5. The *Penn Resiliency Program* (PRP) was developed by Jane Gillham and Karen Reivich to prevent depression by teaching children cognitive–behavioral skills before the development of problems. Its most-studied version is a 12-session program designed for group administration to middle-school students. PRP contains two main components, one cognitive and the other based on social problem–solving techniques. In the cognitive component, core cognitive techniques are translated, through the use of cartoons and skits, into a language that adolescents can understand and apply to their own lives. In the social problem–solving component, students learn skills that help them better interact with this world: assertiveness, negotiation, relaxation, avoidance of procrastination, social skills, decision-making, and problem-solving. PRP has been successfully evaluated in school and managed care settings in both the United States and China. Results indicated that prevention participants report fewer depressive symptoms and are less likely to report symptoms in the moderate to severe range through 2 years of follow-up. Researchers are in the process of investigating the effects of PRP on life satisfaction, which means that it can be construed as a positive psychotherapy.
6. *Action and commitment therapy* (ACT), developed by Steven C. Hayes and colleagues, has not been explicitly discussed by its originators as a positive psychotherapy, although its goals are unambiguously positive: to reduce psychological suffering of clients and to help them live a life of value. ACT is a short-term structured therapy that has been used with individuals and groups with a variety of psychological and medical problems. It provides exercises and assignments that encourage an individual to accept psychological pain as normal and indeed important but also to avoid increasing it unnecessarily. ACT takes issue with the premise of typical cognitive therapies that the direct targeting of problematic ways of thinking is helpful. Indeed, the proponents of ACT argue that too much attention to thinking is counterproductive and may even exacerbate problems. ACT distinguishes between language and experience and teaches clients mindfulness techniques that identify

experience without the entanglement of language. Cognitive defusion is the term used for learning to regard thoughts as mere thoughts. ACT also helps clients to identify their core values, to commit to them, and to take action to live in accordance with them. ACT has a Buddhist flavor acknowledged by its originator, but this therapy was derived from behavior therapy and an explicit psychological theory of thought and language. Of all the positive psychotherapies discussed here, ACT has been among the most frequently tested, and it is as effective in reducing psychological problems as conventional cognitive–behavioral therapies. Most outcome research to date has used pathology measures, although some studies have also used the well-being measures of interest to positive psychology.

7. C. Rick Snyder's *hope therapy* uses cognitive–behavioral techniques to increase hope through a process of setting and monitoring explicit goals. It consists of formal and informal strategies for building and enhancing hope, among children and adults. Versions of hope therapy exist for individuals and groups, and several studies demonstrate that by enhancing hope, hope therapy increases well-being and decreases symptoms of depression and anxiety.
8. *Well-being therapy* was developed by Giovanni Fava and is based on Ryff's model of psychological well-being. As described earlier, Ryff's model distinguishes several components of doing well and overlaps considerably with the positive psychology vision of psychological health. Well-being therapy is a short-term individual treatment that takes a thoroughly cognitive approach. In early sessions, clients are asked to identify and to situate episodes of doing well. Then they are asked to keep a diary or journal about such episodes and to identify the thoughts and beliefs that interrupt them. Finally, they are taught to challenge and to test these beliefs. Special attention is paid to the components of well-being that are frequently impaired, which makes well-being therapy more remedial than other positive psychotherapies. Well-being therapy is effective in reducing anxiety and depression, and it enhances well-being.
9. *Positive behavioral support* is a form of behavior therapy that focuses on the environment and specifically on problem contexts, defined as counterproductive and unfair situations that produce or exacerbate difficulties for people. Originally devised by Jacki Anderson, Edward Carr, Glen Dunlap, Robert Horner, Robert Koegel, Wayne Sailor, and Ann Turnbull to help people with disabilities, positive behavioral support has more general applicability. It attempts to impart to clients skills, coping strategies, and the motivation to change. It also enlists the support of family members and other key figures in the person's life. Positive behavioral support becomes an instance of positive psychotherapy when it expands its attention from what produces

problems to what promotes happiness and life satisfaction. Like positive psychology per se, positive behavioral support is based on the premise that happiness is not simply the absence of conditions that produce problems.

ɔ. *Quality-of-life therapy* was developed by Michael Frisch, who presented it as an instance of cognitive therapy. Its goal is to increase one's quality of life (happiness) by using the sorts of techniques developed by Aaron Beck and colleagues to decrease depression. Like other positive psychotherapies, quality-of-life therapy assumes that there are multiple routes to the good life, and it describes specific techniques for achieving these, from changing one's objective situation to revising one's standards for defining personal success. Quality-of-life therapy can be used with individual clients or groups. Different versions of quality-of-life therapy have been created for clinical versus nonclinical clients, and evidence is starting to accumulate that quality-of-life therapy is successful in its intended goal of increasing life satisfaction.

Taking Stock. The unique and explicit goal of emerging positive psychotherapies is to enhance well-being and to promote the good life among those with obvious psychological problems as well as those without. They are also similar to more established therapies. Positive psychotherapies are short-term structured interventions for individuals or small groups. Most can be placed in the cognitive–behavioral realm, although their techniques could be integrated easily into other treatment models. Most positive psychotherapies entail out-of-sessions exercises and homework assignments, the results of which are discussed in sessions. A number of positive psychotherapies ask clients to keep journals, and many of these therapies rely on ongoing assessment.

Like other cognitive–behavioral interventions, positive psychotherapies take issue with assumptions of the medical model that people in treatment are ill and that their problems are best described as discrete (present-or-absent) entities *à la* DSM. According to positive psychology, people's weaknesses and strengths exist in degrees.

As emphasized, research support is still accumulating. Enough outcome studies have been conducted to conclude that positive psychotherapies are more than just promising, with effect sizes in the small to moderate range typical of psychological interventions. Not known in most cases is how positive psychotherapies fare in direct comparison to conventional treatments for anxiety or depression. As already mentioned, the boundary conditions of effective positive psychotherapy are unknown.

In the past, it was thought that positive psychology interventions were inherently light-handed, meaning that they are met with little resistance and that they are self-sustaining. Why would someone *not* want to be happier and more fulfilled, especially given the additional—presumably

rewarding—benefits of so being?

Current thinking is that positive interventions can challenge both the client and the therapist. People do not always do the right or good (i.e., happy) thing, even when they know perfectly well what is to be done. Challenging one's skills is more exhilarating than watching television. Spending time with close friends is more fulfilling than surfing the Internet. Doing volunteer work pays more dividends than reading the tabloids. Living in accord with explicit values is more satisfying than constant compromising. So why do people live as they do?

This question is among the most crucial for positive psychologists to answer, especially as they develop and deploy positive psychotherapies. The not-so-good life has considerable inertia. In the case of happiness, theorists have made sense of this inertia by positing a hedonic set-point. This set-point may reflect genetic constraints, cognitive styles like defensive pessimism, or habits sustained by given environments. Although recent research shows that the hedonic set-point can be changed by major life events, nothing suggests that change for the better is typical or easy.

CONCLUSIONS

Positive psychology goes beyond a focus on problems and their absence to reflect health and well-being. Positive psychology focuses on identifying and capitalizing strengths and capacities. Evidence is accumulating that positive constructs such as positive emotions, good relationships, meaning and purpose, character strengths, and services for others play important roles in health and well-being, not only as broad protective factors, preventing or mitigating pathology and problems, but also as enabling conditions that promote thriving and flourishing life.

The good life can be taught and learned, but it requires hard work. Psychologists, at least in the United States, have long believed that the human condition can be improved by the intelligent application of what they have learned. Positive psychologists are no exception, and many have turned their attention to interventions that make people more happy, hopeful, virtuous, productive, and socially involved. In some cases, these applications are running in front of data that would support them, but in other cases, outcome research has been done. Even the most compelling research is not based on follow-up that extends beyond a few years, and the research participants are usually motivated and willing volunteers. How well these interventions will generalize—across diverse people and over time—is therefore a research topic of high priority.

It is difficult to predict the future of positive psychotherapies except to say that their success will hinge on the relevant research. Although many therapy techniques informed by positive psychology seem promising, so far only a few of them have been tested rigorously. More work needs to be done.

One point of view is that a thoroughly successful positive psychology will result in the fading away of the perspective, leaving a balanced psychology, one that recognizes the positive and the negative and of course their interplay. As emphasized, positive psychology does not deny the negative, and it may well be that what is most troubling in life can set the stage for what is most fulfilling. Complex emotional experiences often blend the positive and negative; optimism is most apparent when people confront setbacks and failures; crisis reveals strengths of character; ongoing challenge is a prerequisite to experience flow in the moment and to achieve something important in a lifetime; relationship success is foreshadowed not by the absence of problems but by how people resolve those that arise.

All people want to live happy and fulfilling life. It is a fundamental human desire and right. Positive psychology provides a valuable perspective on the good life as well as strategies for assessment, treatment, prevention, maintenance, and promotion. Positive psychology expands the view of psychological health beyond the absence of symptoms and disorders and provides hope that a healthy, fulfilled, and productive life is possible for all.

PSYCHODRAMA, SOCIODRAMA, SOCIOMETRY, AND SOCIATRY

The biological picture of an individual places the psyche within the body (as an epiphenomenon). In the sociometric [and psychodramatic] picture of the individual (person), the psyche appears as outside of the body, the body is surrounded by the psyche, and the psyche is surrounded by, and interwoven, into the social and cultural atom.

—J. L. Moreno, *Sociometry and the Cultural Order*

Psychiatrist Jacob Levy Moreno (1889–1974) hypothesized that human beings learn primarily through interaction with relationship systems, which he called social atoms. Moreno believed that an encounter of the self with creative processes, which he defined as spontaneity-creativity, could deepen and encourage growth for individuals and groups. Psychodrama and related action methods of sociodrama and sociometry facilitate creativity, and the discovery of strengths, based upon J. L. Moreno's understanding of human growth, from infancy to the end of life, with spontaneity-creativity as a central factor.

Psychodrama is used as therapy, in various forms of education, and in training therapists, doctors, lawyers, teachers, social workers, political leaders, public speakers, businesses and organizations, and others. Psychodrama can often be used in conjunction with other forms of therapy.

In a psychodrama, one person, called the protagonist, works with the director and a group, or just individually with a director. In a group, participants may be asked to assume a role in the protagonist's exploration of an aspect of life. Those asked are not obligated to enact any role; it is a matter of choice. The director's role is complex and includes the facilitation of the protagonist, the role players, the group, the multi-phased psychodrama process and techniques, and the integration and sharing phase with protagonist and group. Psychodrama follows a sequence of phases, which includes the *warm up, action, and sharing*. In a training program there is often a *processing* phase for students.

Sociodrama is related to psychodrama, and is a process for a group, organization, or community to explore relevant concerns and issues. In sociodrama, the whole group is on the stage in a role-playing theme-, idea- and setting-based encounter in which participants have taken a role to play in the sociodrama. Sociodrama is used in educational settings, in professional development programs for a wide range of professions, and in clinical settings.

Sociometry, related to psychodrama and sociodrama, although a method of its own, is used to understand and evaluate, and to support, enhance, change, and develop relationship systems, sub-groups in organizations, communities, and entire organizations. Sociometry is a

tested process to address and improve communication, cohesion, functioning, and growth. Sociometry is rich with techniques to measure and examine the often unseen—but felt—networks very much alive in impact within a group and its members.

Sociatry (healing society) utilizes psychodrama, sociodrama, and sociometry to study the forces J. L. Moreno described as impacting all of humankind. J. L. Moreno understood there to be *an actual, underlying, dynamic, central structure impacting all formal and informal groups.* This underlying structure may be seen in groups looking through a sociometric lens, known within sociatry as the social microscope. The social microscope is an educational tool, used to show the forces J. L. Moreno named as the sociodynamic effect and the social and organic unity of mankind. Sociatry deepens relationship to the creative process and mankind's common interrelatedness.

HISTORY

J. L. Moreno was born in Bucharest, Romania and received his MD in Vienna in 1917. In Vienna he began the House of Encounter and formulated ideas about the nature of groups, healing, and society. In 1925, he immigrated to the United States, and in 1931, he inaugurated the Impromptu Theater in New York City and sociometric research at Sing Sing Prison, the Hudson School for Girls, and public schools in New York. In 1936, Moreno opened the Beacon Hill Sanatorium and the psychodrama theater in Beacon, New York. In 1954, he organized the First International Congress of Group Psychotherapy in Toronto, Canada. He is credited with many books, journals, and articles, along with the organizations he began, and his worldwide teaching and training.

J. L. Moreno was a doctor, scientist, psychiatrist, and mystic. To note his mysticism causes alarm for some, but is important in grasping the fullness of his ideas. It is from J. L. Moreno's integration of mysticism and science that this work has come. As a young man J. L. Moreno was fascinated with the cosmos, fixated with the realm of the unknown. He dedicated his life and work to understanding and mapping the connections people make and have in life. J. L. Moreno created dozens of techniques, a complex method to experience and to integrate this creative force—a kind of intelligence as he found it. He taught and trained thousands of practitioners in this method; how the force of spontaneity and creativity can be found; how to touch it, to the benefit of oneself and others. He was also a social scientist and put enormous effort into the investigation and cure of social problems. His goal was ultimately to realize an organic unity within humankind, which he notes in *Who Shall Survive?*

A truly therapeutic procedure cannot have less an objective than the whole of humankind. But no adequate therapy can be prescribed as long as humankind is not a unity in some fashion and as long as its organization is

unknown. It helped in the beginning to think, although there was no definite proof, that humankind was a social and organic unity.

Zerka Toeman Moreno began her study and work with J. L. Moreno in 1941 after having emigrated from England to the United States. Her path to finding J. L. Moreno and the Beacon, NY Hospital is a remarkable story written in her memoirs, *To Dream Again*. Zerka joined J. L. Moreno as his assistant, then as his wife and primary collaborator. J. L. Moreno's work might be just a footnote in history, were it not for the dedication, insight, and skills of Zerka Moreno. During the long period of their developing the method, Zerka emerged as co-developer, went on to teach thousands of students throughout the world, and helped heal many wounded souls.

Zerka Moreno co-authored and edited most of J. L. Moreno's books and articles and served as his primary teacher of the method. After his death, Zerka Moreno continued to teach and to develop psychodrama, and authored articles, chapters, and books, with *To Dream Again—A Memoir* as her last, with this chapter's author as editor.

J. L. Moreno and Zerka Moreno were world-minded. The issues of access to resources and the attention to those left out were of great importance to their work. J. L. Moreno created a therapy of experience, an experience of qualities of being human, to bring understanding and regeneration to individuals and groups.

The method created by J. L. and Zerka Moreno helps many problems. Work is being done throughout the world to bring the method and its practices to assist with the widespread issues that humans face as whole human family. The International Association of Group Psychotherapy and Process (IAGP) Psychodrama Division is a source of information regarding social applications.

METHODS, TECHNIQUES, CLINICAL ISSUES

The method includes psychodrama, sociodrama, sociometry, group psychotherapy, spontaneity testing and training, role testing and training, the therapeutic stage, the empty chair, role playing, role models, role relationships, and the exploration of subgroups and systems in organizations, groups, and communities. The method involves sociometry, surplus reality, tele, the cultural conserve, the social atom, the protagonist, the double, auxiliary egos, the canon of creativity, the director, role theory, role reversal, and a developmental theory based on spontaneity-creativity. There are aspects of the psychodrama method that are not as widely known, such as the cultural atom, the sociodynamic effect, sociogenetic law, sociostasis, socio-gravitation, the autonomous healing center, and sociatry.

Psychodrama

Psychodrama takes place on a stage. A stage can be like the three-level stage J. L. Moreno designed (relocated from the original hospital in Beacon, NY to Boughton Place in Highland, NY) or any space designated as a stage separated from the group. The stage is the location in which the psychodrama and sociodrama takes place. There is flexibility in the stage; the director and protagonist may adjust and change the stage when needed.

The protagonist works with the director in a group, or just individually with a director. In a group, participants may be asked to assume a role in the protagonist's exploration of an aspect of his or her life. The director works with the group and group process during psychodrama, although the focus of the group is on the psychodrama and the protagonist. It requires a combination of techniques and experiential methods to be complete. In psychodrama, a protagonist may examine aspects of life from the past, the present, or the future. The protagonist can explore a relationship, a moment in time, an interaction, a setting, or a scene from life.

According to Zerka Moreno, psychodrama is not so much a method of catharsis of abreaction, as of catharsis of integration—integration of what happened, what was needed but did not happen, what is needed now, or in the future, and how this is to be healed in some way. Integration may take place during the psychodrama or days later, and may include a new defining and developing of skills, relationships, and roles.

An initial task of the director is to discern the general frame and need the protagonist brings, and to determine a place (scene, setting, situation) to begin the psychodrama. There is a warm-up phase in which the protagonist emerges, and also a warm up between the director and the protagonist. The director may suggest an initial scene, often elicited during an interview with the protagonist at the beginning of the psychodrama. A psychodrama may commence with scene setting in which the protagonist creates in action and imagination a setting, a scene, or simply wants the empty stage. There is no requirement to begin with the past. Zerka Moreno suggests that what matters is not so much where the psychodrama begins, *but that it begin*. Psychodrama develops a protagonist's capacities and strengths in their work to create, and to recreate, in an authentic and adequate way.

The double technique in psychodrama is when a member of the group (who is guided by the director) offers statements and actions of support or stabilization, clarification, and amplification to the protagonist during the psychodrama. The double is role-played by someone from the group chosen by the protagonist or the director. The double can add depth, expand expression, extend, or clarify statements or feelings, as well as help the protagonist to gain perspective and integrate, hold, and contain the experiential-based learning.

The mirror technique is when the protagonist is outside of a scene, as though watching or seeing a scene from their life presented by others. A

group member may take the place of the protagonist in the scene, and members may be asked to assume other roles. The protagonist gains an observation, perspective, and emotional distance from the events.

Role reversal is a primary technique in psychodrama. It is a directed experience and, as with other techniques, can be used as therapy, in education, and for training programs. In role reversal, the protagonist presents what needs to be presented to another person, imagined, in a setting or scene on the stage in the psychodrama. The protagonist offers to "that other" what needs to be said. With direction, and when appropriate, the protagonist "takes the role" of that other. The protagonist moves to be in the role of that other, and to eventually respond from the role of the other. Role reversal can continue for a series of directed exchanges, but the protagonist finishes in his or her own space, place, and role as his or her self, with a period of sharing after the psychodrama has been finished. Role reversal may take place with an imagined person, an object, an idea, a place in time, etc. A protagonist may role-reverse with lessons in life, or, as J. L. Moreno described, with creation.

Role reversal expands creativity, though there are contradictions. If there is difficulty with role reversal, this may indicate that other techniques such as the double, the soliloquy, or the mirror may be more useful and appropriate. One needs to have strong and secure boundaries to return to. There is a contraindication and caution for any role reversal with trauma, perpetrators, or violence of any kind. Training is required to facilitate role reversal or any aspect of psychodrama and related methods.

Sociodrama

In psychodrama, one person is the protagonist; in sociodrama, the whole group participates in the action learning. In sociodrama, the group, organization, or community explores concerns, problems, situations, or issues relevant. Sociodrama is used in education, for professional development, and in clinical settings. The group is role-playing within a theme, exploring issues in an imagined setting. Refer to the reference list at the end of the chapter for how themes, issues, concerns, and settings are designed and chosen.

Sociodrama has been used to address global warming; with exchanges between people of differing cultures and religions; with survivors of the Holocaust on both sides; in working with issues and differences between the generations; and between police and gangs, etc. For the last several years a group of practitioners have on one same day, to offer Sociodrama Conference, which takes place every few years, sponsored in association with the International Association of Group Psychotherapy and Group Process (IAGP). Sociodrama develops a group in their capacity to double and reverse roles with others, to see the world from the point of view of another, to find new meaning and learning.

Sociodrama is used for training doctors to better understand the experience of being a patient, and parents to better know the experience of being a parent. Sociodrama increases communication and cohesion and *tele* (two-way empathy). Sociodrama includes techniques and directorial and group processes for how a sociodrama is directed, and how the concerns, themes, roles, and settings are chosen.

Psychodrama and sociodrama are experientially woven applications of the social atom, encounter, the canon of creativity, role theory, concretization, sociometry, catharsis of integration, group psychotherapy, and other techniques, which will be explained further in this chapter. It is human relationships in life that can be concretized and explored through psychodrama, sociodrama, and sociometry.

Sociometry and Tele

Moreno hypothesized that human society has an atomic structure, which corresponds to the atomic structure of matter, and that its existence can be brought to an empirical test by social microscopy, related to sociometry. Sociometry is a method for the examination, exploration, and alteration of the connections and dynamics taking place within a group, organization, or community. The connections are often felt but often not fully recognized. Sociometry makes the connections visible, approachable to growth and change, to increase communication, creativity, cohesion, and resolution.

Sociometry is a method with many instruments for the measurement of connection, the web of tele "meetings" in operation. Telic connections can impact the functioning of a group or organization and individuals within it, and the dynamics of cohesion, inclusion, exclusion, subgroups, etc. Telic constellations form between two or more people often unrealized in their capacity to harness and unleash a kind of inter-feeling that impacts a group's embrace of its members, its creativity, its functioning, cohesion, and learning. Tele is a phenomenon below transference not always seen, with multiple types of often interlocking relationships and groupings in an organization and community.

Telic constellations are made visible with sociometry. Sociometric structures and configurations can regenerate to increase communication, cohesion, creativity, and functioning. Sociometry is used in clinical settings, in training programs, with organizations, and in education.

Zerka Moreno explains tele:

> Empathy and transference are part of a more elementary and more inclusive process of tele. The process of reciprocation does not enter into the meaning of empathy, and transference is considered the factor responsible for dissociation and disintegration of social groups. Tele is the factor responsible for the increased mutuality of choices surpassing chance possibility and responsible for the increased rate of interaction among members of a group.

Telic structures are central to one's personal sociometry, noticed in the

feeling between oneself and others. For personal and professional development, sociometry evaluates and measures this. With a group, sociometry may knit positive telic connection and communication, and to address negative, ambivalent, non-mutual connections. Sociometry can unclog blocked communication by revealing to the group its telic structures. When the structures are more fully understood, they can be changed and developed in a productive way. Telic structures often operate below the formal organization as a matrix of cohesion or not, at a moment in time. Sociometry shows a group the living social atom, the dynamic telic processes commonly unseen but often felt, and the intelligence of life called spontaneity-creativity in action.

THEORIES THAT INFORM THE METHOD

The Social Atom

The social atom is used to depict the relationships of one's life and the nature of each relationship. The social atom can be an instrument used in a written format, or else a psychodrama enactment may depict a social atom by bringing it alive with others taking roles. The social atom can include one's relationship with individuals, groups, animals, communities, etc. The social atom may depict the past, the present, or the needed or hoped for relationships. It is a visual representation of positive, negative, neutral, ambivalent, mutual, and non-mutual relationships.

The social atom depicts those with whom one feels emotionally impacted, connected, or related. The social atom is a relationship map; it brings awareness to relationships. The social atom looks like a bull's-eye; the nucleus represents oneself. In the first circle beyond oneself, one notes those with whom there is such a significant impact. One draws a line connecting the self to that other, and there are specific line notations to show the nature of the relationship. Beyond that, in the next circle, one depicts those with impact best depicted at that level, and so on. *The social atom is a depiction of one's own truth and perception*. The spatial distance from the center to others reflects the perception of the nature and impact of those persons. A menu of symbols and lines are given that denote male and female, positive and negative, neutral, ambivalent, mutual, and one-way relationships.

There is flexibility with this tool, which provides information and insight and points to areas of further exploration. J. L. Moreno believed human are as closely tied to their social atoms as they are to their bodies.

Encounter

Encounter represents a theoretical and practical underpinning to psychodrama. Encounter is an action-instrument, a basic idea, for an existential dialogue with another, imagined or real. With the encounter one

finds oneself in the *psychodramatic experience of me and not me*. This is an existential fiber in life for what connects us, an experience often had with psychodrama. J. L. Moreno gave a name to the mutual feeling of the essentialness of another, calling that sense of another *tele,* noted earlier in this chapter. The interweaving of tele is explored in psychodrama, sociodrama, and sociometry.

J. L. Moreno wrote about the existence of a primordial nature in life, found within humans and within groups. In *To Dream Again—A Memoir,* Zerka Moreno named this primordial nature the *autonomous healing center* within. It is generated in psychodrama to craft a new, novel, and adequate response to life.

This is the case when the protagonist explores a role reversal, in taking another's role in language, behavior, and feeling. One finds a sense of what that other might feel, and what might be learned from this. It is in the encounter of oneself with others and life that spontaneity-creativity are discovered and strengthened. Facilitating role reversal and encounter requires training; for information regarding training and certification for psychodrama, refer to the American Board of Examiners in Psychodrama, Sociometry and Group Psychotherapy. There are similar boards throughout the world.

Canon of Creativity: Formula for Creativity

The Canon of Creativity is a visual diagram to represent a theoretical underpinning to the psychodrama method. The diagram identifies stages of creativity for a person and group. The Canon of Creativity is a theory actualized and brought to life by psychodrama, and includes the warm up where group members prepare for spontaneity-creativity in action. There is then a movement to create something new, which is met at first with resistance. Once resistance is addressed, then renewal and creativity can emerge. There is the movement to form—and presence—in the world and life. The renewal of society was J. L. Moreno's full vision, bring creativity into culture for its renewal.

Human Development

Zerka Moreno describes the perspective for a series of developmental stages through the course of life in *The Quintessential Zerka*. These are the periods from one's birth to one's ending, offering guidance for tasks to be considered for each developmental stage. The developmental stages and tasks are templates for a realization of creative potential and have life tasks for growth.

Psychodrama helps to experience the tasks, even those not originally completed. To become more able to role-reverse with others, including groups of people, is one of the developmental tasks. There is a task of

completing unfinished business with one's parents, and preparing to yield parents back to the cosmos, as people eventually ready themselves. Developmental stages include the taking of new roles, finishing others, and crafting one's continued path.

It is useful to consider that, in each of the developmental phases, different psychodrama tools are highlighted as instruments to help with that phase. It is also wise, in conducting psychodrama, to have as a mental construct the notion that what the protagonists are showing could be related to the tool needed for a developmental stage to be completed.

Role Theory

Role theory suggests that the self develops and emerges through the process and actualization of roles through one's life. Roles are internal and external aspects and functions of self. Role training, learning new roles in life, works according to a three-stage process: (1) deciding to take a role or not, addressing ambivalence and resistance; (2) assuming a role and finding role models and examples of how to function with increasing skill in a role; and (3) emerging more fully as oneself and with increasing skill by creating new and authentic expressions of oneself.

The method considers human psychological and emotional growth comes through how people start, how people learn, play, live, change, and finish the roles and role relationships throughout their lives. To attend to this consciously can be supported by the methods stated here. Psychodrama can be used to explore and prepare for the roles one wants, or wants to change, in some fashion.

Surplus Reality

Surplus reality is a wide-ranging tool for a protagonist and group to explore beyond a present reality. Surplus reality uses a variety of techniques and is a foundation for psychodrama. The protagonist creates a psychodrama that includes and can go beyond known reality, using imagination, perception, creativity, and psychodramatic activity. The director helps the protagonist to explore the real or imagined, and to forge an adequate response.

Techniques include role reversal, double, mirror, soliloquy, aside, concretization, presentation of oneself in the role of another, and changing time, space, and location. Surplus reality can involve empty chairs representing people, events, or aspects of oneself, and stages of life, etc. Surplus reality can offer to the protagonist an experience as it was needed but did not happen, aspects of the past, present, or future, and roles that may be required.

Surplus reality touches upon imagination and creativity. It opens to new worlds, exploring an event, redoing an event, or exploring an event that never happened. Auxiliary egos, as they are called, are group members

asked to take a part in the protagonist's exploration. Regardless of the interaction in many ways the protagonist explores strengths, capacities, and resources along with vulnerabilities and creativity. There is a great range of choice that surplus reality offers.

Universalia of Time, Space, Reality, and the Cosmos

The psychodrama method uses time, space, reality, surplus reality, and the existential realm of the cosmos as J. L. Moreno described it, as psychodramatic tools. The past, present, and future are reflected in the here and now, making time a flexible instrument. A protagonist may explore a scene that happened in childhood, then change scenes to one imagined in the future. A sequencing of scenes and times may be explored, for example, as markers of one's life.

Psychodrama explores life as it happened, or as it was needed or wished for. The director uses psychodrama to facilitate the protagonist's exploration and repair. The connection of human beings to life relates people to an inherent dignity. Many report psychodrama to be an experiential encounter that reveals this universal dimension.

Warm Up, Action, Sharing—the Structure of Psychodrama

Psychodrama is a three-step process of warm up, action, and sharing, with processing for those in training. The warm up constitutes approximately one-third of the session, the action phase one-third, and sharing phase one-third. There are many approaches to conducting a warm up, which can be quite organic to help the group meet one another, for participants to feel present, to make connections to others, and for the director to introduce themes. The warm up is a natural tendency in human life: people have a warm up, for example, as a preparation for going to sleep, or a warm up for going to work, or for addressing difficult issues with another. This phase is natural to how humans live.

The warm-up process introduces creativity in some form to the group and individuals. A warm up may be planned or spontaneous, may include movement, conversation, reflection, art and music, etc. The warm up is preparation for the action phase. The director weaves and orients the positive telic connections, enhancing the social atom of the group.

The action phase is the psychodrama or sociodrama itself. In psychodrama a protagonist may be chosen by the group, at times self-selected, or selected by the director. The protagonist enters the stage and there is often an initial dialogue between the protagonist and the director about goals, boundaries, time frames, and elements of the psychodrama.

The director works in collaboration with the protagonist. The group remains a group, even as some group members may be asked to enact a role in the psychodrama. The action phase often starts with a scene or some

expression of present concerns. There may be a number of scenes or just one scene. There is often a peak of action and integration of the experiential learning.

Sharing is the final third of psychodrama. With the psychodrama completed, group members share with the protagonist and group about how the psychodrama was related to one's life. Those who assumed a role in the psychodrama generally share first, initially from the experience of the role, then as it relates to their life. Sharing is not advice giving or analysis; the director may share as well.

Do–Undo–Redo

Do–Undo–Redo is one option for a methodologic sequence for a psychodrama, as a strategy for change, and a structure for the action phase. The protagonist may begin by showing a condition or concern, perhaps a stepping in and out of the concern, concretized in some way on the stage. The protagonist may encounter an aspect or aspects they wish to address or change. The protagonist can undo things and, following that, redo them differently or from a different vantage point. There can be a scene followed by the redone scene in which something new has been created. There can be a reconstruction of the situation or elements in it. This is a flexible structure adjusted to meet the needs of the protagonist.

One quite beautiful application of this has been the "moments from one's life" in which the protagonist (often many protagonists) may "re-live" an experience in life, often a joyful and enlightening one.

ETHICS IN TRAINING, EDUCATION, AND PRACTICE

A challenge in conducting psychodrama is keeping the experiential structures intact while having flexibility in the application. This places a demand on the director, educator, trainer, and practitioner to evaluate and apply the psychodrama method with a solid foundation of theory, training, education, practice, and certification. The strategic thinking for directing requires training, supervision, and professional development. The American Board of Examiners in Psychodrama, Sociometry and Group Psychotherapy sets standards and examines candidates for two levels of national certification: Certified Practitioner (CP) and Trainer-Educator-Practitioner (TEP). Similar certification boards exist in South America, Australia, Europe, and Asia. The American Board has adopted the ethical standards of the American Psychological Association. Psychodrama should not be practiced without board-approved training, in accordance with the established certification guidelines.

RESEARCH AND THE SOCIAL AND ORGANIC UNITY OF HUMANITY

For the application of research in the use of psychodrama, two sources are

recommended. The American Society of Group Psychotherapy and Psychodrama (ASGPP) is the membership organization of psychodrama in the United States. There are similar organizations throughout the world, for which research information would also be available. The American Board of Examiners in Psychodrama, Sociometry and Group Psychotherapy (ABE) is the certification organization for psychodrama in the United States. Similar boards exist throughout the world.

Social and Organic Unity of Humanity

J. L. Moreno wrote extensively about society and social forces impacting humankind. He makes reference to it in his book, *Who Shall Survive?*

"The discovery that human society has an actual, dynamic, central structure underlying and determining all its peripheral and formal groupings may one day be considered as the cornerstone of all social science. This central structure—once it has been identified—is either found or discernible in every form of human society, from the most primitive to the most civilized: it is in the genesis of every type of society. In addition, it exerts a determining influence upon every sphere in which the factor of human interrelations is an active agent in economics, biology, social pathology, politics, government, and similar spheres of social action."

To see society's actual, dynamic, central structure underlying and determining all peripheral and formal groupings offers a perspective on what impacts present situations. The situation calls for a willingness to reverse roles with others and other groups of people, and to find what is common among us, to find solutions that consider all of mankind and the impacted natural world. Sociatry endeavors to understand this underlying phenomenon to human society and to create education for personal and professional development about the underlying structures impacting humankind and the ecological fabric. It is a creative path for which J. L. Moreno offers:

"A truly therapeutic procedure cannot have less an objective than the whole of humankind. But no adequate therapy can be prescribed as long as humankind is not a unity in some fashion and as long as its organization is unknown. It helped in the beginning to think, although there was no definite proof, that humankind was a social and organic unity."

Based on this, it may be an idea developed of necessity. As the whole of mankind is a unity in some fashion, tendencies emerge between different parts, drawing some apart, drawing some together. This may be advantageous for some at times and disadvantageous to others. If it is true that there is a unity among us, to humanity, biologically or otherwise, if a unity of humankind does exist, how can one find and realize it? From this, further research could be generated.

▲ 33.15 Evaluation of Psychotherapy

MEGAN L. PETRIK, PH.D., AND STEPHEN M. SAUNDERS, PH.D.

PSYCHOTHERAPY RESEARCH

The principal goals of psychotherapy research are to understand what the effective components of psychotherapy are and how they work, to determine how patient and therapist factors influence outcome, to improve the effectiveness of psychotherapeutic interventions, to guide the development of new therapeutic techniques and evaluate their effectiveness, and to inform public policies that increase the availability of quality mental health care.

Past controversies regarding the ability to examine scientifically various psychotherapeutic techniques have largely been settled. Valid and reliable methods for measuring therapeutic events and their effects have been developed. These have included intensive analyses of patient and therapist variables, in-depth assessment of therapeutic processes, and implementation of outcome measures that assess general distress, symptoms related to specific disorders, and functional impairment in

emotional, cognitive, and behavioral domains. Controlled clinical trials comparing replicable, distinct psychotherapeutic interventions are normative, as are sophisticated analytic methodologies, including growth curve analysis, time-series panel analysis, and structural equation modeling. Most significantly, various methods of meta-analysis—techniques that combine results across different studies to evaluate the effectiveness of particular treatments for specific patients and problems—have been applied to psychotherapy research.

This section begins by briefly describing the characteristics of psychotherapy consumers. Definitions of efficacy and effectiveness are provided, and research evidence supporting both with regard to widely used psychotherapy models and techniques are presented, followed by a review of the benefits of combining psychotherapy and pharmacotherapy. Other treatment variables reviewed include the therapeutic alliance and therapist-specific interventions. Patient and therapist variables that have been studied are discussed. Emerging themes and unanswered questions regarding psychotherapy research are considered.

CONSUMERS OF PSYCHOTHERAPY

The effectiveness of psychotherapy must be understood within the context of who receives such help and how they obtain it. Several large-scale national surveys found that two-thirds of those who make at least one mental health visit in any given year are female. Ninety percent of psychotherapy patients are European American, approximately 50 percent have at least some college education, and more than one-half are between 21 and 40 years of age.

Approximately 25 percent of the US population meet criteria for a psychiatric disorder in any given year, but most do not seek any type of formal care. The likelihood of obtaining treatment increases with emotional distress and functional impairment. Accordingly, those with comorbid mental illnesses or with severely disabling disorders, such as schizophrenia, are the most likely to seek professional help. In contrast, a lack of insurance and concerns about how to pay for services decrease the likelihood of seeking treatment. However, the primary barriers to mental health care are psychological, perhaps primarily the stigma related to having a mental illness. Negative attitudes toward admitting that one has a psychiatric problem and toward seeking care from a specialty mental health provider have actually increased over the last five decades. Research suggests that this is related to the increasing conceptualization of mental health problems as medical, which may translate into the impression that the problem is permanent. Consistent with this, most who seek care increasingly do so in the general medical sector rather than from a mental health specialist.

Mary Beth, 36-year-old mother of three, had been struggling with an alcohol use disorder for the last 3 years. Her husband and her mother both discouraged her from drinking, but they also implied that it would be a mistake to seek treatment. They insisted that if she were strong enough, she could recover without help. Mary Beth was worried that if she admitted that she had an alcohol problem and needed treatment, her husband might sue for divorce and try to take her children away from her.

EFFICACY AND EFFECTIVENESS

Psychotherapy researchers distinguish between efficacy and effectiveness research. Each has a distinct purpose, methodology, and interpretative context.

Efficacy

Efficacy studies evaluate the sufficiency of a specific treatment to reduce distress, symptoms, and impairment with a group of patients having a particular psychiatric disorder. To minimize the influence of confounding factors, efficacy studies are conducted using randomized clinical trial methodology in a controlled setting. Patients are screened to control for excessive patient variability and are randomly assigned to interventions that are being compared. The treatment under investigation might be compared to no treatment, a waiting list, placebo, minimal intervention (e.g., psychoeducation), or an alternative treatment. Therapists are trained to conduct the competing treatments to maximize the integrity of putative therapeutic ingredients. To achieve this, most efficacy studies use treatment manuals, which direct (to some extent) the therapist with regard to the intervention offered. Most studies also perform integrity checks, such as reviews of taped sessions, to see whether the therapy under study was actually implemented.

Treatment manuals have been essential in establishing that certain psychotherapeutic techniques are efficacious. Prominent examples of treatment manuals include David Barlow and Jerome Cerny's *Psychological Treatment of Panic;* Aaron Beck, John Rush, Brian Shaw, and Gary Emery's *Cognitive Therapy of Depression;* and Lisa Najavit's *Seeking Safety: A Treatment Manual for PTSD and Substance Abuse*. Other manuals have been published in journals and as chapters in books, such as in David Barlow's *Clinical Handbook of Psychological Disorders*.

Effectiveness

Effectiveness studies are concerned with whether psychotherapy delivered in actual clinical settings is effective in reducing the symptoms, distress, and dysfunction associated with mental illness. The experimental controls used in efficacy studies are absent in effectiveness studies, just as they are absent in community settings. (Indeed, most effectiveness studies are conducted in the community.) For instance, in real-world clinics, patients

with comorbid disorders are commonplace, whereas they tend to be screened out of efficacy studies. Likewise, at the typical clinic, length of treatment is determined by patient need rather than treatment prescription. Thus, the goal of effectiveness research is to describe patient responses to the typical, community-based delivery of psychotherapy.

Effectiveness studies typically assess the characteristics of settings and providers, the generalizability of the patient samples, the features of treatments that are actually delivered, barriers to treatment experienced by patients, and the average costs associated with treatment. In one general theme of research, effectiveness studies have demonstrated that manualized treatments found to be efficacious in randomized clinical trials can be effective when applied in community settings. Research further suggests that the magnitude of treatment effects in effectiveness studies is similar to that found in efficacy studies.

Effectiveness studies have demonstrated a dose–response relation between the number of sessions attended and the probability of improvement. One study found that approximately 50 percent of patients are measurably improved by their eighth session of treatment, and that by session 26, three in four patients have improved. Other effectiveness studies have found that chronically distressed patients, including those with personality disorders, improve more slowly than acutely distressed patients.

The results of effectiveness studies are sometimes seen as more relevant to actual practice than are the results of efficacy studies, but both are important to the implementation of evidence-based practice. Although stringent experimental control reduces the likelihood of confounding variables in efficacy studies, the results can have limited external validity (generalizability) because of those very controls. Effectiveness research is more likely to be conducted in actual clinical settings, but the causal implications of such research must be interpreted with caution because of the likelihood that confounding variables influenced the results.

Systematic Reviews and Meta-Analyses

Common methods to summarize and integrate efficacy and effectiveness research are systematic reviews and statistical meta-analyses. Systematic reviews apply specific strategies to assemble, critically evaluate, and integrate relevant studies that address a specific clinical question. Systematic reviews are exemplified in treatment guidelines published by the American Psychiatric Association and other organizations. Meta-analysis is a particular type of systematic review that uses statistical methods to combine and summarize the results of original studies. The individual studies are quantified and coded, so that they can be compared with one another. Typically, an effect size is a measure of treatment effect that is calculated for each study by computing the size of the difference

between the treated and untreated (or control) groups.

Hundreds of meta-analyses of psychotherapy have been conducted, and most have reached the same general conclusion: Psychotherapy is an effective intervention for psychiatric illness across diverse populations and settings. Most meta-analyses have focused on specific disorders (e.g., the efficacy of psychological treatment for bulimia nervosa) or on specific therapeutic approaches for various disorders (e.g., comparing CBT to other therapies). In general, meta-analytic studies have shown that psychological treatments are vastly more effective than no treatment (e.g., wait-list controls or minimal interventions), are about as effective as biomedical treatments for most disorders, and are about equally effective when compared to each other.

EFFICACY AND EFFECTIVENESS OF COMMON EVIDENCE-BASED TREATMENTS

Effective psychotherapy requires a therapeutic alliance between the therapist and patient, which entails the sense on the part of the patient that the therapist understands, is capable of helping, wants to help, and genuinely cares for the well-being of the patient. This emotional aspect of the alliance enables agreement between the patient and therapist on the necessary therapeutic tasks to achieve the goals of symptom reduction, alleviation of distress, and/or improving life functioning. This section will review the most commonly used and studied psychotherapeutic interventions (i.e., cognitive therapy, behavioral therapy, interpersonal therapy, and psychodynamic therapy), as well as evidence supporting these interventions. There also will be a brief review of the evidence supporting acceptance and commitment therapy (ACT), which is a mindfulness-based cognitive-behavioral approach that has seen a large surge in support for its use over the last 15 years.

Cognitive Therapy

Cognitive therapy is designed to help patients recognize, challenge, and modify irrational or dysfunctional beliefs, ideas, perceptions, and self-statements that are assumed to cause maladaptive emotional reactions to negative or stressful events. The general term for modifying such beliefs is "cognitive restructuring," which entails identifying habitual thinking, understanding that thinking strongly influences emotions, evaluating the rationality of thinking, and modifying the thinking if it is found to be illogical (and pathognomonic). Cognitive therapy has been investigated intensively because it has very specifically detailed putative causes and cures, and as such, these components are easy to describe in treatment manuals and examine in outcome studies.

Cognitive therapy has been found to be effective in a variety of psychological disorders. A review of meta-analyses encompassing 325

studies of cognitive therapy concluded that its efficacy with mood and anxiety disorders in particular is well documented. The reported benefits of cognitive therapy for depression are comparable to those of pharmacotherapy, with some indication that a combination of psychotherapy and medication may be the most effective. However, cognitive therapy may be better tolerated by patients and has better long-term outcomes. Specific cognitive techniques found to be helpful in treating depressive symptoms include monitoring mood, identifying cognitive distortions, and creating rational responses. These interventions are typically conducted via daily or weekly logs that allow the patient to keep track of his or her fluctuating emotional states, to list the related maladaptive thoughts, and to dispute the identified irrational beliefs. Maintenance sessions of cognitive therapy following positive response to the treatment of depression have been shown to reduce relapse rates.

In the treatment of anxiety disorders, cognitive therapy has been shown to be effective with GAD, panic disorder, and both social and specific phobias. Patients with GAD benefit from identifying and challenging habitual and irrational beliefs about events and their ability to cope with worry. Similar results for panic disorder have been reported, in which clinically significant reduction in panic symptoms and panic-related cognitions has been demonstrated. Phobic disorders are also amenable, to a somewhat lesser extent, to modifications of anxiety-provoking cognitions. The effectiveness of cognitive therapy with various other disorders, including substance abuse, schizophrenia, personality disorders, and the eating disorders, has been documented, if not as extensively as with the mood and anxiety disorders.

Janice, a 29-year-old married mother of two school-age children, struggled with moderately severe depression on and off for several years before seeking treatment from a cognitive therapist. With the assistance of the therapist, she learned to become aware of negative self-statements and to identify irrational beliefs related to the requirements of being a "good mother." She came to recognize that these thoughts caused her to feel incompetent and generally upset about how her children were doing. She learned to evaluate and appreciate evidence that her children were, in reality, well adjusted and well liked by both teachers and peers. Via cognitive restructuring, she learned to challenge and modify her thinking so that she could judge herself more accurately as a good mother. Other long-held, negative beliefs that contributed to depressed mood were also identified and challenged. Four months after terminating treatment, she returned for some "booster sessions" that helped her to get even better at recognizing and challenging excessively negative self-evaluations.

Behavior Therapy

Behavior therapy uses operant conditioning, classic conditioning, and modeling to help patients to change maladaptive behavior patterns. Techniques include the use of extinction, positive and negative reinforcement, stimulus control, shaping, and vicarious conditioning.

One of the most elemental behavioral techniques is relaxation training,

which has been evaluated and found effective for various problems in hundreds of studies. Through repetition of relaxation-inducing strategies (such as deep breathing or alternating tensing and relaxing muscles), patients are trained to produce voluntarily the relaxation response, which can be used to alleviate anxious mood, depression, involuntary muscle tension, pain, somatic complaints, and various other stress reactions.

Exposure-based behavioral interventions are often combined with relaxation training, and they have been shown to be highly effective in the treatment of a variety of anxiety disorders. The typical behavioral intervention involves confronting a feared stimulus while preventing the usual anxiety-based reaction (e.g., fleeing, engaging in a compulsion). Research has shown that patients will habituate to the feared stimulus and that the fear-based response will extinguish. For example, exposure and response prevention for OCD is an extremely effective approach that involves presenting the anxiety-provoking stimuli and preventing the patient from performing the compulsions normally engaged to reduce anxiety. Exposure-based treatments have likewise been shown effective for the other anxiety disorders, including GAD, PTSD, panic disorder, and both social and specific phobias. Behavior therapy has also been shown to be effective in the treatment of pain disorders, sleep problems, behavioral disturbances (such as those associated with schizophrenia), and substance use disorders.

