, primarily involving hyperpigmentation of sun-exposed body areas. Hypopigmentation of skin and hair is rather exceptional but occurs, possibly due to a disturbance of phenylalanine metabolism.

PROGRESSIVE MACULAR HYPOMELANOSIS. PMH is an entity that affects the trunk with nummular, hypopigmented nonscaly macules. It affects young adults, mainly women. Although described in people of mixed racial ancestry (known as *Creole dyschromia*),[80] it is seen in all races. It can be mistaken for PA and pityriasis versicolor. Topical and systemic antifungal treatment and topical steroids are ineffective, but the disorder may resolve, sometimes temporarily, after sun exposure or phototherapy.

ACQUIRED DIFFUSE HYPOPIGMENTATION WITH VASCULAR CAUSES

ANEMIA. The color of the skin is determined by several chromophores, usually predominantly melanin pigment, but the hemoglobin content of the skin also contributes to the skin color. The pale skin color observed in anemia is due to decreased levels of circulating oxyhemoglobin and is proportional to the severity of the anemia.

BIER SPOTS. Bier spots are small, irregular apparently hypopigmented areas, usually on arms and legs in young adults, resulting in a reticulated appearance. The surrounding skin is erythematous and blanches with pressure causing the "hypopigmented" macules to disappear. The condition is a vascular anomaly with vasoconstriction in the pale areas and venodilatation in erythematous skin.[81,82]

WORONOFF'S RING. (See Chapter 18). Woronoff's ring represents a blanched halo surrounding a psoriatic lesion. It is observed after UV treatment or topical steroid treatment, but may also occur in untreated psoriasis. The pathogenesis is not clear. A decreased melanin content has been found in both psoriatic and halo epidermis suggesting a true hypomelanosis. A local decreased prostaglandin synthesis with decreased vasodilatation or a diffusion of anti-inflammatory mediators from the psoriatic lesion to the halo is also postulated.

CUTANEOUS EDEMA. Cutaneous edema produces an appearance of leukoderma that is not true hypomelanosis. Decreased absorption of light, reduced capillary blood flow, and increased dermal thickness may contribute to the pale appearance of the skin.

HYPERMELANOSIS

CONGENITAL DIFFUSE HYPERMELANOSIS

CONGENITAL DIFFUSE LINEAR HYPERMELANOSIS

Linear and Whorled Nevoid Hypermelanosis. Linear and whorled nevoid hypermelanosis (LWNH) is characterized by hyperpigmented macules in streaky configuration along the lines of Blaschko without preceding inflammation or atrophy.[89] Similar cases have been described under different descriptive names (*zosteriform hyperpigmentation*, *zosteriform lentiginous nevus*, *zebra-like hyperpigmentation*). Lesions are typically located on the trunk and limbs and do not cross the midline. Face, palms, soles, eyes, and mucous membranes are spared. Kalter et al described LWNH as having onset within a few weeks of age and progression during the initial years of life.[89] The pigmentation can fade gradually with increasing age. Several cases have been reported with both hyper- and hypopigmentations. Pigmentary mosaicism is a useful term to encompass all these different phenotypes.[90]

The presence of mosaicism has been confirmed in a few cases (mosaic trisomy 7, 14, 18, 20, and X-chromosomal mosaicism) by chromosomal analysis on lymphatic cultures or dermal fibroblasts.[91]

LWNH may be differentiated from incontinentia pigmenti (IP) and epidermal nevus.[89]

Extracutaneous abnormalities have been observed in a number of LWNH cases, including developmental and growth retardation, facial and body asymmetry, ventricular septal defect, and pseudohermaphroditism.

Histologic examination reveals increased pigmentation of the basal layer and prominence or vacuolization of melanocytes. Pigment incontinence is usually but not always absent.[92]

Incontinentia Pigmenti. IP, also known as *Bloch–Sulzberger syndrome*, was first described by Garrod et al in 1906. It is an X-linked, dominantly inherited disorder, reported primarily in females, and believed to be embryonic lethal in the majority of males. In most cases, IP is due to a mutation in the gene *NEMO* [nuclear factor κB (NF-κB) essential modulator] on the X chromosome at Xq28.[93–96] In IP females, inactivation of one of the two X chromosomes through a process termed lyonization occurs during embryogenesis. Epidermal cells expressing the defective *NEMO* gene give rise to typical skin lesions along the lines of Blaschko, reflecting the embryonic migration path of the affected keratinocytes. Lesions usually proceed through four cutaneous stages, sometimes with some overlap: (1) vesicular stage (from birth or shortly thereafter), (2) verrucous stage (between 2 and 8 weeks of age), (3) hyperpigmented stage (several months of age into adulthood), followed by (4) hypopigmentation stage (from infancy through adulthood) (Fig. 75-12). A significant percentage of IP patients have ocular, dental, skeletal, and CNS anomalies.[97]

The cutaneous lesions in the first stage represent the population of NEMO-deficient cells that fail to activate NF-κB, leading to apoptosis, as NF-κB normally protects against tumor necrosis factor-induced apoptosis. The number of NEMO-deficient cells decreases secondary to apoptosis and is replaced by cells expressing the normal allele. Subsequently, the inflammatory and vesicular stage ends. The hyperproliferation in the second stage is likely due to compensatory proliferation of normal NEMO keratinocytes. Hyperpigmentation in the third stage results from incontinence of melanin pigment from the destroyed epidermis into the dermis.

The hyperpigmentation appears in streaks and whorls along the lines of Blaschko and is usually most pronounced on the trunk, but can also appear on the extremities. The degree of hyperpigmentation varies among individuals. Histologically, the areas of pigmentation show many melanin-laden melanophages, extensive deposits of melanin in the basal cell layer and dermis. There is vacuolization and degeneration in the epidermal basal cell layer. Usually, the hyperpigmentation fades gradually after several years and the skin can become hypopigmented (stage 4), which represents postinflammatory dermal scarring. The hypopigmentation stage is characterized by linear, atrophic, hairless scars following the Blaschko's lines.

Histologically, the number of melanocytes seems to be normal, although a reduced number of melanocytes also has been reported. The epidermis is thinner and there is an absence or reduction of skin appendages in the dermis that may contribute to the impression of hypopigmentation.[98]

A beneficial effect of topical steroids and topical tacrolimus in the vesicular stage has been described.[99,100]

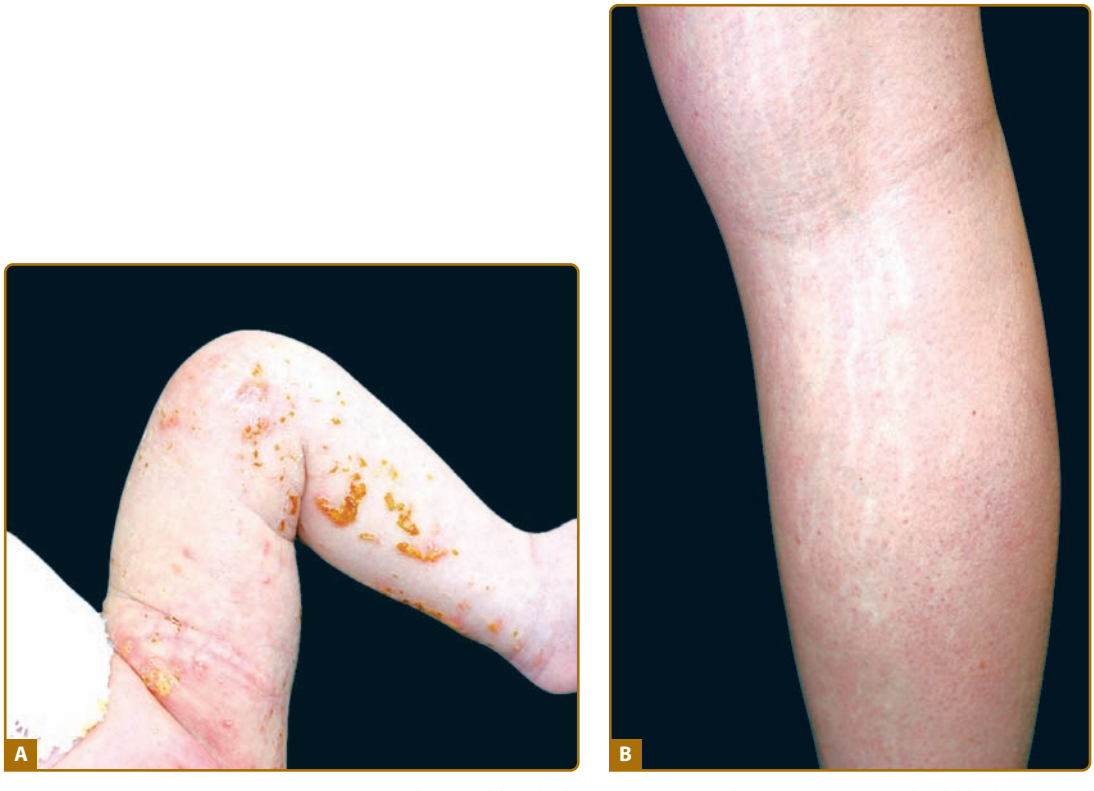

Figure 75-12 Incontinentia pigmenti in a mother and her baby. **A.** Verrucous lesions in a 2-week-old baby. **B.** Hypopigmented atrophic lesions following the Blaschko's lines.

CONGENITAL DIFFUSE RETICULAR HYPERMELANOSIS

Dyskeratosis Congenita. Dyskeratosis congenital (DKC) or *Zinnser–Engmann–Cole syndrome* is characterized by reticulate skin pigmentation, nail atrophy, leukoplakia, and bone marrow failure. Bone marrow failure and malignancy develop in the second and third decades. In all characterized cases of DKC, the causative mutations are present in components of the telomerase complex. Rapidly dividing somatic cells express low but detectable levels of telomerase activity that slows the otherwise progressive telomere shortening that occurs with each cycle of DNA replication and eventually leads to cellular senescence (permanent loss of proliferative capacity). It is now thought that DKC is due to defective telomere maintenance, limiting the proliferative capacity of hematopoietic and epithelial cells. Increased melanin synthesis is now recognized to occur in senescent melanocytes, likely accounting for the pigmentary phenotype of DKC; and critically short telomeres may force cells into "replicative crisis," at which time activation of an alternative "ALT" mechanism for lengthening telomeres in the absence of telomerase may lead to development of malignancies. The finding of shortened telomeres in DKC was indeed the first evidence of the role of telomeres in cell biology (cellular aging).[101]

X-linked DKC is caused by mutations in the *DKC1* gene located at Xq28, encoding for dyskerin. Females carrying one mutated allele are protected by expression of normal telomerase on the unaffected allele. In autosomal dominant DKC the majority of cases are due to mutations in TERC, the RNA component of the telomerase complex. TERT (telomerase reverse transcriptase) is affected much less often in autosomal dominant DKC. The autosomal dominant form has the better prognosis, presumably because some telomerase activity is preserved, due to the presence of an unaffected allele.

In the autosomal recessive form of DKC, mutations in telomerase-associated proteins such as NOP10, NHP2, and TINF2 are involved.[102–104] Skin biopsy of hyperpigmented skin shows nonspecific changes, including epidermal atrophy, a chronic inflammatory infiltrate with numerous melanophages in the upper dermis. DKC may be confused with Fanconi's syndrome, characterized by short stature, hypoplastic or aplastic thumbs, and a reduced number of carpal bones. Here, there is a patchy hyperpigmentation of the trunk, neck, groin, and axillary region that manifests itself earlier than in DKC, i.e., in the first few years of life.

For a discussion of Naegeli–Franceschetti–Jadassohn syndrome, dermatopathia pigmentosa reticularis, Dowling–Degos disease, Galli–Galli disease, Kitamura reticular acropigmentation, Haber's syndrome, and Partington syndrome, see online edition.

CONGENITAL CIRCUMSCRIBED HYPERMELANOSIS

CONGENITAL CIRCUMSCRIBED HYPERMELANOSIS WITH DERMAL MELANOCYTOSIS. Dermal melanocytoses or dermal dendritic melanocytic proliferations are characterized by the presence of melanin-producing dendritic melanocytes in the dermis. They include the nevus of Ito, nevus of Ota, and Mongolian spot and dermal melanocyte hamartoma (Table 75-1). Associated vascular malformation has been described in phakomatosis pigmentovascularis (Port-wine stain type, Klippel–Trenaunay or Sturge–Weber syndrome).[111]

Nevus of Ota. Ota's nevus (nevus fuscocaeruleus ophthalmomaxillaris) was first described by Ota in 1939.[112] It is characterized by blue–black or gray–brown dermal melanocytic pigmentation and typically occurs in areas innervated by the first and second branches of the trigeminal nerve. Mucosal pigmentation may occur involving conjunctiva, sclera, and tympanic membrane (oculodermal melanocytosis), (Fig. 75-13) or other sites. It is most frequently seen in the Asian population, has a female predominance, and is usually congenital, although appearance in early childhood or at puberty has been described. Nevus of Ota is now subclassified as mild (type 1), moderate (type 2), intensive (type 3), and bilateral (type 4). Bilateral cases should be differentiated from Hori nevus, which is acquired, does not manifest mucosal involvement and is less pigmented (see Table 75-1).[113]

Malignant melanoma may rarely develop in a nevus of Ota. This necessitates careful follow-up of the lesion, especially if it occurs in Caucasian patients, in whom malignant degeneration seems to be more frequent. Malignant melanocytic tumors in association with nevus of Ota have been shown to arise in the chorioidea, brain, orbit, iris, ciliary body, and optic nerve.[114,115] In addition, association with ipsilateral glaucoma and intracranial melanocytosis has been described.[116]

Nevus of Ito. Nevus of Ito is a congenital dermal melanocytosis first described by Ito in 1954 as nevus fuscocaeruleus acromiodeltoideus.[117] It can be considered as a variant of nevus of Ota but with involvement of the acromioclavicular and deltoideal region. Clinical, demographical, and histological characteristics are similar to nevus of Ota and both lesions can occur simultaneously (see Table 75-1).

Mongolian Spots. Mongolian spots are congenital, benign hyperpigmentations preferentially occurring in the African, Asian, and Hispanic population and only rarely seen in Caucasians.[118] They occur in both sexes but with a slight male predominance,[119] usually in the sacral area. (Fig. 75-14) They can also be found in the gluteal and lumbar region and on the thorax, abdomen, arms, legs, and shoulders. In most cases Mongolian spots spontaneously regress during childhood, but persistence into adulthood has been described.[120] Histologically, these macules consist of spindle-shaped melanocytes in the lower dermis that have failed to migrate to the dermal–epidermal junction during fetal life. Several cases are described with extensive Mongolian spots involving large areas of the trunk and extremities, associated with inborn errors of metabolism such as GM1 gangliosidosis and mucopolysaccharidosis.[121,122] Laser treatment in childhood or adolescence can give favorable results with sacral Mongolians spots being more laser-resistant than extrasacral ones.

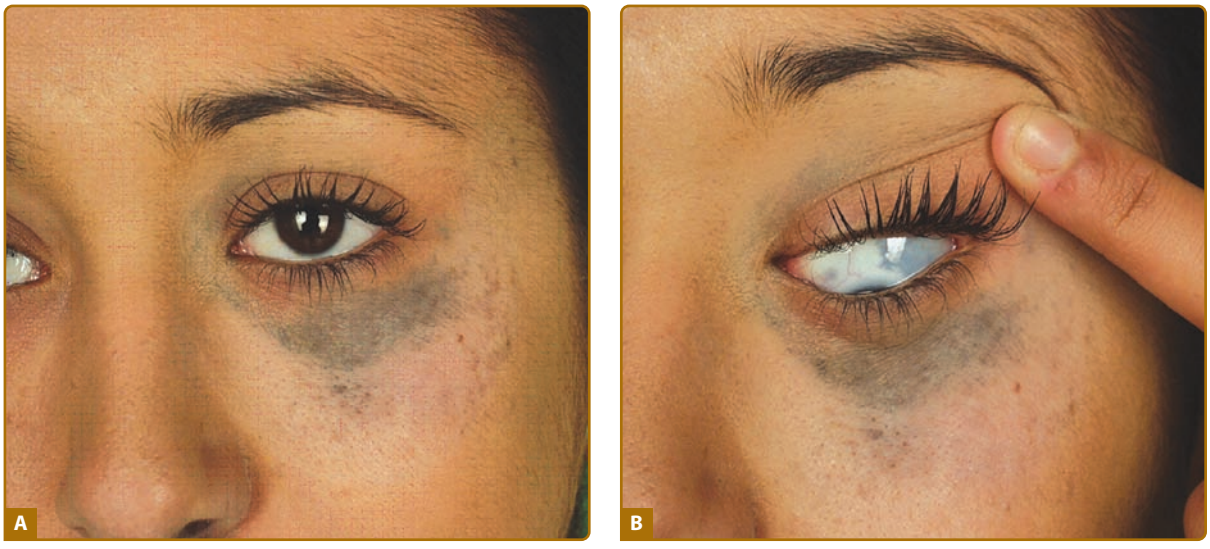

Figure 75-13 Nevus of Ota in a 20-year-old woman. **A.** Hyperpigmentation around the orbita. **B.** The hyperpigmentation extends into the sclera.

Dermal Melanocyte Hamartoma. Dermal melanocyte hamartoma is a distinctive form of congenital dermal melanocytosis first described by Burkhart et al in 1981.[123] Gray–blue pigmentation, caused by melanocytes residing in the dermis, occurs in a dermatomal pattern.

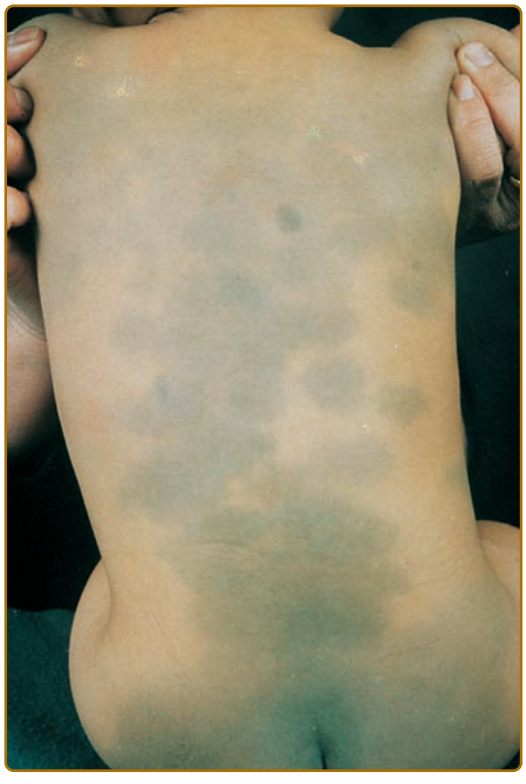

Figure 75-14 Classic Mongolian spot in the lumbosacral region and aberrant or extrasacral Mongolian spots on the back.

CONGENITAL CIRCUMSCRIBED HYPERMELANOSIS WITH LENTIGINOSIS

Familial Lentiginosis Syndromes. Familial lentiginosis syndromes are characterized by the presence of lentigine-circumscribed brown macules (usually <5 mm in diameter), which display an increased number of melanocytes in the epidermis (epidermal melanocytic hypermelanosis) and an increased incidence of cardiovascular, endocrine, or gastrointestinal neoplasias. They include Carney complex, Peutz–Jeghers syndrome (PJS), LEOPARD syndrome (LS) (lentigines, electrocardiogram conduction defects, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and sensorineural deafness), arterial dissection and lentiginosis, Laugier–Hunziker disease, familial benign lentiginosis, Bannayan–Ruvalcaba–Riley syndrome (BRSS), centrofacial lentiginosis, and segmental and agminated lentiginosis.[124] (See Fig. 75-16.) Genetic loci and gene mutations have been identified for Carney complex, PJS, and BRRS.

Peutz–Jeghers Syndrome. PJS is an autosomal dominant cancer predisposition syndrome first described by Peutz (1921) and Jeghers (1949).[125] Mucocutaneous pigmentation and intestinal hamartomatous polyposis are hallmarks of the disease. (See Fig. 75-15.) The pigmentary lesions resemble those of Carney complex, with small hyperpigmented macules typically appearing in childhood (not present at birth) on the lips and buccal mucosa, but they may also involve the eyelids, hands, and feet.[124]

The most common malignancies associated with PJS are gastrointestinal (small intestine, colorectal, stomach, pancreas). In addition, nongastrointestinal neoplasms such as breast, cervix, and endocrine tumors (thyroid, testicular, ovarian) have been described. More than half of all cases of PJS can be attributed to a mutation in the serine/threonine kinase 11 (*STK 11*

Figure 75-15 Peutz–Jeghers syndrome. **A.** Lentigines, which are dark-brown to gray–blue, appear on the lips, around the mouth, and on the fingers. Lip macules may, overtime, disappear. **B.** Macules of the buccal mucosa are blue to blue–black and are pathognomonic; unlike lip lesions, these do not tend to disappear with time.

Figure 75-16 **A** and **B.** A 27-year-old woman with LEOPARD (lentigines, electrocardiogram conduction defects, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and sensorineural deafness) syndrome. Note the characteristic widespread lentigines and several café-au-lait macules.

or *LKB 1*) gene,[126] which is therefore thought to act as a tumor-suppressor gene. Close surveillance of PJS patients from a young age is warranted.

LEOPARD Syndrome. LS is an autosomal dominant genodermatosis[124] The characteristic lentigines usually develop during childhood and in the first months of life. Clinical diagnosis is primarily based on the typical facial features and the presence of hypertrophic cardiomyopathy and/or café-au-lait macules (CALMs). The disorder is caused by mutations in the *PTPN11* gene, coding for the protein tyrosine phosphatase SHP-2 and situated on chromosome 12. LS is allelic to Noonan syndrome and shares several clinical features (Fig. 75-16).[127] Recently missense mutations in the *RAF1* gene were found in two LS patients in whom no *PTPN11* mutations could be discovered.[128]

For Carney complex, BRSS, and centrofacial lentiginosis, see online edition.

CONGENITAL CIRCUMSCRIBED HYPERMELANOSIS WITH CAFÉ-AU-LAIT MACULES. CALMs consist of sharply bordered hyperpigmented patches of skin, varying in size from 0.5 cm to more than 20.0 cm. They are often present at birth or appear in the early months of life. Between 0.3% and 18% of all newborns display isolated CALMs.[137] Histologically, isolated CALMs show a normal number of melanocytes but increased epidermal melanin (epidermal melanotic hypermelanosis). Multiple CALMs are well-known markers for several multisystem disorders.

Neurofibromatosis Type 1. Neurofibromatosis type 1 (NF1) was first recognized by Friedrich von Recklinghausen in 1882 and is therefore also called von Recklinghausen's disease (see Chapter 141 for detailed discussions).

NF1 is an autosomal dominant disease caused by a mutation in the *NF1* gene, situated on chromosome 17q11.2 and encoding the neurofibromin protein. Neurofibromin takes part in several signaling pathways and exhibits multiple isoforms through alternative splicing mechanisms. The most important neurofibromin function involves downregulation of the Ras signal transduction pathway and it is, therefore, considered a tumor-suppressor gene.[124,138]

NF1 has been considered as a neurocristopathy and is characterized by a number of cutaneous and noncutaneous pigment cell-related manifestations such as CALMs, intertriginous freckling, and iris Lisch nodules.[138,139] In 1987, the US National Institutes of Health Consensus Development Conference established clinical diagnostic criteria for NF1 (see Chapter 141). The presence of six or more CALMs greater than 5 mm in greatest diameter in prepubertal individuals or greater than 15 mm after puberty is one of the hallmarks of the disease. NF1-associated CALMs, contrary to isolated CALMs, contain a significantly increased number of melanocytes in the epidermis.[140] Intertriginous freckles, pathognomic for NF1, also display increased numbers of epidermal melanocytes, which differentiates them from ordinary freckles (ephelides). (See eFig. 75-16.1 in online edition.)

Mccune–Albright Syndrome. McCune–Albright syndrome (MAS) was first described by McCune (1936) and Albright (1937) as a triad of poly/monostotic fibrous dysplasia, CALMs, and hyperfunctioning endocrinopathies, including precocious puberty, hyperthyroidism, hypercortisolism, hypersomatotropism, and hypophosphatemic rickets.[141,142] The CALMs are fewer in number and have more irregular borders than those seen in NF1. They are classically demarcated at the midline. MAS is caused by a postzygotic activating mutation of the α subunit of the cAMP-regulating Gs protein. Consequently, a mosaic distribution of MAS cells bears the constitutively active adenylate cyclase.[143]

For Bloom, Watson, and Silver–Russel syndromes, see online edition.

ACQUIRED DIFFUSE NONFIGURED HYPERMELANOSIS

ENDOCRINOPATHIES

Addison's Disease. (See Chapter 151). Addison's disease is a clinical syndrome characterized by salt-wasting and skin hyperpigmentation, associated with adrenal deficiency with inadequate secretion of corticosteroid and androgenic hormones, leading to compensatory overproduction of adrenocorticotropic hormone (ACTH) secretion by the pituitary gland.[157]

In the developed world, Addison's disease is usually autoimmune in etiology.

Hyperpigmentation is the most striking cutaneous sign of patients with chronic Addison's disease and is the consequence of ACTH binding to the melanocortin-1 receptor (see Chapter 72). The hyperpigmentation is diffuse and occurs preferentially on sun-exposed areas (face, neck, hands), on sites of trauma, scars, or chronic pressure (knees, spine, knuckles, elbows, shoulders), in the palmar creases, and on nipples, areolae, axillae, perineum, and genitalia.[157]

Cushing's Syndrome. (See Chapter 151). Cushing syndrome is characterized by clinical signs and symptoms due to chronic glucocorticoid excess.

Various degrees of hyperpigmentation can be seen, usually most severe in patients with the ectopic ACTH syndrome. As in Addison disease, hyperpigmentation is generalized, but most prominent in sun-exposed areas such as face, neck, and dorsal hands, as well as in areas subject to chronic mild trauma or pressure (shoulders, midriff, waist, elbows, knuckles, spine, knees) and on mucosal surfaces.[158,159]

Nelson's Syndrome. Nelson's syndrome comprises an enlarging pituitary tumor associated with elevated fasting plasma ACTH levels, hyperpigmentation, and neuro-ophthalmological symptoms in patients with Cushing's disease after bilateral adrenalectomy and inadequate hormonal replacement.[160]

Pheochromocytoma. Pheochromocytoma is a tumor derived from chromaffin cells of the adrenal medulla with associated excessive production of catecholamines. Pallor of the face due to vasoconstriction may be observed. In contrast, addisonian-like hyperpigmentation has been reported and is probably due to ectopic ACTH and MSH production by the tumor. Pigmentation rapidly fades after surgical treatment.[161]

Carcinoid Syndrome. Diffuse hyperpigmentation due to MSH-producing tumors, such as gastric or thymic carcinoid tumors, have been described in carcinoid syndrome. Carcinoid syndrome can also be accompanied by a pellagra-like rash occurring on light-exposed skin. The rash is secondary to a tryptophan deficiency, as a large amount of dietary tryptophan is diverted to serotonin by the tumor.

Hyperthyroidism. (See Chapter 151). Thyrotoxicosis has multiple causes. The most common cause is Grave's disease, characterized by circulating antibodies against thyroid-stimulating hormone receptors.

The occurrence of hyperpigmentation in thyrotoxic patients has been estimated from 2% to as high as 40% in large series. The increased cutaneous pigmentation can be localized or generalized and is more common in dark-skinned people. The distribution of hyperpigmentation is often similar to that in Addison's disease with pigment deposition in the creases of the palms and soles. However, several features distinct from that of Addison's disease have been noted. Involvement of the mucous membranes is uncommon and pigmentation of the nipples and genital skin is less striking. Hyperpigmentation associated with thyrotoxicosis is thought to be due to an increased release of pituitary ACTH, compensating for accelerated cortisol degradation. The response of hyperpigmentation to therapy for the hyperthyroidism is reported to be poor.[162–164] Autoimmune Grave's disease has been reported in association with vitiligo.

Melasma. Melasma is a common hypermelanosis that typically occurs on sun-exposed areas in the face. The pathogenesis is poorly understood, but genetic and hormonal influences in combination with UV radiation are important. Specific precipitants include birth-control pills, estrogen replacement therapy, mild ovarian or thyroid dysfunction, ovarian tumors, cosmetics, nutrition, phototoxic and photoallergic medications, phototoxic drugs, and medication for epilepsy.

Melasma is rarely reported before puberty and is far more common in women, especially those of reproductive age and often begins or is exacerbated during pregnancy, explaining the common appellation "mask of pregnancy." People with darker skin types are more frequently affected. The lesions are brownish macules with irregular borders and symmetric, photodistribution usually on the face (Fig. 75-17), often coalescing in a reticular pattern. Sun exposure intensifies the lesions. There are three major patterns of distribution of the lesions: (1) centrofacial (63%: forehead, nose, chin, and upper lip), (2) malar (21%: nose and cheeks), and (3) mandibular (16%: ramus mandibulae). The anterior chest and dorsal forearms may also be affected.

Figure 75-17 Melasma. Typical yellowish to brownish macules with irregular borders on the forehead of a young woman.

From its appearance under Wood's lamp, melasma is classically classified into epidermal, dermal, and mixed. (Epidermal pigmentation is accentuated under Wood's lamp, whereas dermal pigmentation is less apparent.)

Sun protection is central to management. Epidermal pigmentation is known to be more responsive to topical treatment than dermal pigmentation. Hypopigmenting agents such as hydroquinone, tretinoin, azelaic acid, rucinol, and kojic acid are helpful when used for prolonged periods. The so-called Kligman formula is a popular combination of hydroquinone, tretinoin, and a mild topical corticoid. Chemical peels and laser therapy may be helpful in the treatment of melasma, but can also result in further unwanted hyperpigmentation. Sometimes, melasma slowly disappears after discontinuation of the hormonal stimulus and/or careful sun avoidance.[165–167]

Pregnancy. During pregnancy increased pigmentation occurs in 90% of women and is most prominent in darker skin types. Preexisting pigmented lesions such as nevi and ephelides become darker. Also, recent scars often darken. In normally pigmented areas, such as nipples, areolae, and genitalia, the pigmentation becomes more intense. The linea alba, the median line on the anterior abdominal wall, often becomes hyperpigmented during pregnancy and is then called linea nigra. In a small proportion of pregnant women, hyperpigmentation occurs in the axillae or the inner upper thighs. Melasma or "mask of pregnancy" (see Section "Melasma") occurs in more than 50% of pregnant women (see Chapter 108).[168,169]

Acanthosis Nigricans. Acanthosis nigricans is discussed in Chapters 151 and 153.

Diabetes. (See Chapter 151.) A higher vitiligo prevalence has been reported in patients with diabetes type I and II compared to the general population. Diabetic dermopathy is characterized by asymptomatic, irregular, light brown, depressed patches on the anterior lower legs,[65] but the pathogenesis is not known.

NUTRITIONAL CONDITIONS.

(See Chapter 130 and online text). Pigmentary changes can be secondary to nutritional conditions such as kwashiorkor, vitamin B_{12} deficiency, folic acid deficiency, or pellagra. The skin changes are reversible on correction of the nutritional deficiency.

METABOLIC CONDITIONS

Porphyria Cutanea Tarda. (See Chapter 132.) Porphyria cutanea tarda is a metabolic disorder that has been associated with diffuse brown hypermelanosis accentuated in sun-exposed areas. In females, a melasma-like hyperpigmentation of the face can be observed.

Hemochromatosis. Hereditary hemochromatosis is an autosomal recessive disorder associated with increased intestinal absorption of iron and deposition of excessive amounts of iron in the liver, pancreas, and other organs, including the skin. In the past, hemochromatosis was usually diagnosed at an advanced stage by the classic triad of hyperpigmentation, diabetes mellitus ("bronze diabetes"), and hepatic cirrhosis. Darkening of the skin was present in 70% of the patients due to two different mechanisms: (1) hemosiderin deposition causing a diffuse, slate-gray coloring and (2) increased epidermal melanin production. Because hemochromatosis is now usually diagnosed early, hyperpigmentation is less frequently observed. The pigmentation is usually generalized, but may be more pronounced in sun-exposed areas, genitalia, and scars. Skin bronzing is reversible by phlebitic therapy.[178–180]

TUMORAL CONDITIONS

Mast Cell Disorders and Melanoma. Mast cell disorders and melanoma can lead to hyperpigmentation and are discussed in Chapters 149 and 124, respectively. Diffuse, generalized melanosis associated with advanced metastatic melanoma is a rare, although well-documented, event. It is characterized by a slate bluish-gray to brown discoloration of the skin (Fig. 75-18). Histology reveals melanin particles and melanin-containing histiocytes and dendritic cells in the dermis and subcutaneous fat. No melanoma cells can be detected in the skin, and there is no increase in epidermal melanin pigment or number of melanocytes. Melanosomes circulating in the blood have been detected, supporting the hypothesis that diffuse melanosis may result from tumor lysis[183] with release of their organelles into the circulation and subsequent deposition in the skin.

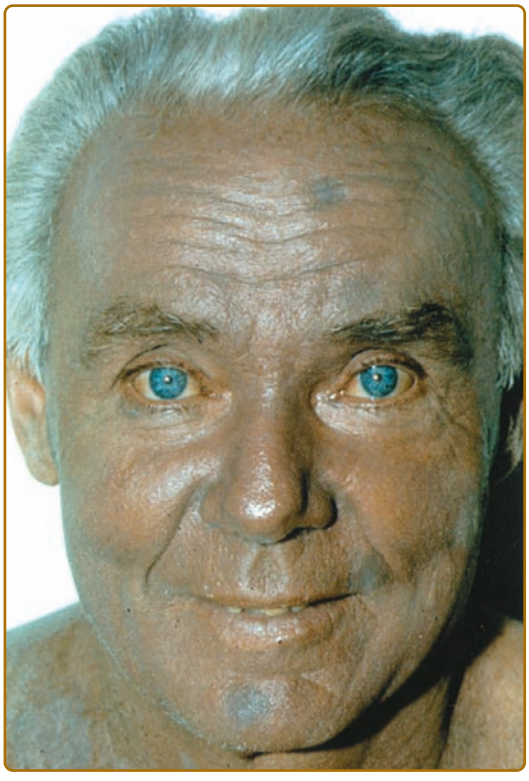

Figure 75-18 Metastatic melanoma-associated, slate-gray, dermal pigmentation involving the entire body. There was melanogenuria and at autopsy all internal organs were found to be black.

PHYSICAL AGENTS

Ultraviolet Radiation. (See Chapter 90.) A major acute effect of UV radiation on normal human skin is tanning.

Ionizing Radiation. (See Chapter 240.) Exposure of skin to ionizing radiation during accidents, such as in Chernobyl, or after local fractionated radiotherapy can give rise to a cutaneous radiation syndrome characterized by fibrosis, keratosis, telangiectasias, and sharply demarcated lentiginous hyperpigmentation, resembling UV-induced lentigines (radiation dermatitis). Small hypopigmented spots can be intermingled with zones of hyperpigmentation. Skin biopsy shows altered melanin content in melanocytes and basal keratinocytes, corresponding to the clinical appearance. Electron beam therapy has been reported to induce tan-like transient hyperpigmentation and transverse melanonychia.[184–189]

Thermal Radiation. In superficial thermal burn injuries, when the melanocyte-bearing basal epidermis has not been destroyed, various degrees of hyperpigmentation result, depending on the skin color and time after the injury. Thermal injury resulting from laser therapy with intense, high-dose visible light also can give rise to hyperpigmentation, especially in dark-skinned patients. Cryotherapy, tissue destruction by application of cold, commonly causes (sometimes permanent) hypopigmentation in combination with

peripheral hyperpigmentation in treated skin due to melanocyte injury.[190–193]

Trauma. Friction melanosis in an acquired pigmentary disorder due to repeated rubbing of the skin [194]

TOXIN- AND MEDICATION-INDUCED HYPERPIGMENTATION

Hyperpigmentation caused by toxic agents or medication accounts for 10%–20% of all cases of acquired hyperpigmentations. CNS drugs, antineoplastic agents, anti-infectious drugs, antihypertensive medications, and hormones are most commonly responsible (eTable 75-1.1 in online edition).

In the majority of cases of medication-induced hyperpigmentation, the underlying pathogenetic mechanism involves one of the following.

Hyperpigmentation can be due to deposition of melanin in the dermis, usually in macrophages. Sometimes this melanin is complexed to the drug [drug-pigment complex (e.g., hydroxychloroquine)]. Accumulation of melanin can occur after cutaneous inflammation (postinflammatory) and/or DNA damage (e.g., carmustine). This type of hyperpigmentation is often increased by UV exposure and is usually more pronounced in sun-exposed areas.

Some substances (e.g., carotene, heavy metals) are directly deposited in the skin. Sometimes this type of pigmentation is also accentuated in sun-exposed areas as UV can induce a transformation in the deposited drugs, which may then become more visible.

In other cases, the dyschromia is caused by nonmelanin pigments synthesized or produced under the direct or indirect influence of the drug.

Clinical features vary with characteristic sites, patterns, and shades of discoloration. The forms associated with melanin accumulation are often worsened by sun exposure. Sometimes, the manifestation is more or less specific for the responsible drug, although the mechanism is often poorly understood. For example, a linear, sometimes flagellate hyperpigmentation can be observed in patients taking bleomycin or zidovudine. A diffuse hyperpigmentation on the palms and soles may be present in patients taking cyclophosphamide or doxorubicin. Bleomycin and doxorubicin may produce localized hyperpigmentation around small joints. Estrogen-related hormonal substances and phenytoin-like medication may cause melasma-like pigmentation. Nail unit involvement can be observed with some medications, most frequently chemotherapeutic agents, zidovudine, psoralens, minocycline, antimalarials, and gold. Mucosal hyperpigmentation has been reported with cyclophosphamide, doxorubicin, zidovudine, minocycline, and some heavy metals.

Amiodarone can produce blue–gray pigmentation in sun-exposed areas due to accumulation of a lipid-like substance in macrophages. Some of these patients display photosensitivity (Fig. 75-19). (Hydroxy) chloroquine may give rise to a yellow–brown to bluish-gray pigmentation on the face, neck, lower extremities, and forearms after several years of intake, due to deposition of a drug–melanin complex in the dermis (eFig. 75-19.1 in online edition). The nail unit and hard palate may also be involved. Exogenous ochronosis has been reported after chronic hydroquinone use (see Section "Ochronosis").

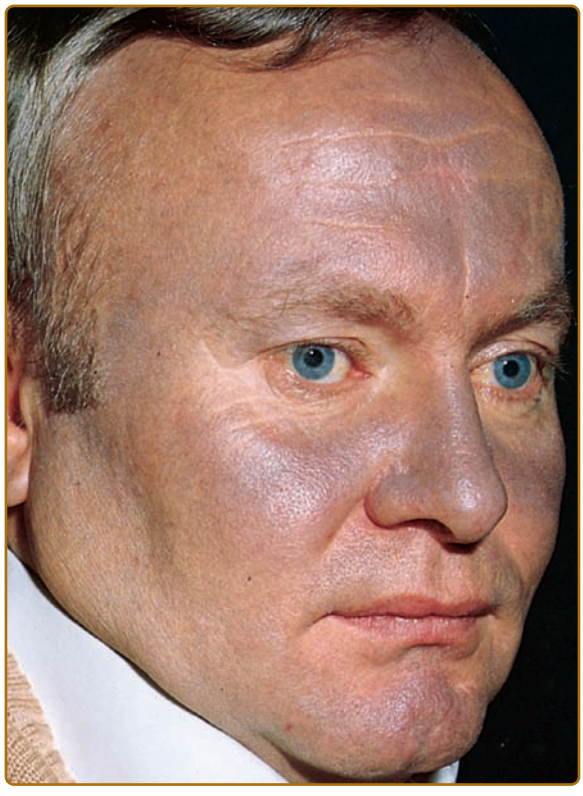

Figure 75-19 Amiodarone hyperpigmentation. This patient exhibits a striking amiodarone-induced, slate-gray pigmentation of the face. The blue color (ceruloderma) is due to the deposition of a brown pigment in the dermis, contained in macrophages and endothelial cells (Lindall effect).

Chlorpromazine and related phenothiazines can produce a bluish-gray pigmentation, especially in sun-exposed areas, and pigmentation of the conjunctivae. Minocycline can induce skin hyperpigmentation, as well as pigmentation of the nails, sclerae, oral mucosa, thyroid, bones, and teeth. Skin hyperpigmentation may present as a blue–black discoloration, especially at sites of inflammation, but also in noninflamed sites, especially the anterior legs. In some patients, there is a dull brown discoloration, especially in sun-exposed areas. Argyria patients present with a generalized grayish-blue pigmentation; the nails and the sclerae may also be involved.

Treatment of toxin- and medication-induced hyperpigmentation involves discontinuation of the responsible agent, if possible. In a small subset of patients, the hyperpigmentation persists even after discontinuation, particularly the bluish or gray pigmentation characteristic of dermal deposition. Sun protection should be advised, especially in forms entailing melanin accumulation. Laser treatment has been reported to be successful in some cases (e.g., amiodarone).[195]

Figure 75-20 Exogenous ochronosis. Hyperpigmentation on the nose and cheeks after the use of a hydroquinone cream.

OCHRONOSIS

Endogenous Ochronosis/Alkaptonuria. Endogenous ochronosis/alkaptonuria is discussed in Chapter 131.

Exogenous Ochronosis. Exogenous ochronosis results from the use of certain medications, which form a homogentistic acid polymer-like substance during their metabolism. It presents as asymptomatic hyperpigmentation of the face, sides and back of the neck, back, and extensor sites of the extremities (Fig. 75-20). Histopathologically, there is a collection of yellowish-brown (ochronotic) globules in the papillary dermis. There is no articular, renal, or cardiovascular involvement. It has been most frequently reported in association with hydroquinone (bleaching creams), usually in skin phototype VI patients, although it has been described in other skin types. Exogenous ochronosis has also been noticed after the use of antimalarials and products containing resorcinol, phenol, mercury, and picric acid. Treatment is rarely helpful, but the offending drug should be stopped to prevent progression.[196]

For POEMS syndrome and Cronkhite–Canada syndrome, and zidovudine-induced hyperpigmentation see online edition. The hyperpigmentation associated with the following disorders is discussed briefly online and/or the other indicated chapters: systemic sclerosis (Chapter 157), pinta (Chapter 201), onchocerciasis (Chapter 207), phytophotodermatitis (Chapter 90), flagellate pigmentation due to bleomycin (Chapter 227).

SYSTEMIC SCLEROSIS. (See Chapter 157.) Different types of abnormal pigmentation have been described in systemic sclerosis. A diffuse, generalized hyperpigmentation similar to Addison's disease but with normal levels of MSH can be observed in severe systemic sclerosis.

Focal depigmentation with perifollicular hyperpigmentation may occur, especially on friction sites (e.g., shins, elbows, and dorsum of the hands). There can be localized hyper- and hypopigmentation.

A streaky hyperpigmentation over blood vessels on a background of depigmentation has been reported. Diffuse reticulated hyperpigmentation accentuated on the trunk has been reported in one case.[43]

INFECTIONS. (See Chapter 201.) Erythematous, scaling papules termed pintids develop during the secondary stage of pinta. These initially red lesions can turn brown, slate-blue, black, or grayish.[52]

Chronic papular onchodermatitis is one of the skin manifestations of onchocerciasis. It is characterized by a severely pruritic maculopapular rash with hyperpigmented macules, most often occurring on shoulders, buttocks, and extremities (see Chapter 207).[53]

ACQUIRED CIRCUMSCRIBED HYPERMELANOSIS

PHYTOPHOTODERMATITIS. Contact with plants containing phototoxic agents such as psoralens, with subsequent UV exposure, may lead to phytophotodermatitis, which is followed by patterned hyperpigmentation.

FLAGELLATE PIGMENTATION DUE TO BLEOMYCIN. (See Chapter 227.)

FLAGELLATE MUSHROOM DERMATITIS. Flagellate mushroom dermatitis is characterized by linear grouped, erythematous, and intensely pruritic papules, a clinical pattern very similar to bleomycin-induced flagellate dermatitis. It is caused by eating raw or insufficiently boiled shiitake mushrooms (*Lentinus edodes*) and is not elicited by topical contact or ingestion of well-boiled shiitake. The pathogenesis is not yet known, but it is hypothesized that a thermolabile polysaccharide is responsible.[199–201]

HYPERMELANOSIS—ACQUIRED DIFFUSE PATTERNED OR RETICULAR

ERYTHEMA AB IGNE. Erythema ab igne is caused by a chronic exposure to moderate heat. The reticular erythema can be accompanied by epidermal atrophy, scaling, and hyperpigmentation. It was seen in the past in people who frequently sat in front of open fires or stoves for warmth, but it occurs less often since the introduction of central heating. Nevertheless, it is still seen after local application of heating pads, hot water bottles, or heating blankets. Modern appliances that have been reported to elicit erythema ab igne are furniture with built-in heaters, car heaters, and laptop computers (Fig. 75-21).[204–206]

PRURIGO PIGMENTOSA. Approximately 200 cases of prurigo pigmentosa have been published in the international literature since it was first described

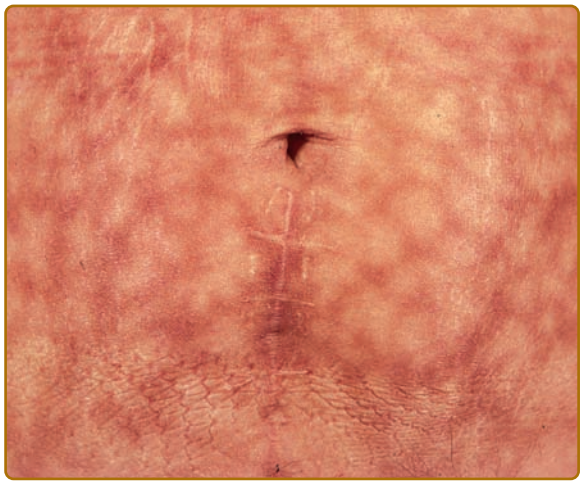

Figure 75-21 Reticular hyperpigmentation (erythema ab igne) resulting from repeated applications of a heating pad over several years.

in 1971 by Nagashima. Prurigo pigmentosa presents itself as intensely pruritic erythematous papules, papulovesicles, and vesicles that involute in several days. The lesions develop symmetrically on the back, chest, neck, and lumbosacral region. The papulovesicular lesions heal spontaneously, leaving a nonpruritic reticular hyperpigmentation (see eFig. 75-21.1 in online edition). The disease has a fluctuating course with exacerbations and recurrences. It is twice as frequent in females as in males. The eruption and pruritus respond well to minocycline and dapsone but the pigmentation does not and must resolve spontaneously. Environmental and metabolic factors have been suggested as causative agents but the pathogenesis remains unknown.[207]

ACQUIRED CIRCUMSCRIBED HYPERMELANOSIS

NEVUS OF HORI. Nevus of Hori was first described in 1984 as acquired, bilateral nevus of Ota-like macules termed ABNOM.[208] It consists of blue–brown to slate-gray mottled hyperpigmentation on the face with predilection for the malar regions. Similar to nevus of Ota, it typically affects the Asian population and has a female predominance. However, the lack of ocular and mucosal membrane involvement and the acquired bilateral character distinguish the entities. Histologically, melanocytes with stage III or IV melanosomes reside in the upper and middle layers of the dermis. Sun exposure and hormonal changes during pregnancy have been described as triggering factors.[209] Hori described three possible mechanisms for the pathogenesis of ABNOM: (1) "dropping" of epidermal melanocytes into the dermis, (2) migration of melanocytes from hair bulbs, and (3) reactivation of preexisting latent or immature dermal melanocytes.[208] The latter has been suggested as being the most probable mechanism with UV-radiation and sex hormones as activating factors. In some cases, ABNOM can occur simultaneously with other pigmentary abnormalities such as melasma, freckles, solar lentigines, and nevus of Ota.[113,209]

Combination treatments of pigment-specific laser (Q-switched lasers) with chemical peels and topical bleaching agents have been used with variable results.[210]

BECKER'S NEVUS (BECKER HAMARTOMA, BECKER MELANOSIS). This acquired hyperpigmented epidermal nevus was first described in 1949 (Fig. 75-22). It preferentially occurs in the scapular region, although it has been described in any area of the body, and classically after an intense sun exposure. The lesion is androgen-dependent and becomes more prominent in adolescence, especially in the male population. Hypertrichosis in the lesion is often associated. Associated anomalies, such as ipsilateral breast hypoplasia, musculoskeletal abnormalities (scoliosis, ipsilateral limb hypoplasia, etc.), maxillofacial abnormalities, and additional cutaneous hypoplasias, occur in the rare Becker's nevus syndrome. Microscopic examination demonstrates normal numbers of melanocytes, but increased levels of melanin in the basal epidermal layer (epidermal melanotic hypermelanosis). The epidermis is acanthotic with variable hyperkeratosis and elongation of the rete ridges. In the dermis, the number of arrector pili muscles is increased, making it difficult to differentiate from the related smooth muscle hamartoma. Good therapeutic results have been reported using a long-pulsed alexandrite laser.[215]

Figure 75-22 Becker's nevus on the upper arm and shoulder of a young man. Note the typical localization and marked hypertrichosis.

Becker's nevus is suggested to follow a paradominant inheritance pattern, which means it (almost) always occurs sporadically. The rare familial cases that have been described (especially in Becker's nevus syndrome) can be explained by a somatic mutation during embryogenesis, resulting in loss of heterozygosity and formation of a mutant cell population. This hypothesis is supported by the identification of chromosomal mosaicism in fibroblasts derived from a Becker's nevus.[216–218]

EPHELIDES. Ephelides or freckles are small light brown macules appearing in sun-exposed skin of fair-skinned individuals, often those with red or blond hair and Celtic ancestry. They are more pronounced during spring and summer and fade during the winter period. They appear in early childhood and often regress later in life. Histopathologic examination shows a normal to reduced number of sometimes hypertrophic melanocytes but increased melanin in the basal epidermal layer.

POSTINFLAMMATORY HYPERPIGMENTATION. Postinflammatory hyperpigmentation (PIH) is a common condition caused by numerous preceding cutaneous insults such as drug and phototoxic reactions, infections, physical injury or trauma, allergic reactions, and inflammatory diseases. Clinically, PIH consists of a macular hyperpigmentation at the site of inflammation (Fig. 75-23).[179] It is far more common and persistent in darker skin types (Fitzpatrick types III–VI) and can be characterized by epidermal as well as dermal melanotic hypermelanosis. A Wood's lamp examination can determine depth of the hyperpigmentation (see Section "Melasma"). Histologic features include pigment incontinence with accumulation of melanophages and increased melanin in dermal or epidermal layers.[219] Management of PIH remains difficult,[220–222] although epidermal PIH often shows slow spontaneous fading.

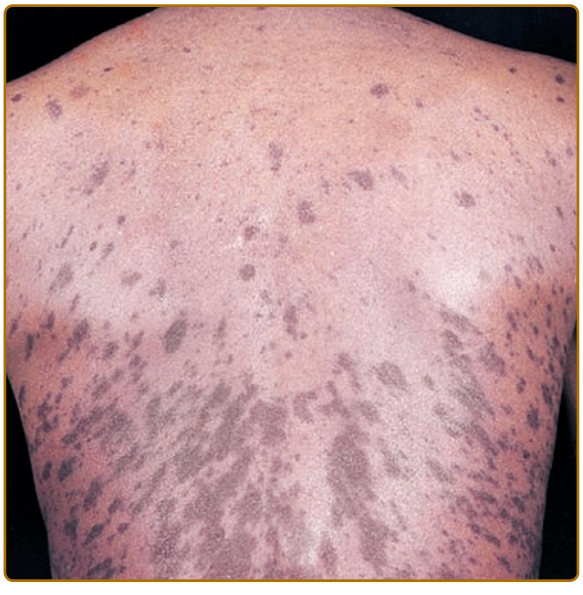

Figure 75-23 Postinflammatory hyperpigmentation. May follow a drug eruption, psoriasis, or lichen planus, especially in skin phototypes V and VI as was the case in this middle-aged East Indian woman. Postinflammatory hyperpigmentation is a major problem in young women with skin phototypes V and VI.

FAMILIAL PERIORBITAL HYPERPIGMENTATION. Increased pigmentation of the upper and lower eyelids has been described in a number of families. Histologically, increased basal pigmentation and dermal melanophages are seen. However, inflammation does not appear to precede the hyperpigmentation.[223]

PARTIAL UNILATERAL LENTIGINOSIS. Partial unilateral lentiginosis (PUL) is also known as unilateral lentigines, lentiginous mosaicism, zosteriform lentiginous nevus, segmental lentiginosis, and agminated lentiginosis.

RIEHL MELANOSIS. Riehl melanosis, also known as female facial melanosis, is mostly seen in middle-aged women, especially in darker skin types, such as Mexicans and Asians (see eFig. 75-23.1 in online edition).

It is characterized by a rapid onset of a reticular gray–brown to almost black hyperpigmentation.

The face (especially the forehead, zygomatic area, and temples) and the neck are principally involved, but the hands, forearms, and trunk can also be affected. Inflammatory findings such as erythema and pruritus are usually absent.

The main histopathologic feature is liquefactive degeneration of the basal layer of the epidermis, resulting in pigment incontinence in the dermis. The pathogenesis is not understood.[226,227]

The hyperpigmentation has been postulated to be induced by repeated contact with threshold doses of a contact sensitizer such as fragrances, some pigments, and bactericides used in cosmetics and optical whiteners, but is poorly documented in most cases.

CUTANEOUS AMYLOIDOSIS. Macular amyloidosis presents as brown to gray–brown macules, mainly on the back (see Chapter 133).

ATROPHODERMA OF PASINI–PIERINI. (See Chapter 67). The cutaneous lesions of atrophoderma of Pasini–Pierini can be described as single or multiple gray to violaceous-brown atrophic patches from 1 cm to more than 10 cm in diameter with slight depression with a characteristic "cliff drop" border.

FIXED DRUG ERUPTION. Fixed drug eruption can cause hyperpigmentation (see Chapter 41).

ERYTHEMA DYSCHROMICUM PERSTANS. Erythema dyschromicum perstans, also known as ashy dermatosis, dermatosis cenicienta, and erythema chronicum figuratum melanodermicum, was first described by Ramirez in 1957. Patients with this eruption were labeled as los cenicientos, the ashy ones.[229]

The disease is characterized by hyperpigmented macules and patches of variable shape and size with an ashen-gray to brown–blue color. They may have a thin, raised erythematous border in the early stage that later can be absent or, mainly in darker skin types, evolve into a hypopigmented border that accentuates the hyperpigmentation. The eruption can also be polymorphic, presenting simultaneously hypo- and hyperpigmented macules. Lesions occur primarily on the face, the neck, the trunk, and the proximal part of the arms. The lesions are usually asymptomatic, although slight pruritus can be present. There is a slow progression of the lesion over several years, usually without spontaneous regression.

Erythema dyschromicum perstans is mainly observed in intermediate skin types. It is a disease of young adults, although there are small series reporting the disease in prepubertal children. There is no clear sexual predilection.[230]

Histologic examination of the inflammatory border may demonstrate lichenoid dermatitis with vacuolization of the basal cell layer, occasional colloid bodies, and increased epidermal melanin. The dermal changes are edema of the papillary dermis, a moderate or mild lymphohistiocytic infiltrate, and dermal melanophages. The pathogenesis of erythema dyschromicum perstans is unclear and likely influenced by many factors. An HLA-DR-associated susceptibility to develop erythema dyschromicum perstans has been described in a Mexican population.[231]

In inactive lesions, there is no vacuolization of the basal cell layer, a diminished dermal infiltrate, and an increased number of dermal melanophages. There is no effective treatment.[229,230]

IDIOPATHIC ERUPTIVE MACULAR HYPERPIGMENTATION

Idiopathic eruptive macular hyperpigmentation is an uncommon disorder of pigmentation characterized, as the name suggests, by an eruption of asymptomatic, brown macules (5 mm to several cm in diameter) involving the trunk, neck, and proximal extremities in children and adolescents. No previous drug exposure has been implicated, and the lesions disappear gradually over several months to years.

Histopathologically, there is hyperpigmentation of the basal layer of the epidermis and prominent dermal melanophages. The number of mast cells is normal.[232]

MIXED HYPO- AND HYPERMELANOSIS

DYSCHROMATOSIS HEREDITARIA UNIVERSALIS

Dyschromatosis hereditaria universalis is an autosomal dominant disorder that usually presents in infancy or early childhood in Asian families and is characterized by pinpoint to pea-sized hypo- and hyperpigmented macules, distributed in a reticulated pattern over the trunk, abdomen, and limbs, usually sparing the face and palmoplantar surfaces.[233]

RETICULATE ACROPIGMENTATION OF DOHI

Reticulate acropigmentation of Dohi is a localized form of dyschromatosis universalis hereditaria, also called dyschromatosis symmetrica hereditaria. It is characterized by small, symmetric hyper-, and hypopigmented macules on the dorsal hands and feet, and is mainly seen in young children in South American and Asian families.

WESTERHOF SYNDROME

Westerhof syndrome, described in three generations of one family, displays congenital hypo- and hypermelanotic macules. There is also small stature and mental retardation.[234]

VAGABOND LEUKODERMA

Vagabond leukoderma is a condition found in persons living in poor hygienic conditions. Many abuse alcohol, live on an inadequate diet, and are infested with lice and/or scabies. Diffuse light-brown hyperpigmentation is present at the shoulder and waist girdle, and the neck and back are dotted with depigmented macules. The condition improves on institutions of a healthier lifestyle and likely represents a coexistence of many of the disorders.[235]

SECTION 12

Disorders of the Oral and Genital Integument

Chapter 76 :: Biology and Pathology of the Oral Cavity

:: Sook-Bin Woo

ORAL MUCOSAL DISEASE AT A GLANCE

- Idiopathic recurrent aphthous ulcers affect 15%–20% of the population; severe cases can be debilitating.
- Oral ulcers may also be associated with Crohn disease and other gastrointestinal disorders or due to herpes simplex, other viral infections, vasculitis, or other autoimmune disorders.
- Candidiasis of the oral cavity is common and painful. Predisposing factors include immunosuppression, hyposalivation, and use of steroids or antibiotics.
- Hair leukoplakia is due to Epstein–Barr viral infection and may be the presenting sign of HIV/AIDS.
- Oral lichen planus (LP) and lichenoid reactions affect 1%–2% of the population and are the most common cause of desquamative gingivitis; LP probably reflects a hypersensitivity response to endogenous or exogenous antigens.
- Leukoplakia is a premalignant condition associated with smoking and/or alcohol ingestion that must be distinguished from LP and benign frictional keratoses.
- Bullous diseases that affect the mouth include pemphigus, pemphigoid, and lupus erythematous.
- Intraoral pigmented lesions include nevi, postinflammatory hyperpigmentation, drug reactions, tattoos, and rarely melanoma.

INTRODUCTION

The mouth is the beginning of the aerodigestive tract and an extension of the skin barrier. It plays an important role in mastication, deglutition and digestion, speech, and immunologic defense. The oral mucosa, salivary glands (both major and minor), jawbones, and teeth are frequently the site of primary inflammatory or neoplastic disease. However, the oral cavity may present with manifestations of systemic disease and in some cases, oral findings may precede systemic signs and symptoms by months or years. Lesions in the maxillary sinus and nasal cavity may lead to pain in the upper teeth or may extend inferiorly and present in the maxilla or palate. Metastatic lesions may present as nodules on the gingiva or masses in the jawbones.

This chapter focuses only on the more common mucosal and salivary gland diseases encountered in dermatology practice.

EVALUATION OF THE PATIENT

As with evaluation of the skin, obtaining a comprehensive medical and medication history and careful inquiry into current symptoms are essential. The extraoral examination should begin with an examination of the skin of the face and in particular the perioral region, palpation of the submandibular and submental lymph nodes, and palpation of the temporomandibular joints for clicking or pain on opening. Clicking with no pain occurs in 20%–30% of the population and is of no clinical significance but should be noted. Clicking with pain and/or limitation of opening may indicate temporomandibular joint myofascial pain syndrome and requires referral to a dental specialist for management.

The intraoral examination should be directed to the following areas:

1. The mucosal surfaces as outlined above, taking note of where the lesions are located, and in particular, whether they are on the keratinized or nonkeratinized sites.

Figure 76-1 Fordyce granules.

2. The presence or absence of saliva in the floor of mouth and whether the saliva is of the usual watery consistency or whether it is ropey.
3. The dentition and whether there are grossly carious teeth.
4. The use of a removable prosthesis (upper and/or lower dentures—complete or partial); this is particularly important for some mucosal diseases caused by denture trauma and for the diagnosis and treatment of candidiasis since the denture acts as a fomite.

NORMAL ANATOMIC STRUCTURES

There are several structures in the oral mucosa that are considered variations of normal. These include:

1. *Fordyce granules*: These are sebaceous glands that present as painless yellow papules, 1–2 mm in diameter located in a bilateral symmetric fashion on the posterior buccal mucosa, and lips (usually vermilion) (Fig. 76-1). Sebaceous hyperplasia of these glands may form discrete larger yellow papules several millimeters in size.
2. *Linea alba*: This is a linear keratosis located on the buccal mucosa bilaterally where the upper and lower teeth meet. It is a form of frictional keratosis and exaggeration of this is seen in patients who habitually chew the buccal mucosa, a condition known as morsicatio mucosae oris (MMO) (see below).
3. *Palatal and mandibular tori*: These are benign, usually symmetric exostoses that are present in the midline of the hard palate or bilaterally on the lingual aspect of the mandible (Fig. 76-2). They may be large and multilobated, but patients are usually unaware of their presence.

PRESCRIBING TOPICAL MEDICATIONS

TOPICAL STEROIDS

Topical steroids are the mainstay of treatment for many inflammatory and autoimmune mucosal diseases.[1] The only topical steroid that is FDA-approved for intraoral use is Kenalog-in-Orabase dental paste (0.1% triamcinolone; Apethecon, Princeton, NJ). This is a Class IV steroid and is weakly efficacious as an anti-inflammatory agent in the oral cavity, although the Orabase (methylcellulose) is useful and soothing as a covering agent in some conditions. In general, most oral medicine specialists use fluocinolone, fluocinonide, clobetasol, and topical tacrolimus for the management of mucosal disease. Principles applying to use of these medications in the oral cavity regardless of specific diagnosis are found in Table 76-1 and eBox 76-0.1 in online edition.

TOPICAL ANALGESICS

Viscous lidocaine (2%) may be used alone or combined with diphenhydramine, Kaopectate (Pfizer, NY), or Maalox (Novartis, NJ) in equal volumes as a swish and spit out preparation for pain control. This is particularly useful for diffuse painful lesions, acute or chronic.

Localized ulcers may be treated with over-the-counter benzocaine preparations, or covering agents such as methylcellulose (Orabase; Colgate-Palmolive, NY).

As with any disease condition, provision of up-to-date information on the disease allays many fears and misconceptions, empowers patients, and helps patients to better understand their condition. Information on the nature, management, and prognosis of common mucosal conditions are available on the Web

TABLE 76-1
Commonly-Used Medications for Oral Lesions

Medication	How to Prescribe
Topical immunosuppressive agents	
Triamcinolone 0.1% dental paste	5-mg tube; apply to affected site tid or qid (this forms a barrier)
Fluocinolone 0.05% gel	15-60 g tube dry area, apply to affected site tid or qid; no food or drink for 30 minutes after OR
Clobetasol 0.05% gel	
Betamethasone 0.05% gel	Place gel in stent and wear for 30 minutes, bid or tid
Dexamethasone elixir 0.5 mg/5 mL	Dispense 300–500 mL; swish 5 mL. (dexamethasone, tacrolimus, or cyclosporine) or 5–10 mL. (prednisolone) for 3 minutes (timed) and spit out tid or qid; no food or drink for 30 minutes after
Prednisolone syrup (15 mg/5 mL)	
Tacrolimus solution (5 mg/mL)	
Cyclosporine (100 mg/mL)	
Nasal sprays used orally (such as fluticasone and budesonide)	1–2 puffs 2–3 times a day
Intralesional steroid injection with triamcinolone	1–5 mg triamcinolone per cm^2 of ulceration
Antifungal therapy	
Nystatin 1:100,000 units/mL[a]	Dispense 300–500 mL; swish and spit out (or swallow) 5 mL tid or qid
Clotrimazole 10 mg troches[a]	Suck on one troche tid or qid
Fluconazole 100 mg	Take one tablet in the morning qd × 3–10 days (depending on the severity of the infection)
Mycostatin/triamcinolone cream	Apply to corners of mouth tid or qid for angular cheilitis Paint onto denture base tid and wear denture
Denture treatment in patients with candidiasis	Soak denture in solution overnight.
Denture soaks such as:	
Nystatin 1:100,000 units/mL	
Chlorhexidine digluconate 0.12%	
3% sodium hypochlorite diluted in water (1:10)	
2% sodium benzoate	
Topical pain medications	
Viscous lidocaine 2%	Swish and spit out tid or qid for pain
Benzydamine hydrochloride 0.15%	
Dyclonine hydrochloride 1%	
Systemic immunosuppressive therapy	Topical therapy should be started concomitant with systemic therapy.
Prednisone	0.5–1.0 mg/kg to begin for 7–10 days with a rapid taper over 2–3 weeks
Pentoxifylline	400 mg three times a day or 800 mg twice a day
Hydroxychloroquine	200–400 mg daily
Dapsone	25 mg to begin, increasing to 75–100 mg/day
Mycophenolate mofetil	1000–3000 mg daily
Colchicine	0.6 mg once or twice a day
Azathioprine	50–100 mg daily
Thalidomide	50–100 mg tid to begin; begin taper to maintenance dose (which may be weekly) or discontinue completely

[a]Formulations contain cariogenic sugars that may lead to caries if used for months.

sites of the American Academy of Oral and Maxillofacial Pathology (www.aaomp.org) and the American Academy of Oral Medicine (www.aaom.com). These can be modified to suit your practice needs.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE AND SYNDROMES

Systemic diseases often have distinctive presentations in the oral cavity and many skin conditions also have concomitant oral findings. eTable 76-1.1 in online edition provides a list of some of the more common systemic diseases and syndromes that present with oral findings. Some are discussed in greater detail below.

DISEASE CLASSIFICATION

The disease entities to be described are those normally treated by the dermatologist and are divided primarily into how the lesions present clinically (e.g., ulcers, nodules, or red and white lesions). However, there is also a section based on lesions that are site-specific. Pathogenetic mechanisms for diseases such as the autoimmune bullous disorders will not be discussed

in any detail since they are presented elsewhere in this book.

ULCERATIVE CONDITIONS

The oral ulcer appears as a yellow–white papule or plaque of fibrin (often referred to as a "pseudomembrane"), usually with a surrounding red rim. It does not appear crusty because of the wet environment. Such lesions are always painful unless the ulcer represents a squamous cell carcinoma (SCC), which is often painless. Several conditions fall into this category and only the most common will be discussed here (eTable 76-1.2 in online edition).

RECURRENT APHTHOUS ULCERS/STOMATITIS ("CANKER SORES"). Recurrent aphthous ulcer (RAU) is a T-cell-mediated disorder and tumor necrosis factor (TNF)-α plays an important role in its occurrence.[2] There is usually a family history of aphthous ulcers and there is a significant association with a number of HLA-haplotypes.[3] Stress, systemic illness, and local trauma predisposes to their occurrence in susceptible individuals.

Aphtheiform ulcers are aphthous-like in their appearance and history but they may occur sometimes on the dorsum of the tongue if they are a result of hematinic deficiency or inflammatory bowel disease. RAU are seen in all patients with Behçet disease and may precede other findings by years. Behçet disease, a vasculitic disorder, has a predilection for Turkish and Japanese populations and is associated with an increase in HLA-B51.[4] In periodic fever-adenopathy, pharyngitis, aphthae (PFAPA) syndrome, ulcers are often so severe that children miss days at school.[5,6] Patients with other systemic or skin conditions and aphthous ulcers form part of the "complex aphthosis" syndrome and include those with MAGIC (mouth and genital ulcers with inflamed cartilage) syndrome (eTable 76-1.2 in online edition). Approximately 3% of patients with RAU have gluten-sensitive enteropathy[7] and some show sensitivity to foods and sodium lauryl sulfate.

Clinical Findings. Idiopathic RAU occurs in 15%–20% of the population beginning in the second decade of life and the disease generally becomes less severe over the age of 50. Patients often report the sensation of a small nodule beneath the epithelium before the ulcer appears. The painful yellow–white ulcers are surrounded by an erythematous halo.

There are four clinical forms of RAU and these are always painful:

a. *Minor* ulcers (<1 cm, 1–10 at each episode lasting 1–2 weeks) (Fig. 76-3A); this is by far the most common form.
b. *Major* ulcers (>1 cm lasting several weeks and healing with scarring) (Fig. 76-3B).
c. *Herpetiform* ulcers (<1 cm, usually 0.1–0.5 cm each, >10 clustered ulcers at each episode, lasting 1–2 weeks (Fig. 76-3C).
d. *Severe* aphthous ulcers where patients have minor ulcers but with continuous ulcerations with minimum or no ulcer-free days for months.

Figure 76-3 **A.** Recurrent aphthous minor. **B.** Recurrent aphthous major. **C.** Recurrent herpetiform aphthous ulcers.

Idiopathic RAU are almost always confined to the nonkeratinized mucosa. They may occur on the nonattached gingiva, but generally do not cross the mucogingival junction onto the attached gingiva, except in some cases of RAU major.

Differential Diagnosis and Laboratory Studies. Traumatic lesions must be considered because the oral cavity is subject daily to mechanical trauma (such as mastication) (eTable 76-1.2 in online edition). However, traumatic ulcers are not the same as RAU, although patients with RAU readily develop ulcers at sites of trauma. A history of trauma and the nonepisodic nature of the condition help to differentiate between traumatic ulcers and those of RAU. Chemotherapy-associated ulcers are not generally considered aphthous ulcers but rather chemotherapy- and neutropenia-associated (similar to cyclic neutropenia); they also tend to occur on the nonkeratinized mucosa. Herpetic ulcers in healthy patients occur intraorally on the keratinized mucosa of the gingival margin and the palate. However, in immunocompromised patients, they may resemble RAU, especially RAU major in patients with HIV disease. Culture and biopsy (Box 76-1) are indicated in such patients. Lesions of chronic recurrent oral erythema multiforme must also be considered in the differential diagnosis. Oral manifestations of Crohn disease and other gastrointestinal conditions are discussed below.

The biopsy is nonspecific and shows only a fibrin membrane with acute and chronic inflammation and granulation tissue, but may exclude an infectious etiology.

Management and Prognosis. Any positive findings should be followed up. For example, it may be useful to keep a food diary and to change toothpaste to one that does not contain sodium lauryl sulfate. In most cases, the work-up is negative.

The treatment for minor RAU is topical steroids (Table 76-1) or intralesional steroid injection if the ulcers are large and persistent, especially those of aphthous major or in patients with HIV disease. Topical agents that may be useful include cyanoacrylate (Soothe-N-Seal; Colgate Palmolive, NY) and anti-inflammatory agents such as amlexanox 5% paste (Aphthasol, Uluru, Texas), 2 mg amlexanox mucoadhesive disc (Oradisc, Uluru, Texas), or tetracycline oral rinse. Lesions may also be cauterized with 28%–50% sulfuric acid and sulfonated phenolics (Debacterol, Epien Medical Inc.) or with silver nitrate (shaving sticks). Topical anesthetics in paste form are available over-the-counter, in particular benzocaine of varying strengths. Systemic therapy with prednisone for a few weeks and maintenance with pentoxifylline may reduce the number, duration and size of ulcers, and reduce the number of episodes. In appropriate patients, thalidomide therapy is extremely effective, although patients often develop irreversible neuropathy with long-term use. Other agents that are variably efficacious include colchicine and azathioprine.

BOX 76-1 OBTAINING A BIOPSY

A biopsy of any mucosal condition is readily performed with a skin punch (3–5 mm in diameter). Here are a few helpful suggestions:

1. Use a local anesthetic such as 2% lidocaine with 1:50,000 epinephrine instead of 1:100,000 epinephrine if possible. Since only a small volume is used, this should not cause problems even with hypertensive patients, but will reduce the amount of bleeding encountered during the biopsy.
2. Punch biopsies of the attached gingiva and hard palate are not readily closed with sutures and the use of silver nitrate or aluminum chloride is preferable.
3. Labial, buccal mucosa, and tongue biopsies should be closed in an anteroposterior direction.
4. Excision using an elliptical incision is preferable to a shave biopsy in most cases, unless the lesion is small, exophytic, and obviously benign (e.g., small fibroma or papilloma).

ORAL ULCERATIVE LESIONS ASSOCIATED WITH GASTROINTESTINAL DISEASE

Clinical Findings. The most common bowel diseases associated with oral ulcers are Crohn disease, ulcerative colitis, malabsorption syndromes leading to hematinic deficiency, and celiac disease.[8]

Oral lesions are seen in up to 20% of patients with Crohn disease if nonspecific mucogingivitis is excluded.[9] Ulcers of Crohn disease typically present as linear lesions along the maxillary and mandibular vestibule/sulcus (Fig. 76-4A). In addition, patients often also present with papulous folds of tissues, swelling of the lips (indistinguishable from cheilitis granulomatosa), and cobblestoning of the mucosa.[10] Other manifestations of Crohn disease include severe and diffuse erythema and inflammation of the mucosa, sometimes associated with *Staphylococcus aureus* infection (Fig. 76-4B).[11] A reliable finding is a dusky-red firm area of the perivermilion skin that has a slight pitted, "orange peel" appearance.

Pyostomatitis vegetans (oral analog of pyoderma gangrenosum) associated with inflammatory bowel disease presents as "snail-track" ulcers of the oral mucosa.[12] Dental enamel defects (enamel hypoplasia) are associated with celiac disease in children.[13]

Differential Diagnosis and Laboratory Studies. Oral ulcers ultimately associated with inflammatory bowel disease may predate gastrointestinal lesions by years in up to 60% of patients,[10] so that absence of gastrointestinal symptoms does not exclude this etiology. Elevated tissue transglutaminase and the presence of endomysial antibodies support the diagnosis of celiac disease.

A biopsy of oral lesions of Crohn disease shows granulomatous inflammation or while pyostomatitis vegetans shows acantholysis.

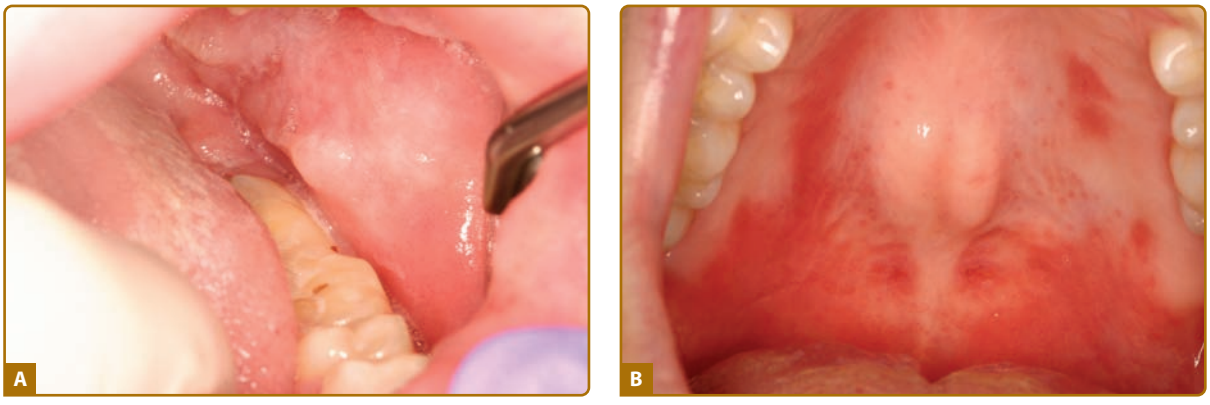

Figure 76-4 **A.** Aphtheiform ulcer in Crohn disease. **B.** Mucosal erythema in Crohn disease.

Management and Prognosis. In the absence of gastrointestinal findings, treatment is with topical steroid therapy and in severe cases, prednisone for rapid control of lesions with maintenance on topical steroids or other anti-inflammatory agents similar to the protocol for management of idiopathic aphthous ulcers.[14] If gastrointestinal disease is active, this should be brought under control first and oral ulcers may then resolve.

Oral manifestations generally wax and wane with the severity of systemic disease.

CHEMOTHERAPY-ASSOCIATED ULCERATIVE MUCOSITIS.

Damage from chemotherapy agents is mediated via production of cytokines, cytokine modulators, and stress responders, leading to apoptosis of dividing epithelial cells.[15] Ulcers are potential portals for bacteremia and septicemia, particularly because patients are also often neutropenic. Depending on the regimen, 25%–30% of patients develop this complication. Agents often associated with such lesions include cytarabine and cisplatin, especially when combined with radiation.

Clinical Findings. These ulcers are generally located on the nonkeratinized sites and in particular the buccal mucosa and ventral tongue. They begin within 3–5 days of the start of chemotherapy and generally resolve when absolute neutrophil counts recover, usually a course of 7–10 days. Lesions are extremely painful and may measure several centimeters in size.[16]

Differential Diagnosis and Laboratory Studies. Recrudescent herpes simplex virus (HSV) infection is common in immunocompromised patients such as patients with cancer and, unlike in healthy hosts, often occurs on nonkeratinized sites. Hence, patients who undergo hematopoietic stem cell transplantation, if seropositive for HSV antibodies, are prophylactically placed on antiviral agents during their hospital course. However, a positive culture may represent shedding of HSV in the oral fluids and saliva rather than true recrudescence within the ulcers.

Deep fungal infections and cytomegalovirus infection may all present with large ulcers on the mucosa, but these generally do not heal with recovery of neutrophil counts.

Radiation to the head and neck leads to severe erythema, inflammation, and ulceration (radiation mucositis).[17,18]

In patients who have received allogenic hematopoietic transplants, persistence of oral ulcers after engraftment may herald the development of acute graft-versus-host disease. In such situations, involvement of the keratinized tissues of the tongue dorsum and hard palate is not uncommon.

Management and Prognosis. Ulcers are self-limiting and therapy is directed toward pain control and prevention of septicemia from bacterial ingress into the oral wounds.[19] Patients are often treated with granulocyte-colony-stimulating factor to reduce the period of neutropenia and this has reduced the frequency of such ulcers.

Topical analgesia such as viscous lidocaine and systemic analgesia (especially narcotics) is the mainstay of pain control. Although chlorhexidine is often used for decontamination, its high alcohol content makes patient compliance poor. Other oral decontamination rinses contain nystatin and antibiotics.

DEEP FUNGAL INFECTIONS.

Zygomycosis is a broad term used to describe fungal infections caused by organisms in the phylum Zygomycota. These include infections caused by organisms in the family Mucorales with organisms in the genera *Mucor* and *Rhizopus*. These are unusual infections, seen usually in patients who have diabetes mellitus (usually ketoacidotic) or are immunocompromised, and are often life threatening. Organisms are inhaled and spread into the adjacent sinuses, eroding through the bone, sometimes presenting on the palate as a necrotic ulcer, a condition also referred to as rhinocerebral zygomycosis.[29] *Aspergillus* infections are seen in neutropenic patients, especially those with leukemia and tend to present as necrotic soft tissue and bony lesions of the gingiva, while histoplasmosis, coccidioidomycosis, blastomycosis, and paracoccidioidomycosis are seen in areas where such infections are endemic such as in South America and in patients with HIV/AIDS.[30–33]

Clinical Findings. Unlike candidiasis, deep fungal infections usually present as necrotic ulcers because they are angioinvasive organisms that cause vascular

TABLE 76-2
Herpes Virus and Oral Lesions

HHV1 (herpes simplex-1)	(a) Primary gingivostomatitis, usually in first to third decades of life (b) Herpes labialis and recrudescent herpetic ulcers on the attached mucosa in healthy patients; in adults (c) Ulcers on any oral mucosal site in immunocompromised patients
HHV2 (herpes simplex-2)	May present with oral ulcers similar to HSV-1; young adults
HHV3 (varicella zoster)	Primary infection may or may not have oral ulcers; recrudescent with unilateral ulcers along distribution of V_{II} or V_{III}; adults and immunocompromised patients
HHV4 (Epstein–Barr)	Oral ulcers in infectious mononucleosis in young adults; nasopharyngeal carcinoma in older adults, hairy leukoplakia in patients with HIV/AIDS
HHV5 (cytomegalovirus)	Oral ulcers; may be seen associated with HSV ulcers; usually in immunocompromised patients
HHV6	Unlikely to have oral manifestations
HHV7	Unlikely to have oral manifestations
HHV8	Kaposi sarcoma; usually seen in patients with HIV/AIDS
HHV 9 (simian)	Unlikely to be seen in humans

thrombosis and ischemia. The most common location for rhinocerebral zygomycosis is the palate, although fungal infections in immunocompromised patients may occur at any site in the mouth.

Differential Diagnosis and Laboratory Studies. Deep fungal infections involving the palate or maxilla are an important differential diagnosis for the clinical entity "midline destructive disease." Other conditions that fall into this category include NKT-cell lymphoma, other infections such as tertiary syphilis, granulomatosis with polyangiitis (Wegener disease), cocaine use, and epithelial malignancy of surface or salivary gland origin.[34] A biopsy readily distinguishes among these entities.

Because these are deep infections, a swab culture may not capture any organisms. A biopsy shows the presence of hyphae. It is useful to submit part of the harvested tissue in saline for speciation in a microbiology laboratory.

A biopsy shows necrosis and inflammation. The morphology of hyphae seen on special stains, together with culture results, confirms the diagnosis.

Management and Prognosis. Treatment is with systemic antifungal agents such as liposomal amphotericin and triazole antifungal agents such as fluconazole, itraconazole, and posaconazole, often with surgical debridement.[35] Mortality is often high in poorly controlled infection. Reducing environmental exposures is a particularly important prophylactic measure for immunocompromised patients.

WHITE LESIONS

It is important to distinguish truly white lesions from ulcerated or necrotic lesions that usually have a creamy-yellow color.

Many well-recognized oral lesions are white, ranging from developmental lesions such as white sponge nevus, to infections such as candidiasis, to immune-mediated disorders such as lichen planus (LP) and to frictional keratoses such as morsicatio mucosae oris (Table 76-3). Such lesions, with specific clinical and histologic findings, are not properly termed "leukoplakia."

True leukoplakias tend to be well demarcated at least around part of the lesion, are frequently dysplastic at first biopsy, and carry a significant potential for developing into SCC over time. White sponge nevus and reactive white lesions are discussed online.

WHITE SPONGE NEVUS.

White sponge nevus is an extremely rare condition, inherited in an autosomal dominant fashion. It affects the oral and genital mucosa, usually in a symmetric and often multifocal pattern, due to mutation in keratin K4 or K13 that results in keratin instability and abnormal keratin aggregation.[53] Spontaneous mutations have been reported.

Clinical Findings. Patients develop poorly demarcated, diffuse, painless white plaques on the oral mucosa, usually the buccal mucosa and tongue, usually within the first two decades of life.[21,54]

Differential Diagnosis and Laboratory Studies. Other conditions that may appear similar clinically include hereditary benign intraepithelial dyskeratosis, another rare mucosal disorder that occurs in a racial isolate in South Carolina,[55–57] and pachyonychia congenita.[58–60] Oral lesions of dyskeratosis congenita are true leukoplakias occurring in approximately 65% of patients and are usually dysplastic.[61,62]

Biopsy or exfoliative cytology is always indicated and shows perinuclear eosinophilic condensations (representing abnormal keratin aggregation) and distinguishes it from other mucosal disorders discussed below.

Management and Prognosis. There is no treatment for white sponge nevus, although some have

TABLE 76-3
Oral White Lesions

Developmental (Often Part of a Genodermatosis)
- White sponge nevus
- Hereditary benign intraepithelial dyskeratosis
- Pachyonychia congenita

Reactive
- Frictional keratoses
  - Morsicatio mucosae oris
  - Benign alveolar ridge keratosis
  - Other nonspecific
- Chemical injury
  - Leukoedema
  - Contact desquamation
  - Smokeless tobacco keratosis
  - Submucous fibrosis (scarring and fibrosis, not keratotic)*
- Retention of secretions and debris
  - Hairy tongue
  - Retention on other surfaces
- Unknown
  - Uremic stomatitis

Infectious
- Candidiasis
- Hairy leukoplakia

Immune-mediated
- Lichen planus
- Chronic graft-versus-host disease
- Lupus erythematosus
- Psoriasis
- Migratory glossitis/stomatitis

Neoplastic
- Leukoplakia
  - Verrucous leukoplakia
  - Proliferative leukoplakia
- Squamous cell carcinoma
- Verrucous carcinoma

reported resolution with antibiotics, in particular tetracycline.[63] It is postulated that tetracycline affects the keratinization process and inhibits epithelial proliferation.

REACTIVE WHITE LESIONS.

These very common conditions are caused by very mild topical injury caused by smoking or other mild contact injury such as strong toothpastes and alcoholic mouth rinses. The following white lesions are in ascending order of severity of injury beginning with changes caused by intracellular edema and swelling to those resulting in keratoses.

Leukoedema.

Many dentists classify leukoedema as a developmental malformation but it is likely a reactive lesion. It occurs in 20%–70% with habits such as using tobacco, coca, or marijuana to >90% of dark-skinned individuals mainly because the whiteness of the lesion shows up more clearly on pigmented mucosa.[54,64]

Clinical Findings. Lesions are usually bilateral on the buccal mucosa or ventral tongue and consist of painless, fine grayish white, opalescent reticulations. They are not well demarcated, but diffuse. Stretching the mucosa completely eliminates these fine lines since this is not a keratotic lesion, but rather caused by intracellular edema of damaged superficial keratinocytes.[21]

Differential Diagnosis and Laboratory Findings. Reticular LP may look similar but they are more densely white and do not disappear on stretching the mucosa.

A biopsy shows typical findings of keratinocyte edema or hydropic degeneration.

Management and Prognosis. No treatment is necessary since these lesions are benign although advice on smoking cessation may be warranted.

Contact Desquamation.

This is a common oral condition, where the injury to the tissue is slightly more severe than in leukoedema causing actual degeneration and detachment of the superficial keratinocytes. The offending agents are mouthwashes and toothpastes that are caustic [in particular Listerine (Pfizer Pharmaceutical, NY) mouthwash that contains 27% alcohol as well as eucalyptol and menthol].

Clinical Findings. This is generally a condition of adults. Patients will often report that their mouth is "peeling." Lesions present as painless sloughs of desquamated tissue that lie in thin ribbons on the mucosa and can be removed without pain or discomfort to the patient, with normal-appearing, pink underlying tissue.[65] Since the keratinized tissues are somewhat protected from the adverse effects of such topical agents, it is generally the nonkeratinized tissues that are involved. A helpful sign is a background of leukoedema with faint reticulations.

Differential Diagnosis and Laboratory Studies. While some bullosing disorders may form such sloughs, those lesions are almost always painful or sensitive, and may bleed. Lack of symptoms is key to the diagnosis of this condition coupled with the typical history.

A biopsy shows desquamating strips of surface keratinocytes.

Management and Prognosis. Patients should discontinue the use of the offending dentrifrice, or change to a less caustic agent.

Morsicatio Mucosae Oris (Pathominia Mucosae Oris, Chronic Bite Injury).

This is a yet more intense local factitial injury to the oral mucosa, caused by a chewing habit, leading to reactive keratosis and benign epithelial hyperplasia. It occurs in 3% of the population.[66] Any other factitial injury either from an unusual habit, or the rough edge of an appliance may lead to a similar lesion.

Clinical Findings. MMO appears as white papules and plaques on either side of the linea alba on the buccal mucosa, lower labial mucosa, or the lateral tongue, usually caused by raking of the teeth over the mucosa[67] Patients may or may not be aware of this habit (especially if this is a nighttime habit). Lesions have a shaggy, rough surface, are poorly demarcated, and

Figure 76-5 Primary herpes simplex virus (HSV) gingivostomatitis with involvement of gingiva and left upper labial mucosa.

occasionally may show evidence of erythema and/or ulceration where the "chewing" has been more intense (eFig. 76-5.3A and 76-5.3B in online edition).

Differential Diagnosis and Laboratory Studies. Candidiasis, some lesions of LP, hairy leukoplakia, and some leukoplakias and erythroleukoplakias may look similar but a biopsy will provide a definitive diagnosis. Such factitial injury may be superimposed upon an underlying condition such as dysplasia or LP, making the diagnosis even more challenging.

A biopsy shows varying degrees of parakeratosis with impetiginization and benign epithelial hyperplasia.

Management and Prognosis. No further management is necessary. These lesions are benign and have no malignant potential. The use of night guards or appliances to break the habit has not been shown to be helpful.

Benign Alveolar Ridge Keratosis (BARK, Oral Lichen Simplex Chronicus). BARK is a very common condition that was recently defined histologically. It occurs primarily on the keratinized mucosa of the gingiva and hard palate as a reaction to frictional trauma. It is the oral equivalent of lichen simplex chronicus.

Clinical Findings. BARK presents as poorly demarcated, painless white papules and plaques, often with a rough surface, usually less than 1 cm in greatest dimension (eFig. 76-5.4 in online edition). The most common location is the retromolar pad (at the site of previously extracted wisdom teeth) and other areas where teeth have been extracted.[68,69] It is not necessary for the opposing teeth to contact the mucosa, since crushing of food against the alveolar ridge that had been previously protected by a tooth is sufficient.

Differential Diagnosis and Laboratory Studies. Leukoplakia, especially verrucous leukoplakia is a very important differential diagnosis and a biopsy should always be performed if the lesion shows signs of sharp demarcation or is extensive. More worrisome, verrucous leukoplakia, a dysplastic lesion, also has a rough surface and is usually greater than 1 cm.

A biopsy shows typical features of lichen simplex chronicus. BARK is closely related to MMO (described above), another frictional keratosis. It is possible that BARK being located on the keratinized mucosa that is closer in histology to the skin, takes on the more typical histologic characteristics of lichen simplex chronicus (LSC).

Management and Prognosis. No treatment is necessary once the histopathologic diagnosis has been established. If a denture is the source of frictional irritation, this should be adjusted accordingly.

Nicotinic Stomatitis. Nicotinic stomatitis is not caused by nicotine as its name suggests but rather by heat, usually from pipe smoking. A similar condition may be seen in patients who reverse smoke, that is, hold the lighted end of the cigarette in the mouth, as is the habit in some South Indian and Southeast Asian populations. It has also been noted in patients who habitually drink very hot beverages.

Clinical Findings. The palate of adult patients is the site most often affected. It is diffusely white with red, punctuate areas representing the openings of salivary ducts. It is usually not a painful lesion although severe cases may be sensitive to hot and spicy foods, and lesions are usually symmetric and diffuse.[21,54]

Differential Diagnosis and Laboratory Studies. Leukoplakia and candidiasis of the palate may both mimic nicotine stomatitis.

A biopsy shows hyperkeratosis with benign epithelial changes and importantly, inflammation of excretory salivary ducts that exhibit squamous metaplasia. This diagnosis is difficult if the ducts are not included in the biopsy specimen.

Management and Prognosis. Lesions may resolve if the habit is discontinued. The risk for malignant transformation has not been well documented. However, the development of raised, indurated areas should raise suspicion for malignant transformation.

Smokeless Tobacco Keratosis. This is a lesion that results from a combination of direct contact toxicity of the smokeless tobacco on the mucosa (early lesions), and from effects of carcinogens within the snuff, namely tobacco-associated nitrosamines (late lesions that represent true leukoplakias). Not all smokeless tobaccos are alike. Snuff may be moist or dry and in general moist Swedish snuff ("snus") is lower in nitrosamines than moist and dry snuff from the United States.[70] Toombak, snuff from Ethiopia, has the highest levels of nitrosamines of all.[71] In many Asian countries, snuff and smokeless tobacco is mixed with other substances such as spices and importantly areca nut, which contains another potent carcinogen, the alkaloid arecoline.[72]

Over the last 10–15 years, there has been increased interest in using smokeless tobacco as a risk reduction measure in subjects who have difficulty discontinuing cigarette smoking because the risk of developing cancer (oral and other cancers) is reduced.[73,74]

Clinical Findings. The lesions are located where the snuff is placed, usually the mandibular sulcus/vestibule, between the teeth and the buccal mucosa. The area looks grayish white, opalescent, and wrinkled, often with fissures.[21,54]

Lesions are generally painless and poorly demarcated (eFig. 76-5.5 in online edition).

Differential Diagnosis and Laboratory Studies. The diagnosis includes leukoplakia, candidiasis, and BARK. Aspirin is much more caustic and causes necrosis and ulceration, rather than this delicate white lesion.

Biopsy reveals thin parakeratosis, intracellular edema, and devitalization of superficial keratinocytes. Any other agent that is locally irritating and slightly caustic may cause this clinical appearance.

Management and Prognosis. Most early lesions are primarily caused by contact injury and are reversible if the habit is discontinued. However, the development of a dense white plaque or erythema may signal transformation to malignancy and these areas should be biopsied. The rate of malignant transformation is only 1%–2% compared with cigarette smoking.

INFECTIOUS LESIONS

Candidiasis. Fungal infections are extremely common in the oral cavity and the most common causative agent is *Candida albicans*. Approximately 20%–30% of the population are carriers. In immunocompromised hosts, other species such as *C. tropicalis, C. dubliniensis, C. glabrata, and C. kruseii* should also be considered, as some of these may be resistant to conventional therapy. Predisposing factors include hyposalivation (see Section "Xerostomia" and "Hyposalivation" in online edition), immunocompromise, topical steroid therapy (for treatment of oral lesions or as inhalers), and antibiotic therapy.

Clinical Findings. Oral candidiasis may present in various forms (Table 76-4) (Figs. 76-6A–76-6E).[1,21] Lesions are almost always painful and dentures act as fomites.[75] Although *C. albicans* is the most common pathogen in denture-associated candidiasis, *C. glabrata* is found in 30% of cases.[76]

Differential Diagnosis and Laboratory Studies. An important differential diagnosis is hairy or coated tongue. This is not a candidal infection, although cultures may grow *Candida* in carriers. These lesions are almost always painless and do not involve mucosa other than tongue dorsum, unusual for candidiasis. It is caused by hyperplasia and hypertrophy of the filiform papillae of the tongue, with retention of keratinaceous debris as a result of hyposalivation and poor oral intake. Patients therefore are often ill, dehydrated, and on antibiotic therapy, further adding to the suspicion that the lesions represent candidiasis.

Culture is not particularly useful for diagnostic purposes since many individuals are carriers. However, culture is important if speciation or sensitivity is required,

TABLE 76-4
Presentation and Management of Oral Candidiasis

Type	Clinical	Treatment
Thrush/Pseudomembranous candidiasis	Curdy yellowish-white papules or plaques; may or may not scrape off Often synchronously on dorsum or tongue and palate so-called "kissing lesions"	Nystatin 1:100,000 iu/mL; swish and spit out 5 mL tid or qid Clortrimazole troche[a] 10 mg; suck on 1 troche tid or qid Ketoconazole 200 mg qd × 7-14 days Fluconazole 100 mg; take one tablet once a day × 3–10 days
Erythematous/Atrophic candidiasis	1. Erythematous areas under a denture 2. Linear gingival erythema in HIV/AIDS	1. Mycostatin and triamcinolone cream on worn denture ("under occlusion"); treat denture with dilute bleach (1:10), sodium benzoate or other antimicrobial soaks 2. See Thrush above
Hyperplastic candidiasis	Primarily white papules and plaques with minimal erythema; associated with mucocutaneous disease or hairy leukoplakia	See Thrush above
Angular cheilitis	Fissured, weepy lesions at the corners of the mouth; often associated with *Staphylococcus aureus*	Mycostatin and triamcinolone cream; may need topical erythromycin
Median rhomboid glossitis	Rhomboidal area in posterior midline of tongue, anterior to circumvallate papillae; maybe slightly depressed and erythematous, or raised	See Thrush above

[a]Troches do not dissolve well in patients with hyposalivation.

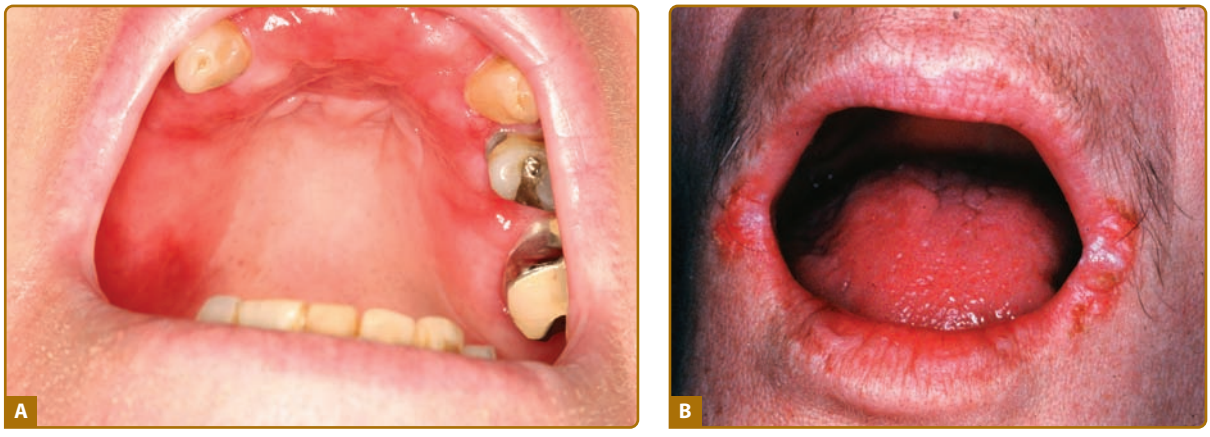

Figure 76-6 **A.** Erythematous candidiasis. **B.** Angular cheilitis.

or to identify carriers prior to the start of long-term steroid therapy. A potassium hydroxide preparation using scrapings from oral lesions is a good way to identify infection. Biopsies show typical candidal organisms.

Management and Prognosis. Patients who have dry mouths from polypharmacy or substantial damage to salivary glands (such as from radiation) are prone to develop recurrent candidiasis and are particularly difficult to manage. Nystatin rinses and clotrimazole troches contain caries-inducing sugars and should be used long-term only with careful monitoring by the dentist. The use of cholinergic agents such as pilocarpine or cevimeline helps to restore some secretory function of salivary glands and may reduce the frequency of candidiasis.

Hairy Leukoplakia. Epstein–Barr virus (EBV) infections in the oral cavity may present as a primary infection (infectious mononucleosis). Hairy leukoplakia is an unusual presentation of recrudescent EBV in the oral cavity, where this normally lymphotropic virus is present within the epithelium.

Clinical Findings. This manifests as a painless, white plaque usually located on the lateral border of the tongue in immunocompromised patients, and in particular, those with HIV/AIDS and after organ transplantation.[77,78]

Typically, these present as white linear lesions running perpendicular to the long axis of the tongue but when more advanced, may extend onto the dorsum and present as a plaque (Fig. 76-7). Lesions are usually asymptomatic and usually superinfected with *Candida*. Infrequently, hairy leukoplakia has been reported in healthy individuals.[79]

Differential Diagnosis and Laboratory Studies. Lesions of MMO and candidiasis often occur on the lateral tongue and may appear similar.