Behavior therapy is commonly used to treat childhood psychopathology. Behavioral interventions might be implemented directly with the child. For example, early intensive behavioral interventions, which heavily rely on principles of positive reinforcement, have been shown to improve social skills, intelligence test scores, and school performance for children with autism spectrum disorders. Alternatively, behavioral principles have been successfully taught to parents for the alleviation of distress, symptoms, and impairment related to attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, school phobia, separation anxiety disorder, and enuresis. Behavioral interventions have also been shown effective in reducing self-injury in children with intellectual disabilities.

Tony, a 10-year-old boy with ADHD, was being maintained on a tolerable dose of stimulant medication. On the advice of their pediatric psychiatrist, the family sought adjunctive behavior therapy to deal with Tony's poor school performance. The therapist and his parents developed a behavioral modification program to change his homework-related behavior. They developed a system for rewarding Tony if he engaged in adaptive behaviors, such as writing down homework in his assignment notebook, bringing home any necessary homework-related school materials, and completing and turning in homework assignments. His parents worked with the teacher to set up similar contingencies to reinforce Tony's compliance, positive peer-related behavior, and general attentiveness in the classroom. After several months, Tony's schoolwork improved dramatically. His parents and teacher noted that he appeared to enjoy school more, to be more self-confident, and to be better liked by classmates.

Cognitive-Behavior Therapy

CBT combines the effective elements of cognitive therapy and behavior therapy. CBT is intended to help a patient develop strategies to change maladaptive thoughts and behaviors. For example, CBT for anxiety might include cognitive restructuring to change irrational fears, relaxation training to reduce physiological arousal, and exposure to extinguish fear reactions.

CBT has been the most extensively studied psychological intervention, and there is ample evidence supporting CBT's efficacy and effectiveness with numerous psychiatric disorders. A recent review of 269 meta-analytic studies determined the average effect size for CBT for different disorders. Regarding depressive disorders, CBT has demonstrated clear benefits as compared to a waiting list or no treatment conditions, but meta-analyses have shown mixed results in suggesting CBT is more effective compared to other active treatments (i.e., psychodynamic or interpersonal therapies). CBT and psychopharmacology have been shown to both produce medium–large effect sizes in treating depression, although a combination of both treatments was more beneficial than either alone. Regarding subgroups of patients with depression, individual studies suggest that CBT is also effective with older adults, adolescents, patients with comorbid diagnoses, and low-income minority women.

The effect sizes for CBT for most anxiety disorders and somatoform were consistently medium to large. CBT has also been shown to have a strong effect in treating insomnia, anger, and bulimia. Meta-analytic reviews suggest that CBT has clear benefit for special subgroups of patients, including treating internalizing disorders in children and emotional distress in older adults. CBT has been shown to have small–medium effects for substance use disorders, with more benefit for cannabis and nicotine dependence, as well as for chronic pain. Although there are small–medium effects of CBT for treating bipolar disorder and schizophrenia, there is less support for the use of CBT without the combination of psychopharmacology for these disorders.

Recently Developed Therapies

Early cognitive-behavioral treatments focused on depression and anxiety. As just reviewed, numerous applications to other disorders have been developed. In addition, the methods themselves have undergone revision to incorporate greater focus on contextual, existential, and developmental issues. The latter approaches have sometimes been referred to as "third wave" cognitive-behavioral treatments.

ACT proposes that psychopathology is due to cognitive fusion (unquestioning adherence to the truth of one's thoughts) and efforts to avoid painful experiences, which lead to maladaptive behavioral restriction.

ACT attempts to inculcate a more skeptical perspective toward one's cognitive habits, a more accepting attitude toward the pains and foibles of life, and a commitment toward behaviors that are consistent with one's deeply held values. Controlled trials of ACT have found it efficacious for depression, OCD, substance use disorders, and PTSD.

DBT proposes that skill deficits in emotion regulation are core causal factors of various disorders. DBT was developed for patients with BPD, but it has also been applied to the substance use disorders and the eating disorders. Controlled trials have demonstrated its efficacy in reducing nonsuicidal self-injury and other aspects of BPD.

Several recently developed therapies utilize mindfulness techniques (e.g., mindfulness-based cognitive therapy [MBCT]). Increasing mindfulness is intended to reduce the pathognomonic habit of ignoring or suppressing one's emotions and thoughts. The practice essentially entails experiencing thoughts and feelings as mental events that may or may not be related to external reality, but which can be experienced without judgment or fear. Controlled trials of mindfulness practices have found it effective for alleviating symptoms of the depression, anxiety, and substance use disorders.

Dan had experienced disabling panic attacks for 20 of his 45 years but only sought treatment when they started to interfere with his career aspirations. Treatment using David Barlow and Jerome Cerny's manualized *Psychological Treatment of Panic* included information regarding the physiology of panic attacks, which helped to reassure Dan that he would not die of an attack. Based on the use of cognitive techniques, other fears and misperceptions regarding his body's reactions to stress were identified and modified (e.g., that increased heart rate was not a sign of impending heart attack but was a normal biological response to stress). Using behavioral techniques, Dan was taught via relaxation training to breathe normally rather than hyperventilate during a panic attack. Over the course of treatment, Dan learned to confront previously feared internal and environmental cues without experiencing a panic attack. After 3 months, Dan felt that he was managing his panic disorder and discontinued treatment.

Interpersonal Therapy

IPT is a structured, time-limited intervention that is based on the notion that interpersonal stress is a causal and maintaining factor in psychological distress. IPT was originally developed to treat depression and it targets the following four domains: interpersonal deficits, role disputes, role transitions, and complicated bereavement. Therapy involves three phases; the therapist initially links the diagnosis of depression to a specific interpersonal problem, implements strategies for resolving the problem in the middle phase, and finally supports the patient's self-efficacy to continually use the strategies at the end of the treatment.

One meta-analysis found that the effect size for IPT was large compared to placebo groups in the treatment of depression, but nonsignificant differential effect sizes when IPT was compared to other psychological treatments. However, other studies have found IPT to have slightly better

dropout and remission rates but may take longer to show a therapeutic effect when compared to CBT. When compared to pharmacotherapy, the combination of IPT and pharmacotherapy prevented relapse better than medication alone.

IPT has been successfully adapted to treat depression in particular subgroups, such as adolescents and women with postpartum depression. In addition, IPT has been applied to patients with eating disorders, particularly bulimia nervosa and binge eating disorder, and has shown modest outcomes. In relation to eating disorders, interpersonal therapy may be most appropriate for patients with bulimia nervosa who are also experiencing interpersonal relationship difficulties.

Maureen sought therapy for depression and anxiety at 45 years of age, 2 years after her youngest of four children departed for college. With her therapist, she was able to recognize that her successful rearing of her children had the unfortunate consequence of their departure from home. Maureen was able to identify and to pursue new activities outside of the home, to appreciate and transfer the skills that she had mastered as a successful mother to outside of the home, and to reestablish musical interest and pursuits that had waned while she raised her children. After several months of therapy, Maureen was less depressed and anxious, as she pursued a teaching certificate in music, with the encouragement of her husband, at her community college.

Psychodynamic Psychotherapy

Psychodynamic therapies derive from Sigmund Freud's psychoanalysis. They are intended to promote self-understanding and insight into recurring problems with others. Psychodynamic therapists typically promote the development of a therapeutic alliance, within which the interpersonal problems recurring in the patient's life develop. In therapy, these interpersonal problems, which are the result of defense mechanisms and intrapsychic conflicts, are identified, interpreted, and managed, with the intent that such understanding and new behaviors transfer to other relationships.

Psychodynamic psychotherapies can range in length and intensity from long-term psychoanalysis to short-term psychodynamic psychotherapy. Short-term psychodynamic therapies have been manualized (e.g., Lester Luborsky's *Principles of Psychoanalytic Psychotherapy: A Manual for Supportive-Expressive Treatment*) and evaluated in controlled trials. Research supports both the efficacy and effectiveness of the treatment, suggesting it is as helpful as cognitive and behavioral approaches. Some studies suggest that patients in psychodynamic therapy better retain long-term gains from treatment. Researchers have documented the effectiveness of psychodynamic therapy in the treatment of various disorders, including the depression, substance use, generalized anxiety, panic, and somatic disorders, as well as the personality disorders.

Dario, a 34-year-old married father of three boys, sought therapy at the insistence of his wife for recurrent problems with anger and depression, both of which seemed to stem from feelings of inadequacy. His marital relationship had worsened considerably since his wife had started a new job. Toward the beginning of psychodynamic therapy, Dario expressed frustration at the situation but insisted that he did not resent his wife's successful career. Dario's underlying feelings toward his wife became evident in the course of treatment, as the feelings were transferred toward his therapist. His therapist helped him to identify and interpret his feelings of anger, fear, and sadness and to recognize that they were a manifestation of feelings of intense inadequacy and fears leftover from an abusive childhood. Dario was able to confront honestly and openly these feelings with his therapist and, ultimately, with his wife. His anger and depression lessened considerably, and his marriage improved.

Psychotherapy and Pharmacotherapy

Perhaps the most consistent finding in comparative research into the treatment of mental illness is that combining psychological and biological treatments provides the maximum likelihood of benefit. Various meta-analyses have found psychotherapy and pharmacotherapy to be equivalent in efficacy at both posttreatment and follow-up, whereas combined psychotherapy and pharmacotherapy has been routinely found to be superior to either alone.

TREATMENT VARIABLES RELATED TO OUTCOME

Therapeutic Alliance

The therapeutic alliance entails the sense of mutual warmth, caring, understanding, empathy, and agreement. Humanistic therapists, such as Carl Rogers, proposed that the alliance is curative in and of itself, theorizing that the patient's experience of a nonjudgmental, warm, genuinely caring attitude on the part of the therapist mediates positive change. In contrast, psychoanalytic and cognitive-behavioral theorists argue that the relationship is only a necessary precondition for the implementation of the active ingredients of therapy, such as interpretation or cognitive restructuring, which are responsible for positive change.

Research suggests that both perspectives are correct. Several meta-analyses have concluded that there is a consistent relation between the quality of the alliance and positive outcome. A strong therapeutic alliance, whether measured from the perspective of nonparticipant observers, the therapist, or the patient, is related to therapy effectiveness. These findings cut across various interventions, suggesting that the alliance in and of itself is curative, rather than that it enhances interventions. Research shows that a positive alliance facilitates patient adherence to treatment, suggesting that it is a necessary condition of successful interventions. Research likewise shows that patients who dropped out of treatment liked the clinician less, felt less respected, experienced a weaker therapeutic alliance, viewed the psychotherapist as more passive, and regarded psychotherapy as being less potent than other interventions.

The alliance is similarly important in nonindividual interventions. Studies examining group therapy have indicated that the benefit of this treatment modality is more likely when there is a strong level of group cohesion throughout the therapeutic process. A family's or couple's alliance with the therapist is an important predictor of positive response. Research into the causes, uses, and effects of the alliance is continuing.

Therapist Interventions

Psychotherapy interventions and procedures have been extensively studied. Some research suggests a significant positive relation between compliance with a treatment manual and outcome, but other research suggests that the therapist's relationship skills and perceived supportiveness may be diminished by excessive compliance with a manual. Moreover, numerous reviews and meta-analyses have concluded that not all therapists obtain equivalent results even if implementing manual-based treatments. One study found that about 30 percent of therapists perform consistently better than their colleagues regardless of approach. Another found that a small portion of therapists accounts for most of the occasional detrimental effects observed in treatment. Therapist characteristics that predict effectiveness include skill (but not necessarily experience), attention to the therapeutic alliance, the ability to repair the so-called "ruptures" in the alliance, and capacity to question and adjust their approach. Research suggests that therapy is most likely to be successful if therapists attend to the therapeutic alliance and make efforts to address potential problem with it. Some research suggests that alliance problems are highly likely, as patients struggle with the effort to implement recommended changes.

The most commonly studied therapist variables are those proposed by Carl Rogers. Research has consistently found therapist in-session empathy, genuineness, and unconditional warmth to be predictive of treatment success. On the other hand, there is minimal evidence to suggest that therapist gender, age, race or ethnicity, socioeconomic background, or indeed therapeutic stance (i.e., preferred treatment modality) is predictive of treatment success.

PATIENT VARIABLES RELATED TO OUTCOME

Patient Demographic Characteristics

A meta-analysis found that there is no association between patient age or gender and treatment effectiveness. Research suggests that older adults benefit from various forms of psychotherapy as much as younger adults, which is important because older adults have been found to prefer therapy over medication.

In terms of ethnicity, research indicates that members of ethnic and racial minority groups obtain fewer benefits from conventional

psychotherapies (in contrast to treatments customized to their sociocultural background) than their European American counterparts. Consistent with this finding, dropout rates are relatively higher for minority groups, especially if the provider and patient come from dissimilar racial, ethnic and cultural backgrounds. Research also suggests that financial difficulties on the part of the patient are related to less likely treatment seeking, greater likelihood of treatment dropout, and worse outcomes, particularly in anxiety and substance abuse treatment. These findings have been shown to be related to lack of trust, a preference for self-reliance, greater skepticism about the benefits of treatment, more concerns about potential negative effects, and enhanced perceptions of stigma, all of which make both treatment initiation and treatment adherence less likely. Research further suggests that these concerns are not altogether invalid. For example, the quality of services available to ethnic and racial minority groups tends to be significantly more poor, including underdiagnosis and inappropriate, ineffective (e.g., nonspecialty), or culturally incompetent treatment.

Patient Cognitive Characteristics

Numerous cognitive variables have been found to be predictive of productively engaging in psychotherapy. The best-supported include motivation to change and willingness to engage in the therapeutic process. Numerous studies have documented the utility, in terms of maximizing the likelihood of successful treatment, of enhancing a patient's motivation to change, or to participate in therapeutic efforts. Patients bring into therapy an attachment style, which research consistently shows is related to the capacity to develop an effective therapeutic alliance. Some evidence suggests that positive outcomes are associated with ego strength (i.e., the capacity to question assumptions and perceptions) and intelligence. A great deal of evidence implicates client expectations of being helped in therapy as a requirement of effective treatment.

Patient Clinical Characteristics

Investigation of the relation between patient disturbance and outcome has yielded consistent findings. Patients with less disturbance at the beginning of treatment are relatively healthier at the end of treatment than their more distressed peers. This is regularly found in studies of the treatment of mood disorders, anxiety disorders, and substance use disorders. (Paradoxically, patient distress is the single best predictor of the likelihood of seeking professional treatment.) Specific to mood disorders, patients with high levels of impairment appear to require relatively long-term, intensive treatment paradigms. Research has also delineated that the diagnosis of a personality disorder either as the primary focus of treatment or as a

comorbid condition of other disorders is an indicator of relatively poorer treatment outcome.

The quality of the alliance appears to be influenced by a variety of intra- and interpersonal patient characteristics. Patients who have a better history of or capacity for social relationships tend to develop a better alliance than defensive or negativistic patients. Problem severity does not appear to affect the quality of the alliance. There is converging evidence that measures of the alliance early in treatment are more strongly related to outcome than later measures. An exciting area of research concerns tracking the alliance across therapy, including monitoring therapist interventions, when there are problems in the alliance; successful treatments are often characterized by rupture and repair of the therapeutic relationship via active intervention on the part of the therapist.

Patient–Therapist Matching

The age, gender and racial and ethnic identity of the patient and therapist do not seem to predict outcome, but patient and therapist similarity in these characteristics does. There is a modest relationship between the age similarity of therapist and patient and treatment outcome. Therapist–patient ethnic similarities (as well as the ethnic sensitivity of the therapist) have been shown to be related to outcome, although the advantages of matching based on ethnicity has been an issue of debate. Some point to findings that ethnic minority patients prefer a therapist that is ethnically similar. For instance, a study in Los Angeles County examined the effect of matching patient and therapist ethnicity in the treatment of Asian Americans, Mexican Americans, African Americans, and European Americans. In all ethnic groups, matched patients stayed longer in therapy, but matching was positively related to outcome only for the Mexican American group. Still, other studies have found that if the therapist makes an effort to addresses openly the dissimilarity of therapist–patient ethnicity, the therapeutic relationship is strengthened.

Perhaps more important than ethnic match is whether the therapist and patient have compatible beliefs about the causes and treatment of psychological problems. That is, the focus on analytical and scientific explanations to mental health conditions has, for the most part, ignored religious and indigenous cultural explanations to mental health problems. Thus, therapists should not only respect patient beliefs about the etiology of their condition, but should also take these attitudes into account when developing and implementing intervention strategies.

Patient–Treatment Matching

There have been efforts to optimize the effects of psychotherapy by matching patient variables to treatment interventions. The aptitude-by-

treatment interaction (ATI) approach to psychotherapy research attempts to identify treatment strategies and procedures that produce optimal outcomes for individual patients. ATI research describes patient and therapist dimensionally with quantitative differences (e.g., resistive, impulsive, extroverted, directive, supportive). The questions addressed in ATI research include the following: (1) What procedures are important to effective treatment in different contexts? (2) Which patients are likely to respond to certain therapist or therapy characteristics? (3) How can patients be effectively assigned to therapies and their responses monitored within those therapies? ATI research is fairly recent and, by definition, requires standardized therapies.

One study examined patient variables of coping style (i.e., externalization and defensiveness) as patients were administered different types of therapy for major depression. Results suggested that externalizing patients and patients low in defensiveness did better in cognitive therapy, which is fairly directive, whereas internalizing patients and patients high in defensiveness did better in supportive, nondirective (or self-directed) therapy. Other research has found that highly anxious, repressed patients are more responsive to emotion clarification and supportive approaches, whereas externally cued patients respond better to more directive therapies, such as cognitive-behavioral psychotherapy. Similarly, whereas supportive therapy has been shown to be more effective with patients having higher levels of distress, cognitive therapy has been shown to be more effective with patients presenting with lower levels of distress. Research has provided evidence that depressed caregivers of older adults are differently responsive to psychodynamic and cognitive-behavioral psychotherapy depending on the length of time in the caregiving role. There is some evidence that panic disorder responds best and most quickly to a combination of behavioral and cognitive interventions.

EMERGING THEMES AND UNANSWERED QUESTIONS

The question of whether psychotherapy works has been definitely answered. There is a plethora of evidence from efficacy and effectiveness studies indicating that therapy is effective in alleviating emotional distress and behavioral dysfunction. Questions being addressed by researchers include the relative importance of specific (e.g., interventions) versus nonspecific (e.g., the alliance) curative factors, differential effects of treatment techniques (i.e., are some interventions more powerful for some clients or conditions?), and the transfer of research methods and technology to actual practice.

Two models of psychotherapy—the medical model and the contextual model—have competed in the last two decades. The medical model suggests that psychotherapies have specific ingredients that address some problem within the patient and account for outcomes. In contrast, the contextual

model holds that therapies are effective owing to universal relational and psychological factors, which vary according to the skills and qualifications of therapists. Meta-analysis supports the contextual framework: There are small, if any, differences among treatments; there is little evidence for the specificity or necessity of any particular intervention; the therapeutic relationship is a necessary aspect of treatment, regardless of the type of psychotherapy; and therapists' qualifications and contributions are a critical factor in the outcome of psychotherapy.

There is emerging consensus on the importance of patient-focused research, which uses research to inform case-based treatment decisions about the effectiveness of a specific treatment with a specific patient. Several systems of case-based decision support have been developed and applied to patient monitoring and therapist feedback. These approaches include the use of a global measure of patient functioning, repeated measurement during the course of therapy, and norms based on large patient and nonpatient samples to assess reliable change and clinically significant change. One approach uses patient profiling techniques to predict the course of response to treatment, given the clinical characteristics of the patient. Monitored progress can be compared to the expected rate of change qualified by the patient's clinical characteristics.

The main questions remaining for psychotherapy researchers entail maximizing the likelihood of positive effects for as many persons in distress as possible. This involves determining the suitable intervention, applied by the properly trained practitioner, to the matching pathological condition in the appropriately identified and amenable patient. As the United States becomes an increasingly diverse society, culturally appropriate treatment paradigms become an essential aspect of psychotherapy research. Accounting for cultural factors involves developing new interventions and/or adapting established protocols to deal with language, ethnic, and generational differences between the patient and therapist. Understanding treatment failure is also a critically important issue, given that the failure rate for certain disorders, such as substance abuse disorders, remains high. Finally, although there has been some progress in promoting psychological interventions as legitimate and beneficial, there remains intense and widespread stigma associated with mental illness and its treatment.

One of the challenges facing the field at present is getting psychotherapists to implement evidence-based treatments that have been developed in the laboratory. Moreover, policy changes, such as the Patient Protection and Affordable Care Act of 2010, have strongly promoted pragmatic, effectiveness-based research designs. As such, there has been a large increase in the last several years in the number of studies that examine how efficacious clinical interventions can be delivered in usual care settings or target patient-centered outcomes. Translational research evaluates the effects of dissemination strategies, which are attempts to

promote the use of research-supported psychotherapy techniques.

▲ 33.16 Individual Psychodynamic Psychotherapy and Cognitive Behavioral Therapy for Psychosis

MICHAEL D. GARRETT, M.D.

INTRODUCTION

This chapter reviews the individual psychodynamic psychotherapy (PDTp) and cognitive behavioral therapy (CBTp) of psychosis. It is organized historically, first describing clinically based psychoanalytic theories developed in the last century, then covering the newer, more research-based CBTp approaches that have evolved in the past 25 years, and finally suggesting the practical integration of both bodies of knowledge.

There is much overlap in these approaches, and there are some significant differences. Both place central importance on a close, collaborative therapeutic relationship, active listening, and a technique

guided by psychological theory. PDTp, framed in a theory that assumes an open-ended receptive technique, places greater emphasis on psychological conflict, dissociated affect, fantasy, and the patient's past, while CBTp, employing a more structured technique, places more emphasis on cognition and behavior in the patient's present life. Each treatment pivots on a different foundation aiming to arrive at a similar place. PDTp seeks to bring insight and reduce suffering in the present by showing patients how psychotic symptoms are disguised expressions of emotionally charged experiences from the past. CBTp seeks to reduce suffering by marshalling the patient's capacity to examine evidence to change delusional beliefs. PDTp therapists focus on the emotional truth of psychotic symptoms; CBTp therapists focus on their literal falsity. These approaches meet and can be integrated where the heart meets the mind. Both may be of value to the same patient; at different times in treatment, patients with different needs may benefit from either approach separately or in combination.

This chapter begins with two clinical vignettes, one of a man with psychosis treated with PDTp and one of a woman treated with CBTp. Both had a similar core psychological schema: abused as children, they were left with a psychological legacy of fear, need, rage, and expectations of mistreatment and abandonment that made it very difficult to establish stable, satisfying adult relationships.

THE MAN WHO CHOKED PEOPLE. First the patient treated with PDTp. Bertram Karon was invited to provide psychotherapy for a man with chronic psychosis, who had been hospitalized for 10 years, a man with a history of unprovoked violence against other people in the hospital. The patient was grossly incoherent, and when he became coherent, he stuttered very badly. Review of his chart revealed that he came from a poor family, his father was an alcoholic, he had developed the stutter as an adolescent, and he had reported to sick call in the Army with a venereal infection of his mouth just before his first assault on a stranger. He would creep up behind other patients and choke them, but he had never killed anyone, as he would drop his victims when he had rendered them unconscious. After establishing rapport with the patient, in the first session Karon discovered that when he was a little boy, his mother, for minor offenses like not eating, would put a cloth around his neck and choke him. After the patient had revealed this piece of history to the therapist, he stopped choking other patients.

The patient began a subsequent therapy hour by yelling, "Why did you do it to me, Dad?" Exploring the psychotic transference, Karon learned that the patient's alcoholic father had come home drunk one day and anally raped him. The patient's terrible stutter was revealed to have an extraordinary cause. Latin words were discernable in the middle of his stutter. When asked if he had been an altar boy, he said, "You swallow a snake, and then you stutter. You must not let anyone know." He was extremely ashamed and guilty at having been compelled to performed fellatio on a priest. The therapist offered direct reassurance that what he had done was all right, and said, "Anyone as hungry (for love) as you were would have done the same thing." At that point the stuttering stopped. When he started to stutter in later sessions, it was only necessary to repeat this interpretation, and the stuttering immediately ceased. As a boy, the patient had turned from his mother who choked him to a father who raped him to a priest who sexually abused him. This succession of horrors drove him out of his mind. Yet his hospital record contained not one word of this history, and 10 years of confinement and treatment as usual had done nothing to allay his primary symptoms. This case illustrates how seemingly bizarre symptoms can be understood to have meaning, and how psychotherapy can ameliorate them. There are many such reports of successful psychotherapy scattered through the literature.

Now the second patient, treated with CBTp by the author.

THE WOMAN WHOSE CAT SOUGHT TO MURDER HER. The patient was a 25-year-old woman divorced mother of three who had made several serious suicide attempts. She reported feeling depressed, hopeless, and terrified when she came to believe that her cat was planning to murder her in her sleep. In the weeks prior to the emergence of this delusion, she had been feeling unusually needy and had begun telephoning her boyfriend at work many times a day, until he began to set limits on the phone calls. She interpreted this as meaning he no longer loved her. She blamed her cat for the loss of his love. At night when she and her boyfriend went to bed, the cat would snuggle up between them, which the patient experienced as the cat "coming between" her and her boyfriend. The boyfriend showed the cat affection, which indicated to the patient that the cat's plan to steal her boyfriend's love was working. She believed the cat planned to murder her so as to have her partner all to herself. The psychodynamic meaning of the delusion was readily apparent. Having been abused as a child and hungry for love, she felt a compelling need to be in sole possession of her boyfriend's affection.

The therapist inquired about the details of how the patient imagined the cat would kill her. The patient responded as though this should be perfectly self-evident. "You see it all the time on TV! Lions and tigers bite their prey in the neck. They bite the jugular!" The patient expected the cat to bite her jugular when she was asleep. While respecting the patient's conviction that the attack was inevitable, the therapist inquired in an offhand manner if the patient knew where her jugular was located. She said she knew it was somewhere in the neck, but did not know exactly where. The therapist commented, again in an offhand manner, that the cat would have to have a much more precise knowledge of human anatomy than she did. While speculating where in the neck the jugular was the patient acknowledged that her being overweight and quite thick in the neck would make it especially difficult for her cat to locate her jugular. The therapist opined that the cat would certainly have one and only one chance to attack her precisely at the jugular, because as soon as she felt the cat's teeth on her neck she would surely awaken immediately and throw the cat off, compress the bite on her neck, and call an ambulance. The patient returned the next session less anxious and less depressed. When the therapist explored her change in mood, she said, "I still believe my cat plans to kill me, but I no longer believe she has the means to do it." This positive shift in mood and decrease in depression, while not resolving the delusion entirely, was a significant gain obtained in a single session. The psychotherapy then continued to explore her relationship with her boyfriend.

Chronic psychosis is the cause of enormous suffering and individual disability. In contrast to significant advances in the treatment of heart disease, cancer, and stroke that have dramatically improved quality of life and life expectancy, most chronically psychotic patients remain functionally disabled in their entire lives and live 15 to 20 years less than the general population. While medication is undoubtedly helpful to some patients at some times in some ways, compared with other branches of medicine, therapeutic outcomes in the treatment of chronic psychosis leave room for improvement. Psychotherapy can help achieve more positive results.

Psychotherapy (broadly defined) is a disciplined professional interaction between a trained psychotherapist and a patient that aims to improve the patient's quality of life by exploring the patient's thoughts, feelings, and behaviors, with the goal of facilitating new possibilities for

emotional growth and more adaptive thinking and functioning. This chapter will assume that the reader has at least some familiarity with such essential concepts in PDT as the existence of unconscious mental processes, unconscious fantasy, transference, and the therapist's interpretation of psychological meaning, and CBT concepts including the existence of cognitive biases in thinking and the A-B-C cognitive sequence in which an activating event is followed by a belief about the meaning of that event, which in turn leads to an emotional and/or behavioral consequence.

Although psychotherapy is widely practiced in the treatment of nonpsychotic patients, psychotherapy has for decades taken a backseat to pharmacological treatments of psychosis. The reason psychotherapy for psychosis is so little practiced is not that psychotherapy has no value. Research to be cited in a later section of this chapter demonstrates its efficacy. This chapter's exclusive attention to psychotherapy should not be taken to suggest that biological factors are less important than psychological factors. Why has psychotherapy lagged so far behind medication as a frontline treatment? In the author's view, the following issues have contributed to marginalizing psychotherapy for psychosis.

1. The biggest obstacle to providing psychotherapy to patients with psychosis is the widespread belief that psychotherapy is of no value. The stunning initial successes in the work of pioneers like Harry Stack Sullivan, Frieda Fromm-Reichmann, and Silvano Arieti and the solid evidence base for CBTp should have put this mistaken idea to rest, but few people have been trained in these approaches. It is not surprising that approaches that are helpful to other patients are insufficient with patients suffering from psychosis and have left clinicians with feelings of inadequacy, failure, and pessimism about therapy for psychosis.
2. The same symptom picture might be diagnosed as "brief reactive psychosis" or "schizophrenia" depending solely on length of illness. This convention implies that schizophrenia is by definition a bear of a disease that never gets better. Such fatalism embedded in diagnostic practice allows clinicians to be complacent about poor outcomes rather than to press hard for better treatments.
3. Understanding the psychology of psychosis requires the clinician to empathize with levels of anguish not often encountered in everyday life. Clinicians may take for granted that psychotherapy can help patients with nonpsychotic depression and anxiety because they know from personal experience that talking things through with the right person can help, but when they see little connection between ordinary mental life and psychotic symptoms, the utility of talk therapy for psychosis may not be intuitively obvious.
4. The introduction of the neuroleptic drug chlorpromazine (Thorazine) in

1954 led to the dramatic amelioration of acute psychotic symptoms in many patients. The observation that effective neuroleptics diminish dopamine transmission led to the dopamine theory of schizophrenia, which added credibility to the idea that schizophrenia is essentially a brain disease, and as such is more likely to respond to medication than to psychotherapy.

5. The obvious efficacy of neuroleptics in relieving some psychotic symptoms fueled a backlash against the unfortunate hypothesis that the "schizophrenogenic mother" was the cause of psychotic illness, but this needed course correction went too far in the other direction, lending support to the idea that psychological factors are of little importance.
6. Freud did not believe that psychotic patients formed a transference that could be analyzed in a conventional psychoanalytic treatment, and so had no faith in the efficacy of psychoanalysis, at least as he practiced it, for psychosis. With some notable exceptions, the psychoanalytic community mirrored Freud's attitude and largely abandoned the care of the severely mentally ill.
7. PDTp failed to establish itself not only because it was crowded from the scene by biological treatments, but because a classical psychodynamic approach is rarely effective without a modification of technique. Psychodynamic therapists have paid too much attention too early to the unconscious psychological meanings of psychotic symptoms and too little attention to the patient's conscious experience of psychotic symptoms. Pioneers of PDTp have often been mythologized as exotically talented clinicians who could do what the average well-trained clinician could not. In fact, doing effective PDTp and CBTp is well within the range of most clinicians in public clinics when they are provided with specialized training and supervision.

The time has come to give renewed consideration to the place of individual psychotherapy in the treatment of psychotic individuals. Not only is individual psychotherapy often effective, but there is also mounting evidence of the limitations of psychopharmacology. The clinical antipsychotic trials of intervention effectiveness (CATIE) study found that newer medications are not decisively more effective than older drugs and cause serious side effects of their own, including metabolic syndrome and diabetes. Two recent studies suggest that structural changes in the brain correlate not only with total period of untreated psychosis but also with total exposure to neuroleptics; that is, both psychosis and the drugs used to treat psychosis may damage the brain. A recent review of the traumagenic neurodevelopmental hypothesis suggests that the brain changes typically attributed to a primary brain disease may reflect changes in the hypothalamic–pituitary–adrenal axis and dopamine system in response to psychological trauma. These studies suggest that psychiatrists should aim

for the lowest dose of medication possible for the shortest period of time. Psychotherapy may help to achieve this goal.

THE WOMAN WHO HAS NEVER BEEN REHOSPITALIZED. In the author's experience, effective psychotherapy can reduce the necessity for dosage increase, polypharmacy, and inpatient admission. Consider an example that illustrates the possibilities for combining medication and psychotherapy. A 30-year-old woman with a chronic paranoid psychosis with a 6-year history of treatment as usual, with 3 to 4 hospitalizations a year and intermittent homelessness, was referred to the author for psychotherapy. She had failed multiple neuroleptics including clozapine (Clozaril) and was being prescribed a high dose of aripiprazole (Abilify) at the time of initiating psychotherapy. In the course of a 5-month, once-a-week CBTp treatment, the patient understood for the first time that her belief that she was being pursued by thugs, her conviction that she was being monitored through a computer chip in her body, and her experience of "voices" telling her she was a child abuser were all manifestations of an illness (the convention "voices" will refer to verbal auditory hallucinations). Aripiprazole was titrated downward to a lower dose, but could not be stopped without a flare-up of psychotic symptoms. She attends session every other week and has never been readmitted. During her 13 years in treatment she suffered two significant recurrences of paranoid ideas and ideas of reference, both of which were worked through psychotherapeutically without recourse to increased medication or hospitalization.

History

In the interest of brevity, one can divide the history of PDTp after its beginnings in the early 1900s into two schools, a European Kleinian School heavily influenced by the ideas of Melanie Klein that was active in the first half of the twentieth century, represented by Hannah Segal, Wilfred Bion, and Herbert Rosenfeld, and an American Interpersonal School based on the ideas of Harry Stack Sullivan that has been influential from the mid-twentieth century on, represented by Harry Stack Sullivan, Frieda Fromm-Reichmann, Silvano Arieti, and Harold Searles. See the review by Michael Stone (11) for a more comprehensive listing of contributors. The history of CBTp that begins in the early 1990s will be covered in a later section. "Cognitive Behavioral Therapy for Psychosis."

Psychodynamic thinking about schizophrenia began at the Burghölzli Mental Hospital in Zurich, Switzerland, when Eugen Bleuler, MD, became Director in 1898. He emphasized the importance of psychological "complexes" in the formation of psychotic symptoms. Carl Jung worked there during Bleuler's tenure. Jung recalled that most psychiatrists at the time paid attention to diagnosis but ignored the meaning of psychotic symptoms.

Jung described a psychotic woman who had spent many years in the hospital who made stereotyped, repetitive, seemingly meaningless gestures. He read her chart and found an entry years prior that described these gestures as a "cobbler's motion," i.e., like the movement a cobbler would make drawing a thread through leather in a shoe he was holding between his knees. The patient died shortly after Jung met her, and her elder brother came for the funeral. Jung asked him, "Why did you sister lose her sanity?" The brother told Jung that she had been in love with a shoemaker who had not wanted to marry her, and when he rejected her, she had "gone off the deep end." Jung concluded that the shoemaker's movements represented the heartbroken patient's identification with her beloved cobbler, a way of keeping her sweetheart

with her psychologically despite his having rejected her in reality. In short, he broke her heart, she lost her mind, and she remained "married" to him in gesture until death did her part.

Paul Federn was one of the few analysts in Freud's circle with significant experience treating psychotic patients. He extended Victor Tausk's concept of the "ego boundary," a fundamental idea in the psychoanalytic theory of psychosis. Federn believed that the fundamental problem in schizophrenia was that the ego boundary that ordinarily separates thoughts and feelings from perceptions is faulty, allowing the content of the unconscious to spill into consciousness where it is perceived as reality.

Theoretical Issues

In both psychodynamic and CBT literatures on borderline personality disorders (e.g., work by Kernberg, Fonagy, Meares, Linehan, and Young), one finds research-based efforts emphasizing specific deviations from ordinary psychoanalytic or cognitive behavioral treatment required for that population. Although there is a small, clinically based psychoanalytic literature on "supportive therapy" of schizophrenia, comparable refinements of theory and technique have yet to be fully realized and widely practiced in the treatment of individuals with psychosis.

As clinical technique should derive from research-supported theory, this chapter now turns to the psychodynamic theory of psychosis. Despite disagreements about the relative importance of biological and psychological factors in the etiology of psychosis, there is substantial agreement among psychodynamic theoreticians about its fundamental psychology: *Psychotic states represent the intrusion into adult mental life of primitive psychological processes that are ordinary in childhood; these early processes normally recede from consciousness by the time a person reaches later childhood (the "latency" period) but they re-emerge in psychosis.*

These intrusions of early mental life are of two sorts. First, individuals in psychotic states utilize *primitive cognitive processes* similar to those operative in the first years of life. Instead of thinking a thought and expressing it in verbal symbols, or feeling a feeling that is subjectively located within the psychological boundary of the self, psychotically disturbed individuals experience a body sensation or experience a distorted perception of the outside world that expresses feelings and thoughts that a nonpsychotic person would express in words. For example, instead of thinking the thought, "I am a bad person" a psychotic individual might *perceive* a "voice" saying, "You are a bad person." Federn called this failure to distinguish between subjective experience and perceptions of the outside world a *breakdown of the ego boundary*. This confusion of thought, feeling, and perception plays a significant role in the formation of ideas of

reference, hallucinations, and delusional beliefs.

Second, *primitive object-related phantasies* (more on this language later) that ordinarily operate in the first years of life re-enter consciousness in psychosis and dominate the person's experience of relationships with other people and the world, shaping the content of delusions and hallucinations and the narratives that patients construct to explain their lives. For example, while normal children might play at being king or queen, treating their parents as vassal subjects while resisting efforts to spoil the fun and expose the game as play-acting, people with schizophrenia might make a literal claim to being a king or queen, insisting that family members and clinical staff bow to their will, while resisting efforts to characterize their belief as illusory.

What remains unconscious in psychosis and in nonpsychotic conditions, respectively, is different. The psychotic person, while closer to primitive childhood mental life, is not consciously aware of using archaic mental processes to keep painful thoughts and feelings about real life outside conscious awareness.

Although there is widespread psychoanalytic agreement about the intrusion of primitive psychological processes in psychosis, historically there has been disagreement about how to deal with these intrusions psychotherapeutically (see Table 33.16–1). Because Federn viewed the psychotic process as a defect in the brain's ability to invest internal mental events with sufficient "ego feeling" to mark them as belonging to the self, he advised clinicians not to encourage the emergence of unconscious material and to harbor no ambition to interpret unconscious processes. Instead, they should attempt to compensate for the patient's defective ego boundary by supportive reality testing. His approach is echoed in current-day psychosocial programs such as day hospitals, supportive housing, and employment arrangements that center treatment in a clinical team rather than a single therapist. Federn's concern that exploratory psychodynamic treatment might undermine the reality-testing of psychotic individuals is mirrored in the empirically unproven belief of some in the 1980s that psychotherapy for patients with psychosis is ineffective or even harmful.

Followers of Melanie Klein, in contrast, advocated direct interpretation of primitive thinking with no modification of classical psychoanalytic technique. They regarded the "psychotic transferences" that then emerged in treatment as important opportunities to make interpretations revealing the unconscious ideas dominating patients' experiences.

Also in contradiction to Federn's ideas, analysts in the American Interpersonal School of Harry Stack Sullivan sought above all to establish trusting relationships with patients that would facilitate their ability to open a dialogue. They did not encourage the development of a psychotic transference, however, nor regard it as the essential focus of therapeutic change. Rather, they would interpret transference distortions when they interfered with the therapeutic alliance. Sullivanians made interpretations at the interface between patients' subjective experiences of painful situations in childhood, latency, and adolescence, and the meaningful expression of these experiences in the form of symptoms such as delusions and hallucinations.

The Psychology of Psychosis

These pioneers, despite their differences, all tried to reduce the apparent distance between psychotic processes and ordinary human psychology. If one cannot understand psychotic states psychologically, how can one hope to treat them psychologically? How can one relate the seemingly bizarre symptoms of psychosis to ordinary human psychology, and in so doing forward a psychological theory of psychosis and a rationale for psychological treatment? Addressing these questions begins in an understanding of the psychology of young children that can be inferred from direct child observation and clinical experience.

The experience of newborns and infants under 4 months old, as best as can be determined, consists of isolated fragments of somatic sensations

associated with perceptual images that have not yet been integrated within the boundary of an organized self. The newborn does not know yet that the hand in its immediate visual field of vision is *its* hand. Children do not recognize themselves in a mirror until roughly 18 months. Very young children do not know that sensations are part of their own personal subjective experience. As development proceeds, consciousness moves beyond somatic perceptions to increasingly complex "mentalized" forms of experience, allowing for symbolic representations, verbal thought, and conscious and unconscious phantasy.

Klein came to believe that early in life, experiences are organized and represented mentally in "phantasy" as *internal object relationships* between psychological "objects," where the self and an "other" (the *object* of the child's interest) are connected by an affectively charged link: the self is doing something to the object or the object is doing something to the self. This chapter adopts her use of "phantasy" to refer to primitive unconscious phantasies and "fantasy" to refer to conscious daydreaming. Given that human beings are fundamentally interdependent social animals, it is not surprising that human phantasy is organized in an object-related form. In object relations theory, the primitive self defends against painful mental experience by splitting into two primal psychological objects: a pristine self that attempts to preserve its freedom from pain by identifying itself with a natural state of being phantasied to be pain-free and a persecutory object that is causing the pain by intruding upon what would otherwise be the satisfactions of the primitive self. In this construction, human suffering does not arise from internal conflict but is rather caused by persecutory attacks of elements experienced as outside the self.

This basic tendency to split off the pristine self from a persecutory object is apparent in childhood stories and their adult derivatives. (Superman is all good; he does not cheat on his taxes. Lex Luther is all bad; he does not spend weekends volunteering at soup kitchens for the homeless.) This psychology leaves many residuals in adult mental life. For example, during a headache someone may say, "My head is killing me." In this case, two psychological objects are being imagined, a "me" that in its natural state would be headache-free were it not for the murderous activity of the head, and a "head," a persecutory object intruding pain into the otherwise pain-free "me." In psychotic illness, this split between the self and a persecutory object becomes the basic psychological structure of a paranoid delusion. The fundamental tendency to split the mind into contrasting mental representations of self and persecutory object is the source of the ubiquitous human tendency to blame others for one's failings and sorrows; for example, the train is responsible for my lateness (not my failure to leave early enough); a particular ethnic group is responsible for society's social ills, and so on.

Child observation suggests that phantasy begins preverbally. Susan

Isaacs described a 20-month-old child with delayed speech development who saw her mother wearing a shoe with a loose sole that was flapping about. The child screamed in terror, and for a week would shrink away if she saw her mother wearing any shoes at all. At 2 years 11 months, when she was able to express herself verbally, she suddenly asked in a frightened voice, "Where are Mummy's broken shoes?" Her mother reassured her that she had sent the frightening shoes away, to which the child replied "They might have eaten me right up." The child at 20 months had seen the shoe as a threatening mouth but could not express this phantasy verbally. Her conception of the shoe as a dangerous mouth can have no other origin than her psychology. Her oral aggressive impulses were projected outside the self and experienced as though residing in the shoe. In this phantasy, the internal danger posed by the child's aggression is transformed into a danger threatening from outside the self; that is, an intrapsychic conflict has become an interpersonal problem between two internal objects, with the persecutory object experienced as located in the outside world. A similar process happens in psychosis, when a man in a state of great internal turmoil conceives his difficulty as an external threat from the Mafia or a government spy agency.

In the first 3 years of life, the child's conception of the world is dominated by projected elements of its own mental life; for example, the shoe is a mouth. This developmental period can be characterized as a two-person psychology in which the child feels inherently related to particular persons. Young children live in a psychic world in which what they feel and think is experienced as real. The girl who was frightened of the shoe was not telling her mother "I am having a phantasy that your shoe is a scary mouth, but I know it is just a shoe." Rather, she *saw* the shoe as a threatening mouth. The child's state of feeling *is* the child's reality during this early phase, and its perception of the world is conditioned by its emotions. This is also the case in psychosis.

Peter Fonagy and Mary Target distinguish two modes of cognitive functioning in young children, the stage of "psychic equivalence" in which whatever is psychically experienced is felt as real, and the "pretend mode," in which ideas are representational but their correspondence with reality is not examined, allowing children to play at pretend games. Consistent with the preoccupations of young children, the primitive object-related phantasies that predominate in the first 3 years of life often have oral and anal themes, such as shoes that bite. The child's experience of eating becomes the body-based metaphor for the psychological processes of *introjection* and *identification,* via which aspects of the environment are taken into the self; defecating becomes the body metaphor for *projection,* in which aspects of the self are extruded and deposited in mental representations of psychological objects outside the self.

In effect, in the service of defense, the mind appropriates the body

processes of taking in and pushing out content and transforms these processes into psychological defenses. At this maturational stage, the mind is like an open international border where heavy trucks rumble back and forth day and night, exporting projected psychic content and importing it back again after it has been modified by the external environment. Residuals of these early, body-grounded mental processes remain in adult metaphors such as "That's food for thought!" where the comprehension of an idea is conceived as the ingestion of a satisfying food, a sort of mental "good breast" experience. When someone says, "I had to swallow my pride," they mean "I didn't abandon my pride. Rather, I temporarily hid it in an interior body space from which it can safely re-emerge when the coast is clear."

If young children are to achieve a firm sense of being real in a real world, they must grow out of their experience of the world as projected fragments of the self. How does this happen? Donald Winnicott, a practicing pediatrician and psychoanalyst, described how a secure attachment to an empathic mothering figure becomes the developmental base for a child's experience of reality. Winnicott's "good-enough mother" responds empathically to the child's authentic strivings while not imposing an alien agenda on the child's gradually emerging unique identity. The child's earliest experience of the external world is its encounter with the mother's body, especially the breast. The empathic mother, attuned to the baby, learns to read the infant's communications so as to feed the baby when it is hungry, and change the diaper when it is wet, and not the other way around.

As described by Winnicott, fancifully, the baby's experience of hunger and feeding might be, "I was feeling uncomfortable just now. I was starting to imagine something that would eliminate the discomfort, when suddenly, as if by magic, the breast appeared. Then I knew I was trying to imagine something like a breast all along. I am of this world. I am in synch with this world. The world sees my existence." The empathic mother delivers the real world to the child at an opportune moment of need, and thereby builds a bridge between the child's psychic reality and the external real world.

Children who find sufficiently resonant correspondences between their mental states and the outside world turn toward reality and begin to feel real in a real world. A child whose authentic stirrings are not met empathically may turn inward and begin living as a "false self" that merely reacts to the impingements of others rather than expressing its authentic nature. If the world returns no resonant ping to a child's sonar probe, the child adapts to living in a dead world that appears to not know the child's true self is alive. In some family systems, the child is recruited to fulfill the psychological needs of others in the family, in which case the family environment impinges upon and distorts the development of the child's authentic individuality. This impingement beggars the self, leaving the

child little base from which to build a sustaining sense of interpersonal competence and independence, a state of vulnerability that can predispose to psychosis.

In secure, empathic environments, the primitive unconscious phantasies of early childhood fade over time, but when the social environment impinges upon a child's authentic self when these phantasies are active, they do not fade. Cumulative disappointments give rise to painful conscious fantasies and unconscious phantasies that are reinforced. These will influence how later life experience is perceived and given meaning, and may leave people with such experiences feeling they have no space for tolerable living. What others have described as the prepsychotic child's difficulty with separation and individuation from a symbiotic relationship with the mother can be viewed as a massive impingement of caregivers on the authentic independence of the child.

Recall the little girl who was frightened that her mother's shoe would eat her. Oral experiences are important to young children, who often phantasize about biting and eating, and being bitten and eaten. Frightening oral themes of this sort appear in fairy tales and also in psychotic delusions. In "Hansel and Gretel," a famine descends upon the land and a terrible mother plans to leave her two children to die in order to conserve the limited food supplies for herself. The children narrowly escape being eaten by a witch. Little Red Riding Hood and her grandmother are both eaten by a wolf who has assumed the grandmother's clothing.

Compare the internal world of a psychotic man from a chaotic family with a drug-addicted mother and absent father, who suffered a delusion composed of primitive oral phantasies. He reported that he had developed a cancer when at birth his mother touched his penis (the mother has put a "persecutory bad object" into him in the form of the cancer), and that this cancer now coated all his internal organs (the "bad object" is about to engulf him). Because he feared that medication would disturb a delicate balance between his organs and the cancer, giving the cancer the upper hand, he refused all pharmacological treatment. In phantasy, taking medication would destabilize his resistance to the persecutory object. This man was frozen in a state of terror in which he feared his true self would disappear inside a bad object (the cancer) and be annihilated. In effect, his delusion is a horrifying version of "Hansel and Gretel" and "Little Red Riding Hood" with no happy ending, a personal fairy tale with a readership of one.

Similarly, a 30-year-old man with two prior psychotic episodes reported in a first psychiatric consultation an intense anxiety he associated with his belief that a terrible drought was about to occur, which had led him to fill his apartment with many gallons of stockpiled water. At the end of the consultation, the patient said, "You have asked me a lot of questions. Can I ask you some questions?" The therapist said he would be happy to answer

any questions the patient had relating to his treatment. The man then asked how old the therapist was, was he married, did he have children, and where did he live? Before offering any answer the therapist stated, "I am wondering why it is important for you to know the answer to these particular questions." The patient responded in a matter-of-fact tone as though the reason was perfectly obvious. "If I am to model myself after you, I must know everything about you! I must know details."

A primitive phantasy of being deprived of essential oral supplies, akin to the famine of fairy tales, emerged in his delusion of an impending drought. He imagined his relationship with the therapist as equivalent to swallowing him whole; that is, indiscriminately absorbing attributes of the therapist's identity into himself. Before swallowing the therapist and taking on his identity (just as the wolf swallowed Little Red's grandmother and assumed her identity), the patient sought to determine in detail what the therapist was made of, so as not to ingest a toxic persecutor inadvertently. Indeed, the devil is in the details.

In psychosis there is regression to Fonagy's "psychic equivalence" mode, in which what is felt to be real is experienced as being real. Segal called this cognitive process "symbolic equivalence"; other writers have referred to "concrete thinking" or the experience of projected parts of the personality as "things." Segal describes a women who, when nonpsychotic, wrote a story depicting her mother and the analyst as being *like* a Lancashire witch (a fantasy), but when psychotic, believed the analyst *was* a Lancashire witch (a concrete metaphor that constitutes a delusion). Franz Kafka's famous story *The Metamorphosis,* in which Gregor Samsa comes to experience himself as a monstrous insect, can be viewed as a psychotic sequence beginning with Samsa's feeling of being a nobody, an anonymous functionary in an industrial society, thus being *like* an insect, then experienced as the concrete metaphor that he *is* an insect. In the "psychic equivalence" mode, if two people or things share a common attribute, they are experienced not as being similar, but as being the same.

This primitive mode of psychic functioning can be observed in young children trying to figure out what categories different objects belong to. One imaginative 3-year-old who was delighted to receive a paper origami bird requested "More ohwogamee!" but burst into tears when offered an origami flower. "That not ohwogamee!" Are all instances of "ohwogamee" avian? Does a folded paper bird belong to the category "paper" or "bird"? In psychosis, instead of figurative metaphorical thoughts of the "X is like Y" variety that form a basis for consensual symbols, individuals aggregate disparate objects and people that share some quality of emotional significance to themselves in a single identity, like a child sorting experience according to categories different from those of most adults.

Such "X = Y" statements, when reported to clinicians, are seen as delusions. For example, a man diagnosed with schizophrenia reported that

a nurse's aide on the inpatient unit, who had a last name with four letters in common with his mother's name, was in fact his mother in disguise. This primitive type of cognition forms a basis for a variety of delusional beliefs and ideas of reference in psychosis.

In his description of what others have called "concrete thinking," Arieti describes how in psychosis, thinking regresses to "paleologic" or "predicate logic" (according to the Von Domarus principle), where parts or attributes of a person or thing become equated with the whole. This regression in psychosis has a psychodynamic purpose. When people in psychotic states try to think about their lives and feelings, clear thinking that maintains discernable symbolic emotionally charged connections between thoughts and events can be unbearably painful. Concrete thinking damps down the symbolic emotional resonance of thought, thereby blurring its clarity and emotional significance, making it harder for the patient to think clearly to a painful endpoint.

Concrete thinking also turns attention away from intolerable internal experience, outward to the perception of concrete objects and external entities. But the suffering that the patient wishes to avoid nevertheless persists in disguised form, hidden in plain sight in the suffering associated with psychotic symptoms. A psychotic person continues to suffer mightily, but achieves a modicum of relief by displacing the suffering away from the core interpersonal relationships that gave rise to the pain and projecting it outward into mental representations of the real world.

For example, a psychotic woman who was conflicted about her wish for a life insurance payout following her husband's death developed a delusion that her father-in-law intended to kill her to steal the money. Hospital staff were unable to confirm the existence of any insurance policy, and there was no evidence the father-in-law wished her harm. She reported seeing a red car drive by her home and concluded that the driver was her father-in-law (who had a red car), circling in the neighborhood with plans to kill her. Her paleological equation of any driver of any red car with her father-in-law degraded her ability to think clearly in her bereavement. Instead of feeling her pain over her husband's failure to provide a comfortable inheritance for her, she dealt with her guilt over her wish to profit from her husband's death by becoming preoccupied with an external danger. Greed and murderous feeling have gone missing from her mind and reappeared in the imagined mind of her father-in-law.

In the 4th and 5th years of life, the "psychic equivalence" and "pretend" modes evolve into a more fully developed "theory of mind," in which the child can distinguish between dream images, thoughts, and real things, and appreciate that others may have thoughts and feelings that differ from those of the child. The stage is set for the three-person psychology of Freud's oedipal period, where the child registers the parents' relations to each other and also begins relating to a wider network of people. Figure

33.16–1 depicts the normal course of development of children: mental life before age 3 is dominated by primitive phantasies and metaphors for body processes, especially taking in external objects and extruding internal ones. As the child grows up, the fantastic, primitive two-person psychology of early childhood is gradually replaced by more realistic mental representations of others.

Examples of the disappearance of fantastic conceptions of the world in favor of more realistic representations include the disappearance, normally around age 8, of beliefs in Santa Claus, the Easter Bunny, and the Tooth Fairy. Just as the Wizard of Oz is revealed as an ordinary man operating a hand crank, not a phenomenal being wielding a magic wand, such entities become understood as parental inventions. This change is shown in Figure 33.16–1 as the gradually widening swath of more realistic mental representations of others, progressing through latency and adolescence into young adulthood.

The Impact of Less than Optimal Family Relations in Solidifying Primitive Unconscious Phantasy

Tolstoy's observation that "Happy families are all alike; every unhappy family is unhappy in its own way" might be rephrased here as "Happy children are all alike, but unhappy children who are vulnerable to developing a psychotic illness are each unhappy in their own way." Because the failures in development that make people vulnerable to psychosis can take many forms, the roads to psychosis are as varied as there are different patterns of troubled development. Just as no single gene has been identified to account for all instances of psychosis, no single psychological dynamic has been implicated in all cases of psychosis. There are many fault lines along which the mind can shatter. In some cases there is a massive failure in the early caretaking environment that ushers in the psychosis, or an evident trauma such as physical or sexual abuse, rape, or persistent bullying at school, but in many cases no such massive trauma is apparent.

Arieti observed the so-called "schizophrenogenic mother" (a regrettable term coined by Fromm-Reichmann) in less than 20 percent of families, and found that most parents of children who became psychotic were loving and concerned. Karon makes the important point that psychological processes in parents that may predispose to psychosis in children often operate outside the parents' conscious awareness. The caregivers fail to give the child what is needed but do not harm the child intentionally; in such cases both child and parent may be victims of the parent's unconscious psychology. In most cases, the erosion of good-enough development occurs gradually, one disappointment at a time, one failed interpersonal exchange after another, until the young person's psyche can no longer hold on. After having failed to achieve a positive standing in the peer group despite repeated efforts to do so, the about-to-be psychotic person one day

surrenders and says simply, without much fanfare, "I'm done. I give up."

In her account of her psychosis and psychotherapy with Fromm-Reichmann in her book *I Never Promised You a Rose Garden,* Joanne Greenberg describes her mother and father as loving parents desperate to help her, but not knowing how. In her case, her psychosis issued from the accumulation of many factors—her younger sister's birth, traumatizing urological surgery at age 5, the impinging presence of her charismatic, demanding maternal grandfather (who to a great extent defined her parents identities and accordingly hers), a move away from a familiar neighborhood where she felt safe, and the antisemitic bullying she encountered in summer camp.

Internal Object-Relations

FIGURE 33.16–1. Stages of Development and Internal Object-Relations.

Greenberg describes her retreat from the real world, where she found it impossible to live, into a psychotic world she called Yr, inhabited by a host of magical characters with their own language, personas as beautiful, compelling, and terrifying as in any fairy tale. She hears the "voice" of a hallucinated being named Anterrabae, who says to her "Bird-one, you are not of them," which confirms her conclusion that she is impossibly misfit to the real world. As she descends into psychosis, her sense of self disintegrates, and her mind drifts away from verbal thought that would require her to think clearly about her pain, toward a succession of images and sensations characteristic of the preverbal mental processes of early childhood.

A black wind came up. The walls dissolved and the world became a combination of shadows. Seeking for the shadow of firm ground on which to stand, she was only deceived again when it

warped away like a heat mirage; she looked toward a landfall and the wind blew it away. All direction became a lie. The laws of physics and solid matter were repealed and the experience of a lifetime of tactile sensation, motion, form, gravity, and light were invalidated. She did not know whether she was standing or sitting down, which way was upright, and from where the light, which was a stab as it touched her, was coming. She lost track of the parts of her body; where her arms were and how to move them. As sight went spinning erratically away and back, she tried to clutch at thoughts only to find that she had lost all memory of the English language and that even Yri was only gibberish. Memory went entirely, and then mind, and then there was only the faster and faster succession of sensations, unidentifiable without words or thoughts by which to hold them. These suggested something secret and horrible, but she could not catch what it was because there was at last no longer a responding self. The terror, now, could have no boundary.

How can one conceive of the ways adverse experiences trigger psychosis? To be psychologically significant, an event must, by definition, have personal meaning for an individual, whether that meaning is good or bad. Because the unconscious phantasies laid down in childhood become the foundation of the adult's system of meanings, inferences about significant life events are inevitably linked to, and elaborated by, unconscious phantasy. If someone passes a test, the world appears to welcome them; if they fail a test, the world turns away, and so on, in the ongoing, never-ending cascade of meaning that is the human psyche. Unconscious phantasy always operates in the background of conscious experience, inevitably shaping one's thoughts, feelings, and actions over the course of an ordinary day. Most such phantasy is not experienced as an ego-dystonic intrusion, but rather as a source of value, meaning, and goal directedness.

When people have a sense that they are *over-reacting* to an event, they know they are experiencing the intrusion of an unconscious phantasy that is emotionally coloring their view of the event. They know that what has just happened is somehow not as bad as they have felt it to be. With cognitive effort, and in a brief time, people can usually temper their over-reaction. The unconscious phantasy that lent its overcharged emotions to the experience fades, and people go on with their day. But when a traumatic event or succession of events kindles powerful emotions that resonate with primitive unconscious phantasies that have been reinforced by early failures of development, people may become convinced that a scene expressive of their primitive unconscious phantasies is actually happening now, in reality. Any feeling person can empathize with the reactions of helplessness, rage, fear, and betrayal of someone raped by a parent or sexually abused by a priest—or both, as was true for Karon's patient.

But in psychosis the enormity of what has happened goes even deeper. A child who desperately wants a parent's love and needs the parent's protection with the intensity that only a vulnerable child can feel, who is instead used like a condom and thrown away, may not be able to bear such events within an integrated experience of self. As the trauma resonates with the deep object-related phantasies of early childhood, the mind begins to

vibrate with pain, then shake, then fall apart into pieces. At the deepest levels of the psyche, where the most joyous phantasies of loving others should ordinarily reside and give hope at times of adversity, a sort of wholesale genocide of good psychological objects occurs. The psychotic person's mind then becomes a fragmented collage of fantastic figures that tend to be all good or all bad.

This experience of one's worst unconscious anxieties coming true is accompanied by a pervasive terror that has been termed *annihilation anxiety*. On the brink of psychosis, the self sees itself beginning to fall apart and disintegrate. As individuals descend into the "psychic equivalence" mode, where what they feel is experienced as real, primitive unconscious phantasies surface in consciousness as delusions, hallucination, or other psychotic symptoms, whereby the psychotic person's thoughts and feelings are expressed in a psychotic "fairy tale," in idiosyncratic concrete metaphors, and in altered perceptions of other people and the outside world.

The author once supervised the psychotherapy of a young woman, who routinely sat down to what on the surface was expected to be a warm family dinner where one might be expected to say such things as "How was school today?" or "Can you pass the potatoes?" knowing that within three hours her father would likely be raping her. When she was unable to bind this experience within an integrated view of herself and the world, her mind fell apart, first into two pieces in addition to the self, and later into four. She began to hear the "voice" of a "good angel" on her right shoulder, and a "bad angel" on her left. The bad angel urged her to kill herself, the good angel to stay alive. As she descended further into psychosis, she came to hear three distinct "voices," that of "Darryl," who combined traits of her violent father and a fantasied older brother who might have defended her; "Baby," who cried and was weak, who represented the needy child who had been betrayed; and "Tamika," who was brash, irreverent, street-wise, so tough she could not be hurt. She described how the Tamika "voice," like in a professional wrestling match where one wrestler tags off to another, would command her to take certain actions when she felt at a loss as to what to say, feel, or do. Her psychotherapist established a trusting rapport, which over time allowed her to put Humpty Dumpty back together again. She came to understand that the states of mind composed of her cast of hallucinated characters were aspects of her own feelings. Darryl's violence and Tamika's indifference evolved into a confident self-assertiveness that allowed her to stand up for herself without need for recourse to auxiliary internal objects.

Here are examples of how different family constellations may predispose to psychosis by impinging upon the good-enough development of children, leaving them unhappy in their own way. In good-enough development, parents support independence when the growing child shows this developmental striving but allow dependence when needs for reassurance and security are paramount, as is particularly apparent in the practicing and rapprochement phases of development described by Mahler. If this empathically alternating relationship between parent and child is kept in mind as a central arc of development that leads from the nuclear family out eventually into the adult world, the disturbances that predispose to psychosis can be viewed, broadly defined, as a disturbance in the child's

separation and individuation from the parent; that is, a failure in the child's becoming an authentic, self-inhabiting person.

In the severe cases of childhood onset psychosis, florid acute psychosis in adults, and severe chronic psychosis, individuals may literally not know where other people end and they begin. More often, however, the disturbance is less dramatic but nevertheless profoundly important. Some parents need their child or imagine their child to be someone other than who the child authentically is. They impose their own mental representation of an internal object on the identity of the child. Rather than discovering who the child is as the child's identity unfolds, they decide who the child is and require the child to inhabit that identity as a condition of relating to the parent.

The father of a son might have wanted a daughter to avoid the competitive feelings he might experience with a son. Or a mother with an inadequate relationship with her husband may want an enmeshed relationship with a child who will remain dependent upon her, allaying the mother's loneliness and separation anxiety. Or a father may have wanted an athlete, but the son prefers to draw, or a mother who has lost a child in infancy may subtly communicate to another child in the family the parent's wish that it had been the other child who had died, or the next child born may be viewed as a replacement for the dead child, and so on. The possibilities for mismatches between the child's authentic identity and the imposition of a parent's need are many. These sorts of stories routinely emerge in the individual psychotherapy of psychosis.

Theodore Lidz described two basic patterns in which the psychology of one or both parents impinges upon and dominates the development of the child, patterns he termed the "skewed" and the "schismatic" family, respectively. The former serves the needs of one of the parents, most commonly the mother. The other parent and the children accept the dominance of one parent's needs, knowing that servicing them is necessary to the parent's psychological survival and therefore the survival of the family. In the latter, both parents attempt to impose their own differing and distorted view of the world on the family, and no consistent consensus is achieved. When two very different parental agendas are imposed upon the identity of the child, the child has difficulty forming a stable identity.

Arieti described a psychotic patient who grew up in a schismatic family environment. His father was a war hero killed in World War II. The father's loss so crippled the patient's mother that she was unable to invest emotionally in her son. The patient translated this seeming lack of interest into a feeling of his being a bad person. His maternal grandmother, however, encouraged him to believe he was an exceptional person who would grow up to be a hero like his father. In the face of these two contradictory imposed identities, the patient grew up with no core identity and no realistic self-esteem, a condition that left him vulnerable to psychosis.

Another patient Jason grew up in an atmosphere of constant bickering and fighting between his parents, who frequently urged him to take sides. The parents, who divorced when he was 16, forced him to decide which parent he wished to live with, making no effort to arrange an amicable joint custody. He chose his father, who promised Jason a motorcycle when he was 18.

The father had little interest in his son except to demonstrate the son's preference of him over his wife. Jason soon became disenchanted, and one evening returned to his mother's house, hat in hand. At first she barred him from her home, haranguing him about how he had betrayed her by choosing his father, saying he must live with his choice. She eventually relented and allowed him in, but she said, amidst angry declarations of what a monster the father was, that nothing would please her more than to read in the newspaper that Jason's father had been murdered. Jason got the message: The price of his return was to be his father's life. He was psychotic by daybreak. Both parents viewed Jason as belonging either to themselves or to the other parent, and if the other parent, their mental representation of Jason was infiltrated by their hatred of their ex-spouse.

Karon describes a mother–child dyad in which an insidious mismatch arose around feeding. A psychotic man who went on hunger strikes and believed he was being poisoned reported, "The Athenian girls are laughing at me. They say their breasts are poisoned." There was at first pass no apparent trauma in the patient's history. His mother, who had breast fed him for a year and weaned him gradually, asked her son "Did I give you enough milk?" He replied cryptically, "The cow gave her calf milk and then kicked it. She shouldn't do that. It's something that happened hundreds of times in the history of the world." Karon inferred that the cow represented his mother, the calf represented the patient, and the history of the world represented his life history. Thus, the patient was complaining that every time his mother fed him she got angry, or "kicked" him. This pattern was apparent in their relationship as adults. If the mother cooked a meal and he ate it, they quarreled afterwards. If she cooked and he was on a hunger strike, or if someone else cooked, there was no quarrel. When the patient was a child his need to be fed produced anxiety in the mother, which made her angry. The same sequence occurred in their adult relationship, in which she would find pretexts for a squabble after feeding her son.

The essential aim of PDTp can be stated rather simply in relationship to the theory outlined above. The therapist tries to help patients tell their stories, to say what has happened to them in their lives and how this has made them feel, and what thoughts and feelings are currently being expressed in the psychotic symptoms. In this sense, each patient's psychotic symptoms are a Rosetta Stone by which one person's emotional life can be translated into simple human terms.

TECHNIQUE

As noted, most psychoanalytic theorists would agree that psychotic mental states represent the intrusion of primitive psychological processes into adult waking life, and that those processes were originally most clearly explicated by Melanie Klein and her followers. Although Kleinian analysts made brilliant contributions to the psychoanalytic understanding of psychosis, their way of working using classical psychoanalytic technique has no direct application in the public mental health sector. But if one regards psychoanalysis as a body of ideas applicable in a variety of settings, not as a specific clinical technique, Kleinian ideas are a compass in psychotic chaos, invaluable tools for understanding the psychotic process and guiding care wherever it occurs with whatever technique is applied. This chapter begins with a short review of Kleinian technical ideas, as they illuminate some general principles of therapy for psychosis, followed by the recommendations of therapists of the American Sullivanian School.

The European Kleinian School

Segal describes the treatment of a chronically psychotic man with multiple delusions and hallucinations who believed that he was a prisoner, not a mental patient, and that the world had been changed and was being destroyed. His two core delusions, that he was in prison and that the world was changing, were connected to primitive internal object-related phantasies. He complained that he was being given plenty to eat in the hospital, but not enough to do or think about, which led him to believe his head, arms, and legs were shrunken while his stomach had become huge. Instead of saying he was bored and that he felt like he was being force fed, he expressed these sentiments in a somatic delusion (a concrete metaphor). Because in the hospital he thought about little else than eating, he believed the world was obsessed with eating, to the point that people had neglected to plant new crops, which would lead to famine and the destruction of the world. After Segal consistently interpreted his primitive object-related phantasies and analyzed the psychotic transference, within a year all his delusions disappeared.

Wilfred Bion extended the work of Freud, Klein and Segal in novel ways with his concept of *attacks on linking*. In psychosis, individuals turn away from painful realities by internally undermining (attacking) the connecting links between memories and verbal thoughts that give experience meaning. Instead of thinking a verbalizable thought, psychotically disturbed individuals project the part of their cognitive apparatus that would ordinary maintain a conscious awareness of reality outside the self into what Bion called a "bizarre object." The familiar computer chip in the brain, a common delusion, is a "bizarre object." The person's cognitive capacity to observe reality has gone missing from the person's mind and has been projected into a mental representation of the chip. The chip operates within the person's body but is separate from the person's ability to think. The capacity most often projected into the chip is that of monitoring thoughts and transmitting them to an external agency such as the FBI, in which case the chip has taken over one's capacity to know one's own thoughts and evaluate them.

Herbert Rosenfeld believed in the importance of analyzing the psychotic transference. In his experience, primitive phantasies of intruding upon others or being intruded upon to the extent of annihilating the self are common in the psychotic transference. He describes a patient who feared that one day she would begin to speak in a strange voice that belonged not to her but to Rosenfeld. In keeping with Klein's emphasis on primitive body-related phantasies in which children imagine taking something out of or putting something into the mother's body, or having the same done to themselves, Rosenfeld interpreted the negative psychotic transference to this woman, telling her she feared that he was going to force himself into her body and her mind and take control of her thoughts so as to cause her to lose her identity entirely.

The American Interpersonal School

Harry Stack Sullivan's ideas about the etiology and treatment of psychosis are important not only because they are persuasive, but because of their simplicity. Sullivan believed that disturbances in the early mother–child relationship predispose to psychosis. According to Sullivan, all human beings have basic needs for *security* and *satisfaction*. His concept of security roughly parallels current concepts of secure attachment, positive self-esteem, and associated expectation of esteem from others. His concept of satisfaction roughly corresponds to Freud's conception of drive satisfactions, including the gratification of sexual needs. In order to achieve security and satisfaction, children must cultivate sufficient interpersonal competence to ensure that these basic needs are met in childhood, latency, adolescence, and adulthood.

According to Sullivan, when an infant's need for maternal care makes the mother anxious, this anxiety is communicated to the child, undermining the child's capacity to feel secure and to develop the interpersonal competence necessary for independent living. This failure of relatedness arises in interactions with the small group of people that compose the child's core care-giving environment. He considered the developmental milestone of having a "chum" during latency to be an important marker of mental health, as it signals the growing person's ability to establish a stable and gratifying relationship outside the nuclear family.

Sullivan died at 57 before ever writing a comprehensive manual for technique. His recommendations are scattered throughout his writings. Much of his initial work with psychotic patients was done on a special six-bed inpatient unit that he designed at Sheppard Enoch Pratt Hospital, where, without medication, he reportedly achieved an average 85 percent recovery rate for acute psychosis. Consistent with his theory, he placed significant emphasis on the quality of interpersonal contacts in the ward milieu. He took care to alert ward staff to the exquisite sensitivity of psychotic patients, encouraging them to spend considerable time fostering a relationship in which the patient could feel secure. Believing that his patients felt interpersonally incompetent in their family settings, he placed them in a humane environment in which all patients could feel themselves as valued members of the community. He resisted objectifying diagnoses while teaching that, however, strange their symptoms, people with psychosis should be considered "more simply human than otherwise." (In a similar vein, CBTp recommends *normalizing* to emphasize the continuity between psychosis and ordinary mental life.)

A central aim in Sullivan's approach was to reconstruct the chronology of the onset of the psychosis, so as to impress upon patients that whatever psychotic reaction had befallen them was the result of their profound

disappointments in life experiences with a small number of people. Sullivan cautioned that it is extremely important to use simple, clear language because people in psychotic states have difficulty communicating in consensually familiar verbal symbols. Talking in too complex or fancy a way would be, in his words, "asinine behavior." With hebephrenic patients who had retreated into an autistic self-involvement, or paranoid patients with fixed delusions, he sought to revive a state of confusion present in an earlier phase of the psychosis. This goal is similar to the CBTp aim of encouraging a state of uncertainty in patients about their delusional beliefs. The therapist must spend sufficient time with the patient to let the treatment unfold. When the patient is not communicating clearly, the therapist should welcome the attempt to communicate but not pretend to understand what is still confusing.

Sullivan offers occasional examples of his work with patients. A psychotic man who had been severely disappointed in love said of the woman who had rejected him, she is "of the past" and "out of my mind" and someone "of no importance." Sullivan took advantage of this moment of denial to say something along the lines of, "Nonsense! You are happy with her." Having startled the patient into alertness, Sullivan continued, "and there is no reason on earth why the pleasure you had in her company should be thrown away just because the relationship didn't last forever."

If all goes well enough on the inpatient service and some degree of human contact can be re-established, allowing some degree of social recovery, the patient can be treated as an outpatient. Sullivan believed the training, experience, and personality traits of the therapist were crucial to a positive outcome. (Training and experience do matter, a fact often lost in RCTs of PDTp.)

Frieda Fromm-Reichmann worked closely with Sullivan. She distinguished *psychoanalytically oriented psychotherapy* from classical psychoanalytic technique and believed that even the most psychotic patients were capable of some degree of interpersonal relatedness. Her success as a clinician stemmed from her warmth, humility, and exquisite psychological intuition. She stressed that when the therapist inevitably disappoints the patient in some way, it will likely be experienced as a repetition of early traumas, and will provoke anger and intense hostility that can be understood and worked through. She emphasized how lonely psychotic people are, noting that in spite of their retreat from the real world, people in psychotic states nevertheless retain some dim notion of the unreality of their substitute delusional world. A longing for human contact and understanding remains, yet patients are afraid to admit this to themselves or to the therapist for fear of further disappointments.

Fromm-Reichmann emphasized that to establish trust the therapist must treat patients with kindness and consideration, without infantilizing them. She would explain to them that symptoms were ways of remodeling life experiences in consequence of, or in accordance with, their thwarted past or present relationships. She recommended telling hallucinating and

delusional patients that the therapist does not see, hear, and believe the same things the patient does, but that the two parties can investigate together the reasons for the differences in their experiences. She wanted patients to become aware of and to grieve the losses they had sustained in early life without distorting them symbolically as psychotic symptoms. This approach is reflected in the title of Greenberg's book *I Never Promised You a Rose Garden*. Interestingly, at one point in Greenberg's psychotherapy Fromm-Reichmann used CBTp-like technique to array evidence against her patient's belief she had tried to kill her sister.

Silvano Arieti won the National Book Award in Science in 1975 for his seminal work *Interpretation of Schizophrenia*. This 756 page book is arguably the most comprehensive and coherently organized text currently available on PDTp, with Karon and VandenBos's *Psychotherapy of Schizophrenia* a close second. Sullivan, Arieti, Fromm-Reichmann, and Karon share much in their clinical style, an approach which might be called an *interpersonal interpretive technique*. What follows is a description of this technique following Arieti's outline of three phases of treatment, written as an amalgam of his approach and others.

Interpersonal Interpretive Technique

Arieti conceptualized PDTp as proceeding in three stages. First, the *engagement* phase, in which the therapist attempts to connect with a person who has largely withdrawn from social contact and consensual reality. Next, a phase that focuses on showing patients how they express themselves in a variety of *psychotic mechanisms,* such as hallucinations, delusions, and ideas of reference. Specific techniques are required to bring the thoughts and feelings experienced as perceptions back within the boundary of the self, where they can be experienced as mental events and examined in more traditional psychodynamic fashion. CBTp techniques that can be a stand-alone practice can be extremely useful into this second phase, about which there is more in the CBTp portion of this chapter.

Third, when patients have learned to identify the psychotic mechanisms that disguise their thoughts and feelings, they can begin to reclaim their inner life as the therapist interprets the meaning of symptoms in relationship to disowned emotions, memories, distorted thinking, and current life events. The therapist attempts to help the patient see his psychotic symptoms as meaningful reactions to problems in living, without accepting the psychotic distortions or promising the patient compensation or an ideal world. These three phases of treatment will now be described in more detail.

Engaging the Patient and Establishing a Therapeutic Alliance

Establishing a trusting emotional relationship with a patient suffering

psychotically is the first and most important step in the psychotherapeutic process. The patient is caught in a devilish version of Schopenhauer's porcupine dilemma, in which too much closeness with other human beings brings the prick of the quill, and too much distance the chill of a cold that withers the spirit. Having found that attempts to relate to others have in the past occasioned intense anxiety and repeated interpersonal failures, the psychotic person withdraws from consensual reality and ordinary social contact into a solitary delusional world. Patient who can be engaged in psychotherapy must find a way to set the value of a relationship with the therapist against the unaltered continuation of their psychotic existence.

All clinicians, whether in psychiatry, internal medicine, or surgery, will see in their patients a balance of health-promoting factors and pathology. The clinician will not know all the variables involved, or their ultimate strength in the clinical equation defining outcome. The same is true in the initial engagement phase of therapy with patients suffering psychosis. The therapist cannot always know beforehand how the need for human contact will play out against the patient's aversion to the real world. Patients who lack basic trust will approach all relationships, including a relationship with the therapist, with trepidation. When a person's development has been significantly impinged upon by others, the patient may experience being influenced by the therapist in any way as an impingement.

For example, a psychotic woman revealed after months of psychotherapy that she did not think about what the therapist said during the sessions; instead, she tried to memorize the therapist's words so that she could digest them later, alone, when she felt she could exert more control and avoid the therapist's ideas taking over her mind. Patients who have had a symbiotic relationship with their primary caregiver may adopt an opposite course and rush to fuse with the therapist's identity in an attempt to reserve no mind of their own with which to feel their own pain.

The minimum conditions for psychotherapy require the patient to be able attend sessions, whether as an inpatient or outpatient, and to curtail violent behavior directed toward themselves, the therapist and others. The therapist cannot allow socially intolerable behaviors such as stealing from the therapist, inappropriate touching, or significant disruptions of the therapist's life. A minority of patients, even when properly approached, are too damaged or too terrified to engage in treatment, at least within the parameters of the current mental health system. The therapist needs to strike a flexible balance between authoritarian controls over the patient's behavior and sitting passively by while the patient contemplates some ruinous action.

Confidentiality should be discussed early in treatment. With respect to parents, significant others, and public authorities, the therapist should explain that the treatment will remain confidential except when the therapist believes that the patient presents a clear danger to self or others,

in which case the therapist may need to contact family, friends, or the authorities. If a patient cannot allow the therapist to call in help if need be, the patient may be best treated in a more structured clinical setting. The therapist can share a draft of insurance forms, psychosocial summaries, and disability applications prior to releasing confidential information.

Patients with psychosis do not necessarily expect to have rewarding conversations with mental health professionals. They may find that the delusions and hallucinations that are the most compelling concerns in their lives may be brushed aside as "imaginary" by others. After establishing rapport with his therapist, a psychotic man acknowledged that the most important relationship in his life was his ongoing dialogue with a female "voice" he believed to be the voice of God. He said, "I never tell the doctors much at all about God. I know what they are going to think! They will just think I am crazy. They don't want to talk. They are just Haldog (*sic*) terrorists. So I take the medication and then after a while they let me go, and I stop taking the medication after I leave. I trust you. Maybe I shouldn't, but I do. There is something about your way of speaking, something about your manner, that makes me trust you."

Establishing rapport is not a mechanical matter of technique, but fundamentally *it is a matter of the heart*. The therapist's relationship with the patient will reflect what the therapist genuinely thinks and feels about the psychotic person. Just as children readily discern when meeting an adult for the first time whether it feels safe to proceed, psychotic individuals will know by the therapist's words, gestures, facial expressions, and tone of voice, whether the therapist's greeting is a well-intentioned but generic professional posture, or whether the therapist is motivated by an affectionate, abiding respect for the patient's individual personhood. Patients must know that they are truly seen by the therapist as discrete individuals. Unlike nonpsychotic patients, who can explore their fantasies about who the therapist is, the psychotic patient cannot wait to know, for fear of the worst. Adrift in a sea of madness, the psychotic patient must find something real in the therapist to hold on to that is sufficiently reassuring to allow the patient to risk connecting.

Greenberg illustrates the sensitivity of psychotic patients to the therapist's true feelings in her description of the reaction of inpatients to a conscientious objector who was unhappily assigned to the hospital as a therapy aide in lieu of military service. The patients sensed that he was frightened of them and that he defensively held them in contempt. "His rigid fundamentalist beliefs made him see insanity is a just desert for its victims, as God's vengeance, or as the Devil's work, and sometimes as all three at once. As the days passed, his fear waned in time and his righteous wrath was at hand ... Against his loathing, the sick fought in their sick way. The literate rewrote the Bible or ridiculed its passages to make him horrified. Constantia made flagrant sexual advances to him. And Debra made a few pointed observations about the similarity between psychotics and religious fanatics."

The seeming failure of people around them to see the world as they do leads psychotic patients to believe that at best the therapist will not understand, and at worst the therapist is directly involved in the patient's delusions. The therapist's attempt to communicate effectively is paramount. Initially the therapist should not ask the patient any

complicated questions, because a person who is desperately fighting for psychological survival will be unable to attend to the therapist's queries. A patient's wish to talk to the therapist is a good sign, no matter the subject. When the patient is unable to talk directly about the psychosis, the therapist should encourage the patient to talk about something else.

When the therapist does not understand what the patient has said, the therapist should not pretend to understand, but rather say the therapist is trying to understand but is not yet certain what the patient is trying to say. When the patient cannot or will not speak, the therapist must be able to tolerate periods of silence, but the therapist should not allow protracted silence to develop. Based on whatever the therapist knows about the patient, the therapist can keep talking, musing, meandering, speculating, allowing the patient to feel the therapist's effort to communicate. The therapist should be emotionally engaged, firm, honest, and familiar in his manner as opposed to emotionally distant.

The therapist need not withhold direct reassurance. Arieti describes his approach with a patient with postpartum psychosis. "In many cases, I have told the patient that she is in great distress because she rejects the baby, she feels guilty about it and believes that the baby is going to suffer. I have reassured the patient by telling her that she must accept the fact that she rejects the baby and that the baby will not suffer. Adequate provisions are being made for the baby. We shall eventually discover why she feels this way and her feelings will change. In the meantime, she cannot feel guilty because she cannot help rejecting the baby. I have found that even very disturbed women understand these explanations, partially or totally, and are relieved by them." Karon routinely reassured terrified patients saying, "I will not let anyone kill you."

The therapist should ally with the nonpsychotic part of the psychotic patient's personality that remains capable of standing outside the psychosis and reflecting on it, thin ledge along a deep chasm though this foothold may be. The therapist should not collude with the patient's delusional beliefs, nor should the therapist side-step the issue of the patient's being ill, though the matter of what to call the patient's condition must be handled with finesse. The patient's condition may have been called "schizophrenia," "mental illness," "bipolar disorder," or "a chemical imbalance." It is important to understand the labels that have been applied, the meaning of these descriptors to the patient, and what words the patient might use to describe their condition. How the label is worded shapes patients' self-image and the way they believe the therapist will see them. Patients will sometimes talk comfortably, for example, about an "emotional breakdown" while being allergic to the word "schizophrenia."

A woman with a delusion about a man at her church was willing to consider that she might be mistaken about his intentions toward her, but she was absolutely certain that the label

"schizophrenia" did not apply to her. She had looked up "schizophrenia" on the Internet and had taken away the idea that "schizophrenics imagine things that are not real." This could not possibly apply to her, she thought, because she had no doubt that the man at church had in fact said certain things to her, as indeed he had. Although she granted that she may have misinterpreted what he said, she had certainly not *imagined* him saying what he said. She had understood the diagnostic label "schizophrenia" to apply to people who imagined things that never happened rather than people who misinterpreted things that did happen. The fact that her doctors had given her a diagnostic label that she believed clearly did not apply to her led her to conclude that they must have some malicious purpose. The therapeutic alliance foundered until this issue was identified and worked through.

Although it would not be accurate to characterize psychosis as a freely chosen, alternative way of living, people who have recovered from psychosis and written autobiographical accounts of their illness describe needing to give up on an impossibly painful real world and to surrender, subjectively voluntarily, to psychosis. Greenberg describes her escape from the real world into her delusional Yr, where in her mind she lived apart from the pain of the real world for years. Fromm-Reichmann stood patiently at the boundary between Yr and the real world, encouraging Greenberg to step across the boundary back into reality when she could, accepting Greenberg's need to step back into Yr when she needed to.

People with psychotic illnesses may feel they have less to lose than nonpsychotic individuals because they have already lost so much. Having already given up on life, such patients may feel freer to tell the truth about what they think has been going on in their core relationships, including with the therapist. When a patient with a psychotic condition comments accurately on something the therapist has said or done, the therapist must acknowledge the truth of the perception. As Arieti put it, "... on the one hand [the psychotic person] is very sensitive and is capable of seeing through a situation to perceiving the truth even more so than the normal person; on the other hand, what he does with what he sees is so distorted that it will increase, rather than decrease, his difficulties."

If attempts to engage the patient are successful, the clinician may recognize a "breaking through" from the profound isolation of psychosis. Arieti quotes a patient who describes such a breakthrough moment. "There was a reading room on the ward, with a piano and magazines. I went there and I looked at the cover of a magazine. The nurse stepped in. I had never seen her before. She started a conversation with me as if I were a normal person. I told her with tremendous emotion, 'You're the first person who has broken through to me.' She was not on guard. I was not on guard. She was an ordinary girl. She made me feel communication with people was worthwhile. Before that nothing was worthwhile. People were hateful."

Identifying Psychotic Mechanisms

Arieti distinguished between *psychotic mechanisms,* meaning the form the symptom takes, and the content and psychodynamic meaning of the psychotic symptom. For example, auditory hallucinations may be similar in form from patient to patient, but different in content and personal meaning. Arieti helped patients recognize when these psychotic

mechanisms were operating in their minds. CBTp-like techniques were thus essential to Arieti's method. Through a process that CBT therapists would now call "guided discovery" of a cognitive bias Arieti helped patients understand that they heard "voices" when they *expected* to hear them: "A patient goes home after work and expects the neighbors to talk about him. As soon as he expects to hear them, he hears them. In other words, he puts himself in what I have called '*the listening attitude*.'" The patient comes to see that there is an internal mental contingency to what would otherwise be experienced as an external event. A similar realization happens when patients in CBTp understand that their "voices" follow stress or lack of sleep.

Even after recognizing that their expectation of abuse leads them to imagine an abusive attitude in strangers, or to trigger critical "voices," patients may remain puzzled as to why specific charges have seemingly been brought against them. They have no conscious awareness of ever having had thoughts about themselves of the sort given voice in the attack. Klein's ideas about primitive splitting and projection are extremely useful in understanding and working with this state of mind. In psychosis, repudiated thoughts and feelings literally go missing from the patient's mind and reappear as infiltrations of the patient's perception of reality. The patient who reports being unaware of ever having any thoughts similar to the persecutory charges is telling the truth. Arieti offers the example of a woman who heard "voices" telling her she was a prostitute, who was puzzled because she had no conscious awareness of thinking such thoughts about herself, until in PDTp she became aware of a variety of sources of poor self-esteem that had condensed in her mind into the "prostitute" charge.

Arieti approached ideas of reference and delusions with a technique similar to his approach to auditory hallucinations, by helping the patient identify what he called a "referential attitude." A man enters a public park feeling a vague, abstract sense of foreboding. Once in the park he notices children running in a direction opposite from him, and he jumps to the conclusion that he is being perceived as a child molester and the children are running from him. What Arieti called a "referential attitude," CBT therapists would call a jumping-to-conclusions bias and a self-referential bias.

Arieti taught patients to recognize the vague antecedent referential attitude that preceded and became concretized in ideas of reference. PDTp attempts to reverse this sequence, to move from the perception of concrete exterior events to the mental interior of more specific thoughts and feelings, and finally to the developmental origins of these feelings.

For example, Arieti describes a patient who believed she was getting Morse code messages she could feel when she palpated pulsations in her wrist that gave her directions about what to do and not to do to remain safe. Arieti interpreted that that she was actually giving herself advice,

but she needed to experience the directives as originating in some august authority outside herself. He related this symptom to her parents never having provided the confident guidance she needed to grow into an independent person.

In some cases, the patient's delusions reflect a sensitive awareness of an actual social reality. Arieti calls this a "punctiform insight." He gives the example of a compliant woman who was in fact being overworked and taken advantage of by her employer, who received a present of yellow roses from her boss for her birthday. She associated the color yellow with jealousy and in a turn of "paleologic," she decided that yellow roses had been selected to show her that her office-mates knew she was jealous of the boss's wife. Arieti interpreted that she was in a state of anxiety at work relating to her self-doubts and poor self-esteem, and that she had used a special type of thinking to express her feelings of unworthiness, in which she attributed her thoughts about herself to others. The boss did in fact appear to be hostile and demanding, and it did in fact appear she was being exploited, but her punctiform insight into this social reality had been expressed in a widening circle of paleological ideas of reference in which the entire social surround was seen as being hostile.

Interpreting the Relationship between Psychotic Symptoms and the Patient's Current and the Past Life

Assuming that the therapist has been able to engage the patient and has made progress in the second phase of treatment in helping the patient to identify psychotic mechanisms and not regard their content reflexively as reality, the therapy can turn gradually toward a more traditional psychodynamic approach. Impingements upon the good-enough development of an authentic independent self have left the psychotic person with a socially incompetent personality incapable of meeting the person's adult needs for security and satisfaction. Painful, repressed elements of the person's mental life have so distorted the psychotic person's mental representations of other people and reality that it has become impossible for the person to form gratifying relationships with others. Psychotherapy offers patients the opportunity to rethink these distortions so as to do better with other people and have a second chance at finding their lost authentic self.

The therapist tries to create a psychological holding environment in which, session by session, the patient's authentic thoughts and feelings can emerge in treatment. Week after week, the patient speaks to the therapist of thoughts, feelings, and actions, and the therapist helps the patient by interpreting the unconscious meaning of the patient's productions, including especially the patient's psychotic symptoms The patient may say things that are fragmented and initially incomprehensible. The therapist must gather up these mental shards over time to make coherent sense of what the patient is saying. The therapist's genuine concern and ability to

bear empathic witness to the patient's emotional life provides a corrective emotional experience that offsets a childhood environment that failed to bear witness to the child's true self.

The third phase of PDTp, while similar in broad outline to work with nonpsychotic patients, poses unique challenges. The nonpsychotic person in psychotherapy has the challenge of trying to find links between an affectively charged experience in the present and an affectively charged experience in the past; such patients come to see that the way they are feeling in the present is an expression of a childhood state of mind. Once nonpsychotic persons can see that the possibilities of the present have been constrained by the past, they can work themselves free of the past and return to the full possibilities that life offers in the present. The psychotic person's task in PDTp involves an additional intermediate step that the therapist must help the patient accomplish. In psychosis, affectively charged experiences from the past are experienced as altered perceptions of the outside world that are elaborated in delusional accounts of reality. The psychotic person in psychotherapy must first translate a current perception, or a belief regarded as a real perception of the objective world, into an affectively charged thought and/or feeling about people and the world, and then link that affectively charged experience with an affectively charged experience from the past.

THE MAN WITH PEOPLE INSIDE HIM. Consider, for example, a typical sort of session that might be occurring in any number of public clinics across the country. The author supervised a social worker who had been seeing a 22-year-old man who had become psychotic at the age of 17 for supportive sessions once a month. He had been tried on adequate doses of several neuroleptics with no seeming impact on his core delusion that people he did not know were having sex inside his body, an activity he found very distressing. The patient reported vague somatic sensations that he took as indications of the movement of other people's bodies inside his body. The therapist was encouraged to see the patient more often and to take a careful developmental history, which he did.

Lo and behold, the therapist discovered that the patient had been seduced into an ongoing sexual relationship by his older sister when he was 8 years old, a fact not known previously, which appeared nowhere in the patient's chart. In supervision, the author suggested that the therapist might consider the patient's perceptions of movements inside his body as a kind of sexual daydream in which the patient was experiencing his thoughts and feelings as perceptions. Following up on the history he had obtained, the therapist remarked to the patient in an offhand manner that most young men his age have fantasies about sex from time to time, and asked if it was possible that his sense of movement inside his body, which he thought was sexual activity, might be a form of sexual daydreaming?