Both cytologic smears and biopsies show characteristic findings and the presence of EBV can be confirmed by in situ hybridization.

Management and Prognosis. The presence of hairy leukoplakia may be the first indication that a patient is infected with HIV. In patients with established HIV/AIDS, hairy leukoplakia is usually associated with a low CD4 count and high viral load.[77] Treatment with an antifungal medication (see Section "Candidiasis") will resolve the associated candidiasis and treatment with antiretroviral therapy results in resolution.

ORAL LICHEN PLANUS

Oral LP is an immune-mediated disorder and an interface stomatitis characterized by T-cell destruction of the basal cells of the epithelium, possibly as a result of altered antigen presentation on these cells, mediated by TH1 cytokines. Interferon-α production is thought to mediate lesions involving the oral cavity only while TNF-α may mediate systemic disease.[80] Whether this is a disease in and of itself or whether it represents a "final common pathway" of mucosal reaction is unclear at this time. Many local and systemic conditions predispose to the development of such "lichenoid lesions" in the oral cavity. The term "lichenoid" used here to describe reticulated, often erythematous and/or ulcerated lesions, usually bilateral and symmetric. Unfortunately, many erythroleukoplakias that are by definition red and white lesions but usually without significant reticulation are also clinically described as "lichenoid"

Figure 76-7 Early hairy leukoplakia (Used with permission from Dr. Mark Lerman, Harvard School of Dental Medicine).

by some investigators, causing confusion and leading to the concept of LP as a premalignant lesion.

Local lichenoid reactions may develop as a result of contact injury to amalgam restorations or cinnamic aldehyde from chewing gum. Medications implicated in the development of oral LP include antihypertensive agents (especially hydrochlorthiazide), some hypoglycemic agents, allopurinol, sulfasalazine, carbamazepine, and the new biological agents.[80–82] It is often impossible to differentiate either clinically or histologically, between lesions of idiopathic LP and lichenoid hypersensitivity reactions.[83]

Other conditions associated with oral lichenoid lesions include hepatitis C in Mediterranean races and this is associated with HLA-DR6[84,85]; chronic graft-versus-host disease, and lupus erythematosus.[86,87]

CLINICAL FINDINGS. Oral LP occurs in 1%–2% of the population in the United States and affects females more than males, usually those in the fifth decade of life and older. Three clinical forms are noted—(1) keratotic/reticular, (2) erythematous/erosive, and (3) ulcerative—and these often occur in combination.[21,54] The most recognizable is the keratotic/reticular form (Wickham striae) that is usually not painful. This is symmetric in distribution and reticulations almost always occur on the buccal mucosa and tongue although any oral mucosal site may be affected (Figs. 76-8A and 76-8B). Lesions on the dorsum of tongue tend to be subtle and more papular with atrophy of filiform papillae giving the tongue a white cast and smooth appearance (Fig. 76-8C). The erythematous or erosive form is usually painful and this is particularly common as a primary presentation on the gingiva (clinically desquamative gingivitis).[88] LP on the gingiva is also noted in the gingival–genital syndrome.[89] Ulcerative LP usually occurs in association with the other two forms. The finding of intact blisters (bullous LP) is rare in the oral cavity because it is a trauma-intense environment. Concomitant skin involvement is noted only in 10%–15% of patients.

A controversial entity is the so-called "plaque-type LP." If this lesion occurs as a unilateral plaque without reticulations, it should be considered a leukoplakia. If it occurs within an established, typical symmetric oral LP, it should be considered "leukoplakia developing within LP." In either case, biopsy is indicated to exclude dysplasia or malignancy.

Several scoring systems have been developed for evaluating the severity of disease but none are universally accepted.[90–92]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. Many conditions may result in the development of LP and lichenoid reactions. However, the most important is erythroleukoplakia. It can be differentiated from oral LP in that it is not usually definitively reticulated (although it may have subtle linear areas), is

Figure 76-8 **A.** Reticular lichen planus (LP) of right buccal mucosa. **B.** Reticular, erythematous and ulcerative LP of left buccal mucosa in same patient as 76-8A. **C.** LP of dorsum of tongue; **D.** LP of gingiva.

usually asymmetrically distributed, and often presents at a high-risk site for cancer such as the ventral tongue unilaterally. It is strongly associated with dysplasia and carcinoma (see below). Other lesions include candidiasis and contact stomatitis such as to chewing gum.

Chronic ulcerative stomatitis is an entity that resembles erythematous/erosive LP but is associated with antibodies directed against δNp63α.[93] Direct immunofluorescence studies reveal nuclear binding of keratinocytes in the basal and lower one-third of the epithelium. Serum immunoglobulin (Ig) G can be detected using guinea pig esophagus as substrate and an ELISA is now available.[94]

The reticulated white areas on the buccal mucosa may sometimes resemble MMO. Erythematous LP lesions on the gingiva are often indistinguishable from other diseases presenting as desquamative gingivitis such as mucous membrane pemphigoid, hypersensitivity reaction, or plasma cell gingivitis. Pure ulcerative lesions without reticulations are more likely to be aphthous ulcers.

Diagnostic histopathologic findings for oral LP, are squamatization of basal cells and a lymphocytic band at the interface. Direct immunofluorescence studies show shaggy fibrinogen and often IgM at the interface and IgM staining of colloid bodies.

MANAGEMENT AND PROGNOSIS. Management of oral LP and lichenoid lesions involves pain control and treatment with topical steroids and other anti-inflammatory agents (Table 76-1).[95] Gingival lesions are effectively treated with topical steroids held in a stent. Systemic therapy with prednisone (at 1 mg/kg for 1 week with a fairly rapid taper) or hydroxychloroquine should be instituted in severe cases and topical therapy started concomitantly.

Localized, unliateral lesions may respond to removal of dental restorations and a short course of topical steroids. Disease remission occurs in <10% of cases.

The rate of malignant transformation (often given as 1% every 5 years) is controversial because some studies do not correct for confounding factors such as smoking, while other included erythroleukoplakias, leukoplakias (diagnosed as "plaque-type" LP), and proliferative leukoplakia in the group of "lichenoid" lesions. Classic, bilaterally symmetric, reticulated LP has a very low malignant potential.[96]

LEUKOPLAKIA AND ERYTHROPLAKIA

This is one of the more challenging diagnostic entities of oral mucosal disease. Leukoplakia is defined as a "white plaque of questionable risk having excluded other (known) diseases or disorders that carry no increased risk for cancer."[97] It is a clinical diagnosis only and modified once the histopathologic diagnosis is known. For example, what may appear to be a provisional diagnosis of leukoplakia on the buccal mucosa may histopathologically prove to be MMO as a final definitive diagnosis. Frictional keratosis is NOT a leukoplakia and the only two histologically well-defined frictional keratoses are (1) MMO and (2) BARK. Because frictional injury is very common in the oral cavity and usually presents as a hyperkeratosis, it is likely that many so-called leukoplakias actually represent nonspecific frictional keratoses that are not MMO or BARK.

Leukoplakias occur in 2%–4% of the population.[98] Any lesion that carries a provisional diagnosis of leukoplakia must be biopsied because approximately 20%–50% of these lesions are dysplastic or cancerous at the time of biopsy.[99,100]

Leukoplakia is strongly associated with smoking and/or alcohol ingestion. Other predisposing factors are similar to those for oral cancer and will be discussed below.

CLINICAL FINDINGS. Leukoplakia is more common in adult males. It presents as a painless, white plaque that may be homogenous or nonhomogenous.[97] It may occur anywhere in the oral cavity and generally shows areas that are sharply demarcated from the surrounding mucosa (Fig. 76-9). Homogenous leukoplakia may show areas of fissuring. Nonhomogenous leukoplakia have areas of erythema (erythroleukoplakia), rough, warty areas (verrucous leukoplakia), or nodular areas; they have a higher association with dysplasia and carcinoma, as do lesions on the floor of mouth, ventral tongue, and soft palate.[101,102]

Proliferative verrucous leukoplakia (PVL)[103,104] tends to occur in middle-aged females and, as its name suggests, tends to spread or proliferate over the mucosa over time, and is usually multifocal (eFigs. 76-9.1A–76-9.1C in online edition). It is associated with smoking in less than 30% of cases. Patients are usually diagnosed with this condition one to two decades after the first appearance of the white lesion. Areas of it may become verrucous, although not invariably, and other areas may appear red, in which case the term proliferative erythroleukoplakia may be appropriate. Approximately 70%–100% of cases develop SCC over time.[103,105] These lesions are particularly difficult to diagnose because patients often have had multiple biopsies over many years, and each time, the diagnosis is one of "hyperkeratosis" only without evidence of dysplasia.

Oral *erythroplakia*, although a red lesion, will be discussed here because of its high associated dysplasia. It is an uncommon lesion and in its pure form

Figure 76-9 Leukoplakia of tongue (dysplasia).

presents as a painless, red, sometimes velvety plaque of the oral mucosa (eFig. 76-9.2 in online edition). More than 90% of cases are associated with dysplasia or carcinoma at the time of diagnosis.[106,107] It is much more common to see it in combination with leukoplakia (erythroleukoplakia).

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. The clinical differential diagnosis list for leukoplakia is long (Table 76-3). However, sharp demarcation at least one border is a helpful finding and usually excludes an inflammatory/reactive lesion. A biopsy should be performed for any white lesion if the etiology cannot be established with confidence on clinical grounds.

Approximately 20%–50% of leukoplakias are dysplasias or carcinoma at the time of biopsy.[100,101,106,108] However, 5%–18% of lesions diagnosed as "benign hyperkeratosis," when followed over time, transform to carcinoma.[99,102,108] This is particularly true of lesions of proliferative leukoplakia where multiple biopsies show "benign hyperkeratosis" until many years later when overt dysplasia or carcinoma develops.

Research using microarrays and other techniques to better characterize the genome of these lesions will shed light on this in coming years. The concept of "oral" or "squamous intraepithelial neoplasia" similar to "cervical intraepithelial neoplasia" has not received acceptance although it is likely a useful concept to adopt.

Management, prognosis, and risk of progression to oral SCC are discussed online.

There is controversy as to whether leukoplakias should be excised.[109] Some suggest that small leukoplakias should be excised, while extensive lesions could be managed with multistage stripping.[110] While some clinicians and pathologists believe that mild dysplasias may just be observed since some of these regress, it is likely that some of these "regressing mild dysplasias" represent only keratotic lesions with reactive atypia. True dysplasias are intraepithelial neoplasias that have not yet become invasive. If such lesions can be removed without excessive morbidity, this seems prudent.

Options for the 50%–80% of cases diagnosed as "benign hyperkeratosis," include periodic rebiopsy or excision. It is suggested that "benign hyperkeratoses" that are not clearly frictional or reactive in nature and are in high-risk sites be narrowly excised and followed and that recurrent lesions be excised with a margin of several mm. Because leukoplakia is a clinicopathologic entity, it is important that the clinician work with a pathologist who is experienced in the diagnosis of reactive and nonreactive oral keratotic lesions.

Smoking cessation counseling should always be part of the overall management strategy for patients who smoke.

ORAL SQUAMOUS CELL CARCINOMA

Head and neck cancer is the 11th most commonly occurring cancer in the United States, and there are approximately 35,000 cases per year, with one-third of these occurring in the oropharynx.[111] Risk factors include smoking cigarettes, excessive use of alcohol, chewing areca nut, a past history of cancer and/or immunosuppression, family history of cancer, exposure to high-risk forms of human papilloma virus (HPV) (especially for carcinomas of the posterior oral cavity and oropharynx), age, and for lip cancer, sunlight.[112,113]

CLINICAL FINDINGS. Oral SCC affects males more often than females in a 2:1 ratio and usually affects older adults. Excluding the lip, the most common sites are the ventral tongue, gingiva, and floor of mouth. It may present as a leukoplakia, erythroplakia, proliferative leukoplakia, a nonhealing ulcer or ulcerated nodule, or a mass.[112] The tumor may have a verrucous or papillary surface (eFig. 76-9.3 in online edition). Pain may or may not be present and there may be paresthesia. Advanced lesions infiltrate the underlying bone or muscle and may lead to difficulty with movement of the tongue, adversely affecting speech and eating. Metastases to the submandibular and upper cervical lymph nodes are common, and nodes should be palpated in patients with suspicious lesions.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. The differential diagnose for leukoplakia are presented in Table 76-3. Traumatic ulcerative granuloma (see above) may be mistaken for oral carcinoma because it is often on the lateral/ventral tongue, may not be particularly painful and is often present for weeks. Benign neoplasms of soft tissue or salivary gland origin may be traumatized and present as an ulcerated nodule, raising the suspicion of oral carcinoma.

A biopsy shows a proliferation of malignant epithelial cells infiltrating the stroma as single cells or in a bluntly invasive fashion. The latter is a particular feature of verrucous carcinoma that tends not to metastasize.

MANAGEMENT AND PROGNOSIS. Management and prognosis is dependent on the stage. Most Stage I and II lesions are treated with surgical excision (usually en bloc resection) with an objective of obtaining clear margins.[114] Some Stage II lesions are treated with a supraomohyoid neck dissection. Studies on sentinel node biopsy have shown metastatic lesions in 20%–30% of patients.[115,116] Stage III and IV tumors may be treated with surgery, radiation or chemoradiation (the chemotherapy being a radiation sensitizer) for organ-sparing purposes.[117] The use of cetuximab, a monoclonal antibody against the epidermal growth factor receptor, which is highly expressed in many oral cancer, has resulted in improved disease control.

Five-year survival for patients with local disease only, locoregional disease and distant metastases are 81%, 50%, and 14%, respectively.[114]

BULLOUS DISORDERS/RED LESIONS

Many autoimmune bullous disorders present as erythematous and/or ulcerative lesions. It is rare for intact bullae to be present in the oral cavity.

MUCOUS MEMBRANE PEMPHIGOID

Mucous membrane pemphigoid is a heterogeneous group of disorders characterized by subepithelial blistering and antibodies, usually IgG or IgA, directed against a variety of antigens such as BP230, BP-180, laminin-332, laminin-331, Type XVII collagen, Type VII collagen, or β 1 integrin subunit,[121] to name a few.

CLINICAL FINDINGS. This is a disease of middle aged and older adults with a slight female predisposition. The most common presentation for mucous membrane pemphigoid is desquamative gingivitis. This presents as a band of bright red, painful gingiva, often denuded of epithelium, with areas that are ulcerated or with necrotic epithelium lying on the surface (Fig. 76.10). Patients have difficult eating coarse, acidic, or spicy foods and the gingiva bleed readily on brushing. Oral mucosa lesions rarely cause scarring and most patients who present with oral lesions initially do not usually develop skin lesions. It is uncommon to see lesions on sites other than the gingiva in the oral cavity.

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS. LP is the most common disease (70%–75%) presenting as desquamative gingivitis, with mucous membrane pemphigoid representing 9%–14% of cases.[122,123] Other conditions include hypersensitivity reactions such as plasma cell gingivitis and less commonly other autoimmune bullous disorders such as pemphigus vulgaris, linear IgA disease, and epidermolysis bullosa acquisita. LP may or may not show reticulations on the gingiva or elsewhere in the oral cavity and pemphigus vulgaris almost always involves mucosal sites other than the gingiva. Linear IgA disease and epidermolysis bullosa acquisita always present with concomitant skin lesions. Granulomatosis with polyangiitis (Wegener disease) produces a granular, erythematous gingivitis.

All patients with a clinical diagnosis of desquamative gingivitis should have a biopsy both for routine histology and for direct immunofluorescence studies. The presence of linear IgG, IgA, and/or C3 at the basement membrane zone on direct immunofluorescence testing is strongly suggestive of pemphigoid. The diagnosis of linear IgA disease should not be made in patients with mucosal disease alone. Indirect immunofluorescence using salt-split skin may also be helpful.[121]

Figure 76-10 Mucous membrane pemphigoid.

MANAGEMENT AND PROGNOSIS. The most effective way to treat mucous membrane pemphigoid presenting as desquamative gingivitis is with a topical steroid gel held in a soft stent (similar to a bleaching or fluoride tray extended over the gingiva) for 30 minutes twice a day. Clobetasol may be used for the first few months, switching to fluocinonide when disease is better controlled. Application may also be reduced to 10–15 minutes once a day for maintenance. Prednisone and dapsone may be used if lesions are recalcitrant.[124] Azathioprine and cyclophosphamide are also effective in some cases.[121] It is unclear whether patients with IgA on direct immunofluorescence studies have more recalcitrant disease. Some cases may respond to etanercept.[125]

This disease is chronic and the disease rarely remits completely. Since ocular complications may be severe, all patients with oral lesions are referred for baseline ophthalmologic examination. Long-term topical steroid therapy may lead to hypertension, hyperlipidemia, and poor control of diabetes mellitus, so periodic blood pressure measurements, ACTH and cortisol levels, and lipid and glucose levels are indicated.

PEMPHIGUS

The oral cavity may be involved by pemphigus vulgaris and paraneoplastic pemphigus. There is a predilection for this condition among Ashkenazi Jews and those living around the Mediterranean and South Asia and a strong association with HLA-DR4, Drw14, and DQB1*503.[126] The antigen is desmoglein 3.

CLINICAL FINDINGS. Pemphigus vulgaris is an uncommon condition, most often seen in adults. Patients may present with lesions in the mouth before developing skin lesions. Lesions may present as desquamative gingivitis, but almost invariably, other mucosae are involved, in particular the hard and soft palate. Oral lesions are denuded and erythematous, painful, and slightly depressed. Remnants of the bullae or necrotic debris may overlie the erosion, or be heaped up at the edges (eFig. 76-9.4 in online edition). Some patients have lesions limited to the oral cavity and never develop skin lesions.

In addition to the erosions and ulcers present intraorally, patients with paraneoplastic pemphigus (also known as paraneoplastic autoimmune multiorgan syndrome) present with hemorrhagic crusting of the lips. It is usually associated with a lymphoid malignancy.[127]

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS. Large ulcers of Behçet disease and recurrent aphthae major may look similar to pemphigus vulgaris. Stevens–Johnson syndrome and the more severe toxic epidermal necrolysis may resemble lesions of paraneoplastic pemphigus.

Figure 76-11 Lupus erythematosus of buccal mucosa.

The biopsy for pemphigus vulgaris shows suprabasilar acantholysis and direct immunofluorescence studies show intercellular deposition of IgG. Paraneoplastic pemphigus shows deposition of IgG and C3 both intercellularly and at the basement membrane zone. Patients with only oral lesions of pemphigus usually do not exhibit elevated serum IgG.

MANAGEMENT AND PROGNOSIS. Treatment for pemphigus vulgaris is with topical steroids in mild cases with the use of a stent for gingival lesions. More severe cases can be successfully treated with prednisone and mycophenolate mofetil in conjunction with topical steroids.

LUPUS ERYTHEMATOSUS

Patients with systemic and discoid lupus erythematosus present with oral findings in up to 25% of cases.[128]

Figure 76-12 Plasma cell gingivitis.

CLINICAL FINDINGS. Patients may present with erythematous and eroded mucosa, especially on the buccal mucosa and palate with a hint of white reticulations. Ulcers may be present (Fig. 76-11).

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS. LP can usually be differentiated by well-formed reticulations of the buccal mucosa. Patients with lupus erythematosus usually have an established diagnosis and present for management of painful oral lesions.

The biopsy shows an interface stomatitis with linear IgG deposition along the basement membrane zone on direct immunofluorescence.

MANAGEMENT AND PROGNOSIS. The mainstay of treatment is topical steroid therapy. Symptoms usually wax and wane with systemic and skin disease.

PIGMENTED LESIONS

The two most common pigments of exogenous origin are amalgam and graphite from pencil lead. Pigmented lesions of endogenous origin are usually caused by melanin or hemosiderin.

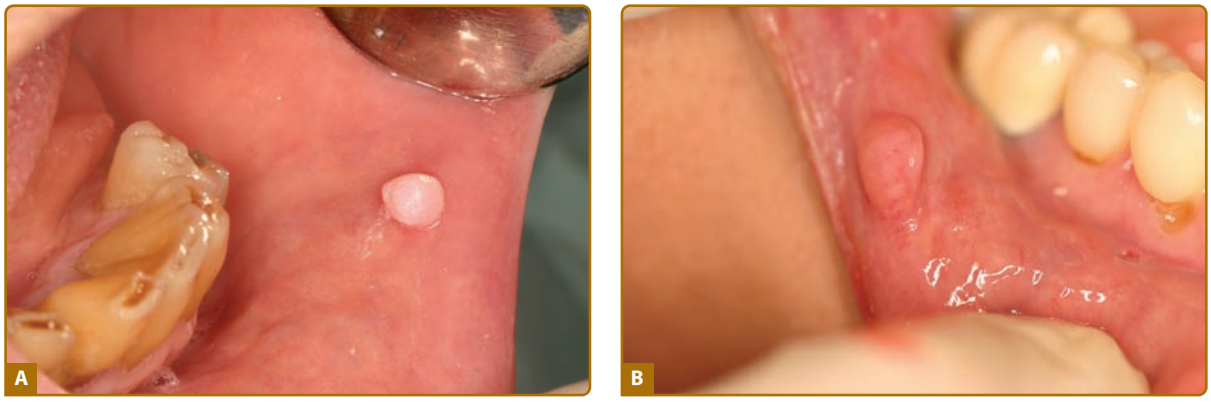

Figure 76-13 **A** and **B.** Fibroma.

Figure 76-14 Gingival nodule.

AMALGAM TATTOO

Dental amalgam restorations are primarily composed of silver and mercury with smaller amounts of other elements such as tin. The silver particles stain the reticulin fibers leading to the tattoo.[165]

CLINICAL FINDINGS. This presents in adults usually, as a discrete, nontender, slate-gray, or black macule of the oral mucosa that is usually less than 1 cm.[166–168] The patient is usually unaware of the lesion. When it is noted adjacent to a silver or amalgam restoration because of leaching out of particles, the diagnosis is straightforward. However, if it is located at a site away from the restoration, such as the buccal mucosa, tongue, sulcus, or palate, the diagnosis may not be as obvious (Fig. 76-15).

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS. Any other dark foreign material such as graphite may look similar. Melanotic lesions especially the oral melanotic macule and postinflammatory hypermelanosis may look similar although in general these are more tan and dark brown rather than dark blue. Dysplastic melanocytic lesions and melanoma usually have less uniform pigmentation and irregular borders. A vascular lesion such as a varix or venous lake may look similar, although those intend to appear as blebs or papules and blanch with pressure.

The histopathology is distinctive. Pigmentation by other materials not containing silver such as graphite does not cause staining of the reticulin fibers.

MANAGEMENT AND PROGNOSIS. A biopsy is usually not required if the lesion is adjacent to a restoration. However, if there is any doubt about the diagnosis, a biopsy is recommended.

Figure 76-15 Amalgam tattoo in floor of mouth.

Figure 76-16 Physiologic pigmentation.

PHYSIOLOGIC PIGMENTATION (RACIAL PIGMENTATION)

This is very common in dark-skinned individuals of African, South and Southeast Asian, and Mediterranean descent.

CLINICAL FINDINGS. Physiologic pigmentation presents asymptomatic diffuse, even or patchy, brown-to-black macular pigmentation of the oral mucosa and in particular the attached gingiva (Fig. 76-16). This usually has a symmetric distribution.[21]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. The patient is usually unaware of this. Postinflammatory hypermelanosis from diffuse and symmetric involvement by oral LP may also have a similar appearance. However, the pigmented areas tend to be located where the obvious white reticulations are present. Cosmetic tattooing of the gingiva is a prevalent practice in some African cultures and this may lead to extensive and symmetric pigmentation.

The biopsy shows the presence of melanin within basal cells in the absence of melanocytic hyperplasia.

MANAGEMENT AND PROGNOSIS. Recognition of the condition is sufficient and a biopsy is seldom necessary.

ORAL MELANOTIC MACULE

The etiology of the solitary melanotic macule is unclear. It is possible that at some of the lesions may have an inflammatory etiology.

CLINICAL FINDINGS

The most common sites of involvement are the lower lip vermilion, gingiva, and hard palate.[169,170] They are asymptomatic, discrete, tan, brown, or black macules, usually less than 1 cm with even pigmentation (eFig. 76-16.1 in online edition). Unlike ephelis, they do not darken in summer or lighten in winter. While most lesions are solitary, multiple macules are not uncommon in dark-skinned individuals, and they may proliferate in middle age.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

Multiple oral melanotic macules are seen in idiopathic lenticular mucocutaneous pigmentation (Laugier–Hunziker syndrome) associated with melanonychia.[171] Multiple melanotic macules are often seen neurofibromatosis, McCune–Albright syndrome, Peutz–Jeghers syndrome, LAMB (lentigenes, atrial myxoma, blue nevus) syndrome, and the associated Carney syndrome.[21]

The sudden onset of melanotic macules should raise the possibility of Addison disease and ACTH levels should be measured. History and clinical examination usually exclude the other syndromes.

Multifocal oral melanosis is also associated with postinflammatory conditions such as LP and the so-called "smoker's melanosis" that occurs on the gingiva around the canine teeth (see below).

Biopsy reveals increased melanin pigment in the basal cells in the absence of melanocytic hyperplasia, and many melanophages in the lamina propria.

MANAGEMENT AND PROGNOSIS

No treatment is necessary. Laser therapy may be useful in patients who are concerned with the esthetic appearance of the macules.[172]

POSTINFLAMMATORY HYPERMELANOSIS

These pigmented lesions occur in particular in dark-skinned patients, similar to lesions of postinflammatory hyperpigmentation on the skin. They may be localized or diffuse depending on the underlying inflammatory process.

CLINICAL FINDINGS

LP is often associated with postinflammatory hypermelanosis and the pigmentation underlies the reticulations of the disease (Fig. 76-17). Smoker's melanosis is often described as a separate entity but likely represents a postinflammatory hypermelanosis occurring in approximately 20% of subjects who smoke. It tends to occur on the buccal gingiva around the canine teeth or on the buccal mucosa.[173,174] Resolution of these lesions after smoking cessation supports an inflammatory etiology.[175]

Figure 76-17 Postinflammatory hypermelanosis from lichen planus.

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS

Oral melanotic macules may resemble melanoacanthosis, another likely inflammatory reactive disorder in which there is proliferation of dendritic melanocytes throughout acanthotic epithelium.

Biopsy helps exclude a dysplastic melanocytic lesion.

MANAGEMENT AND PROGNOSIS

No treatment is necessary unless the patient is concerned about esthetics. Lesions generally fade over time if the inflammation resolves.

MEDICATION-INDUCED HYPERPIGMENTATION

The medications most commonly associated with oral pigmentation do so via several different mechanisms.[176] Minocycline and tetracycline chelate to apatite crystals in bones and teeth and their metabolic products chelate iron and melanin in the soft tissues.[177] The latter mechanism is also seen during therapy with antimalarial drugs. Pegylated interferon used with ribavirin may stimulate melanin production by stimulating production of α-melanocyte stimulating factor.[178,179] Heavy metals such as lead is secreted into the gingival fluids and likely chelate with sulfides (usually black) produced by plaque bacteria.[180] Bismuth subsalicylate ingestion is also associated with pigmentation of the tongue either from systemic ingestion and tissue deposition, or direct conversion of the compound to bismuth sulfide from oral bacteria.[181,182]

CLINICAL FINDINGS

The most common site of pigmentation caused by minocycline and antimalarial medications is the palatal mucosa, which assumes a slate-gray to blue diffuse macular discoloration that is generally bilateral and symmetric. The lesions are asymptomatic.

Tongue pigmentation caused by pegylated interferon accentuates the papillae in a punctate configuration; this has been reported mainly in dark-skinned individuals.[178] Heavy metals deposit on the gingiva in linear fashion (Burton line in plumbism).[180]

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS

The history of ingestion of the drug followed by the appearance of a diffuse pigmentation of the oral mucosa and sometimes skin after several months or years is diagnostic.

Biopsy shows pigment granules that stain for both iron and melanin.

MANAGEMENT AND PROGNOSIS

Depending on the length of exposure, discontinuation of the drug may or may not result in eventual complete resolution of the lesion.

MELANOACANTHOSIS

This is an uncommon inflammatory condition of the oral mucosa. Although this condition is also reported under the term "melanoacanthoma," melanoacanthosis is preferred because this is a macular lesion, may be multifocal and is not a tumor-like lesion. Many cases of multifocal melanoacanthoma and melanoacanthosis reported in the literature represent either multiple melanotic macules or postinflammatory hypermelanosis. This raises the question as to whether oral melanotic macules and melanoacanthosis are just two manifestations of postinflammatory hypermelanosis.

CLINICAL FINDINGS

Black females in the second to fourth decades are most often affected. The lesion starts as a brown macule, usually on the buccal mucosa, that over days and weeks spreads rapidly, but still in a macular fashion.[183,184]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

While dysplastic nevi and melanoma may grow rapidly, the rate of expansion of the lesion is so fast that an inflammatory condition is more likely.

A biopsy shows acanthosis with benign melanocytes throughout the full thickness of the epithelium.

MANAGEMENT AND PROGNOSIS

No treatment is necessary; this condition regresses over time.

NEVOMELANOCYTIC NEVI

CLINICAL FINDINGS

The most common is the intramucosal nevus that accounts for two-thirds of cases, followed by the compound nevus and the blue nevus (17%) each; junctional nevus constitute only 3% of lesions.[168] The most common location is the palate (40%) followed by the buccal mucosa (19%).[185] Most were identified in the third and fourth decades of life.

Intramucosal and compound nevi tend to be nodular, while junctional and blue nevi tend to be macular. Most nevi are pale-tan to dark-brown or black while blue nevi are slate-blue in color. Approximately 15%–20% of intramucosal nevi are nonpigmented clinically.[185]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

Intramucosal and compound nevi may be mistaken for fibromas or any other benign mesenchymal tumor. Blue nevi resemble melanotic macules, amalgam tattoo, or even a varix. Intraoral Spitz nevi are rare but have been reported.

A biopsy shows the presence of nevomelanocytic cells in nests in the lamina propria and/or the epithelial–connective tissue interface. Blue nevi consist of spindled melanocytes in the lamina propria.

MANAGEMENT AND PROGNOSIS

In general, nodular lesions are excised or shaved.

MELANOMA

Intraoral melanomas constitute 0.7% of all melanomas and occur on average 20 years later than cutaneous melanomas.[186,187] The etiopathogenesis in this UV-protected site is unknown and lesions behave similarly to acral lentiginous melanoma.

CLINICAL FINDINGS

Oral melanomas are tumors of adults in the fifth to seventh decades of life with a male predilection and usually evolve from preexisting dysplastic melanocytic lesions.[188,189] They are more frequent in black and Japanese patients and the most common site is the palate or maxillary gingiva. By the time they are diagnosed, they are fairly large, asymmetric, and unevenly pigmented. Areas of ulceration and bleeding may be present. Approximately 40% are amelanotic.[188]

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS

Kaposi sarcoma tends to be purple or bluish-red, while melanomas tend to be brown-to-black. A large pyogenic granuloma or other vascular lesion with a dark coloration may resemble a melanoma, although a surrounding macular dysplastic melanocytic lesion would be absent.

A biopsy shows an invasive proliferation of melanocytes from an intraepithelial component.

MANAGEMENT AND PROGNOSIS

Five-year survival is approximately 20%–30%.[190,191] Excision with clear margins is the treatment of choice and survival is closely related to the depth of invasion.[192] Surgery with radiotherapy greatly reduces local relapse and metastasis to lymph nodes, although it may not improve survival.[190,193]

DISORDERS OF THE LIPS

Disorders of the lips including actinic cheilitis, orofacial granulomatosis,[200,204] angular cheilitis, and lip nodules are discussed online.

ACTINIC CHEILITIS

Some use the term actinic cheilitis to encompass atrophy of the lips caused by actinic damage without evidence of dysplasia. Here, it will be defined as actinic keratosis of the lip, a dysplastic lesion.

CLINICAL FINDINGS

Because the etiology is related to sun-damage, patients are generally adults in the sixth decade and beyond.[194,195] There is usually a background of chronic actinic damage and atrophy of the lip with blurring of junction of the vermilion and the skin, predominantly involving the lower lip. Actinic cheilitis presents as single or multiple crusted or scabbing, slightly scaly lesions and plaques on the vermilion of the lip, usually several millimeters in size, that heal and then break down. These occur on a whitish, keratotic background. Fissuring and erosions of the vermilion may be present. Discomfort is variable.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

An early SCC, traumatized adnexal or salivary gland tumor, or recrudescent herpes simplex infection should be considered in the differential diagnosis.

A biopsy is diagnostic and shows keratinocytic dysplasia.

MANAGEMENT AND PROGNOSIS

Several treatment options are available depending on the size of the lesion and patient preference. Lesions may be surgically excised, treated with cryotherapy or carbon dioxide laser,[196] or managed with topical agents such as 5-fluorouracil or 5% imiquimod for 4–6 weeks.[197,198] In patients prone to herpes simplex recrudescence, antiviral prophylaxis should be considered. More recently, the use of photodynamic therapy with 5-aminolevulinic acid has shown complete clinical response in two-thirds of cases and partial response in one-third; follow-up revealed recurrence in approximately one-third of cases.[199]

CHEILITIS GRANULOMATOSA (OROFACIAL GRANULOMATOSIS)

This is the best known of the noninfectious granulomatous diseases that affects the orofacial region. Like other granulomatous disease, it likely represents a delayed-type hypersensitivity reaction to antigens.[200] Elimination diets and removal of amalgam restorations have resulted in complete remission of some cases, but no obvious etiologic agents is identified in many cases. There may be a genetic predilection and the reaction is mediated via Th1 pathways.[201,202]

Patients with orofacial granulomatosis who present only with lip involvement have cheilitis granulomatosa. The term Melkersson–Rosenthal syndrome refers to the triad of fissured tongue, facial palsy, and cheilitis granulomatosa, but it is rare to see the triad fully expressed clinically. It is also unclear whether fissured tongue, a fairly common condition, is truly part of the syndrome.

CLINICAL FINDINGS

Most patients are young adults and the presentation is variable. Some present with unilateral, soft (early lesions), or firm-rubbery (more established lesions) painless swelling of the lip, and others present with symmetric swelling of the upper or lower lips or, less frequently, both (eFig. 76-17.1 in online edition). Periorbital or zygomatic swelling are atypical presentations.[203] The swelling is originally relapsing–recurring and then becomes persistent, often with fissuring of the lips. There may also be a history of facial swelling, VII nerve palsy (uncommon), and gingival involvement. The last presents as nodular swellings on the gingiva or a cobblestoning of the buccal mucosa. While some also include linear ulcers in the maxillary and mandibular vestibule/sulcus as part of orofacial granulomatosis, such ulcers are more typical of Crohn disease (see Section "Differential Diagnosis and Laboratory Findings").

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS

Early Crohn disease and sarcoidosis are indistinguishable from lesions of orofacial granulomatosis, both

clinically and histopathologically. Therefore, patients should be questioned regarding gastrointestinal symptoms such as cramping, diarrhea, and blood in stools. Endoscopy is often uninformative in asymptomatic patients since gastrointestinal manifestations may occur years later. Patient should be made aware that this may represent early Crohn disease so that they can self-monitor for gastrointestinal symptoms. In sarcoidosis, angiotensin-converting enzyme levels are often elevated and hilar lymphadenopathy may be present.

Angioedema is never persistent, but rather shows complete resolution between acute episodes; and patients may show increased levels of C1 esterase inhibitor. Cellulitis from infections of the anterior teeth may lead to lip swelling, but these are acute and painful and the offending tooth is always identified.

Biopsy reveals the presence of nonnecrotizing granulomas without foreign material or identifiable infectious agent.

MANAGEMENT AND PROGNOSIS

Topical and intralesional steroid injections are the mainstay of treatment.[204] The dose depends on the severity of swelling and usually patients are treated every week for 2–3 weeks.[205] Systemic therapy in recalcitrant or severe disease includes the use of prednisone (1 mg/kg), thalidomide, minocycline, and more recently, monoclonal antibodies against TNF-α.[206,207]

Less than 50% of patients are in remission on follow-up.[204] In long-standing cases, fibrosis from the inflammation may lead to cosmetic problems that can only be corrected with cheiloplasty.

ANGULAR CHEILITIS

In most cases, this represents a form of candidiasis (see Section "Candidiasis") often with concomitant *S. aureus* infection.[21] The prevalence is approximately 1% in the general adult population and 28% in denture wearers.[211,212] Drooping of the corners of the mouth with drooling and retention of saliva in the creases leading to candidiasis, often associated with wearing of full dentures that do not provide adequate soft tissue support is a major predisposing factor. Patients with hematinic deficiencies or who are immunocompromised are also prone to developing this condition.[213]

CLINICAL FINDINGS

There is painful, usually bilateral maceration of the corners of the mouth with ulceration, crusting, cracking, and, in severe cases, fissuring.[214] Lesions may heal and recur within days or weeks. Some patients develop a diffuse cheilitis due to candidiasis.[215]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

Recrudescent HSV infection in immunocompromised patients may lead to bilateral ulcers and maceration of the corners of the mouth, although usually other intraoral sites are also involved. A culture or direct fluorescent antibody testing will establish the diagnosis.

Patients should have bloodwork to rule out a hematinic deficiency.

MANAGEMENT AND PROGNOSIS

Antifungal creams with topical steroid therapy (see Table 76-4) are particularly useful in the treatment of this condition. The usual anticandidal regimens employing nystatin, clotrimazole, and chlorhexidine are also effective.[216] If lesions only partially resolve, *S. aureus* infection should be suspected and treatment with topical erythromycin usually resolves the residual lesion.[217,218]

If there is a hematinic deficiency, repletion should be undertaken and dentures may need to be relined or remade to better support the soft tissues.

EXFOLIATIVE CHEILITIS

This is a rare inflammatory condition of the lip and some cases are associated with factitial injury and lip licking or picking, sometimes associated with psychological distress; however, many cases are of unknown etiology. It is seen in approximately 25% of patients with HIV infection.[219]

CLINICAL FINDINGS

The lip is covered by fine or thick scales and crusts that can be peeled away, leaving an erythematous, raw area (eFig. 76-17.1 in online edition). Patients will report that within a few hours, a new scale or crust forms.[220,221] The lips may also appear cracked, fissured, and chapped. Some patients admit picking at the lesions while others deny this.[222] Cultures in patients with HIV disease yield *Candida* in 50% of cases.[219]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES

Actinic keratosis is an important consideration and this also causes scaly plaques but these do not tend to peel and recur as quickly. Plasma cell cheilitis should be considered although this presents as an erythematous rather than scaly lesion.[223,224]

A biopsy shows parakeratosis, acanthosis, and chronic inflammation, either somewhat consistent with factitial injury or nonspecific in nature.

MANAGEMENT

Some patients have been at least partially successfully treated with antidepressants, suggesting that factitial

injury associated with psychological distress plays a role.[221,225] Other treatment modalities include mupirocin and tacrolimus.[222]

LIP NODULES

On the lower lip nodules usually result from trauma and include bite or irritation fibromas and mucoceles (both discussed above under Nodular Lesions). The upper lip is traumatized much less frequently and mucosal nodules at this site usually represent one of the following:

1. Benign salivary gland neoplasm (such as pleomorphic adenoma or canalicular adenoma)
2. Malignant salivary gland neoplasm (such as mucoepidermoid carcinoma)
3. Benign nerve sheath tumor (such as solitary circumscribed neuroma)
4. Benign vascular tumor (such as pyogenic granuloma)
5. Nasolabial cyst, a developmental malformation

All require excisional biopsy. Histopathology is diagnostic for each condition.

TONGUE

ATROPHIC GLOSSITIS

Atrophy of the filiform and fungiform papillae of the tongue leads to a bald shiny, erythematous tongue dorsum. Such atrophy is often seen in hematinic deficiencies and in patients with prolonged hyposalivation such as those with Sjögren syndrome or after head and neck radiation therapy.[213]

CLINICAL FINDINGS. The tongue presents with a smooth, bald appearance and papillae are atrophic (Fig. 76-18). Patients often complain of a burning sensation and experience sensitivity when eating acidic, salty, or crunchy foods.[21] They may have associated angular cheilitis if there is a hematinic deficiency. Patients who develop malabsorption after intestinal surgery are prone to developing atrophic glossitis.[226]

Figure 76-18 Atrophic glossitis.

LABORATORY STUDIES AND DIFFERENTIAL DIAGNOSIS. Patient should have blood work to rule out hematinic deficiencies, in particular iron and vitamins B6 and B12 deficiency. For the last, assay of methyl malonic acid may be more sensitive than just a B12 level alone.

MANAGEMENT AND PROGNOSIS. Treatment is with repletion of deficient elements. Topical anesthetics help to control symptoms.

HAIRY TONGUE (BLACK HAIRY TONGUE, COATED TONGUE)

This is an extremely common condition that causes much confusion. There is generally an antecedent history of illness and antibiotic use, leading to a common misdiagnosis of candidiasis. There are usually no other lesions on other oral mucosal sites and no pain, which would be highly unusual for candidiasis. To further add to the confusion, a small number of such patients will grow *Candida* on culture because they are carriers.

Hairy tongue is caused by retention of keratinaceous debris on the tongue dorsum resulting from two factors acting alone or in combination: (1) dehydration (leading to more sticky and mucous rather than serous saliva) and (2) poor oral intake (eating a soft diet or one low in fresh fruits and vegetables).[54] Since most patients have an antecedent history of illness or are hospitalized, they often are dehydrated and have poor appetite. Chromogenic bacteria that reside in the tongue produce metabolic by-products that sometimes stain the tongue, as do food dyes.

CLINICAL FINDINGS. The tongue presents with a matted or coated appearance that is usually symmetric (Fig. 76-19). If located on the posterior midtongue, patients may experience gagging if the "hairs" are long. The thickened matte of keratin on the tongue leads to increased bacterial colonization and their metabolic products (often sulfides) may lead to a foul or stale breath. Such metabolic products may stain the tongue a variety of colors such as brown or black.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. Candidiasis involving the dorsum of the tongue is an important differential diagnosis, but has more patchy distribution of the curdy plaques, associated erythema, a less symmetric distribution, and involvement of other parts of the oral cavity by similar candidal papules and plaques. Ingestion of bismuth subsalicylate may transiently lead to a black tongue.[182]

There is no test that is useful. Rare cases have been biopsied and show only elongated filiform papillae. Cultures for *Candida* are positive in 20%–30% of patients and likely indicate carrier status.

MANAGEMENT AND PROGNOSIS. Vigorous hydration and return to a normal diet with fresh fruits and vegetables generally resolve the lesions.

Figure 76-19 **A.** Hairy tongue. **B.** Brown hairy tongue.

The tongue may be brushed as part of the daily oral hygiene regimen to help to dislodge loose keratin squames and reduce discoloration. Hairy tongue is not harmful to the patient.

FISSURED TONGUE

This is a common condition that occurs in 1%–2% of the population and is generally believed to be developmental in etiology.[211]

CLINICAL FINDINGS. It is fairly uncommon in the first and second decade of life and usually seen in adults. Some believe that *Candida* reside within the fissures and cause symptoms.

There are two main patterns. The first consists of a central fissure, either alone or with smaller fissures radiating from it at right angles (Fig. 76-20A). The second pattern is one of short fissures distributed evenly throughout the tongue without the central fissure (Fig. 76-20B). Some patients report some sensitivity of the tongue with spicy or acidic foods, although in general, this condition is asymptomatic.[21] Approximately one-third of patients with migratory glossitis (see below) have concomitant fissured tongue.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. The clinical presentation is striking and a biopsy is not useful. The presence of sensitivity should prompt a careful examination for the presence of migratory glossitis, atrophic glossitis, or even candidiasis within the fissures.

MANAGEMENT AND PROGNOSIS. Most lesions are noted on routine examination, are asymptomatic and do not require therapy. Some patients who are symptomatic show resolution of symptoms with a short course of antifungal therapy, but predisposing factors for candidiasis must be addressed or the lesions will recur.

In general, fissured tongue is a permanent condition. However, some patients report that fissures are evanescent.

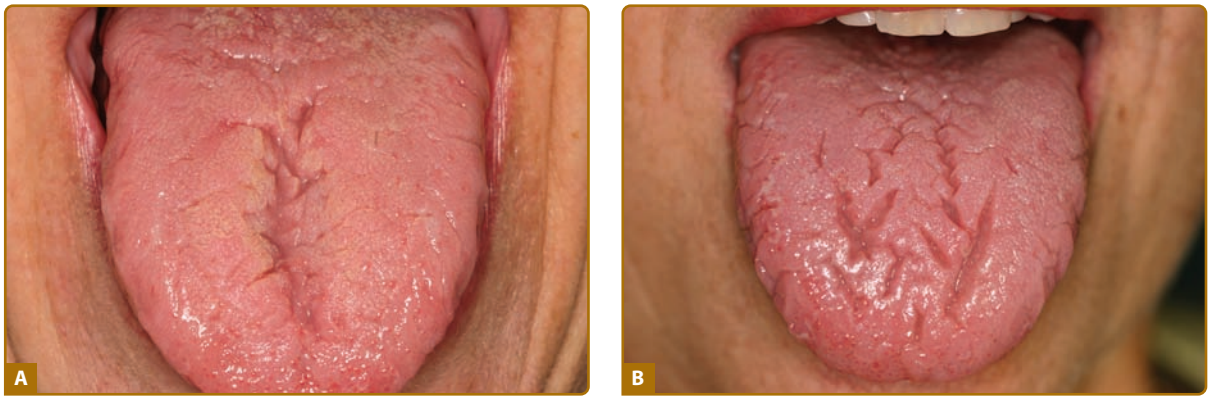

Figure 76-20 **A.** Fissured tongue. **B.** Fissured tongue with migratory glossitis on right.

Figure 76-21 Typical migratory glossitis.

BENIGN MIGRATORY GLOSSITIS/ STOMATITIS (GEOGRAPHIC TONGUE)

CLINICAL FINDINGS. This occurs in 1%–2% of the population and is associated with a fissured tongue in about 30% of cases.[211,227] There is an area of atrophy of the tongue dorsum leading to loss of filiform papillae and a slightly depressed erythematous area that is usually sensitive or painful, especially when acidic foods come in contact with it (Figs. 76-21 and 76-22A and B). Such demarcated areas rimmed by a raised white border that is circinate or serpiginous are diagnostic.[228] Waning lesions are often merely well-demarcated erythematous patches. A history of atopy is often elicited from such patients or from immediate family members.[227] Approximately 13% of patients with psoriasis develop this tongue condition.[229] Flare-ups are associated with both physical and psychological stress.

Infrequently, other mucosal sites such as the palatal mucosa, floor of mouth or buccal mucosa may be involved. In such cases, the term "migratory stomatitis" should be applied.[230]

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. Erythematous candidiasis may cause depapillation of the tongue dorsum and cause some soreness and sensitivity.[231] Identification of candidal hyphae via cytology distinguishes the two. LP and MMO on the lateral tongue are white lesions that are sometimes mistaken for this condition, but biopsy showing a psoriasiform pattern with many spongiotic pustules in the absence of candidal hyphae is diagnostic.

MANAGEMENT AND PROGNOSIS. Patients should be reassured that this is not infectious in etiology, a common concern. Diphenhydramine used as a swish and spit preparation or 2% viscous lidocaine may reduce symptoms. If severe, topical steroids (especially dexamethasone) are helpful. However, patients need to realize that this is an evanescent lesion that tends to recur.

Macroglossia, hyperplastic lingual tonsil, papillitis of the tongue, and tongue nodules are discussed online.

CLINICAL MACROGLOSSIA

Macroglossia refers to the diffuse enlargement of the tongue that may be symmetric or asymmetric. Patients report that the tongue seem enlarged and is more readily traumatized by biting since it may now overly the mandibular teeth. Mild symmetric enlargement is usually caused by loss of muscle tone such as in aging or with some systemic conditions such as amyloidosis.

Loss of muscle tone ("flabby tongue") is particularly obvious in older patients who have lost all their teeth so that there is concomitant loss of bone height in the mandible. The tongue appears to "spread" over the edentulous mandibular ridge and this also makes it difficult for the lower denture to stay in place. Patients with trisomy 21 often have such flabby tongues.

Asymmetric enlargement is usually caused by the presence of a tumor, in particular a vascular malformation of either lymphatic (lymphangioma) or blood vascular origin (venous malformation) that tends to insinuate between the muscle fibers rather than produce an encapsulated mass.

DIFFERENTIAL DIAGNOSIS AND LABORATORY STUDIES. In cases of amyloid deposits or a

Figure 76-22 **A.** Migratory glossitis presenting with mostly erythema and atrophy. **B.** Subtle migratory glossitis.

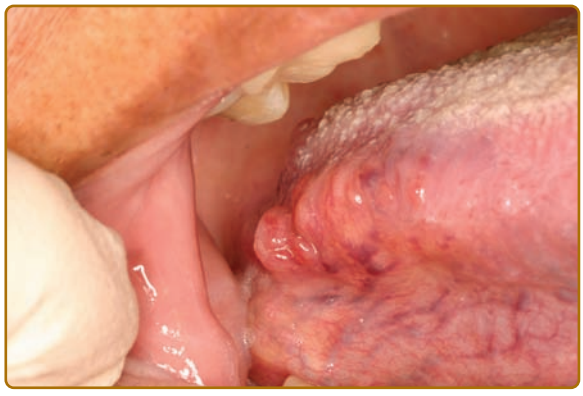

Figure 76-23 Hyperplastic lingual tonsil.

Figure 76-24 Fungiform papillitis.

neoplasm, a biopsy is diagnostic. An MRI study is usually helpful for soft tissue tumors in the tongue that present with asymptomatic enlargement.