The patient took readily to this suggestion. As if to say "Now that you mention it," he shared with the therapist for the first time some doubts he had about his delusion. He was at a loss to understand how the people having sex entered and left his body without leaving scars. He acknowledged that when he imagined what the woman inside him might be like, he imagined her as having some of his sister's attributes. After exploring his memories, thoughts, and feelings about his relationship with his sister in four subsequent sessions, the body sensations faded, his delusion receded, and his interest turned to how he might get a job.

In psychoanalytic terms, his sister's early sexual overstimulation was an impingement upon what should have been a slower, more natural development of his sexuality. At age 8, he was not emotionally prepared to reject his sister's advances, nor was he able to absorb them emotionally. Unable to integrate these highly charged experiences within his latency age

identity, he found them persisting in the form of unabsorbed introjects that he experienced as moving around inside his body. Consistent with primitive object-related phantasy that imagines the movement of internal objects in and out of the body, the patient believed that two people were moving in and out of his physical self. This is an example of the meat-and-potatoes sort of psychotherapy work that can occur in public clinics where earnest, well trained clinicians are supervised by a clinician with more experience doing PDTp or CBTp.

The therapist will want to accumulate a chronology of significant life events and interpersonal relationships with the aim of relating this history to the patient's psychotic symptoms. It will likely not be possible to take an orderly history in a single sitting. In modern treatment-as-usual, the life histories of psychotic patients are sometimes reduced to a clinical shorthand that may be adequate for pharmacological treatment, but falls short of what is needed for PDTp. For example, one might read in a chart, "This is the fifth psychiatric hospitalization for this 26-year-old male with a diagnosis of chronic paranoid schizophrenia who presents with auditory hallucinations telling him to kill himself that recurred 10 days after he stopped taking his neuroleptic." This sentence contains enough information to sketch out a bare-bones pharmacological plan: restart his medication because it worked before and discharge him when the "voices" abate. A good clinical service will address the questions "Why five admissions?" and "Why did he stop his medication?" although important issues like these are difficult to work through in a 10-day admission, and this focus is often entirely lost in the transition to outpatient services. Rarely will the origins of the patient's self-hatred, so intense as to be expressed in a "voice" telling him to kill himself, be a central concern. Rarely will his self-hatred be the focus of a treatment plan that includes PDTp or CBTp as the treatment of choice to explore this issue.

While helping the patient translate altered perceptions and concrete metaphors into more ordinary human thoughts and feelings, the therapist must also help the patient deal with the strong affects that in the first place drove the patient's thoughts out of the patient's mind and into the patient's perceptions of the outside world. Repressed affects that commonly emerge in PDTp include intense terror, rage, shame, guilt, longing, loneliness, despair, and self-hatred. Andrew Lotterman advocates the therapist's occasionally disclosing the therapist's feelings to the patient as a way of modeling how a person can contain and verbally express distressing affects. For example, if the patient were to arrive quite late for a session, the therapist might say simply, "I was worried when you weren't at our appointment on time." The therapist's modest, measured disclosure of the therapist's feelings helps the patient to keep in mind the person the therapist really is.

In psychosis, affect may cease to operate as a signal triggering defense, but may course through the patient's mind like a runaway train, becoming traumatic in its own right. The patient can be taught that no emotion, no

matter how strong or seemingly out of place, is entirely irrational. If angry, it is likely the patient has felt hurt, though the hurt may not be conscious, or may relate to something in the past, or be symbolic in nature. All felt emotion is real in the sense it is really experienced, and all emotion is commensurate and in proportion to the mental events that aroused the emotion. The therapist can aim to say, "Given your experience of those events, it is not surprising you felt as angry [frightened, needed, guilty, etc.] as you did." In keeping with the playground adage, "Sticks and stones can break my bones, but words can never hurt me," the patient can be encouraged to understand that emotion alone does not harm.

Psychotic individuals inevitably suffer from poor self-esteem, and more often from self-hatred. People who have not felt their existence empathically recognized, who enter adolescence and young adulthood lacking the social competence to meet age expectable goals in social interaction will judge themselves to be a failure and a lost cause. Many delusions directly reveal patients' poor self-esteem, as when they think they have a vile odor, or skin eruptions, or are harangued by "voices" telling them that they are worthless and should kill themselves to spare the world their presence.

For example, a young man who regarded it as his duty to lead his family out of poverty and set a positive example for his siblings believed he was a total failure after this younger brother was killed in a drug-related slaying. The patient came to believe that dogs in the neighborhood were looking through his clothing, and with their eyes were mocking his puny body. This man's self-hatred had gone missing from his own mind and reappeared in the mocking eyes of the dog. The therapist's devotion of considerable time and effort on the patient's behalf can go a long way to shore up self-esteem. Unfortunately, it is difficult to spend much time with patients in current care delivery models.

As the patient comes to doubt that his problems are caused by a delusional persecutor, the patient may mount an antiparent campaign with a similar accusatory theme. Descriptions of parents that first emerge may be malignantly distorted images of the parents, infiltrated by primitive projections quite at variance with the therapist's impression of the parents on meeting them. Because the patient has come to give some credence to what the therapist says, the therapist can point out distortions in current events related to the parents. For example, a psychotic man, who had come to understand that his perceptions of what his students said in the classroom were distorted, accused his parents of tormenting him by the offhand mention at family dinners of the names of his prior homosexual lovers. In the course of therapy, he acknowledged that his parents could never have been aware of the existence of the lovers in question, and so could not have known their names. He was able to see that events similar to the "voice hearing" intrusions in the classroom were happening around the family dinner table.

When over time the therapist has come to a more measured view of the patient's development, the therapist should acknowledge the very real limitations of the parents and the hurts they inflicted. In some cases, the patient may be told that despite the parent's actions being hurtful, there is no clear evidence the parents intended to hurt the patient in the way they ultimately did. In keeping with Klein's conception of the depressive position as including complex, integrated images of other people that

tolerate ambivalence, the therapist endeavors to help patients away from the paranoid-schizoid position to the more mature depressive position, where they can see their parents as having both good and bad traits.

Patients can also be shown that their behavior may reinforce negative interactions with parents that foreclose the possibility of making whatever connection might be possible. As is true in the psychotherapy of nonpsychotic individuals, patients with psychosis must learn that they will not get what they want by putting their parents on trial with the expectation they will now make good on what was missing in childhood. Patients must face the necessity of going out into the world and finding their own adult satisfactions. When Greenberg ("Deborah" in her book) complained to her therapist about how hard it was to live in the real world, Fromm-Reichmann responded, "I never promised you a rose garden," from which the book took its title.

Over the many months of her treatment, Greenberg worked to understand the meaning of her psychotic symptoms in terms of her life experience. Well into treatment, she revealed to her therapist that she believed herself to be a Japanese soldier. She knew about the "Japanese menace" in World War II and had heard the phrase on the radio, "If you aren't with us you are against us." Socially estranged from her peer group, she heard her "voices" repeating "You are not of them," which she took to mean that people thought of her as they thought about the hated Japanese soldiers. Instead of feeling *like* a Japanese soldier (a figurative metaphor), in her delusion she believed she *was* a Japanese soldier (a concrete metaphor). As she imagined herself into the identity of the hated Japanese soldier, her urological surgery at age 5 became a soldier's war wound, and the soldier's wish to escape was her wish to escape from a painfully overwhelming real world. At a point late in her treatment, when Greenberg had recovered her will to live, she made an additional discovery regarding the Japanese soldier. Greenberg writes:

> "It's a description of ... why ... why, it's grandfather!" Deborah [Greenberg] cried, having unearthed the familiar tyrannical Latvian to whom she had given such an unrecognizable mask. It was a description of him and it fitted him better than height or weight or number of teeth. Dr. Fried [Fromm-Reichmann] then said, "Coming to see this ... does it hurt so much?" Deborah replied, "A good hurt." Then Dr. Fried continued, "The symptoms and the sickness and the secrets have many reasons for being. The parts and facets sustain one another, locking in and strengthening one another. If it were not so, we could give you a nice shot of this or that drug or a quick hypnosis and say, Craziness, begone!' and it would be an easy job. But these symptoms are built of many needs and serve many purposes, and that is why getting them away makes so much suffering."

In addition to disclosing emotions, Lotterman advocates structured modifications of free association that he calls "naming" and "enlargement" that can help the patient get in touch with repressed emotions and put them into words, as well as role playing, in which the therapist might say "Imagine you are a poet trying to put your feelings into worlds." For

example, when a patient offers a vague description of a feeling state such as "I felt bad," the therapist might encourage the patient to linger over the statement to name more specifically the emotions involved. The therapist may note a particular phrase that appears to have a significant emotional valence, as when a patient said her feelings had been "interred. "When the therapist drew her attention to this word, she at first dismissed it as just an expression, but when encouraged to stay on point and enlarge her associations to the word, she began to talk about how cut off from people she felt and how hopeless she felt about anyone ever discovering her; that is, about her ever being disinterred.

At the beginning of treatment, the relationship with the therapist as a supportive real presence is paramount. As awareness of psychotic mechanisms increases and examination of the patient's family relationships proceeds, treatment may pay more attention to transference distortions. For example, a patient who believed she had an offensive odor recalled that the therapist had opened the window to his office when she arrived—to air the stink out of the room, she assumed. She believed that the therapist and most strangers on the street thought she had a bad smell. The therapist was able to point out that he had actually *closed* the window to shut out noise from the air well, but she had distorted her memory of his actions in keeping with her negative expectations. The patient was able to work through her conviction that the therapist thought she had a bad smell (but withheld telling her because he did not want to hurt her feelings).

At the beginning of treatment, the therapist offers a sincere commitment to provide whatever support is needed for the patient to survive. Later in treatment, the therapist may move toward a more demanding stance that conveys the expectation the patient will be able to live in the real world. As is true in the back-and-forth movement between dependence and independence in childhood, the patient may resent and resist such encouragement. The therapist must go slowly, showing the patient that the expectation of independence is an expression of confidence.

Aside from the fear of psychosis that may inhibit a therapist's close work with psychotic people, and aside from feelings in the countertransference that can provide clues to the patient's preverbal states, several other forms of countertransference reactions may arise during the course of treatment. Therapists may feel so deeply gratified by the intimately meaningful reward of the work that they do not recognize that a patient has made significant progress toward termination. Or they may become so habituated to a patient's peculiarities that they fail to recognize the pervasiveness of a patient's psychosis. Or they may experience a diminished interest in a patient as the person becomes less psychotic. There is little idle chit-chat in work with people who suffer from psychosis. Therapists may find the courage and raw vitality in psychotic patients an

appealing environment in which to work, especially when compared with the deeply defended "normalcy" one often encounters working with personality disorders.

As in any psychotherapy, the patient changes not only from insight but from internalizing aspects of the therapist. The patient may identify with the therapist's accepting attitude such that the patient's excessively harsh superego is softened. The patient may take the relationship with the therapist as a model of how a human relationship might be. When therapy succeeds in reducing a patient's distortions of reality, expressed in psychotic symptoms, and when the relationship with the therapist provides a sufficient basis for self-esteem, the patient can get on with the sometimes difficult business of adult living. After all, the therapist never promised the patient a rose garden—just a better chance at living.

Cognitive Behavioral Therapy for Psychosis

Cognitive behavior therapy, as first described by Aaron Beck in 1979, was not applied to the treatment of psychosis in earnest until the early 1990s. The first comprehensive textbook of CBTp appeared in 1995, and many have appeared since. Interventions shifted from the primarily behavioral focus in token economies to cognition in psychosis, and a vibrant several decades of clinical research and refinement of technique ensued and continues. The following account of CBTp is written by a psychoanalyst who practices CBTp. The same material described by a therapist dedicated to cognitive behavioral therapy would read somewhat differently.

A basic tenant of cognitive theory is that a person's beliefs about events mediate between those events and the emotional and behavioral consequences that follow them. This paradigm is summarized in the A-B-C sequence familiar to all cognitive therapists, in which "A" is an activating event, "B" is a belief about the meaning of that event to the individual, and "C" is the emotional and behavioral consequence of that belief. Assuming that emotional distress and maladaptive behavior are a consequence of delusional beliefs, CBTp researchers set out to determine how delusional beliefs and beliefs about "voices" arise, hoping to find ways to help patients change these beliefs and reduce suffering.

Their research revealed that a number of cognitive biases found in ordinary people were exaggerated in people with psychosis, including attributional bias, self-referential and attentional bias, a tendency to jump to conclusions, dichotomous thinking, belief inflexibility, and theory of mind deficits. A cognitive model of psychosis emerged, in which prior expectations were seen to shape the cognitive processing of an external life event or an internal event like hearing a "voice." Informational events that have the qualities of being expected, external, clear, common, neutral in affective significance, voluntary, public, and irrelevant to the person, may be ignored. But when, as is often the case with psychotic experiences, an

event is unexpected, internal, ambiguous, unusual, affectively loaded, involuntary, private, and personally relevant, the event proceeds to further cognitive processing according to the individual's information-processing style under conditions of high emotional arousal. Delusional people tend to have a cognitive style that focuses on current stimuli as opposed to past regularities of experience, and they tend to make rapid, overconfident judgments that are lacking in nuanced cognitive complexity.

Descriptions of the cognitive biases operating in psychosis allowed clinicians to tailor CBTp interventions to research findings. Through a process of guided discovery, patients can be shown that their belief is not the only possible explanation for events. Patients were taught to identify the cognitive biases operating in their own thoughts and to question the conclusions that followed from these biases. Many of the cognitive biases revealed by empirical research are known in the psychoanalytic clinical literature by different names. For example, Klein's idea of a primal split, in which the self is identified with good elements of the psyche and bad elements are projected into a persecutory object, is a description of what CBTp therapists would call an "attributional bias." What Freud described in 1926 in *Inhibitions, Symptoms, and Anxiety* as a constriction of the ego in the service of defense, CBTp would call a "safety behavior." There are many such crosswalks between psychoanalytic and cognitive theory. It may be reassuring to experienced clinicians to find that the psychoanalytic and cognitive behavioral traditions have found their way to many of the same ideas, and that CBTp has demonstrated the value of those ideas in empirical research.

CBTp continues to advance at a rapid pace. In a so-called "third wave" of clinical interventions, new types of therapy continue to emerge. Over time, early attempts to mitigate suffering by changing beliefs have made room for more meta-cognitive approaches; that is, helping patients change the way they think about their own thinking. These innovative techniques include, among others, mindfulness-based approaches that draw upon the wisdom of Eastern traditions to foster a more accepting attitude toward suffering, with an emphasis on kindness and compassion. In contrast to traditional CBTp, which might encourage patients who are hearing distressing "voices" to turn their attention away from the "voice" and to change their beliefs about the "voice," a mindfulness approach would encourage them to adopt a more tolerant, more meditative, less emotionally reactive response to the presence of the "voice."

Acceptance and commitment therapy does not have the primary aim of changing beliefs, but rather hopes to encourage patients to identify and keep clearly in mind their personal values, and to act on these values rather than acting on the prompt of a psychotic symptom. Compassionate mind training aims to help patients increase self-esteem by resisting self-critical elements in their personality more effectively. For example, the "two chair

technique' allows the patient to imagine sitting in one chair while conducting a dialogue with an inner "bully." This technique echoes the voice dialogue approach developed in the late 1980s, and Gestalt approaches promulgated earlier, and is in keeping with a fundamental goal of most psychodynamic psychotherapy: diminishing the impact of an overly punitive superego.

CBTp offers a variety of effective interventions that can be offered in their own right. It can be effectively integrated into the second phase of PDTp to help patients recognize the operation of distorting psychotic mechanisms. This sets the stage for more effective PDTp work, if the patient needs, wants, and can use this treatment approach. Like psychodynamic approaches, CBTp therapies are too richly diverse to summarize. Below find a description of how a more traditional CBTp might be conducted in the following sequence: (1) engaging the patient, (2) eliciting the patient's story, (3) introducing CBTp with an emphasis on coping mechanisms, (4) reviewing the three treatment models underlying CBTp, (5) applying these models to the patient's experience, (6) challenging beliefs and reformulating the patient's personal life narrative, and (7) maintaining contact and employing "booster sessions" as needed.

Engaging the Patient in CBTp

The therapist should pay attention to how the patient came to be referred. Was it the patient's idea, or someone else's? What is the patient's understanding of the purpose of the meeting? Does the patient have any specific anxieties about the meeting? Patients may wonder why the therapist is offering to see them more frequently than they expected. One patient joked, "Do you have a new supervisor?" The therapist might say, "If it is okay with you, we can meet a few times and talk about what has been happening in your life and see if we can figure out a way for things to be less distressing." Does the patient have an immediate, over-riding concern that must be addressed before the patient can focus on the therapy? A patient who is worried about being evicted from home, or who does not have enough to eat, will have difficulty paying attention until these needs are addressed.

The therapist will want to know about prior interactions with the mental health system, particularly those that have been notably problematic for the patient. Allowing the patient a virtual "panic button" that the patient can activate if the patient gets overly anxious in the session may be helpful. The therapist can ask occasionally, "How are we doing so far?" The therapist must be sensitive to the fact that the patients may believe they are putting their life at risk by even talking with a therapist. If the patient is reluctant to talk about what the therapist sees as psychotic symptoms, the therapist can find something else the patient is willing to discuss. In summary, as was emphasized by the American Sullivanians,

contemporary CBTp therapists establish a relaxed conversational manner that levels the power relationship between patient and therapist.

Eliciting the Patient's Story

It is vital to ask what the patient thinks is happening and why. What evidence does the patient have for a problematic idea? The patient will often point either to one seminal event that fostered the delusional belief or to a series of events given meaning by ideas of reference, in which case the patient may have pondered, "If this happened once or twice, it might be a coincidence, but it has happened over and over again, so there must be something going on." It is extremely important to elicit any aspects of the patient's experience about which the patient feels confused, as these doubts can often be used to forward later work.

For example, a man who had no doubt that he was an angel reported he had had an experience when he was being taken to the hospital that made no sense to him. The ambulance had passed children playing in school yard. He saw a good aura around the heads of some of the children, and a bad aura around others, but he knew there must have been something wrong with his perception because he believed all children were innocent and good. To encourage a therapeutic alliance based on evaluating data, the therapist might ask such a patient to rate his degree of preoccupation and conviction regarding a delusion on a 1 to 100 percent scale. If the patient reports being 99 percent certain of the delusion, the therapist might quip, "So we can work with the 1 percent."

Because the wish to reduce distress drives treatment, the therapist must determine what the patient finds most distressing about the current situation. While a diagnostically oriented clinician might aim at eliminating symptoms like "voices," the patient may be initially unconcerned about the "voices" and yet quite distressed that the patient's family regards them as imaginary. The therapist will want to establish rapport by empathizing with the patient's beliefs and feelings from the patient's point of view. The therapist might say, "Having heard what you went through, I can see why you came to the conclusions you did. When you first noticed strangers in your neighborhood looking at you, you concluded that you were under surveillance. I can see how that made sense to you at the time." The therapist may go on to ask what other people think about the patient's belief. What does the patient's family say? Does anyone share the patient's point of view?

The therapist can record the patient's life history on a *time line* sketched out along a horizontal line on paper and add to the time line as history accumulates. Putting the patient's history down on paper will frame the therapeutic alliance around a shared data set. In many cases, the time line will be the first occasion the patient has ever constructed any organized, linear sequence of personal history. Life events that psychotic individuals

have trouble connecting in mind can sometimes be connected on paper by noting their physical proximity on the page. For example, the therapist might say, "We marked your parent's getting divorced right here when you were away at school, and I see the 'voices' started up a short time after that."

Temporal sequences, and therefore causal links, can often be better established on paper than in the flow of conversation. The use of paper also gets the patient used to working with diaries and documents in homework assignments. At a later time in treatment, it will be useful for the therapist to draw two columns representing alternative beliefs so that evidence for and against each belief can be arrayed in each column. It is important to inquire about a history of physical or sexual abuse or bullying, but it is wise to establish some rapport with the patient before venturing into this territory. Even when the patient has been abused, the patient may not tell the therapist early in treatment. Substance abuse is usually more easily acknowledged.

If the patient hears "voices," the therapist should inquire about the identity, purpose, power relationship to the patient, consequences of noncompliance with the "voices," and whether the patient regards them as omnipotent or omniscient. As noted earlier, the therapist should inquire what diagnosis the patient has been given, by whom, and what it means to the patient. The therapist will want to know what the patient's daily life is like, and what relationships are important to the patient. The therapist should consult the chart and collaterals for additional information, and, of course, screen for danger to self or others.

Introducing the Principles Underlying CBTp with an Initial Emphasis on Coping Mechanisms

After the therapist has constructed a comprehensive time line and identified the primary sources of the patient's distress, goals for treatment with the patient can be addressed. The fundamental aim is to reduce distress rather than necessarily to eliminate symptoms. Goals might include an increased understanding of what triggers psychotic symptoms, improved coping with residual symptoms, reduction in stress related to delusions and hallucinations, and maintaining gains and preventing relapse. The therapist should inquire as to what coping mechanisms the patient currently uses.

If a patient has abandoned hope of coping, this may be a grave sign. The therapist may ask patients if they would be interested in learning how other patients cope with distressing experiences. Most will say yes. This conveys the implicit message that what is happening to the patient has happened to other people: the patient is not alone. Most coping techniques involve the redirection of attention away from distressing symptoms or toward more rewarding interests. Patients may distract themselves by listening to music

or practice focusing away from symptoms and on to pleasant imagery. The therapist can go through a list of possible coping techniques with the patient and choose several to try as a homework assignment. Coping cards that the patient can carry are useful. By highlighting the patient's coping capacity, the therapist underscores that symptoms are not entirely outside the person's control.

The therapist can explain the three basic models underlying the CBTp approach: (1) the stress/vulnerability model that emphasizes the importance of stressful life events in the genesis of distressing experiences, (2) the continuum model that finds analogies to psychotic symptoms in ordinary mental life, and (3) the A-B-C model noted earlier. The therapist should be fluent in each of these models and be able to explain them clearly to the patient. The stress/vulnerability model is a good place to start. The therapist should avoid appearing to be an expert lecturing the disempowered student. One might say, "Everyone experiences stress at some point in life. Stress can result in worries and lack of sleep. I have certainly felt the effects of stress myself."

Discussing the Normalizing and A-B-C Models in More Detail

Normalizing psychotic symptoms equalizes the power relationship between the patient and therapist, which encourages a good-faith exploration of the patient's symptoms without serious risk that the patient will feel diagnostically stigmatized. The patient will hear the therapist saying, "We all have a bit of what you have, though you have more than most." Normalizing encourages patients to place their symptoms in a psychological realm rather than to regard them as problematic realities. The therapist should be prepared with a variety of personal examples of psychosis-related mental events that can be shared. One might normalize hearing "voices" by describing hallucinations of everyday life such as hearing one's name on the street when no one is speaking, or by describing how "voice" hearing is a variant of the self-talk and internal dialogues everyone engages in from time to time, as when people say to themselves subvocally, "You idiot!" or when, on a diet, they say to themselves "Who are you kidding! You don't need dessert!"

Although affect and cognition interact in a dialectic manner, it is useful to teach patients the A-B-C model that emphasizes beliefs. This can be taught first in abstract outline, then from the therapist's personal examples, then from mundane examples from the patient's experience, and eventually in relationship to the patient's core delusional beliefs. The A-B-C model can be used to analyze a relatively neutral event in the patient's life. This gives patient and therapist practice with the concept. The patient is invited to examine a distressing "A," ideally an event about which the patient already expresses some doubt.

As patient and therapist begin to use the A-B-C model to examine the

patient's core psychotic experiences, the therapist can return to normalizing to emphasize the range of beliefs and perceptions that occur in ordinary mental life. The author sometimes tells patients the story of how in dim light he "hallucinated" the image of a black dog curled up on a bed that turned out to be a black sweatshirt thrown on the bed in such a way that the arms of the sweat shirt looked like the folded legs of a curled up dog. This example illustrates how people sometimes "see" what they expect to see, or do not want to see.

Applying These Models to the Patient's Experience and Begin Investigating Core Psychotic Beliefs

The therapist can with advantage adopt a "Columbo-style," offhand way of talking. "Columbo" was a detective on television, played by Peter Falk, who spoke in a casual manner that belied what he knew. The therapist fosters a therapeutic alliance not based on the therapist's claim to know what is in the patient's mind, but on the joint investigation of data consciously available to both patient and therapist. The treatment team consists of Watson and Crick sitting side by side, rather than Freud sitting behind Dora (one of his first patients).

The A-B-C model can be used to examine core psychotic experiences. The therapist can put two columns down on a piece of paper, to examine alternative theories. First, the therapist and patient clarify the "A": What precisely did the patient experience? What precisely did the patient hear? The patient may have actually experienced only a muffled sound, but later concluded it was a threat. An "A" may be a mental event, like a "voice," or and external event, like the glance of a stranger. Patients often merge the "A" and the "B" such that the event and the patient's belief about an event are a simultaneous, equated experience. CBTp aims to separate the "A" from the "B" so that the patient's beliefs can be examined. The therapist might say, "If your explanation for 'A' is correct, your reaction is understandable. If there is any other way of understanding what is happening to you that would be less distressing, it would be important for us to discover it. Let's look at the evidence, and see what we can figure out."

A rich toolbox of CBTp techniques has been developed to examine beliefs; for example, the practice of rating the patient's degree of conviction on a scale from 1 to 100 percent. If patients can be made aware of their convictions changing, the therapist can point out that while facts do not change, beliefs do, thereby categorizing the delusion as a belief rather than a fact. Other techniques include rating the likelihood of a belief, rating the value of evidence, agreeing to disagree about final conclusions pending further assessment, peripheral questioning, informational handouts that increase real-world knowledge, googling topics during session, inference chaining ("If this turned out to be true, what would it mean to you? Which explanation would you prefer to be true?"), homework assignments and

diaries, reality-testing experiments, and self-esteem building exercises.

Challenging Delusional Beliefs and Reformulate the Patient's Personal Life Narrative

On the basis of their joint investigation, the therapist can offer a tentative formulation based on the stress/vulnerability, cognitive, or biopsychosocial model that leads to a more adaptive alternative belief. A formulation using the stress/vulnerability model might be: "Your mother's death was very stressful for you. You weren't sleeping well, and were using drugs to ease the pain. In that stressed-out state, you had some disturbing experiences, like thinking your neighbor was trying to poison you. We can now see that those beliefs were the result of the upset state of mind you were in at the time." Or, a formulation based on identifying cognitive biases: "You have a cognitive bias that leads you sometimes to jump to the conclusion that people know you and want to hurt you. You tend to personalize events, believing people are referring to you when they are not." Or, a fuller biopsychosocial formulation: "You felt that if you had set a better example for your brother, he might not have died so young. You felt guilty, and when you couldn't get your life together after the Navy, you felt ashamed. You criticized yourself. Over the years those feelings of guilt and shame built up, and you came to feel that shame everywhere you went, including in the eyes of the dogs in your neighborhood." The therapist should determine whether the patient engages in safety behaviors that constrict life experience, precluding positive experiences that would contradict delusional beliefs.

As described in the earlier part of the section on technique, the CBTp work outlined above can lead into a final phase of therapy that seeks to find psychological explanations for the formation of the patient's psychotic symptoms. CBTp is the preferred method for showing patients the *literal falsity* of their delusional beliefs. PDTp is the preferred method for exploring the *figurative truth* of their delusional beliefs.

Maintaining Contact and Employ "Booster Sessions" as Needed

Therapists should develop with each patient a description of possible stressors and early signs of relapse to look out for. They need to anticipate what the patient should do if these signs appear. Working collaboratively, they should encourage the patient to practice the ability to identify signs of relapse and to implement the recommended course of action. Continuing to see the patient on a regular basis is critical for supporting positive changes.

ETHICAL ISSUES

The ethical constraints, such as maintaining professional boundaries, that govern the practice of psychotherapy with nonpsychotic patients are well

known, and apply equally to the treatment of psychotic patients, and so will not be addressed here. Because most individuals with chronic psychosis are treated in the public psychiatry sector, or in hospitals or clinics funded by government third party insurance, their well-being is directly affected by how resources are allocated and what kinds of care are reimbursed, a circumstance that poses ethical concerns.

In the study of ethics, there is a time-honored tradition of using a hypothetical situation to think through an issue. Consider the following hypothetical: Assume that chronic psychosis is a complex biopsychosocial disorder that has no single cause. Assume that no mental health system has developed a way of treating psychosis that avoids the prescription of neuroleptic medications in all patient cases, despite evidence that these drugs may cause structural damage to the brain. Also assume that individual psychotherapy is an effective treatment of psychosis that in some cases may resolve psychotic symptoms unresponsive to medication, improve quality of life, and reduce or even on occasion eliminate the need for medication. If these assumptions are made in the author's thought experiment, and assuming that physicians are ethically bound to provide patients access to quality care, what ethical implications follow from the above assumptions?

The author suggests that psychiatry has an ethical obligation to consider the following:

1. At present there are insufficient numbers of therapists trained in psychotherapy for psychosis to meet patient need, and there are not enough supervisors who can train additional therapists. Federal and state agencies should fund pilot training programs with a research component to develop supervisors and therapists with the needed skills. Psychiatric residency programs should find ways to teach psychotherapy for psychosis.
2. In understaffed public clinics, where too many patients are assigned to too few clinicians, administrators should pilot psychotherapy initiatives coupled with research that allow clinicians to see at least a few patients frequently enough to provide PDTp and/or CBTp.
3. To foster a therapeutic alliance that creates a bridge between inpatient acute care and outpatient PDTp and CBTp, suitable patients nearing discharge on inpatient units should begin working with an outpatient therapist while the patient is still in the hospital.
4. Granting agencies should encourage research that explores whether PDTp and CBTp can help reduce the total neuroleptic exposure patients receive.

Despite the enormous amount of information accumulated about the functioning of the brain, most psychiatrists regard neuroscience as still in its infancy. Psychiatry should also regard the psychotherapy of psychosis as

still in its infancy, but as a childhood with much promise. Improvements in outcome seen in the last two decades with CBTp suggest there is much progress to be made in the psychotherapy of psychosis when a critical mass of researchers and clinicians put their minds to the challenge.

Since Bleuler's time, there has always been a small chorus of voices in the clinical community who were convinced from personal experience that psychotherapy can be an effective mode of treatment of psychosis. If it is true (as personal experience and research evidence suggest) that psychotherapy can be an effective element of treatment, psychiatry has an ethical obligation to understand why patients with psychotic disorders have little or no access to psychotherapy, and to devise the psychiatric educational, political, economic, and clinical vehicles that would allow psychotherapy to be delivered. As Karon put it a decade ago, "The real tragedy of schizophrenia is not the severity of the symptoms and the suffering that results for patients and for their families, but that we know psychotherapies that work and we are not using them."

RESEARCH AND EVALUATION

There is solid evidence for the efficacy of CBTp, supported by multiple RCTs and meta-analyses. An early meta-analysis of 34 CBTp clinical trials found an effect size of .4, in the range of effect sizes for some neuroleptics (typically in the .4 to .5 range, with the exception of clozapine at .8). A more recent meta-analysis of CBTp RCTs showed a somewhat smaller average pooled effect size of .33. CBTp is included in the British National Institute for Health and Care Excellence (NICE) guidelines. A recent review of six different psychological interventions for psychosis found that CBTp was significantly more efficacious than other interventions in reducing positive symptoms, while social skills training showed an advantage in improving negative symptoms. Thus, it is clear that CBTp works. There are no head-to-head RCTs comparing psychopharmacology alone against CBTp alone.

The many published case histories, autobiographical accounts, and the testimony of many therapists and patients bear witness to the efficacy of PDTp, and the positive experiences of the Soteria Project and the Open Dialogues program lend support to treating psychosis without neuroleptics, but if one considers RCTs to be the gold standard of evidence, the RCT base for PDTp is small, methodologically flawed, and outdated. The Michigan State Psychotherapy Project, in which hospitalized patients with psychosis were randomly assigned to either individual psychotherapy without medication, therapy with medication, or medication without therapy, reported that psychotherapy produced significantly greater improvement than medication alone and was particularly effective in changing thought disorder. The investigators also concluded that more experienced therapists produced more improvement. A more recent study compared expressive insight-oriented therapy (EIO) with reality adaptive supportive

therapy (RAS) and found that both were effective. RAS had a clearly greater impact on recidivism and social functioning, while EIO had a modestly more positive effect on ego functioning and cognition. The conclusion of a 2001 Cochran Database Review of randomized individual psychodynamic psychotherapy and psychoanalysis for schizophrenia, however, did not support the efficacy of those approaches. The review concludes by saying there is an urgent need for research in this area. It is apparent that while RCT support for CBTp is strong, PDTp has been insufficiently studied.

FUTURE DIRECTIONS

CBTp is structured and brief compared with PDTp, which is less structured and more open-ended. This makes PDTp more difficult to study than CBTp. Developing new ideas and conducting research requires a critical mass of clinicians trained in the techniques to be studied. At present there exists more than a critical mass of CBTp trained clinicians working and doing research in many centers. The same cannot be said for PDTp, where more teaching and practice opportunities need to be developed.

At this point, what is known about the comparative efficacy of psychopharmacology and psychotherapy? It is known that the majority of patients treated in a care system with a predominantly pharmacological paradigm remain chronically disabled. It is known that all neuroleptics have potentially significant side effects and that psychotherapy for psychosis has never been proven to have any. It is known that roughly a quarter of patients initially treated with medication after years of pharmacological treatment can do well off medication, but how to identify these people is unknown, or how to wean them off medication even if they could be identified.

It is not known how to teach psychotherapy and integrate it into current care systems. Whether psychotherapy combined with medication can reduce dosage creep or reduce total neuroleptic exposure for patients on maintenance medication is unknown. It is not known if the current psychotherapeutic techniques are the best that can ever be devised. Whether psychotherapy is more effective for some symptoms and medication is more effective for others remains unclear. Many important questions remain to be answered, but until there is a more vibrant clinical community doing psychotherapy with psychotic patients that can collaborate doing research with psychopharmacologists, these questions will likely go unanswered.

THE WOMAN WHO MURDERED HER PARENTS. The author will now describe the psychotherapy of a psychotic woman who, prior to her beginning an integrated CBTp/PDPp treatment, had been an inpatient in a state hospital for 15 years, after she stabbed both her parents to death while in an acute psychotic state. At the time she began psychotherapy, she had been taking 600 mg of clozapine for the prior 8 years, with no change in her core delusions, and accordingly no hope of ever leaving the hospital. After a successful course of

psychotherapy, she was discharged to a community residence.

Loretta was an only child who returned home after college and worked a number of low-demand jobs. She joined an Evangelical church and became preoccupied with church activities. Soon afterward, she suffered her first psychotic episode and psychiatric admission. After discharge, she was followed in a community clinic on psychotropic medication. Five years later, she again became preoccupied with the church. One evening after an altercation with her father, she murdered her parents. She recalled that prior to the homicides, "one of the Evangelicals had looked at me with a piercing stare" that she believed had placed her in a hypnotic trance that led her to murder her parents. Staff believed that she might seek revenge if she were discharged. In 15 years in the hospital, she had never been involved in a violent incident, though she feared assault by other patients and believed that nursing staff were intentionally provoking her to violence.

The therapist followed a CBTp approach for the first 20 sessions. At one point during this period, the therapist focused in detail on the subjective events that had occurred during the psychotic episode when Loretta killed her parents, framing these as "A"s to be investigated in A-B-C format. Loretta acknowledged that people might stare for a variety of reasons. The therapist drew two columns of paper: one for the "Evangelical" explanation and one for the "mental health" explanation. He then asked which Loretta hoped was true. He had been imagining that the patient might welcome the mental illness explanation, but much to his surprise, she said the opposite. "If the Evangelicals hypnotized me, I was just stupid. But if I killed my parents because of mental illness, I am a piece of garbage and I should rot in hell!"

Moving into the PDTp phase of treatment with more focus on life history and affect, the therapist conceived a role-playing exercise to explore the patient's dissociated guilt. The therapist asked if she were familiar with the case of the woman who claimed to be David Letterman's wife, who kept breaking into his house, and she said she was. The therapist then pretended to be an attorney who presented three different scenarios to Judge Loretta, asking whether she would recommend treatment or punishment. In the first scenario the woman resists police, but no one is hurt. She recommended treatment. In the second scenario, a policeman receives a minor physical injury; she again recommended treatment. In the third scenario, the woman strikes a policeman in the head with a lamp and kills him. Judge Loretta paused. She said she needed more information. Was the attack premeditated? If there was premeditation, Judge Loretta would recommend punishment. If not, she would rule for treatment. The therapist then asked Loretta if she had premeditated the murder of her parents. As if taken aback, she replied "No" with confidence and calm. In 15 years of inpatient treatment-as-usual, no one had ever given her an opportunity to talk about her terrible guilt over murdering her parents.

The next week as the therapist turned the key and stepped through the door into Loretta's ward, she rushed to greet him, a broad smile on her face, a brand new shawl around her shoulders. She announced she had recovered the ability to pray, and that she felt once again able to communicate with God! The therapist feared that the previous session had undone her, and that she was now hallucinating. But this was not the case. She explained that after she murdered her parents, she had a feeling that God had turned his back and would no longer listen to her prayers. In the previous week, she had not heard the "voice" of God, but rather she had recovered a feeling that God was once again listening to her! This was a deeply moving moment. Her psychotherapy had begun to mitigate the agonizing guilt that she had carried for 15 years in the Evangelical delusion. Her obsession with the Evangelicals faded, staff grew increasingly confident in her recovery, and she was discharged to a community residence within a year. The therapist met Loretta at Dunkin'Donuts a year after her discharge. She was doing well. Both ordered coffee and a jelly-filled donut, and both agreed the donuts were delicious.

Loretta's story and the stories of many patients like her who have benefited from PDTp and CBPp constitute evidence, even if those stories have not been studied via RCTs, of the importance and efficacy of psychotherapy in the treatment of individuals with psychotic suffering.

▲ 33.17 Hallucinogen-Assisted Psychotherapy

STEPHEN ROSS, M.D., AND MICHAEL P. BOGENSCHUTZ, M.D.

INTRODUCTION AND DEFINITION

In this section, the historical and recent literature on the clinical use of the classic or serotoninergic hallucinogens (SHs) (i.e., those hallucinogens that are thought to exert their psychedelic or consciousness-altering effects primarily through agonist or partial agonist activity at serotonin 2A [5HT2A] receptors) as adjuncts to psychotherapy will be reviewed. Although the SHs have been used by humans for millennia, known to science for over a century, and subjected to extensive basic research for decades, the rigorous study of their clinical use as adjuncts to psychotherapy is in its infancy. Promising early-phase research conducted from the 1950s through the early 1970s was discontinued before any conclusions could be reached concerning the efficacy of any of the classic hallucinogens for any clinical condition. However, the research that was conducted in that era strongly suggests that classic hallucinogens have clinically relevant effects, particularly in the case of lysergic acid diethylamide (LSD) treatment of alcoholism and cancer-related psychological and existential distress.

In the past decade, clinical trials have resumed investigating the effects of classic hallucinogens in the treatment of various mental illnesses (i.e., cancer-related psychological and existential distress, treatment-resistant depression, OCD) and addictive disorders (i.e., alcohol, nicotine). The studies that have been completed to date are small open label or randomized controlled trials (RCTs), and although the results have been very promising, they are not sufficient to definitively establish treatment efficacy. The encouraging results that have been seen historically with classic hallucinogen treatment across alcohol, nicotine, and opioid dependence suggest the possibility that other chemical and behavioral addictions may also respond to treatment with these agents. While it cannot be assumed that addictions are interchangeable or that classic hallucinogen all have comparable efficacy in the treatment of addiction, it seems reasonable to pursue additional indications. One such possibility is currently being explored in an ongoing RCT that is the first to evaluate the effects of psilocybin-assisted treatment of cocaine addiction (NCT 02037126). Other promising psychiatric indications that are worth exploring using hallucinogen-assisted psychotherapy could include: PTSD, Generalized Anxiety Disorder, eating disorders, anti-social personality disorder/criminal recidivism, and narcissistic personality disorder. If the data ultimately supports treatment efficacy, hallucinogen-assisted

psychotherapy would truly constitute a novel psychopharmacological–psychosocial treatment paradigm to treat these disorders, although the risk of adverse psychological events would have to be controlled through a careful screening process.

The clinical safety of SHs, well documented by extensive research in the 1950s through early 1970s, has been confirmed in the rigorous clinical work which began again in the 1990s. Although physical and psychological risks exist, they can be minimized through the safety procedures followed in recent clinical studies, including careful screening of participants, thorough training of therapists, close attention to dose, set, and setting, preparation, support, monitoring, and follow-up of participants, and predetermined procedures for dealing with medical and psychiatric emergencies. Since the resumption of clinical research with classic hallucinogens in the 1990s to date, there have been no reported hallucinogen-related serious adverse events or cases of persistent harm to participants. Although it would be unrealistic to believe that any medication is harmless, this fact is encouraging. Future research must continue to make every effort to maximize safety. Should a classic hallucinogen be approved for clinical use in the future as an adjunct to psychotherapy, it will also be critical that rigorous safety procedures be built into the approved conditions of clinical use.

Although research has elucidated many of the acute neurobiological and psychological effects of classic hallucinogens on humans, animals, and in vitro systems, the mechanisms of clinically relevant persisting effects remain poorly understood. Although neuroimaging studies have begun to characterize the acute effects of psilocybin on brain function, how these changes neuro-biologically mediate therapeutic benefit is unclear at present. Changes in 5HT2A receptors, serotonin transporters, neurotrophic factors, and other relevant brain chemicals have not been measured in the context of clinical studies of classic hallucinogen treatments. At this point, the causal mechanisms with the strongest support relate to neuroplasticity, in terms of intensely memorable and highly meaningful experiences, particularly those of a mystical character. Much more work is necessary better to understand the mechanisms by which such experiences, and their neurobiological correlates, can lead to persisting psychological, behavioral and neurobiological change.

Although the small trials that have been conducted have provided some information concerning the psychological processes that may underlie behavior change, future trials should continue to characterize both the acute medication effects and the longer-term psychological changes that are associated with desired clinical outcomes.

Although interest in clinical use of SHs has increased dramatically in the past decade, significant barriers remain to a full exploration of their clinical potential. Due to the high costs, almost all new drugs today are

developed through investment by private, for-profit corporations. Such investment is unlikely in the case of classic hallucinogens such as psilocybin and LSD, because the compounds have been known for over 60 years and are not patentable. For this reason, funding through federal agencies such as the National Institutes of Health is particularly important. No trial has yet received federal funding, although preclinical work and neuroimaging studies have been supported. To date, funding of clinical research with classic hallucinogens has come entirely from private, nonprofit organizations such as the Heffter Research Institute. Currently the Usona Research Institute and the Heffter Research Institute are planning development of psilocybin for the indication of treatment of anxiety and depression associated with a cancer diagnosis and are in discussions with FDA about a potential phase 3 trial.

HISTORY

Early Academic Research with Hallucinogens

Although classic hallucinogens have been used by humans for at least 5 millennia, western scientific study of hallucinogens dates to the late 1800s, when mescaline was isolated and its effects described by Arthur Heffter. In 1943, Albert Hofmann discovered the psychoactive effects of LSD when he accidentally ingested traces of an ergot derivative he had synthesized, and confirmed the effects through self-experimentation. He quickly recognized the therapeutic potential of LSD, within psychiatry as did other investigators. Following Gordon Wasson's report of hallucinogenic mushroom use by the Mazatec tribe in Mexico, Hofmann isolated psilocybin from samples of the mushrooms and synthesized it in the laboratory in 1958.

Following the discovery or LSD, research on LSD and other classic hallucinogens expanded rapidly. Initially, the main focus of research was on the use of LSD as a model of psychosis. However, clinicians and clinical scientists in Europe, Canada, and the United States soon began to explore the use of these unregulated chemicals, in combination with various forms of psychotherapy, in the treatment of alcohol and drug addiction, existential crisis related to death in the terminally ill, personality disorders (in particular antisocial personality disorder), and various neurotic conditions being addressed in the context of psychodynamic psychotherapy. From the early 1950s to the mid-1960s, over 1,000 scientific articles were published reporting on the treatment of over 40,000 patients with classic hallucinogens.

In reaction to the cultural upheaval of the 1960s and concern about the dangers of wide-spread illicit use of psychedelics during that era, clinical research on hallucinogens came to halt in the early 1970s. The Controlled Substances Act of 1970 placed LSD, psilocybin, and related compounds in

Schedule I, and human research was not allowed to continue. Basic research continued, and many additional compounds were and continue to be discovered, most of which have never been subjected to the most basic pharmacological study, let alone human laboratory studies or clinical trials. Illicit use for recreational, therapeutic, and/or spiritual purposes continued.

Reemergence of Research Using Hallucinogens

After a hiatus of about two decades, human research on psychedelics resumed in the early1990s with Rick Strassman's studies of the subjective and physiological effects of intravenous dimethyl tryptamine (DMT) on normal volunteers. Since the beginning of the 21st century, there has been a sharp increase in research in this area especially pertaining to the use of psilocybin-assisted psychotherapy for psychiatric conditions such as psychological distress associated with cancer and addiction (tobacco and alcohol). The safety of classic hallucinogens (particularly psilocybin) in clinical research settings has been well documented. A considerable body of work has characterized the acute effects of classic hallucinogens on physiology, cognition, emotion, and brain function. All of these factors have motivated the resumption of research into the possible clinical applications of these drugs.

THEORETICAL ISSUES

Soon after Hoffman's accidental discovery of LSD in 1943, mental health practitioners and researchers began to explore the therapeutic potential of LSD, and later other hallucinogens, as adjuncts to psychotherapy for a range of psychiatric disorders. Although classic hallucinogens were sometimes used in a strictly biological or pharmacological model of treatment, hallucinogen-assisted psychotherapy became a newly developed model within psychiatry in Europe, Canada, and the United States. There was excitement that it represented a novel pharmacological–psychotherapeutic technique that could expedite the psychotherapeutic process by shortening the length of traditional treatment and that it could be used to help patients that did not respond well to traditional psychotherapies at the time (i.e., addiction, existential anxiety associated with terminal cancer). The two models used in the 1950s through early 1970s were *psycholytic* and *psychedelic* therapy. Although both combined administration of hallucinogens with psychotherapy to achieve therapeutic change, they emphasized different processes in bringing about these changes.