MANAGEMENT AND PROGNOSIS. The diagnosis relies on a careful clinical history and examination, with biopsy as necessary. For symmetric lesions, there is no treatment unless the patient resorts to a surgical recontouring of the tongue.

For patients with amyloidosis, a work-up for plasma cell dyscrasia is indicated. For patients with other tumors, excision with/out the use of embolization in the case of vascular tumors is the treatment of choice.

HYPERPLASTIC LINGUAL TONSIL

The lingual tonsil is located on the posterolateral aspects of the tongue bilaterally and is part of Waldeyer ring. In its healthy form, it lies below the foliate papillae (Fig. 76-23). Inflammation of this tissue from trauma or upper respiratory tract infection leads to hyperplasia. Although the term "foliate papillitis" is often used for this condition, the more accurate term is "hyperplastic lingual tonsil."

CLINICAL FINDINGS. The hyperplastic lingual tonsil, when inflamed, protrudes as a fleshy, soft area with a slightly irregular surface (because of the crypts in the overlying foliate papillae), which then becomes more readily traumatized that then makes it even more inflamed and protuberant.[21]

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS. This posterolateral tongue is a common site for SCC and the fairly rapid appearance of this lesion may mimic cancer. Lymphomas may also develop in this area.

Biopsy shows benign hyperplasia of lymphoid tissue.

MANAGEMENT AND PROGNOSIS. Excision is curative. Intralesional steroid injections may reduce the size of the lesion so that it is no longer traumatized.

There are several forms of papillitis and they represent irritation of the tongue papillae either from local trauma, dryness, or a hypersensitivity reaction (possibly to a contactant).

CLINICAL FINDINGS. One form is transient lingual papillitis that presents as multiple enlarged white papillae scattered over the surface of the tongue that tends to be relapsing–recurring.[232–234] Another form presents as reddened and enlarged fungiform papillae on the dorsum of the tongue (Fig. 76-24). A rare form is eruptive papillitis with intrafamilial transmission.[235]

MANAGEMENT AND PROGNOSIS. Dexamethasone mouth rinse reduces inflammation. However, the inciting factor must be addressed to prevent recurrence.

TONGUE NODULES

As with the lip, nodules on the lateral tongue tend to have a traumatic etiology and include fibromas (and its variant giant cell fibroma) and traumatic neuroma. More common tumors of the tongue include benign nerve sheath tumors, granular cell tumors, oral lymphoepithelial cyst, vascular lesions such as pyogenic granulomas or venous malformations, and osseous and cartilaginous hamartomas.

All require excisional biopsy and have diagnostic histopathology.

Chapter 77 :: Diseases and Disorders of the Male Genitalia

:: Christopher B. Bunker

DISEASES AND DISORDERS OF THE MALE GENITALIA AT A GLANCE

- Men with genital skin problems can present to physicians who are not trained or experienced in the diagnosis and management of these problems.
- Skin problems of the male genitalia may be any of the following:
  - Normal variants.
  - Manifestations of sexually transmitted diseases.
  - Dermatoses that may be generalized or found at extragenital sites but that have a predilection for the genitalia.
  - Dermatoses that are specific to the genitalia.
- Much dermatologic disease of the male organ can be linked to the causes or consequences of preputial dysfunction.
- The guiding philosophy behind diagnosis and management is to exclude sexually transmitted disease and to minimize or abolish sexual and urinary dysfunction and the risk of cancer of the penis.
- Circumcision is controversial, but it is indispensable in the management of some diseases of the penis and foreskin.

EPIDEMIOLOGY

The incidence and prevalence of male genital dermatoses are not known with accuracy, but most, like sexually transmitted diseases, are more common and more severe in the uncircumcised; these include psoriasis, seborrheic dermatitis, and lichen planus (LP).[1] The global prevalence of circumcision is estimated at 25%–33% and in the United States, 85%.[1–5] Religious and cultural practices and medical intervention account for these rates. Circumcision has been adopted as a measure to reduce human immunodeficiency virus (HIV) transmission.[6–17] Neonatal circumcision is a topic that evokes controversy, but some benefits are accepted (Table 77-1).[1,2,3,10,18–41] Although there is little evidence of significant adverse effects on health and psychosexual function, circumcision can have side effects and complications, especially when performed "ritually."[3,5,17–19,42–47] Although views of circumcision range from prophylaxis to child abuse, the rational stance is that nontherapeutic circumcision of male infants should be left to parental discretion.[3,48–50]

ETIOLOGY AND PATHOGENESIS

Etiologic and pathogenetic factors have to be understood in relationship to structure, function, and micro-

TABLE 77-1
Benefits of Circumcision

Reduced or abolished risk of penile cancer
Decreased risk of cervical cancer in partners
Protection from sexually transmitted infections, including human immunodeficiency virus infection (controversial)
Reduced risk of urinary tract infections (controversial)
Reduced risk of inflammatory genital skin diseases

ecology.[3] Obviously the genital area differs between the sexes, but it also provides a good example of regional human variation.

Although the whole organ of the skin is concerned with sexual expression and activity, the penis is the male structure most intimately involved in sexual intercourse. It is also the conduit for urinary excretion. The scrotum is the extracorporeal sack that maintains the testes at the ideal temperature for spermatogenesis. The essential structures of the penis and its important landmarks are illustrated in Figure 77-1.[3] As at other sites, topographical and regional anatomic nomenclature is an essential part of the vernacular for a dermatologist. The anatomic position is that of full penile erection.

The perineal area is abundant in eccrine and apocrine (some functionless) sweat glands and holocrine sebaceous glands, usually in association with hair follicles as pilosebaceous units but also occurring as free glands at some sites such as the anal rim or around the coronal sulcus (Tyson glands). Adnexal secretions lubricate the hinge between limb and torso, lubricate hair, lubricate the mucocutaneous junctions to assist in the voiding of excreta, and protect the epithelia from irritation and lubricate the penis for the retraction of the foreskin during sexual activity. The pattern of keratinization differs throughout the male genital tract area, most markedly so at the mucosal junctions, the prepuce and distal penile shaft, especially the

Anatomy and landmarks of the penis

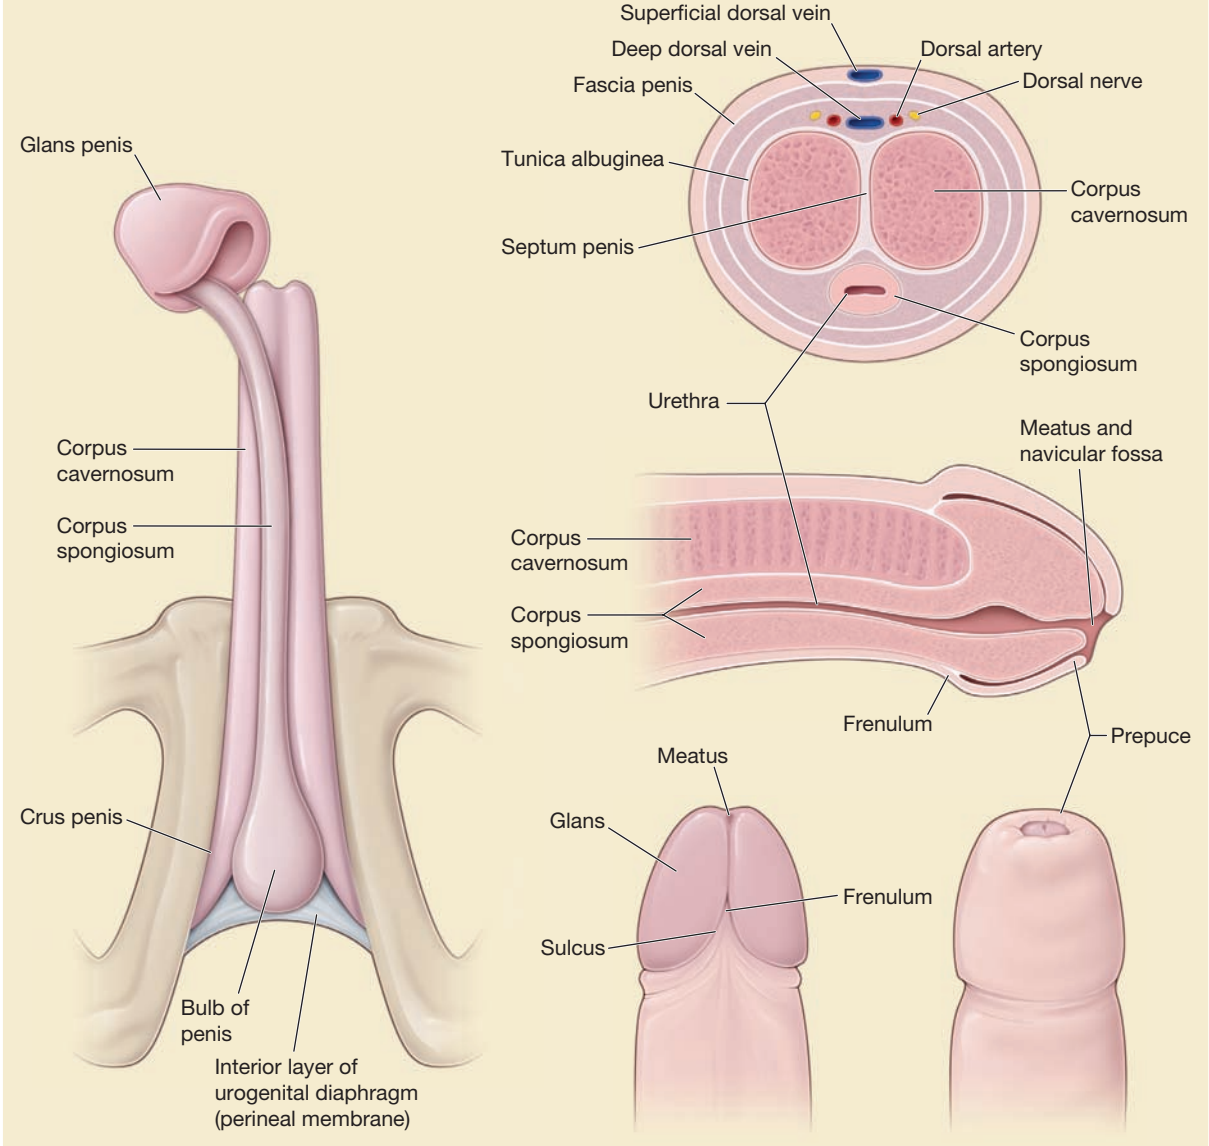

Figure 77-1 Anatomy and landmarks of the penis. (Adapted from Bunker CB: *Male Genital Dermatology.* London, Saunders, 2004.)

glans in the circumcised individual. The detritus of mucosal turnover combines with adnexal secretions to produce smegma that can accumulate in the preputial sac of the uncircumcised individual, especially if hygiene is poor. There is wide normal variation in the anatomy of the penis (particularly the urethral meatus) and its relationship to the prepuce, which perhaps reflects susceptibility to minor embryologic anomalies; the embryogenesis of the anogenital structures is complex.[3] The foreskin is a delicate, busy tissue that is in close contact with urine and exposed to sexual secretions, detergents, and infectious agents, especially opportunistic organisms and those that are sexually transmitted. Of the latter, human papillomavirus (HPV) is the most important known from the point of view of precancerous dermatoses and invasive squamous carcinoma. All these congenital and acquired factors can conspire to produce a dysfunctional foreskin,[51] often clinically expressed as male sexual dysfunction in the form of male dyspareunia. The genitals may be a site of predilection or exclusive manifestation of disorders often encountered extragenitally (e.g., vitiligo, psoriasis, and LP), in part due to the Koebner phenomenon.[3]

CLINICAL FINDINGS

The algorithm shown in Box 77-1 emphasizes the need to obtain a complete history, perform an adequate examination, and construct a differential diagnosis. Initiating investigations to exclude sexually transmitted disease or performing a biopsy may be indicated. Occasionally, a trial of treatment may help crystallize a diagnosis.

The responsibility for the elucidation of anogenital symptoms may need to be shared with the genitourinary physician, pediatrician, urologist, or colorectal surgeon.

HISTORY

Although classic dermatologic symptoms (itch, rash, lumps or bumps, or ulceration) may be present, the physician must be alert to symptoms of sexually transmitted disease (e.g., discharge, dysuria), urologic disease (e.g., pain, hematuria, dysuria), and male sexual dysfunction. Symptomatic male sexual dysfunction equates with male dyspareunia, that is, painful or

BOX 77-1 CLINICAL APPROACH TO MALE GENITAL DERMATOLOGY

HISTORY

- Age

difficult sexual intercourse. Many men will not volunteer such information, so specific inquiry should be tactfully made. The components of normal male sexual function are libido, erection, ejaculation, and orgasm.

CUTANEOUS LESIONS

A systematic approach to the penis and prepuce is summarized in the algorithm (see Box 77-1). The foreskin (if present) should be gently retracted, the gluteal and crural folds and the meatal lips parted, and the rectum examined digitally. Site, distribution, and morphology of lesions should be conventionally noted and analyzed. Specific male genital signs include phimosis (nonretractable foreskin; Fig. 77-2), paraphimosis (foreskin fixed in retraction; Fig. 77-3), balanitis (inflammation of the glans penis), posthitis (inflammation of the prepuce), and dorsal perforation of the prepuce (glans and shaft of penis ulcerated through the prepuce, which lies ventrally as an empty sleeve). Phimosis should be regarded as a sinister situation and impedes complete inspection and palpation of the glans and coronal sulcus. The causes of phimosis are listed in Table 77-2. Paraphimosis is rarer and is usually an acute emergency presentation caused by vigorous sexual activity, acute contact urticaria, acute allergic contact dermatitis, and lichen sclerosus (LSc). Chronic paraphimosis is increasingly recognized in India and is due to chronic inflammation and fibrosis of the foreskin in the retracted state. *Balanitis* and *posthitis xerotica (obliterans)* can be confusing terms, used to signify the end stage of all chronic cases of balanitis and posthitis (e.g., scarring dermatoses such as LP and cicatricial pemphigoid), but these conditions are usually due to LSc and are therefore considered synonymous by some. Dorsal perforation of the penis is very rare and is caused by gross penile disease such as hidradenitis suppurativa, pyoderma gangrenosum, florid condylomata, chancroid, herpes simplex, idiopathic balanoposthitis, and podophyllin misuse.[3,53,54]

RELATED PHYSICAL FINDINGS

The algorithm (see Box 77-1) underlines the necessity to examine patients conventionally, systematically, and completely, because important signs will be found at nongenital sites.

LABORATORY TESTS

The most commonly required special investigational procedures are taking a swab or smear for microbiologic

TABLE 77-2

Cicatricial pemphigoid
Chronic penile lymphoedema
Kaposi sarcoma

or virologic analysis, obtaining scrapings for fungal microscopic examination and culture, taking scrapings for mite identification, and performing a skin biopsy. Wood's light examination is helpful in the clinical diagnosis of vitiligo, erythrasma, and fungal infections. The investigations pertinent to the diagnosis of sexually transmitted disease are discussed in Section 32 (see Chapters 200, 202, 203, 204 and 205).

A genital skin biopsy is informative under selected clinical conditions. It is important to obtain the right specimen from the right site at the right time (the most floridly inflamed areas may not be the best from which to obtain a specimen and histologically often show nonspecific or zoonoid features) and to provide the pathologist with a differential diagnosis. Examination of biopsy specimens should not be regarded as a substitute for clinical diagnosis. It is safe and helpful to use small amounts of adrenaline—the region is highly vascular. Knowledge of anatomy is crucial: ventrally, the urethra can lie very close to the surface in the coronal sulcus. It is not often necessary to suture a preputial punch biopsy site.[3,55]

SPECIAL TESTS

Diagnostic imaging of the penis, scrotum, and perineum by ultrasonography or magnetic resonance can be helpful under some circumstances.[56–58] Patch testing is sometimes indicated.[3]

DIFFERENTIAL DIAGNOSIS

The principal presenting scenarios are tabulated in Box 77-2.

NORMAL VARIANTS

PEARLY PENILE PAPULES (ANGIOFIBROMAS)

Pearly or pink penile papules,[3] which may be found in between 15% and 48% of men, are flesh-colored, smooth, rounded papules (1–3 mm) occurring predominantly around the coronal margin of the glans, rarely on the glans. Often there are rows or rings of the papules. They are commoner in the uncircumcised male and regress with age.[59] Ectopic lesions, for example, on the penile shaft, have been reported. They are frequently mistaken for warts or Tyson "ectopic" sebaceous glands (of Tyson) and sometimes cause anxiety in adolescents. The histologic findings are those of angiofibroma, and the lesion is analogous to other acral angiofibromas such as adenoma sebaceum, subungual and periungual fibromas, fibrous papule of the nose, acquired acral angiofibroma, and oral fibroma. Reassurance should suffice, but cryotherapy and laser treatment have been used.[3]

SEBACEOUS GLAND PROMINENCE

Sebaceous gland prominence, Tyson glands, sebaceous hyperplasia, and "ectopic" sebaceous glands (Fordyce condition) are all essentially equivalent, common, normal variants of the skin of the scrotal sac and penile shaft, analogous to the situation on the vermillion of the lips. Nevoid linear lesions on the penile shaft and lesions on the glans have been reported. Reassurance is usually adequate, but patients can be inordinately distressed.[3]

MELANOCYTIC NEVI

It is possible that nevi on the penis occur more frequently in patients with the atypical nevus syndrome.[3] A divided or "kissing" nevus is a lesion with one-half located on the glans and the other half located on the distal penile shaft separated by uninvolved skin across the coronal divide; an analogous nevus affects the eyelids.[60] Epithelioid blue nevus of the genitals is very rare.[61]

PROMINENT VEINS

Prominent veins are common and very occasionally give rise to concern but very rarely cause complications.[3]

ANGIOKERATOMA

Angiokeratomas are more common in white men and are common on the genitalia (where, confusingly, together with prominent sebaceous glands they have attracted the eponymous epithet of *Fordyce spots*). Angiokeratomas are blue to purple, smooth, 2–5-mm papules on the scrotum, penile shaft, or glans. They generally appear and multiply during life but occasionally present as singletons. They may bleed after trauma and may be mistaken for a nevus, melanoma, or Kaposi sarcoma. The angiokeratomas of Fabry disease (see Chapter 136) are smaller than common angiokeratomas, presenting as less hyperkeratotic pinhead lesions, and are found more extensively around the lower limb girdle and upper thighs from the navel to the knees. Angiokeratoma circumscriptum very, very rarely may affect the penis (see Chapter 172).

Electrocautery or laser ablation can be offered, but the lesions may recur.

CONGENITAL ABNORMALITIES

The complicated embryogenesis of the anogenital region involving sexual differentiation and pubertal determination of secondary sexual characteristics means that congenital and developmental anomalies are common. Consequent anatomic and functional

BOX 77-2 DIFFERENTIAL DIAGNOSIS OF MALE GENITAL DERMATOSES

MALE GENITAL PRURITUS

Most Likely
- Eczema/dermatitis
- Psoriasis
- Lichen sclerosus
- Lichen planus
- Herpes simplex
- Candidosis
- Scabies
- Pediculosis
- Dysesthesia syndromes

Consider
- Insect bite/papular urticaria
- Hirsutism
- Hyperhidrosis
- Fox–Fordyce disease
- Urticaria and dermatographism
- Dermatitis herpetiformis
- Trichosporosis
- Larva currens/cutaneous larva migrans
- Onchocerciasis
- Drugs and foods

Always Rule Out
- Sexually transmitted diseases
- Bowen disease
- Erythroplasia of Queyrat
- Extramammary Paget disease
- Langerhans cell histiocytosis

MALE GENITAL HYPOPIGMENTATION/LEUKODERMA/PLAQUES

Most Likely
- Scar
- Vitiligo
- Postinflammatory
- Lichen sclerosus
- Viral warts

Consider
- Bier's spots
- Striae
- Cicatricial pemphigoid
- Pityriasis versicolor

Always Rule Out
- Squamous hyperplasia
- Extramammary Paget disease
- Mycosis fungoides

MALE GENITAL HYPERPIGMENTATION

Most Likely
- Hyperpigmentation of median raphe
- Postinflammatory hyperpigmentation
- Lentigines
- Melanosis

Consider
- Tattoos
- Purpura
- Addison and Nelson syndromes
- Laugier–Hunziger syndrome
- Peutz–Jeghers syndrome
- LAMB (*l*entigines, *a*trial *my*xoma, *b*lue nevi) syndrome
- LEOPARD (multiple *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, growth *r*etardation, *d*eafness) syndrome
- Ruvalcaba–Myhre–Smith syndrome
- Pseudoacanthosis nigricans
- Drugs and metals

Always Rule Out
- Acanthosis nigricans
- Acral lentiginous melanoma

MALE GENITAL POSTINFLAMMATORY HYPOPIGMENTATION

Most Likely
- Postcryotherapy
  - Electrotherapy
  - Chemocautery
- Lichen sclerosus
- Lichen planus

Consider
- Contact dermatitis
  - Condom leukoderma
- Systemic sclerosis
- Cicatricial pemphigoid
- Gonococcal dermatitis
- Herpes simplex
- Pityriasis versicolor
- Onchocercal "leopard skin"
- Peyronie disease

Always Rule Out
- Leprosy
- Syphilis
  - Leukoderma—postsecondary syphilide gumma
- Pseudoepitheliomatous and micaceous keratotic balanitis

MALE GENITAL POSTINFLAMMATORY HYPERPIGMENTATION

Most Likely
- Posttraumatic
- Lichen planus
- Herpes simplex

Consider
- Fixed drug eruption

Always Rule Out
- Bowenoid papulosis

MALE GENITAL PURPURA

Most Likely
- Physical (e.g., from suction)
- Zoon balanitis
- Lichen sclerosus

Consider
- Henoch–Schönlein purpura

Always Rule Out
- Amyloidosis

(*continued*)

BOX 77-2 DIFFERENTIAL DIAGNOSIS OF MALE GENITAL DERMATOSES (*Continued*)

MALE GENITAL RED SCALY PATCHES

Most Likely
- Eczema/dermatitis
- Psoriasis
- Lichen sclerosus
- Lichen planus
- Erythrasma
- Candidosis
- Scabies
- Bowen disease

Consider
- Inflammatory linear verrucous nevus
- Reiter syndrome
- Pityriasis rosea
- Acrodermatitis enteropathica
- Hailey–Hailey disease
- Darier disease
- Kawasaki syndrome
- Primary and secondary syphilis
- Pityriasis versicolor
- Tinea
- Porokeratosis
- Fixed drug eruption

Always Rule Out
- Psudoepitheliomatous and micaceous keratotic balanitis
- Mycosis fungoides
- Extramammary Paget disease
- Langerhans cell histiocytosis

MALE GENITAL RED PLAQUES

Most Likely
- Psoriasis
- Lichen planus
- Bowen disease and bowenoid papulosis
- Fixed drug eruption

Consider
- Giant lichen simplex (of Pautrier)
- Inflammatory linear verrucous nevus
- Leishmaniasis

Always Rule Out
- Extramammary Paget disease
- Kaposi sarcoma
- Carcinoma erysipeloids
- Langerhans cell histiocytosis

BALANOPOSTHITIS AND INTERTRIGO

Most Likely
- Eczema/dermatitis
  - Contact, seborrheic
- Psoriasis
- Zoon balanitis
- Nonspecific balanoposthitis
- Lichen sclerosus
- Candidosis

Consider
- Reiter syndrome
- Acrodermatitis enteropathica
- Hailey–Hailey disease
- Darier disease
- Crohn disease
- Streptococcal dermatitis
- Staphylococcal cellulitis
- Nonsyphilitic spirochetal ulcerative balanoposthitis
- Tinea
- Amebiasis
- Myiasis
- Scabies
- Eccrine syringofibroadenomatosis
- Chronic lymphatic leukemia
- Fixed drug eruption

Always Rule Out
- Sexually transmitted disease
  - Gonorrhea
  - Syphilis
  - Chancre with balanitis
  - Human papillomavirus infection
  - Herpes simplex
  - Mycoplasma infection
  - Trichomonas vaginalis infection
  - Lymphogranuloma venereum
- Leprosy
- Erythroplasia of Queyrat
- Squamous carcinoma
- Carcinoma erysipeloides
- Extramammary Paget disease
- Kaposi sarcoma

MALE GENITAL EROSIONS

Most Likely
- Trauma
  - Excoriated pruritic dermatoses (e.g., scabies)
- Inverse pattern psoriasis
- Zoon balanitis
- Lichen sclerosus
- Lichen planus
- Herpes simplex
- Candidosis
- Erythroplasia of Queyrat

Consider
- Autoimmune bullous diseases
  - Pemphigus
  - Bullous pemphigoid
  - Cicatrizing pemphigoid
  - Linear immunoglobulin A disease
  - Dermatitis herpetiformis
- Streptococcal dermatitis
- Gonorrhea
- Secondary syphilis
- Herpes zoster
- Acute primary human immunodeficiency virus (HIV) infection
- Cytomegalovirus in HIV infection
- Tinea
- Paracoccidioidomycosis
- Pediculosis
- Porokeratosis
- Topical steroids
- Fixed drug eruption

Always Rule Out
- Kaposi sarcoma
- Langerhans cell histiocytosis

BOX 77-2 DIFFERENTIAL DIAGNOSIS OF MALE GENITAL DERMATOSES (*Continued*)

MALE GENITAL VESICLES AND BLISTERS

Most Likely

- Erythema multiforme/Stevens–Johnson syndrome
- Lichen sclerosus
- Bullous impetigo
- Herpes simplex
- Fixed drug eruption

Consider

- Acute contact dermatitis (e.g., phytophotodermatitis)
- Lichen planus
- Autoimmune bullous diseases
  - Bullous pemphigoid
  - Cicatrizing pemphigoid
  - Linear IgA disease
  - Dermatitis herpetiformis
- Herpes zoster

PENILE NECROSIS

Most Likely

- Decubitus ulcer
- Spider bite
- Strangulation/tourniquet syndromes
- Vacuum erection device use
- Priapism
- Embolism
- Pyoderma gangrenosum
- Coagulopathy
- Warfarin

Consider

- Chronic renal failure
- Diabetes mellitus
- Thrombocytopenia
- Polycythemia
- Cryoglobulinemia
- Vasculitis
- Calciphylaxis
- Ecthyma gangrenosum
- Herpes simplex

Always Rule Out

- Fournier gangrene
- Leukemia

MALE GENITAL ULCERS

Most Likely

- Trauma
- Aphthae
- Erythema multiforme
- Ulcerative sexually transmitted disease
  - Chancre of primary syphilis
  - Chancroid
  - Donovanosis
  - Lymphogranuloma venereum
  - Syphilis
- Squamous carcinoma

Consider

- Dermatitis artefacta
- Spontaneous scrotal ulceration
- Hidradenitis suppurativa
- Crohn disease
- Sarcoid
- Behçet disease
- Autoimmune bullous diseases
  - Bullous pemphigoid
  - Cicatrizing pemphigoid
  - Linear immunoglobulin A disease
- Necrobiosis lipoidica
- Hypereosinophilic syndrome
- Gonorrhea
- Tuberculosis and tuberculids
- Leprosy
- Yaws
- Nonsyphilitic spirochetal ulcerative balanoposthitis
- Herpes simplex (e.g., in HIV)
- HIV giant aphthae
- Deep fungal infections
  - Histoplasmosis
  - Blastomycosis
  - Paracoccidioidomycosis
  - Cryptococcosis
- Actinomycosis
- Leishmaniasis
- Amebiasis
- Filariasis
- Porokeratosis
- Basal cell carcinoma
- Drug reaction

Always Rule Out

- Embolization
- Penile necrosis
- Pyoderma gangrenosum
- Necrotizing vasculitis
  - Granulomatosis with polyangiitis (Wegener)
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
  - Idiopathic systemic vasculitis
- Hereditary spherocytosis and vascular necrosis
- Degos malignant atrophic papulosis
- Calciphylaxis
- *Pseudomonas* infection
  - Ecthyma gangrenosum
  - Necrotizing anorectal ulcer in leukemia
- Fournier gangrene
- Sweat gland carcinoma
- Kaposi sarcoma
- Langerhans cell histiocytosis
- Extramammary Paget disease
- Leukemia
- Lymphoma

MALE GENITAL FLESH-COLORED PAPULES AND MICROPAPULES

Most Likely

- Scrotal calcinosis
- Lichen nitidus
- Viral warts
- Secondary syphilis
- Mollusca
- Acrochordons (skin tags)
- Angiofibroma (pearly penile papules)

Consider

- Median raphe cyst
- Mucoid cyst
- Tick bite/tick in situ
- Sclerosing lymphangitis
- Lichen nitidus and lichen planus
- Mucinous syringometaplasia
- Demodicidosis

Always Rule Out

- Amyloidosis
- Squamous hyperplasia
- Amelanotic malignant melanoma
- Malignant schwannoma

(*continued*)

BOX 77-2 DIFFERENTIAL DIAGNOSIS OF MALE GENITAL DERMATOSES (*Continued*)

MALE GENITAL FLESH-COLORED PAPULES AND MICROPAPULES

Most Likely	*Consider*	*Always Rule Out*

- Connective tissue nevus
- Fibrous hamartoma of infancy
- Leiomyoma
- Neurofibroma
- Hemangioma
- Masson tumor (intravascular papillary endothelial hyperplasia)
- Epithelioid hemangioma
- Angiolymphoid hyperplasia with eosinophilia/Kimura disease
- Lymphangioma circumscriptum
- Solitary reticulohistiocytic granuloma
- Penile horn
- Keratoacanthoma
- Basal cell carcinoma

Always Rule Out
- Buschke–Lowenstein tumor/giant condyloma
- Extramucosal anorectal carcinoma
- Malignant melanoma
- Merkel cell carcinoma
- Malignant eccrine poroma
- Sarcoma
- Malignant schwannoma
- Kaposi sarcoma
- Chronic lymphocytic leukemia
- Langerhans cell histiocytosis
- Metastases

PENOSCROTAL SWELLING

Most Likely
- Paraphimosis
- Foreign body
- Strangulation of the penis
- Iatrogenic
  - Continuous ambulatory peritoneal dialysis
  - Raised right heart filling pressure in intensive therapy unit
  - Postsurgery
  - Postradiotherapy
- Varicocele
- Hydrocele
- Priapism
- Peyronie disease
- Epididymitis and orchitis
- Cellulitis
- Idiopathic penile edema
- Testicular tumors

Consider
- Idiopathic congenital lymphedema
- Giant hemangioma
- Urethral diverticulum
- Segmental urethral hypospadias
- Accessory scrotum
- Herniation of scrotal contents into penile shaft
- Foreign body
- Lipogranuloma/silicone granuloma
- Scrotal fat necrosis
- Henoch–Schönlein purpura
- Familial Mediterranean fever
- Acute hemorrhagic edema of childhood
- Granulomatous lymphangitis
- Sarcoid
- Infected cyst
- Tuberculosis
- Paracoccidioidomycosis
- Giant scrotal tumor (e.g., neurilemoma)
- Epithelioid hemangioma
- Epithelioid hemangioendothelioma
- Drugs (e.g., angioedema due to lisinopril)

Always Rule Out
- Aortic aneurysm
- Abscess of corpus cavernosum
- Kaposi sarcoma
- Lymphoma
- Sarcoma
- Fournier gangrene

abnormality may increase the vulnerability of the area to dermatoses (such as LSc) and infections.

Common abnormalities include meatal pit, hypospadias, median raphe cysts, canals and sinuses, and ambiguous genitalia. Rarer anomalies include hypospadias variants, meatal stricture, mucoid or urethral cysts, dermoid cysts, buried penis, urethral atresia, penoscrotal transposition, congenital lymphedema, giant preputial sac, megaprepuce, accessory scrotum, hemangiomas, strawberry nevus, os penis, and true aposthia. These entities may be features of congenital syndromes.[3]

SEXUALLY TRANSMITTED DISEASES

VENEREAL DISEASES

The clinical manifestations on the male genitals of syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale, gonorrhea, and other venereal diseases as well as their pathogenesis, diagnosis, treatment, and complications are discussed in depth in Chapters 200, 202–205). Here it may suffice to remind the physician that any inflammatory, papulonodular, or ulcerative genital presentation requires consideration and exclusion of sexually transmitted diseases.

PEDICULOSIS

(See Chapter 208)

Pediculosis pubis, or lice infestation ("crabs"), can cause severe genital itching with few physical signs unless the hairs are examined assiduously for nits and the base of individual hairs is scrutinized with a hand lens for the crab lice (1–2 mm), which will be tightly adherent to the skin because their mouth parts are embedded in perifollicular blood vessels. Sometimes gray–blue macules (tache bleu, maculae caeruleae) are seen on the affected sites.

SCABIES

(See Chapter 208)

Scabies is a cause of intense itching that characteristically keeps patients awake at night. Usually there is a rash of diagnostic distribution and morphology. Some patients with scabies—who may have been infested for a long time, have had it before, have been inadequately treated, or have been adequately treated but develop secondary eczema or nodules—may have itch in the anogenital region only.

VIRAL WARTS

(See Chapter 196)

CLINICAL FINDINGS. Genital HPV infection can usually be diagnosed with certainty on clinical grounds (Figs. 77-4 and 77-5). Morphology is described in Chapter 196. Clinically inapparent penile warts may present as balanoposthitis.[62–64]

Figure 77-4 Viral warts. Condyloma acuminata. (© Medical Illustration UK.)

DIFFERENTIAL DIAGNOSIS. Disorders from which viral warts must be differentiated are listed in Box 77-3.

COMPLICATIONS. HPV infection is a risk factor for anogenital cancer, particularly of the cervix and anus. HPV is associated with the clinical expressions of penile carcinoma in situ (PCIS), or Bowen disease of the penis, erythroplasia of Queyrat (EQ), or bowenoid papulosis (BP) and approximately 50% of cases of

Figure 77-5 Viral warts. Confluent plaque. No histologic dysplasia. Patient with diabetes. (© Medical Illustration UK.)

BOX 77-3 DIFFERENTIAL DIAGNOSIS OF VIRAL WARTS

Most Likely
- Pearly penile papules

Trichloroacetic acid
5-Fluorouracil
Imiquimod

squamous carcinoma of the penis.[65,66] Infection with HIV may alter and worsen the expression and consequences of anogenital HPV infection: high-grade dysplasia associated with high-risk HPV types have been found in the urothelium and genital warts from HIV-positive individuals and the penis cancer risk is increased three- to sixfold (the anal cancer risk may be increased by as much as 100).[3,67–75]

TREATMENT. Patients presenting with warts, as well as their sexual partners, should be counseled and screened for HPV, other sexually transmitted diseases including HIV infection, and cervical neoplasia.

HPV infection may be very difficult to treat. Subclinical infection is very common, difficult to detect, and virtually untreatable, so there is divergence between ambitions for treatment and achievability. The principles of management are based on diagnosing and treating relevant lesions that are causing personal genital morbidity or psychosexual stress or long-term risk to the patient or his partner. Reasonable goals include (1) inducing cure or wart-free periods, (2) relieving or improving symptoms such as dyspareunia, (3) ensuring that side effects or complications of the treatment are no worse than the symptoms or risks of the warts, (4) minimizing morbidity and mortality from cervical cancer in female partners, (5) minimizing mortality and morbidity from PCIS and frank cancer in the patient especially those with HIV.[62,69,72,73]

Treatments are listed in Box 77-4.[3,62,69,76,77]

MOLLUSCA

(See Chapter 195)

Mollusca may be sexually acquired, as in adult men, but genital lesions caused by autoinoculation are common in children. Classically small, flesh-colored, monomorphic, dome-shaped papules indented by a central dell or umbilicus are seen. Multiple lesions are usually present. Giant and polypoidal lesions may occur in the setting of HIV infection. Inflammation and purulence may be due to infection but are a common phenomenon when individual lesions spontaneously involute. Condylomata lata (secondary syphilis) and LP enter the differential diagnosis of mollusca, as do simple HPV infection and BP. Treatment may not be necessary especially in children. Options are similar to those for viral warts.[3,77]

DERMATOSES WITH A PREDILECTION FOR THE MALE GENITALIA

VITILIGO

(See Chapter 74)

Vitiligo commonly affects the genitalia in men and may be the only site to be affected. Perianal involvement is also common.[3] Other organ-specific autoimmune diseases should be excluded. Vitiligo has been reported after treatment of genital warts with imiquimod.[78,79] An important rare differential diagnosis is depigmented extramammary Paget disease (EMPD).[80] Phototherapy of vitiligo might lead to squamous cell carcinoma (SCC).[81]

SEBORRHEIC DERMATITIS

(See Chapter 22)

A diagnosis of seborrheic dermatitis is made when a nonspecific psoriasiform or eczematous balanitis or balanoposthitis is found in conjunction with classic symptoms and extragenital manifestations of the diathesis.[3]

No treatment other than reassurance may be required. However, treatments that diminish the commensal pityrosporum load and reduce irritation and eczematization can be very successfully and safely used long term. These include topical antifungals (such as clioquinol, nystatin, and imidazoles) in the

Figure 77-6 Psoriasis. Circumcised glans penis. (© Medical Illustration UK.)

form of ointments, creams, lotions, or shampoos and mixtures of the same agents with mild and moderately potent topical corticosteroids used alongside emollients and soap substitutes. In severe cases, such as with concomitant seborrheic folliculitis or in acquired immunodeficiency syndrome (AIDS), treatment with an oral imidazole might be indicated.

PSORIASIS

(See Chapter 18)

Psoriasis is probably the most common dermatosis of the male anogenitalia, either in isolation or in association with frank or mild, subtle extragenital disease.[3] The Koebner phenomenon is a likely factor in site predilection. Drugs such as lithium, β blockers, antimalarials, and angiotensin-converting enzyme inhibitors may be responsible for the onset or exacerbation of psoriasis.

In circumcised men, genital psoriasis presents with variably itchy, silvery-scaled, erythematous patches or plaques (Fig. 77-6). On the glans or in the preputial sac of the uncircumcised patient, scale is absent from the patches or plaques because of the mucosal site (Fig. 77-7). The scalp, ears, umbilicus, and face (in sebopsoriasis) may be involved, and there may be variable additional anogenital involvement, especially of the sacrum, buttocks, intergluteal cleft, pubic mound and groin, perianal skin, and, less commonly, the scrotum. Psoriatic balanoposthitis can be part of the spectrum of inverse-pattern psoriasis and may be associated with intertriginous disease of the axillae, intergluteal cleft, gluteal folds, and groin.

Patients with the reactive arthritis syndrome (see Chapter 20) may sometimes have involvement of the penis with circinate balanitis or small, flat pustules. These penile lesions have the same histopathology and ultrastructure as psoriasis. Sometimes this morphology is seen clinically with no background urethritis, gastroenteritis, or arthritis (Fig. 77-8).

Figure 77-7 Psoriasis. Uncircumcised glans penis and prepuce. (© Medical Illustration UK.)

Usually the diagnosis of psoriasis is clinical. Soreness might indicate superinfection, especially with *Candida*. Inordinate itch would make one suspect another dermatosis such as an eczematized dermatitis or tinea. A biopsy

Figure 77-8 Circinate balanitis. HLA-B27 positive. No background urethritis, gastroenteritis, or arthritis. (© Medical Illustration UK.)

may be necessary if there are solitary mucosal lesions in the uncircumcised to exclude Zoon balanitis (ZB), LP, EQ, and Kaposi sarcoma. Bowen disease and EMPD may be misdiagnosed as psoriasis when there are single or several foci on the penile shaft and/or in the groin.

Topical treatment is based on the use of emollients, soap substitutes, corticosteroids combined with antibiotic and antifungal agents, or weak tar solutions. Atrophy is a risk with long-term use of potent topical steroids, and anogenital skin has a heightened tendency to absorb topical agents. Strong crude tar preparations should also therefore be avoided at this site because of the risk of genital cancer. Dithranol application may lead to burning and so is usually avoided in this region. Vitamin D analogues and calcineurin inhibitors seem safe, but with the latter, the prescriber must be certain of the absence of PCIS. Severe anogenital inverse psoriasis can be an indication for systemic treatment. Phototherapy is conventionally contraindicated because of the risk of anogenital cancer. It is possible that chronic anogenital psoriasis and its treatment may create a risk for anogenital squamous cancer.

LICHEN PLANUS

(See Chapter 26)

LP has a particular predilection for the mucosa, which is perhaps partly explained by the Koebner phenomenon. LP can present in, and remain focalized to, the pelvic girdle, the genital area including the groin, and the perianal skin. Alternatively, symptoms and morphology of the classic disease—lilac papules and plaques with white lacy scale—may be present at other sites (Fig. 77-9). However, it may affect the penis (like the mouth, vulva, and anus) in isolation as the cause or consequence of foreskin dysfunction (by "koebnerization") and so present as dyspareunia and a nonspecific dermatosis.[3]

The differential diagnosis includes eczema, psoriasis, seborrheic dermatitis, nonspecific balanoposthitis, ZB, LSc, drug eruption, porokeratosis, viral warts, penile precancer, and frank SCC. LP can cause phimosis; the differential diagnosis of phimosis is given in Table 77-2.

Figure 77-9 Lichen planus. Annular plaque. Circumcised glans penis. Coronal rim. (From Bunker CB: *Male Genital Dermatology*. London, Saunders, 2004. © Medical Illustration UK.)

Figure 77-10 Lichen planus. Erosions on glans penis and prepuce. Severe dyspareunia. (© Medical Illustration UK.)

Just as extragenital disease, for example, on the palms and soles, may be erosive in rare cases, occasionally an erosive form of genital disease is encountered (Fig. 77-10). A male equivalent of the vulvovaginal syndrome of Hewitt with chronic erosive gingival and genital lesions (genito-gingival syndrome) has been described.[82] Bullous penile LP has also been reported.[83]

Although LP is self-limiting, some patients experience relapses and remissions. Adhesions can form. Postinflammatory hyperpigmentation can persist for months or years.

Chronic mucosal erosive LP is associated with a risk of SCC, although most reports linking the two concern oral LP. SCC may complicate chronic hypertrophic LP of the lower leg but has also occurred in the context of hypertrophic LP of the glans penis.[3,84,85]

A biopsy is frequently necessary for diagnostic purposes but, more importantly, is performed in following up the rare cases of chronic anogenital disease in which the appearance of ulcero-erosive or verrucous features leads to concern about the development of SCC. The classic histologic findings are discussed in Chapter 114.

Potent or very potent topical corticosteroids usually produce remission. Patients should be warned about postinflammatory hyperpigmentation. Systemic corticosteroids are sometimes indicated for severely symptomatic disease, erosive orogenital involvement, and scarring of the scalp and nails. Topical and systemic cyclosporin has been used. Circumcision may be necessary if there is phimosis and should be seriously considered in cases of refractory disease, especially the erosive form, because the removal of "koebnerizing" influences may allow the LP to remit. The toxicity and the lack of efficacy of systemic therapy in treating this distressingly symptomatic situation are other powerful arguments in favor of circumcision.[3,86]

LICHEN NITIDUS

(See Chapter 27)

Lichen nitidus is sometimes held simplistically and controversially to be a micropapular variant of LP. It has an affinity for the penis and can be difficult to diagnose because the signs may be subtle, even when the lesions are widespread. Also, when the lesions are very pruritic, the signs due to excoriation and eczematization may eclipse those due to the lichen nitidus.[3]

GRANULOMA ANNULARE

(See Chapter 44)

Erythematous smooth, ovoid nodules of granuloma affecting the penis have been described. They are perhaps related to trauma and koebnerization, because circumcision can be curative.[87]

NECROLYTIC MIGRATORY ERYTHEMA

Necrolytic migratory erythema can be focalized to the male genitalia as a sore or painful annular erythematous eruption with a central glassy appearance and serpiginous border surrounded by scaling. It is a characteristic cutaneous manifestation of the glucagonoma syndrome (see Chapter 153).[88]

APHTHAE

The diagnosis of aphthous ulceration of the genitalia requires the exclusion of sexually transmitted diseases and other causes of genital ulceration, especially Behçet disease. This is in contradistinction to oral ulceration, in which a clinical diagnosis is acceptable practice.[3] The causes of aphthae are obscure. The histologic findings of idiopathic aphthous ulceration are nonspecific. Aphthae and idiopathic orogenital ulceration are more common and are worse, symptomatically and morphologically, in HIV-infected individuals. In patients with AIDS, biopsy must be performed on all mucocutaneous ulcers and specimens must be cultured; several pathologies may coexist. Treatment of simple aphthae is with topical corticosteroid/antibiotic/anticandidal combinations. In patients with AIDS, thalidomide may be efficacious.

BEHÇET DISEASE

(See Chapter 166)

The genital ulcers in men are painful, sometimes very painful, and this distinction may be helpful. They occur anywhere on the anogenitalia, including the scrotum and perianal skin. They are said to be bigger, deeper, fewer, and less recurrent than those in the mouth.

To diagnose Behçet disease according to strict diagnostic criteria, oral ulceration must be present; then patients must also either manifest genital ulceration and ophthalmic involvement or genital ulceration and skin signs (or a positive pathergy test result). In practice, there are many patients who have an incomplete syndrome. Although their disease does not satisfy these rigid diagnostic criteria, "possible" or "probable" Behçet disease is an acceptable label for everyday practical purposes. Essentially, Behçet disease is a systemic vasculitis that may involve many organs, so that protean presentations and complications are possible. Patients with relapsing polychondritis (see Chapter 159) and Behçet disease have been reported, and the term *MAGIC* (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage) *syndrome* applied.[89,90] Histologic findings are usually nonspecific and do not distinguish idiopathic aphthae, although sometimes necrotizing vasculitis can be seen. Topical treatment with corticosteroid/antimicrobial combinations may suffice. Topical interferon α lozenges have been advocated.[91] However, some patients will require systemic treatment with colchicine, prednisolone, azathioprine, cyclosporin, thalidomide, infliximab, or etanercept.[3,92,93] (See Chapter 166).

MUCOUS MEMBRANE PEMPHIGOID

(See Chapter 57)

Mucous membrane (cicatricial) pemphigoid is a rare disease that must be in the differential diagnosis of blistering, erosions, ulcers, transcoronal adhesions, scarring, and phimosis.[3,94] These manifestations can occur in isolation, but ophthalmic, oropharyngeal, and cutaneous lesions are more common than genital involvement. Direct immunofluorescence usually yields positive results, but indirect immunofluorescence does not. Topical and oral steroids may be ineffective. Dapsone, sulphamethoxypyridazine, mycophenolate, and biological therapies may be used.

PYODERMA GANGRENOSUM

(See Chapter 33)

Pyoderma gangrenosum is a rare event but is frequently misdiagnosed or diagnosed late while infections and cancer are pursued diagnostically (Fig. 77-11). It may represent a pathergic reaction after urologic surgery or complicate inflammatory bowel disease or leukemia. Treatment must be aggressive to avoid permanent damage to the urethra and erectile tissues.[3]

DRUG ERUPTIONS

(See Chapter 41)

The penis is a classic site of predilection for fixed drug eruptions.[3] Clinically, fixed drug eruption is characterized by the acute eruption of itchy, painful, swollen plaques, sometimes with central blister formation, erosion, and ulceration. Postinflammatory hyperpigmentation can be persistent. On first exposure to the drug the eruption can take 1–2 weeks to appear but subsequently appears just a few hours after administration. Recurrence is at the same site(s) each time the drug is encountered, and rechallenge/provocation can be used as a diagnostic test. For causes, see Chapter 41.

Ulceration due to papaverine can occur when the drug is inadvertently injected subcutaneously for the treatment of erectile impotence.[95] Heparin and warfarin have induced skin necrosis of the genitalia.[3] All-*trans* retinoic acid has been reported to induce genital

Figure 77-11 Pyoderma gangrenosum. Most of the shaft of the penis, but not the glans, has been destroyed. (© Medical Illustration UK.)

ulceration in patients with hematologic malignancy.[96] Foscarnet can create genital ulceration in HIV-infected patients due to the high urinary concentrations of the drug.[97] Nicorandil is a newly-appreciated cause of anogenital and peristomal ulceration.

Lisinopril has been associated with genital angioedema.[98] The cutaneous side effects of topical steroids are well known: striae, atrophy, erythema, telangiectasia, erosion, and modification of cutaneous, bacterial, viral, and fungal infections occur commonly. Drugs can also cause pruritus and urticaria.

STREPTOCOCCAL DERMATITIS

(See Chapter 176)

Streptococcal dermatitis causing a perianal cellulitis is a recognized syndrome in children, but a similar clinical situation occasionally occurs in adults and might affect the genitalia alone.[3] It is much more common in boys, and if the penis is involved, there may be dysuria, erythema, swelling, and balanoposthitis. Group A β-hemolytic streptococci can be isolated, and the lesions may be associated with streptococcal infection of the upper respiratory tract in other members of the family. Treatment is generally with systemic penicillin.

HERPES ZOSTER (SHINGLES)

(See Chapter 194)

Sacral herpes zoster is relatively rare but can be associated with severe morbidity due to nocturia, dysuria, acute urinary retention, constipation, and fecal retention.[3] When the pain precedes the rash, the differential diagnosis of an acute surgical emergency is evoked. Painful, grouped, crusting, vesicopustular lesions may be found unilaterally on the buttock, in the perineum, on the scrotum and penis, in the groin, and on the upper thigh. Hospitalization, urologic assessment, observation, possibly catheterization and sigmoidoscopy, and possibly assisted fecal extraction are indicated. Treatment should be with intravenous acyclovir.

TINEA

(See Chapter 188)

Tinea of the penis or scrotum is not common, and when it occurs it is usually associated with crural disease. Rarely encountered is tinea that occurs on the glans penis as a seat of itch or pain and produces an erythematous patch or a crop of scaly papules.[3] In India, it is associated with penile lesions due to the wearing of a langota, an occlusive T-shaped loincloth.[99]

SCHISTOSOMIASIS

(See Chapter 207)

Perineal granulomatous lesions are a rare manifestation of schistosomiasis (infection with *Schistosoma haematobium*).[3,100] Rarely genital skin lesions may lead to the diagnosis. They occur because of ova shed by worms that have entered the perineal vessels from the pelvic venous plexuses. Papules and nodules may be itchy; may be skin-colored, pink, or brown; may be scattered or grouped; and may affect the penis and scrotum. They can spread onto the perineum and around the anus and may develop into soft, warty, vegetating lesions but remain relatively asymptomatic. Ulceration is rare and carcinoma even rarer. Diagnosis is by biopsy (see Chapter 207). Ova may be recovered from urine or stool.

ONCHOCERCIASIS

(See Chapter 207)

The dermatologic genital consequences of onchocerciasis are pruritus, "leopard skin" hypopigmentation (on shins and scrotum), nodules (on ileal crests, scrotum, and ribcage), dermatitis, including "lizard skin" lichenification, "hanging groin," and scrotal enlargement.[3] The differential diagnosis of the scrotal enlargement includes bancroftian filariasis. The diagnosis is made by demonstrating microfilariae in skin snips.

POROKERATOSIS

Genital porokeratosis of Mibelli (see Chapter 52) is rare.[3,101] Annular raised (double-rimmed) lesions have been found in the intergluteal cleft, on the scrotum, and on the penis, including the glans. Rarely lesions may be ulcerative. Porokeratosis may be misdiagnosed clinically as psoriasis, Bowen disease, granuloma annulare, or LP but histologic examination of the margin shows the characteristic cornoid lamella. Cryotherapy and topical 5-fluorouracil can be used for treatment.

KAPOSI SARCOMA

(See Chapter 128)

Solitary Kaposi sarcoma of the penis was recognized, if rarely, before the HIV epidemic, and cases are still occasionally seen in HIV-negative patients.[3] AIDS-related Kaposi sarcoma is usually multicentric and often involves the face, oral mucosa, palate, and penis (20%). A solitary lesion is not unusual. It can present as a dull red patch or plaque on the glans penis or in the preputial sac and can also affect the penile shaft, scrotum, and perianal skin in one of its more classic manifestations—namely, purple, slightly scaly patches or plaques, nodules, and ulcerative lesions. An engorged, "hypervascular" presentation has been described, as has penile lymphedema, acute phimosis, and rectourethral fistulation. Odd morphology should arouse suspicions of mixed pathology.

LYMPHOMA, LEUKEMIA, METASTASES

Ulceration of the penis in chronic lymphocytic leukemia and scrotal ulceration in acute myelogenous leukemia due to leukemic infiltration have been reported.[3] Pyoderma gangrenosum, *Pseudomonas* infection, and Fournier gangrene can be associated with hematologic malignancy. Although the groin is a classic site of involvement in Langerhans cell histiocytosis (see Chapter 147), involvement of the penis is very rare. Metastases to the penis and scrotum occur uncommonly.[102] They are usually secondary to cancer of the urogenital tract or gastrointestinal system (e.g., rectum) or complicate other common cancers such as those of the lung. They may present with pain, swelling, priapism, urinary symptoms, or hematuria. A cutaneous nodule or nodules may be seen or infiltration of the deeper penile structures palpated.

PRIMARY MALE GENITAL DERMATOSES

PENILE MELANOSIS AND LENTIGINOSIS

Several terms have been coined to describe benign pigmented macules of the penis such as penile melanosis, penile melanotic macules, and atypical pigmented penile macules: penile melanosis, vulvovaginal melanosis, and the predominantly oral mucosal hyperpigmentation of Laugier–Hunziker syndrome (see Chapter 75) may be grouped under the umbrella of essential melanotic hyperpigmentation of the mucosa.[3,103] Some if not all cases may represent postinflammatory hyperpigmentation from previous disease or insult [e.g., phimosis, balanoposthitis, topical treatment, LSc (Fig. 77-12), LP, circumcision]. It has been suggested that adjacent depigmentation is an essential element of the condition.[104] Although *penile melanosis* is a good term for lesions without lentiginous hyperplasia on histologic examination, there may be increased basal epidermal pigmentation with or without benign lentiginous melanocytic hyperplasia, including ultrastructurally. The possibility of Addison or Nelson syndrome should be entertained, as should the possibility of a lentiginosis syndrome [Peutz–Jeghers, LAMB (*l*entigines, *a*trial *m*yxoma, *b*lue nevi), LEOPARD (multiple *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, growth *r*etardation, *d*eafness), or Bannayan–Riley–Ruvalcaba syndrome (see Chapter 75)], although idiopathic lentigines of the penis are recognized.

Figure 77-12 Penile melanosis. Glans penis. Postlichen sclerosus. (© Medical Illustration UK.)

If lesions are large or enlarging, with irregular edges and multifocal and variegated pigmentary patterns, concern may be raised about atypical melanocytic proliferation and acral lentiginous melanoma.

Despite being benign, penile melanosis can be cosmetically disturbing. Laser treatment may be helpful.

ZOON BALANITIS

ZOON BALANITIS AT A GLANCE

- Zoon plasma cell balanitis (ZB; properly balanoposthitis) affects the middle-aged and older uncircumcised male.
- ZB is a chronic, reactive, irritant mucositis.
- ZB is characterized by silent symptomatology and florid signs.
- Zoonoid inflammation is a common corollary of other dermatoses that cause a dysfunctional prepuce. Asymmetric, atypical, or unusual morphology should be viewed with suspicion.
- Circumcision is the definitive treatment in the majority of cases.

ETIOLOGY AND PATHOGENESIS. The evidence indicates that ZB is a chronic, reactive, principally

Figure 77-13 Zoon balanitis. Symmetric red patches. Glans penis and prepuce. (© Medical Illustration UK.)

Figure 77-14 Zoonoid inflammation. Florid zoonoid balanoposthitis complicating lichen sclerosus. (© Medical Illustration UK.)

irritant mucositis that causes, or is due to, a dysfunctional foreskin.[3,51] Irritation is induced by retention of urine and squames between two tightly apposed and infrequently and inadequately separated and/or infrequently or inappropriately bathed, commensally hypercolonized, desquamative, secretory epithelial surfaces.

CLINICAL FINDINGS. An asymptomatic presentation with little or no dyspareunia is classic. Conversely, the signs can be florid. Well-demarcated, glistening, moist, shiny, bright red, or autumn brown patches symmetrically involve the glans and inner prepuce, sparing the keratinized penile shaft or foreskin (Fig. 77-13). Other signs include dark red stippling or "cayenne pepper spots" due to hemosiderin deposition and solitary or multiple lesions of differing sizes (guttate or nummular), characteristically "kissing." Rarely, erosive and vegetative presentations have been reported, but lesions with asymmetric, atypical, or unusual morphology should be viewed with great suspicion and the organ inspected diligently for other, less florid signs. ZB may be secondary and may thus conceal more subtle evidence of underlying preputial disease such as LSc, precancer, or frank cancer that might have induced the manifest zoonoid changes. Overt cases of other dermatoses such as contact dermatitis, psoriasis, LSc, LP, penis precancer, and penile cancer may appear to have zoonoid changes on clinical and histologic examination (Fig. 77-14). It is possible that some of the clinical and histologic variants that have been reported and the dubious claim that ZB per se is a premalignant condition are a consequence of this phenomenon.[105]

LABORATORY TESTS. On histologic examination the epidermis is attenuated with absence of the granular and horny layers, sparse dyskeratosis and spongiosis, and diamond- or lozenge-shaped basal cell keratinocytes. In the dermis there are variably seen a band of plasma cells infiltration, extravasated erythrocytes, hemosiderin, fibrosis, and vascular proliferation.[106]

DIFFERENTIAL DIAGNOSIS. Disorders from which ZB must be differentiated are listed in Box 77-5.

TREATMENT. Although the condition may be ameliorated by improvement in washing habits and micturition

BOX 77-5 DIFFERENTIAL DIAGNOSIS OF ZOON BALANITIS

Most Likely
- Psoriasis
- Seborrheic dermatitis
- Lichen sclerosus

- Viral warts
- Herpes simplex
- Fixed drug eruption

Always Rule Out
- Erythroplasia of Queyrat
- Kaposi sarcoma

practices and by the intermittent application of mild or potent topical corticosteroids (with or without antibiotics and anticandidals) and topical tacrolimus, ZB usually persists or relapses. Definitive curative treatment is surgical circumcision.[3,107,108]

LICHEN SCLEROSUS

LICHEN SCLEROSUS AT A GLANCE

- Male genital lichen sclerosus (LSc) is an idiopathic inflammatory fibrosing dermatosis.
- It is principally a disease of uncircumcised men, although it can persist or recur after circumcision.
- LSc can be the cause of significant morbidity expressed as preputial dysfunction and male dyspareunia.
- Between one-fourth and one-half of cases of squamous cell carcinoma (SCC) of the penis may be preceded by LSc. SCC complicating LSc carries a high mortality.

(See Chapter 65)

EPIDEMIOLOGY. Genital LSc is more common than extragenital disease, but there may very occasionally be involvement in both areas. In adults, anogenital LSc is said to be about ten times more common in women than in men. Perianal disease is very rarely, if ever, encountered in the male. LSc may be much more frequent than is generally supposed in young boys. In boys, persistent primary phimosis or the secondary development of phimosis in a previously retractable foreskin should be viewed with suspicion: some, many, or most of such cases will be due to LSc.[3,51,107,109]

ETIOLOGY AND PATHOGENESIS. The pathogenesis of LSc, particularly the role of autoimmunity, is discussed in Chapter 65. Antiextracellular matrix protein 1 antibodies have been found in the sera of male and female patients with genital LSc.[110,111] In male genital LSc, roles seem likely for trauma (as suggested by cases in which the development of LSc was related to injury or surgery[112]) and contact with urine (as suggested by the association of genital LSc with anatomic abnormality, particularly hypospadias,[113] and the striking differences in the pattern of distribution between the sexes) but not for infection (men with genital LSc rarely if ever have sexual partners with LSc[3,107]). It is likely that chronic exposure of susceptible epithelium to urine due to a dysfunctional naviculomeatal valve accounts for most cases in men.[114]

CLINICAL FINDINGS. LSc is discussed in detail in Chapter 65. The symptoms and signs of male genital LSc are summarized in Table 77-3 and partially illustrated in Figs. 77-15 and 77-16. The principal presentation in men is of dyspareunia. The classic genital morphologic manifestations of LSc are of atrophic white patches or plaques or lilac, slightly scaly patches with telangiectasia and sparse purpura, like those of

TABLE 77-3
Symptoms and Signs of Male Genital Lichen Sclerosus

Asymptomatic
Spontaneous
Itching, burning, soreness, pain, adhesions, blisters, white patches, purpura, balanoposthitis, phimosis
Dyspareunia
Itching, burning, soreness, pain, bleeding, tearing, splitting,
Effacement of normal architectural features
Phimosis, narrow meatus, dissolution of frenulum, short frenulum, broad frenulum, "bunched" frenulum, white papules and patches, loss of coronal definition, adhesions, telangiectasia, scarring, fibrotic band ("waisting" or "bunching"), constrictive posthitis
Posthitis and balanitis xerotica
Dysuria, voiding difficulties, urinary retention
Renal failure
Cancer

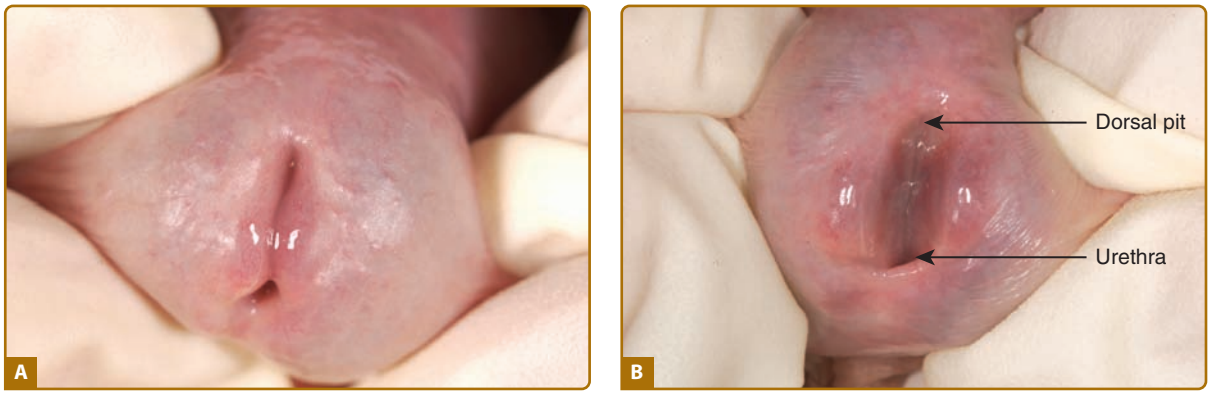

Figure 77-16 Lichen sclerosus affecting the glans penis. Etiolation (washed out appearance) is apparent. **A.** Apparent partial hypospadias. **B.** Meatal lips parted to reveal the deep navicular fossa with dorsal pit. This naviculomeatal architecture leads to an incompetent valve and urinary dribbling postmicturation. (© Medical Illustration UK.)

the classic clinical manifestations of extragenital LSc, may be seen. A constrictive lichenoid posthitis is commonly seen associated with a fibrotic preputial band causing "hourglass" "waisting" of the penile shaft.[3] Urethral involvement may be more common and extensive than hitherto supposed.[115,116]

Most cases of LSc can be diagnosed clinically. If there is clinical doubt, then a biopsy should be performed. The histologic findings are discussed in Chapter 65.

DIFFERENTIAL DIAGNOSIS. Disorders from which LSc must be differentiated are listed in Box 77-6.

COMPLICATIONS. The urological morbidity due to urethral disease can be severe.[116] The psychological consequences of sexual dysfunction for men and their partners are frequently overlooked. SCC of the penis is the most worrying complication of LSc: the published risk is 2%–12.5% and the latent period may be 10–30 years.[3,51,117–126] Involvement of the glans with LSc is a significant risk.[126] Carcinoma complicating LSc constitutes approximately 25%–50% of all cases of penile cancer.[3,107,120,127–130] LSc is histologically associated with differentiated PCIS, basal epithelial atypia and 'usual' or verrucous (rarely pseudohyperplastic) SCC.[131]

BOX 77-6 DIFFERENTIAL DIAGNOSIS OF LICHEN SCLEROSUS

Most Likely
- Lichen planus
- Nonspecific balanoposthitis

Consider
- Cicatricial pemphigoid

Always Rule Out
- Child sexual abuse
- Squamous carcinoma

TREATMENT. Treatment of extragenital LSc[132] is discussed in Chapter 65. The aims in male genital disease are to minimize or abolish male sexual dysfunction (dyspareunia), urinary dysfunction, and the risk of penis cancer.[114] Avoidance of contact with soap and urine are essential. Very potent topical steroids acheive remission in 50%–60% and the majority of the remainder are cured by circumcision.[133] Topical steroids are safe but occasionally HPV may be reactivated.[134,135] Topical calcineurin inhibitors should not be used.[136,137] Some men require sophisticated urethromeatal surgery.[116,125,138]

NONSPECIFIC BALANOPOSTHITIS

Nonspecific balanoposthitis is viewed either as a diagnosis of exclusion or as a descriptive term that indicates the limitations of diagnostic acumen.[3,51,107,] Sexually transmitted disease, immunosuppression, and diabetes or an identifiable primary dermatosis such as psoriasis, seborrheic dermatitis, ZB, LSc, LP, warts, or carcinoma in situ must be sought. A biopsy is essential. When patients present with symptoms and signs of balanoposthitis, nonspecific histopathologic features are found in approximately 10% of biopsy specimens.[139] Genitourinary physicians frequently diagnose candidosis, but dermatologists believe that *Candida* infection may complicate any inflammatory mucocutaneous dermatosis and is found as a secondary opportunistic phenomenon rather than as a primary cause of disease.[3] Phimosis may be the end stage situation including in diabetes.[140] Preputial dysfunction is the cause or consequence ofprobably all cases of nonspecific balanoposthitis, and many patients probably have LSc as the underlying morbid state. Treatment[141] can be very difficult, and the disease may fail to respond to local hygienic measures, soap substitution, topical steroids, and topical and systemic antibiotics.

The ultimate recourse is circumcision, which is curative in most instances. Histologic examination of the whole prepuce may substantiate the presence of an underlying genital dermatosis such as LSc. However, in a significant number of patients the circumcision histologic findings will be nonspecific, even after review

with the pathologist for early signs of LSc and even if there had been either hard or soft signs of an underlying dermatosis such as LSc on clinical evaluation on one or more occasions. These observations imply that such patients have nonspecific preputial dysfunction due to nonspecific irritation, trauma, and secondary candidosis such that a genuine nonspecific balanoposthitis ensues, with the pace of normal preputial repair and regeneration being exceeded by the pace of day-to-day attrition or wear and tear.[3,51,107]

DERMATOLOGIC NONDISEASE, DYSESTHESIA, AND CHRONIC PAIN SYNDROMES

Dermatologic nondisease[142] should be considered when florid symptomatology is accompanied by a paucity or complete absence of any primary dermatologic signs.[143] Patients with symptoms of itching, burning, redness, and pain focalized to the penis or scrotum, in some cases so severe as to prevent the patient from sitting down, are not uncommonly encountered. The chronic urogenital and rectal pain syndromes are described by the terms *penodynia*, *scrotodynia*, *orchialgia*, *prostatodynia*, *coccygodynia*, *proctalgia fugax*, *perineal pain*, *descending perineum syndrome*, and *vulvodynia*.[144–147]

The red or burning scrotum syndrome has been defined as "persistent redness of the anterior half of the scrotum that may involve the base of the penis… usually accompanied by a persistent itching or burning sensation and hyperalgesia."[148] Accompanying the erythema there may be telangiectasia. It is a chronic condition that is resistant to treatment and its cause is unknown.[143,148]

The neuroanatomy of the pelvis is complicated, and the neuropathophysiologic basis of these syndromes is poorly understood. They seem to share features of neurogenic inflammation and neuropathic pain.[149] Although their clinical presentations are well recognized by physicians in many specialties, these diagnoses should be arrived at after comprehensive clinical assessment, contemplation of the differential diagnosis, and a process of exclusion based on suitable investigations and response to treatment.[150] Localized dermatographism should be sought by stroking the inside of the thigh. Contact urticaria, irritant and contact dermatitis, and scrotal rosacea due to topical steroid application should be considered. Tinea and candidosis must be excluded. Intercurrent herpes simplex or postherpetic neuralgia might mislead. Angiokeratoma corporis diffusum and multiple sclerosis are causes of odd sensory symptoms. Zinc deficiency and migratory necrolytic erythema could be entertained. Penile sensitivity is reduced in diabetic patients, and this may correlate with erectile dysfunction in some of these men.[151] The drug chart should be reviewed. Some men with "idiopathic" anogenital pruritus may be found to have lumbosacral radiculopathy if investigations such as plain radiography, nerve conduction studies, computerized tomography, and needle electromyography are performed, and significant improvement may be obtained by paravertebral injections of triamcinolone and lidocaine.[152]

A diagnosis of a chronic pain syndrome carries the possibility of considerable psychological morbidity. Dysmorphophobia, depression, and psychosis may be present, and attempted or completed suicide is a real risk in such patients.[14]

Scrotal rosacea (see Chapter 81) should be treated with oral tetracycline's and these (e.g., doxycycline) may be effective in the red scrotum syndrome.[153] If anogenital dermatographism and/or urticaria is suspected, oral antihistamines can be prescribed. Prednisolone and antidepressants such as doxepin, amitriptyline, and paroxetine can afford some relief. Neuromodulation by sacral root stimulation might be tried.[96] However, treatment is generally problematic and at best only empiric. Invasive and irreversible procedures should be avoided if at all possible. Multidisciplinary management is the ideal.[3,107]

PENILE ACNE

Penile acne is an poorly-documented entity occasionally encountered in clinical practice.[3] Young men complain of penile spots or boils or blackheads and on examination have comedones, papules, pustules, and inflammatory nodules of the proximal penile shaft. An important differential diagnosis of acneiform disease presenting at any site is chloracne caused by occlusion of the skin with machine oil. Conventional treatment for acne is prescribed in a hierarchical manner: topical keratolytics, antibiotics, and retinoids; oral antibiotics; and isotretinoin (see Chapter 80).

CHRONIC "IDIOPATHIC" PENILE EDEMA

Chronic idiopathic penile edema is a rare, ill-understood condition.[3,154] It is the cause of significant morbidity, sexual dysfunction, and phimosis. Patients present with swelling and intercurrent attacks of cellulitis and lymphangitis of the penis, scrotum, and pelvic girdle. Recurrent sexually transmitted diseases, a chronic dermatosis, and hypoplastic lymphatics are sometimes incriminated. The antistreptolysin-O titer may be elevated, and a biopsy specimen may show granulomatous lymphangitis, and Crohn disease (Fig. 77-17) should be sought even if the patient has no gastrointestinal symptoms. Sarcoidosis should be excluded. Treatment has to be aggressive to prevent intercurrent infection and further lymphatic damage and scarring. Long-term treatment with oral antibiotics such as erythromycin, clarithromycin, clindamycin, trimethoprim, cotrimoxazole, or ciprofloxacin is advocated. Occasionally, a short cause of oral prednisolone is helpful. The goal should be to reduce the preputial edema to allow circumcision.

SPONTANEOUS SCROTAL ULCERATION

Rare cases of spontaneous scrotal ulceration in young, previously fit men have been described.[155] Histologic examination showed nonspecific vasculitis and

Figure 77-17 Chronic penile edema. Crohn disease. Histologic examination showed a granulomatous lymphangitis. (© Medical Illustration UK.)

spontaneous resolution occurred. A related entity may be idiopathic scrotal panniculitis and fat necrosis,[156] because trauma, extreme cold, and Fournier gangrene were excluded.

FOURNIER GANGRENE

(See Chapter 179)

Fournier gangrene is a medical and surgical emergency.[3] Patients present with systemic upset and painful erythematous swelling of the genital, perianal, or lower abdominal skin and may be in urinary retention. An ominous black spot may appear on the scrotum. There is gross systemic toxicity (peculiarly, sometimes absent in children) and no suppuration. Necrosis of skin and deeper tissues rapidly supervenes and death ensues (the mortality may be higher than 50%) unless diagnosis is prompt and radical management is instituted. In its clinical picture Fournier gangrene overlaps with necrotizing fasciitis and Meleney gangrene. Risk factors are presented in Table 77-4.

The process probably begins with appendageal or urethral infection, and polybacterial infection develops. Most of the organisms isolated from cases prove to be resident urethral or lower gastrointestinal flora, and most patients have mixed infections. What then follows is a necrotizing cellulitis, perhaps exotoxin mediated that affects skin, subcutis, fascia, and muscle—the human counterpart of the local Shwartzman phenomenon. In children, the most commonly isolated pathogens are staphylococci and streptococci. Radiologic studies may show soft tissue gas.

Disorders from which Fournier gangrene must be differentiated are listed in Box 77-7.

If the clinical diagnosis of Fournier gangrene is entertained, then drastic emergency management is required. Surgical and microbiologic expertise, often in an intensive care setting, may be required. Radical surgical débridement of all affected tissue is undertaken and broad systemic antibiotic therapy initiated. If the patient survives, then plastic surgical repair can be performed.[157] Hyperbaric oxygen treatment has been advocated, as has high-dose systemic corticosteroid treatment. Children can be treated with more conservative surgery, and the mortality rate is lower.[158]

In adults, the mortality is around 25% and is highest in disease of anorectal rather than urogenital origin, which likely reflects a less typical presentation and longer delay in diagnosis.[3]

Most Likely
- Trauma
- Herpes simplex
- Cellulitis
- Gonococcal balanitis and edema

Consider
- Migratory necrolytic erythema
- Allergic vasculitis
- Polyarteritis nodosa
- Ecthyma gangrenosum
- Warfarin necrosis

Always Rule Out
- Necrotizing fasciitis
- Vascular occlusion syndromes

NONSYPHILITIC SPIROCHETAL ULCERATIVE BALANOPOSTHITIS

Nonsyphilitic spirochetal ulcerative balanoposthitis is recognized in the tropics and South Africa and presents as large, serpiginous, foul-smelling ulcers in uncircumcised men, associated in some with nontender inguinal lymphadenopathy.[159] Treatment is with penicillin or metronidazole.

SCROTAL CALCINOSIS

Scrotal calcinosis is a relatively common, benign idiopathic disorder presenting as rock-hard smooth white papules or nodules on the scrotum, multiple or

solitary.[3] Occasionally, the lesions may become secondarily inflamed or infected after trauma. Rarely, a lesion or lesions occur on the penis. The differential diagnosis includes epidermoid cyst. Indeed, it is debatable whether the lesions are indeed idiopathic or whether they arise from epidermoid cysts, eccrine duct milia, eccrine epithelial cysts, dystrophy of the dartos muscle, trauma, or foreign bodies (e.g., thorn or even *Onchocerca* organisms). Cold, trauma, and the thinness and specialization of scrotal skin are thought to be etiologic factors. Treatment is by surgical excision, but the lesions recur.

SCLEROSING LYMPHANGITIS

Nonvenereal sclerosing lymphangitis [there are a confusing number of synonyms: *penile venereal edema*, *Mondor phlebitis*, *localized penile (venereal) lymphedema*, *penile lymphocele*] is increasingly recognized.[3] Patients present with a serpiginous mass in the coronal sulcus, spreading sometimes onto the dorsal penis. The lesion may appear for the first time or become tender and enlarge after prolonged or frequent sexual intercourse. In circumcised men the circumferential scar may be a predisposing factor. It has not been established whether this entity represents a posttraumatic lymphangitis or phlebitis. The problem may resolve spontaneously or surgical excision may be required.

True thrombophlebitis of superficial penile and scrotal veins is analogous to Mondor phlebitis of the chest wall. Herpes simplex virus infection, polyarteritis nodosa, and thromboangiitis obliterans may initiate it. Penile thrombophlebitis has been seen as the initial presentation of a paraneoplastic migratory thrombophlebitis caused by pancreatic cancer.

VERRUCIFORM XANTHOMA

Verruciform xanthoma is a rare entity that principally involves the mouth. Genitalia are the next most frequently affected area, where it presents as a painless, yellow–brown or red, verrucous, sessile, or papillary plaque.[3] Histologically there is hyperkeratosis, focal parakeratosis, and irregular epidermal acanthosis. Rete ridges are lengthened and extend into the dermis, forming areas called *dermal papillae* and which enclose capillary vessels surrounded by foam cells that are $CD68^+$ but $S100^-$. It is thought that the lesion results from epidermal degeneration and that keratinocyte lipid is taken up by dermal macrophages or fibroblasts to form the foam cells. HPV-6 DNA has been found in one case. SCC may arise within the lesion. Treatment is by surgical excision.

PENILE CARCINOMA IN SITU AND SQUAMOUS CELL CARCINOMA

EPIDEMIOLOGY.

SCC of the penis accounts for 0.3%–0.6% of cases and less than 1% of cancer deaths in the United States.[3,51,65,107,160] One hundred deaths and 400 cases are seen per year in the United Kingdom.[161,162] It is estimated that penile SCC represents 10%–20% of tumors seen in males in the developing world, where neonatal or infantile circumcision is not part of the culture.[163] However, in developed countries such as Japan and Denmark where circumcision is not routinely practiced, penile cancer incidence is falling and is approximating that in the United Kingdom and United States.[164,165] The epidemiology of PCIS is not well established; it is probably underdiagnosed and underreported.[161,166]

ETIOLOGY AND PATHOGENESIS.

(See Chapters 114). The precise causes of the different types of PCIS and SCC of the penis are unknown. Acknowledged risk factors for SCC are presented in Table 77-5.

HPV (high-risk and mixed infections), LSc, and immunoincompetency are the most important considerations.[65,66,74,75,107,129,130,167–169]

CLINICAL FINDINGS.

EQ manifests as bright red, shiny patches, or plaques of the mucosal sites, the glans, and prepuce of the uncircumcised (Fig. 77-18

PENILE CARCINOMA IN SITU AND SQUAMOUS CELL CARCINOMA AT A GLANCE

- Erythroplasia of Queyrat (EQ), Bowen disease of the penis (BDP), urethral disease and bowenoid papulosis (BP) are synonymous in describing clinical situations in which histologically carcinoma in situ (CIS) is present.
- *Penile carcinoma in situ* (PCIS) is a better term than *penile intraepithelial neoplasia* or PIN (corresponding to cervical intraepithelial neoplasia, vulval intraepithelial neoplasia, and anal intraepithelial neoplasia) because of the potential for confusion with prostatic intraepithelial neoplasia.

and eFig. 77-18.1 in online edition). Bowen disease of the penis (BDP) is characterized by red, scaly patches and plaques of the keratinized penis (Fig. 77-19 and eFig. 77-19.1 in online edition). Both affect the older male. BP presents as multiple warty lesions rather than as erythematous patches or red, scaly plaques

Figure 77-19 Bowen disease. (© Medical Illustration UK.)

Figure 77-20 Bowenoid papulosis. Red papules, distal penile shaft. (© Medical Illustration UK.)

(Fig. 77-20). BP is pigmented in keratinized sites, and lesions are multiple and more inflamed in mucosal sites; lesions are more polymorphic, more coalescent, less papillomatous, and smoother topped than common genital viral warts. BP is seen in younger, sexually active men. Pseudoepitheliomatous micaceous and keratotic balanitis is probably not a separate entity but a clinical variant of PCIS, probably associated with LSc and conferring a risk of development of invasive SCC.[3,65]

In SCC irregular nodular and ulcerative morphology is encountered (Fig. 77-21). Clinically, there may be evident background PCIS and/or LSc (or even LP). Inguinal lymphadenopathy may be present, although in penile cancer only 50% of enlarged glands will be found to contain tumor. Verrucous carcinoma, warty carcinoma, Buschke–Lowenstein tumor (BLT), and giant condyloma may be dramatic clinical lesions, often polypoid or cauliflower-like. Although locally deeply invasive, they are well demarcated from surrounding tissue. These terms are often used synonymously to describe rare, low-grade, well-differentiated squamous carcinomas.[170–177] The potential for aggressive behavior, mortality risk, and clinical, histologic, and virologic differences may distinguish them. Giant condyloma and BLT are thought likely to have their origin from common genital warts. BLT has also been associated with LSc.[178]

DIFFERENTIAL DIAGNOSIS (Box 77-8). A biopsy is indicated in most instances.

Figure 77-21 Squamous carcinoma. HIV-positive patient. (© Medical Illustration UK.)

- Behçet disease

Always Rule Out
- Fournier gangrene
- Pyoderma gangrenosum

HISTOLOGY. The histopathology of mucosal PCIS is generally that of a bowenoid pattern of dysplasia with dysmaturation and atypical cells and increased mitoses at different levels of the epithelium. This is often accompanied by HPV-related cytopathic changes in the upper layers of the epithelium, but there is as yet no formal consensus on clinicopathologic classification and clinical utility. Increasingly encountered are the terms *squamous hyperplasia* and *squamous intraepithelial lesion* of squamous, basaloid, or warty type and low or high grade to describe the histologic findings of epithelial lesions associated with penile SCC.[179,180] Differentiated PCIS and basal epithelial atypia are associated with LSc and full thickness, undifferentiated bowenoid dysplasia with HPV.[131]

In SCC, tongues of invasive atypical keratinocytes invade the lamina propria or deeper structures and contain foci of aberrant and ectopic keratinization (squamous pearls). Penile SCC is morphologically and histologically heterogenous.[65,128,131,181–186] The frequency of occurrence of different types in 61 U.S. cases was 59% usual (squamous), 15% papillary (not otherwise specified), 10% basaloid, 10% warty (condylomatous), 2% verrucous, and 2% sarcomatoid.[181] Usual or verrucous (rarely pseudohyperplastic) SCC are associated with LSc whereas warty, basaloid or mixed types are associated with HPV.[131]

Suspected verrucous carcinoma demands a deep surgical biopsy. Verrucous carcinoma has different pathologic features from typical squamous carcinoma, showing well differentiated and maturing squamous epithelium with very little atypia or pleomorphism and few mitoses. The diagnosis of verrucous carcinoma in biopsy specimens may be difficult to establish because it relies very much on the depth of invasion of the lesion in relation to surrounding epidermis, and the growth pattern is of a "pushing" margin rather than infiltration. Warty carcinoma, BLT, and giant condyloma differ further in having marked squamous proliferation with HPV-related changes; they are not associated with bowenoid dysplasia but do have more atypia and mitoses than classic verrucous carcinoma.

PROGNOSIS. Quantifying the malignant potential of BDP/EQ/BP/PCIS is not easy. EQ is probably more dangerous than BDP in terms of risk of progression to invasive SCC. BP may remit spontaneously and probably has less malignant potential than EQ or BDP.[3,14,16] The prognosis of established, thick, invasive SCC remains poor, but that of early thin disease is much better. HPV status does not correlate with survival.[187] In the United States, previously or currently married men present earlier and have increased survival overall; African-Americans present later and do less well.[188] In India late presentation is common.[189]

The histologic type of SCC has a bearing on prognosis: low mortality risk is associated with mixed, papillary, and warty types, intermediate risk with usual and basaloid types and high risk with sarcomatoid cancers.[65,181,182,185,186,190,191] The prognosis is also related to the depth of invasion of crucial anatomic landmarks. Features imparting a poor prognosis include perineural invasion and vascular invasion and high histological grade.[192]

The role of SCC antigen as a biomarker for penile cancer remains speculative.[193,194]

TREATMENT. There are several approaches to the treatment of PCIS, summarized in Box 77-9. The guiding principle is to be conservatively ablative.[65,107,161] A rational initial step is to recommend circumcision. Patients presenting with these conditions (and their sexual partners) should be counseled and screened

BOX 77-9 TREATMENTS FOR PENILE CARCINOMA IN SITU

- Circumcision
- Cryotherapy
- Salicylic acid
- Podophyllin/podophyllotoxin
- Curettage and cautery
- Simple excision
- Mohs micrographic surgery
- Laser therapy
- Photodynamic therapy
- Radiotherapy (not advised)
- 5-Fluorouracil
- Imiquimod

for HPV and other sexually transmitted diseases, including HIV infection. Smoking should be discouraged. Follow-up should be long term, and the focus should include the whole perineum, anus, and perianal skin.

For SCC, adequate surgical excision is required. This may need to be radical (i.e., penile amputation), depending on location and extent, but the trend is toward tissue-conserving techniques for functional and cosmetic reasons.[107,162] Mohs micrographic surgery and laser procedures have their proponents. Local staging to inform management decisions is achieved by clinical evaluation, histologic analysis, sonography, and magnetic resonance imaging. The histologic grade helps predict proximal histologic extent beyond grossly visible tumor margin. Sentinel node biopsy has been advocated, but the management of ilioinguinal lymphadenopathy is controversial. Established lymphatic or hematogenous dissemination requires individualized multidisciplinary management. Combination chemotherapy has been used for palliation and proposed for adjuvant treatment but is of uncertain value. Brachytherapy or external beam radiotherapy and chemoradiotherapy have their proponents.

PREVENTION. Chronic disease and dysfunction of the foreskin confer a significant risk of PCIS or frank SCC. The "field changes" due to LSc and HPV create situations of multifocality or multicentricity and a temporal dynamic, contributing to long-term risk even if corrective treatments have been initiated. Feasible measures for penile cancer prophylaxis are treatment of chronic inflammatory conditions such as LSc, LP, and nonspecific balanoposthitis; prevention of phimosis; limitation of psoralen and ultraviolet A treatment; smoking cessation; and prophylaxis for HPV infection.[165,195]

MELANOMA

(See Chapter 124)

Melanoma is a rare neoplasm of the penis, but the prognosis is poor because of late diagnosis and early lymphovascular invasion. It should always enter the differential diagnosis of penile melanosis and lentiginosis as well as genital papules, nodules, and ulcers.[3]

EXTRAMAMMARY PAGET DISEASE

(See Chapter 121)

EMPD[3] presents as an irritating, itchy, burning, red scaly patch or plaque and may be multicentric. It can be found anywhere around the anogenital area, including the glans penis. An "underpants" pattern of erythema has been described in some patients. EMPD is frequently misdiagnosed as an inflammatory dermatosis, such as psoriasis, eczema, or Bowen disease. Subclinical EMPD disease occurs, in which the skin looks normal macroscopically but is involved microscopically. The disease behaves indolently, spreading by local extension and metastasis. The combination of genital and extragenital EMPD is rare but overt, and latent axillary EMPD disease may coexist. Axillary macular lesions that changed shape and color daily have been reported in association with penile and pubic Paget disease. Very rarely, depigmented EMPD disease presents as a pale patch in the genital area, evoking a differential diagnosis of vitiligo, hypopigmented mycosis fungoides, and LSc.[80]

EMPD has been treated with cryotherapy and topical 5-flurouracil, but wide excisional surgery (e.g., Mohs), with plastic repair if needed, is probably the treatment of choice. Radiotherapy is controversial. Photodynamic therapy is under evaluation. Topical imiquimod holds promise.[196]

Chapter 78 :: Diseases and Disorders of the Female Genitalia

:: Lynette J. Margesson & F. William Danby

VULVOVAGINAL DISEASES AT A GLANCE

- Common problems, including the following:
  - Infections
  - Inflammatory dermatoses
  - Bullous and erosive diseases
  - Ulcers
  - Vulvodynia
- Evaluation, diagnosis, and management are challenging because:
  - Normal vulvar anatomy is often unfamiliar to the physician.
  - Morphology and histologic features of dermatoses are often nonspecific.
  - Causes are often multiple and complex.
  - Patient anxiety and depression are often severe and can worsen symptoms.

EPIDEMIOLOGY

The incidence and prevalence of dermatoses affecting the female genitalia are generally not well established. The vulva has been referred to as "the forgotten pelvic organ." Despite being the visible female genital structure, it is least described in the medical literature.[1] Teaching about vulvar conditions and even the normal vulva is sadly lacking for most medical practitioners, so it is not surprising that vulvar conditions are both underreported and underdiagnosed. Approximately 16% of women report undiagnosed chronic vulvovaginal pain at some time in their lives.[2,3]

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of many diseases of the female genitalia are likewise not well understood. Those that also affect other areas of the body are better characterized, but the environment of the vulva strongly affects the course of disease.

CLINICAL FINDINGS

HISTORY

The approach to the patient with vulvar complaints requires directed history taking, as outlined in Box 78-1.

CUTANEOUS LESIONS AND SYMPTOMS

The warm moist environment of the vulva often alters disease morphology or symptomatology. For example, usually scaling dermatoses may lack clinically obvious scale, and in diseases that usually exhibit well-demarcated plaques, the lesions may be less distinct. In addition, diseases that normally do not produce scarring of keratinized skin or oral mucosa can induce resorption of the labia minora, narrowing of the introitus, and

BOX 78-1 ELEMENTS OF HISTORY TAKING FOR PATIENTS WITH VULVOVAGINAL COMPLAINTS

- Symptoms: onset, initial trigger, duration, alleviating, and exacerbating factors
- Previous treatments: duration and effectiveness
- Copies of previous physicians' evaluations, culture, and biopsy reports
- Daily cleansing and care practices
- Contactants: tampons, pads, lubricants, deodorants, fragrances
- Gynecologic history
- Menstruation/menopause/estrogen and other hormone replacement
- Pap test results
- Contraception
- Pregnancy
- Sexual activity

- Surgery
- Gastrointestinal history
- Diarrhea
- Constipation
- Psychiatric history

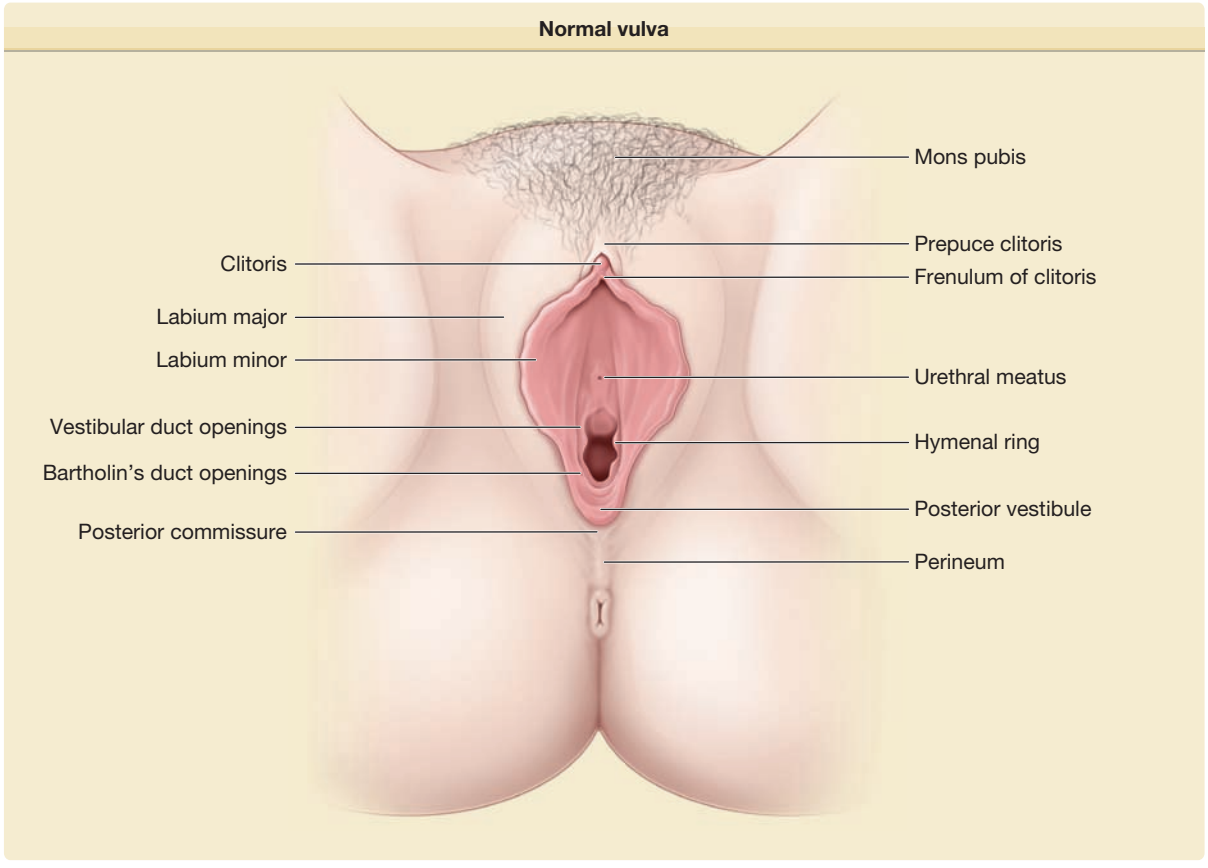

Figure 78-1 Normal vulva.

scarring of the clitoral hood. Vulvar scarring can occur from any inflammatory condition.[4]

When examining the vulva, it is important to make sure there are no physical abnormalities, particularly, that all normal anatomy is present. Using a diagram can help and this also can be shared for patient education (Fig. 78-1). Unimpressive physical findings are sometimes associated with severe itching and vulvar pain. Lichenification manifested only by a slight change in texture can present with severe pruritus deserving of and responsive to aggressive therapy. Finally, a complete mucocutaneous examination is crucial, because extragenital findings can assist in the diagnosis of several genital conditions.

RELATED PHYSICAL FINDINGS

Skin disease affecting the vulva more often has a multifactorial etiology, compared to other areas of the body. The primary skin disease is often accompanied by and driven by a secondary yeast infection, bacterial colonization, or lack of estrogen, even in the absence of obvious clinical findings. The infection can be purely cutaneous, purely vaginal, or both. Irritant contact dermatitis from topically applied agents often exacerbates both signs and symptoms. Such contributors need to be constantly sought.

Vulvar symptoms cannot be divorced from vaginal abnormalities. Irritating or infected vaginal secretions are a common cause of vestibular (introital) symptoms, which makes a speculum examination highly advisable in many instances.

LABORATORY TESTS

Skin biopsy specimens for hematoxylin and eosin staining and direct immunofluorescence testing may be required. Sometimes multiple biopsy samples are required to establish a specific histologic diagnosis. When previously well-controlled dermatoses flare, repeat biopsy may be needed to rule out squamous cell carcinoma or a second disease process. When doing a vulvar biopsy, preanesthetizing the area with a topical anesthetic can be very helpful.

Culture of cutaneous swab samples, for *Candida* and bacteria, is indicated when concurrent infection is considered. Infection can complicate treatment at any point in the course of a disease.

A microscopic evaluation of vaginal smears allows inspection for yeast (see Chapter 189), *Trichomonas*, and bacterial vaginosis (see Chapter 205). Abnormalities such as an increased number of white blood cells or the presence of immature epithelial cells may be seen as well and may be markers for inflammatory skin diseases, estrogen deficiency, foreign body, or pyogenic bacterial infection. Vaginal cultures, done in addition, can identify infection caused by a nonalbicans *Candida*

organism, a pathogen difficult to see on microscopic smears but occasionally a cause of significant symptoms.

Patch testing is important if allergic contact dermatitis is suspected (see Chapter 13). Consultation with specialists in gynecology, urology, or urogynecology may be necessary to assist with diagnosis, management, or treatment. This is particularly true in the setting of multifactorial processes (e.g., incontinence as a contributing factor) or diseases requiring surgical intervention (e.g., posterior fourchette fissuring).

DIFFERENTIAL DIAGNOSIS

Because of the varied morphologies and frequent multifactorial presentations, the differential diagnosis of a vulvar condition can be quite broad (Box 78-2). Normal variants can be confusing as well. The diseases discussed in this chapter are grouped into the categories of inflammatory dermatoses, bullous and erosive diseases, ulcers, abscesses, and vulvodynia.

BOX 78-2 DIFFERENTIAL DIAGNOSIS OF VULVOVAGINAL DISORDERS

INFLAMMATORY DERMATOSES

- Lichen simplex chronicus
- Irritant contact dermatitis
- Allergic contact dermatitis
- Psoriasis
- Lichen sclerosus
- Vulvar fissures

BULLOUS AND EROSIVE DISEASES

- Lichen planus
- Erythema multiforme major
- Toxic epidermal necrolysis
- Cicatricial pemphigoid
- Pemphigus vulgaris
- Fixed drug eruption
- Herpes simplex
- Extramammary Paget disease
- Vulvar carcinoma

ULCERS

- Aphthous ulcers
- Crohn disease
- Syphilis
- Chancroid
- Other in sexually transmitted diseases

ABSCESSES

- Bartholin gland abscess
- Hidradenitis suppurativa

PROGNOSIS AND CLINICAL COURSE

Women with vulvovaginal symptoms assume they have a curable, infectious disease. Patients need to be counseled that many genital dermatoses are controllable but not curable. These women cannot be evaluated and treated in a 10-minute office visit; they require adequate time for education and reassurance. Frequently they need to be followed long term.

TREATMENT

Several factors need to be considered when treating most dermatoses of the female genitalia.

Many women are unfamiliar with their genital anatomy and do not have the vocabulary to accurately discuss their problem or follow instructions for applying topical medications. Diagrams and/or a use of a hand-held mirror are extremely helpful for patient education. The vulvar diagram (Fig. 78-1) can be very important here.

An ointment is generally the most comfortable vehicle for delivering medication to the modified mucous membranes of the vulva. Ointments spread easily, require very small volumes per application, are less sensitizing and generally cause less burning.

Irritant contact dermatitis is a common complicating factor in any genital dermatosis. Aggressive washing and use of soaps, topical medications, and home remedies are the most common offenders. Because soaps, douches, disinfectants, and very hot or cold water often are not considered relevant by patients, information regarding their use is often not volunteered, and very careful questioning is warranted. Gentle cleansing of the area can be accomplished by flushing once a day with water (or mild cleanser and water) and patting dry. Washcloths for washing and towel rubbing while drying must be avoided.

Superpotent glucocorticoids such as clobetasol propionate are often required to treat dermatoses of the female genitalia. Fortunately, glucocorticoid atrophy is surprisingly uncommon on the modified mucous membranes of the vulva. Nonetheless, patients should be reevaluated monthly during periods of daily use and warned about side effects due to spread of medication to the surrounding areas where atrophy is more likely to occur such as the inguinal crease, proximal medial thighs, and perianal skin. Limit the amount of topical steroid prescribed.

Tacrolimus or pimecrolimus can be used as steroid-sparing medications on vulvar skin. Stinging or burning frequently occurs with initial application. This is especially true for very inflamed or eroded areas. These agents are often less effective than glucocorticoids and their long-term safety is still in question. Despite these issues they are a useful second line option.[5] (For efficacy and side effects, see Chapter 221.)

Warmth and moisture of the genital area are unavoidable and promote infection and maceration. Bacterial

superinfection can be treated with oral antibiotics. Yeast infections are especially common, particularly when patients are treated with topical glucocorticoids and/or oral antibiotics. The identification of infection on red, scaling, and often exudative skin can be difficult and should be pursued actively in patients with recalcitrant symptoms.

COMMON NORMAL VARIANTS

There is great variety in normal vulvovaginal anatomy. Vulvar and vaginal erythema of varying degrees is present in most asymptomatic premenopausal women, but this redness is rarely noticed before the onset of discomfort. Architecturally, the labia minora exhibit a wide range of asymmetry and sizes. Normal but very small labia minora may be difficult to differentiate from scarring produced by inflammatory skin disease. Sebaceous glands may be prominent on the inner labia minora. Harmless, soft, finger-like, skin-colored, monomorphous papules called vulvar papillomatosis can be seen around the hymenal ring. (See eFig. 78-1.1 in online edition) These can be confused with genital warts.

INFLAMMATORY DERMATOSES

Clinically subtle inflammation of the vulva sometimes produces remarkable symptoms. Therefore, a very careful examination with a high index of suspicion for a dermatosis is required.