Psycholytic Therapy

In the *psycholytic* method, low-to-moderate doses of hallucinogens were

administered on multiple occasions to facilitate therapy that was based on traditional psychoanalytic principles, that is, helping the patient to become aware of unconscious desires, emotions, attachments, self-representations, and intra-psychic conflicts.

Psychedelic Therapy

The *psychedelic* method was a new and radical treatment model for psychiatry that used higher doses of LSD administered on no more than a few occasions, with the goal of occasioning a "peak-psychedelic" or mystical/spiritual experiences that were felt to be at the core of clinical improvement in conditions such as death anxiety in the context of cancer, and alcoholism. These experiences are classically characterized by the phenomenology of unity (sense of oneness), transcendence of the ordinary experience of space and time, sense of sacredness, sense of deep truth or ultimate meaning (noetic quality), deeply felt positive mood, and ineffability. It was held that such experiences often facilitated lasting change in habitual patterns of thought, behavior, experience of emotion, and even personality. Although these two models are conceptually distinct, some clinicians and investigators used both, or created hybrid models.

TECHNIQUES AND GOALS OF THERAPY

The first attempts at using hallucinogens (LSD) to treat psychiatric distress were based on a purely pharmacological model of intervention that did not account for set, setting, or psychotherapeutic preparation or integration. It was applied to patients with major depression, traumatic spectrum disorders, pain and existential distress associated with terminal cancer and patients with refractory personality or neurotic spectrum disorders. This technique was ultimately abandoned by most researchers as it became apparent to clinicians and researchers that the therapeutic outcome of the use of the hallucinogens was critically dependent on a variety of extrapharmacological factors. After trial and error, a new technique of hallucinogen-assisted psychotherapy became a newly developed model within psychiatry in Europe, Canada, and the United States. This new treatment model established the importance of ***set*** (psychological frame of mind, intention), excluding participants with major mental illness (especially psychotic illness or family history of psychotic illness), ***setting*** (environment/room on dosing days), and ***drug dose*** (and associated intensity of experience). It combined the administration of hallucinogens with psychotherapy before, during, and after the drug experience, believing that the subjective experience during the drug's acute effects, and the successful integration of these experiences, was crucial to the therapeutic benefit of the treatment.

Psycholytic Therapy

Psycholytic, and especially psychedelic therapy, had elements that made them unique forms of psychotherapy. Psycholytic therapy represented an extension and modification of psychoanalytically oriented psychotherapy, involved administration of low-to-medium doses of a hallucinogen (usually LSD), included a variable number of sessions depending on the therapeutic indication (range between 15 and 100 sessions), was conducted over months to sometimes more than 1 year, and had an emphasis on the phenomena emanating from the drug sessions. The drug dosing sessions would occur in a darkened, quiet room prepared to look like someone was in their home and would usually involve more than one therapist with sessions lasting a variable amount of time depending on the hallucinogen but typically for 8 hours or more since LSD was the most predominant drug used. General principles of psychoanalytically oriented therapy would be applied during sessions and during interim nondrug psychotherapy sessions with an intensification of the usual elements of psychoanalytic technique such as exploration of unconscious material (from the drug dosing session), interpretation and analysis of defenses and transference. The technique tended to be different from the more orthodox applications of Freudian psychoanalysis and would be more along the lines of supportive psychodynamic treatment with more personal involvement, physical contact, and genuine human support on the part of the treatment providers.

Psychedelic Therapy

Psychedelic therapy differed from psycholytic therapy in several important aspects and represented a completely new pharmacological–psychotherapeutic model when it was first introduced into psychiatry in the 1950s. It was developed based on the observation of sudden and dramatic clinical improvements associated with high-dose hallucinogen administration and quantum shifts in perception and cognition in patients who typically experienced “transcendental” “peak” experiences marked by highly salient spiritual, religious, or mystical phenomenon. One of the main goals of psychedelic therapy is to create an optimal treatment environment during the preparatory psychotherapy and during dosing sessions to foster such “peak” experiences and for the patient to experience a sense of unity of consciousness, egolysis, and an experience of transcendence associated with a sense of death and rebirth. During preparatory psychotherapy, the therapist reviews the patient’s life narrative; explores the narrative of the psychopathological disease state being treated (e.g., addiction, terminal cancer distress); focuses on personality factors and resistances to achieving a peak state; focuses on philosophical/spiritual/religious beliefs as well as existential themes and hierarchical life values; reviews the range of phenomenological effects of the drug experience ranging from esthetic changes to psychodynamic to archetypal to mystical; reviews techniques

used to deal with difficult psychological experiences, and emphasizes the importance of "letting go" and yielding to the experience knowing that skilled therapists will be with the patient for the duration of the experience and that the patient will return to their normative consciousness after the effects of the drug wear off. Psychedelic therapy emphasizes creating an optimal esthetic environment for the dosing sessions which are usually conducted in comfortable living room–like settings decorated with flowers, fruit, esthetically pleasing and evocative art, and items (i.e., photographs, art, spiritual/religious icons) that have a highly personally meaningful and symbolic value for the patient. Unlike conventional individual psychotherapy conducted by one therapist, there is commonly a male–female psychotherapy dyad that treats the patient during the preparatory, dosing, and integrative phases of the treatment. During the initial part of the dosing sessions (which last for hours depending on the hallucinogen used—i.e., 6 to 8 hours for psilocybin and 8 to 12 hours for LSD), the dyad team typically will ask the patient to state their specific intention for the dosing experience and day. After receiving the drug, the patient is instructed to lie down on a coach (with a comfortable blanket and pillow), is given eyeshades and instructed to focus internally on their experience. Preselected music accompanies the experience and is selected in relation to varying stages of the experience (i.e., before, during, and post the peak of the experience). The default position is for the patient to lie supine with eyeshades on and focusing internally, rather than with eyes open attending to external stimuli or interacting or talking with the therapists. Toward the end of the dosing session, the treatment providers will typically ask the patient to recount their experiences which can be difficult to describe, ineffable, transient, and quick to fade from memory. They will also typically instruct the patient to reflect on the experience of the day and write down as much of the experience as they can as a way to further facilitate encoding and remembering of the experience so as to optimally guide postsession integrative psychotherapy. At the end of the dosing session, the treatment providers assure that the patient has returned to their normal state of consciousness and is safe from a psychological and medical perspective before being discharged home, usually accompanied by a family member or a friend. Compared to conventional psychotherapy, psychedelic therapy is more concerned about transcending psychopathology than necessarily an interest in its analysis, although postsession integrative psychotherapy occurs to incorporate the experiences during the dosing sessions into further psychotherapy with the goal of consolidating psychodynamic changes that have occurred, and fostering a change in psychopathological symptoms.

CLINICAL ISSUES

Indications

Hallucinogen-assisted psychotherapy has historically been applied to a variety of psychiatric conditions including: addiction, existential distress associated with cancer, mood and anxiety disorders, and personality disorders. The first three conditions mentioned have the most historical and current empirical data assessing their use in these disorders (see Research and Evaluation section).

Limitations

There are several key limitations to providing hallucinogen-assisted psychotherapy. For one, all of the SHs are currently schedule I drugs that are not available for clinical use and are only able to be used in clinical research treatment studies. Given the onerous nature of obtaining approval for schedule I research with hallucinogens and the lack of federal funding in this area, currently these types of treatments are very limited to a few major academic medical centers in the United States and Europe and confined to a small group of psychopathological conditions. If the SHs were rescheduled and available as adjuncts to psychotherapy, there would be significant limitations to their broad use among mental health practitioners. For one, the time commitment is vastly different than the typical 45- to 50-minute individual psychotherapy session and the therapist would need to spend the entire day with the patient (considering drugs like psilocybin and LSD). Also, it is unlikely the drug would be available by prescription to acquire at a pharmacy to be taken at home by the patient. It is more likely that the treatment would be restricted to specially designated and regulated psychedelic treatment clinics. Financial issues such as the cost of treatment (relative to the intensity of therapist resources necessary) and whether insurance companies would reimburse such treatments may further limit the broader use of this type of treatment. Also, given that this is a highly specialized form of psychotherapy, there might be a requirement for therapists to undergo specific training in a psychedelic psychotherapy training program and to obtain special certification to use the treatment. However, on the other hand, if limited pharmacological-type interventions (i.e., one to three drug sessions) can cause immediate and sustained clinical improvements, they would be ideal for insurance companies to reimburse because of the potential cost savings of such an intervention model especially compared to the normative daily and extended use of most pharmacological agents (i.e., antidepressants) for most psychiatric disorders.

COMPLICATIONS

Physiological Toxicity

In general, classic hallucinogens possess remarkably low physiological toxicity and are not associated with end-organ damage, carcinogenicity,

teratogenicity, lasting neuropsychological deficits or overdose fatalities. The classic hallucinogens produce sympathomimetic effects and can moderately increase pulse as well as diastolic and systolic blood pressure, although this has not been associated with cardiac, neurological, or other organ damage. Common physiological side effects of the classic hallucinogens include: mydriasis, blurry vision, dizziness, tremors, weakness, paresthesias, and increased deep tendon reflexes.

Psychological Toxicity

The acute psychological and behavioral effects of the classic hallucinogens are greatly influenced by set (personality and expectations of the individual), setting (environmental conditions and context of use) and dose, with the factors combining to influence the valence (positive or negative) of the experience. Affective changes can range from euphoric or ecstatic spiritual states to anxiety, terror, and panic. Perception is intensified and amplified with alterations in time, space, and boundaries between self and others. Synesthesia is common with mixing of various sensory stimuli (e.g., hearing colors). Sensory illusions (e.g., walls breathing) are common, and frank hallucinations can occur, though less frequently. Thought processes are loosened, with effects ranging from increased creativity to thought disorder. Cognition is altered and can range from increased and sudden insight ("noetic" effect) to confusion and disorientation. The sum total of the experience can range from positive mystical type experiences associated with enduring positive changes in affect/cognition/behavior to very unpleasant experiences dominated by fear and dysphoria. Severe adverse psychological experiences ("bad trips") tend to occur in poorly prepared individuals who use the substance in an uncontrolled setting and who have psychological risk factors (e.g., severe mental illness, recent trauma). These experiences typically include anxiety, panic, dysphoria, depersonalization, paranoid ideation, fear that the experience will never end, and fear of losing one's mind. Despite such adverse reactions, users usually retain insight into the fact that their symptoms are related to drug ingestion and they usually respond to verbal reassurance. Classic hallucinogens can acutely engender frank psychosis marked by hallucinations, thought disorder, and delusions, although this is rare in individuals without underlying psychotic spectrum illness. Such adverse psychological experiences can potentially lead to dangerous behavior toward self or others especially when used by vulnerable individuals without proper preparation and supervision. In a review of LSD research conducted during the 1950s in thousands of research participants who were carefully screened and prepared for dosing sessions, the reported suicide attempt and completed suicide rates were very low at 1.2 and 0.4, respectively, per 1,000 patients.

In the modern era, over 2,000 doses of psilocybin (ranging from low-to-

high doses) have been administered safely in the United States at major academic medical centers (Johns Hopkins, NYU, UCLA, University of New Mexico, University of Arizona) with no reports of any medical or psychiatric serious adverse events attributed to psilocybin (including acute or prolonged psychosis or HPPD). In addition, approximately 200 doses of intravenous DMT were administered at the University of New Mexico to normal participants without any SAEs and LSD has now been administered to approximately 2 dozen research participants in Europe in the last several years (Switzerland, England) without any SAEs reported. The key commonality among all these studies is the careful attention to set, setting, dose, session preparation, and integration.

Contraindictions

Given the known link between SHs and their ability to initiate or exacerbate psychosis in patients with underlying psychotic spectrum illness, they are contraindicated in anyone with a significant history of psychosis whether it be from a primary psychotic spectrum illness (i.e., schizophrenia, schizoaffective disorder), affective psychotic illnesses (i.e., bipolar I disorder with psychotic features, major depression with psychotic features), severe personality disorders associated with micro or frank psychosis, patients with borderline to psychotic level ego function, severe anxiety disorders associated with psychotic phenomenon (OCD with psychotic features), or chronic psychosis due to drugs (i.e., alcohol-induced psychotic disorder, Korsakoff psychosis) or due to general medical conditions. Furthermore, they would be contraindicated in patients at high risk for psychosis (i.e., strong family history of psychosis), children and adolescents. Age limitations should exist (i.e., ê25 years old), given the potential risk for precipitation of psychosis (i.e., schizophrenia) in vulnerable individuals (even those without any family history). The SHs are also contraindicated in individuals who have chronic HPPD.

Case Examples

Because the process of treatment with classic hallucinogens is so different from other pharmacotherapies, it may be useful to provide descriptions of the treatment process in specific cases. Below two brief case reports from the authors' clinical trials are presented: one of a cancer patient struggling with depression and anxiety, and the other a patient treated for alcohol addiction. Details of these cases have been altered to obscure the identity of these individuals. The cases include elements of both psychedelic and psycholytic-assisted psychotherapies.

PSILOCYBIN-ASSISTED TREATMENT OF CANCER-RELATED PSYCHOLOGICAL AND EXISTENTIAL DISTRESS

E is a 22-year-old woman, a first year law student, with recent diagnosis of leukemia. She had

no prior medical or psychiatry history. She was treated successfully for her leukemia with chemotherapy and was told by her oncologist she had a very good prognosis and was likely cured of her cancer. For the first 6 months following diagnosis and treatment, she did not experience any adverse psychological effects of the cancer diagnosis. However, at the 6-month point of remission, E started to become frightened that the cancer could recur. Even though she understood the good prognosis, she experienced increasing anxiety about the cancer returning and what that would mean for her. These thoughts continued to get worse to the point where E started experiencing panic attack–like events related to an acute fear of death. She had always thought of death as a distant event, something that she would not have to contend with for decades. However, the cancer provoked a kind of crisis and she began to feel that there was now a short distance between herself and death. She began to experience a dysphoric and anxious mood accompanied by anhedonia, poor concentration, preoccupation with death, and a desire for a hastened death because she felt that the end was imminent. From a Catholic faith background, she became angry at God for allowing her to get cancer and started for the first time in her life to have doubts about the existence of God. She stopped attending church and felt she had lost access to the nurturing parts of her religion and spirituality. She told her oncologist about these symptoms, and her oncologist referred her to the NYU Psilocybin Cancer Project. E was a casual user of alcohol and had no prior use of other drugs including hallucinogens and marijuana. She was intrigued by the use of psilocybin to treat anxiety but admitted that she was skeptical that it would actually do anything to decrease her anxiety or fear of death related to her cancer diagnosis. She felt it was worth a try given her level of distress and because she trusted her oncologist's judgment.

E underwent her first dosing session and happened to be randomized to the group that received psilocybin (0.3 mg/kg) first. On the day of the session, she reported having some trouble sleeping the night before and being somewhat apprehensive about the dosing session. She wanted to make sure that she would return to normative reality when the session ended. Her treatment dyad team did some deep breathing with her before the session and reassured her of all the ways the team would address any difficult or anxious psychological experiences. E received her psilocybin capsule at 9 AM. The treatment team checked in every hour to assess E's mental state. For the first 3 hours, E reported nothing suggestive of a psychoactive experience (unusual for those that receive psilocybin whose effects usually are experienced in the first hour postdosing). She told the dyad team that she was sure she must have gotten the placebo. At approximately 12:30, E sat up and took off her eye shades. She reported that the music sounded "trippy." When the dyad team inquired more, she said that she felt anxious and wondered if she would feel normal again. After verbal reassurance, E lay back down and placed the eye shades on. At approximately 2 pm, she sat up and reported the following visions: she journeyed back to parts of her childhood and came upon multiple scenes of her and her family (two parents, and younger brother) joined together in laughter and love that made her feel a sense of unity and support; she reported a scene where she saw herself standing in front of a hospital and saw a cauldron of black, hot smoke circling inside of her body (which she interpreted as her cancer), followed by her boyfriend and family forming a loving circle around her which caused the black smoke inside of her to disappear outside of her body and into the sky (she interpreted this as a cathartic experience of the fear of cancer leaving her); she reported seeing her cancer-riddled body die in front of her eyes while the treatment providers and a transcendental entity together solved a complicated mathematical equation (she interpreted this as God and the treatment team working together to figure out the biological nature of her cancer-related anxiety). At the end of the experience, E declared that she felt "reborn" and freed from the anxiety and fear of death caused by her cancer diagnosis. Her scores on the main outcome measures of anxiety and depression (i.e., Hospital Anxiety and Depression Scale, Beck Depression) dropped dramatically from very high clinically significant values at baseline to almost zero, 7 hours postdosing with psilocybin. Her follow-up distress scores on all of these scales remained close to zero for the next 6 months until the final follow-up point. It is now 3.5 years after her treatment, and she continues to report no anxiety or distress associated with her cancer diagnosis. She is flourishing as a law student and reports a sense of calmness and psychological well-being that she continues to attribute to the psilocybin dosing experience. She has taken up a meditation practice and still can remember salient aspects of the experience that have stuck in her memory.

PSILOCYBIN-ASSISTED TREATMENT OF ALCOHOLISM

C is a 59-year-old divorced mother of two who had struggled with alcohol since age 15. Her drinking had led to problems including recurrent physical violence, multiple arrests, poor work history, and intermittent homelessness. She had suffered severe abuse in the context of relationships with partners who also drank, including being beaten unconscious and suffering from intracranial bleeding on at least one occasion. She had made several past attempts to stop drinking, with little success. When she volunteered for the psilocybin trial, she had been sober for 11 days, and had been drinking 7 out of the past 84 days, an average of 16.9 standard drinks per drinking day. During the preparatory phase of treatment in the study, she stated a goal of total abstinence, and rated the importance of abstinence as high and her readiness for abstinence as high, but her confidence in achieving it was low. She said that she wanted to understand why she drank, and hoped that this would help her stay sober. She listed God's will, forgiveness, humility (to be) loved, and self-control as her most important values, and saw clearly that her drinking was in conflict with these values.

During her first psilocybin session, she reported that she experienced powerful feelings of sorrow and remorse regarding the course of her life, and particularly concerning her perceived failures as a parent as a result of her drinking. This experience was quite painful, and she believed that she was sobbing uncontrollably during much of this time, although she was actually lying quietly on the couch at the time. After the session, she felt a sense of relief, and said that she had been able to let go of these feelings and experience a sense of forgiveness. She was hopeful that the experience would help her stay sober, and had no desire to drink after the session. C remained sober between the first and second psilocybin session. During the second session, she reported that she experienced a visual image of a small child lying "broken" on the floor. She realized that this child was her, and experienced herself as a 3-year-old child, devastated by abandonment by her father, an issue that she had not discussed in the preparatory sessions. After this, she began to perceive a white light, which she called "God's healing light," and felt a profound sense of love. She felt that she had been healed by this experience, and that she now felt "whole" and worthy of love. In discussing these experiences afterward, C said that she thought her drinking had been an attempt to escape the painful feelings of being unworthy of love, as well as the painful feelings of shame and loss related to her life as an alcoholic. She had avoided these feelings, believing that she would "fall apart" if she faced them. Following the sessions, she now felt that she was strong enough to face these feelings, and that she was a whole person, worthy of love. At her most recent follow-up, 5 months after the first psilocybin session, she remained abstinent and continued to feel that her life had been transformed, in spite of the unexpected death of a close family member during the interim.

Ethical Issues

The ethical concerns involved in the hallucinogen-assisted therapies are the same as those for other forms of psychotherapy and pharmacotherapy, but there are particular issues that require special attention due to the nature of the process and the possible effects. Patients must be informed of the risks and benefits of any therapy so they can make an informed decision about whether to proceed. Although the medical risks of hallucinogen administration are minor and easily described, the nature of the experience and the attendant psychological risks are much harder to describe, particularly if the patient has no prior experience with hallucinogens. It is important that the therapists describe the full range of possible experiences. This should be done in a way that prepares the patient as well as possible for both pleasant and challenging experiences, without minimizing possible difficult aspects or unnecessarily heightening anxiety about them. Undergoing any form of psychotherapy can result in changes

that are difficult to predict, and may not always be desired. These could include recognition of painful or traumatic experiences, relationship difficulties, or strong emotions that were unconscious or dormant. In hallucinogen-assisted therapy, mystical experiences can result in changes in beliefs about the nature of reality. All of these changes can have unpredictable consequences, for example, desire for changes in relationships, career, or other important life domains. None of this is unique to hallucinogen-assisted therapy, but such changes, if they occur, can happen very rapidly due to the nature of the process. Finally, as in all therapy relationships, there is a power differential, and patients are vulnerable to exploitation. In hallucinogen-assisted therapy, patients are often incapacitated during the drug administration sessions, and are in a state of heightened suggestibility during and possibly after the sessions. Therapists must resist any temptation to misuse power during the therapy, including being overly directive during the drug administration sessions.

RESEARCH AND EVALUATION

Use of Psychedelics in the Treatment of Addiction

Lysergic Acid Diethylamide. The use of LSD in the treatment of alcoholism was studied extensively in the 1950s through early 1970s. The earliest investigations in Saskatchewan, led by the pioneering psychedelic researcher Humphrey Osmond, were based on a model which held that the LSD experience mimicked the experience of delirium tremens, and that this negative experience of "hitting bottom" could induce abstinence in some cases. However, based on their experience and the recommendations of A. M. Hubbard, the treatment was modified to facilitate the positive experience of self-surrender, consistent with the psychedelic model. Treatment of alcoholism with LSD became an accepted clinical treatment in Saskatchewan and several thousand patients would end up being treated by Dr. Osmond and colleagues using this model. Uncontrolled trials with severe, chronic alcoholic patients using a single high-dose LSD session had variable but generally encouraging results.

Controlled trials of LSD for alcoholism were largely underpowered and had mixed results, leading reviewers to conclude that few conclusions could be drawn from these studies. However, a recent meta-analysis revealed consistent and clinically meaningful effects of LSD over control treatment in the six randomized trials of LSD for alcohol dependence that reported drinking outcomes. Across the 6 studies, 325 participants received active treatment with LSD, and 211 received control treatment. In all of the studies, LSD was administered in a single high-dose session, in doses ranging from about 210 to 800 mcg. At the first posttreatment follow-up, LSD-treated patients were more likely to show significant improvement in drinking outcomes (odds ratio = 1.96, 95 percent CI 1.36 to 2.84, p =

0.0003). Treatment effects remained significant at 6 months. The effect of LSD treatment was homogeneous across the six studies, in spite of great variability in the psychotherapeutic components of treatment and the control treatments employed. These promising findings strongly support renewed clinical investigation of LSD for the treatment of alcoholism.

Studies were also conducted using LSD as a component of treatment for opioid addiction. Seventy "postnarcotic drug addicts" at the US Public Health Service Hospital in Lexington, Kentucky received a single 2- to 3-hour therapeutic session in which they were randomly assigned to receive one of five treatments: (1) insight-oriented psychotherapy, (2) hypnotherapy (psychotherapy conducted under hypnosis), (3) LSD with no psychotherapeutic intervention, (4) LSD with psychotherapy, or (5) LSD with hypnotherapy. At 2-month follow-up, all groups showed significant improvement on a questionnaire designed to measure various dimensions of psychopathology, with greater improvement in the group that received LSD with hypnotherapy. Drug use behavior after discharge from the hospital was not investigated. The dose of LSD used in this study (0.2 mcg/kg, or 140 mcg for a 70-kg person) was lower than the doses used in the controlled alcohol trials summarized above. Savage and McCabe randomly assigned 78 incarcerated male heroin addicts to outpatient treatment as usual versus psychedelic therapy followed by treatment as usual. The psychedelic therapy included a single high-dose (300 to 500 mcg) LSD session in the context of 4 to 6 weeks of residential treatment that included extensive psychotherapy before and after the session. Participants who received psychedelic therapy had better outcomes during the 12-month follow-up period (25 percent vs. 5 percent continuous abstinence). The design of this study did not separate the effects of the LSD from other aspects of the residential treatment.

Psilocybin. The effects of psilocybin were described over 50 years ago and at least 2,000 individuals have received psilocybin in clinical and laboratory studies (since the early 1990s) using the *psychedelic* and *psycholytic* models of treatment. However, other than very brief reports of psilocybin used in combination with LSD the first trial of psilocybin used to treat alcoholism was completed very recently. In this proof-of-concept study, ten volunteers with DSM-IV alcohol dependence received orally administered psilocybin in one or two supervised sessions scheduled 4 weeks apart. Psilocybin was administered in the context of a 12-week manualized therapy program, in doses of 0.3 mg/kg and 0.4 mg/kg. Drinking decreased significantly following psilocybin administration, and gains remained significant during 36 weeks of follow-up. The intensity of self-reported effects during the first psilocybin session at week 4 strongly predicted improvement in drinking during weeks 5 to 8 (r = 0.76 to r = 0.89). A double-blind, multi-center, efficacy RCT using a similar model of

treatment is currently under way being conducted at the New York Langone Medical Center (NCT02061293) and the New Mexico School of Medicine. Although there were not published trials of classic hallucinogens administered in the treatment of nicotine addiction, a recent open-label pilot study, utilizing a model of high-dose psilocybin assisted CBT, has reported remarkably positive outcomes using psilocybin in the treatment of this addiction. Fifteen nicotine-dependent smokers received psilocybin (20 to 30 mg/70 kg in 2 to 3 sessions) during a 15-week course of manualized therapy. At 6-month follow-up, 12/15 (80 percent) were abstinent based on self-report and verified by biological measures (urinary cotinine and breath carbon monoxide). This success rate far exceeds those seen in clinical trials of any currently available pharmacotherapies for tobacco addiction. Measures of mystical experience during psilocybin sessions and of spiritual significance and personal meaning attributed to the sessions were significantly correlated with smoking outcomes. Based on these very promising results, a comparative efficacy trial (psilocybin vs. nicotine replacement) is now being conducted at the Johns Hopkins School of Medicine (NCT01943994). In addition, a pilot RCT is underway investigating the effects of psilocybin-assisted psychotherapy in the treatment of cocaine addiction (NCT02037126) at the University of Alabama School of Medicine. Given the persistent lack of effective medications to treat cocaine addiction, this study will be the first to use a classic hallucinogen in the treatment of cocaine use disorder.

Use of Psychedelics to Ameliorate Cancer-Related Psychological and Existential Distress

Psychological and Existential Distress in Patients with Cancer. With limited evidence from randomized controlled trials (RCTs) in cancer populations, there are no well-established evidence-based treatment algorithms to guide the optimal pharmacological or psychosocial treatment of cancer patients with depressive and anxiety spectrum disorders; rather, treatment guidelines have had to be derived from the available research conducted in cancer populations as well as from the more extensive research in psychiatric and other medical illness populations. Also, given the relationship between spiritual well-being and improved psychiatric outcomes in patients with advanced cancer (most importantly decreased depression, decreased hopelessness, decreased desire for hastened death, and possibly decreased suicide), it would make sense to develop treatment (psychosocial, pharmacological, or combined pharmacological–psychosocial) paradigms to specifically target such spiritual/existential distress when it manifests. Although a handful of manualized existentially oriented psychotherapies have been developed to address the existential/spiritual issues faced by patients with advanced/terminal cancer, with some empirical support from clinical trials, there are no

current pharmacologic-psychosocial interventions to treat this typology of distress in cancer patients.

History of Psychedelic Therapy with Terminally Ill Patients. The first scientific exploration of psychedelics as stand-alone pharmacological interventions to help the dying in a medical setting occurred in the early 1960s with Eric Kast, M.D., an internist and psychiatrist at the University of Chicago Medical School. Kast was a specialist in pain medicine and became interested in studying LSD as a novel analgesic agent in patients with terminal cancer and pain syndromes by exploring LSDs ability to alter pain attention and perception. In his first paper published in 1964 on the topic, Kast conducted a blinded comparative efficacy trial of LSD (100 mcg orally) compared to Demerol 100 mg and dilaudid 2 mg in a sample of 50 gravely ill patients, mostly with terminal cancer but also included those with severe burns and infectious illnesses. Kast reported that the LSD group had statistically significant reductions in pain compared to the two opioid groups, from 3 hours postdosing to up at least 19 hours postdosing. In addition, he noted that the patients in the LSD group appeared to display a type of detachment from the fear of dying that he thought was useful given their grave medical conditions. Based on this observation, he extended his LSD research by administering LSD 100 mcg to over 200 patients with terminal cancer and pain syndromes in an open-label design and paid increasing attention to psychological phenomenon (in addition to pain perception) such as sleep, affective changes, and attitudes toward death and dying. In further published research, Kast confirmed his earlier findings by observing: decreased pain perception acutely and lasting up to 2 weeks postdosing, improved sleep and mood, improved communication between treatment provider and patients, enhanced morale and outlook on life, reports of mystical-type experiences ("happy, oceanic feelings"), enhanced philosophical and spiritual states, and decreased fear of cancer diagnoses and death. It is important to note that Dr. Kast viewed LSD treatment in his patients as a type of pure pharmacological intervention and did not account for or introduce the well-known components of set, setting, dose titration, and psychotherapeutic preparation and integration relative to the dosing sessions. The other significant historical research utilizing psychedelics to treat psychological distress associated with advanced or terminal cancer occurred from the early 1960s to the mid-1970s at the Spring Grove State Hospital in Maryland, a research affiliate of the Johns Hopkins School of Medicine and the University of Maryland School of Medicine at the time. Starting in 1963, a group of psychiatrists, psychologists, nurses, and social workers began examining LSD-assisted psychotherapy to alcoholics. In 1965, when one of the nurses on the research team became ill with metastatic breast cancer, one of the research psychologists (Sidney Wolf) suggested that a course of psychedelic therapy

might help alleviate her anxiety associated with cancer. After she underwent LSD-assisted treatment and reported relief, the researchers at Spring Grove decided to embark on research utilizing LSD-assisted psychotherapy (a pharmacological–psychosocial paradigm) to help patients with terminal cancer and psychological distress. This research project began in 1967 and was headed by the psychiatrists Stanislav Grof and Walter Pahnke. The treatment model utilized was significantly different from the pharmacological only model developed by Dr. Kast. It was based on Dr. Grof's LSD research in administering moderate-to-high doses of LSD to normal volunteers (developed while doing research at the Psychiatric Research Institute in Prague, Czechoslovakia), paying careful attention to set, setting, as well as session preparatory psychotherapy and postsession integrative psychotherapy. The treatment model drew from psychoanalytic theory as well as transpersonal psychology, and Grof commented that "many individuals who had the experience of death and rebirth sometimes accompanied by feelings of cosmic unity independently reported that their attitudes towards dying and their concepts of death underwent dramatic changes." Fear of their own physiological demise diminished, they became open to the possibility of consciousness existing after clinical death, and tended to view the process of dying as an adventure in consciousness rather than the ultimate biological disaster. A total of 60 patients participated in the open-label experimental trial with 44 of the patients receiving LSD (200 to 500 mcg orally) and 19 patients receiving dipropyltryptamine (DPT) (60 to 105 mg IM). Systematic, longitudinal analyses performed on a subsample of 31 participants found statistically significant prepost reductions in the following domains: depression, anxiety, pain, isolation, and fear of death; in addition, a global index of improvement broke down as follows (29 percent dramatically improved, 42 percent moderately improved, 23 percent unimproved, 6 percent worse).

Phase II LSD-Assisted Psychotherapy for Anxiety Associated with Life-Threatening Disease. The reemergence of LSD-assisted psychotherapy clinical trials to treat psychosocial distress associated with life-threatening illnesses has resumed with a recently completed trial in Switzerland. This double-blind, randomized, placebo-controlled phase II trial with a crossover design (2 months) included a sample of 12 participants with life-threatening medical disorders (including cancer and other medical conditions) who received either the experimental condition (LSD 200 mcg orally) or the active control (LSD 20 mcg orally) in conjunction with psychotherapy. Safe administration of LSD was established in this small cohort with no reported serious adverse events. Compared to the active control, the experimental group had significant short-term (2-month follow-up) reductions in anxiety as measured by the State-Trait Anxiety Inventory (STAI). A recent 12-month follow-up study of participants from

the above trial reported sustained reductions in anxiety (as measured by the STAI), increases in quality of life, and no reports of any adverse psychological or medical sequelae.

PHASE II AND PHASE III PSILOCYBIN-ASSISTED PSYCHOTHERAPY FOR CANCER-RELATED PSYCHOLOGICAL DISTRESS RANDOMIZED CONTROLLED TRIALS. RCTs utilizing psilocybin-assisted psychotherapy to treat psycho-social-spiritual distress (depression, anxiety, existential suffering) associated with advanced or terminal cancer have resumed in the United States within the last two decades as part of a research collaboration between UCLA, NYU, and Johns Hopkins. At all three sites, the treatment model was similar and was based on the Spring Grove psychedelic-assisted psychotherapy model, developed by Dr. Grof and colleagues. Important similarities among the three sites were as follows: (1) Double-blind design methodology; (2) Randomization among groups; (3) Use of validated outcome measures for cancer-related psychological and existential distress; (4) The use of exclusion criteria such as major unstable medical illnesses (i.e., cardiac/renal/hepatic failure) and major mental illness (i.e., schizophrenia, bipolar spectrum disorder, or a family history of these disorders); (5) The participants were carefully prepared for the experimental sessions by trained monitors after a thorough life review and review of their cancer diagnosis narrative with an emphasis on spiritual/existential themes of distress; (6) Participants underwent the dosing sessions in a comfortable living room–like setting designed for maximal comfort and safety; (7) To increase the likelihood of the induction of mystical states of consciousness, participants were instructed to lie down on a couch with eyeshades to reduce external visual distractions with a preselected music program played and with instructions to focus on their inner experiences during the session; (8) Integration of the experience during the dosing sessions as part of postintegrative psychotherapy. The three studies differed by: (1) Dose of psilocybin—UCLA (0.2 mg/kg); NYU (0.3 mg/kg)/JHU (0.43 mg/kg); (2) the active control: niacin (UCLA, NYU), low-dose psilocybin (JHU); (3) Inclusion of nonterminally ill cancer patients (NYU, JHU).

The first double-blind placebo-controlled phase II trial of single low-dose (0.2 mg/kg) psilocybin-assisted psychotherapy for advanced-stage cancer was conducted at Harbor-UCLA (N = 12) and suggested an acute and short-term sustained antidepressant and anxiolytic effect associated with psilocybin versus placebo (Grob, 2011). Two other RCTs of single-dose psilocybin-assisted psychotherapy for patients with cancer related psychosocial and existential distress (NYU, N = 29; Johns Hopkins, N = 51) have recently been published. The findings are strikingly similar in a number of ways in terms of the efficacy of psilocybin: (1) Rapid/acute acting anti-depressant and anxiolytic responses with substantial effect sizes and clinically meaningful results (i.e., approximately 80 percent with

clinically significant anti-depressant or anxiolytic responses); (2) Enduring clinically significant anti-depressant and anxiolytic effects for as long as 5–7-weeks, but possibly up to 6–8 months with 60–80 percent meeting criteria for clinically meaningful anti-depressant or anxiolytic responses at 6–6.5 month final follow-up; (3) Decreases in existential distress (i.e., cancer-related demoralization, hopelessness, meaninglessness of life); (4) Improved anxiety or attitudes towards death; (5) Improved quality of life; (6) Mystical experiences induced by psilocybin; (7) Psilocybin-induced mystical experience partially mediated the therapeutic effect of psilocybin on anxiety and depression; (8) Substantial personal meaningfulness of the experiences; (9) Improved spiritual well-being. Overall, the systematic replication of the main outcomes across two sites contributes to the confidence of the robustness of the finding that a single dose of psilocybin has rapid, substantial, and enduring anti-depressant and anxioloytic benefits in patients with life-threatening cancer diagnoses.

Phase III Trial. The Heffter Research Institute (the sponsor of the above-mentioned phase II RCTs) and the Usona Research Institute are currently in discussions with FDA regarding the optimal design of a potential phase III RCT of psilocybin-assisted psychotherapy for psychological distress associated with a cancer diagnosis. If such a trial would demonstrate a statistically and clinically meaningful therapeutic effect of psilocybin-assisted treatment (vs. placebo) on psychological/existential distress in cancer, it would potentially lead to the historic rescheduling of psilocybin from schedule I to another schedule (likely II or III) to be made available as a prescription medication to be used (likely only to be dispensed and administered in specialized designated and regulated psychedelic treatment clinics) as an adjunct to psychotherapy to treat psychological and existential/spiritual distress associated with cancer, whether it occurs early in the illness or as part of the death and dying process. Training of therapists and fidelity to treatment models would have to be considered in and it would be important to establish specific psychedelic therapy training programs. Oversight, quality control, and strict measures to reduce adverse psychological events would have to be key components of maintaining a psychedelic treatment clinic.

Treatment Resistant Depression (TRD). The acute and sustained anti-depressant effects of psilocybin in the above 2 psilocybin cancer trials are consistent with a recently published open-label study (N = 12) of oral psilocybin treatment in patients with treatment-resistant depression (TRD), where psilocybin (25 mg) was associated with 1-week and 3-months post-psilocybin anti-depressant effects (Carhart-Harris et al., 2016). As a follow-up to this open-label trial, several academic medical centers (NYU,

Hopkins, UCSF, Imperial College, U Zurich) are planning RCTs using oral psilocybin treatment for TRD.

▲ 33.18 Mentalization-Based Treatment

ANTHONY W. BATEMAN, F.R.C.PSYCH., AND PETER FONAGY, PH.D.

INTRODUCTION AND DEFINITION

Mentalization-based treatment (MBT) is an evidence-based treatment for BPD. Randomized controlled trials (RCTs) have demonstrated its effectiveness in reducing the core symptoms of BPD and it is currently being studied for other conditions, including antisocial personality disorder (ASPD) and avoidant personality disorder, substance abuse, depression, and eating disorders.

This chapter will outline the theoretical basis of MBT and the core treatment model in relation to BPD.

What Is Mentalizing?

Mentalizing is the social cognitive ability to understand actions by other people and oneself in terms of mental states, including thoughts, feelings, wishes, and desires; it is a very human capability that underpins everyday interactions. In nontechnical language, it is attentiveness to thinking and feeling in oneself and others. It is beyond question that mental states influence behavior. Beliefs, wishes, feelings, and thoughts, whether within or outside people's awareness, always influence what people do. Mentalizing involves a whole spectrum of capacities: critically, this includes the ability to experience one's *own* behavior as coherently organized by mental states, and to differentiate oneself psychologically from others. These capacities are reduced in individuals with a personality disorder, who lose cognitive and emotional coherence, particularly at moments of interpersonal (relational) stress, which challenge one's mentalizing capacities. In the authors' view, many symptoms characteristic of BPD emerge in association with a distortion or reduction in mentalizing. Based on this understanding of BPD, MBT is a psychotherapy that focuses specifically on the mentalizing vulnerabilities of the patient in the context of an understanding of attachment process, which is the developmental context in which mentalizing is originally acquired.

HISTORY

The word "mentalizing" has been in existence for two centuries and in the *Oxford English Dictionary* for the past century. French psychoanalysts introduced the concept into the professional psychotherapy literature in the second half of the 20th century, and mentalizing came into the English professional literature on the cusp of the final decade, conceived of initially as a deficit in autism and as a transiently impaired process associated with profound insecurity in attachment relationships in the developmental psychopathology of BPD. This proposal was the origin for the development of MBT. The approach is rooted in attachment theory and psychoanalytic ideas, but in the interest of parsimony sheds many of the core assumptions of both theoretical approaches while negating neither body of work. Its

historical origin is born from the authors' wish to extend what they saw as the clear benefits of using a psychotherapeutic approach to professionals (nurses, rehabilitation or addiction counsellors, activity therapists) who normally did not have opportunities to undertake extensive training in particular psychotherapeutic modalities. The authors wished to extract core elements of a therapeutic approach that could be linked to experimentally observed distortions of mental function in personality disorders.

THEORETICAL ISSUES

The Role of Mentalizing in Therapy

MBT is based on the assumption that failure of mentalizing, while common to everyone, becomes a dominant feature in individuals with personality disorders, leading to both serious interpersonal problems and profound psychological distress. A number of therapies that have been shown to be successful in addressing the difficulties experienced by individuals with BPD appear to strengthen the patient's capacity to mentalize; for example, conversational therapy, cognitive analytic therapy, and certain aspects of dialectical behavior therapy. MBT is unique in attempting to understand the problematic and distressing aspects of severe personality disorder in terms of a failure of mentalizing (see later) and to focus a structured therapeutic approach on addressing problems of mentalizing as they occur in a therapy session. The overarching principle of MBT is to enhance mentalizing in the context of the therapeutic relationship (in both individual and group sessions) by systematically addressing instances of nonmentalizing and using these moments of discourse as opportunities to work with the patient to achieve a fuller psychological understanding of behavior. The significance of this process rests in the hope of generalization from the therapeutic situation to the wider social context. It is in this wider context that, from the perspective of the MBT clinician, the key difficulties blocking the possibility of change lie for the patient with BPD.

The Multidimensional Nature of Mentalizing

Mentalizing is not an entirely stable, consistent, or unidimensional capacity. Neuroscience has identified four distinct components to mentalizing, which the authors have organized into dimensions that they see as helpful for therapists to identify in the clinical practice of MBT:

1. Automatic versus controlled mentalizing
2. Mentalizing the self versus others
3. Mentalizing with regard to internal versus external features
4. Cognitive versus affective mentalizing.

To mentalize effectively requires the individual not only to be able to maintain a balance across these dimensions of social cognition but also to

apply them appropriately according to context. Consistent favoring of one or other side (or *pole*) of these dimensions leads to distorted understanding of mental states, associated with profound social and emotional difficulties.

In an adult with personality disorder, consistent distortions of social cognition consequent on imbalanced mentalizing on at least one of these four dimensions would be evident. Commonly, one or more of the dimensions underperforms at one end, and consequently the opposite pole comes to dominate social cognition. For example, excessively emotional thinking emerges in the absence of cognitive mentalizing, or the influence of others dominates if subjective experience of self-states is reduced. From this perspective, different types of psychopathology can be distinguished on the basis of different combinations of impairments along the four dimensions. In other words, personality disorders (and, to some extent, other psychiatric disorders) can be understood according to different characteristic *mentalizing profiles*.

Automatic versus Controlled Mentalizing. The most fundamental dimension to mentalizing is the spectrum between *automatic* (or *implicit*) and *controlled* (or *explicit*) mentalizing.

Controlled mentalizing reflects a serial and relatively slow process, which is typically verbal and demands reflection, attention, awareness, intention, and effort. For example, a person might misunderstand someone, so they stop them and ask them to explain more clearly what is underlying their statements, or they focus their own mind to work out what their opinion may be. People tell stories to others about their mental states; they think back into their past and report how they felt long ago; they enjoy autobiographical coherence in their personal lives and tell others about it.

The opposite pole of this dimension, *automatic mentalizing,* involves much faster processing, tends to be reflexive, and requires little or no attention, awareness, intention, or effort. In day-to-day life and ordinary social interaction, most mentalizing tends to be automatic because most straightforward exchanges do not require more attention. People in conversation naturally take turns, adapt their tone and posture to others' emotional states, and reflexively take into account their knowledge.

Self versus Others. This mentalizing dimension involves the capacity to mentalize one's own state—the *self* (including one's own physical experiences)—or the state of *others*. The two are closely connected, and an imbalance signals vulnerability in mentalizing of both others and/or the self. Individuals with mentalizing difficulties are likely to preferentially focus on one end of the spectrum, although they may be impaired at both. Awareness of the mental states of others is in part mediated by neural structures that organize one's own actions (the *mirror neuron system*), moderated by explicit reflective processes that reinforce the self–other

distinction. If explicit mentalizing is weakened, the influence of the current mental state of the other will increase.

Internal versus External Mentalizing. Mentalizing can involve making inferences on the basis of the *external* indicators of a person's mental states (e.g., facial expressions, tone of voice, body posture) or figuring out someone's *internal* experience from what one knows about them and the situation they are in. This dimension does not simply refer to a process of focusing on the externally visible manifestations versus the internal mental state of others, it also applies to the self—it includes thinking about oneself and one's own mind state versus considering one's current (external) situation and physical (interoceptive) state. Someone who has poor access to and great uncertainty about their subjective experience, for example, as is often seen in individuals with BPD, may come to a conclusion about what they are feeling from the reactions of others as well as from observing their own behavior: for example, their legs are restless, therefore they must be feeling anxious.

Cognitive versus Affective Mentalizing. *Cognitive* mentalizing involves the ability to name, recognize, and reason about mental states (in both oneself and others), whereas *affective* mentalizing involves the ability to experience and understand associated *feelings* (again, in both oneself and others). Both are required for any genuine experience of empathy or true sense of self-coherence. Some individuals give undue weight to either cognitive or affective mentalizing. People with obsessional characteristics may be masters at explicating in detail the internal states of themselves and others, but this may be devoid of emotional content and meaning. Conversely, people with BPD are flooded with emotion and so prone to automatic process, reactivity, emotional contagion, and poor self–other differentiation. Intense emotion can disrupt the process of cognitive appraisal that normally helps to regulate it.

Dimensional Mentalizing Profile and BPD

Particularly when arousal increases, as is typical in the context of intense attachment relationships, individuals with BPD easily find themselves switching to automatic mentalizing. Stress and arousal, especially in an attachment context, bring automatic mentalizing to the fore and disengage the neural systems that are associated with controlled mentalizing. Under these conditions, interactions become nonquestioning precisely when they need to be more controlled and contextualized. Thinking becomes impulsive: the individual makes quick assumptions about others' thoughts and feelings, which are not reflected upon or tested. Logic is intuitive, unreasoned, and nonverbal; it is marked by an unwarranted certainty, which betrays its unreflective origin. As a consequence, patients show

severe impairments in interpersonal and intimate relationships; for example, they may be overly distrustful (paranoid) or, indeed, overly trustful (naive).

Patients with BPD may show excessive concern about their own internal state, that is, they *hypermentalize* in relation to the self. At the same time, these views of the self develop without reference to social reality, namely an awareness of how others perceive one. Failure to balance self-perception with sincere curiosity about how one is perceived by others can lead to exaggerations of the self-image, in both positive and negative directions. A balanced, adaptive form of self-mentalizing conditioned by the social context is lost.

Patients with BPD pay more attention to external indicators of mental states, and their initial ideas arising from automatic mentalizing are left unchecked by controlled/reflective mentalizing. For example, if the clinician frowns, perhaps pensively, the patient may interpret this as looking angry or disgusted with them; seeing the clinician look at the clock during a session can stimulate an internal state of overwhelming unease and an experience that the clinician wants to be rid of them when, in reality, the internal state of the clinician is concern about the time left to work on the issue being discussed. A focus on external features, in the absence of reflective mentalizing, makes an individual highly vulnerable in social contexts, as it generates interpersonal hypersensitivity.

Modes of Nonmentalizing: Psychic Equivalence

Clinical appearance	Certainty/suspension of doubt Absolute Reality is defined by self-experience Finality—"It just is" Internal is seen as equivalent to external
Clinician's experience	Puzzled Wish to refute Statement appears logical but obviously overgeneralized Not sure what to say Angry or fed up and hopeless
Intervention	Empathic validation with subjective experience Curious—"How did you reach that conclusion?" Presentation of clinician's puzzlement (marked) Linked topic (diversion) to trigger mentalizing then return to psychic equivalent area
Iatrogenic	Argue with patient Excessive focus on content Cognitive challenge

The Reemergence of Nonmentalizing Modes and BPD

While the dimensions of mentalizing can reflect anomalies in terms of

mechanisms, that is not what the clinician sees. What the patient and the mentalizing clinician experience is a product of a malfunctioning mentalizing system, driven by imbalances in the dimensions of mentalizing. The outcomes of these malfunctions can be grouped into three typical modes of subjectivity for the purpose of illuminating clinical experience. The modes are termed *psychic equivalence mode, teleological mode,* and *pretend mode*. These modes are summarized in Tables 33.18–1 through 33.18–3, which also outline MBT interventions to address each nonmentalizing mode.

The nonmentalizing modes are important for the clinician to recognize and understand, as they tend to emerge in the consulting room and reflect core aspects of the patient's experience. It is important to address them because they cause considerable interpersonal difficulties and result in destructive behaviors.

Table 33.18–2.
Modes of Nonmentalizing: Pretend Mode

Clinical appearance	Inconsequential talk/groundless inferences about mental states Lack of affect. Absence of pleasure Circularity without conclusion—"spinning in sand" (hypermentalizing) No change Dissociation—self-harm to avoid meaninglessness Body and mind decoupled
Clinician's experience	Boredom Detachment Patient agrees with clinician's concepts and ideas Identification with clinician's model Feels progress is made in therapy
Intervention	Probe extent Counterintuitive Challenge
Iatrogenic	Nonrecognition Joining in with acceptance as real Insight-orientated/skill acquisition intervention

Table 33.18–3.
Modes of Nonmentalizing: Teleological Mode

Clinical appearance	Expectation of things being "done" Outcomes in physical world determine understanding of inner state—"I took an overdose; I must have been suicidal" Motives of others are based on what actually happens Only actions can change mental process "What you do and not what you say"
Clinician's experience	Uncertainty and anxiety Wish to do something—medication review, letter, telephone call, extend session
Intervention	Empathic validation of need Do (or do not do) according to exploration of need

	Affect focus of dilemma of doing
Iatrogenic	Excessive "doing"
	"Prove" clinician cares in the belief it will induce positive change
	Elasticity (extending what clinician does, e.g., providing extra sessions, only to rebound with extra constraints) rather than flexibility

Psychic Equivalence Mode. In the *psychic equivalence mode*, thoughts and feelings become "too real" to a point where it is extremely difficult for the patient to entertain possible alternative perspectives. When mentalizing gives way to psychic equivalence, what is thought is experienced as being real and true, leading to what clinicians describe as "concreteness of thought" in their patients. Patients with BPD who are in this mode describe an overriding sense of certainty about their beliefs, for example, "the therapist does not like me" or "I am a wicked person." Such a state of mind can be extremely frightening, adding a powerful sense of drama and risk to life experiences. The sometimes extreme reactions of patients are justified by the seriousness and realness with which they can experience their own and others' thoughts and feelings. The vividness and bizarreness of subjective experience can appear as quasipsychotic symptoms and are also manifested in the physically compelling memories associated with trauma. More important to appreciate is that negative affect in this mode will be overwhelming and cause very deep distress to the sufferer. Psychic equivalence permits no alternative perspectives to be taken. The patient can feel locked into an extraordinarily profound sense of pain without the slightest possibility that matters could be any different from how they currently are. This state of hopelessness makes suicidality comprehensible.

Teleological Mode. In the *teleological mode,* states of mind are recognized and believed only if their outcomes are physically observable. Hence, the individual can recognize the existence and potential importance of states of mind, but this recognition is limited to very concrete situations. For example, affection is perceived to be true only if it is accompanied by physical contact such as a touch or caress. The teleological mode shows itself in patients who are imbalanced toward the external pole of the internal–external mentalizing dimension—they are heavily biased toward understanding how people (and they themselves) behave and what their intentions may be in terms of what they physically do. Impulsivity involves function in teleological mode and a heavy emphasis on the automatic pole of the automatic–controlled dimension. There is insufficient reflection concerning the impact of one's actions on others, or on oneself. In teleological mode, the individual cannot accept anything other than a physical action as a true expression of the other person's intentions. Friends of a patient might constantly assure the patient of their love and support, and yet none of that feels real: it does not address the "hole" that the patient falls into at certain, especially lonely, times when they feel

terrible emptiness. Feeling that interpersonal affection can only be real if it is accompanied by physical behavior explains some risky sexual behavior, but also the need to create physical distractions that help with the feeling that all verbal expressions of interpersonal affection are without real meaning (see case example, later). The teleological mode makes the need for action and generation of "real" change overwhelming. The so-called "manipulativeness" of patients with personality disorder is little more than the experience of a pressing need to feel genuine reactions from others in terms of actions rather than words.

Pretend Mode. In the *pretend mode,* thoughts and feelings become severed from reality. Taken to an extreme, this may lead to feelings of derealization and dissociation. Patients in pretend mode can discuss experiences without contextualizing these in any kind of physical or material reality, as if they were creating a pretend world. The patient may *hypermentalize* or *pseudomentalize,* a state in which they may say much about states of mind but with little true meaning or connection to reality. Attempting psychotherapy with patients who are in this mode can lead to lengthy but inconsequential discussions of internal experience that have no link to genuine experience and will achieve no change. The limited capacity to experience a sense of an internal world gives rise to a deep and extremely distressing sense of emptiness. Dramatic action—for example, sometimes violent action against the self—may be experienced as the best way of addressing such feelings.

In summary, imbalances within the dimensions of mentalizing predictably generate the nonmentalizing modes. Psychic equivalence is inevitable if emotion (affect) dominates cognition. Teleological mode follows from an exclusive focus on external features to the neglect of the internal. Pretend mode thinking and hypermentalizing are unavoidable if reflective, explicit, controlled mentalizing is not well established.

Attachment

It is a central tenet of the mentalization-based approach that a sense of self and the capacity to mentalize both develop in the context of attachment relationships. The child observes, mirrors, and then internalizes their attachment figures' ability to represent and reflect mental states. So the reflections need to be *contingent*—that is, related to the child's internal experience—accurate, and *marked*—that is, indicating, for example, using "motherese" (a special tone of voice), that what is being expressed is a representation of the mind of the child and not that of the caregiver. Hence, the self and others—and the capacity to reflect on the self and others—are inevitably closely intertwined. Disorders that are characterized by severe impairments in feelings of self-identity, a central tenet of the pathology of BPD—, are also characterized by severe deficits in the ability to reflect

about others' mental states. However, this should not be taken to mean that an individual whose capacity to mentalize themselves is impaired will always show similar impairments in their ability to mentalize others. For example, individuals with ASPD can often be surprisingly skilled in "reading the mind" of others, but typically lack any real understanding of their own inner world.

In BPD there is commonly a history of early (in particular emotional) neglect, and a disrupted early social environment in general, and this may contribute to undermining the ability of some individuals to develop full mentalizing capacities. Subsequent adversity or trauma may further disrupt mentalizing, in part as an adaptive maneuver on the part of the individual to limit exposure to a brutalizing psychosocial environment, and in part because the high level of arousal generated by attachment hyperactivation and disorganized attachment strategies serve to disrupt less well-practiced and less robustly established higher cognitive capacities. In addition, genetic influences may be expressed through the mediation of mentalizing.

In sum, the mentalizing model is not strictly an etiological model, although it clearly prioritizes a social psychiatry perspective; it points to a final common developmental pathway that a range of biological, family, and broader social contextual influences may take to generate the range of difficulties that are normally considered under the term "personality disorder."

TECHNIQUES

MBT is a group and individual treatment. It is anticipated that, at times, the patient will experience strong affect while focusing on identified problems in treatment sessions and their mentalizing will be limited or failing, and/or the patient's understanding of the way mental states link to behavior is inadequate.

The clinician addresses this by a structured process (the sessional intervention trajectory) of:

1. Empathy and validation about problem areas
2. Clarification, exploration, and, where necessary, challenge
3. Following a structured process to gently expand mentalizing and encourage the patient to identify the mental states previously outside their awareness.

The process is primarily in the here and now of the session but increasingly, as the patient's mentalizing improves, it comes to concern core attachment relationships, including how these are activated with the clinician and key figures in the patient's life and how they influence mentalizing itself. Gradually, improvements in mentalizing serve to enable the patient to address their distorted representations of personal and social relationships.

Therapeutic Alliance and Engagement in the Model

The assessment and introductory process in MBT facilitates the alliance between patient and clinician (see Table 33.18–4) and introduces the patient to the treatment frame. An MBT-Introductory group of 10 to 12 sessions assists in the development of the formulation and facilitates the alliance. This psychoeducational intervention covers all areas of mentalizing, attachment processes, personality disorder, emotion management, and treatment itself. This preparatory work aims to ensure patients know what they are facing in trying to address their problems and are fully aware of the method and focus of treatment.

Alliance Building in MBT

Agreement of short-term and long-term goals

MBT is collaborative. Nothing can occur without joint discussion, taking into account the mental experiences and ideas of both patient and clinician. The process of mentalizing requires an authentic desire to understand the mental processes of oneself and others. This applies as much to the clinician as to the patient. So the MBT clinician focuses on the patient's mind and attempts to understand their experience. Similarly, the patient is asked to aim to do the same in relation to the clinician—for example, the patient's perspective "Why does my clinician want me to focus on this at the moment?" may be paired with the clinician's, "Why does my patient *not* want to focus on this at the moment?" The therapeutic process has to become a shared endeavor aimed at extending the influence of explicit, reflective, cognitive, internally focused mentalizing. Initial goals, on the road to improved mentalizing, are jointly developed and focused on. The goals cannot solely be those of the patient, although the patient's aims take priority unless they are antithetical to the whole process of treatment. The sharing of responsibility for the therapeutic process is at the core of the effectiveness of the treatment approach in the pursuit of improved mental state understanding.

Assessment involves delineation of the patient's mentalizing vulnerabilities and mentalizing profile, identification of nonmentalizing cycles (see case example, later) and a shared formulation, which includes specific detail of attachment patterns and areas of vulnerability to emotional dysregulation. This has to be understood by the patient and is for both patient and clinician. The formulation identifies common relational fears, for example, abandonment, which stimulate the patient's

attachment system and result in the use of maladaptive attachment strategies in interpersonal interactions. In brief, the pattern of the patient's relationships informs an understanding of the relationship in treatment, and the relationship in treatment is used to reappraise the relationships in life outside treatment. Finally, it is important that the patient and clinician consider establishing a goal of improving social function. This will include work, social activity, voluntary work, education and other constructive life-affirming activity.

Clinical Principles in MBT

Clinicians follow a number of principles when treating patients with MBT (see Table 33.18–5). MBT recommends an authentic "not-knowing" stance that forms the bedrock for exploration of the patient's perspective. The not-knowing stance refers to respecting the opacity of mental states. Minds can never be "known" and it is important that the clinician recognizes that mental processes generate experiences imbued with uncertainty. The clinician's task is to take an inquisitive stance—a wish to inquire and a willingness to be surprised by the patient's response—with the aim of facilitating the patient's increased awareness of their internal states through a social process. This may be particularly important around the point at which experiences of ideas and feelings begin to collapse into nonmentalizing modes, leading to destructive behaviors or intolerable feeling states. It is not for the clinician to compensate for the patient's mentalizing failure with their own high-level mentalizing, "explaining" to the patient what they may have experienced. Nonmentalizing in the patient cannot be met by mentalizing in the clinician; it can be met only by "switching on" mentalizing in the patient via the range of techniques that MBT uses in the clinical situation.

Table 33.18–5.
Clinical Principles in MBT

The clinician must:

- ► Remain alert to imbalances of the mentalizing dimensions and emergence of nonmentalizing modes
- ► Monitor the patient's arousal levels to maintain optimal mentalizing
- ► Seek moments of mentalizing vulnerability related to events in the patient's life or in the session itself
- ► Maintain their own mentalizing
- ► *Not* meet nonmentalizing in the patient with high-level mentalizing
- ► Match interventions to the patient's mentalizing capacity

Primarily, the clinician is alert to nonmentalizing in terms of the different manifest modes of nonmentalizing, but also in terms of the indications that the patient's functioning is fixed at one pole of any of the dimensions of mentalizing. In general, as described earlier, mentalizing is

optimal when the dimensions—for example, emotion and cognition, or representation of self and other—are in balance and nonmentalizing modes are inactive. The key for the clinician is to be constantly aware of imbalance and lack of flexibility in terms of the dimensions and if any dimension is operating in a nonmentalizing mode. Nonmentalizing in a dimension or mode is an indication that intervention is necessary. An exclusive focus on feelings and ideas in relation to the self should suggest to the clinician that exploring the mental states of the other is called for. Similarly, exclusive concern with emotions suggests the need to bring cognitions into the foreground through judicious inquiry.

Second, the clinician monitors arousal levels carefully, ensuring that anxiety is neither too low nor too high, as both interfere with mentalizing. Similarly, if attachment feelings (e.g., in relation to the therapist) become too strong, a shift to less charged relationships may help restore mentalizing.

Third, the focus of a session is maintained through the clinician always seeking moments of mentalizing vulnerability either in relation to events in the patient's life or in the session itself. Mentalizing failure is best indicated by the clinician's experience of being challenged to understand the patient and consequently feeling a degree of confusion about how to respond. At these times, rewinding to moments when shared understanding characterized the discourse is the best solution.

Fourth, the clinician makes sure that their own mentalizing is maintained. It is not possible to deliver effective treatment if the clinician's mentalizing is compromised. So the MBT clinician always monitors their own capacities and may even have to explicitly own this experience, for example, by saying that their mind has become muddled and they cannot think. This type of self-disclosure of the mind state of the clinician should not be confused with sharing personal information. Sharing the effect that a patient's actions and state of mind is having on the clinician acts in the service of asking the patient to consider another mind as well as their own and has the implicit aim of enhancing mentalizing.

Sessions are focused. They do not consist of free associative dialogue that seeks to illuminate unconscious process. The target area is working memory or preconsciously held experience. It is expected that a focus for a given session will have been achieved after 10 to 15 minutes of the session, and this focus will then become the pivotal point around which the clinician and patient orient themselves, returning to it whenever nonmentalizing comes to dominate the interaction.

Finally, interventions are carefully matched to the mentalizing capacities of the patient. It is no good offering complex interventions that require considerable thought and appraisal to an individual functioning in psychic equivalence mode. At best, this serves to take over their mentalizing for them, rather than facilitating its rekindling. As stated

earlier, nonmentalizing in the patient cannot be recovered by mentalizing in the clinician, but only by reactivating mentalizing in the patient. This is achieved through a series of steps, which underpin the trajectory of every MBT session and may recur several times within each session.

Trajectory of MBT Session and Interventions

Empathic Validation. The initial step in a session is listening to the patient's narrative. Listening to the patient's story allows the clinician to begin by empathic validation. Empathic validation and establishing a shared affective platform held between patient and clinician increases the patient's experience that they are not alone and indicates that another mind can be useful to clarify mental states and increase a sense of agency. Increasing focus on affect and interpersonal interaction during a session and over time provides the context in which to explore ever more complex states of mind within an attachment context that would normally trigger loss of mentalizing.

Empathic validation requires the clinician to find something in the story that they can empathize with. This is not the same as behaving in a sympathetic manner or saying things that repeat the patient's story. Empathic validation seeks to engender in the patient a sense that the clinician really understands the patient, their internal state, and the issue they are talking about. This is the clinical equivalent of attachment-based contingent responsiveness. Validation is an affectively based intervention with important cognitive components; the key component is the creation of a sense of alignment with the patient's internal emotional state by demonstrating an appreciation of the experience and the consequent secondary emotions triggered by a powerful emotional reaction (e.g., the patient's fury with a partner engenders deep distress and anxiety). A lack of appreciation of the patient's emotional experience and its impact on the patient's current state (noncontingent responsiveness on the part of the clinician) is likely to trigger nonmentalizing (e.g., pseudomentalizing) or generate avoidant or other insecure and disorganized attachment strategies. Once contingent responding has increased collaboration and reduced the patient's arousal, maintaining emotions at a manageable level, the clinician can consider sensitive but less contingent responses to try to stimulate mentalizing about the story the patient brings.

Clarification and Exploration. The second step is clarification and exploration (see case example, later). The "story" the patient brings is clarified. This is not clarification of facts about the narrative or events, although this must also take place. The clinician establishes the facts as quickly as possible. For example, if the patient speaks about an act of self-harm or a suicide attempt, a drunken brawl or an emotional outburst, the clinician quickly elicits when it occurred, who was there, what were the

circumstances, and so on. This will indicate the level of risk and provide other important information. More than this, though, the MBT clinician wishes to contextualize events with mentalizing. Clarification establishes the reflection the patient has on the events—what was their "premorbid" state of mind, what were their hopes, what was their experience when they were waiting for their boyfriend to return home, what thoughts intruded into their mind, what feelings did they identify, and can they reflect on it differently now? This process of clarification, in the service of engaging mentalizing, links inextricably with affect identification and exploration, which is the third step.

Affects and Affect Identification. Affects and interpersonal relationships reciprocally interact and are core to the personality problems characteristic of BPD. Unmanageable emotions impinge on relationships, and relationships stimulate powerful feelings. Patients may not be able to identify their feelings accurately but experience them primarily as inchoate bodily experiences. Working with the patient to identify a range of feelings is part of the clarification and exploration component of MBT (see case example, later). Sometimes, emotions in specific contexts have to be normalized. Too often, patients feel that their experience is wrong; in effect, they invalidate their own internal perceptions and feel ashamed. It may be that their feeling is appropriate but excessive, or at other times inexplicably absent. All this becomes clear if the clinician systematically focuses on affects. Initially, the affects associated with the events are established, then any reflection on those feelings are clarified, followed by eliciting current concerns about the events.

Clarification of current affect in the session is included as the third step if the patient and clinician retain their capacity to jointly mentalize around the focus. This is more than asking the patient how they feel at the moment or how they "feel about" an experience they reported, although this may be an initial component. The process requires the identification of *current* affect *related to talking about events to the clinician in the session*.

This expansion from identifying affects in relation to events to affect experienced while talking to the clinician about the events is named the *affect focus* of the session. The patient may initially bring intense rage into the session in relation to an experience of rejection, which is gradually clarified as having been caused by characteristic inappropriate behaviors on the part of the patient. The affect focus turns out to be a sense of humiliation the patient experiences in once again failing to manage their own actions in a more effective manner. The aim throughout this process is to build a robust platform of mentalized experience jointly recognized and shared by the patient and clinician, which incorporates the complexity of mental states and moves the patient beyond a nonmentalizing, narrow oversimplification of their uncontextualized feelings.

The affect focus, that is, identification of the interpersonal interaction in the session and the associated affect, if accurate, heightens the focus on the clinician–patient interaction in the moment of the session. This often indicates that a patient's attachment strategies and relational patterns, or possibly those of the clinician, are being activated. So it allows a move toward *mentalizing the relationship,* the final step of the intervention trajectory.

Presenting Alternative Perspectives. Before extending to incorporate the relationship with the clinician into the patient's narrative, the clinician endeavors to enhance the patient's mentalizing by broadening the patient's perspectives on an event. This follows naturally from clarification and the affect focus, and entails elaborating the mental states of the participants in an event. However, it gradually moves the focus from emotion to cognition. The clinician explores alternative ways of looking an event, at first playfully but sometimes in a mildly challenging manner. If the affect focus helped reestablish more balanced mentalizing, then considering additional possibilities of what may have happened, at the level of thoughts and feelings, helps further reengage the patient's mentalizing processes.

Alternative perspectives may entail reconsiderations of entire scenarios from the point of view of the patient's hypotheses about the thoughts and feelings of others, or a reevaluation of the putative sequence of the patient's reactions—reframing their version of events in the light of alternative thoughts and feelings which they may have also been experiencing. The aim of alternative perspectives is the gentle expansion of the patient's mentalizing, to move from the certainty of affect toward the doubt of cognition. In general, the move is also from situational (external determinants) to exploring putative internal states. If the patient's focus was exclusively on their own state of mind the alternative perspective may bring in the other, while if the focus was on all protagonists other than the patient, the alternative perspective can focus on the self. Overall, the clinician engenders a recognition that a pause for reflection and explicit mentalizing may be of value in addition to intuition and the certainty automatic mentalizing can bring.

Mentalizing the Relationship. The groundwork for mentalizing the relationship will have been done through the development of the formulation, which identifies the predominant attachment strategies of the patient.

Mentalizing the relationship in a session is conceptualized as a training ground for managing difficult feelings in interpersonal situations in daily life through maintaining mentalizing while within an emotional interaction. The authors have identified a number of steps for the clinician to consider, which follow closely the three steps of technique described

above. First, the clinician has to empathically validate the patient's perception of the clinician. If the patient says that they experience the clinician in a particular way, then the clinician needs to find part of that experience that they can validate. The clinician actively avoids invalidating the patient's experience. Second, the clinician needs to work out their contribution to the patient's experience of the clinician. The clinician does this explicitly by thinking aloud about it and asking the patient to explain how they have come to that conclusion. This questioning must be authentic and genuinely curious, and must not come from a perspective that implies that the patient's experience is inaccurate or a reemergence of the past distorting the present. Such an invalidating attitude will lead to therapeutic rupture because invalidation (a noncontingent response) will lead to increased arousal and a consequent reduction in mentalizing. Mentalizing the relationship can meaningfully take place only in the context of mentalizing. Once the clinician has accepted their role in the relational process, the next step of more detailed exploration can occur. In this step, the aim is to generate a more complex understanding of the relationship, to see it from a different angle, and to see what its relevance is for the patient's life. It is not to engender insight in the sense of understanding the operation of the past in the present, although this may arise as part of the patient's broader understanding of their emotional experience. Critically, the past is used only sparingly as an explanation of the present, in case considering the past leads to a nonmentalizing, reductionist "short-cut" that obscures rather than elaborates the patient's current experience. In MBT, the clinician is cautioned about offering historical interpretation in the context of nonmentalizing process. For the exploration of the therapeutic relationship to contribute to enhanced mentalizing, the clinician works toward increased complexity and the establishment of multiple mental models of relationships.

Mentalizing the *counter-relationship,* or the feeling in the clinician, is the counterweight to mentalizing the relationship. The feelings and mind state of the clinician are given considerable weight in MBT—not as representing the patient's projected feeling, but as a meaningful aspect of an interactive relationship, to be used to demonstrate how minds affect minds. MBT clinicians monitor their experience of the patient. Not knowing what to say to the patient may be the best indicator of the patient's inadequate mentalizing. The dominance of the pretend mode in the patient may be indicated by a sense of boredom, while teleological mode may be indicated by a sense of confusion and anxiety. The interaction becomes the subject of useful concern, removing obstacles to mentalizing and enhancing accurate mentalizing of the relationship. For example, if the clinician is frightened of a patient with ASPD, this is an important feeling in the clinician that interferes with treatment and dictates the form of the therapeutic relationship. The clinician finds a way of expressing their

experience of the patient in a way that makes it palatable and recognizable as something worth exploring. The authors recommend that this is done through a number of steps. First, the clinician works out exactly what their feeling is and what it relates to in the patient–clinician interaction. Second, the clinician considers the patient's likely response to an explicit statement of this current feeling state, and states this before talking about the current feeling. Third, in the dialogue, the clinician identifies the experience as their own, marks it, and, finally, monitors the patient's reaction to the statement:

> "It is possible that what I am going to say may make you feel I am telling you off or being critical but I assure you that is not the case [anticipating the response of the patient].
>
> The problem is that when you sit forward like that and raise your voice I start to feel anxious and under threat [identifying the behavioral evidence and focus of external mentalizing, presenting his own affect and the effect it has on him].
>
> I realize that this may be me [marking the feeling] but it makes it difficult for me to concentrate on what you are talking about [additional effect on him, interfering with the relationship]."

From here the patient's reaction can be taken into account and the session can continue. But if the threatening attitude and angry presentation is something that permeates all the patient's relationships, then further exploration is essential.

In conclusion, the key to MBT is to:

1. Develop a focused narrative around the problems of the patient, especially interpersonal issues
2. Infuse the narrative with mentalizing process and prevent a collapse into nonmentalizing experience
3. Work with the patient to reinstate mentalizing when it is lost, to prevent destructive behavior and personal distress. Mentalizing oneself with others is the basis of satisfactory social and personal relationships, which so often is the goal of people with psychiatric problems and yet seems to them so unreachable.

CLINICAL ISSUES

Indications

MBT is effective in treatment for severe BPD. Patients in the early studies of the intervention (see Research and Evaluation, later) had made serious suicide attempts, been admitted to psychiatric hospital for risk, and/or had self-harmed. Both men and women were included in trials and patients showed high levels of comorbidity. Analysis of the data suggested that patients who showed comorbidity for a number of personality disorders, including ASPD, did preferentially better in MBT than comparison treatment. At a clinical level, patients with marked interpersonal problems who have a personality disorder rooted in mentalizing vulnerability and

attachment problems may benefit from MBT.

Limitations

Patients treated with MBT show a reduction in life-threatening behaviors and distressing psychiatric symptoms at the end of treatment, require less mental health care, and demonstrate improved social and interpersonal functioning. Nevertheless, long-term follow-up shows that patients continue to underfunction in their personal lives. Follow-up over up to 8 years shows that individuals remain with lower levels of social and relational satisfaction than expected, although the benefit of the therapy remains possible to detect.

It should be noted that the evidence for mentalizing mediating therapeutic change in MBT is currently limited, and more evidence is available in relation to mentalizing mediating change in other treatment modalities.

Complications

Psychotherapy can be harmful and MBT is probably no exception. However, MBT pays particular attention to ways in which patients may be harmed by treatment. On the basis that patients with BPD are uniquely sensitive to attachment process, and the stimulation of attachment reduces mentalizing, the MBT clinician focuses on levels of arousal in treatment sessions, constantly trying to balance arousal and mentalizing, ensuring that the therapeutic relationship is not a source of excessive attachment stress. Overstimulation of patients with avoidant attachment patterns is likely to trigger retreat and drop-out. Drop-out rates in MBT in clinical services in the United Kingdom are around 15 percent of people offered treatment, although in Scandinavia drop-out is as low as 2 percent. This suggests that the treatment overall is acceptable to people with BPD.

The aim of treatment is to increase the robustness of the patient's mentalizing capacity, and yet clinicians in many psychotherapeutic modalities may often tell patients "how they feel" or "what they are really saying." This undermines the mentalizing of the patient and so is avoided in MBT.

Contraindications

MBT is a generic treatment constructed to optimize access both by creating a low-demand treatment protocol and by facilitating access to training by a range of professionals. Individuals who have problems with mentalizing rooted in nonattachment contexts—for example, those with ASPD or psychosis—may not benefit from MBT; if they do, the mechanism of change should be assumed to be different from that in BPD. Individuals with relatively simple problems, such as phobias or uncomplicated depression,

may do better with more direct approaches such as cognitive-behavioral therapy. Even within a population of patients with BPD, patients with more complex presentations (multiple personality disorder diagnoses) are more likely to require MBT than those with a single BPD diagnosis, who may do as well in structured clinical management.

A 24-year-old patient, Sharon, was referred following a number of suicide attempts. She self-harmed, engaged in frequent polydrug misuse, and described emotionally volatile and occasionally violent relationships with men. She had a 2-year-old daughter who had recently been removed by child protection services. The clinician was able to take a detailed history, which elicited a number of vulnerability factors. Sharon was taken into care at the age of 5 and had a number of foster placements. She experienced recurrent sexual abuse from a carer around the age of 8. Her behavior was described in social reports as "over-sexualized" around the time of puberty and she attended an adolescent unit from the age of 13 to 15 years. She left school at 16 years having not attended for the previous year. The formulation was developed, which included these vulnerability factors but also identified the interpersonal vulnerabilities that led to mentalizing failures. The clinician explored two relational events with her boyfriend in which she had been violent, and two contexts in which she had tried to kill herself. Unsurprisingly, these events were interlinked

FORMULATION AND NONMENTALIZING INTERACTIONAL PATTERNS

In the formulation in MBT, mentalizing vulnerability points are identified and placed in the context of attachment strategies. In this patient there was evidence that she had an insecure attachment with marked ambivalence. She would seek something from her boyfriend, but when he did not respond she became desperate and increasingly demanding and clinging, eventually attacking him. She stated that if she could not "have him" she would "prefer to die," or alternatively she would "trap him" forever by getting pregnant. This nonmentalizing interactional cycle of need, demand, rejection, coercion, and the associated nonmentalizing modes were jointly explored, written down and shared with the patient. It is anticipated that the pattern will occur in relation to the clinician in a less intense way—the patient might seek some reassurance, for example, and the clinician may fail to respond contingently, triggering feelings of rejection. Identification and reduction of the nonmentalizing interactional process was an initial goal of treatment because the interactions occurred frequently and were an important area of vulnerability leading to suicide attempts.

CLARIFICATION AND ELABORATION AND AFFECT IDENTIFICATION

Sharon reported that she had been in a fight with her boyfriend. She had telephoned her boyfriend to find out when he would be back from work because she was looking forward to seeing him and to tell him that she loved him. He said that he was leaving soon and would be back within an hour. A few minutes later, a friend telephoned and, in their conversation, said that she had seen Sharon's boyfriend in a bar with a blonde woman only 30 minutes ago. When the boyfriend arrived home, Sharon asked why he had said that he was at work when she knew he was in a bar with a blonde woman. He said that he had called in for a drink on the way home. They had an argument during which Sharon attacked him and then, after smashing some crockery, cut herself.

Clarification of mental states about this event suggested that Sharon initially felt that she was looking forward to seeing her boyfriend, which was why she phoned him. His response was "contingent" with her feeling for him—he said he would be home soon. When her friend reported having seen him in a bar, this feeling was replaced with doubt about his love for her and a sense of rejection. Rapidly, she started to have thoughts that he was having an affair with the blonde woman, and in the context of feeling a loss of being loved this was experienced in psychic equivalence—"I am unlovable"—with some elements of hypermentalizing about his motives—"he was having an affair and I am certain of it." This was the nonmentalizing cycle and associated modes identified in her formulation.

When Sharon's boyfriend arrived home, there was no doubt in her mind about what had happened. He was unable to persuade her it was not true. In nonmentalizing states, actions are

the only meaningful way of communicating and she was therefore left with being coercive to "make" him love her. But to do this she tried to lock him in the house so he could not go out and she demanded sex. He resented this, refused, and the violence occurred. At this point her demand was driven by teleological belief that only his actions could prove his love for her.

The task in MBT is now to identify how Sharon manages her initial excitement about seeing her boyfriend, the sudden collapse of these feelings, and her collapse into psychic equivalent thoughts about his infidelity. To do this the clinician engages in detailed delineation of her mental states while asking her to re-present them to herself to instill a sense of uncertainty: can she manage emotional turmoil between excitement and disappointment; can she question her certainty over her boyfriend's activities and motives; can she engage with him to establish a more robust way of managing the distrust in their relationship other than teleological demand?

AFFECT SESSIONAL FOCUS AND MENTALIZING THE RELATIONSHIP

The clinician asked Sharon how she felt about her boyfriend now and she said that she still felt that he did not care for her. She was miserable. But, in addition, she felt that she had created problems, which was "typical of me." This is identification of current affect in relation to the focus. But, as she was talking to the clinician, she said that she felt that the clinician was judging her and would give up on treating her as it had happened again. She was a failure. This is the identification of current affect in the session and was quickly explored. At this point Sharon became coercive to some degree, suggesting that the clinician could not stop seeing her and to prevent it she would take an overdose. It becomes possible at this point to mentalize the relationship. Sharon thinks that the clinician will not meet her need and so automatically engages in a nonmentalizing interactional process. This needs to be discussed in the context of the clinician stating that it is not in his mind to stop seeing her in treatment (statement of clinician counter-relationship), so it is important to understand what is fuelling her belief and to question it. It is not for the clinician to interpret the repetition in the session of the interaction with the boyfriend but to define the emotional need that Sharon reacts to that makes her become coercive.

Goals of Treatment

The primary aims of MBT are to rekindle mentalizing when it is lost, to maintain it when it is present, and to increase the resilience of the individual's capacity to keep it going when it would otherwise be lost. But mentalizing is about something. So, the development and maintenance of mentalizing is initially focused on the core symptoms of BPD (or another condition), such as suicide attempts, self-harm, and other self-destructive behaviors and emotional instability. This is followed by emphasis on interpersonal problems because the key area of vulnerability to losing mentalizing in BPD is the interpersonal domain, especially when attachment processes are activated. So the clinician–patient relationship is a significant area of scrutiny. Patient and clinician increase attentiveness to mental states and interpersonal contexts in which they become disordered.

ETHICAL ISSUES

A key feature of MBT is the collaborative stance, which engages patients in a mutually agreed protocol, each phase of which focuses on achieving shared understanding between the patient and the clinician. In other words, it may be argued that MBT clinicians are less likely to encounter ethical issues than proponents of other therapeutic approaches in which collaboration is perhaps seen as a necessary condition but not the aim of

the treatment.

However, MBT clinicians should be well aware that the nature of the clinical problems they are dealing with invariably and unavoidably creates ethical issues daily. Working with a person whose capacity to represent themselves in an agentive way is lacking, whose attachment system is disorganized, and who is extremely vulnerable to creating a dependent relationship, will present a consistent problem for the clinician to avoid exerting undue influence. MBT clinicians—like therapists working in other orientations—can prolong relationships beyond their useful timespan, citing the patient's need for their input as justification. In particular, when patients pay for their treatment either themselves or through a third party, financial exploitation is a real and present risk. Beyond this, undue influence may manifest through the uncritical acceptance of the clinician's frame of reference: a nonmentalizing individual has no alternative and gratefully grabs hold of a powerful, coherent model when it is presented to them. The teleological predisposition of patients sometimes leads clinicians to find themselves caught up in action-oriented attempts to address the patient's distress, offering more than they should, yet delivering less than they could.

RESEARCH AND EVALUATION

MBT for BPD

There have been several recent reviews of psychosocial interventions for BPD. These recognize the evidence base for MBT for BPD as generally inferior only to that for dialectical behavior therapy, although not from a health economic perspective. Encouragingly, a large qualitative study of patients' treatment goals established that the goals of MBT were closely allied with what patients hoped to gain from their therapies.

A small number of RCTs and a number of naturalistic studies have tested the effectiveness of the MBT approach for BPD patients.

In an RCT of MBT for BPD in a partial hospital setting, an 18-month program achieved significant and enduring changes in mood states and interpersonal functioning. Outcome measures included frequency of suicide attempts and acts of self-harm, number and duration of inpatient admissions, service utilization, and self-report measures of depression, anxiety, general symptom distress, interpersonal function, and social adjustment. The benefits, relative to treatment as usual (TAU), were large, with a number needed to treat of approximately two; in addition, the benefits were observed to increase during the follow-up period of 18 months. Analysis of participants' healthcare use suggested that day hospital treatment for BPD was no more expensive than general psychiatric care and showed considerable cost savings after treatment. A follow-up study of BPD patients 5 years after all treatment was completed and 8 years after

initial entry into treatment, comparing patients treated with MBT and those receiving TAU, found that those who received MBT remained better than the TAU group. Superior levels of improvement were shown on levels of suicidality (23 percent in the MBT group vs. 74 percent in the TAU group), diagnostic status (13 percent vs. 87 percent), service use (2 years vs. 3.5 years), and other measurements such as use of medication, global functioning, and vocational status.

Two well-controlled single-blind trials of outpatient MBT have been conducted, one with adults with BPD and the second with adolescents presenting to clinical services with self-harm, the vast majority of whom met BPD criteria. In both trials, MBT was found to be superior to TAU in reducing self-harm, including suicidality, and depression. Importantly, in the adult trial, the control group received a manualized, highly efficacious treatment, structured clinical management; MBT was superior to this intervention, particularly in the long term. A posthoc analysis of moderators found that the number of personality disorder diagnoses in addition to BPD was the key indicator of severity that predicted the need for the MBT approach, as structured clinical management appeared to have little benefit on most outcome measures among these patients. Furthermore, in the trial with an adolescent sample, improvements generated by MBT appear to have been mediated by improved levels of mentalizing, reduced attachment avoidance, and amelioration of participants' emergent BPD features; participants treated with MBT showed a recovery rate of 44 percent, compared with 17 percent of those who received TAU. Ongoing follow-ups of both these trials indicate that improvements in the MBT groups have been at least maintained, and in most cases improvements continued after treatment termination, and differences relative to the comparison group remain significant.

Three recent studies provide further support for the efficacy of MBT in BPD. An RCT from Denmark investigated the efficacy of MBT versus a less intensive, manualized supportive group therapy in patients diagnosed with BPD. Patients were randomly allocated to MBT (n = 58) or the manualized supportive therapy (n = 27). Each intervention was delivered in combination with psychoeducation and medication. Both the combined MBT treatment and the less intensive supportive therapy brought about significant improvements on a range of psychological and interpersonal measures (e.g., general functioning, depression, and social functioning) and decreased the number of diagnostic criteria met for BPD; effect sizes were large (d = 0.5 to 2.1). The combined MBT was superior to the less intensive supportive group therapy on clinician-rated Global Assessment of Functioning. An 18-month naturalistic follow-up found that treatment effects at termination were sustained at 18 months. Half of the patients in the MBT group met criteria for functional remission at follow-up, compared with less than one-fifth in the supportive therapy group, but

three-quarters of both groups achieved diagnostic remission, and almost half of the patients had attained symptomatic remission. A limitation of this study is that the same clinicians delivered both interventions (and thus there was a high risk of spillover effects between the two treatments); incomplete data was a further significant limitation. In a second study from Denmark, a cohort of patients treated with partial hospitalization followed by group MBT showed significant improvements after treatment (average length 2 years) on a range of measures including Global Assessment of Functioning, hospitalizations, and vocational status, with further improvement at 2-year follow-up.

A quality improvement study examined the outcomes for BPD patients treated in an MBT program in a Norwegian specialist treatment unit compared with a former psychodynamic treatment program. This longitudinal comparison had a sample of 345 BPD patients, including 282 patients treated on the psychodynamic program and 64 who received MBT, who had comparable baseline severity and impairments of functioning on all measures. Outcome measures included Symptom Checklist-90 symptom distress, interpersonal problems, and global functioning assessed routinely throughout treatment, and suicidal/self-harming acts, hospital admissions, medication, and occupational status assessed at baseline and discharge. The change in program from traditional psychodynamic therapy to MBT led to a reduction in unplanned discharges (MBT had a low drop-out rate of 2 percent). Measured benefits from the change of program included greater improvements in symptom distress and interpersonal, global, and occupational functioning. Although the change was associated with the introduction of MBT, specific causal attributions are hard to establish in such a design.

A naturalistic study in the Netherlands investigated the effectiveness of an 18-month manualized program of MBT in 45 patients diagnosed with severe BPD. There was a high prevalence of comorbidity of DSM-IV Axis I and Axis II disorders. Results showed significant positive change in symptom distress, social and interpersonal functioning, and personality pathology and functioning; effect sizes were moderate to large (d = 0.7 to 1.7). The study also showed that the use of additional treatments and psychiatric inpatient admissions decreased significantly during and after treatment. The lack of a control group in this study limits the ability to draw conclusions about the efficacy of MBT. Another study applied propensity score matching to determine the best matches for 29 MBT patients from within a larger (n = 175) group who received other specialized psychotherapeutic treatments. These other specialized treatments yielded improvement across domains, which was generally only moderate; in contrast, pre–post-effect sizes were consistently large for MBT, with Cohen's d for reduction in psychiatric symptoms of −1.06 and −1.42 at 18 and 36 months, respectively, and ds ranging from 0.81 to 2.08 for

improvement in domains of personality functioning. Given the nonrandomized study design and the variation in treatment dose received by participants, the between-condition difference in effects should be interpreted cautiously. A multisite randomized trial by the same group comparing intensive outpatient and partial hospitalization-based MBT for patients with BPD is currently underway.

A recent naturalistic pilot trial studied the feasibility and effectiveness of an inpatient adaptation of MBT in 11 female adolescents (14 to 18 years) with borderline symptoms. One year after the start of treatment, significant decreases in symptoms and improvements in personality functioning and quality of life were observed; effect sizes were between d = 0.58 and 1.46, representing medium to large effects. Further, 91 percent (n = 10) of the adolescents showed reliable change on the Brief Symptom Inventory and 18 percent (n = 2) moved to the functional range on this measure. A report of the application of MBT principles to a therapeutic community also yielded positive results. Patients who completed 18 months of treatment showed significant self- and clinician-rated symptomatic improvement and significant change on clinician-administered measures of social and occupational functioning.

MBT for ASPD

Research into treatment for ASPD up to 2009 is summarized in the United Kingdom's National Institute for Health and Clinical Excellence clinical guideline for ASPD, which confirmed that interventions for ASPD are poorly researched and that evidence on its treatment is scarce. The authors of the guideline concluded that the evidence for treatments for ASPD was extremely limited, and did not support the development of any guidance on treatment recommendations. Two Cochrane reviews concluded that there was no consistent evidence for any intervention for ASPD, and recommended that research to test interventions for the disorder is urgently needed.

A feasibility study of MBT for ASPD reports findings from a small sample (n = 9) receiving group and individual MBT. Preliminary results on the Overt Aggression Scale suggested that the participants rated the severity of their aggression toward others and themselves as decreasing over the first 6.5 months of treatment; in contrast, their rating of irritability did not change. Psychiatric symptom severity on the Brief Symptom Inventory showed a reduction in the distress participants experienced in relation to their symptoms at a 6-month follow-up, with participants reporting greatest decreases in distress resulting from symptoms of depression, anxiety, and hostility.

Finally, the authors note that a significant subsample of the participants in the outpatient treatment trial of MBT for BPD described earlier also met criteria for ASPD. A separate analysis of these individuals with comorbid

ASPD revealed that they benefited significantly from MBT.

34 Biological Therapies

▲ 34.1 General Principles of Psychopharmacology

OLUSOLA AJILORE, M.D., PH.D., AND MARK M. RASENICK, PH.D.

Psychopharmacology is the use of medications as a treatment of mental disorders. Previous editions of this textbook have chronicled the evolution of psychopharmacology as a medical discipline. The first edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry,* published in 1967, appeared a decade after the appearance of modern antidepressants, antipsychotics, mood stabilizers, and anxiolytics. Of the nearly 1,700 pages in that first edition, a mere 25 pages were devoted to drugs as treatments of mental disorders. Chlorpromazine (Thorazine), approved by the U.S. Food and Drug Administration (FDA) 15 years earlier, was alone among the drugs acknowledged to be a significant therapeutic breakthrough. Other psychotropic agents, including the benzodiazepines (introduced in 1959), were characterized as playing a minor therapeutic role, serving as adjuncts to psychotherapy or as a last resort for patients failing to respond to therapy. There was no intimation that benzodiazepines would become the most widely prescribed drugs of any type within a few years. Lithium (Eskalith), which had been described as an effective treatment of mania in 1949, was mentioned in a brief paragraph. Indeed, in reading the first edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* and other textbooks of that time, it would have been difficult to predict how psychotropic drugs would soon transform the treatment of mental disorders. In a reversal of positions, psychoanalytic theory, which once served to define the practice of psychiatry, has been supplanted by psychopharmacology as the most widely used form of treatment of psychiatric disorders. However, there is concern by many in the field that psychopharmacology has stalled in the last few years. Since the last edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* published in 2009, there have been only 13 new FDA-approved agents for psychiatric indications that have come to the market, compared to over 20 for neurology. In addition, none of the new agents have involved mechanisms

with novel therapeutic targets. In 2014 alone, there were 20 new drugs for cancer and a single, non-novel agent for psychiatry. This crisis is due, in part, to the high cost of failure for new drug trials, particularly as it is difficult to separate out from placebo for many psychiatric drugs. This crisis is also due to declining government budgets for basic research. As researchers fail to find new targets, the ability of pharmaceutical companies to develop truly novel psychiatric drugs is in jeopardy. It is important to understand the present state of psychopharmacology in order to advance the current knowledge in the field. In this context, this chapter begins by describing basic principles of both pharmacology and psychopharmacology.

In order to engender complete understanding of the basic principles of psychopharmacology, it is first necessary to understand the principles of pharmacology—particularly those relating to receptors and cellular signaling. This chapter is organized into two sections: the first section will introduce those basic principles of pharmacology and the second section will build upon them to discuss general issues with psychotropic drugs.

RECEPTOR PHARMACOLOGY

The majority of drugs used for palliation of psychiatric symptoms either mimic, block, or modify the actions of neurotransmitters, and most do so by binding to receptors for those transmitters. While receptors can be located either on the plasma membrane or intracellularly, the neurotransmitter receptors relevant for the drugs to de discussed in this chapter are transmembrane molecules, with outer surfaces forming binding pockets for neurotransmitter.