LICHEN SIMPLEX CHRONICUS

(See Chapter 15)

Vulvar lichen simplex chronicus is most often seen in atopic individuals with sensitive skin. It can complicate other vulvar dermatoses, especially contact dermatitis, lichen sclerosus and, less frequently, lichen planus.

The morphologic manifestations of lichen simplex chronicus when it occurs on the vulva vary from minimal hyperpigmentation and dullness of texture of the modified mucous membranes to remarkable lichenification and edema (see Fig. 78-2 and eFigs. 78.2.1–78.2.5 in online edition). Erythema can be subtle on the labia majora because hair obscures the skin. Excoriations and fissures within skin folds are common but heal quickly and may not be seen in the office. Sometimes hydrated, thickened lichen simplex chronicus appears white, mimicking lichen sclerosus, or the leukoplakia of intraepithelial neoplasia.

Although the histologic findings, differential diagnosis, and therapy are similar for lichen simplex chronicus affecting the vulva as for that involving other parts of the body, there are several notable modifications.[6] Contact dermatitis needs to be recognized and treated as it frequently confounds management. Women overwash and especially scrub the area and also may apply topically whatever they can find. Topical glucocorticoid therapy is a mainstay, but prompt alleviation of symptoms often requires a higher potency preparation than is standard for intertriginous skin. Those with significant lichenification do well with a superpotent preparation such as clobetasol propionate for the first few weeks. The potency or frequency can be decreased as the patient improves. Nighttime sedation is often required to interrupt the itch–scratch cycle.[7] Skin and vaginal infections, often subclinical, are extremely common and often drive lichen simplex chronicus. Therefore, skin and vaginal cultures for yeast, and especially to rule out methicillin-resistant *Staphylococcus aureus* (MRSA), should be performed, especially since treatment will normally require potent topical glucocorticoid therapy for control. Treat bacteria and *Candida* infections orally because topical treatment can irritate and intensify pruritus. Proper hydration is essential for healing. Patients with lichen simplex chronicus that is intensely inflamed, excoriated, or eroded generally require medications in an ointment base, to avoid additional sensitizers and the drying effects of cream and lotion bases. A plain water soak in a tub for 5 minutes three times a day, followed by gentle patting of excess moisture and the application of a Class 3–1 corticosteroid ointment is the best approach for initial therapy, and must be done under cover of an appropriate oral antibiotic and fluconazole. Sedation is very helpful initially to stop scratching, with hydroxyzine or doxepin at night to tolerance. Systemic corticosteroids should be used for short periods of time for severe pruritus. Follow-up to prevent and manage relapse is essential.

Figure 78-2 In this case of lichen simplex chronicus of the vulva there is thick dramatic whitening bilaterally and symmetrically around the vulva and perianal area.

IRRITANT AND ALLERGIC CONTACT DERMATITIS

(See Chapters 48 and 13)

Vulvar skin is thin, damp, and permeable. It is exposed to a wide range of insults from washcloths and vigorous scrubbing to caustic, irritating or allergenic cleansers, and topical products applied to alleviate symptoms. Irritant vulvar dermatitis is common, ranging from the diaper dermatitis seen in infants and elderly incontinent ladies to the chapped, sore vulva of the overzealous scrubbers. Allergic vulvar contact dermatitis is less common, with relevant allergens found in 30% of those tested.[8]

Irritant and allergic contact dermatitis of the vulva can be either a primary or secondary diagnosis, acute or chronic. Either or both may commonly complicate any vulvar dermatosis. A patient with acute irritant contact dermatitis experiences burning on contact with the offending substance. Deep erythema is common. Vesiculation, rare, can occur on keratinized skin, whereas erosion is usual on modified mucous membranes (Fig. 78-3). Therapies such as fluorouracil, imiquimod, podophyllin resin, benzocaine, some topical antifungal creams, and topical gentian violet can produce a brisk reaction.[9] Chronic irritant contact dermatitis is characterized by poorly demarcated erythema or hyperpigmentation that can be difficult to appreciate because the vulva normally is pink or dusky (eFig. 78-3.1 in online edition). Lichenification and scale, when present, make diagnosis easier. Pruritus can be intense.

Figure 78-3 Patchy erythema, superficial desquamation, and small erosions are often seen with an irritant contact dermatitis such as this eruption caused by benzocaine and resorcinol.

Although the British have found allergic contact dermatitis to be a common finding on the vulva, American physicians report few relevant positive results on patch tests for patients with eczematous vulvar skin.[8–11]

Nevertheless, women with refractory vulvar symptoms should be evaluated clinically and a thorough history taken to identify allergic contact dermatitis. In acute allergic contact dermatitis of the genital area, vesicles erode as quickly as they form, producing painful exudative erosions and plaques. Chronic allergic contact dermatitis is manifested more often by mild erythema and subtle edema. Notable scale is infrequent. Scratching in more severe and chronic cases induces lichenification. Common allergens include diphenhydramine, neomycin, polymyxin, sulfonamides, benzocaine, some antifungal creams, spermicides, glucocorticoids, some antiseptics, fragrances, and preservatives (see Chapter 13). As can occur with eyelid dermatitis, allergens can be carried inadvertently from fingertips to the vulva during the course of scratching or wiping. In addition, the habits of sexual partners can be important (consort dermatitis).

The therapy for vulvar contact dermatitis is the same as for this disease occurring in other areas and hinges most importantly on avoidance of irritants and allergens. Irritant, and to a lesser extent allergic, contact dermatitis can be a complicating factor in most vulvar conditions.[12] It can also obscure underlying disease. Women with chronic symptoms often are well served by discontinuing all topical therapies (eFigs. 78-3.2 and 78-3.3 in online edition). For a severe or extensive eruption, use systemic steroids, avoiding topicals except for a bland emollient like petrolatum. Be sure to stop all offending hygiene practices and control secondary infection and pruritus. For a mild-to-moderate eruption a Class II–IV topical steroid ointment applied twice daily can hasten improvement. Reevaluation 1 or 2 weeks later may reveal an underlying primary process.

PSORIASIS

(See Chapter 18)

Vulvar psoriasis is too often missed. Women are embarrassed to mention it to their dermatologist. They show it to the gynecologist, unfamiliar with skin conditions, who cannot help with recognition and management. Dermatologists need to ask female psoriatics if they have genital rashes. Although vulvar psoriasis generally is accompanied by psoriasis in other typical locations, the vulva is a common site of Koebnerization. Vulvar psoriasis usually affects only fully keratinized skin, sparing the modified mucous membrane of the inner labia majora and the labia minora. Vulvar psoriasis typically exhibits dusky red, well-demarcated plaques. Rather than thick, silvery scale, the moistness of inverse psoriasis or a glazed, shiny surface texture is seen (Fig. 78-4, eFigs. 78-4.1–78-4.3 in online edition).

Genital psoriasis often responds well to topical therapy. A mid- or high-potency glucocorticoid ointment generally is required for significant clinical or symp-

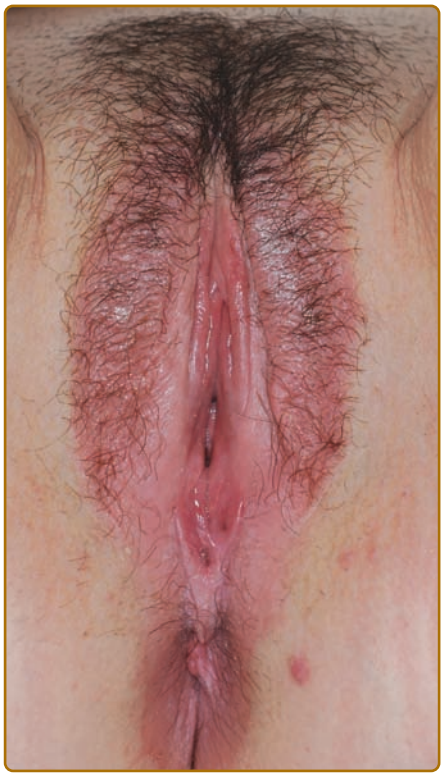

Figure 78-4 Psoriasis of the vulva with symmetrical, papulosquamous, scaling, and erythema typically seen on the hairy area of the labia majora with a thin pink plaque extending to the perianal area.

tomatic improvement. Calcipotriene ointment, tacrolimus ointment, or pimecrolimus cream can be tried as well, but some patients find these too irritating. For extensive psoriasis, methotrexate, oral retinoids, cyclosporine, or the newer biologics are required.

LICHEN SCLEROSUS AT A GLANCE

- Inflammatory condition of the vulva occurring at any age.
- Most symptomatic in childhood and postmenopausal years (low estrogen levels).
- Cellophane paper-like texture to the white plaques classically.
- Chronic, long-term disease leads to scarring and resorption.
- Chronic active disease increases risk of vulvar squamous cell carcinoma.
- Treatment is with superpotent steroid (clobetasol propionate) ointment.
- Maintenance therapy is needed for long-term control.

LICHEN SCLEROSUS

(See Chapter 65)

Lichen sclerosus is the commonest cause of chronic vulvar dermatosis. The prevalence is 1:300–1:1,000. The onset is bimodal in premenarchal girls and perimenopausal women.

CLINICAL FINDINGS. Lichen sclerosus begins asymptomatically in most patients. Women often tolerate their disease comfortably until they develop a superimposed complicating event, such as candidiasis or atrophic vaginitis that produces itching, followed by scratching, and the process becomes self-perpetuating. At presentation, the most common symptom of lichen sclerosus is pruritus (mild or severe). Because vulvar skin affected by lichen sclerosus is fragile, scratching often produces painful erosions. Many women, by the time they come for treatment, exhibit late signs of lichen sclerosus, including remarkable textural changes and scarring with loss of normal vulvar architecture. Scarring and narrowing of the introitus may make intercourse painful, even intolerable.

Lichen sclerosus begins with white papules or plaques that often occur first on the anterior vulva and periclitorally. Although these papules and plaques are sometimes smooth and somewhat waxy, especially when they occur on moist skin, the classic presentation is one of a hypopigmented, well-demarcated plaque with a shiny, crinkled cellophane-like surface

Figure 78-5 Hypopigmentation, crinkled texture, and purpura are classically seen in lichen sclerosus.

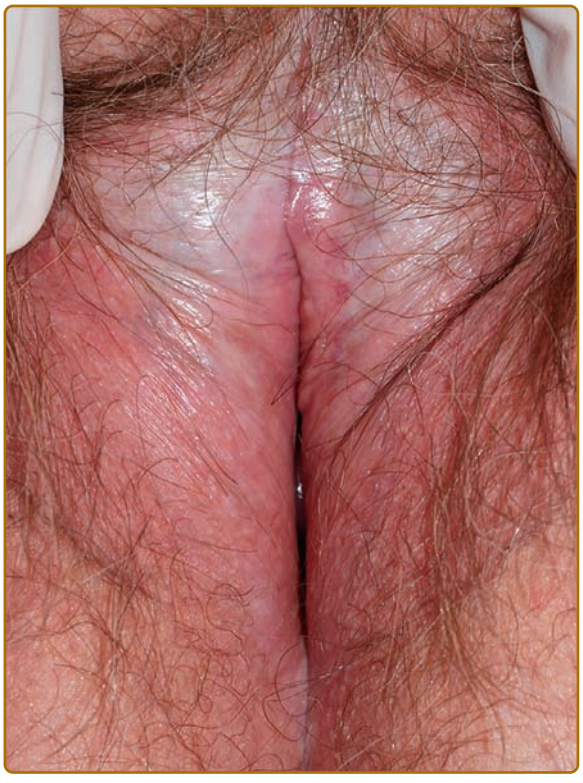

Figure 78-6 Occasionally, the texture of lichen sclerosus can be waxy or even thin and smooth, as seen here, rather than crinkled. The loss of labia minora and midline agglutination of the clitoral hood are also seen commonly in late lichen sclerosus.

(Fig. 78-5 and eFigs. 78-5.1–78-5.4 in online edition). Generally, the skin is quite thin and fragile, with erosions and purpura being common manifestations. Some women, particularly those who experience intolerable itchiness, exhibit thickened hyperkeratotic skin with extensive secondary changes, including fissuring, crusting, and even bleeding (eFig. 78-5.5 in online edition). Many patients with lichen sclerosus experience progressive scarring (eFig. 78-5.6 in online edition). Resorption of the labia minora and scarring of the clitoral hood, which buries the clitoris, are common in long-standing disease (Fig. 78-6). Extragenital lichen sclerosus of keratinized skin occurs in a minority of women with vulvar lichen sclerosus and is most often located on the upper trunk and arms (see Chapter 65). Usually, extragenital lesions are asymptomatic.

An association of lichen sclerosus with circulating autoantibodies has been reported, but the only association with autoimmune disease sufficient to justify laboratory testing is with hypothyroidism.[13]

DIFFERENTIAL DIAGNOSIS.

Fully developed lichen sclerosus with hypopigmentation and distinctive shiny or crinkled textural changes is easily recognized. Unfortunately, lichen sclerosus is sometimes subtle or mimics other diseases (Box 78-3).

COMPLICATIONS.

Sexual dysfunction results from scarring and introital narrowing. Four to five percent of patients are reported to develop squamous cell carcinoma in the natural course of lichen sclerosus.[4,15] Squamous cell carcinomas occurred primarily in patients with chronic hyperkeratosis or erosions. With effective topical therapy, this risk is understood to be lower.

BOX 78-3 DIFFERENTIAL DIAGNOSIS OF LICHEN SCLEROSUS OF THE VULVA

Most Likely
- Lichen simplex chronicus
- Lichen planus
- Vitiligo

Consider
- Immunobullous disease
- Contact dermatitis

Always Rule Out
- Squamous cell carcinoma

TREATMENT.

Although topical glucocorticoids reduce symptoms, they do not always normalize the skin texture or prevent scarring. The application of a superpotent topical preparation once or twice a day alleviates symptoms within a few days, but several months of therapy is required for resolution of the clinical findings.[14,15]

Most patients require 3–5 months of once- or twice-daily application to achieve maximal improvement. Patients should be followed monthly during periods of daily treatment to monitor the skin for steroid side effects and for improvement so that the frequency of application can be decreased.[16] As an adjunct therapy for the first week or two to control scratching and hasten healing, sedating dosages of an antihistamine or a tricyclic antidepressant are helpful. Any infection must be controlled.

Lichen sclerosus usually is not eliminated permanently by therapy. One survey showed an 84% recurrence rate among patients off therapy.[17] Despite the frequent requirement for long-term maintenance therapy, however, there is no proven optimal schedule. Most patients do well with two to three carefully localized weekly applications of a superpotent glucocorticoid on an ongoing basis.

No other treatments for lichen sclerosus produce the striking and prompt benefit of a topical superpotent glucocorticoid. Intralesional triamcinolone is used in resistant areas. In addition, other medical therapies generally have shown benefit only in open-label series. Tacrolimus and pimecrolimus (see Chapter 221) have been reported effective.[18]

Beneficial effects have also been described historically with topical testosterone, progesterone, and estrogen, but the benefit is minimal and equivalent to that of vehicle or lubrication alone.[19–21]

Topical tretinoin 0.025% and calcipotriol sometimes produce improvement, but their usefulness is limited because they can cause irritation.[22,23]

Oral retinoids have been reported to be helpful for some.[24] The Chinese literature abounds with reports of benefit from traditional Chinese herbs and acupuncture for lichen sclerosus.[25]

Surgical therapies, including cryotherapy, vulvectomy, carbon dioxide laser vaporization, pulsed dye laser therapy, and photodynamic therapy have been advocated for the treatment of lichen sclerosus.[26–30]

VULVAR FISSURES

Small, linear fissures on the vulva are common causes of itching, stinging, and dyspareunia.[31] Sometimes these fissures present clinically as painful, erythematous lines in skin folds and at other times they present as obvious linear erosions.

Most well recognized are fissures at the posterior fourchette that split during intercourse (Fig. 78-7 and eFig. 78-7.1 in online edition). These produce tearing pain initially, followed by burning and stinging when alkaline semen touches the area. The skin heals quickly, but splits recur with intercourse. The cause is unknown. The condition usually occurs suddenly, after years of comfortable coitus. Adequate lubrication and positioning of the woman on top can minimize tearing. Otherwise, surgical excision (perineoplasty) is required, with the vertical fissure excised and the skin closed front to back with advancement of the vaginal mucosa to cover the area.[32]

Recurrent fissuring within skin folds, especially in the interlabial sulci of the vulva, is a common cause of stinging and irritation of the vulva. Women typically complain of a sensation of "paper cuts." Intercourse and tight clothing are often precipitating events. Isolated acute fissuring is associated most often with *Candida* colonization or infection. Skin fold fissures can result from any inflammatory dermatosis, including psoriasis, lichen sclerosus, and lichen simplex chronicus. When one of these factors is identified, treatment is directed toward its correction. When no specific underlying cause is found, a topical glucocorticoid ointment combined with an oral antibiotic and anticandidal medication often eliminates the fissuring. However, almost immediate recurrence is common, and prolonged therapy may be required to break the cycle.

Figure 78-7 Recurrent fissuring of the posterior fourchette with intercourse is a commonly recognized phenomenon of unknown cause that often requires perineoplasty, a type of excisional surgery.

BULLOUS AND EROSIVE DISEASES

LICHEN PLANUS

(See Chapter 26)

Vulvovaginal lichen planus is much less common than vulvar lichen sclerosus with a likely prevalence of 1 in 2,500–4,500. It is often misdiagnosed as lichen sclerosus.[33]

CLINICAL FINDINGS. Vulvovaginal lichen planus has a wide variety of clinical manifestations. Erosive vulvovaginal lichen planus is most common and is generally very symptomatic. It presents with burning, rawness, and dyspareunia with variable itching. Nonerosive lichen planus of the vulva may appear bland with mainly itching and irritation, but it can be very symptomatic and be accompanied by serious accompanying erosive vaginal disease. Irritating inflammatory vaginal secretions can produce symptoms of introital burning and stinging. Disease may be restricted to the vagina with no vulvar manifestations. Rectal and perianal disease is common and often produces pain.

White, lacy, reticulate striae resembling papular oral lichen planus sometimes occur on the modified mucous membranes of the vulva (Fig. 78-8 and eFig. 78-8.1 in online edition). Less easily recognized are solid, uniformly hypopigmented, flat white plaques that mimic lichen sclerosus except for the absence of crinkled cellophane paper-like texture (eFig. 78-8.2 in online edition). Erosive lichen planus is manifested by a glazed erythema and variable red, painful erosions that are either nonspecific or surrounded by typical white, often scalloped, epithelial changes (eFigs. 78-8.3 and 78-8.4 in online edition). Erosive vulvovaginal lichen planus is often accompanied by erosive buccal and gingival oral disease.[34,35]

Lichen planus, especially when erosive, produces remarkable scarring (eFig. 78-8.5 in online edition). Resorption of the labia minora and obliteration of the clitoris under an agglutinated clitoral hood are very common. Narrowing of the introitus occurs more often and more severely than with lichen sclerosus, and vaginal adhesions can close the vagina, preventing both intercourse and introduction of a speculum (eFig. 78-8.6 in online edition).

Vaginal erosions are often obvious, appearing as bright red, often raw, patches, but sometimes equally painful disease can be subtle and show only mild erythema on a speculum examination. Scarring may vary from a minor synechia, slight narrowing or vaginal

Figure 78-8 Although these white, well demarcated linear papules are typical for papular lichen planus, they are often accompanied by nearby erosive disease.

shortening to vaginal obliteration. Vaginal discharge can be light to heavy and bloody. An examination of vaginal smears is a sensitive test for the presence of vaginal inflammation. Large, flat, cuboidal, mature desquamated vaginal epithelial cells are replaced by smaller, rounded basal cells shed from erosions and rapidly proliferative inflamed vaginal epithelium and sheets of leukocytes are seen. Up to 77% of patients with oral lichen planus have vulvovaginal lichen planus, but are often unaware and should be examined for asymptomatic involvement.[36,37]

The diagnosis of lichen planus is made either by biopsy or by the identification of classic lacy lesions in association with other typical mucous membrane lesions. Biopsies are often nonspecific and a negative biopsy does not rule out this diagnosis.

DIFFERENTIAL DIAGNOSIS.

When lichen planus presents classically and involves oral and genital mucosa, it is easy to diagnose. Unfortunately, lichen planus on the vulva alone can be indistinguishable from other diseases (Box 78-4).

COMPLICATIONS.

The inflammation, pain, and scarring commonly cause sexual dysfunction, and at times, anger and depression. Vulvar squamous cell carcinoma has been well described in patients with erosive genital lichen planus. The magnitude of this risk is not known, but patients should be evaluated for this condition regularly.

BOX 78-4 DIFFERENTIAL DIAGNOSIS OF VULVAR LICHEN PLANUS

Most Likely
- Lichen sclerosus
- Immunobullous disease
- Stevens–Johnson syndrome

Consider
- Fixed drug eruption
- Contact dermatitis

Always Rule Out
- Squamous cell carcinoma

TREATMENT.

The aggressive treatment of vaginal lichen planus is crucial for patient comfort. Meticulous local care with early treatment of infection, minimization of external irritants, and attention to any underlying atrophy of estrogen deficiency are important measures. A vaginal dilator should be used daily to prevent adhesions of the vaginal walls. Emotional support and careful patient education regarding the nature of the disease, its prognosis, and its therapy are vital.

Pruritic, noneroded vulvar lichen planus is usually quite well managed simply by the application of a potent topical glucocorticoid ointment. Severe erosive vulvovaginal lichen planus can present a difficult therapeutic problem. A superpotent glucocorticoid ointment applied to the vulva is standard first-line therapy. For mild-to-moderate disease, a gram of the glucocorticoid ointment can be inserted into the vagina as well, or hydrocortisone acetate 25 mg rectal suppositories can be inserted nightly into the vagina.[38]

For severe disease, use a compounded 100-mg/g hydrocortisone acetate vaginal cream, 3–5 g nightly for 2 weeks, decreasing to three times a week as maintenance. Systemic steroids are also used and the least toxic is deep intramuscular triamcinolone 1 mg/kg up to 80 mg/dose. This may be repeated monthly for 3 months and limited to four doses per year (personal experience). Patients are warned about adrenal suppression and given fluconazole 150 mg weekly to prevent candidiasis. Any patient with vulvar disease receiving an intravaginal glucocorticoid should be told of her increased risk for yeast infection. There is little tendency for erosive vulvovaginal lichen planus to remit, but it can be well controlled. The severity tends to wax and wane, sometimes as a result of secondary infections, exposure to irritants, or stress but more often for no identifiable cause. Bursts of oral predniso(lo)ne or intramuscular triamcinolone can be helpful for flares.

Topical tacrolimus and pimecrolimus have been reported to be useful in the treatment of vulvar lichen planus, but these medications are irritating.[39,40] They can be used as "steroid sparers" once the inflammation is controlled.

Other medications that have been reported primarily in open trials as useful for the treatment of erosive mucous membrane lichen planus include hydroxy-

chloroquine, methotrexate, retinoids, azathioprine, cyclophosphamide, mycophenolate mofetil, and thalidomide.[41–45]

ERYTHEMA MULTIFORME MAJOR, STEVENS–JOHNSON SYNDROME, AND TOXIC EPIDERMAL NECROLYSIS

(See Chapters 39 and 40)

Erythema multiforme major, Stevens–Johnson syndrome, and toxic epidermal necrolysis all lead to erosive vulvar disease. One retrospective survey of 40 women with toxic epidermal necrolysis revealed that 28 had vulvovaginal involvement with severe erosions, of whom five experienced permanent scarring.[46] These patients were unable to engage in intercourse, even after corrective surgery. Local care during the serious phase of the illness can prevent long-term dysfunction due to scarring. Prompt treatment of secondary bacterial or *Candida* infection may be important. In addition, daily insertion of a vaginal dilator (such as an inexpensive syringe cover) is important to ensure patency.

CICATRICIAL PEMPHIGOID

(See Chapter 57)

Cicatricial pemphigoid regularly produces multiple mucosal erosions. The nonspecific, painful erosions of the vulva and surrounding epithelium can be clinically indistinguishable from lichen planus and lichen sclerosus. Vulvar erosions generally are accompanied by nonspecific vaginal erosions that can result in significant vaginal scarring. Management consists of both local glucocorticoid therapy and systemic treatments.[47] Vaginal treatment is the same as for erosive vaginal lichen planus. Again, local care, the use of vaginal dilators, and secondary infection control are important factors in management.

PEMPHIGUS VULGARIS

(See Chapter 54)

Pemphigus vulgaris often presents with mucosal erosions on the vulva. Although pemphigus vulgaris is usually considered to be a nonscarring disease, vulvovaginal involvement can lead to scarring, with vaginal adhesions and obliteration of vulvar architecture. As with cicatricial pemphigoid, a high index of suspicion and confirmatory biopsies are important in reaching the correct diagnosis. For treatment, see Chapter 54.

FIXED DRUG ERUPTION

(See Chapter 41)

Erosions due to fixed drug eruption sometimes occur on the vulva. Common offenders include acetaminophen, hydrochlorothiazide, nonsteroidal anti-inflammatory medications, oral contraceptives, sulfa drugs, penicillin, tetracyclines, allopurinol, barbiturates, and furosemide.[48,49] Lesions are most often located in the vestibule or on the modified mucous membranes of the labia minora or medial labia majora. Unlike the classic, round, edematous plaques or blisters seen on keratinized skin, the erosions of a fixed drug eruption on the vulva are often irregular, sometimes with a slightly shaggy border. Often there are one or a few typical lesions on keratinized skin, or there are oral erosions. The deepening hyperpigmentation seen on keratinized skin affected by recurrent fixed drug eruptions is usually absent on the modified mucous membranes of the vulva (Fig. 78-8.7 and eFig. 78-8.8 in online edition).

HERPES SIMPLEX

ULCERS

APHTHAE

(See Chapters 76 and 166)

Aphthae, "canker sores," common in the oral cavity, are often misdiagnosed on the vulva where they occur more frequently than the few literature reports would suggest. These are acute, painful ulcers that can be single or multiple (Fig. 78-9).

They typically affect girls 9–19 years of age and present with the sudden onset of painful, punched-out,

Figure 78-9 Aphthae of the vulva are characterized by large size, punched-out borders, and a white fibrin base as seen on the medial labium minus of this patient with concomitant vaginal candidiasis.

well-demarcated vulvar ulcers, usually less than a centimeter (range 0.5–5 cm). The ulcers are most often found on the vulvar trigone, the labia, and less frequently the lower vagina. Typically there is a prodrome with flu-like symptoms of mild fever, headache, and malaise. There may be a past history of oral aphthae. The ulcers last 1–3 weeks and resolve. Scarring is variable. Usually there is just one episode but these can recur. The pathogenesis probably involves the interaction of genetic factors with infection as a trigger. The hypothesis is that microbial antigens with molecular mimicry induce a reactive process directed at host antigens. Commonly the antigenic agent is unknown, but a number of cases have been associated with Epstein–Barr virus, a few cases with *Mycoplasma pneumoniae*, HIV, or cytomegalovirus[50–52] (eFig. 78-9.1 and 78-9.2 in online edition). The combination of recurrent oral plus genital ulcers is complex aphthosis.[53] This pattern is seen most commonly with inflammatory bowel disease, Crohn disease and ulcerative colitis and, less commonly with, celiac disease. It also can occur infrequently with medications, myeloproliferative diseases, neutropenia, lymphopenia, and some rare syndromes like FAPA syndrome (fever, aphthae, pharyngitis, and adenitis). Rarely, in North America, these ulcers are associated with Behçet's disease. This is a frequent association in the Middle East.

Diagnosis is one of exclusion. Biopsies are often taken but are usually nonspecific. For acute ulcers, test for Herpes simplex, sexually transmitted diseases including HIV, Epstein–Barr virus, and *Mycoplasma*. For chronic recurrent ulcers investigate for inflammatory bowel disease and the less common causes above. The differential diagnosis includes herpes simplex, other sexually transmitted infections (syphilis, chancroid), and pyoderma gangrenosum.

A short course of prednisone is best for acute disease. For recurrent aphthae, colchicine, dapsone, colchicine combined with dapsone, cyclosporine, and thalidomide have been used.[53]

CROHN DISEASE

(See Chapter 150)

Crohn disease is a noninfectious granulomatous inflammatory disorder that primarily involves the bowel, but vulvar and perianal skin are sometimes affected. Vulvar involvement is underrecognized and misdiagnosed.[54] Only 55 cases are reported in the literature, but most vulvar specialists have managed vulvar Crohn cases.

The average age is 34 years. Metastatic spread is the most common presentation (91%). Symptoms include swelling (62%) and pain (20%). Examination usually shows swelling and induration in the labia majora with or without ulcers that extend to the groin. The ulcers occur in 41% and can be the classic "knife-cut" type in the skin folds, aphthous ulcers, or both[55] (Fig. 78-10 and eFigs. 78-10.1–78-10.3 in online edition).

The diagnosis is made on the basis of biopsy results and identification of the bowel disease, but 25% of vulvar Crohn disease patients have no gastrointestinal symptoms. The primary disease to be differentiated from anogenital Crohn disease is hidradenitis suppurativa (see Section "Hidradenitis Suppurativa"), which is said to coexist in 17% of cases of Crohn disease. Other diseases to rule out are sarcoidosis, tuberculosis, lymphogranuloma venereum, and atypical pyogenic infections. Treatment is with systemic therapy for the underlying intestinal Crohn disease.[56,57]

Figure 78-10 Diffuse firm vulvar edema is a common presentation of Crohn disease.

Topical and intralesional glucocorticoids and local care can help to induce healing of ulcerations.

SYPHILIS

(See Chapter 200)

CHANCROID

(See Chapter 202)

OTHER ULCERATIONS IN SEXUALLY TRANSMITTED DISEASES

(See Chapters 203 and 204)

ABSCESSES

Abscesses occur in Crohn disease (see Section "Crohn Disease"), gonorrhea (see Chapter 205), hidradenitis suppurativa (see Section "Hidradenitis Suppurativa"), and Bartholin gland (see below).

BARTHOLIN'S CYST AND ABSCESSES

The Bartholin's glands are the largest of the vulvar vestibular glands. They secrete mucus-like material for

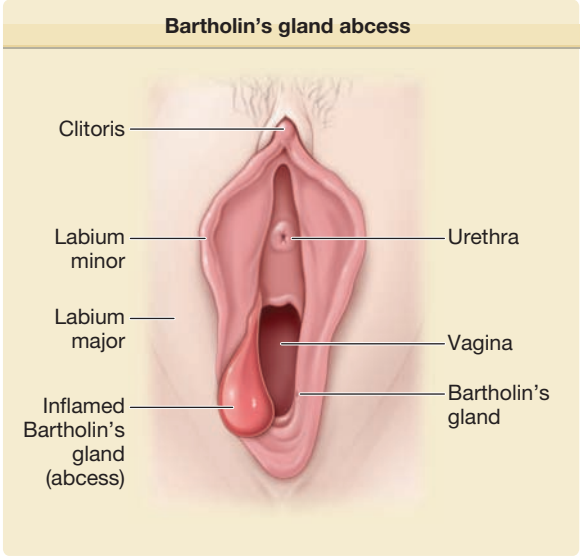

Figure 78-11 Bartholin's gland abscess. This schematic drawing shows the exact location of Bartholin's gland and abscess. (Used with permission from Petra Kohlberger, MD.)

lubrication during sexual activity. Cysts form due to occlusion of the opening ducts. They are located on the lower labia minora at 5 and 7 o'clock just lateral to the hymenal ring. Cysts can range from 1–3 cm in size and are often asymptomatic.[58]

Diagnosis is clinical with the typical nodule of varying size lying in the posterior vestibule with the labium minus classically "transecting" the cyst (Fig. 78-11). No treatment is necessary for asymptomatic Bartholin's cysts unless the patient is over 40 and there is concern about carcinoma.

Bartholin's duct abscesses develop as an infected obstruction of the Bartholin's duct. Infection is typically from *Escherichia coli*, *Staphylococcus*, or *Streptococcus*.[59,60] Occasionally, it is a sexually transmitted infection. Patients present with severe pain and swelling and sometimes an inability to sit or walk. The cyst is warm, swollen, and tender with a varying degree of surrounding edema and erythema. Treatment is with incision and drainage and for complicated infections appropriate antibiotics. Recurrent lesions require specific surgery.

HIDRADENITIS SUPPURATIVA

(See Chapter 85)

Hidradenitis suppurativa is a chronic, inflammatory, recurrent, debilitating, follicular disorder predisposed to involve intertriginous areas.[61–64] It presents with painful, deep seated, inflamed lesions, note that the newest classification makes no mention of apocrine gland involvement.

The Second International Hidradenitis Suppurativa Research Symposium (San Francisco; March, 2009) adopted the following diagnostic criteria that must be met to establish the diagnosis:

1. Typical lesions—i.e., deep-seated painful nodules: blind boils in early lesions; abscesses, draining sinuses, scars, and "tombstone" open comedones in secondary lesions.
2. Typical topography—i.e., axillary, groin, perineal and perianal lesion, buttocks, infra and intermammary folds.
3. Chronicity and recurrence.

Most commonly the axillary, inguinal, inframammary, and anogenital regions. This disease is more common in women than men, with a ratio of 3.3 to 1 and affects 1% of the general population. It is frequently misdiagnosed as "boils," delaying diagnosis, and leading to fragmented care and progression to a chronic, disabling condition that has a profoundly negative impact on quality of life.[62] Onset is usually in a woman's twenties with remission after menopause. The course varies from intermittent and benign to continuous and severe.

In women these "boils" present classically in the groin and around the hair-bearing areas of the vulva, less often on the modified mucous membranes, but commonly in the axillae and under the breasts (Fig. 78-12).

The nodules can be extremely painful nodules and very debilitating. Rupture and drainage of malodorous purulent material can be very distressing. Lesions vary from a few acneform nodules that last 7–15 days to persistent chronic hypertrophic scars, with dense fibrosis forming linear rope-like bands with varying degrees of drainage from interconnecting sinuses. In more severe cases, hidradenitis suppurativa results in chronic erosions from draining ulcerations and lymphedema from lymphatic obstruction. It can be difficult to differentiate from Crohn disease and they can coexist.[65]

The Second International Hidradenitis Suppurativa Research Symposium (San Francisco; March, 2009) adopted the following diagnostic criteria that must be met to establish the diagnosis:

Figure 78-12 Hidradenitis suppurativa (Hurley's Stage III) of the vulva with chronic interconnecting draining sinuses, painful swelling and discharge for years.

1. Typical lesions—i.e., deep-seated painful nodules: blind boils in early lesions; abscesses, draining sinuses, scars, and "tombstone" open comedones in secondary lesions.
2. Typical topography—i.e., axillary, groin, perineal and perianal lesion, buttocks, infra and intermammary folds.
3. Chronicity and recurrence.

Treatment depends on severity, using the Hurley classification.[66]

At all stages, if appropriate, androgen blockade with nonandrogenic birth control pills, spironolactone, and/or finasteride are used.[67] Smoking must cease. All friction or trauma to the areas of involvement must be avoided. Oral zinc has been used as an anti-inflammatory.[68]

STAGE I (ABSCESS FORMATION WITHOUT SINUS TRACTS). Treatment is aimed at reducing flares using topical clindamycin lotion, courses of antibiotics for 7–10 days (tetracycline, doxycycline, clindamycin), oral zinc gluconate, and intralesional triamcinolone or a short oral course of predniso(lo)ne. Low-dose isotretinoin is useful in a minority of cases.[69]

STAGE II (RECURRENT ABSCESSES WITH SINUS TRACTS AND SCARRING, SINGLE OR MULTIPLE WIDELY SEPARATED LESIONS). (eFig. 78-12.1 in online edition). Management requires the above medical therapy as baseline plus surgical treatment to reduce activity to Stage I and also to prepare for wide unroofing of sinuses and persistent cysts. Antibiotics such as the tetracyclines or clindamycin and rifampicin are used in combination for 3 months.[70,71] At times dapsone may be helpful. Intralesional triamcinolone and short courses of predniso(lo)ne are used to quickly control swelling and inflammation.

STAGE III (DIFFUSE OR EXTENSIVE INVOLVEMENT, OR MULTIPLE INTERCONNECTING TRACTS AND ABSCESSES ACROSS THE ENTIRE AREA). This is a surgical disease. Medical treatment is essential in preparation for surgery.[72] Anti-inflammatories may be necessary. The biologics can provide dramatic preoperative improvement but are not a cure.[73,74]

Surgical management need not be heroic and widely ablative in Stage II and early Stage III. The preferred technique is to unroof the sinuses as early as possible, to include a thorough exploration and exposure of any secondary sinuses and cysts, and then eradicate to the extent possible inflammatory masses responsible for perpetuating the lateral extension of lesions.[75,76]

VULVODYNIA

Vulvodynia is chronic vulvar pain *with no identifiable cause*. Vulvar pain is a challenging problem for caregivers and, too often, a very difficult problem for women. Pain can seriously impact their lives, affecting not only their sexuality but also their daily activities, even what they can wear. Vulvar pain and vulvodynia have been defined and classified by the International Society for the Study of Vulvovaginal Disease.[77] (Box 78-5). Vulvodynia is defined as vulvar pain in the absence of relevant, visible physical findings or a specific clinically identifiable neurological disorder. All vulvar pain conditions due to specific disorders, infections, inflammatory disorders, neoplastic conditions, or neurological conditions must be excluded.[78–80]

Vulvodynia is divided into localized (formerly vulvar vestibulitis) (eFig. 78-12.2 in online edition) and generalized (formerly dysesthetic vulvodynia). Both of these groups can be further divided into those who experience provoked (brought on by touch), unprovoked (spontaneous), or mixed (both provoked and unprovoked) pain. Localized vulvodynia can be primary as in pain present with first tampon use or vaginal entry, or secondary, as in acquired after some years of no pain on touching/vaginal entry.

BOX 78-5 CLASSIFICATION OF VULVAR PAIN

SECONDARY VULVAR PAIN (RELATED TO A SPECIFIC DISORDER)

1. Infectious, e.g., candidiasis
2. Inflammatory, e.g., erosive lichen planus
3. Neoplastic, e.g., squamous cell carcinoma
4. Neurologic, e.g., postherpetic neuralgia

PRIMARY VULVAR PAIN (WITHOUT VISIBLE LESIONS)

1. Localized vulvodynia (formerly vulvar vestibulitis)
2. Generalized (formerly dysesthetic or essential vulvodynia)

EPIDEMIOLOGY

Unexplained vulvar pain is highly prevalent among women of reproductive age with lifetime prevalence estimates ranging from 16%–28%. The prevalence of true vulvodynia is unknown because careful clinical evaluation is required for a definitive diagnosis.[3,81,82] Localized provoked vulvodynia usually affects younger women and is more common than generalized vulvodynia.[83]

ETIOLOGY AND PATHOGENESIS

The etiology of vulvodynia is unclear. It is likely multifactorial with both organic and functional components. Etiological factors being studied range from neuropathic mechanisms, neural hyperplasia, neurogenic inflammation, abnormal nociception, and neurotransmitter and neuropeptides anomalies, to pelvic floor muscle dysfunction. There are localized processes in the vulva that can trigger pain and changes centrally

in the dorsal root ganglia and in the brain, changes that keep the pain active. The result is abnormal pain perception so that light touch causes pain (allodynia).

More work has been done on localized vulvodynia. Patients are overly sensitive to pain and cannot downregulate it. They have increased nerve fibers, inflammatory cells, and mediators in the vulvar vestibule along with a poor ability to modify pain. The pelvic floor muscles are dysfunctional, tight, and weak, and play an important role in causation or perpetuation (and are not just a consequence) of vulvodynia. Underlying psychosexual issues or personality traits, such as somatization disorder, can be important.[84] Depression and anxiety have been reported. These patients may have other comorbid hypersensitivity syndromes with centralized pain such as migraines, irritable bowel syndrome, and fibromyalgia.[85,86] Very few studies have looked at generalized vulvodynia, and it may represent pudendal neuralgia or a regional pain syndrome.

CLINICAL FINDINGS

Patients with localized vulvodynia are usually between the ages of 20–50. Typically there is pain on touch or attempted vaginal entry (referred to as provoked pain). This may be with the first use of a tampon or sexual intercourse (primary vulvodynia) or after years of no discomfort (secondary vulvodynia). The patient complains of burning, stinging, irritation, or a raw sensation at the vaginal entrance (hymenal ring area).[87–89] The pain can be moderate-to-severe. Sexual intercourse is difficult to impossible. They may complain of constant vaginal infections despite negative tests or that their partner is too big. They are often distressed, anxious, and/or depressed. Patients with generalized vulvodynia, usually over 40 years old, have constant or episodic vulvar pain. They complain of burning, soreness, rawness, stabbing pain, irritation, aching, or stinging, but they usually can have sexual intercourse. They are hyperaware of their genital area. They often complain of "constant yeast." These patients have often seen many caregivers, had multiple incorrect diagnoses, and tried many treatments.

On examination there is no visible abnormality. The pelvic floor muscles may be tight and sensitive. Q-tip sensitivity (see below) may be prominent in localized vulvodynia.

DIFFERENTIAL DIAGNOSIS

The diagnosis of vulvodynia is one of exclusion. The diagnosis of localized vulvodynia is made on history and the demonstration of pain on Q-tip touching around the hymenal ring. Patients with vulvodynia should be examined carefully for any underlying skin disease, infection, neoplasm, or well-defined neurologic disorder. Irritant contact dermatitis, vulvar fissures, and lichen planus are the most common skin diseases to be mistaken for vulvodynia. Painful vaginitis from nonalbicans *Candida* infection or a noninfectious inflammatory vaginitis (desquamative inflammatory vaginitis) can be confused with vulvodynia. Desquamative inflammatory vaginitis is manifested by grossly and microscopically purulent vaginal secretions and immature epithelial cells similar to those seen in lichen planus. Nonalbicans *Candida* infections, such as *C. glabrata*, *C. krusei*, and *Saccharomyces cerevisiae* infection also can cause chronic vulvovaginal pain. These infections are easily missed unless a culture is performed, and they can be resistant to therapy. Finally, neurologic disorders such as postherpetic neuralgia, pudendal nerve entrapment, pudendal neuralgia, and spinal compression need to be addressed through history and imaging studies when appropriate.

TREATMENT

Vulvodynia is complex, and with multiple possible contributing factors many medical/surgical, psychological, and alternate approaches have been used. The different aspects of vulvodynia therapy are ideally addressed simultaneously using a multidisciplinary approach.

Education and support are vital. There are excellent resources through the National Vulvodynia Association (http://www.nva.org).

All irritating hygiene practices must stop. Good education here is needed to avoid laundry detergents, cleansers, pads, ill-fitting clothing, etc., that could cause local harm. Activities that hurt, like bike riding, must stop. Sexual intercourse should be avoided when there is pain.

For topical pain control lidocaine 5% ointment has decreased pain up to 50%. Topical 6% compounded gabapentin cream has been helpful for over 50% of generalized vulvodynia patients. Topical estradiol cream has been used for cases of localized vulvodynia. Other local treatments with a few reports include topical capsaicin, and local injections (as pain blocks) using lidocaine with methylprednisolone.

Systemic medications are often used as pain modulators. Tricyclic antidepressants such as amitriptyline or desipramine, beginning at very low dosages and increasing up to 150 mg or until the patient is comfortable, are first-line.[90] For women who do not tolerate tricyclic antidepressants or who experience suboptimal improvement, gabapentin has been used.[91] The newer antidepressants venlafaxine and duloxetine have been used effectively as well. Pregabalin provides yet another possible option. Combinations of these medications can be used.

Pelvic floor dysfunction needs to be addressed with the help of a pelvic floor physiotherapist who can also assess the back and hips to make sure no other confounding biomechanical problems are present. Treatments to normalize pelvic floor function include myofascial release, trigger-point pressure, biofeedback, vaginal dilation, and exercises.

Attention to depression and sexual dysfunction is mandatory. Most patients benefit from referral for counseling to help them cope with their debilitating symptoms. Behavior and cognitive-behavior therapy

can reduce the fear of pain and improve sexual functioning with good results.

For localized vulvodynia, surgical vestibulectomy has been successful in over 60% of cases. It is best for secondary vulvodynia, especially when combined with pelvic floor therapy. It is usually chosen only when conservative treatment fails.

For generalized vulvodynia with neuralgia, management in a pain clinic using nerve blocks and interventional devices (sacral nerve root stimulators) may be needed.

However, improvement is usually slow and trial-and-error therapy with support by the physician is required.[85,86,83,92,93]

PRURITUS VULVAE

Pruritus vulvae is common, affecting perhaps 10% of women. It can be acute or chronic, minor, or debilitating. The most common cause is candidiasis. Irritant contact dermatitis is next, due to overwashing and topical irritants, particularly urine, feces, and sweat, as well as various topical medications.

The commonest chronic vulvar conditions are lichen simplex chronicus and lichen sclerosus and, less frequently, lichen planus and psoriasis. Often there is a combination of infection, contact dermatitis, and one or more dermatoses. Rarely the problem is due to a neuropathy or underlying malignancy. Investigation and treatment is directed at the individual causes. It is always important to eliminate all irritants and control infection. Sedation to stop scratching is often imperative. Topical or at times systemic corticosteroids can be very effective for inflammation. The calcineurin inhibitors can be used as "steroid sparers."

There is a group of women in whom it is very difficult to pinpoint a cause for the itching. The majority of these have some degree of neuropathy with or without anxiety or depression. Treatment is with neurotropic agents as used for vulvodynia; anxiety andor depression must be addressed.[94–96]

Disorders of the Skin Appendages

PART 3

Disorders of the Sebaceous Glands

Chapter 79 :: Biology of Sebaceous Glands

:: Amanda M. Nelson & Diane M. Thiboutot

SEBACEOUS GLANDS AT A GLANCE

- Sebaceous glands are unilobular or multilobular structures that consist of acini connected to a common excretory duct and are usually associated with a hair follicle.
- Sebaceous glands vary considerably in size, even in the same individual and in the same anatomic area.
- The sebaceous glands exude lipids by disintegration of entire cells, a process known as *holocrine secretion*.
- Human sebum, as it leaves the sebaceous gland, contains squalene, cholesterol, cholesterol esters, wax esters, and triglycerides.
- Sebaceous glands are regulated by androgens and retinoids.
- Other factors, such as melanocortins, and peroxisome proliferator-activated receptors (PPARs), may regulate sebaceous gland activity as well.

ANATOMY OF THE SEBACEOUS GLAND

HISTOLOGY

Sebaceous glands are unilobular or multilobular structures that consist of acini connected to a common excretory duct, which is composed of stratified squamous epithelium. Sebaceous glands are composed of lipid-producing sebocytes and of keratinocytes that line the sebaceous ducts and are usually associated with a hair follicle. The periphery of the sebaceous gland is a basal cell layer composed of small, cuboidal, nucleated, highly mitotic sebocytes. Cells progress toward the middle of the gland and accumulate lipid droplets as they terminally differentiate. These fully differentiated sebocytes are full of lipid and lack all other cellular organelles (Fig. 79-1). Surrounding the glands are connective tissue capsules composed of collagen fibers that provide physical support.[1]

LOCATION

Sebaceous glands are associated with hair follicles all over the body. A sebaceous gland associated with a hair follicle is termed a *pilosebaceous unit*. The glands may also be found in certain nonhairy sites, including the

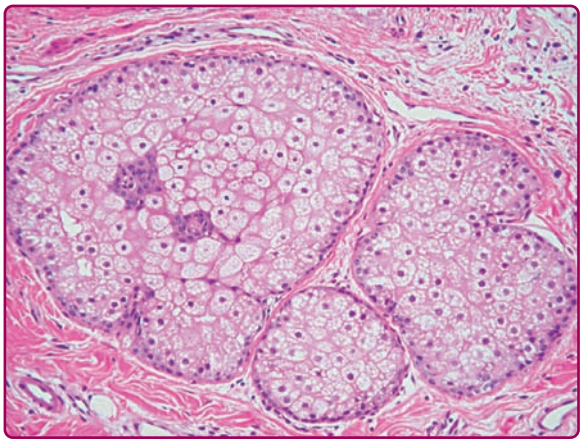

Figure 79-1 Hematoxylin and eosin-stained section of the human sebaceous gland showing its multilobular structure.

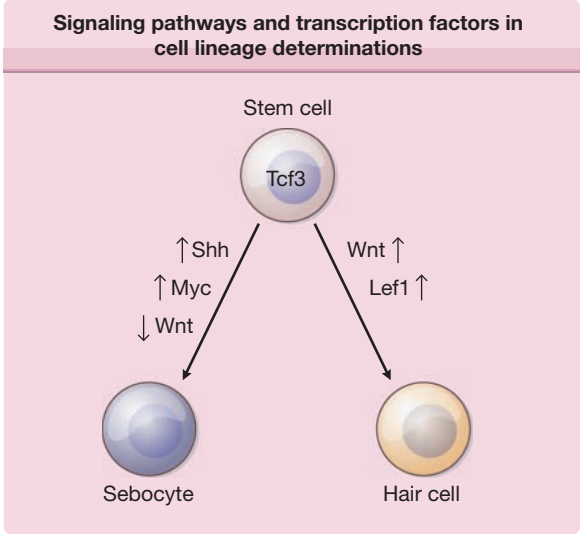

Figure 79-2 Signaling pathways and transcription factors that are involved in cell lineage determinations. As daughter cells migrate from the bulge region, changes in the expression patterns of numerous transcription factors determine their final cell lineage. Data is far from complete in this area; it is very likely that other pathways and transcription factors will play a significant role in determining each cell lineage. Lef1 = lymphoid enhancer binding factor 1; Myc = myelocytomatosis oncogene; Shh = Sonic Hedgehog; Tcf3 = transcription factor 3; Wnt = wingless (wg)/int.

eyelids (Meibomian glands), the nipples (Montgomery glands), and around the genitals (Tyson glands). Only the palms and soles, which have no hair follicles, are totally devoid of sebaceous glands. Sebaceous glands vary considerably in size, even within the same individual and within the same anatomic area. On the external body surface, most glands are only a fraction of a millimeter in size. The largest glands and greatest density of glands (up to 400–900 glands/cm^2) are located on the face and scalp.[1–3] The hairs associated with these large glands are often tiny, and it has been suggested that the total structures be more properly termed *sebaceous follicles* rather than hair follicles.