The receptors discussed in this chapter are either ion channels (ionotropic) or metabotropic (G protein coupled) and many neurotransmitters (e.g., acetylcholine, glutamate, gamma aminobutyric acid [GABA], and serotonin) act as agonists for receptors in each class. This chapter will discuss the basic biology of many of these transmitters and receptors. It begins with a description of characterization and quantitation of different receptors.

Receptor Analysis

There are two basic mechanisms for studying receptors. One is to measure the binding of a ligand (often radioactively labeled) and the other is to measure the physiological consequences of agonist binding (and the effects of antagonist).

Binding Assays. In order to study receptors with radioligand binding, hormones, neurotransmitters, or their analogs have been labeled with a variety of radioactive compounds. Membranes prepared from cultured cells or brain tissue (or intact cells) can be assayed for their ability to bind these

radioactive drugs. The radioactive compounds can be either agonist or antagonist, and through the use of these compounds, a quantitation of both the number of receptors and the affinity of those receptors for the drug can be determined.

In order to quantify binding, ligands are added to membrane preparations at known concentrations and competed with nonradioactive ligands in order to determine the extent to which binding is specific. Membranes are trapped on filters, the filters are washed and radioactivity is determined by scintillation spectrometry. Typical results are illustrated in Figure 34.1–1. Specific binding can be transformed by Scatchard analysis (Fig. 34.1–2) to reveal the existence of multiple affinity states for agonist and Hill analysis to determine the whether binding is cooperative.

FIGURE 34.1–1. Kinetics of ligand (agonist or antagonist) binding. **A:** Measurement of receptors using radioligand binding. Membranes (or cells) are incubated with radioactive agonist or antagonist and collected by sedimentation or filtration. Radioactivity in particulate fractions is calculated and plotted as shown above. Nonspecific binding refers to that portion of the total binding that persists in the presence of an excess of unlabeled

compound. Specific binding is saturable, within the range of the experiment shown, but nonspecific binding does not saturate. **B:** Two plots of specific binding versus concentration of ligand. **C:** The approximate Kd is represented by the ligand concentration at 50 percent saturation of specific binding. DPM, disintegrations per minute. (From Felig P, Frohman LA. *Endocrinology and Metabolism*. McGraw-Hill Education; 2001.)

Some receptors are oligomeric. Many ionotropic receptors have multiple subunits and two or more of these bind agonist, often displaying cooperative binding. G protein–coupled receptors (GPCRs) have been shown to dimerize as well, and this can take the form of homodimers or heterodimers, in the case of multiple receptor species. Although dimerization is obligatory only for GABAB receptors, many other forms of receptors have been demonstrated to dimerize.

Biological (Efficacy) Assays. In addition to direct determination of agonist or antagonist binding to receptor, the biological consequences of this binding can be assessed. One of these methods involves a biological assay. A classical biological assay utilizes an isolated organ strip, such as the guinea pig ileum, and measures changes in both the frequency and strength of contraction of the intestinal smooth muscle in response to the presence of an agonist. Such a system allows the investigator to coordinate the dose of hormone with the strength of the response, but quantification is often imprecise.

More recent biological assays rely on enzyme "effectors" activated subsequent to receptor activation. In the case of the guinea pig ileum, this might involve measuring the cyclic adenosine monophosphate (cAMP) produced by the enzyme adenylyl cyclase subsequent to the activation of the β-adrenergic receptor. Higher throughput assays designed to screen drugs that may act as agonists or antagonists for a given receptor might involve fluorescent sensors detecting an increase in Ca^{2+} subsequent to activation of a receptor that activates phospholipase c (e.g., 5HT2A), a process that ultimately increases cellular calcium. Such assays are referred to by the acronym FLPR (fluorescence imaging plate reader) and are used routinely in the process of drug discovery and development. These high-throughput assays employ fluorescent calcium (or other small molecule) sensors to determine GPCR activation and determine the efficacy of an agonist or potency of an antagonist at a given receptor.

FIGURE 34.1–2. Computational analysis of receptor binding. **A:** Scatchard plots. (Left) a receptor with a single affinity state for the binding of ligand; (right) two-site fit. **B:** Hill plots for the determination of cooperativity in ligand–receptor binding. Three Hill plots are shown here. (**a**) Four binding sites (possibly a tetramer); (**b**) is representative of a single site; (**c**) cooperative binding of fewer than four but more than one site. (From Felig P, Frohman LA. *Endocrinology and Metabolism*. New York: McGraw-Hill Education; 2001.)

Efficacy could also be plotted in a manner similar to that used in Figure 34.1–1. The x-axis would continue to represent the amount of drug required (potency) and the degree of activation (efficacy) would be represented on the y-axis.

G Protein Modulation of Agonist Binding. GPCRs show a significant decrease in agonist affinity following the introduction of guanosine 5′-triphosphate (GTP) into the medium. This is demonstrated in Figure 34.1–3. Isoproterenol, a β-adrenergic agonist, displaces iodocyanopindolol (a radioactive antagonist) with less potency in the presence of GTP. It is suggested that the complex between receptor and G protein represents the

high-affinity state for agonist binding. Agonist allows the active receptor to induce the G protein to bind GTP (this will be explained more completely below), which then causes the G protein to dissociate from the receptor. This "free receptor" has a lower affinity for agonist than does the receptor–G protein complex. Note that some antagonists also show the ability to undergo this "GTP shift." As will be noted below, some antagonists also modify the conformation of certain other GPCRs.

FIGURE 34.1–3. Guanosine 5'-triphosphate (GTP) decreases agonist affinity. In the example shown, the β-adrenergic agonist, isoproterenol, is used to displace the labeled β-adrenergic antagonist, 125I-iodocyanopindolol (ICYP). In the presence of GTP significantly more isoproterenol is required to displace the iodocyanopindolol. This "right shift" of the binding curve indicates that, in the presence of GTP, affinity for agonist by the receptor is decreased. (From Felig P, Frohman LA. *Endocrinology and Metabolism*. New York: McGraw-Hill Education; 2001.)

Structure and Function of Receptors

Ionotropic receptors were first to be characterized structurally, as the nicotinic acetylcholine receptors (nAChRs) are present in large concentration in the electroplax organs of electric fish and eel, and proved rich sources of receptor that was modeled by x-ray diffraction. Many years later, outer segments of retinal rod photoreceptors proved a similarly rich source of rhodopsin, the first GPCR to be crystalized by Palczewski and colleagues. While solving the structures of GPCRs more relevant to psychiatry was daunting, Kobilka, Stevens and their colleagues devised a mechanism for modifying these receptors and a number of pharmacologically-relevant GPCRs have now been determined,

structurally.

In the case of ionotropic receptors, the binding of agonist elicits a cascade that initially creates a channel for ion conductance. Second messenger systems (elicited subsequent to GPCR activation) modify channel function considerably. In the case of GPCR, activation subsequent to agonist binding results in a change in receptor morphology that releases GDP from the bound G protein α subunit. The subsequent binding of GTP activates the G protein, allowing α subunits to engage intracellular effector enzymes such as adenylyl cyclase or phospholipase and β/γ subunits to engage voltage-dependent ion channels.

Ionotropic Receptors

VOLTAGE GATED. These receptors, which are intrinsic ion channels, are either voltage gated or ligand gated. The first class, consisting of Na^+, K^+, and Ca^{2+} channels, possesses sensors (arrays of charged amino acids within transmembrane regions). Many of these receptors have multiple (4 or 5) subunits that combine to form a functional receptor. Several mutations have been identified for voltage-sensitive channels and these result in a variety of maladies (channelopathies) ranging, in the case of calcium channels, from familial migraine to dystonia (Fig. 34.1–4).

FIGURE 34.1–4. Mutations in Ca^{2+} channels and disease phenotypes (channelopathies). This model of a voltage-dependent Ca^{2+} channel shows clusters of mutations and the relevance of mutations in a particular region for a particular malady. (Adapted from Purves D, Augustine G, Fitzpatrick D, Hall W, LaMantia A, White L. *Neuroscience*. 5th ed. Sunderland, MA: Sinauer; 2012.)

LIGAND GATED. These receptors, which also form ion channels that open in response to agonist, often share the quatrameric or pentameric structure of the voltage-gated receptors, but have specialized regions that bind one or two molecules of agonist. nAChRs, GABAA receptors, glutamate receptors (either kainate or *N*-methyl-D-aspartate [NMDA]), and 5HT3 receptors fall into this class (Fig. 34.1–5). While some of these receptors (e.g., nAChR) are regulated by binding of agonist, others have more complex regulation, GABAA have binding sites for benzodiazepines that increase agonist potency as well as binding sites within the channel region that decrease chloride conductance, hence acting as convulsants (Strychnine) (Fig. 34.1–6). Similarly, NMDA receptors, which normally act as Na^+ channels, conduct Ca^+ subsequent to membrane depolarization (Fig. 34.1–7) and can even participate in rapid remodeling of the synapse. Curiously, glycine, which is an agonist for a Cl-channel receptor similar to GABAA (but found primarily in spinal cord), also acts as to promote activity of glutamate at the excitatory NMDA receptor.

Receptors for Growth Factors. Receptors for neurotrophins, such as nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF), have intrinsic tyrosine kinase activity and dimerize upon agonist binding (Fig. 34.1–8). These receptors include trkA, trkB, and p75NTR. Regardless of the specific receptor type, most of the members of this receptor family consist of two subunits. Sometimes receptors form a homodimer and, at other times, a heterodimer. Formation of a dimer, which is a result of receptor activation, leads to autophosphorylation or transphosphorylation of the receptor within its cytoplasmic domain. Consequently, other substrates for that receptor phosphate are found and phosphorylate. Signal propagation often is a result of an activation of a series of kinase cascades resulting in cell growth or differentiation.

Metabotropic (G Protein–Coupled) Receptors. GPCRs are a large family of receptors for light, ordorants, small molecule neurotransmitters as well as a variety of peptide agonists. It is estimated that somewhere between 50 and 70 percent of current drugs target GPCRs, elevating their importance for psychopharmacology. GPCRs regulate a multitude of physiological functions through activation of heterotrimeric G protein α and βγ subunits that directly bind to target proteins to initiate cellular signal transduction cascades, a process that is critically important for neurons and neurotransmitter action. Nearly 800 GPCRs have been identified in the human genome and include both chemosensory receptors and receptors for hormones and neurotransmitters. Approximately 100 of these GPCRs have not been linked to an endogenous ligand. These are known as orphan receptors. All GPCRs share a similar structure, which includes seven transmembrane domains, an extracellular amino terminal, an intracellular

carboxyl terminal, three extracellular loops, and three cytosolic loops (Fig. 34.1–9). While each of the seven transmembrane domains comprises somewhere between 20 and 27 amino acids, the end-terminal segments as well as either the extracellular or cytoplasmic loops can vary greatly among the different receptor types.

FIGURE 34.1–5. Families of ligand-gated ion channels. **A:** Nicotinic AChR, GABA, and glycine receptor channels are all pentamers and are comprised of many different types of subunits. There actions are explained in the text. **B:** Glutamate receptors are tetramers, usually comprised of two each of similar subunits. **C:** Purinergic (ATP) receptors are trimmers, each subunits with 2 membrane-spanning domains. FIGURE 34.1–7. Glutamate receptors. Three classes of glutamate receptor regulate excitatory synaptic actions in neurons in the spinal cord and brain. Two types of ionotropic glutamate receptor gate ion channels directly. Two subtypes of non-*N*-methyl-D-aspartate (NMDA) receptor bind the glutamate agonists kainate or alpha-amino 3-hydroxy-5--methylisoxazole-4-proprionate (AMPA) and regulate a channel permeable to Na^+ and K^+. The NMDA receptor (left) regulates a channel permeable to Ca^{2+} and Na^+ and has binding sites for glycine, Zn^{2+}, phencyclidine (PCP or "angel dust"), MK801, and Mg^{2+}, which modulate the functioning of this channel in the direction indicated.

FIGURE 34.1–8. Neurotrophin receptors. **A:** All neurotrophins bind p75NTR, a receptor lacking tyrosine kinase activity. The receptors with tyrosine kinase activity are selective for the molecules indicated in the figure. **B:** Upon activation, the three Trk receptors dimerize, autophosphorylate, and phosphorylate intracellular targets. A variety of survival or differentiation pathways can be activated.

FIGURE 34.1–9. Model of a "classic" G protein–coupled receptor. The β1-adrenergic receptor is shown. Highly conserved residues (among all G protein–coupled receptors) are shown in black. Boxed residues are conserved in catecholamine receptors and the serine marked with * is conserved in all G protein–coupled serotonin receptors. Diamond residues are involved in G protein coupling. (Modified from Probst WC, Snyder LA, Schuster DI, Brosius J, Sealfon SC. Sequence alignment of the G-protein coupled receptor superfamily. *DNA Cell Biol.* 1992;11(1):1–20.)

Changes in Receptor Conformation upon Agonist Activation. Mutational analysis suggested several regions of GPCRs were involved in coupling to and activating G proteins. Curiously, the elucidation of the crystal structure of the β_2 receptor, suggested that there were distinct pattern of among GPCRs and their cognate G proteins.

Receptors with constitutive activity, which are active in the absence of agonist, can be generated by mutation. The importance of the C-terminal portion of the third intracellular loop was demonstrated in studies on the adrenergic receptor that is linked to norepinephrine-induced activation of phosphatidylinositol metabolism.

Another region relevant for G protein coupling is located at the junction between the third transmembrane segment and the second intracellular loop of many GPCRs. This region is delineated by a motif known as E/DRY (Glu/Asp-Arg-Tyr), which is highly conserved among GPCRs and

mutations result in constitutive activation of many different GPCRs.

Some naturally occurring mutations result in constitutive receptor activity. Shenker and colleagues (1993) identified a mutation (Asp578Gly/Tyr) in the sixth transmembrane domain of the luteinizing hormone receptor, which confers constitutive activation. Males carrying this mutation display precocious puberty. Some types of GPCRs display constitutive activity in their normal state. While D1a dopamine receptors require the presence of agonist to activate G protein, D1b receptors show high constitutive activity, almost completely activating G protein in the absence of agonist.

INVERSE AGONISM. The demonstration of naturally occurring constitutive activity for GPCRs raises the possibility that inhibition of such constitutive activity should have a functional effect. Thus, for a number of receptors, compounds exist that simply inhibit the binding of agonist (neutral antagonists) and other compounds exist that inhibit the activity of a constitutively active receptor (inverse agonists). This was demonstrated for the δ opiate receptor in studies which revealed that the "inverse agonist" ICI 174864 lowered the basal activation of Gi by these receptors. Considering the model of receptor–G protein complexes presented above, it would be predicted that inverse agonists would show preferential binding to receptors that were uncoupled to G proteins. Inverse agonism has been demonstrated at a number of receptor types.

BIASED AGONISM. Endogenous agonists for most GPCRs (with the possible exception of Wnt) activate the receptor so that it engages both a G protein and β-arrestin. While the G protein pathway often generates cellular second messengers, the β-arrestin pathway evokes receptor internalization and a series of β-arrestin-mediated intracellular events. Over the past few years, compounds have been developed that select (are biased for) either the G protein pathway or the β-arrestin pathway. While the usefulness for compounds that modify cardiac contractility without modifying hypertrophy are readily apparent, the therapeutic potential for biased agonism in psychiatry remains unestablished (Fig. 34.1–10).

RECEPTOR DESENSITIZATION. Receptors are also capable of becoming desensitized. This process involves the attenuation of receptor response in the continued presence of agonist. The process is quite different for ion channels and ionotropic receptors versus GPCRs. In the case of voltage-gated ion channels, there are processes that either desensitize or actually inactivate channels, and some of these events result from second messengers created subsequent to activation of GPCRs. Similarly, ionotropic receptors are often modified, either by altering affinity for agonist or by altering channel characteristics. Again, this is due to second messengers, often through phosphorylation events.

GPCRs, however, have specific accessory proteins that mediate their desensitization. During the process, G protein receptor kinases (GRKs) an enzyme family, phosphorylate receptors in the activated (agonist-bound) conformation and these receptors become a target for β-arrestins, which herd them into clathrin-coated pits from whence they internalize. Once internalized, they either recycle back to the surface or are degraded. Figure 34.1–10 illustrates the process.

Heterotrimeric G Proteins. Table 34.1–1 reveals the current list of G protein α subunits. Currently, there have been identified 17α, 5β, and 13γ genes in humans. Alternative splicing increases the number of available proteins. Each of these G proteins interacts with specific effector molecules. These can be enzymes like adenylyl cyclase, which makes cAMP; phospholipase C, which generates lipid messengers and increases intracellular calcium; or voltage-gated ion channels (particularly K^+ or Ca^{2+}), which are modified by Gβγ subsequent to activation of Gα.

FIGURE 34.1–10. G protein–coupled receptor (GPCR) internalization and biased agonism. In the long-established model of GPCR signaling, an agonist binds to extracellular and/or transmembrane regions of the receptor, leading to its activation of G protein that results from exchange of GDP for GTP on Gα subunit, creating active Gα and Gβγ subunits. Termination of receptor activation can occur through GPCR phosphorylation by GPCR kinases (GRKs) and concomitant GPCR association with arrestins, which interact with clathrin to internalize GPCRs in endosomes. Recruitment of arrestins to activated GPCRs can also lead to the initiation of distinct arrestin-mediated signaling pathways, including activation of the mitogen-activated protein kinase extracellular signal-regulated kinase

(ERK) pathway. This can be done absent involvement of G protein, and agonists engaging either G protein or arrestin pathways are referred to as biased. Subsequent to internalization, GPCRs can be trafficked to lysosomes, where they are ultimately degraded, or to recycling endosomes for reinsertion to the plasma membrane. (From Ritter SL, Hall RA. Fine-tuning of GPCR activity by receptor-interacting proteins. *Nat Rev Mol Cell Biol.* 2009;10(12):819–830.)

THE ACTIVATION CYCLE. Prior to binding agonist, GPCRs exist in a complex with heterotrimeric G proteins (αβγ subunits). The latter two exist as a "fused complex" and the former releases GDP and binds GTP upon receptor activation. This shifts the Gα to an active conformation and alters the association between Gα and Gβγ in such a manner that both engage effector molecules. Hydrolysis of GTP, by a GTPase intrinsic to the α subunit, terminates the activation cycle (Fig. 34.1–11).

RGS Proteins. For many Gα proteins, the GTPase is relatively slow, and regulators of G protein signaling (RGS) proteins facilitate the process. RGS proteins are a family of GTPase-activating proteins with conserved RGS domains (also called the RGS box) of about 120 amino-acid residues in length. RGS proteins interact directly with a subunit of heterotrimeric G proteins to catalyze GTP hydrolysis by enhancing the intrinsic GTPase activities of Gα, thus converting G proteins from a GTP-bound active state to a GDP-bound inactive state and terminating G protein–mediated signaling. While most G protein α subunits have been demonstrated to have their GTPase activated by a member of this large family of proteins, Gsα may be excluded. There are two sorting nexins that associate with Gsα (SNX13 and SNS14) that bind specifically with Gsα and are also known as RGSPX1 and RGSPX2, respectively. It is not clear that these proteins activate GTPase, and RGSPX2 clearly lacks this effect. Curiously, RGSPX2, a brain specific protein, helps mediate the trafficking of Gsα from the cell

membrane and also specifically modulates the cell-surface expression of the Gs-associated 5HT6 receptor.

Bacterial Toxins and G Proteins. Two bacterial toxins are known to modify G proteins by covalently ADP-ribosylating select amino acids within those G proteins. Cholera toxin inactivates the intrinsic GTPase of Gsα that results in sustained (permanent) activation of Gs and subsequent hyperactivation of adenylyl cyclase. Pertussis toxin primarily acts on Gi and Go proteins and uncouples these proteins from the receptors that activate them. Since a prominent effect of Gi/o is inhibition of adenylyl cyclase, pertussis toxin will attenuate this inhibition with the net effect of increasing cAMP.

FIGURE 34.1–11. Activation cycle for G protein heterotrimers. Activation of the GPCR by agonist (described in Fig. 34.1–10) evokes release of GDP by G protein α subunit, allowing the binding of GTP. The GTP-bound conformation of Gα activates Effector molecules such as adenylyl cyclase of Phospholipase C. The activation of Gα is terminated by the hydrolysis of GTP for GDP. While the GTPase is intrinsic, there are molecules, such as RGS proteins, that facilitate the process.

Microdomains in the Plasma Membrane and GPCR Signaling

The plasma membrane, while comprised of lipids and proteins, enjoys a more complex organization than would be predicted from proteins floating in a lipid bilayer. Membranes are highly compartmentalized and are rife with domains of highly ordered and less ordered membrane lipids. The more highly ordered regions tend to be cholesterol-rich and these domains are normally associated with cytoskeletal proteins as well. The term used to describe these areas is "lipid rafts" and they are thought to range in diameter between 20 and 100 nM. Some of these structures contain the protein caveolin and form invaginated structures known as caveolae (little caves). At this point, these structures are conceptual, since they are below the level of resolution of the light microscope. Regardless, they can be manipulated experimentally, and it now appears that neurotransmitter action is, depending on the ligand and second-messenger pathway, facilitated or inhibited in caveolae and lipid rafts. Figure 34.1–12 shows the postulated organization of signaling molecules into lipid rafts and caveolae. These membrane microdomains have been suggested to be important sites of action for antidepressants and may be instrumental in evoking the disrupted signaling seen in depression.

G PROTEIN EFFECTORS

A vast array of cellular processes is mediated by G proteins. These molecules can be either activated or inhibited by G proteins and either α or βγ subunits have been demonstrated to function as activators. A list of some of these G protein–mediated events is given in Table 34.1–1 and a scheme is shown in Figure 34.1–13.

FIGURE 34.1–12. Lipid raft microdomains and membrane organization of neurotransmitter signaling molecules. **A:** There are two common raft domains in mammalian cells: planar lipid rafts and caveolae. Both possess a similar lipid composition. Planar rafts are essentially continuous with the plane of the plasma membrane and lack distinguishing morphological features. By contrast, caveolae are small, flask-shaped membrane invaginations of the plasma membrane that contain caveolins. Caveolins and flotillin can recruit signaling molecules into lipid rafts. Many neurotransmitter receptors (both ionotropic and G protein-coupled), G proteins, and signaling effectors such as second-messenger-generating enzymes are found in lipid rafts. Neurotransmitters might activate receptors that are located both within and outside lipid rafts. **B:** The lipid raft signaling hypothesis proposes that these microdomains organize, spatially, signaling molecules at the membrane, perhaps in complexes, to promote interactions that are necessary for signal transduction. **C:** Alternately, lipid rafts might inhibit interactions by separating signaling molecules, disrupting complexes and damping neurotransmitter response. (From Allen JA, Halverson-Tamboli RA, Rasenick MM. Lipid raft microdomains and neurotransmitter signalling. *Nat Rev Neurosci.* 2007;8:128–140.)

FIGURE 34.1–13. Coupling of G proteins to receptors and effectors. The activation of a G protein–coupled receptor (GPCR) by agonist allows -activation of the G protein (the α subunits exchange guanosine diphosphate [GDP] for guanosine 5'-triphosphate [GTP]) and subsequent activation of an effector molecule by α or βγ subunits. Several types of effector are listed. (From Felig P, Frohman LA. *Endocrinology and Metabolism*. New York: McGraw-Hill Education; 2001.)

Adenylyl Cyclase

This is the effector system that was being studied by Sutherland and Rall in their pioneering work on the activation of glycogen phosphorylase—work that led to the identification of cAMP and the concept of intracellular messenger molecules. Adenylyl cyclase, which generates cAMP from adenosine triphosphate (ATP), is a family of nine membrane-bound enzymes (plus a soluble version), each with a different mode of regulation. A common feature of all the adenylyl cyclase enzymes is activation by Gsα and (to varying degrees) by the diterpene, forskolin (Table 34.1–2). While Giα (three genes encode different forms of protein) was called "i" because it was inhibitory to adenylyl cyclase, only a few forms of adenylyl cyclase are inhibited directly by Giα. Calcium can act to stimulate some forms of the enzyme (in conjunction with calmodulin) and other forms are inhibited by calcium. While all forms of adenylyl cyclase are found in brain, these calcium-regulated types may be particularly relevant for psychopharmacology, as neurotransmitters that increase calcium (glutamate or acetylcholine) can also modify cAMP indirectly.

Phospholipases

Phospholipases responsive to G proteins fall into three families: phospholipase A, phospholipase C, and phospholipase D (Fig. 34.1–14). The products of phospholipase A are metabolites of arachidonic acid and are known as eicosanoids. The eicosanoids fall into the subgroups of prostaglandins and leukotrienes, and these molecules function as extracellular signals. The next group of phospholipids includes those that result from the breakdown of diacylglycerol and the inositol phosphates and these are the result of the actions of the phospholipase C enzymes. Gq and G11 activate phospholipase C, which has the net effect of increasing intracellular cellular calcium, both through the release of Ca^{2+} from intracellular stores and increasing capacitive calcium entry. 5HT2A receptors activate phospholipase C through a Gq intermediary. Finally, phospholipase D, which uses phosphatidyl choline as a substrate, can generate diacylglycerol and phosphatidic acid as well as lysophosphatidic acid. This latter molecule also has extracellular signaling properties.

G Protein–Activated Ion Channels

Direct activation of potassium channels by G proteins is important for the agonist-induced, rapid inhibition of membrane excitability in nervous tissue, and is essential for modifying both excitation and neurotransmitter release. As noted above, activation of GPCRs induces activation of G proteins, and both Gα and Gβγ can activate effector molecules, in this case, channel proteins. These channels (G protein–gated inward rectifier Kþ channels, GIRK) have been shown to bind directly and become activated by Gβγ. They are strictly voltage-independent, and channel gating requires association with intracellular proteins. Just as prominently (and also

resulting in an inhibition of a voltage-activated process), Gβγ subunits inhibit voltage-gated Ca^{2+} channels, attenuating neurotransmitter release. In these processes, the G protein, itself, is the second messenger (Fig. 34.1–15). Thus, the activation/inhibition of ion channels is somewhat more rapid than the generation of a second messenger and subsequent modification of channel function by phosphorylation.

INTRACELLULAR SIGNALING PATHWAYS

cAMP is synthesized by adenylyl cyclase and degraded by cAMP phosphodiesterase (PDE), which causes cAMP to be hydrolyzed to 5′AMP. Initial hormonal signals are more likely to regulate cAMP by the activation or inhibition of adenylyl cyclase than they are by altering PDE, but this is primarily because the receptors are coupled to G proteins that then directly stimulate or inhibit adenylyl cyclase. However, activation of a Gq-coupled receptor an NMDA receptor or a nAChR will increase cellular Ca^{2+}, which will activate calcium-sensitive variants of PDE, decreasing cAMP.

Regulation of cAMP and Ca^{2+} signaling begins with the activation of specific protein kinases sensitive to those messengers. For cAMP, the primary kinase is protein kinase A (PKA) (Fig. 34.1–16), while Ca^{2+} activates either calcium/calmodulin-activated kinases (CaM kinase) or protein kinase C, which is activated by Ca^{2+} and diacylclycerol. Each of these have a series of targets that engage a series of intracellular pathways, including modification of ion channels, modification of cytoskeletal elements (and cellular fine structure) and modification of neurotransmitter synthesis, transport, release or catabolism as well as modification of gene expression via cyclic AMP response element (CREB) phosphorylation (Fig. 34.1–17).

As a rule, intracellular messages require a specific termination switch, and phosphoprotein phosphatases served this purpose for the phosphorylations described above. Some of these enzymes are specific for PKA (protein phosphatase IIb) or CaM kinase (calcineurin).

Regulation of adenylyl cyclase has been discussed above. The regulation of PDEs is quite complex, and much of it is due to the exquisite and unique subcellular localization of a myriad of PDE species. Further, the localization of cAMP-activated protein kinases (PKA) and a variety of PDEs is regulated by a family of proteins known as A kinase anchoring proteins (AKAPs). These proteins, often referred to as cellular scaffolds, provide a spatial dimension to second messenger signaling as well as a temporal discretion provided by close physical relationship of the relevant proteins.

In this instance, activation of an mAChR by acetylcholine allows Gβγ to bind to and open a K^+ channel known as a G protein–coupled inwardly rectifying K^+ channel (GIRK). Similarly, Gβγ can bind to and inhibit voltage gated Ca^{2+} channels.

Epac, Another cAMP Target

The default cAMP pathway is PKA, but it is noteworthy that other cellular proteins are regulated by cAMP independent of phosphorylation. One of these cAMP targets is a family of proteins known as Epac (exchange proteins activated by cAMP). These elicit guanine nucleotide exchange and subsequent activation of a number of small G proteins involved in cell growth and synaptogenesis. Furthermore, there are ion channels (particularly important in olfaction) that are directly opened subsequent to the binding of cAMP.

FIGURE 34.1–16. Activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA). Binding of cAMP to the regulatory subunits induces a conformational change, causing these subunits to dissociate from the complex, thereby activating the catalytic subunits. Each regulatory subunit has two cAMP-binding sites, and the release of the catalytic subunits requires the binding of more than two cAMP molecules to the tetramer. This greatly sharpens the response of the kinase to changes in cAMP concentration. There are at least two types of A kinase in most mammalian cells: type I is mainly in the cytosol, whereas type II is bound via its regulatory subunit to the plasma membrane, nuclear membrane, and microtubules. In both cases, however, once the catalytic subunits are freed and active, they can migrate into the nucleus (where they phosphorylate gene-regulatory proteins such as CREB; see Fig. 34.1–17). Table 34.1–3. Psychotropic Drugs with Postmarketing Black Box Warnings

Drug	Psychiatric Application	Basis for Warning
Clozapine (Clozaril)	Refractory schizophrenia	Myocarditis
Droperidol (Inapsine)	Sedation of agitated patients	Torsades de pointes or QT and QTc prolongation, or both, and other cardiovascular events
Thioridazine (Mellaril)	Psychosis	Torsades de pointes or QT and QTc prolongation, or both, and other cardiovascular events
Divalproex (Depakote)	Acute mania	Hemorrhagic pancreatitis and hepatic failure
Nefazodone (Serzone)	Depression	Acute hepatic failure
Pemoline (Cylert)	Attention-deficit/hyperactivity disorder	Acute liver failure
Antidepressants (in patients <24 years old)	Depression	Increased risk of suicidality

Antipsychotics (for dementia-related psychoses)	Psychosis	Increased risk of mortality

INTEGRATION OF NEUROTRANSMITTER SIGNALS

Most diagrams of synaptic signaling, including those in this chapter, depict a single neurotransmitter, engaging a single receptor, which then evokes a programmed series of responses through a set pathway. While as a didactic principle this is useful, neurotransmitter signaling, both at extracellular pathways and within cells, enjoys a far greater complexity. First, hundreds (even thousands) of axons converge upon a single dendrite (or even on a single dendritic spine). Second, a single transmitter, acting through a myriad of receptor types, could evoke multiple intracellular pathways. This is illustrated for serotonin in Table 34.1–3. Finally, each of these pathways are interdependent, as illustrated for Ca^{2+} and cAMP signaling pathways in Figure 34.1–18.

GENERAL ISSUES IN CLINICAL PSYCHOPHARMACOLOGY

Reflecting the expanded role of psychopharmacology, as well as the variety and sheer number of psychotropic drugs available, the sections on psychotropic drugs that follow represent a virtual textbook within a textbook. These sections are also complemented by discussions in other chapters that focus on the treatment of specific disorders and special patient populations. This section is intended as a review of important principles underlying the selection and use of psychotropic medications. It provides a review of common issues that arise in the clinical setting, as well as considerations for more effective use of available agents. Every effort has been made to provide a comprehensive discussion of the properties of the drugs, as well as guidance on their most appropriate use. Nevertheless, it needs to be emphasized that psychopharmacology is a rapidly evolving field and that many patients experience idiosyncratic or paradoxical responses to treatment.

History

For centuries, people have used plant extracts and naturally occurring substances to influence mood and anxiety, to modulate sleep and arousal, to produce euphoria, and to alter consciousness. Notable examples include alcohol, coffee, tea, opium preparations, bromides, and hallucinogens. Use of cocaine-containing soothing syrups and elixirs was common. In the nineteenth and early twentieth centuries, several types of *sedatives* were developed. Some of these compounds, chloral hydrate (Aquachloral Supprettes), and the barbiturates, are still in use. From the 1930s to the 1950s, the most effective biological treatment of a mental disorder was electroconvulsive therapy (ECT), but the image of the so-called shock

therapy was unpalatable to many patients. In 1931, two psychiatrists in India, Ganpath Sen and Kartik Chandra Bose, described the ability of *Rauwolfia serpentina* to reduce symptoms of psychosis, but this report was overlooked by Western medicine for many decades. When rediscovered, reserpine (Serpalan) became one of the first agents to offer benefit to patients with schizophrenia. Understanding of reserpine's effects on monoamine neurotransmitters spurred further research into the involvement of norepinephrine, serotonin, and dopamine in the treatment of psychiatric disorders, and the synthesis of drugs that targeted these agents. Similarly, published findings on the antimanic properties of lithium salts appeared in 1949, but were neglected by most psychiatrists. It was more than two decades before lithium became accepted as the standard treatment of bipolar disorder.

FIGURE 34.1–18. Interface among second messenger systems: many roles for calcium. Several conduits for Ca^{2+} signaling are shown and the interactions among them and cAMP signaling pathways are described in the text.

The field of psychopharmacology evolved rapidly during the second half of the 20th century. It was the nearly simultaneous discoveries of several classes of medications that began the transformation of psychiatric treatment from a psychoanalytic to a biological orientation. The first breakthrough occurred between 1950 and 1952 with the observation by Jean Delay and Pierre Deniker that chlorpromazine—a presurgical antihistamine—brought about dramatic control of psychotic symptoms associated with mania and schizophrenia. The effect of the drug was described as "miraculous" and "astonishing." Chlorpromazine was released for clinical use in 1954, and within 8 months, was administered to more than 2 million patients. Patients with long histories of hospitalization

owing to disorganized thinking and bizarre behavior demonstrated sufficient improvement to be discharged from their overcrowded institutions. For a time, there were expectations that chlorpromazine and its analogs, then referred to as *tranquilizers,* could eradicate or permanently cure schizophrenia. Although this turned out to be a false hope, newer versions of these drugs improve the quality of life of many patients, enabling them to be productive and to live in the community.

In 1952, iproniazid (Marsilid), a drug being tested as a treatment of tuberculosis, was observed to cause a dramatic elevation in mood. Over the next few years, psychiatrists came to recognize this antidepressant action of iproniazid and similar isonicotinic hydrazide analogs. Cases of unexpected hypertensive episodes associated with monoamine oxidase inhibitors (MAOIs) were reported soon after the introduction of these drugs. Some patients died of strokes. An explanation for this so-called cheese reaction did not emerge until 1963 in an article by Barry Blackwell.

Shortly after the discovery of MAOI antidepressant activity, imipramine (Tofranil), a derivative of chlorpromazine, was observed to alleviate depressive symptoms. Imipramine, the first tricyclic antidepressant (TCA), and iproniazid, the first MAOI, became available for clinical use in 1957. Within 1 year of its release, more than 400,000 patients received imipramine for depression.

Despite the progress that has been made in more than a half century, no antidepressants have surpassed the TCAs and MAOIs in efficacy. Nevertheless, these drugs have never lived up to their full potential because of troublesome side effects and concerns about safety. The dietary restrictions reduced the acceptability of MAOI treatment. The anticholinergic side effects of TCAs and their toxicity in overdose also had a restraining effect on their use.

The availability of meprobamate (Equanil) in 1955 marked the first time that a treatment of anxiety had a relatively wide margin of safety. Compared to the barbiturates, meprobamate caused less dose escalation and a less severe withdrawal syndrome. By the end of that decade, an even better tolerated and safer alternative emerged. In 1957, the benzodiazepine chlordiazepoxide (Librium) was found to produce sedative, muscle relaxant, and anticonvulsant properties but without significant risk of serious toxicity in overdose or during withdrawal. By 1960, chlordiazepoxide was marketed, soon followed by diazepam (Valium). It is worth noting that chlordiazepoxide was introduced into clinical practice just 2.5 years after its pharmacological studies were started.

In 1958, Paul Janssen synthesized another important chemical family of compounds used to treat psychoses—the butyrophenones. The prototype of this class—haloperidol (Haldol)—remains one of the most popular drugs used for the management of psychosis. The first atypical antipsychotic was synthesized in the late 1950s, but it was another of Paul Janssen's

compounds, risperidone (Risperdal), that became the first widely prescribed *atypical* neuroleptic or serotonin-dopamine antagonist.

Attitudes toward psychotropics were transformed in the early 1980s after reports were published that alprazolam (Xanax) could suppress panic attacks. Until that time, only TCAs and MAOIs had been shown to control panic symptoms, and benzodiazepines were not thought to be effective in treating this severe form of anxiety.

Based on the newly gained understanding that TCAs block not only norepinephrine reuptake but also serotonin, Arvid Carlsson and his colleagues set out to develop a selective inhibitor of serotonin reuptake. Zimelidine, the first of these selective serotonin reuptake inhibitors (SSRIs), was developed in the early 1970s, and was found to be a potent antidepressant. It was marketed in Europe but was quickly withdrawn from clinical use because of a rare neurological side effect. It was not until the introduction of fluoxetine (Prozac) late in 1987 that an SSRI became available in the United States. Early clinical experience with fluoxetine was followed by the surprising realization by patients and physicians that the drug sometimes produced dramatic responses without the same type of tolerability problems associated with the TCAs. Quickly, first-line treatment of depression quickly shifted from the TCAs to fluoxetine and other SSRIs. Even around the start of the 21st century, the majority of new prescriptions for antidepressant treatments were for SSRIs.

The first psychotropic drugs were thus discovered through observations of behavioral effects in animals or humans. As the mechanisms underlying the actions of these drugs have been determined, it has facilitated rational drug development of new compounds, such as the SSRIs, with more selective action. It also has led to the identification of disorders that are preferentially responsive to specific agents. Patients now have many more treatment options; the drugs used are better understood. One of the more remarkable transformations in the field of psychopharmacology has been the degree to which psychotropic drugs are now routinely prescribed by nonpsychiatrists.

Two large studies have helped to provide a perspective on how difficult it is to differentiate the growing number of psychotropic agents in terms of their overall effectiveness. The findings of these studies, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) and the Sequential Treatment Alternatives to Relieve Depression (STAR*D) trial, point out that patient responses to medications tend to be unpredictable, that no interventions are effective in all patients with a specific disorder, and that tolerability and safety often become the determinant of treatment success or failure.

The STAR*D trial was a large, federally funded study that investigated treatment effectiveness in a “real-world” sample of depressed outpatients treated in psychiatric and primary care practices. There were 3,671

participants in the trial. It found that remission was more common among patients in their first or second treatment trial (37 and 31 percent, respectively) than among those requiring three or four trials (14 and 13 percent, respectively). Patients needing more treatment steps tended to have more chronic depression and more coexisting psychiatric and general medical disorders. Overall, 67 percent of patients who completed up to four treatment steps reached remission. Results for STAR*D revealed higher relapse rates for those who required more initial treatment steps. Patients were allowed to choose among groups of subsequent treatments, which included cognitive therapy alone or combined with medication, as well as several different antidepressants used alone or in combination. The study failed to show any advantage, in terms of switching or combining drugs, for one strategy over another. The study found higher relapse rates among patients who failed to reach full remission and among those who went through a higher number of treatment steps to reach remission.

The CATIE study, funded by the National Institutes of Health's National Institute of Mental Health (NIMH), analyzed the effectiveness of an older (first-generation) antipsychotic medication perphenazine versus the newer (second-generation) medications during initial treatment. It found that the older medication might be more cost-effective for some patients with schizophrenia. Perphenazine was less expensive and no less effective than the newer drugs used in the trial. In phase 1 of the trial, patients were randomly assigned to receive olanzapine, perphenazine, quetiapine, risperidone, or ziprasidone for up to 18 months. Clozapine was included in phase 2 of the study. The study found that olanzapine had the longest time to discontinuation in phase 1 but caused the most weight gain and metabolic syndrome. Perphenazine did not significantly differ in overall effectiveness from quetiapine, risperidone, and ziprasidone. There were no differences in neurocognitive or psychosocial functioning in response to medications.

Classification

Traditionally, classification and categorization of psychotropic medications have been based on the primary indication for these medications. With each subsequent edition of this textbook, the classification and categorization of psychotropic drugs have changed. This is not merely a consequence of the development of new compounds. It is also the result of advances in the understanding of how these compounds produce their clinical effects. It was not long ago that psychotropic drugs were broadly defined as either stimulants or sedatives. The term *tranquilizer* was applied to antianxiety/sedative drugs (minor tranquilizers) and antipsychotics (major tranquilizers). At first, the only antidepressants were TCAs or MAOIs. However, when newer antidepressant drugs emerged in the 1970s and 1980s, they were labeled as second- or third-generation

antidepressants.

Defining drugs by their major indications is problematic. For example, the standard categories of drugs are (1) antipsychotic drugs or neuroleptics used to treat psychosis, (2) antidepressant drugs used to treat depression, (3) mood stabilizers used to treat bipolar disorder, (4) antianxiety or anxiolytic drugs used to treat anxious states, (5) hypnotic agents to promote sleep, and (6) psychostimulants to treat attention-deficit disorder. As a rule, clinicians think of drugs primarily in terms of their major clinical application. However, few psychotropic drugs are diagnosis specific, and most of the newer drugs assume multiple therapeutic roles over time. Benzodiazepine "anxiolytics," for example, are also very effective as hypnotics. Antidepressant drugs have a wide spectrum of action. Tricyclics like amitriptyline, which have significant histamine H1 antagonism, have been used in urticarial and other dermatologic disorders. Agents such as the SSRIs and venlafaxine (Effexor), all originally used to treat depression, have gained FDA approval as treatments of disorders as diverse as panic disorder, generalized anxiety disorder, social anxiety disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and premenstrual dysphoric disorder and chronic pain. Similarly, all atypical antipsychotic agents have become commonly used as mood stabilizers and as augmentation agents to treat depression and OCD. Such drugs as clonidine (Catapres), propranolol (Inderal), verapamil (Isoptin), and pregabalin (Lyrica), all not officially recognized as psychotropic agents, are widely used to manage a variety of psychiatric disorders. As a result, there is a growing movement to reclassify psychotropic drugs according to mechanism of action rather than by indication. The major neuropsychopharmacology societies around the world have come together to create a pharmacologically driven nomenclature for psychiatric drugs. While this system has yet to widely accepted and adopted, it suggests a more rational way of conceptualizing these medications.

REGULATORY ISSUES

In the United States, the FDA determines the safety and efficacy of medication. The FDA has the authority to approve a drug for clinical use if it is found to be "safe for use" and "effective in use." The FDA is also charged with ensuring that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug. This includes monitoring the postmarketing experience with a drug, proposing changes in the product information, and overseeing the way in which drugs are manufactured. Antidepressants, antipsychotics, hypnotics, mood stabilizers, and psychostimulants have been among the drugs with additional warnings due to postmarketing monitoring. In addition to the FDA, another level of government regulation is directed by the Drug Enforcement Agency (DEA), which classifies drugs according to their abuse

potential. Clinicians are advised to exercise increased caution when prescribing controlled substances (control levels II through IV).

Prescribing Information

FDA-approved product information for marketed drugs appears as a package insert. It is also referred to as the *product labeling*. The *Physicians' Desk Reference* (PDR) is an annual collection of product information for prescription drugs. The product information for most drugs—not just psychotropic agents—contains an extensive list of potential side effects, drug interactions, the need for special monitoring, and restrictions for use. This information reflects the results of critical evaluations submitted to the FDA about the safety and efficacy of the drug for the approved indications. Postmarketing experience is added to the product information over time. The limitations of the prescribing information are evident in the many adverse events that are underreported during clinical trials and the frequent use of doses of medications in clinical practice that exceed the recommended dosing limits. Product information is also widely available through online resources such as drugs.com and Epocrates.

Black Box Warning

The prescribing information for a drug sometimes contains a *black box warning* to alert physicians about potentially important safety information. The term describes a black box at the beginning of the package insert that encloses the warning. It is considered the strongest warning, being more serious than just bolded text. A black box warning may be included in the product information when a drug is approved by the FDA or it can be added later. The presence of a black box warning deters some clinicians from using a drug as a first-choice agent. In some cases, manufacturers have decided against bringing a drug to market because of the competitive disadvantage that a warning label confers. A controversial example is the black box warning for the increased risk of suicidality in young patients taking antidepressants issued in 2004. The biostatistician Robert Gibbons and his colleagues noted that prescribing rates decreased and suicide rates increased since the publication of the warning. Studies such as this led to revised wording of the warning by the FDA so that clinicians would not be discouraged from using antidepressants when clinically indicated. In 2005, the FDA issued a black box warning about increased risk of mortality with the use of atypical antipsychotics for dementia-related psychosis. This was expanded to include conventional antipsychotics in 2008.

The longer that a drug has been in clinical use, the better is the understanding of its side effect profile. Even though new agents undergo extensive scrutiny for safety and tolerability, clinical trials do not typically

capture the full range and severity of all side effects. Most clinical trials are of too short duration and lack sufficient power to detect the full extent of side effect risk. Approximately 10 percent of all drugs approved in the United States in recent years have acquired a black box warning after marketing or have been withdrawn. In terms of timing, one half of black box additions occurred within the first 7 years after a drug was marketed. Psychotropic drugs with added black box warnings (Table 34.1–3) include nefazodone (Serzone), pemoline (Cylert), droperidol (Inapsine), lamotrigine, clozapine (Clozaril), divalproex (Depakote), and thioridazine (Mellaril). In the last-named case, the warning was added after the drug had been in use for many decades. In the context of safer alternatives, the benefits of thioridazine no longer outweighed the risk of cardiac conduction abnormalities. A warning about the risk of stroke in elderly patients with dementia has been added to the prescribing information for risperidone.

Approximately one half of drug withdrawals due to safety issues occur within the first 2 years after a drug is marketed. Between 1993 and 2002, there were seven drug recalls that followed reports of death or severe health complications. None of these involved psychotropic drugs. This is a remarkable testimonial to an often-overlooked fact: Psychotropic drugs are among the safest drugs available. Since nomifensine (Merital) was withdrawn in 1986, within 1 year of its marketing, no other psychotropic agent has been withdrawn because of serious side effects.