In the oral epithelium, sebaceous glands known as *Fordyce spots* are sometimes present. Fordyce spots are visible to the unaided eye because of their large size (up to 2–3 mm) and the transparency of the oral epithelium. In this location, the sebaceous ducts open directly to the surface.

EMBRYOGENESIS AND MORPHOGENESIS

In the human fetus, sebaceous glands develop in the 13th to 16th week of gestation from bulges (epithelial placodes) on the developing hair follicles. The bulge region of the follicle contains the epidermal stem cells that generate multiple cell lineages, including epidermal and follicular keratinocytes, as well as sebaceous glands. As daughter cells migrate from the bulge region, changes in the expression patterns of numerous transcription factors determine their final cell lineage. Wnt/wingless (Wnt) and Sonic Hedgehog (Shh) signaling pathways are intricately involved in embryonic patterning and cell fate decisions. Cells destined to become sebocytes have increased Shh and Myc signaling and decreased Wnt signaling (Fig. 79-2). In transgenic mouse models, intact Wnt signaling promotes hair follicle differentiation, whereas inhibition of Wnt signaling by preventing the Lef1/B-catenin interaction leads to sebocyte differentiation.[4] Loss-of-function and gain-of-function transgenic mouse models demonstrated that blocking Shh signaling inhibited normal sebocyte differentiation and constitutively activating Shh signaling increased the number and size of sebaceous glands in skin.[5] When fully formed, the glands remain attached to the hair follicles by a duct through which sebum flows into the follicular canal and eventually to the skin surface.

PHYSIOLOGY OF THE SEBACEOUS GLAND

HOLOCRINE SECRETION

The sebaceous glands exude lipids by disintegration of entire cells, a process known as *holocrine secretion*. The life span of a sebocyte from cell division to holocrine secretion is approximately 21–25 days.[6] Because of the constant state of renewal and secretion of the sebaceous gland, individual cells within the same gland are engaged in different metabolic activities dependent upon their differentiation state.[7] The stages of this process are evident in the histology of the gland.[8] The outermost cells, basal cell layer membrane, are small, nucleated, and devoid of lipid droplets. This layer contains the dividing cells that replenish the gland as cells are lost in the process of lipid excretion. As cells are displaced into the center of the gland, they begin to produce lipid, which accumulates in droplets. Eventually the cells become greatly distended with lipid droplets and the nuclei and other subcellular structures disappear. As the cells approach the sebaceous duct, they

disintegrate and release their contents. Only neutral lipids reach the skin surface. Proteins, nucleic acids, and the membrane phospholipids are digested and apparently recycled during the disintegration of the cells.

LIPID COMPOSITION OF SEBUM

Human sebum, as it leaves the sebaceous gland, contains squalene, cholesterol, cholesterol esters, wax esters, and triglycerides (Fig. 79-3). During passage of sebum through the hair canal, bacterial enzymes hydrolyze some of the triglycerides, so that the lipid mixture reaching the skin surface contains free fatty acids and small proportions of mono- and diglycerides, in addition to the original components. The wax esters and squalene distinguish sebum from the lipids of human internal organs, which contain no wax esters and little squalene. However, human sebaceous glands appear to be unable to cyclize squalene to sterols such as cholesterol. The patterns of unsaturation of the fatty acids in the triglycerides, wax esters, and cholesterol esters also distinguish human sebum from the lipids of other organs. The "normal" mammalian pathway of desaturation involves inserting a double bond between the ninth and tenth carbon of stearic acid (18:0) to form oleic acid (18:1Δ9). However, in human sebaceous glands, the predominant pattern is the insertion of a Δ6 double bond into palmitic acid (16:0). The resulting sapienic acid (16:1Δ6) (Fig. 79-3) is the major fatty acid of adult human sebum. Elongation of the chain by two carbons and insertion of another double bond gives sebaleic acid (18:2Δ5,8), a fatty acid thought to be unique to human sebum.[9]

Sebaceous fatty acids and alcohols are also distinguished by chain branching. Methyl branches can occur on the penultimate carbon of a fatty acid chain (iso branching), on the third from the last (antepenultimate) carbon (anteiso branching), or on any even-numbered carbon (internal branching). Examples of these unusual unsaturated and branched-chain moieties are included in the lipid structures in Fig. 79-3.

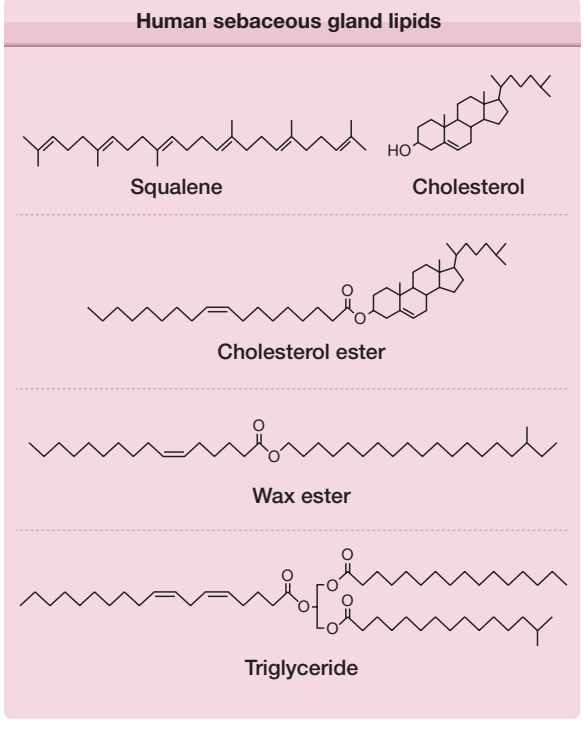

Figure 79-3 Human sebaceous gland lipids. The structures of the cholesterol ester, wax ester, and triglyceride are representative of the many species that are present. Two sebaceous-type unsaturated fatty acid moieties are shown: sapienic acid (16:1Δ6) (in the wax ester structure) and sebaleic acid (18:2Δ5,8) (in the triglyceride structure). Anteiso branching is shown in the alcohol moiety of the wax ester, and iso branching is shown in the triglyceride.

FUNCTION OF SEBUM

The precise function of sebum in humans is unknown. It has been proposed that its solitary role is to cause acne.[10] It has been suggested that sebum reduces water loss from the skin's surface and functions to keep skin soft and smooth, although evidence for these claims in humans is minimal; however, as demonstrated in the sebaceous gland-deficient (Asebia) mouse model, glycerol derived from triglyceride hydrolysis in sebum is critical for maintaining stratum corneum hydration.[11] Sebum has been shown to have mild antibacterial action, protecting the skin from infection by bacteria and fungi, because it contains immunoglobulin A, which is secreted from most exocrine glands.[12] Vitamin E delivery to the upper layers of the skin protects the skin and its surface lipids from oxidation. Thus, sebum flow to the surface of the skin may provide the transit mechanism necessary for vitamin E to function.[13]

INNATE IMMUNITY

Antimicrobial peptides, including cathelicidin, psoriasin, β-defensin 1, and β-defensin 2 are expressed within the sebaceous gland. Functional cathelicidin peptides have direct antimicrobrial activity against *Propionibacterium acnes*, but also initiate cytokine production and inflammation in the host organism.[14,15] In addition, free fatty acids in human sebum is bactericidal against Gram-positive organisms as a result of its ability to increase β-defensin 2 expression.[16] Innate immune Toll-like receptors 2 and 4 (TLR2, TLR4), CD1d and CD14 molecules are also expressed in sebaceous glands and immortalized human sebocytes. With the expression of innate immune receptors and antibacterial peptides, the sebaceous gland may play an important role in pathogen recognition and protection of the skin surface.

FACTORS REGULATING SEBACEOUS GLAND SIZE AND SEBUM PRODUCTION

Serum production is continuous and is not controlled by neural mechanisms. The exact mechanisms

underlying the regulation of human sebum production are not fully defined.

A variety of experimental models are used to study the factors involved in sebaceous gland regulation, including cell culture of isolated human sebaceous glands, primary sebocytes, and immortalized sebocyte cell lines; as well as mouse and hamster animal models. Results from these investigations clearly indicate that sebaceous glands are regulated by androgens and retinoids. Recent evidence suggests that melanocortins, peroxisome proliferator-activated receptors (PPARs), and fibroblast growth factor receptors (FGFRs) play a role as well.

ANDROGENS

Sebaceous glands require androgenic stimulation to produce significant quantities of sebum. Individuals with a genetic deficiency of androgen receptors (complete androgen insensitivity) have no detectable sebum secretion and do not develop acne.[17] A question still exists about which androgen is physiologically important. Although the most powerful androgens are testosterone and its end-organ reduction product, dihydrotestosterone (DHT), levels of testosterone do not parallel the patterns of sebaceous gland activity. For example, testosterone levels are many fold higher in males than in females, with no overlap between the sexes. However, the average rates of sebum secretion are only slightly higher in males than in females, with considerable overlap between the sexes. Also, sebum secretion starts to increase in children during adrenarche, a developmental event that precedes puberty by about 2 years.

The weak adrenal androgen, dehydroepiandrosterone sulfate (DHEAS), may be a significant regulator of sebaceous gland activity through its conversion to testosterone and DHT in the sebaceous gland. Levels of DHEAS are high in newborns, very low in 2- to 4-year-old children, and start to rise when sebum secretion starts to increase. In adulthood, DHEAS levels show considerable individual variation, but are only slightly higher in men than in women on the average. There is a decline in DHEAS levels in both sexes starting in early adulthood and continuing throughout life; this decline parallels the decline of sebum secretion. DHEAS is present in the blood in high concentration. The enzymes required to convert DHEAS to more potent androgens are present in sebaceous glands.[18] These include 3β-hydroxysteroid dehydrogenase, 17β-hydroxysteroid dehydrogenase, and 5α-reductase. Each of these enzymes exists in two or more isoforms that exhibit tissue-specific differences in their expression. The predominant isozymes in the sebaceous gland include the type 1 3β-hydroxysteroid dehydrogenase, the type 2 17β-hydroxysteroid dehydrogenase, and the type 1 5α-reductase.

RETINOIDS

Isotretinoin (13-*cis*-retinoic acid, 13-*cis*-RA) is the most potent pharmacologic inhibitor of sebum secretion. Significant reductions in sebum production can be observed as early as 2 weeks after use.[19] Histologically, sebaceous glands are markedly reduced in size and individual sebocytes appear undifferentiated lacking the characteristic cytoplasmic accumulation of sebaceous lipids.

Isotretinoin does not interact with any of the known retinoid receptors. It may serve as a prodrug for the synthesis of all-*trans*-retinoic acid or 9-*cis*-retinoic acid, which do interact with retinoid receptors. However, it has greater sebosuppressive action than do all-*trans*- or 9-*cis*-retinoic acid.[20] The mechanism by which 13-*cis*-RA lowers sebum secretion is currently under investigation. Experimental evidence shows that 13-*cis*-RA inhibits the 3α-hydroxysteriod activity of retinol dehydrogenase leading to decreased androgen synthesis.[21] In addition, isotretinoin triggers cell cycle arrest in human sebocytes and immortalized cell culture models of human sebocytes (SZ95 and SEB-1), as well as induces apoptosis in SEB-1 sebocytes.[22,23,24] Inhibition of androgen synthesis, cell cycle arrest, and apoptosis by 13-*cis*-RA may explain the reduction of sebaceous gland size after treatment.

MELANOCORTINS

Melanocortins include melanocyte-stimulating hormone (MSH) and adrenocorticotropic hormone (ACTH). In rodents, melanocortins increase sebum production. Transgenic mice deficient in the melanocortin-5 receptor have hypoplastic sebaceous glands and reduced sebum production.[25] The melanocortin-5 receptor has been identified in human sebaceous glands, where it may play a role in the modulation of sebum production.[26] Further experimentation is required to test this hypothesis.

PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS

PPARs are orphan nuclear receptors that are similar to retinoid receptors in many ways. Each of these receptors forms heterodimers with retinoid X receptors in order to regulate the transcription of genes involved in a variety of processes, including lipid metabolism and cellular proliferation and differentiation. PPAR-α, -δ, and -γ receptor subtypes have been detected in basal sebocytes. PPAR-γ is also detected within differentiated sebocytes. In patients receiving fibrates (PPAR-α ligands) for hyperlipidemia or thiazolidinediones (PPAR-γ ligands) for diabetes, sebum secretion rates are increased.[27] Rat preputial cells serve as a model for human sebocytes in the laboratory.[28] In rat preputial cells, agonists of the PPAR-γ receptor, such as drugs of the thiazolidinedione class, increase lipid accumulation.[29]

FIBROBLAST GROWTH FACTOR RECEPTORS

FGFR1 and FGFR2 are expressed in the epidermis and skin appendages. Expression of FGFR3 and FGFR4 are

localized to dermal vessels and microvessels and are notably absent in epidermis and appendages.[30] FGFR2 plays an important role during embryogenesis in skin formation.[31] Germ line mutations in FGFR2 lead to Apert syndrome, which is commonly associated with acne. In addition, somatic mutations in the same location can lead to acne, but how this receptor is involved in sebaceous gland development and how its mutation leads to acne is unknown.[32,33]

CONCLUSION

The regulation of sebaceous glands and human sebum production are complex. Advances are being made in this area, which may lead to alternative therapies for the reduction of sebum and improvement in acne.

Chapter 80 :: Acne Vulgaris and Acneiform Eruptions

:: Andrea L. Zaenglein, Emmy M. Graber, & Diane M. Thiboutot

ACNE AT A GLANCE

- Common disorder of the pilosebaceous unit.
- Four key elements of pathogenesis: (1) follicular epidermal hyperproliferation, (2) excess sebum production, (3) inflammation, and (4) the presence and activity of *Propionibacterium acnes*.
- Comedones, papules, pustules, nodules on face, chest, and back.
- Treatment often includes combinations of oral and topical agents such as antimicrobials, retinoids, and hormonal agents. Laser and light sources are additional treatment options.
- Acne variants and acneiform eruptions also exist, many of which have an identifiable and reversible etiology.

ACNE VULGARIS

Acne vulgaris is a self-limited disorder of the pilosebaceous unit that is seen primarily in adolescents. Most cases of acne present with a pleomorphic array of lesions, consisting of comedones, papules, pustules, and nodules with varying extent and severity. While the course of acne may be self-limiting, the sequelae can be lifelong, with pitted or hypertrophic scar formation.

EPIDEMIOLOGY

Acne is sufficiently common that it often has been termed physiologic. Mild degrees of acne are frequently seen at birth, probably resulting from follicular stimulation by adrenal androgens, and may continue into the neonatal period. However, in the vast majority of cases it is not until puberty that acne becomes a more significant problem. Acne often heralds the onset of puberty. In girls, the occurrence of acne may precede menarche by more than a year. In these very young patients, the predominant lesions are comedones. Acne prevalence hits its peak during the middle-to-late teenage period, with more than 85% of adolescents affected, and then steadily decreases. However, acne may persist through the third decade or even later, particularly in women. One study demonstrated a prevalence of facial acne in women between ages 26 and 44 to be 14%.[1] Acne severity seems to be familial. The prevalence of high school students with moderate-to-severe acne was 19.9% in those students with a family history of acne and 9.8% in those students without a family history of acne.[2] In twin studies, 81% of the population variance in acne was found due to genetic factors (vs. 19% environmental

factors).[3] Nodulocystic acne has been reported to be more common in white males than in black males, and one group of investigators has found that acne is more severe in patients with the XYY genotype.[4,5]

ETIOLOGY AND PATHOGENESIS

Understanding the underlying basis for acne, and the mechanisms of action of the multitude of therapeutic options in treating acne will assure better therapeutic results. The pathogenesis of acne is multifaceted, but four basic steps have been identified. These key elements (Fig. 80-1) are: (1) follicular epidermal hyperproliferation, (2) excess sebum production, (3) inflammation, and (4) the presence and activity of *Propionibacterium acnes*. Each of these processes are interrelated and under hormonal and immune influence.

Follicular epidermal hyperproliferation results in the formation of a microcomedo. The epithelium of the upper hair follicle, the infundibulum, becomes hyperkeratotic with increased cohesion of the keratinocytes. The excess cells and their tackiness result in a plug in the follicular ostium. This plug then causes downstream concretions of keratin, sebum, and bacteria to accumulate in the follicle. These packed concretions cause dilation of the upper hair follicle producing a microcomedo.

The stimulus for keratinocyte hyperproliferation and increased adhesion is unknown. However, several proposed factors in keratinocyte hyperproliferation include: androgen stimulation, decreased linoleic acid, increased interleukin-1 (IL-1) α activity, and effects of *P. acnes*. Dihydrotestosterone (DHT) is a potent androgen that may play a role in acne. Fig. 80-2 demonstrates the physiologic pathway for dehydroepiandrosterone sulfate (DHEA-S) conversion to the androgen DHT. 17-β hydroxysteroid dehydrogenase (HSD) and 5-α reductase are enzymes responsible for converting DHEA-S to DHT. When compared to epidermal keratinocytes, follicular keratinocytes have increased 17-β HSD and 5-α reductase, thus enhancing DHT production.[6,7] DHT may stimulate follicular keratinocyte proliferation. Also supporting the role of androgens in acne pathogenesis is the evidence that individuals with complete androgen insensitivity do not develop acne.[8] Follicular keratinocyte proliferation may also be regulated by linoleic acid. Linoleic acid is an essential fatty acid in the skin that is decreased in subjects with acne. The quantity of linoleic acid normalizes after successful treatment with isotretinoin. Subnormal levels of linoleic acid may induce follicular keratinocyte hyperproliferation and produce proinflammatory cytokines. It has also been suggested that regular quantities of linoleic acid are actually produced but are simply diluted by increased sebum production.[9] In addition to androgens and linoleic acid, IL-1 α may also contribute to keratinocyte hyperproliferation. Human follicular keratinocytes demonstrate hyperproliferation and microcomedone formation when IL-1 α is added. IL-1 receptor antagonists inhibit microcomedone formation providing additional support for the cytokine's role in acne pathogenesis.[10,11] Fibroblast growth factor receptor (FGFR)-2 signaling may also be involved in hyperkeratinization. There is a long established relationship between acne and Apert syndrome, a complex bony malformation syndrome, due to a gain in function mutation in the gene encoding FGFR-2. Mutations in FGFR-2 in a mosaic distribution underlie a nevus comedonicus-like lesion.[12] The FGFR-2 pathway is androgen dependent and proposed mechanisms in acne include an increased production of IL-1 α and 5-α reductase.[13,14]

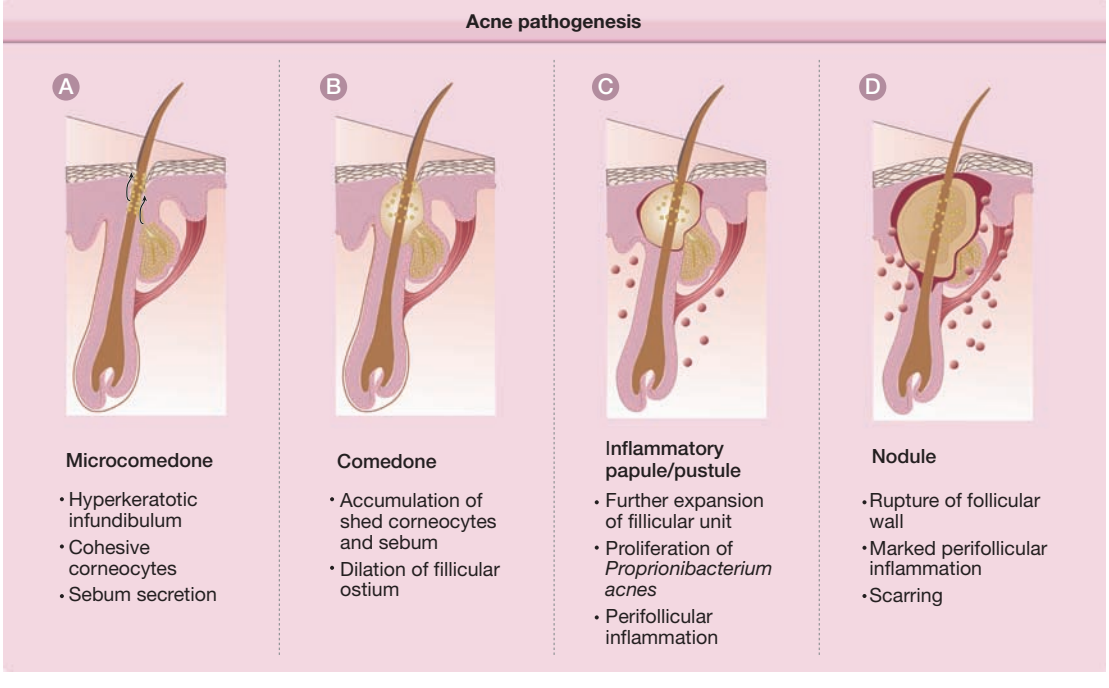

Figure 80-1 **A–D.** Acne pathogenesis.

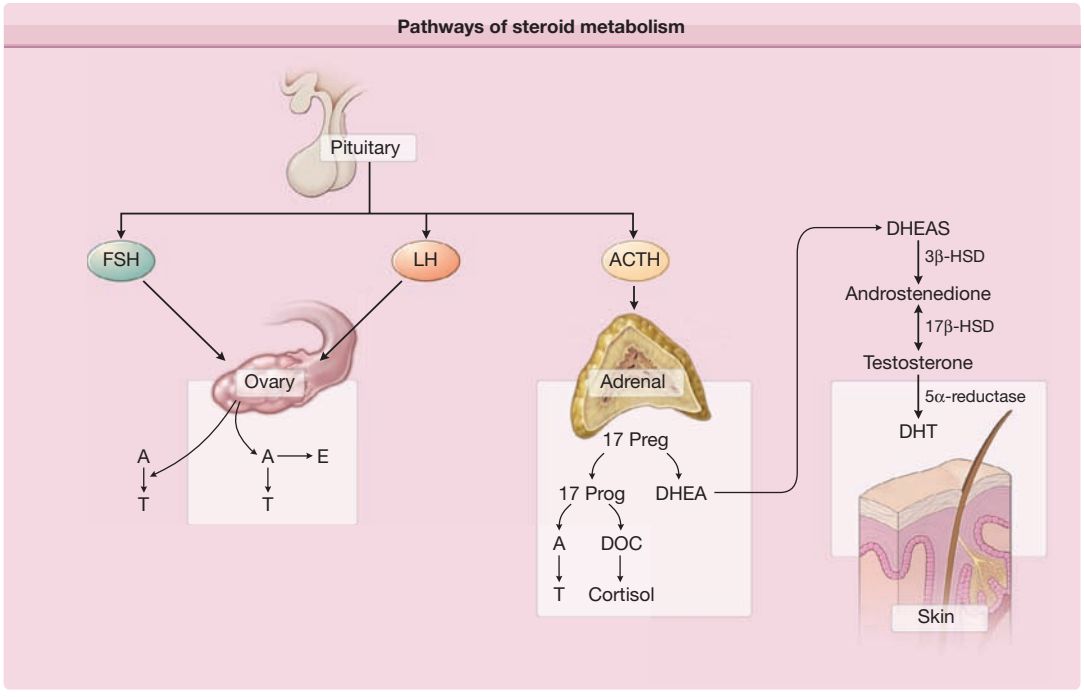

Figure 80-2 Pathways of steroid metabolism. Dehydroepiandrosterone (DHEA) is a weak androgen that is converted to the more potent testosterone by 3β-hydroxysteroid dehydrogenase (HSD) and 17β-HSD. 5-α reductase then converts testosterone to dihydrotestosterone (DHT), the predominant hormonal effector on the sebaceous gland. The sebaceous gland expresses each of these enzymes. A = androstenedione; ACTH = adrenocorticotropin-stimulating hormone; DHEAS = dehydroepiandrosterone sulfate; E = estrogen; FSH = follicle-stimulating hormone; LH = luteinizing hormone; T = testosterone; DOC = deoxycortisol.

The second key feature in the pathogenesis of acne is excess sebum production from the sebaceous gland. Patients with acne produce more sebum than those without acne, although the quality of sebum is the same between the two groups.[15] Components of sebum—triglycerides and lipoperoxides—may play a role in acne pathogenesis. Triglycerides are broken down into free fatty acids by *P. acnes*, normal flora of the pilosebaceous unit. These free fatty acids promote further bacterial clumping and colonization of *P. acnes*, incite inflammation, and may be comedogenic.[16] Lipoperoxides also produce proinflammatory cytokines and activate the peroxisome proliferator-activated receptors (PPAR) pathway, resulting in increased sebum.[17,18]

Androgenic hormones also influence sebum production through actions on sebocyte proliferation and differentiation. Similar to their action on the follicular infundibular keratinocytes, androgen hormones bind to and influence sebocyte activity.[19] Those with acne have higher average serum androgen levels (although still within normal range) than unaffected controls.[20,21] 5-α reductase, the enzyme responsible for converting testosterone to the potent DHT, has greatest activity in areas of skin prone to acne, the face chest and back.[14]

The role of estrogen on sebum production is not well defined. The dose of estrogen required to decrease sebum production is greater than the dose required to inhibit ovulation.[22] The mechanisms by which estrogens may work include: (1) directly opposing the effects of androgens within the sebaceous gland; (2) inhibiting the production of androgens by gonadal tissue via a negative feedback loop on pituitary gonadotropin release; and (3) regulating genes that suppress sebaceous gland growth or lipid production.[23]

Corticotropin-releasing hormone may also play a role. It is released by the hypothalamus and increased in response to stress. Corticotropin-releasing hormone receptors are present on a vast number of cells, including keratinocytes and sebocytes, and are upregulated in the sebocytes of patients with acne.[24]

The microcomedo will continue to expand with densely packed keratin, sebum, and bacteria. Eventually this distension will cause follicular wall rupture. The extrusion of the keratin, sebum, and bacteria into the dermis results in a brisk inflammatory response. The predominant cell type within 24 hours of comedo rupture is the lymphocyte. $CD4^+$ lymphocytes are found around the pilosebaceous unit, while $CD8^+$ cells are found perivascularly. One to two days after comedo rupture, the neutrophil becomes the predominant cell type surrounding the burst microcomedo.[25]

It was originally thought that inflammation follows comedo formation, but there is evidence that dermal inflammation may actually precede comedo formation. Biopsies taken from comedo-free acne-prone skin, demonstrate increased dermal inflammation compared to normal skin. Biopsies of newly formed comedos demonstrate even greater inflammation.[26] This may suggest that inflammation actually precedes comedo formation, again emphasizing the interplay between all of the pathogenic factors. As mentioned above, *P. acnes* also plays an active role in the process

of inflammation. *P. acnes* is a Gram-positive, anaerobic, and microaerobic bacterium found in the sebaceous follicle. Adolescents with acne have higher concentrations of *P. acnes* compared to nonacne controls. However, there is no correlation between the raw number of *P. acnes* organisms present in a sebaceous follicle and the severity of the acne.[27] Sebocyte differentiation and proinflammatory cytokine/chemokine responses are varied depending on the strain of *P. acnes* predominating within the follicle.[28]

The cell wall of *P. acnes* contains a carbohydrate antigen that stimulates antibody development. Those patients with the most severe acne have the highest titers of antibodies.[29] The antipropionobacterium antibody enhances the inflammatory response by activating complement initiating a cascade of proinflammatory events.[30] *P. acnes* also facilitates inflammation by eliciting a delayed type hypersensitivity response and by producing lipases, proteases, hyaluronidases, and chemotactic factors.[31,32] Reactive oxygen species and lysosomal enzymes are released by neutrophils and levels may correlate with severity.[33] Additionally, *P. acnes* has been shown to stimulate expression of cytokines by binding to toll-like receptor 2 (TLR-2) on monocytes and polymorphonuclear cells surrounding the sebaceous follicle.[34] After binding TLR-2, proinflammatory cytokines such as IL-1α, IL-8, IL-12, and TNF-α are released.[35,36] The antimicrobial peptides, histone H4 and cathelicidin, are also secreted locally in response to *P. acnes.* Histone H4 exerts direct microbial killing, while cathelicidin interacts with components of the innate immune system, such as β defensins and psoriasin, in response to *P. acnes*.[37,38] Another indicator of the role of innate immunity in the pathogenesis of acne is the differentiation of peripheral blood monocytes to $CD209^+$ macrophages and $CD1b^+$ dendritic cells in response to *P. acnes*.[39]

The impact of diet on acne is an emerging area of interest, particularly relating to glycemic index and dairy consumption. Both are thought to increase insulin-like growth factor (IGF)-1 with possible proacne effects and an increase in androgen activity.[40,41]

CLINICAL FINDINGS

HISTORY. Most patients with acne vulgaris report gradual onset of lesions around puberty. In other cases, acne can be seen in the neonatal or infantile age. Neonatal acne appears at about 2 weeks of age and infantile acne develops at 3–6 months of age (see Chapter 107). Since classic acne vulgaris is usually gradual in onset, patients describing an abrupt onset of acne should be questioned to possibly discover an underlying etiology, such as an androgen-secreting tumor.

Hyperandrogenism should be considered in the female patient whose acne is severe, sudden in its onset, or associated with hirsutism or irregular menstrual periods. The patient should be asked about the frequency and character of her menstrual periods and whether her acne flares with changes in her menstrual cycle. Hyperandrogenism can also result in deepening of the voice, an increase in libido and hirsutism. A complete medication history is important, as some medications can cause an abrupt onset of a monomorphous acneiform eruption. Drug-induced acne may be caused by: anabolic steroids, corticosteroids, corticotropin, phenytoin, lithium, isoniazid, vitamin B complexes, halogenated compounds, and certain chemotherapy medications, particularly with epidermal growth factor receptor (EGFR) inhibitors.

CUTANEOUS LESIONS. The primary site of acne is the face and to a lesser degree the back, chest, and shoulders. On the trunk, lesions tend to be concentrated near the midline. The disease is characterized by several clinical lesion types (Fig. 80-3). Although one type of lesion may predominate, close inspection usually reveals the presence of several types of lesions. The lesions may be either noninflammatory or inflammatory. The noninflammatory lesions are comedos, which may be either closed (whiteheads; Fig. 80-3A) or open (blackheads; Fig. 80-3B). The open comedo appears as a flat or slightly raised lesion with a central dark-colored follicular impaction of keratin and lipid (Fig. 80-4). Closed comedones, in contrast to the open comedones, may be difficult to visualize. They appear as pale, slightly elevated, small papules, and do not have a clinically visible orifice (Fig. 80-3A). Stretching of the skin is an aid in detecting the lesions.

The inflammatory lesions vary from small papules with a red border to pustules and large, tender, fluctuant nodules (see Figs. 80-3C and 80-3D and Figs. 80-4–80-6). Some of the large nodules were previously called "cysts" and the term *nodulocystic* has been used to describe severe cases of inflammatory acne. True cysts are rarely found in acne; this term should be abandoned and substituted with *severe nodular acne* (see Figs. 80-3D and 80-6). Whether the lesion appears as a papule, pustule, or nodule depends on the extent and location of the inflammatory infiltrate in the dermis.

Scarring can be a complication of both noninflammatory and inflammatory acne. There are four general types of acne scars: (1) ice pick, (2) rolling, (3) boxcar, and (4) hypertrophic[42] (Fig. 80-7). Ice pick scars are narrow, deep scars that are widest at the surface of the skin and taper to a point in the dermis. Rolling scars are shallow, wide scars that have an undulating appearance. Boxcar scars are wide sharply demarcated scars. Unlike ice pick scars, the width of boxcar scars is similar at the surface and base. In rare instances, especially on the trunk, the scars may be hypertrophic.

Acne vulgaris is usually an isolated cutaneous finding, other than in the presence of hyperandrogenism. Such cases may have associated hirsutism, precocious puberty, and other signs of hyperandrogenism.

LABORATORY TESTS

In general, laboratory workup is not indicated for patients with acne unless hyperandrogenism is suspected. There are numerous clinical studies relating acne to elevated serum levels of androgens in both adolescents and adults. Among 623 prepubertal girls, girls with acne had increased levels of DHEAS as compared

Figure 80-3 Clinicopathologic correlation of acne lesions. **A.** Closed comedone. The follicular infundibulum is distended, filled with keratin and sebum, and the follicular epithelium is attenuated. The follicular ostium is narrow. **B.** Open comedone. Resembles the closed comedone with the exception of a patulous follicular ostium. **C.** Inflammatory papule. Acute and chronic inflammatory cells surround and infiltrate the follicle, which shows infundibular hyperkeratosis. **D.** Nodule. The follicle is filled with acute inflammatory cells. With the rupture of the distended follicle, there is a foreign body granulomatous response.

Figure 80-4 Acne vulgaris mild. **A.** A 13-year-old girl with mild acne vulgaris. Scattered comedones and/or inflammatory lesions are seen, usually limited to less than half of the face. The T-zone of the face is commonly involved. No nodules are present. **B.** An adult female with primarily inflammatory acne. Note the typical involvement of the jawline.

Figure 80-5 Acne vulgaris moderate. **A.** A 15-year-old male with moderate acne is seen. Typically more than half of the face is involved with increasing numbers of lesions, usually a mix of lesions is seen: papules, pustules, and comedones. Infrequent and limited nodules may be present. Chest and back involvement may also be moderately affected. **B.** A 16-year-old female with open and deep closed comedones is pictured. Scarring and postinflammatory changes are possible sequelae.

Figure 80-6 Acne vulgaris severe. **A.** A 17-year-old female with extensive acne is seen. Numerous pustules and nodular lesions admixed with comedones and smaller papules cover the entire face. **B.** Deep, friable nodules that coalesce into pseudocysts are seen in acne conglobata. **C.** Chest and back involvement can be extensive and severe. Scarring is a common complication in severe acne.

Figure 80-7 Acne vulgaris, scarring. **A.** Honeycomb scarring is seen in this young girl with mild-to-moderate inflammatory acne. **B.** Extensive keloidal scarring occurring as sequelae of acne fulminans. **C.** Rolling scars.

to age-matched controls without acne.[43] DHEAS can serve as a precursor for testosterone and DHT. Elevated serum levels of androgens have been found in cases of severe cystic acne and in acne associated with a variety of endocrine conditions, including congenital adrenal hyperplasia (11β- and 21β-hydroxylase deficiencies), ovarian or adrenal tumors, and polycystic ovarian disease. However, in the majority of acne patients serum androgens are within the normal range.[44,45]

Excess androgens may be produced by either the adrenal gland or ovary. The laboratory workup should include measurement of serum DHEAS, total testosterone, and free testosterone. Additional tests to consider include the luteinizing hormone (LH) to follicle-stimulating hormone (FSH) ratio or serum 17-hydroxyprogesterone to identify an adrenal source of androgens in cases where testing does not clearly indicate an adrenal or ovarian source of androgens. Testing should be obtained just prior to or during the menstrual period, not midcycle at the time of ovulation. Patients on contraceptives that prevent ovulation will need to discontinue their medication for at least 1 month prior to testing. Values of DHEAS in the range of 4,000–8,000 ng/mL (units may vary at different laboratories) may be associated with congenital adrenal hyperplasia. Patients with a serum level of DHEAS >8,000 ng/mL could have an adrenal tumor and should be referred to an endocrinologist for further evaluation. An ovarian source of excess androgens can be suspected in cases where the serum total testosterone is >150 ng/dL. Serum total testosterone in the range of 150–200 ng/dL or an increased LH/FSH ratio (>2.0) can be found in cases of polycystic ovary disease. Greater elevations in serum testosterone may indicate an ovarian tumor, and appropriate referral should be made. There is a significant amount of variability in individual serum androgen levels. In cases in which abnormal results are obtained, it may be wise to repeat the test before proceeding with therapy or additional testing.

Many patients report that their acne flares during periods of stress. Although objective data are limited, stress is known to increase the output of adrenal steroids, which may affect the sebaceous gland.[46] It has been shown that patients with acne have a greater increase in urinary glucocorticoid levels after corticotropin administration.[47]

DIFFERENTIAL DIAGNOSIS

Although one type of lesion may predominate, acne vulgaris is diagnosed by a variety of acne lesions (comedones, pustules, papules, and nodules) on the face, back, or chest (see Box 80-1). Diagnosis is usually easy, but inflammatory acne may be confused with folliculitis, rosacea, or perioral dermatitis. Patients with

BOX 80-1 DIFFERENTIAL DIAGNOSIS OF ACNE

Most Likely

- Closed comedonal acne
  - Milia
  - Sebaceous hyperplasia
- Open comedonal acne
  - Dilated pore of Winer
  - Favre–Racouchot syndrome
- Inflammatory acne
  - Rosacea
  - Perioral dermatitis
- Neonatal acne
  - Miliaria rubra

Consider

- Closed comedonal acne
  - Osteoma cutis
  - Trichoepitheliomas
  - Trichodiscomas
  - Fibrofolliculomas
  - Eruptive vellus hair cysts, steatocystoma multiplex
  - Colloid milia
  - Flat warts
- Open comedonal acne
  - Trichostasis spinulosa
  - Nevus comedonicus
- Inflammatory acne
  - Pseudofolliculitis barbae, acne keloidalis nuchae
  - Keratosis pilaris
  - Neurotic excoriations/factitial
  - Lupus miliaris disseminatus faciei
- Neonatal acne
  - Sebaceous hyperplasia
  - Milia

Always Rule Out

- Closed comedonal acne
  - Acne due to systemic agents (e.g., corticosteroids)
  - Contact acne (e.g., occupational acne)
  - Chloracne
- Open comedonal acne
  - Acne due to systemic agents
  - Contact acne
  - Chloracne
- Inflammatory acne
  - Acne due to systemic agents
  - Staphylococcal folliculitis
  - Gram-negative folliculitis
  - Eosinophilic folliculitis
  - Furuncle/carbuncle
  - Angiofibromas of tuberous sclerosis
- Neonatal acne
  - Candidal infections
  - Benign neonatal cephalic pustulosis

tuberous sclerosis and facial angiofibromas have been misdiagnosed as having recalcitrant midfacial acne. Facial flat warts or milia are occasionally confused with closed comedones.

Acne can be seen in association with endocrinologic abnormalities. Patients with hyperandrogenism may have acne plus other stigmata of increased androgen levels (i.e., hirsutism, deepened voice, irregular menses). Endocrinologic disorders such as polycystic ovarian syndrome (including HAIR-AN syndrome), congenital adrenal hyperplasia, and adrenal and ovarian neoplasms often have accompanying acne.

Variants of acne must also be differentiated from typical acne vulgaris in order to guide treatment. These types of acne include: neonatal acne, infantile acne, acne fulminans, acne conglobata, acne with solid facial edema, and acne excoriée des jeunes filles. These variants are discussed in detail later in the chapter.

There are several less common acneiform eruptions that can be confused with acne vulgaris. These mimickers include: medication-induced acne, halogen acne, chloracne, acne mechanica, tropical acne, radiation acne, and other various miscellaneous acneiform disorders that are discussed subsequently.

COMPLICATIONS

All types of acne lesions have the potential to resolve with sequelae. Almost all acne lesions leave a transient macular erythema after resolution. In darker skin types, postinflammatory hyperpigmentation may persist months after resolution of acne lesions. In some individuals, acne lesions may result in permanent scarring.

Acne vulgaris may also take a psychological toll on many patients. It is estimated that 30%–50% of adolescents experience psychiatric disturbances due to acne.[48] Studies have shown that patients with acne have similar levels of social, psychological, and emotional impairment as those with asthma and epilepsy.[49] Additional studies have also shown that unemployment rates are higher among adults with acne than those without.[50] When appropriate, patients should be referred for psychiatric counseling.

PROGNOSIS AND CLINICAL COURSE

The age of onset of acne varies considerably. It may start as early as 6–8 years of age or it may not appear until the age of 20 or later. The course is one of several years' duration followed by spontaneous remission in the majority of cases. While most patients will clear by their early twenties, some have acne extending well into the third or fourth decades. The extent of involvement varies, and spontaneous fluctuations in the degree of involvement are the rule rather than the exception. In women there is often a fluctuation in association with menses, with a flare just before the onset of menstruation. This flare is not due to a change in sebaceous gland activity as there is no increase in sebum production in the luteal phase of the menstrual

cycle. It has been shown that prepubescent females with comedonal acne and those females with high DHEAS levels are predictors of severe or long-standing nodulocystic acne.[51]

TREATMENT

Tailoring a patient's acne regimen with the knowledge of the pathogenesis of acne and the mechanism of action of the available acne treatments will ensure maximum therapeutic response. Treatment regimens should be initiated early and be sufficiently aggressive to prevent permanent sequelae. Often multiple treatments are used in combination so as to combat many factors in the pathogenesis of acne (Table 80-1). The mechanism of action of the most common treatments for acne can be categorized in the following categories as they relate to the pathophysiology:

1. Correct the altered pattern of follicular keratinization.
2. Decrease sebaceous gland activity.
3. Decrease the follicular bacterial population, particularly *P. acnes*.
4. Exert an anti-inflammatory effect.

LOCAL THERAPY

Cleansing. The importance of cleansing in the treatment of acne is generally intuitive. Twice daily washing with a gentle cleanser followed by the application of acne treatments may encourage a routine and therefore better compliance. Overcleansing or using harsh alkaline soaps are likely to increase the

TABLE 80-1
Treatment Algorithm for Acne Vulgaris

	Mild	Moderate	Severe		
	Comedonal	Papular/ Pustular	Papular/Pustular	Nodular	Conglobata/ Fulminans
First	Topical retinoid or combination[a]	Topical retinoid + topical antimicrobial or combination[a]	Oral antibiotic + topical retinoid ± BPO or combination[a]	Oral antibiotic + topical retinoid ± BPO	Oral isotretinoin ± oral corticosteroids

skin's pH, disrupt the cutaneous lipid barrier, and compound the irritancy potential of many topical acne treatments. Use of a syndet (synthetic detergent) will allow cleansing without disruption of the skin's normal pH. Antibacterial soaps, containing agents such as triclosan, inhibit Gram-positive cocci but may increase Gram-negative rods; their overall affect on acne is unclear. Medicated cleansers, containing benzoyl peroxide or salicylic acid, offer convenience as a wash and are excellent for hard to reach areas like the back.

Topical Agents. (See Table 80-2)

Sulfur/Sodium Sulfacetamide/Resorcinol. Products containing sulfur, sodium sulfacetamide, and resorcinol, once favored treatments for acne, are still found in several over-the-counter and prescription niche formulations. Sulfonamides are thought to have antibacterial properties through their inhibition of *para*-aminobenzoic acid (PABA), an essential substance for *P. acnes* growth.[52] Sulfur also inhibits the formation of free fatty acids and has presumptive keratolytic properties. It is often combined with sodium sulfacetamide to enhance its cosmetic tolerability due to sulfur's distinctive odor. Resorcinol is also indicated for use in acne for its antimicrobial properties. It is generally found in 2% concentration in combination with 5% sulfur.

Salicylic Acid. Salicylic acid is a ubiquitous ingredient found in over-the-counter acne preparations in concentrations ranging from 0.5% to 2%. This lipid soluble β-hydroxy acid has comedolytic properties, though somewhat weaker than those of a retinoid. Salicylic acid also causes exfoliation of the stratum corneum though decreased cohesion of the keratinocytes. Mild irritant reactions may result.

Azelaic Acid. Azelaic acid is available by prescription in a 20% cream or 15% gel. This dicarboxcylic acid has both antimicrobial and comedolytic properties.[53] It is also a competitive inhibitor of tyrosinase and thus may decrease postinflammatory hyperpigmentation.[54] It is generally well tolerated, though transient burning can occur, and is safe in pregnancy.

Benzoyl Peroxide. Benzoyl peroxide preparations are among the most common topical medications prescribed by dermatologists and are also readily available over-the-counter. Benzoyl peroxide is a powerful antimicrobial agent through decreasing both the bacterial population and the hydrolysis of triglycerides. Benzoyl peroxide preparations are available in creams, lotion, gels, washes, and pledgets. Products that are left on the skin, such as a gel, are generally considered more effective. Benzoyl peroxide can produce significant dryness and irritation. Allergic contact dermatitis has been uncommonly reported. Of significance, bacteria are unable to develop resistance to benzoyl peroxide, making it the ideal agent for combination therapy.[55]

Topical Antibiotics. (See Chapter 218). Erythromycin and clindamycin are the most commonly used topical antibiotics for the treatment of acne. These two agents have also been used in combination preparations with benzoyl peroxide. Increased levels of *P. acnes* resistance have been reported in patients who are being treated with antibiotics. However, the development of resistance is less likely in patients who are treated with a combination of benzoyl peroxide/erythromycin or clindamycin.[56] Therefore, the combination of these two products is preferable over monotherapy with topical antibiotics. Topical dapsone is the most recently approved topical antibiotic for acne. With twice daily application topical dapsone has shown better efficacy in controlling inflammatory lesions (58%) versus non-inflammatory lesions (19%).[57,58] Unlike oral dapsone, topical dapsone is safe for use even in patients with a G6PD deficiency.[59] It is generally well tolerated but should not be applied concomitantly with benzoyl peroxide or it may impart an orange color on the skin.[60]

Retinoids. (See Chapter 217). Retinoids are defined by their ability to bind to and activate retinoic acid receptors (RAR) and in turn activate specific gene transcription resulting in a biologic response. Some have chemical structures similar to tretinoin (all-*trans*-retinoic acid), but they may be entirely dissimilar, such as adapalene or tazarotene, and still potentiate a retinoid effect. In general, the binding of these agents to nuclear RAR affects the expression of genes involved in cell proliferation, differentiation, melanogenesis, and inflammation.[61,62] The result is modification of corneocyte accumulation and cohesion, and inflammation. Thus, retinoids have both comedolytic and anti-inflammatory properties.[62]

Tretinoin is commercially available in several strengths and formulations. Having both potent comedolytic and anti-inflammatory properties, it is widely used. In general, all retinoids can be contact irritants, with alcohol-based gels and solutions having the greatest irritancy potential. Some newer formulations utilize a microsphere delayed-delivery technology (Retin A Micro® 0.04% or 0.1% gel) or are incorporated within a polyolprepolymer (PP-2) (Avita® cream) to decrease the irritancy potential of tretinoin while allowing greater concentration of medication. Advising patients to apply tretinoin on alternate nights during the first few weeks of treatment can help ensure greater tolerability. Patients must also be cautioned about sun exposure due to thinning of the stratum corneum, especially those with any irritant reaction. Regular use of a sunscreen should be advised. The comedolytic and anti-inflammatory properties of topical retinoids make them ideal for maintenance therapy of acne. Generic tretinoin is inactivated by concomitant use of benzoyl peroxide and is photolabile. Therefore, patients should be counseled to apply tretinoin at bedtime.

Adapalene is a synthetic retinoid widely marketed for its greater tolerability. It specifically targets the RARγ receptor. It is both photostable and can be used in conjunction with benzoyl peroxide without degradation. Adapalene 0.1% gel has been shown in clinical trials to have greater or equal efficacy to tretinoin 0.025% gel with greater tolerability.[63,64] It is available at a 0.1% concentration in both a nonalcohol gel and

cream and as a 0.3% gel. The 0.3% adapalene gel has been shown to have similar efficacy to tazarotene 0.1% gel with increased tolerability.[65] A combination topical agent containing 0.1% adapalene and 2.5% benzoyl peroxide is also available.[66,67]

Tazarotene, also a synthetic retinoid, exerts is action through its metabolite, tazarotenic acid, which in turn inhibits the RARγ receptor. It is a potent comedolytic agent and has been show to be more effective than tretinoin 0.025% gel and tretinoin 0.1% microsphere gel.[68,69] Both the 0.1% cream and gel formulations are approved for the treatment of acne. The irritant properties of tazarotene can be minimized by the use of short-term contact therapy. In this regimen, the medication is applied for 5 minutes then washed off with a gentle cleanser. Tazarotene has been given a pregnancy category X rating and female patients of childbearing age should be adequately counseled.

An overview of topical agents for acne treatment is outlined in Table 80-2.

SYSTEMIC THERAPY

Antibiotics and Antibacterial Agents. (See Chapter 230).

Tetracyclines. Broad-spectrum antibiotics are widely used in the treatment of inflammatory acne. The tetracyclines are the most commonly used antibiotics in the treatment of acne. Although the oral administration of tetracyclines does not alter sebum production, it does decrease the concentration of free fatty acids while the esterified fatty acid content increases. Decreases in free fatty acid formation also have been reported with erythromycin, demethylchlortetracycline, clindamycin, and minocycline. The free fatty acids are probably not the major irritants in sebum, but their level is an indication of the metabolic activity of the *P. acnes* bacteria and its secretion of other proinflammatory products. The decrease in free fatty acids may take several weeks to become evident. This, in turn, is reflected in the clinical course of the disease during antibiotic therapy, as several weeks are often required for maximal clinical benefit. The effect, then, is one of prevention; the individual lesions require their usual time to undergo resolution. However, the fact that a decrease in free fatty acids does occur strengthens the rationale for the use of tetracycline. Tetracycline may also act through direct suppression of the number of *P. acnes,* but part of its action may be due to its anti-inflammatory activity. In clinical practice, tetracycline is usually given initially in dosages of 500–1,000 mg/day. Higher doses of up to 3,500 mg/day have been used in severe cases, but prudent monitoring of liver functions is warranted. Tetracycline should be taken on an empty stomach, 1 hour before or 2 hours after meals, to promote absorption; thus, compliance by adolescents with its administration can be challenging. Gastrointestinal (GI) upset is the most common side effect, with esophagitis and pancreatitis possible. Uncommon side effects include hepatotoxicity, hypersensitivity reactions, leukocytosis, thrombocytopenic purpura, and pseudotumor cerebri. Tetracyclines should be used with caution in patients with renal disease as they may increase uremia. Tetracyclines have an affinity for rapidly mineralizing tissues and are deposited in developing teeth, where they may cause irreversible yellow–brown staining; also, tetracyclines have been reported to inhibit skeletal growth in the fetus. Therefore, they should not be administered to pregnant women, especially after the fourth month of gestation and are not recommend for use in children younger than 9 years of age in the treatment of acne.

The tetracycline derivatives, doxycycline and minocycline, are also commonly used in the treatment of acne. They have the distinct advantage of being able to be taken with food without impaired absorption. Doxycycline is administered in dosages of 50–100 mg twice daily. Its major disadvantage is the potential risk of photosensitivity reactions, including photo-onycholysis, and patients may need to be switched to another antibiotic during summer months. Minocycline is given in divided dosages at a level of 100–200 mg/day. Patients on minocycline should be monitored carefully, as the drug can cause blue–black pigmentation, especially in the acne scars, as well as the hard palate, alveolar ridge, and anterior shins. Vertigo has occasionally been described. Minocycline-induced autoimmune hepatitis and a systemic lupus erythematosus-like syndrome have been reported during minocycline therapy, but these side effects are very rare.[70,71] Of note, patients who develop lupus-like reactions can be safely switched to an alternative tetracycline. Serum sickness-like reactions and drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome have also been reported with minocycline use.

Macrolides. Due to the prevalence of erythromycin-resistant strains of *P. acnes*, the use of oral erythromycin is generally limited to pregnant women or children. Azithromycin has been used more often for acne, typically at dosages of 250–500 mg orally three times weekly.[72] Azithromycin undergoes hepatic metabolism with GI upset and diarrhea as the most common side effects.

Trimethoprim–Sulfamethoxazole. Trimethoprim–sulfamethoxazole combinations are also effective in acne. In general, because the potential for side effects is greater with their use, they should be used only in patients with severe acne who do not respond to other antibiotics. GI upset and cutaneous hypersensitivity reactions are common. Serious adverse reactions, including the Stevens–Johnson syndrome-toxic epidermal necrolysis spectrum (see Chapter 40) and aplastic anemia, have been described. If trimethoprim–sulfamethoxazole is used, the patient must be monitored for potential hematologic suppression approximately monthly.

Cephalexin. Cephalexin, a first generation cephalosporin, has been shown in vitro to kill *P. acnes*. However, because it is hydrophilic and not lipophilic it penetrates poorly into the pilosebaceous unit. Success with oral cephalexin[73] is most likely due to its anti-inflammatory rather than antimicrobial properties. Due to the risk of promoting the development of bacterial resistance,

particularly to *Staphylococcus*, the authors discourage the use of cephalexin for acne.

Clindamycin and Dapsone. Less commonly used antibiotics include clindamycin and dapsone. Oral clindamycin had been used more readily in the past, but because of the risk of pseudomembranous colitis, it is now rarely used systemically for acne. It is still commonly used topically, however, often in combination with benzoyl peroxide. Dapsone (see Chapter 225), a sulfone often used for cutaneous neutrophilic disorders, may be beneficial in severe markedly inflammatory acne and select cases of resistant acne. It is used at doses of 50–100 mg daily for 3 months. G6PD levels should be examined prior to initiation of therapy and regular monitoring for hemolysis and liver function abnormalities is warranted. While not as reliably effective as isotretinoin, it is relatively low cost and should be considered in severe cases where isotretinoin is not an option.

Antibiotics and Bacterial Resistance. Antibiotic resistance is a growing concern worldwide and should be suspected in patients unresponsive to appropriate antibiotic therapy after 6 weeks of treatment. Increasing propionobacterium resistance has been documented to all macrolides and tetracyclines commonly used in the treatment of acne. A prevalence rate of 65% was documented in one study performed in the United Kingdom.[74] Overall, resistance is highest with erythromycin and lowest with the lipophilic tetracyclines, doxycycline, and minocycline.[75] The least resistance is noted with minocycline. To prevent resistance, prescribers should avoid antibiotic monotherapy, limit long-term use of antibiotics and combine usage with benzoyl peroxide whenever possible.[55]

HORMONAL THERAPY OF ACNE.

The goal of hormonal therapy is to counteract the effects of androgens on the sebaceous gland. This can be accomplished with the antiandrogens, or agents designed to decrease the endogenous production of androgens by the ovary or adrenal gland, including oral contraceptives, glucocorticoids, or gonadotropin-releasing hormone (GnRH) agonists.

Oral Contraceptives. Oral contraceptives can improve acne by four main mechanisms. Firstly, they decrease the amount of gonadal androgen production by suppressing LH production. Secondly, they decrease the amount of free testosterone by increasing the production of sex hormone binding globulin. Thirdly, they inhibit the activity of 5-α reductase activity, so as to prevent the conversion of testosterone to the more potent DHT. Lastly, progestins that have an antiandrogenic effect can block the androgen receptors on keratinocytes and sebocytes. The third-generation progestins—gestodene (not available in the United States), desogestrel, and norgestimate, have the lowest intrinsic androgenic activity.[76] Two progestins have demonstrated antiandrogenic properties: (1) cyproterone acetate (not available in the United States) and (2) drospirenone. There are three oral contraceptives currently Food and Drug Administration (FDA) approved for the treatment of acne: (1) Ortho Tri-Cyclen, (2) Estrostep, and (3) Yaz. Ortho Tri-Cyclen is a triphasic oral contraceptive comprised of a norgestimate (180, 215, 250 mg)–ethinyl estradiol (35 μg) combination.[77] In an effort to reduce the estrogenic side effects of oral contraceptives, preparations with lower doses of estrogen (20 μg) have been developed for the treatment of acne. Estrostep contains a graduated dose of ethinyl estradiol (20–35 μg) in combination with norethindrone acetate (1 mg).[78] Yaz contains ethinyl estradiol (20 ug) and the antiandrogen drospirenone (3 mg). Drospirenone is a 17 α-spironolactone derivative that has both antimineralocorticoid and antiandrogenic properties, which may improve estrogen-related weight gain and bloating.[78] An oral contraceptive containing a low dose of estrogen (20 μg) in combination with levonorgestrel (Alesse) has also demonstrated efficacy in acne.[79] Side effects from oral contraceptives include nausea, vomiting, abnormal menses, weight gain, and breast tenderness. Rare but more serious complications include thrombophlebitis, pulmonary embolism, and hypertension. With the use of estrogen–progestin-containing oral contraceptives rather than estrogen alone, side effects such as delayed menses, menorrhagia, and premenstrual cramps are uncommon. However, other side effects such as nausea, weight gain, spotting, breast tenderness, amenorrhea, and melasma can occur.

Glucocorticoids. Because of their anti-inflammatory activity, high-dose systemic glucocorticoids may be of benefit in the treatment of acne. In practice, their use is usually restricted to the severely involved patient, often overlapping with isotretinoin to limit any potential flaring from at the start of treatment. Furthermore, because of the potential side effects, these drugs are ordinarily used for limited periods of time, and recurrences after treatment are common. Prolonged use may result in the appearance of steroid acne. Glucocorticoids in low dosages are also indicated in those female patients who have an elevation in serum DHEAS associated with an 11- or 21-hydroxylase deficiency or in other individuals with demonstrated androgen excess. Low-dose prednisone (2.5 mg or 5 mg) or dexamethasone can be given orally at bedtime to suppress adrenal androgen production.[44] The combined use of glucocorticoids and estrogens has been used in recalcitrant acne in women, based upon the inhibition of sebum production by this combination.[80] The mechanism of action is probably related to a greater reduction of plasma androgen levels by combined therapy than is produced by either drug alone.

Gonadotropin-Releasing Hormone Agonists. GnRH agonists, such as leuprolide (Lupron), act on the pituitary gland to disrupt its cyclic release of gonadotropins. The net effect is suppression of ovarian steroidogenesis in women. These agents are used in the treatment of ovarian hyperandrogenism. GnRH agonists have demonstrated efficacy in the treatment of acne and hirsutism in females both with and without endocrine disturbance.[81] However, their use is limited

by their side effect profile, which includes menopausal symptoms and bone loss.

Antiandrogens. Spironolactone is an aldosterone antagonist and functions in acne as both an androgen-receptor blocker and inhibitor of 5-α reductase. In doses of 50–100 mg twice a day, it has been shown to reduce sebum production and to improve acne.[82] Side effects include: diuresis, potential hyperkalemia, irregular menstrual periods, breast tenderness, headache, and fatigue. Combining spironolactone treatment with an oral contraceptive can alleviate the symptoms of irregular menstrual bleeding. Although hyperkalemia is a risk of spironolactone, this risk has shown to be minimal, even when spironolactone is administered with other aldosterone antagonists (such as drospirenone containing oral contraceptives).[83] As an antiandrogen, there is a risk of feminization of a male fetus if a pregnant female takes this medication. Long-term studies in rats receiving high doses of spironolactone demonstrated an increased incidence of adenomas on endocrine organs and the liver. These findings recently led to a black box warning by the FDA.[84]

Cyproterone acetate is a progestational antiandrogen that blocks the androgen receptor. It is combined with ethinyl estradiol in an oral contraceptive formulation that is widely used in Europe for the treatment of acne. Cyproterone acetate is not available in the United States.

Flutamide, an androgen receptor blocker, has been used at doses of 250 mg twice a day in combination with oral contraceptives for treatment of acne or hirsutism in females.[85] Liver function tests should be monitored, as cases of fatal hepatitis have been reported.[86] Pregnancy should be avoided. Use of flutamide in the treatment of acne may be limited by its side effect profile.

Isotretinoin. (See Chapter 228). The use of the oral retinoid, isotretinoin, has revolutionized the management of treatment-resistant acne.[87] It is approved for use in patients with severe recalcitrant nodular acne. However, it is commonly used in many other acne scenarios, including any significant acne that is unresponsive to treatment with oral antibiotics and acne that results in significant physical or emotional scarring. Isotretinoin is also effective in the treatment of Gram-negative folliculitis, pyoderma faciale, and acne fulminans.[88] The remarkable aspects of isotretinoin therapy are the complete remission in almost all cases and the longevity of the remission, which lasts for months to years in the great majority of patients. However, due to its teratogenicity its use has become highly regulated in the United States with the initiation of the iPledge program in March 2006 to insure that pregnancy-prevention procedures are followed.

The mechanism of action of isotretinoin is not completely known. The drug produces profound inhibition of sebaceous gland activity, and this undoubtedly is of great importance in the initial clearing.[89,90] In some patients, sebaceous gland inhibition continues for at least a year, but in the majority of patients, sebum production returns to normal after 2–4 months.[89] Thus, this action of the drug cannot be used to explain the long-term remissions. The *P. acnes* population is also decreased during isotretinoin therapy, but this decrease is generally transient.[90,91] Isotretinoin has no inhibitory effect on *P. acnes* in vitro. Therefore, the effect on the bacterial population is probably indirect, resulting from the decrease in intrafollicular lipids necessary for organism growth. Isotretinoin also has anti-inflammatory activity and probably has an effect on the pattern of follicular keratinization. These effects also are temporary, and the explanation for long-term remissions remains obscure.

Given the ubiquitous distribution of RAR, isotretinoin almost always causes side effects, mimicking those seen in the chronic hypervitaminosis A syndrome.[92] In general, the severity of side effects tends to be dose dependent. The most common side effects are related to the skin and mucous membranes. Cheilitis of varying degrees is found in virtually all cases. Other side effects that are likely to be seen in over 50% of patients are dryness of the mucous membranes and skin. An eczematous dermatitis is occasionally seen, particularly in cold, dry weather. Thinning of hair and granulomatous paronychial lesions are less common. Ophthalmologic findings include xerophthalmia, night blindness, conjunctivitis, keratitis, and optic neuritis. Corneal opacities and hearing loss (both transient and persistent) have also been reported with isotretinoin use. Pseudotumor cerebri, also known as benign intracranial hypertension, is evidenced by severe headache, nausea, and visual changes. The risk of pseudotumor cerebri may be increased with concomitant use of tetracyclines and isotretinoin; therefore, these two medications should not be used together without careful prior consideration. If symptoms suggest benign intracranial hypertension, prompt neurological evaluation for evidence of papilledema is required. Vague complaints of headache, fatigue, and lethargy are also not infrequent.

The relationship between isotretinoin use and psychiatric effects is currently being examined. Risk of depression, suicide, psychosis, and aggressive and/or violent behavior are all listed as possible side effects. While no clear mechanism of action has been established, some evidence for biologic plausibility does exist. Psychiatric adverse events are described with high-dose vitamin A and etretinate. Also, retinoids have the demonstrated ability to enter the central nervous system (CNS) of rats and mice. And finally, there are documented case reports and studies linking isotretinoin use to depression in certain individuals.[93] A meta-analysis of nine studies looking at the possible link between isotretinoin and depression found that the incidence of depression in patients on isotretinoin ranged from 1%–11%.[94] The authors importantly pointed out that this range is similar to control group patients on oral antibiotics. Another author examining case-control studies on isotretinoin and depression found the relative risk to range from 0.9 to 2.7 with wide confidence intervals.[95] Some studies demonstrate that those on isotretinoin have an overall improvement in mood.[96] Retinoids have not been shown to activate genes to induce behavioral/psychiatric changes. Nor

is there evidence demonstrating functionality of retinoid signaling pathways in the mature CNS. Large population-based studies have not supported causality. As dermatologists are often on the front line seeing adolescents at risk for depression, careful screening of adolescents is particularly needed, since the risk of depression in this population is 10%–20%.[97]

GI symptoms are generally uncommon, but nausea, esophagitis, gastritis, and colitis can occur. Acute hepatitis is rare but liver function studies should be regularly monitored, as elevation in liver enzymes can occur in 15% of patients, sometimes necessitating dose adjustments. Elevated levels of serum triglycerides occur in approximately 25% of patients on isotretinoin. This elevation, which is dose-related, typically occurs within the first 4 weeks of treatment and is often accompanied by an overall increase in cholesterol with a decrease in the high-density lipoprotein levels. The effect of this transient alteration on overall coronary artery health is unclear. Acute pancreatitis is a rare complication that may or may not be related to triglyceride levels. There are case reports documenting a potential link between isotretinoin and new-onset or flared inflammatory bowel disease. However, a study that critically examined these case reports found no grounds for a causal relationship between isotretinoin use and inflammatory bowel disease.[98] A recent population-based case-control study found that patients with inflammatory bowel disease were no more likely to have used isotretinoin than those without inflammatory bowel disease.[99] Patients with a family history of inflammatory bowel disease, or those with a preexisting inflammatory bowel disease, should be counseled regarding the possibility of isotretinoin-induced inflammatory bowel disease.

Isotretinoin has effects on bone mineralization as well. A single course of isotretinoin was not shown to have a significant effect on bone density.[100] However, chronic or repeated courses may result in significant osteopenia. Osteoporosis, bone fractures, and delayed healing of bone fractures have also been reported. The significance of reported hyperostosis is unclear, but the development of bony hyperostoses after isotretinoin therapy is more likely in patients who receive the drug for longer periods of time and in higher dosages, such as for disorders of keratinization.[101] Serial bone densitometry should be done in any patient on long-term isotretinoin. Myalgias are the most common musculoskeletal complain, seen in 15% of patients. In severe cases, creatine phosphokinase levels should be evaluated for possible rhabdomyolysis.

Other laboratory abnormalities that have been reported with isotretinoin use are an elevated erythrocyte sedimentation rate and platelet count. Alterations in the red blood cell parameters with decreased white cell counts can occur. White blood cells in the urine have rarely been linked to isotretinoin use. Most laboratory changes are mild and spontaneously resolve upon discontinuation of medication use.

The greatest concern during isotretinoin therapy is the risk of the drug being administered during pregnancy and thereby inducing teratogenic effects in the fetus.[102,103] The drug is not mutagenic; its effect is on organogenesis. Therefore, the production of retinoic embryopathy occurs very early in pregnancy, with a peak near the third week of gestation.[102,103] A significant number of fetal abnormalities have been reported after the use of isotretinoin. For this reason, it should be emphasized that isotretinoin should be given only to patients who have not responded to other therapy. Furthermore, women who are of childbearing age must be fully informed of the risk of pregnancy. The patient must employ two highly effective contraception techniques such as the use of an oral contraceptive and condoms with a spermicidal jelly. Contraception must be started at least 1 month before isotretinoin therapy. Female patients must be thoroughly counseled and demonstrate an understanding of contraception techniques before starting isotretinoin. Two forms of contraception should be used throughout the course of isotretinoin and for 1 month after stopping treatment. No more than 1 month's supply of isotretinoin should be given to a female patient so that she can be counseled on a monthly basis on the hazards of pregnancy during isotretinoin therapy. A pregnancy test must be repeated monthly. Abstinence as a form of birth control should only be allowed in special instances. Because the drug is not mutagenic, there is no risk to a fetus conceived by a male who is taking isotretinoin. Although it may seem obvious, it is important to remind men who are taking isotretinoin not to give any of their medication to female companions under any circumstances.

The recommended daily dosage of isotretinoin is in the range of 0.5–1 mg/kg/day. A cumulative weight-based dosing formula may also be used with a total dose of 120–150 mg/kg of isotretinoin during a course of therapy.[104] This dosing regimen is of particular use in patients who have variable dosages or interrupted periods of treatment as achieving the total dose will ensure the greatest chance of long-term remission. Because back and chest lesions show less of a response than facial lesions, dosages as high as 2 mg/kg/day may be necessary in those patients who have very severe truncal involvement. Patients with severe acne, particularly those with granulomatous lesions, will often develop marked flares of their disease when isotretinoin is started. Therefore, the initial dosing should be low, even below 0.5 mg/kg/day. These patients often need pretreatment for 1–2 weeks with prednisone (40–60 mg/day), which may have to be continued for the first 2 weeks of therapy. A typical course of isotretinoin is 20 weeks, but the length of the course of treatment is not absolute; in patients who have not shown an adequate response, therapy can be extended. Additional improvement may be seen for 1–2 months after discontinuation, so that complete clearance may not be a necessary endpoint for determining when to discontinue therapy. Low-dose regimens, 0.1–0.4 mg/kg/day, have shown efficacy. However, with such dosages, the incidence of relapses after therapy is greater. Approximately 10% of patients treated with isotretinoin require a second course of the drug. The likelihood for repeat therapy is increased in patients younger than 16–17 years of age. It is standard

practice to allow at least 2–3 months between courses of isotretinoin.

Furthermore, laboratory monitoring is indicated. It is appropriate to obtain a baseline complete blood count and liver function tests, but the greatest attention should be paid to following serum triglyceride levels. Baseline values for serum triglycerides should be obtained and repeated at 3–4 weeks and 6–8 weeks of therapy. If the values are normal at 6–8 weeks, there is no need to repeat the test during the remaining course of therapy unless there are risk factors. If serum triglycerides increase above 500 mg/dL, the levels should be monitored frequently. Levels above 700 to 800 mg/dL are a reason for interrupting therapy or treating the patient with a lipid-lowering drug. Eruptive exanthemas or pancreatitis can occur at higher serum triglyceride levels.

DIET. Several articles suggesting a role for diet in acne exist.[105,106] A recent review of these studies concluded that there may be some link between milk and acne as well as between high-glycemic index foods and acne.[107] Yet, overall the implications of these studies is not clear and the role of chocolate, sweets, milk, high-glycemic index foods, and fatty foods in patients with acne requires further study. There is no evidence to support the value of elimination of these foods. However, restricting a food firmly thought by the patient to be a trigger is not harmful, as long as the patient's nutritional well-being is not compromised.

ACNE SURGERY. Acne surgery, a mainstay of therapy in the past used for the removal of comedones and superficial pustules, aids in bringing about involution of individual acne lesions. However, with the advent of comedolytic agents, such as topical retinoids, its use is primarily restricted to those patients who do not respond to comedolytic agents. Even in those patients, the comedones are removed with greater ease and less trauma if the patient is pretreated with a topical retinoid for 3–4 weeks. Acne surgery should not be performed at home, as inaccurate placement of the comedo extractor may rupture the follicle and incite an inflammatory reaction. The Unna type of comedo extractor, which has a broad flat plate and no narrow sharp edges, is preferable. The removal of open comedones is desirable for cosmetic purposes, but does not significantly influence the course of the disease. In contrast, closed comedones should be removed to prevent their rupture. Unfortunately, the orifice of closed comedones is often very small, and usually the material contained within the comedo can be removed only after the orifice is gently enlarged with a no. 25 needle or other suitable sharply pointed instrument.

INTRALESIONAL GLUCOCORTICOIDS. Intralesional injection of glucocorticoids can dramatically decrease the size of deep nodular lesions. The injection of 0.05–0.25 mL per lesion of a triamcinolone acetate suspension (2.5–10 mg/mL) is recommended as the anti-inflammatory agent. This is a very useful form of therapy in the patient with nodular acne, but it often has to be repeated every few weeks. A major advantage is that it can be done without incising or draining the lesions, thus avoiding the possibility of scar formation. Hypopigmentation, particularly in darker skinned patients, and atrophy are risks.

PHOTOTHERAPY AND LASERS. Various forms of phototherapy are under investigation for their use in treating acne vulgaris. Ultraviolet (UV) light has long been thought to be beneficial in the treatment of acne. Up to 70% of patients report that sun exposure improves their acne.[108] This reported benefit may be due to camouflage by UV radiation induced erythema and pigmentation, although it is likely that the sunlight has a biologic effect on the pilosebaceous unit and *P. acnes*. Although ultraviolet B (UVB) can also kill *P. acnes* in vitro, UVB penetrates poorly to the dermal follicle and only high doses causing sunburn have be shown to improve acne.[109,110] UV radiation may have anti-inflammatory effects by inhibiting cytokine action.[111] Twice-weekly phototherapy sessions are needed for any clinical improvement. The therapeutic utility of UV radiation in acne is superseded by its carcinogenic potential.[112–116]

Other types of phototherapy for acne treatment utilize porphyrins. Treatment of acne with phototherapy works either by activating the endogenous porphyrins of *P. acnes* or by applying exogenous porphyrins. Coproporphyrin III is the major endogenous porphyrin of *P. acnes*. Coproporphyrin III can absorb light at the near-UV and blue light spectrum of 415 nm.[117] Irradiation of *P. acnes* with blue light leads to photoexcitation of endogenous bacterial porphyrins, singlet oxygen production, and subsequent bacterial destruction.[118] A visible light source, either blue or red, or both may be used to excite the endogenous porphyrins. The high intensity, enhanced, narrow-band (407–420 nm) blue light known as ClearLight (Lumenis) is currently FDA approved for the treatment of moderate inflammatory acne.[116] Red light too may be beneficial, as it penetrates deeper into the dermis and has greater anti-inflammatory properties, but causes less photoactivation of the porphyrins. Therefore, the combination of blue and red light may prove the most beneficial. Treatments should be given twice weekly for 15-minute sessions for the face alone, and 45 minutes for the face, chest, and back. A multicenter study has shown that 80% of patients treated with the ClearLight for 4 weeks had a 60% reduction in acne lesions. There was a gradual return of lesions over 3–6 months.[119]

The most consistent improvement in acne after light treatment has been demonstrated with photodynamic therapy.[120] Photodynamic therapy involves the topical application of aminolevulinic acid (ALA) 1 hour prior to exposure to a low-power light source. These sources include the pulsed dye laser, intense pulsed light, or a broadband red light source. The topical ALA is taken up by the pilosebaceous unit and metabolized to protoporphyrin IX.[121] The protoporphyrin IX is targeted by the light and produces singlet oxygen species, which then damage the sebaceous glands.[122] Several studies utilizing ALA-PDT maintained clinical improvement for up to 20 weeks.[123,124]

Although lasers are beginning to find a role in the treatment of acne, the authors consider them inferior to the traditional medical treatments. They work by emitting minimally divergent, coherent light that can be focused over a small area of tissue. The pulsed KTP laser (532 nm) has demonstrated a 35.9% decrease in acne lesions when used twice weekly for 2 weeks. Although there was no significant decrease in *P. acnes*, there was significantly lower sebum production even at 1 month.[125] The pulsed dye laser (585 nm) can also be used at lower fluences to treat acne. Instead of ablating blood vessels and causing purpura, a lower fluence can stimulate procollagen production by heating dermal perivascular tissue.[122] The beneficial effects of a single treatment can last 12 weeks.[126] Some of the nonablative infrared lasers, such as the 1,450 nm and 1,320 nm laser, have shown to be helpful in improving acne.[127,128] These lasers work by causing thermal damage to the sebaceous glands. The concurrent use of a cryogen spray device protects the epidermis while the laser causes necrosis of the sebaceous gland.[129] In a pilot study, 14 out of 15 patients treated with the 1,450 nm laser had a significant reduction in inflammatory lesions that persisted for 6 months. The 1,320 nm Nd:Yag and the 1,540 erbium glass lasers have also been demonstrated to improve acne.[130,131] Multiple treatments are needed with either of these lasers to lessen acne lesions. These treatments tend to be painful and show a gradual modest improvement, limiting their utility.

One of the newer uses of light for treating acne is with a photopneumatic device (Isolaz, Solta Medical). This photopneumatic device has a handpiece that applies negative pressure (i.e., suction) to the skin and then delivers a broadband-pulsed light (400–1,200 nm). The suction is employed to unplug the infundibulum of the pilsebaceous unit and the light is delivered to activate the *P. acnes* porphyrins, thus releasing singlet oxygen species. Patients treated with this device may experience some posttreatment erythema or purpura. Results are modest and temporary and the device is best for inflammatory lesions.[132,133] Although the light-based treatments are beneficial in that they avoid some of the side effects of the oral medications, the cost of these light and laser treatments tends to be prohibitive.

ACNE VARIANTS

NEONATAL ACNE

Neonatal acne can occur in up to 20% of healthy newborns. Lesions usually appear around 2 weeks of age and resolve spontaneously within 3 months. Typically, small, inflamed papules affect the nasal bridge and the cheeks. Because comedone formation is absent, many consider neonatal acne a variant of neonatal cephalic pustulosis. However, it has been shown that sebum excretion rates in newborns are transiently elevated in the perinatal period.[134] Additionally, *Malassezia sympodialis*, a normal commensal on human skin, may also play a role. Some reports have demonstrated positive cultures of the pustules with *Malassezia* and improvement with ketoconazole cream.[135] While there appears to be a strong association between *Malassezia* and neonatal acne, definite causality has not yet been proven.[136]

INFANTILE ACNE

Infantile acne presents at 3–6 months of age and typically shows comedones. Papules, pustules, and nodules can also present on the face and scarring may occur even with relatively mild disease. Infantile acne is caused in part by the transient elevation of DHEA produced by the immature adrenal gland. Additionally, during the first 6–12 months of life boys may also have an increased level of LH that stimulates testosterone production. Around 1 year of age, these hormone levels begin to stabilize until they surge again during adrenarche. As a result, infantile acne usually resolves around 1–2 years of age. Treatment generally consists of topical retinoids and benzoyl peroxide. Oral therapy with erythromycin, trimethoprim, or isotretinoin can be used in severe or refractory cases.[136]

ACNE CONGLOBATA

This severe form of nodular acne is most common in teenage males, but can occur in either sex and into adulthood. Acne conglobata (*conglobate* means shaped in a rounded mass or ball) is a mixture of comedones, papules, pustules, nodules, abscesses, and scars. It can be on the back, buttocks, chest, and, to a lesser extent, on the abdomen, shoulders, neck, face, upper arms, and thighs (Fig. 80-6). The comedones often have multiple openings. The inflammatory lesions are large, tender, and dusky-colored. The draining lesions discharge a foul-smelling serous, purulent, or mucoid material. Subcutaneous dissection with the formation of multichanneled sinus tracts is common. Healing results in an admixture of depressed and keloidal scars. The management of these patients is very difficult and the effect of treatment is often temporary. Several medications have been used, including intensive high-dose therapy with antibiotics, intralesional glucocorticoids, systemic glucocorticoids, surgical debridement, surgical incision, and surgical excision. The use of isotretinoin has produced dramatic results in some of these patients. In severe cases, dosages as high as 2 mg/kg/day for a 20-week course may be necessary. However, because severe flares may occur when isotretinoin is started, the initial dose should be 0.5 mg/kg/day or less, and systemic glucocorticoids are often required either before initiating isotretinoin therapy or as concomitant therapy.

ACNE FULMINANS

Acne fulminans (also known as acute febrile ulcerative acne) is the most severe form of nodular acne and is accompanied by systemic symptoms. The sudden appearance of massive, inflammatory, tender, oozing, friable plaques with hemorrhagic crusts characterize acne fulminans. The lesions predominate on the chest

Figure 80-8 Acne fulminans. An eruptive form of acne with extensive inflammatory papules and nodules on the chest (**A**) and back (**B**). Systemic symptoms may accompany this extreme form of acne and scarring is usually quite extensive.

and back (Figs. 80-8A and 80-8B) and rapidly become ulcerative and heal with scarring. The disease is reported to occur primarily in teenage boys. The face is often uninvolved. The patients are febrile, have a leukocytosis of 10,000–30,000/mm^3 white blood cells, and usually have polyarthralgia, myalgia, hepatosplenomegaly, and anemia. Bone pain is common, especially at the clavicle and sternum. Radiologic examination may demonstrate lytic bone lesions. Occasionally there is accompanying erythema nodosum. Although this disease is often classified with acne conglobata, there are basic differences. The onset of acne fulminans is more explosive; nodules and polymorphous comedones are less common; the face is not involved as frequently and the neck is usually spared; ulcerative and crusted lesions are unique; and systemic symptoms are more common. Systemic glucocorticoid therapy, along with oral antibiotics and intralesional glucocorticoids, is the treatment regimen required for these patients. Isotretinoin is also of benefit in these patients, but in order to prevent explosive flares, systemic glucocorticoids must be started before isotretinoin and continued during the first few weeks of isotretinoin therapy. The initial dosing of isotretinoin must also be lowered accordingly in the initial weeks of therapy until the inflammation is controlled. The daily dose of glucocorticoids should be slowly decreased as tolerated. Dapsone in conjunction with isotretinoin has been reportedly beneficial in the treatment of acne fulminans associated with erythema nodosum.

SAPHO SYNDROME

SAPHO syndrome is manifested by synovitis, acne, pustulosis, hyperostosis, and osteitis. It is predominantly associated with hyperostosis of the anterior chest, palmoplantar pustulosis, hidradenitis suppurativa, and acne fulminans. Its etiology is unknown. Reported successful treatments for SAPHO syndrome are NSAIDS, sulfasalazine, and infliximab.[137] The bisphosphonates are beneficial for treating the associated bone pain.[138]

PAPA SYNDROME

PAPA syndrome, another acne variant with systemic symptoms, is marked by sterile pyogenic arthritis, pyoderma gangrenosum, and acne. Patients with PAPA syndrome may also give a history of sterile cutaneous abscesses, inflammatory bowel disease, and pancytopenia following administration of sulfa-containing medications.[139] It is an autoinflammatoy disorder inherited in an autosomal dominant manner. Due to mutations in the CD2 binding protein-1 gene (also known as the protein serine–threonine phosphatase interacting protein), there is an increase in IL-1β production.[140] There have been reports of successful treatment with infliximab and anakinra.[139,140]

ACNE EXCORIÉE DES JEUNES FILLES

Acne excoriée des jeunes filles, as the name suggests, occurs primarily in young women who are picking at their skin. Mild acne may be present and is accompanied by extensive excoriations. Comedones and papules are systematically and neurotically excoriated leaving crusted erosions that may scar. Often the lesions that are excoriated are minute. This condition may suggest underlying depression, anxiety, obsessive–compulsive disorder, or a personality disorder. Antidepressants and psychotherapy can be helpful in treating these patients.

ACNE MECHANICA

Acneiform eruptions have been observed after repetitive physical trauma to the skin such as rubbing. This can occur from clothing (belts and straps) or sports equipment (football helmets and shoulder pads). Occluding the skin with adhesive tape can also produce acne mechanica. Obstruction of the pilosebaceous gland results in comedo formation. It presents as a well-defined, lichenified, hyperpigmented plaque interspersed with comedones. A classic example of

acne mechanica is fiddler's neck, produced where the violin pad repetitively rubs against the player's lateral neck.

ACNE WITH SOLID FACIAL EDEMA

A rare and disfiguring variant of acne vulgaris is acne with solid facial edema, also known as Morbihan's disease. There is a woody edema of the midthird face with accompanying erythema and acne. Similar changes have been reported with rosacea, Melkerson–Rosenthal syndrome, and rosacea. There may be fluctuations in the severity of the edema, but spontaneous resolution does not occur. Oral antibiotic treatment is ineffective. Treatment with low dose isotretinoin (0.2–0.5 mg/kg/day) alone or in combination with oral glucocorticoids, ketotifen (1–2 mg/day), or clofazimine for 4–5 months has been reported to be beneficial.[141,142]

ACNE WITH ASSOCIATED ENDOCRINOLOGY ABNORMALITIES

Although the majority of cases of acne vulgaris occur in patients without endocrinologic disturbances, there is a certain population whose acne is driven or worsened by endocrine abnormalities. As mentioned previously, it is important to screen patients for such abnormalities by taking a thorough history. In addition to the presence of acne, endocrinologic disturbances may be marked by irregular menstrual cycles, deepened voice, increased libido, and hirsutism. Laboratory work can help define an endocrinologic problem causing acne.

POLYCYSTIC OVARY SYNDROME. Polycystic ovary syndrome (PCOS) occurs in roughly 3%–6% of the general population. Patients with PCOS, also called Stein–Leventhal syndrome, ovulate infrequently or not at all, have multiple cysts on their ovaries, and often have irregular menses, obesity, androgenic alopecia, hirsutism, and acne. There is an increased risk of diabetes mellitus and endometrial carcinoma in patients with PCOS.[143] Serum total testosterone in the range of 150–200 ng/dL or an increased LH/FSH ratio (greater than 2.0) can be found in cases of PCOS. Patients with signs of hyperandrogenism should also be asked about insulin resistance, since acne can occur with the HAIR-AN syndrome, a subset of PCOS. Hyperandrogenism, acne, insulin resistance, and acanthosis nigricans are markers of this syndrome. It is important to identify these patients because they are at increased risk for accelerated cardiovascular disease and diabetes mellitus.

CONGENITAL ADRENAL HYPERPLASIA. Congenital adrenal hyperplasia, usually caused by defects in the adrenal enzyme 21β-hydroxylase, occurs as both a classic severe type and as a nonclassic mild type. Neonates are screened at birth for the classic type and typically present with ambiguous genitalia and salt-wasting. The nonclassic type is not identified at birth and can present throughout childhood and adolescence. The prevalence of the nonclassic type in the white population is 1 in 1,000. Patients with this type of congenital adrenal hyperplasia have normal cortisol levels but increased androgens. Female patients present with precocious puberty, irregular menses, polycystic ovaries, hirsutism, and acne.[144] Values of DHEAS in the range of 4,000–8,000 ng/mL are suggestive of congenital adrenal hyperplasia. Findings of CAH in males are often subtle, as acne may be the only sign, but CAH should be considered in patients who do not respond to treatment.[145] Treatment of congenital adrenal hyperplasia consists of low dose replacement of glucocorticoids, as well as oral contraceptives, spironolactone, or flutamide in females.

ACNEIFORM ERUPTIONS

STEROID FOLLICULITIS

Following administration of systemic glucocorticoids or corticotropin, folliculitis may appear. This is very uncommon in children but may occur in any adult as early as 2 weeks after steroids are started. Similar lesions may follow the prolonged application of topical glucocorticoids to the face. For this reason, topical glucocorticoids have no place in the treatment of acne, and their use on the face, in general, should be limited. The pathology of steroid acne is that of a focal folliculitis with a neutrophilic infiltrate in and around the follicle. This type of acne clearly differs from acne vulgaris in its distribution and in the type of lesions observed. The lesions, which are usually all in the same stage of development, consist of small pustules and red papules. In contrast to acne vulgaris, they appear mainly on the trunk, shoulders, and upper arms, with lesser involvement of the face. Postinflammatory hyperpigmentation may occur, but comedones, cysts, and scarring are unusual. Treatment consists primarily of stopping any corticosteroid use. Typical acne treatments such as topical retinoids and antibiotics may also be helpful.

DRUG-INDUCED ACNE

In addition to glucocorticoids, other medicines can also cause a monomorphic, diffuse popular eruption that mimics steroid folliculitis. Such drugs include: phenytoin, lithium, isoniazid, high doses of vitamin B complexes, halogenated compounds, and certain chemotherapy medications (see Box 80-2). Halogenated compounds containing either bromides or iodides are often found in cold and asthma remedies, sedatives, radioopaque contrast material, kelp (in many fad diet pills), and other vitamin–mineral combinations. With iodides, in particular, inflammation may be marked.[146,147] The iodine content of iodized salt is low and, therefore, it is extremely unlikely that enough iodized salt could be ingested to cause this type of acne.

BOX 80-2 DRUG-INDUCED ACNEIFORM ERUPTIONS

- Glucocorticoids
- Phenytoin
- Lithium
- Isoniazid
- High-dose vitamin B complex
- Halogenated compounds
- Epidermal growth factor receptor inhibitors

EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITOR ASSOCIATED ERUPTION

A newer class of chemotherapy medicine, known as the EGFR inhibitors, may also cause a follicular-based eruption. EGFR inhibitors are primarily used to treat nonsmall-cell lung cancer, colorectal cancer, and breast cancer. Some of the EGFR inhibitors include: gefitinib (Iressa), cetuximab (Erbitux), erlotinib (Tarceva), and trastuzumab (Herceptin). In treatment responsive patients, the EGFR inhibitors are indefinitely administered for their long-term ability to inhibit tumor growth, progression, cell proliferation, and angiogenesis. A frequent side effect of the EGFR inhibitors is a perifollicular, papulopustular eruption distributed on the face and upper torso. The eruption occurs in up to 86% of patients treated with EGFR inhibitors. An associated lateral paronychia may also occur. Histopathological sections of lesional skin show a noninfectious perifolliculitis.[148] The etiology of the acneiform eruption is not clear, but it may occur because EGFR is highly expressed in the basal cell layer of the epidermis, follicular keratinocytes, and the sebaceous epithelium. The presence and severity of the eruption correlates with a positive treatment response. If the eruption is absent, dosing may be inadequate or the patient's tumor may be unresponsive to EGFR inhibitor therapy.[149]

OCCUPATIONAL ACNE AND CHLORACNE

Several different groups of industrial compounds encountered in the workplace may cause acne. These include coal tar derivatives, insoluble cutting oils, and chlorinated hydrocarbons (chloronaphthalene, chlorobiphenyls, and chlorodiphenyloxide). Chloracne is the term that is used to describe occupational acne caused from chlorinated hydrocarbons. Occupational acne tends to be quite inflammatory and, in addition to large comedones, is characterized by papules, pustules, large nodules, and true cysts. Tar acne is often accompanied by hyperpigmentation. The lesions of occupational acne are not restricted to the face and, in fact, are more common on covered areas with intimate contact to clothing saturated with the offending compound. Because the cutting oils are so widely used, they are the most common cause of industrial acne. However, the chlorinated hydrocarbons, which cause chloracne, have posed a more difficult problem because of the severity of the disease induced with these compounds. Exposure can cause comedones, cysts, and pigmentary changes of the skin but can also affect the ophthalmic, nervous and hepatic systems.[150] Many cases have occurred as the result of massive exposure in industrial accidents.[151] Chlorinated hydrocarbons are found in fungicides, insecticides, and wood preservatives. Chloracne classically affects the malar, retroauricular, and mandibular regions of the head and neck, as well as the axillae and scrotum (see eFig. 80-7.1 in online edition), Pathology demonstrates multiple tiny infundibular cysts.[152] In 2,004, Ukrainian President Viktor Yushchenko was poisoned with dioxin, causing severe chloracne. Most chloracne lesions clear up within 2 years, providing exposure to the chemical has stopped. Treatment with topical or oral retinoids and oral antibiotics may be beneficial.

GRAM-NEGATIVE FOLLICULITIS

Gram-negative folliculitis may occur in patients with preexisting acne vulgaris treated with long-term oral antibiotics, especially the tetracyclines. Patients usually give a history of initial success with oral tetracyclines followed by a worsening of their acne. Gram-negative folliculitis may appear as either papulopustules concentrated around the nose or as deep-seated nodules. Culture of these lesions may reveal *Enterobacter*, *Klebsiella*, or *Escherichia* in the papulopustules or *Proteus* in the nodules. An appropriate antimicrobial agent with adequate Gram-negative coverage should be used. In recalcitrant cases, Gram-negative folliculitis improves with oral isotretinoin for 4–5 months. Gram-negative bacteria require a moist environment for survival and the drying action of isotretinoin will kill the bacteria.

RADIATION ACNE

Different types of radiation such as ionizing radiation and UV radiation may induce acneiform eruptions. Previous sites of therapeutic ionizing radiation (e.g., external beam) can develop comedo-like papules. These lesions begin to appear as the acute phase of radiation dermatitis is resolving. The ionizing rays induce epithelial metaplasia within the follicle, creating adherent hyperkeratotic plugs in the pilosebaceous unit. These keratotic plugs are resistant to extraction. Excessive exposure to UV radiation may produce a yellow, atrophic plaque studded with large open comedones. This condition is known as Favre–Racouchot, but has also been called solar comedones, senile comedones, nodular cutaneous elastosis with cysts and comedones, and nodular elastoidosis with cysts and comedones. It has been estimated to occur in 6% of persons above age 50.[153] The lesions are usually

symmetrically distributed on the temporal and periorbital areas. The exact pathogenesis of Favre–Racouchot is unknown, but it is suggested that extensive UV exposure as well as exposure to harsh climates and smoking may be risk factors. It can be treated with oral or topical retinoids as well as extraction.[154]

TROPICAL ACNE

In extreme heat, a severe acneiform folliculitis may develop. This can be seen in tropical climates or in scorching occupational environments, as in furnace workers. This acneiform eruption is a major cause of dermatologic disability in military troops serving in tropical climates. Tropical acne occurs mainly on the trunk and buttocks. It has many deep, large, inflammatory nodules with multiple draining areas, resembling acne conglobata. The pathogenesis of this type of acne is unknown, although secondary infection with coagulase-positive *Staphylococci* almost always ensues. Systemic antibiotics must be given, but often more important is removing the patient to a cooler environment.

ACNE AESTIVALIS

This monomorphous eruption consists of multiple, uniform, red, papular lesions seen after sun exposure. It is referred to as *Mallorca acne* because it occurred in many Scandinavians after they had been on a sunny vacation in Mallorca in southern Europe after a long, dark winter. Almost all cases have occurred in women, mainly 20–30 years old. The lesions are common on the shoulders, arms, neck, and chest. Histologically, the lesions resemble steroid acne in that they show a focal follicular destruction with neutrophilic infiltrate. Comedones are not part of the clinical or histologic picture. The eruption is due to the effects of UV radiation, primarily ultraviolet A (UVA). Rarely, a similar clinical picture can be observed after starting psoralen and UVA (PUVA) treatment. The eruption will subside if the patient is protected from UV light for several months. Oral antibiotics are ineffective in speeding up the resolution, but topical retinoids and benzoyl peroxide may be helpful. Like polymorphous light eruption, patients with acne aestivalis will flare on reexposure to UV light.[147]

PSEUDOACNE OF THE NASAL CREASE

The transverse nasal crease is an anatomic variant that appears as a transverse linear groove across the middle of the nose. Preadolescent patients have been described to develop acneiform red papules within the nasal crease along with milia (Fig. 80-9). Histologic examination of the papules reveals keratin granulomas that may be derived from ruptured, inflamed milia. Due to its similarity in clinical appearance to acne, but deviation from acne histologically, it has been termed "pseudoacne of the nasal crease."[155]

Figure 80-9 Pseudoacne of the nasal crease. Open and closed comedones and small papules line up along the transverse nasal crease.

APERT SYNDROME

Apert syndrome, also known as acrocephalosyndactyly, is an autosomal dominant disorder marked by synostoses of the cranium, vertebral bodies and hands and feet. It is caused by a mutation in the gene encoding FGFR-2. These patients have a diffuse acneiform eruption that often involves the arms, buttocks, and thighs. It is typically very resistant to treatment but excellent responses to isotretinoin have been reported. Patients with Apert syndrome may also present with severe seborrhea, nail dystrophy, and cutaneous and ocular hypopigmentation.

Chapter 81 :: Rosacea

:: Michelle T. Pelle

ROSACEA AT A GLANCE

- Rosacea affects all races, but is most common in fair-skinned individuals.
- Triggers of rosacea may include hot or cold temperature, sunlight, wind, hot drinks, exercise, spicy food, alcohol, emotions, cosmetics, topical irritants, menopausal flushing, and medications that promote flushing.
- There are four rosacea subtypes: erythematotelangiectatic, papulopustular, phymatous, and ocular.
- The primary clinical features of rosacea include flushing, inflammatory papules, pustules, and telangiectases.
- Secondary features of rosacea may include facial burning and stinging, edema, plaques, a dry appearance, phyma, peripheral flushing, and ocular manifestations.
- Sun protection and trigger avoidance are important for prevention in all types of rosacea.
- Rosacea therapy may include barrier protection practices, topical antimicrobials, oral antibiotics, retinoids, intense pulsed light, and vascular laser modalities for adequate long-term control of symptoms.

ROSACEA

Despite universal recognition, rosacea is clinically varied and of uncertain pathophysiology. Practitioners and the public can easily identify the prototypical red face of rosacea; however, confusion arises when photodamage, perioral dermatitis, postadolescent acne, and topical steroid overuse present in a similar guise. Recent theory has shifted conceptually from staged progression of rosacea signs and symptoms to a new classification that defines four subtypes with variable severity and potential overlap.

Rosacea is characterized by erythema of the central face that has persisted for months or more. The convex areas of the nose, cheeks, chin, and forehead are the characteristic distribution. Primary features of rosacea, which may be observed but are not required for the diagnosis, include flushing, papules, pustules, and telangiectases. Secondary features include facial burning or stinging, edema, plaques, a dry appearance, phyma, peripheral flushing, and ocular manifestations. Erythema in peripheral locations (the scalp, ears, lateral face, neck, and chest) can be observed in rosacea, but is also a common feature of physiologic flushing and chronic sun damage, and therefore must be interpreted carefully.[1]

SUBTYPE CLASSIFICATION

The subtypes of rosacea were defined provisionally by the National Rosacea Society (NRS) Expert Committee in 2002 and include erythematotelangiectatic, papulopustular, phymatous, and ocular subtypes.[1] These represent the most common groupings of rosacea signs and symptoms. The subtypes coincide with the first rosacea "staging" classification devised by Plewig and Kligman.[2] The erythematotelangiectatic subtype is analogous to Plewig–Kligman stage I disease, the papulopustular subtype to Plewig–Kligman stage II, and the phymatous subtype to Plewig–Kligman stage III. In contrast, the NRS classification maintains that progression of rosacea in stages (from one subtype to another) does not occur, but that subtypes may overlap in the same individual. A provisional grading system was also incorporated by the NRS Expert Committee to standardize the clinical assessment of rosacea.[3] Rosacea severity assessments must additionally include consideration of the psychological, social, and occupational impacts of this disorder and individual responsiveness to treatment.

EPIDEMIOLOGY

Although the prevalence of rosacea is unknown, the vast majority of cases occur in fair-skinned populations and it is common. However, persons of African and Asian descent may also develop rosacea.[2,4] The NRS has estimated that rosacea affects 14 million Americans. Rosacea occurs in both men and women, with onset typically after age 30.[1,5] However, children, adolescents, and young adults may develop rosacea.[6–8]

ETIOLOGY AND PATHOGENESIS

Because of prominent clinical variation among the rosacea subtypes, it has been hypothesized that etiologic and pathophysiologic differences may exist. Such differences may involve facial vascular reactivity, dermal connective tissue structure or composition, matrix composition, pilosebaceous structure, microbial colonization, or a combination of factors that alter the cutaneous response to rosacea trigger factors.[9] Rosacea is unmasked or induced by chronic, repeated trigger exposure, in particular by triggers of flushing that may

include hot or cold temperature, sunlight, wind, hot drinks, exercise, spicy food, alcohol, emotions, cosmetics, topical irritants, menopausal flushing, and medications that promote flushing.[10] Both neural and humoral mechanisms produce flush reactions that are visibly limited to the face. Facial prominence occurs because baseline facial blood flow is increased compared with other body sites,[11,12] and the facial cutaneous vasculature is more superficial and comprised of larger and more numerous vessels when compared with other sites.[13]

New investigations have demonstrated that exacerbation of the innate immune response occurs in rosacea.[14,15] Individuals with rosacea express high levels of cathelicidin peptides, and those peptides are processed atypically compared to normal skin. Cathelicidin peptides appear to enable stratum corneum tryptic enzyme (SCTE)-mediated inflammation in the epidermis.[14,15]

Dermal factors also play a role in rosacea pathogenesis. Matrix degeneration and endothelial damage have been demonstrated histologically in rosacea specimens.[16,17] Factors that contribute to matrix degeneration include inherent problems with vessel permeability and/or delayed clearance of inflammatory mediators and waste products. Alternatively, photodamaged connective tissue may alter vascular and lymphatic structure and support within the dermis.[18] In either case, chronic and persistent dermal inflammation may occur and ultimately manifest as erythema of the facial convexities in predisposed individuals.[19]