PHARMACOLOGICAL ACTIONS

Heterogeneity of response characterizes all psychotropic drugs. Among other considerations, genetic and environmental factors influence individual response to and tolerability of psychotropic agents. Thus, a drug that may not prove effective in large numbers of patients with a disorder can dramatically improve symptoms in some. In these cases, the identification of characteristics that might predict potential candidates for that drug becomes important but often remains elusive. Attention is being focused on gaining a better understanding of the thousands of genes that regulate the expression of drug-metabolizing enzymes and of the complex functions of the brain.

Even drugs within the same class are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, combined with the biochemistry of the patient, account for the profile of efficacy, tolerability, and safety and the risk–benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug's effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of

pharmacokinetics, which describes what the body does to a drug, and pharmacodynamics, which describes what the drug does to the body.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients with respect to how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research is attempting to identify the role of genetics in drug response.

DRUG FACTORS

Pharmacodynamics

The time course and intensity of a drug's effects are referred to as its *pharmacodynamics*. Major pharmacodynamic considerations include receptor mechanisms, the dose–response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. Drug mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient's susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

Mechanisms

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, GABA, or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. Thus, a drug can be an agonist for a receptor, thus stimulating the specific biological activity of the receptor, or an antagonist, thus inhibiting the biological activity. Some drugs are partial agonists, in that they are not capable of fully activating a specific receptor. Partial agonists may also act as a competitive antagonist in the presence of full agonist. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium may act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D_2) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

It is important to note that action mechanisms for most psychotropic

drugs are poorly understood and that even the current classification of drugs (e.g., SSRI and 5HT2A antagonist) is problematic. There are two reasons for this. Studies of binding properties of many drugs have revealed complex patterns of receptor agonism and antagonism. For example, olanzapine has 5HT2 antagonist properties, but it also is an antagonist for 5HT 1B, 1D, 2A, 2C; α1 adrenergic; H1 histamine and D2 dopamine receptors while acting as a partial agonist for dopamine D1 and muscarinic AChR m1 receptors. This polyspecificity has been extensively by Roth and colleagues. The second issue is the assignation of mechanism based upon a single target. For example, while SSRIs do, indeed, inhibit 5HT transport, they do so within hours after being administered, while the clinical effects of these compounds require weeks to develop. Furthermore, at least some biochemical properties have been attributed to multiple classes of antidepressant drugs. SSRIs can elicit these in cells lacking 5HT transporters.

Thus, accounts of so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs actually work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a drug, then all drugs that cause these changes should produce equivalent benefits. This is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, may well be responsible for the therapeutic effects of psychotropic drugs. These *downstream* elements are postulated to represent the actual reasons that these drugs produce clinical improvement.

Pharmacokinetics

Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and pharmacodynamic drug interactions are the effects of drugs on the biological activities of each other. Pharmacokinetic concepts are used to describe and to predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the central nervous system (CNS). From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their absorption, distribution, metabolism or excretion.

Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. It is likely that the identification of patient genotypes will facilitate the prediction of clinical response to different types of drugs.

Drugs differ in their propensity to interact with other drugs. Awareness

of potential drug–drug interactions has grown dramatically over the last two decades. Most clinicians need to consult charts or online resources to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces minimal risk of drug interactions. In addition, it is recommended that prescribers know the interaction profiles of the drugs that they most commonly prescribe.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some cases, there also may be interference with the conversion of a drug to its active metabolite. There is enormous variability among patients with respect to pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides decrease the renal clearance of lithium, increasing the likelihood of its severe elevation. Drug interactions may be pharmacokinetic or pharmacodynamic.

Pharmacogenetics is being used to study why patients differ in the way that they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected. There are now commercially available assays that determine the potential of individual subjects for metabolizing various psychiatric drugs, in an attempt to create a profile of agents to be used and those to be avoided. Unfortunately, the actual therapeutic efficacy of a compound may not be dictated simply by the ability of the patient to process it, since an individual's profile of receptors, transporters and intracellular signaling cascades (described above) is likely essential to the action of a given agent.

PATIENT-RELATED FACTORS

Response to medication, as well sensitivity to side effects, is influenced by factors related to the patient. This is why there is no one-size-fits-all approach to pharmacological treatment. This is reflected in the finding that, although drugs used to treat a specific disorder demonstrate comparable efficacy in head-to-head studies, these drugs are not equally effective in all patients. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and past history of drug response. A patient's attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Accurate diagnosis is an integral component of the treatment process. Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but at times it also can produce a worsening of symptoms. Inadvertently diagnosing and treating a patient in the depressed phase of bipolar disorder as having unipolar depression can result in the induction of mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response

A specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, and adverse effects), the patient's family history of drug response, the profile of adverse effects for that drug with regard to the particular patient, and the prescribing clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. While this makes intuitive clinical sense, the evidence base for this has not been well-established, particularly for family history of treatment response. One study by Fava and colleagues demonstrated the response to a second trial of fluoxetine after placebo was similar to an initial trial with fluoxetine, suggesting that past performance predicts future results. Current studies like the PReDICT trial, examining predictors of depression remission, will be key in determining relevant patient-related factors that predict treatment response. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: The drugs prescribed, in what doses, for how long, and in what combinations. Often while patients may have tried a medication, they may not have had an adequate trial, either by dose or duration. Unfortunately, because of their mental disorders, many patients are poor historians. If possible, patients' medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Concurrent Medical or Psychiatric Disorders

Initial assessment should elicit information about coexisting medical disorders. In some cases, there may be a medical disorder that is responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine–Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess significant psychoactive properties and, in some cases, may represent the source of the patient's symptoms. It is reasonable to ask patients to abstain from use of these substances at least until the benefits of psychotropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol, tea, and coffee can then take place. Patients can then observe whether there are any untoward effects on their clinical status.

Drug Preference

Some prescribers have obvious favorites among the available psychotropic agents. This bias or *allegiance effect* regarding a treatment can stem from a combination of factors. A dramatically successful patient response during early experience with a new drug can produce a *conversion experience,* in which the prescribing physician forms a highly positive opinion of that drug. Patients being treated by that physician are more likely to receive that medication than alternatives. Previous studies have cited physician experience and prior treatment history as among the most highly ranked factors in treatment selection.

INFORMED CONSENT AND PATIENT EDUCATION

Establishing trust and providing motivation to comply with the medication regimen are essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected, unless there is a compelling advantage involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

Physicians no longer have a monopoly over the knowledge regarding psychotropic drugs. Many patients now routinely search the Internet for information about available treatments. What physicians do have is an understanding of the clinical circumstances that would lead to the choice of one drug among the many that are available.

Medication treatment benefits from a strong therapeutic alliance between a clinician and a patient. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about or fear of taking medication, a positive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient's confidence in the

physician's knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes. In particular, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. With the patient's consent, relatives and other clinicians should be instructed on the reasons for the drug treatment, as well as the expected benefits and potential risks. In addition, the clinician may also find it useful to explain the theoretical basis for pharmacotherapy to the patient and other significant parties.

DOSING, DURATION, AND MONITORING

Dosing

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity to and ability to metabolize a drug, concurrent medical disorders, use of concurrent medication treatments, and history of exposure to previous medications.

Doses used in clinical practice often differ from those used in pivotal studies, which, in turn, form the basis for dosing recommendations that eventually appear in the product information. The reason for this divergence is that patients in pivotal trials are highly selected and are not representative of the people who are ultimately treated. Once a drug achieves widespread use in real-world patients, it might be discovered that the doses needed for optimal efficacy need to be higher than suggested by clinical trial findings. Similarly, the doses needed for tolerability might be lower than thought. Even when a disparity on dosing between actual practice and clinical trial is established, the package insert is rarely, if ever, changed. This would involve the conduct of costly and time-consuming studies and submission of an application for change. At times, it may be clinically beneficial to exceed the upper dose limit for a drug—so-called high-dose therapy. However, it is best not to exceed the recommended upper dose threshold without a clear understanding of the potential benefits and risks involved. This caution is particularly important when a drug is associated with a severe concentration-dependent side effect.

Plasma concentrations of many psychotropics can vary up to 10-fold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. Some drugs demonstrate a clear relationship between increases in dose and clinical response. This dose–response curve plots the drug concentration against the effects of the drug.

The *potency* of a drug refers to the relative dose required to achieve

certain effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. However, these drugs are equal in their clinical efficacy—that is, the maximum clinical response achievable by administration of a drug.

Drugs must be used in effective doses for sufficient periods. Although drug tolerability and safety are always a consideration, subtherapeutic doses and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects without providing the probability of therapeutic benefit. In view of the wide margin of safety associated with most currently prescribed medications, there is more risk in underdosing than in overshooting the recommended dose range.

Time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or with disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is less clear-cut. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests that there is a significant dissociation between brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to misunderstanding of necessary schedules.

Duration of Treatment

A common question that a patient typically asks is "How long do I need to take the medication?" The answer, of course, depends on multiple variables, including the nature of the disorder, the duration of symptoms, the family history, and the extent to which the patient tolerates and benefits from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see whether the medication works for him or her and whether the side effects are acceptable. Any more definitive discussion of duration of treatment can be held once the degree of success is clear. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on medication indefinitely if the magnitude of improvement is great. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent recurrence. Nevertheless, the fact remains that psychiatric treatments are not said to cure the disorders they treat, but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: The initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterizes most classes of psychotropic drugs.

The required duration of a *therapeutic trial* of a drug should be discussed at the outset of treatment, so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a poor initial reaction to medication is not an indicator of the ultimate outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting on tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that there is a delay in clinical onset. In most cases, their hypnotic and antianxiety effects are evident immediately.

Ongoing use of medication does not, however, provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and depends on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and greater comorbidity than late-onset chronic major depression. In addition to early onset, a history of multiple past episodes, severity of the current episodes, and length of current episode would make longer, even indefinite, treatment appropriate.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of disorder, thus enabling the patient to regain the ability to function and to enjoy life as fully as before he or she became ill. This degree of improvement below the syndromal threshold is defined as *remission*.

Response and Remission

Remission is the preferred outcome of treatment not only because of the immediate effect on functioning and state of mind, but also because emerging evidence suggests that remitted patients are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, *response* is usually defined as a 50 percent or greater decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAMD) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). *Remission* is defined as an absolute score of 7 or less on the HAMD Scale or 10 or less on the MADRS. Expectations about the likely degree of improvement should be based on what is known about the responsiveness of specific disorders to medication therapy. OCD and schizophrenia, for example, are more likely

to be associated with residual manifestations of illness than major depression or panic disorder. The probability of full remission from OCD with SSRI treatment alone over a 3-year period is 38 percent, and the probability of partial remission is approximately 65 percent.

Treatment Failure

The initial treatment plan should anticipate the possibility that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms. Second, are the observed symptoms related to the original disorder or are they actually adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression.

Intolerance of side effects may be the most common reason for treatment failure. Third, was the drug administered at an appropriate dose for a sufficient length of time? Because patients can vary greatly in their absorption and metabolism of drugs, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug. Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug? Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dose), adverse effects (especially if unnoticed by the clinician), and poor patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance

Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and the use of unconventional drugs. There is limited evidence on the comparative success rates associated with any given strategy. This is one area that illustrates the critical need to develop biomarkers to determine trait, state, and therapeutic response. Often patients are given extended (2 months) drug trials before a decision is made to revise therapy. Thus, it may take 8 months to declare a patient

"treatment-resistant." As indicated above, it is not known whether a given patient is inherently treatment resistant or whether treatment resistance evolves as a result of repeated failures.

Tolerance

The development of tolerance is marked by a need, over time, to use increased doses of a drug to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacological actions often exhibit cross-tolerance.

Sensitization

Clinically manifested as the reverse of tolerance, sensitization is said to occur when there is increased sensitivity to a drug effect over time. In these cases, the same dose typically produces more-pronounced effects as treatment progresses. Conversely, if the therapeutic index is low, as it is for lithium, careful monitoring of serum levels is essential. For most psychotropic drugs, the therapeutic index is high.

Withdrawal

The development of physiological adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more common with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. With some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended when possible. Although this reduces the risk of withdrawal reactions, it does not ensure that they will not occur. So-called sedative–hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as the barbiturates, withdrawal can be fatal.

There are marked differences among agents, even within a given class, with respect to the probability and severity of discontinuation effects. For example, among the benzodiazepines, alprazolam commonly produces more-immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal

syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine may be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated due to the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces a severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, for example, can play a role. Paroxetine is primarily metabolized by the cytochrome P450 (CYP) 2D6 isozyme. However, paroxetine is also a potent inhibitor of CYP 2D6. This results in *autoinhibition,* a dose-dependent inhibition of its own metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased but a second agent that had been inhibiting its metabolism is stopped. For example, paroxetine is metabolized via the CYP 2D6 enzyme system. Bupropion inhibits that enzyme. If a patient taking both agents for several weeks discontinues the bupropion, it could result in a rapid increase in the rate of paroxetine metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs such as alprazolam, paroxetine, and venlafaxine has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of fall-off in plasma concentrations.

Poor bioavailability with a generic agent may account for an unexpected loss of clinical effect in the emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to ascertain whether generic medications are truly equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke a rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders, “the use of multiple agents should be avoided if possible” in the treatment of psychiatric disorders. Although *monotherapy* represents the ideal, *polypharmacy*—the simultaneous use of psychotropic medications—has been commonplace since chlorpromazine was combined with reserpine in the early 1950s. The practice of combining drugs is commonplace, and the merits of various *augmentation* or *combination* strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. In response to some of these trends, The Joint Commission has recently instituted quality measures to reduce the inappropriate use of antipsychotic polypharmacy.

Sometimes distinctions are made between augmentation and combination therapy. When two psychotropics with the same approved indications are used concurrently, this is termed *combination therapy*. Adding a drug with another indication is termed *augmentation*. Augmentation often entails use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is common to add thyroid hormone to an approved antidepressant. Some strategies are more popular or are preferred but are not necessarily more effective than any other. Augmentation was built into the treatment algorithm for the STAR*D trial, where there was option to add either lithium or thyroid hormone. In a STAR*D study that examined these augmentation options, the authors found that lithium and thyroid for equally effective in improving response rates in patients that failed monotherapy, but that thyroid hormone was better tolerated.

The widespread reliance on multiple-drug therapy, in the face of official discouragement and the absence of objective evidence supporting this practice, is easy to explain: Many patients do not become well with monotherapy with existing drugs. In a typical scenario, a patient has little or no response to a medication, so the physician adds a second agent to induce a better response. This need not be a second drug, as some studies suggest improved efficacy for SSRIs with the addition of omega 3 polyunsaturated fatty acids (fish oil).

In some cases, the use of multiple medications is the rule. Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and a dopamine-receptor antagonist or serotonin-dopamine antagonist has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so that the addition of a serotonin-dopamine antagonist may be helpful.

Medications may be also be combined to counteract side effects, to treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the

discontinuation of a prior drug, particularly when the first drug has provided partial benefit. This can be done as part of a plan to transition from an agent that is not producing a satisfactory response or as an attempt to maintain the patient on combined therapy.

One limitation is that there is increased noncompliance and adverse effects and that the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad-spectrum effect and also changes the ratio of metabolites.

The merits of going to a single drug with a different pharmacological profile include lower risk of drug–drug interactions, simplicity, and lower cost. It is less burdensome to be taking one medication than two or three and is less likely to meet resistance by the patient. Many patients are ambivalent about taking even one medication, let alone two. This practice is less justifiable in newly treated patients than in those who have failed repeated trials.

SPECIAL POPULATIONS

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, certain patient populations require special consideration. When treating the young, the elderly and those with medical disorders, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions because populations in these studies consisted of healthy young adults. Studies of children and adolescents have become more common, so that understanding of treatment effects in this population has grown.

Children

Understanding of the safety and efficacy of most psychotropic drugs when used to treat children is based more on clinical experience than on evidence from large clinical trial data. Other than attention-deficit/hyperactivity disorder (ADHD) and OCD, commonly used psychotropic drugs have no labeling for pediatric use, so results from adult studies are extrapolated to children. This is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child's higher rate of metabolism suggests that a higher ratio of milligrams of drug to kilograms of body weight should be used. In practice, it is best to begin with a small dose and to increase it until clinical effects are observed. However, the clinician should not hesitate to use adult doses in children if these doses are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided for special encouragement and incentives to study drugs for pediatric use. Since then, there have been expanded indications for FDA-approved medications to treat psychiatric conditions in children, such as risperidone for the treatment of schizophrenia in adolescents and manic/mixed episodes of bipolar I disorder in children and adolescents ages 10 to 17.

Some drugs used to treat psychiatric disorders carry a higher risk of serious side effects. Lamotrigine, for example, is associated with a substantially higher incidence of serious rash among children than among adults.

Elderly Patients

Elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower doses of medication. In practice, clinicians should begin treating geriatric patients with a small dose—usually approximately one half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although most geriatric patients require a small dose of medication, there are others who require a full therapeutic dose. Thus, sound clinical judgment and close monitoring are necessary.

A major concern about psychotropic drugs in the elderly is the well-established causal relationship between the use of these agents and falls. It has been shown that elderly users of psychotropic medications have a 47 percent increased risk of falls. This risk of falls and hip fractures may be minimized by selecting compounds that produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Historically, antipsychotics have been used to treat nonpsychotic, agitated patients. This practice has been called into question primarily as a result of the CATIE-AD trial that showed limited benefit of atypical antipsychotics in the treatment of agitation in dementia. Although they may reduce paranoia, there was no significant benefit in improving function or quality of life and there is evidence of worsening cognitive outcomes with these medications. There is an FDA warning regarding the use of atypical antipsychotics in the treatment of behavioral disorders in elderly patients with dementia. Studies have shown a higher death rate associated with their use. Accordingly, antipsychotic drugs should be reserved for psychosis.

Response to treatment is less predictable among older adults than

younger adults. Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication, as well as with the rate of dose titration. The frequent presence of medical disorders and the use of medications to treat them make it necessary to recognize how psychotropic drugs interact with the nonpsychiatric disorders and medications. Within any class of agents, those with fewer drug interactions or side effects with potentially serious consequences, such as hypotension, cardiac conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, may mimic or exacerbate symptoms of dementia. Similarly, dopamine-receptor antagonists can worsen or induce Parkinson disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients. A common ethical dilemma with the medically ill elderly or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or ECT.

Medically Ill Patients

When selecting and monitoring psychiatric drugs, the patient's medical disorders and their treatment need to be considered. Most important, the medical disorder or disorders and their treatments should be ruled out as a cause of the observed psychiatric symptoms. For example, patients with neurological or endocrine disorders or human immunodeficiency virus (HIV)–infected patients may experience disturbances of mood and cognition. Common medications, such as corticosteroids and L-dopa, are associated with induction of mania.

Although obvious, when various options are available, a psychotropic should be chosen that does not exacerbate or counteract the treatment of the existing medical disorder. For example, a psychotic patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion and topiramate (Topamax) can be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. Use of the tuberculosis treatment rifampicin (Rifadin) with carbamazepine is an example. Use of drugs that inhibit CYP 2D6—agents such as paroxetine and

fluoxetine—can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form.

NSAIDs are also a rare cause of perceptual disturbances and psychotic symptoms. Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug, and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dose, increase it slowly, and watch for clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available. Special caution is needed with potential drug–disease interactions. In patients with diabetes mellitus, drugs such as valproic acid or olanzapine, which are associated with increasing body weight, and insulin resistance, should be avoided. Patients with seizure disorder should not receive bupropion, or clomipramine (Anafranil), which lower the seizure threshold.

Substance Abuse

Many patients who seek or need treatment of a psychiatric disorder engage in chronic use of illicit substances or drink excessive amounts of alcohol. Marijuana is the most commonly used illicit drug in the United States.

Discontinuation of chronic drug or alcohol use can result not only in craving but also in clinically significant psychiatric and physiological withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. There is little research and no consensus about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs. If these agents are used as a method of coping—so-called avoidance coping—it appears to not be effective.

FUTURE DIRECTIONS

After decades of progress in bringing new treatments to the clinical setting, there has been a marked decline in the development or discovery of truly innovative drugs. Although researchers continue to search for medications with new modes of action and that are both more effective and better

tolerated than existing treatments, there needs to be a better understanding of the underlying neurochemical abnormalities that cause psychiatric disorder. Researchers may be close to significant breakthroughs by which research findings can be translated into better treatments. It is also possible that it will be years before new options are available to clinicians. There is a need to be able to predict more reliably which individuals will respond to specific agents because it is clear that there is no "one-size-fits-all" approach to psychopharmacology. There also needs to be more systematic postmarketing surveillance of drugs for potentially serious side effects. In the meantime, it is imperative that clinicians remain current with the clinical literature and remain thoughtful about the drug choices that they make.

▲ 34.2 Drug Development and Approval Process in the United States

SCIENTIFIC CHALLENGES IN CNS DRUG DEVELOPMENT

Anyone following the news will be aware of challenges faced by the pharmaceutical industry. The financial challenges are driven by many factors including the "patent cliff," where the expiration of the patents on many recent blockbuster treatments has led to severely reduced revenues for many companies resulting in cutbacks in research and development. Increased scrutiny by payors and governments, as to the value and novelty of new treatments, as well as price controls in many countries, has added to these challenges.

The latest figures estimate that the cost to develop a new drug is an average of $2.6 billion. Drugs that treat CNS diseases take more than a year longer to develop and are less than half as likely to obtain marketing approval as other drugs, according to a newly completed study by the Tufts Center for the Study of Drug Development.

In addition to the financial challenges, companies must leverage basic science to develop new and innovative treatments that are more effective or safer than current treatments available as generics. This has proved particularly challenging in psychiatric disorders for several reasons including an incomplete understanding of the basic science, and lack of a diagnostic system based on etiology, leading to a heterogeneous population in clinical studies.

Add to this the methodological challenges in conducting clinical trials in psychiatry, including subjective outcome measures, lack of medication adherence and increasing placebo response, it is not a surprise that this area is seen as high risk and has seen several companies abandon the area. These factors will be further elaborated below.

The good news is that due to the clear unmet patient need, many new companies are entering this area of drug development.

The Basic Science Challenge

In spite of research conducted in both academic and industry settings, including under the auspices of the Decade of the Brain at the end of the 20th century, and subsequent large initiatives involving academia, government, and corporate pharmaceutical entities, the pathophysiological underpinnings of most conditions affecting the CNS are virtually unknown. This lack of understanding of etiology complicates attempts to construct in vitro or in vivo nonclinical models with which to identify or to test therapeutic molecules before taking them into the clinical phases of drug development. In addition, when potential compounds are tested in accepted nonclinical models, the benefits conferred in these models do not predict similar benefits in man. An example would be Alzheimer disease. For more than 40 years, a deficit of brain acetylcholinergic function has been hypothesized to play a role in the condition, and therefore it was rational to test compounds that diminished the metabolism of acetylcholine: acetylcholinesterase inhibitors. Resulting from a global drug development process that tested many compounds with this pharmacological mechanism of action, four acetylcholinesterase inhibitors have been approved by regulatory authorities to treat dementia of the Alzheimer type. This might be viewed as a triumph of disease understanding, except that these agents offer symptomatic treatment of lesser magnitude and shorter duration than was predicted on the basis of the known acetylcholinergic deficit.

The Biomarker Conundrum

A more cautionary tale is the meager success of very expensive and long-duration clinical trials that have tested monoclonal antibodies designed to clear beta-amyloid from the brains of patients with the more advanced stages of Alzheimer disease. Beta-amyloid has been considered by some to be a surrogate biomarker for the Alzheimer disease process because the progressive brain deposition of beta-amyloid plaques has been a well-known pathophysiological hallmark of the disease since its description by Alois Alzheimer more than 100 years ago. Indeed, this lack of translation from bench to bedside is the rule in the field of Alzheimer disease, where more than 99 percent of clinical trials have failed. Clearly more predictive nonclinical models and a better choice of surrogate biomarkers are needed.

THE CLINICAL SCIENCE CHALLENGE: FACTORS IMPACTING SIGNAL DETECTION IN CLINICAL TRIALS

There is no one reason some CNS clinical trials fail. There are multiple factors that occur to one extent or another in any clinical trial. The following section reviews some of the most important of these.

Study Design

Clearly the design of any clinical trial is a key factor in its success or failure. In general, there are some basic trial principles, such as blinding and randomization that are followed in most drug development clinical trials. However, sometimes small design changes can have unintended consequences, which emphasize the importance of thoughtful clinical trial design.

Effect Size

In general, the effect sizes of compounds developed so far for psychiatric disorders are not large, which makes signal detection more challenging. One may argue that if treatments had larger effect sizes, other methodological issues would not matter.

Dose

Animal models for psychiatric disorders are not good at predicting dosing in humans, and there is a history in CNS drug development of the optimal clinical dose of a compound not being established during the development stage. Several compounds have had negative programs only to be later shown to be effective at different doses.

Diagnosis and Appropriate Patient Selection

Translation from bench to bedside is only one aspect of the issues

confronting CNS drug development. Even if clinical research investigators knew a priori that they were about to test the right therapeutic molecules, enrolling the right patients can be just as much of a challenge to successful trial outcomes. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) provides a standard language by which clinicians, researchers and public health officials in the US communicate about mental health disorders. The DSM Fifth Edition (DSM-5), published in 2013, marked the first significant revision since the DSM-IV in 1994.

Although useful for administrative and clinical reasons, as DSM is not based on biological etiology of psychiatric disorders, the subjects selected for a trial are clearly a heterogeneous group, and it is not surprising that this dilutes drug effects shown. There have been recent attempts to categorize patients with new models of diagnosis such as the NIMH Research Domain Criteria Project (RDoC).

Because there is little understanding of the pathophysiology of CNS disorders, it is not known whether the phenotypically similar features of clinically diagnosed patients may in fact result from a multiplicity of underlying genotypes. Compounds with discrete mechanisms of action may offer benefit to patients with only one or a few, but likely not all of these underlying genetic etiologies. Given this etiological heterogeneity of the population with a clinical disease phenotype, how does the clinical trial investigator choose the right patient who might benefit from a promising new compound? Greater knowledge of the heterogeneous pathophysiological causes and the contributing roles of genetic variants or environmental factors on CNS conditions are necessary.

Another question to ask is whether one treatment can be realistically expected to treat all aspects of a disorder such as depression, schizophrenia, or dementia? However, currently in psychiatry, the labels are granted by regulatory agencies map to the DSM.

Other fields such as oncology have faced these issues earlier and it has been new knowledge about the basic science and etiology that has led to breakthrough success.

Expectation Bias

This effect describes a situation where either the staff conducting the trial or subjects in the trial, or both groups, expect that the test drug will confer a benefit or that it is unlikely to do so. In the case of a positive bias, this expectation creates a cognitive bias that increases the effect that is being measured. Suppose a large clinical trial of a new antidepressant molecule (Drug X) is being conducted. Going into the trial, it is already known that Drug X has a mechanism of action that is similar to other drugs which produce true antidepressant effects. It is also known that in a prior, smaller clinical trial, Drug X produced a measureable effect when compared to placebo. These facts are known by the staff conducting the new and larger

trial, and they are also explained to each subject enrolling in the trial, as a part of informed consent. These facts may create an expectation of drug benefit in the staff who use rating scales to measure the symptoms produced by depression; and so the staff may thereby have an unconscious bias toward rating more beneficial effects than are actually present. What might be the outcome of this larger trial? Drug X produces the same benefit as it did in the earlier trial, but placebo produces a greater effect in this trial, shrinking or completely eliminating any measureable difference in the effects produced by Drug X and placebo.

Subjective Outcome Measures

Unlike objective measure used in other therapeutic areas such as blood pressure measurements, death, or the presence of a microorganism, psychiatry trials currently rely on outcome measures based on questions that subjects answer on a rating scale. These outcome measures are prone to a greater degree of uncertainty (and often a greater variance), as well as issues such as recall bias, and inter-rater reliability in a multicenter clinical trial.

Regression to the Mean

As already discussed, variance is a way to capture the random change in repeated measurements of the same variable. In a group if people in whom repeated measurements are performed, some people will have values that are far from the mean on one measurement, and values that are quite close to the mean on another measurement—all due to the randomness with which repeated measurements may vary. The presence of an extreme value (one far from the mean) on one measurement, and a value much closer to the mean at another measurement, is what is termed regression to the mean. Extreme values tend to move closer (regress) to the mean on different measurements.

As many trials enroll patients during an exacerbation of their illness, the phenomenon would tend to mean that future measurements would be less extreme even if the subject is on placebo. This phenomenon will therefore act to diminish any drug placebo difference that might be present.

Increased Interaction with Health Care Professionals

During the conduct of a clinical trial, subjects are seen much more frequently than in clinical practice and the visits can last several hours to conduct all the assessments required by the protocol. This increased interaction is well known to increase placebo response.

Medication Nonadherence in Clinical Trials

Another important reason for failed clinical trials is nonadherence to

clinical trial medication. Reasons for this are complex and multifactorial in nature. Whether intentional or unintentional, nonadherence to medication has major consequences in clinical trials leading to a lack of good quality data and poor signal detection, which can often times lead to an incorrect assumption that a drug is ineffective when it just has not been taken correctly or taken at all.

New digital and mobile technologies are emerging where adherence can be monitored remotely, which allow for active intervention by Investigators with nonadhering patients. While these technologies have great potential, it is important to remember that these are only the instruments which will aid investigators in oversight of treatment adherence and enhanced patient engagement.

Statistical Considerations

The proper use and interpretation of statistical methods is important in interpreting any clinical trial result.

FEW USEFUL DEFINITIONS

Positive, Negative, and Failed Trials

How does the scientist or clinician detect whether a therapeutic molecule (we will call it Drug X) offers a benefit (i.e., greater efficacy) in a clinical trial? One method is to perform a test to determine if the effect of Drug X on a variable of interest (like blood pressure) has a greater benefit when compared to the effect of either an inert agent that cannot be visually distinguished from the molecule (i.e., a placebo), or a greater benefit when compared to some other compound (Drug Y) that is already known to produce a beneficial effect. But how does one then detect whether there is a beneficial difference between Drug X and placebo, or between Drug X and Drug Y?

Before this question is answered, one needs to look a little more closely at what happens when a variable is measured over and over again. Again, take blood pressure as an example. Successive measurements of blood pressure in the same person, even when performed just moments apart, will yield different values with each measurement—tiny differences, perhaps, but real ones. A portion of this difference may be explained by physiological changes in the blood pressure from moment to moment, but another portion of the difference arises simply from small errors in the measurement itself. If this is the case, then how does one decide if Drug X produces the same benefit to drop high blood pressure as Drug Y, if measurements of either drug's effect on blood pressure are subject to error? If one does detect a difference in their measured effects on blood pressure, is that difference real, or could it be due completely to the variation in repeated measurements? To circumvent this inherent difficulty in

comparing two measurements, statisticians have defined methods to measure the extent to which multiple measurements will result in a spread of their values around the true average (mean) of that measurement. Not surprisingly, one of these methods to detect the random differences between repeated measurements is termed variance. Signal detection methods take the variance of two sets of measurements (say, from two groups of patients, each group administered a different treatment) into account to determine if there is a true difference conferred by the two treatments. There are many statistical methods to compare groups and to test whether the differences appear to be real, and these methods are chosen depending on the type of clinical trial, and on the outcome being studied (e.g., a change in a numerical value versus a discrete endpoint, such as death). Typically, the statistician hypothesizes that there is no difference in the signal produced by two treatments, and then the statistical tests are performed to see if the signal appears to be present after all, suggesting that the initial hypothesis is false (i.e., that there appears to be a real difference between the treatments).

Given these definitions, signal detection methods may, in principle, give rise to three sets of clinical trial outcomes. If the hypothesis is that two treatments are the same, then a positive trial outcome is one in which the effect of Drug X is statistically different from and better than that of another treatment (better than Drug Y, or better than placebo). A negative trial outcome is one in which this statement cannot be made; namely, Drug X produces an effect that is not statistically different than that of another treatment, thereby suggesting no additional benefit of Drug X.

But how does one know that a negative outcome is truly due to a nonefficacious drug, and not simply to some arbitrary factor such as a poor clinical trial design or a poorly chosen patient population—one that does not allow detection of a positive signal even when a positive signal should be present? To answer this question, some clinical trials will add a third treatment that produces a well-known clinical effect. For example, a test drug, Drug X, will be compared to placebo; and in the same trial, a known beneficial drug, Drug Z, is also compared to placebo. If Drug Z produces a signal that is significantly different from placebo, as it is should, and then if the effect produced by Drug X is not different than placebo, then this is a well-designed clinical trial that yields a very interpretable result: namely, Drug X does not produce an effect. However, what if the trial is so poorly designed or conducted that Drug Z itself fails to separate from placebo? This is an example of a failed clinical trial—one that is poorly designed or conducted, and which is therefore not even interpretable because even a drug with a known effect cannot be detected.

Repeated Measures

Sometimes companies conducting trials wish to explore the effect of

different doses of a compound on multiple symptom domains. Although this sounds like an efficient way to conduct an experiment, it turns out that if there is a small chance that a measured effect of the drug on a single variable is due to chance (and therefore that this is a true effect); it is unfortunately also true that many measurements of many doses on many effects may appear to produce a measureable effect of the drug, and some of these effects are false. Why? Random chance has been multiplied across all of these tests due to multiple measurements, a factor termed repeated measurements. Various statistical techniques have been constructed to overcome the effect of repeated measurements.

A more recent development in statistical design of clinical trials has been alternative clinical trial designs such as adaptive designs (Bowalekar, 2011) and Bayesian methods, but there has been few examples of their adoption in the CNS clinical trials so far.

FUTURE DIRECTIONS FOR DRUG DEVELOPMENT

The cost of developing a new treatment has been increasing to the point that further increases are unsustainable. There is a realization in the pharmaceutical industry that the current model has to change. This will drive a much more synergistic model that includes a whole network of collaborators who by fostering collective scientific creativity will ensure future long-term success. Competitive and technological changes in the pharmaceutical industry—from powerful new drug chemistries to innovative R&D partnerships—have the potential to improve productivity that will in turn increase output with greater efficiency, less cost, and more value.

Collaborative Networks

Some clinical trial goals require larger and longer trials, namely those designed for disease modification or for long-term follow-up to examine durability of effect. For example, in examining clinical trial outcome measures that target negative symptoms in schizophrenia, Laughren and Levin (2011) proposed that for FDA regulatory purposes, a 6-month or longer treatment period was desirable in order to examine durability of effect of the therapeutic molecule proposed for that indication.

Taking this trend toward longer trial durations much further, trials designed to examine the effects of treatments for prodromal Alzheimer disease may last 12 to 24 months, and involve a large sample size in order to detect small changes in neuropsychological measures and/or in functional or clinical outcomes. To accomplish these large trials, involving many thousands of patients and years of treatment duration, collaborative networks have been established between one or more biopharmaceutical companies, academia, and government agencies. These large collaborations

will not only facilitate the conduct of the trials but also decrease the per-entity cost and spread the risk of negative trial outcomes.

Globalization

There has been a marked trend toward drug development programs becoming more and more global. This is occurring for several reasons. Regulators and patient advocates are rightly demanding data that is obtained in ethnically relevant research subjects that address the possibility of differential efficacy and safety, and optimal dosing in these populations.

This trend to globalization has its challenges, including more complexity, longer regulatory reviews in some regions, different standards of medical care in some countries, and the transcultural issues in ensuring consistent reliable administering of subjective outcome measures.

Personalized Technology

CNS trials often use outcome measures that require patient entries into diaries. These can include subjective judgments on sleep quality, symptoms of depression, quality of life, and functional measures. In the past, these entries were made using paper diaries, but increasingly trials have turned to electronic devices that patients use for their entries. Device-based entries offer a number of advantages over the older paper-based methods. For example, entries can be both time stamped and immediately uploaded to a trial database. This speeds the acquisition of data, and it also allows the trial analysis staff to determine that entries were made at the times and dates specified by the protocol, rather than just before a patient's next clinic visit. Finally, electronic devices are increasingly familiar to people through their use of personal smart phones and other handheld devices; this tends to enhance patient interest in and familiarity with the use of these devices.

The introduction of Apple's ResearchKit (http://www.apple.com/researchkit/), holds the promise of taking clinical research into the mainstream with the availability of clinical research to everyone via their mobile devices, with enabling modules such as eConsent. Digital Medicine is profoundly influencing health care delivery systems and disease management.

Personalized Medicine

Currently most treatments available to patients were developed based on their effect on a patient population. It has been a long held aspiration to develop treatments that are personalized to patients based on factors such as genetics. This goal can be termed personalized medicine.

An example of an efficacy-targeted success in personalized medicine is the use of HER2 screening in patients with metastatic breast cancer.

Patients who over-express (are positive for) HER2 have a greater likelihood of responding to trastuzumab (Herceptin).

A similar example of a safety-targeted success is the use of CYP450 testing in order to predict drugs that should be dosed at different strengths in order to avoid excess or poor metabolism of drugs handled by those metabolic paths; and also to avoid drug: drug interactions. How does this affect the use of psychiatric drugs? Fluoxetine inhibits activity of CYP2D6, which metabolizes more than 100 commonly used medications. This means that patients taking fluoxetine may be at risk of receiving a functional overdose of other compounds that are metabolized by 2D6, unless the potential for a drug interaction is avoided by measuring 2D6 function in patients taking fluoxetine, or by tailoring the doses of coadministered drugs that are metabolized by 2D6.

The field of personalized medicine extends much further than these two examples about its applicability to efficacy and safety. Two basic approaches will be considered: tailoring drugs for the individual and identification of genetic susceptibility to disease.

Numerous large clinical trials targeting CNS and other indications routinely collect genetic information on patients in those trials, allowing the retrospective identification of a gene variant profile that correlates with efficacy or safety signals observed during the trial. If identified, then prospective use of these gene variant profiles is feasible, by screening patients for these gene variants in order to predict the efficacy or safety of the drug in question before it is administered to them.

Whole genome sequencing (WGS) is now available through many avenues for the individual patient. WGS approaches conducted in large populations can help identify variants that confer susceptibility to a variety of conditions, and then individual WGS results can be correlated with these population databases to seek clues about that individual's likelihood of harboring or developing those conditions. Caution must be exerted in applying this information to individual genomic data because of the ethical and interpretative issues that may be encountered. For example, if an asymptomatic individual has the variant profile consistent with schizophrenia, how likely is it that this person will ever be symptomatic? And how will this information influence: that person's lifestyle; the extent to which this information is shared with family members, friends, work colleagues, or insurance providers; the advisability of parenting; or if already a parent, the extent to which this information is communicated to the offspring? These issues and many others must be carefully considered by each individual in consultation with his/her health care providers.

Biomarkers

In the broadest sense, biomarkers are any measureable feature of a patient that can serve to predict disease likelihood and severity, disease course,

disease response to treatment, or the current general health status of the patient. Optimally, a surrogate biomarker for disease severity with disease severity can be objectively measured; and so can serve as a clinical trial outcome measure in place of a more subjective "soft" outcome measure such as a symptom rating scale. Biomarkers for psychiatric conditions have been sought for decades. Laughren (2010) discussed the last 50 years of psychiatric drug development and concluded that biomarker approaches were the most likely methods to help advance the field. This has been echoed by many in the research community (e.g., Filiou and Turck, 2011; Li et al., 2012; Nutt and Attridge, 2014). The challenge has been to identify and validate biomarkers meeting these criteria that can be used as trial outcome measures and that would also be accepted by regulatory authorities for drug approvals. To date, this has had no more than limited success in most indications, and no success yet in psychiatric indications. Hopefully the wide variety of imaging, genetic, and other approaches that are underway will soon change this landscape.

Patient Centricity

Traditional drug development processes have not been particularly patient centric. As an example, research protocols had little, if any input from patients, resulting at times in complex burdensome protocols that either excluded most patients or negatively impacted recruitment and retention of research subjects, and the success of the programs.

More recently, there has been a realization that this needs to change. Also in some disease areas, especially rare and orphan diseases, patient advocacy groups are themselves funding clinical trials and having a stronger voice.

More "Real-World" Data

One of the criticisms of drug development programs has been that the data generated is not particularly helpful to clinicians in helping them make treatment decisions and choices. This is driven by a misunderstanding of the purpose of phase 2 and phase 3 clinical trials. These programs are conducted to meet the requirements of regulatory authorities and traditionally it was the postapproval phase 4 studies that were conducted to address questions that would help prescribers understand the optimal use of the new treatment.

As payors across the world have increased their demand for data that justifies pricing above generic treatments, it has become imperative to generate this data earlier in development of new treatments. This will lead to a modification of the issues that are addressed in drug development in preapproval programs.

MORE RELEVANT OUTCOME MEASURES

Traditionally in psychiatric drug development, outcome measures used, measured symptom severity and the impact of new treatment on these symptoms. However, it has become clear that reducing symptoms is not enough. Both payors and patients are looking for the impact on functioning and other novel domains. This will lead to new ways of assessing the impact of a new treatment on patients.

Disease Interception

Throughout the history of medicine, the main focus has been on treating diseases once they have become manifest. It is clear that in many conditions this may be too late, the clearest example currently being Alzheimer disease. There are efforts underway across neuroscience to identify patients that may be at risk and developing interventions that would prevent the disease before it develops. This approach has implications both for regulatory bodies and payors if physicians are to intervene that early in the natural history of a disease.

Regulation of Drug Approvals

When clinical trials yield results that demonstrate the potential benefits of efficacious and safe compounds, these data must be submitted to regulatory authorities for their scrutiny before approval for marketing is granted. It is important to understand the landscape in which regulatory guidelines have developed in order to put the challenges of drug development into perspective. This section reviews the history and the current US regulatory environment for drug development.

Background

The FDA, according to its mission statement, "is responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation's food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing the public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable; and helping the public get the accurate, science-based information they need to use medicines and foods to improve their health." The FDA plays a role in overseeing and guiding development of the medications and devices that are used in the practice of psychiatry and ensuring that they are effective, offer a favorable risk to benefit ratio, are accompanied by adequate directions for use, can be manufactured with reliable quality, and are not promoted in a misleading fashion.

HISTORY OF DRUG REGULATION

The history of American drug regulation features a series of legislative responses to public concerns. A century ago there were no restrictions on what could be sold as medicine and what claims could be made about the products. *Patent* medicines were widely sold for a variety of ailments. Labels did not list ingredients. Some medicines contained ethanol, opium, morphine, heroin, or cocaine; others contained harmless (and ineffective) ingredients. Popular press accounts of the harms of these *tonics* sold to unsuspecting customers, along with concerns about food adulteration and the dangers of chemical additives, led to the passage of the Pure Food and Drug Act of 1906, championed by Harvey Wiley, head of the Bureau of Chemistry in the Department of Agriculture.

Pure Food and Drug Act of 1906

Wiley law, the Pure Food and Drug Act of 1906, was only six pages long. It prohibited the manufacture and interstate shipment of "adulterated" and "misbranded" foods and drugs. This gave the government the authority to go to court against illegal products but did not require any premarketing approval. Initially, the law also did not outlaw false therapeutic claims. A 1912 amendment declared such claims illegal but required that the government prove fraudulent intent. Thus, the only requirement was that the purveyor of a medication believes that the drug was effective. Regarding labeling, the law required only that a contents statement, if used, must be truthful. Not until a 1913 amendment was a statement of contents required.

Elixir Sulfanilamide Tragedy of 1937

The shortcomings of the 1906 law limited the government's ability to ensure the safety of drugs. Although the need for reform of drug regulation was apparent by the early 1930s, legislation proposing expansion of the regulatory authority of the FDA was held up by debate in Congress and opposition from the food and drug industries. Finally, in 1937, a public health scandal emerged that generated the political will to pass the bill. A chemist at Massengill, attempting to develop a palatable formulation for a sulfa antibiotic, created a product that used diethylene glycol as a solvent. No premarket testing, in humans or animals, was required under the laws then prevailing, and none was undertaken. As a result of exposure to this solvent (akin to antifreeze), more than 100 people died, and many of them were children. As it happens, the Pure Food and Drug Act gave the government the authority to take action against the manufacturer, only because the product was labeled an *elixir*. By definition, an *elixir* uses ethanol as a solvent; had the manufacturer labeled the product a *solution,* it would not have been in violation of any law.

Food, Drug, and Cosmetic Act of 1938

Although there had been other crises associated with the marketing of untested, unsafe drugs, the elixir sulfanilamide tragedy spurred the passage of the Food, Drug, and Cosmetic Act of 1938. This law contained a number of important provisions concerning drug regulation. The 1938 law required that new drugs undergo safety testing, the results of which would be submitted to the FDA in a new drug application (NDA). Premarketing approval of the NDA was required before a drug could be sold. The law also required that drugs have adequate labeling for safe use. Furthermore, it clearly prohibited false therapeutic claims for drugs, without the requirement that the government show fraudulent intent. In addition, the FDA was given authority to conduct factory inspections.

Thalidomide Tragedy of 1962

By the early 1960s, Senate hearings on strengthening the regulation of drugs were once again under way. In the midst of these hearings, chaired by Senator Estes Kefauver, came the news of the devastating effects of thalidomide (Thalomid), which was being marketed in Europe. Although the NDA had been submitted to the FDA for review, the medical officer responsible for the review, Frances Kelsey, had requested additional safety information, and the drug had not yet been approved. Kelsey's role in protecting the American public from the dangers of thalidomide was widely reported and generated support for passage of what became known as the Kefauver-Harris Amendments in 1962. These amendments required drug manufacturers to prove to the FDA that their products were safe *and* effective before marketing. They established that the evidence of efficacy must be derived from "adequate and well-controlled trials." Furthermore, the amendments also addressed the use of drugs in clinical trials. Under the Kefauver-Harris Amendments, the current investigational new drug (IND) process was established. Under the law, the FDA had to be provided with full details of the clinical investigations, including drug distribution, and the clinical studies had to be based on previous animal investigations to ensure safety.

After the addition of the efficacy requirement, the FDA commissioned a review by the Institute of Medicine of all drugs approved between 1938 and 1962 to determine whether they were effective as well as safe. This process, known as the drug efficacy study implementation (DESI), resulted in the removal of some drugs from the market, whereas others were determined to be effective. Nonprescription drugs were also evaluated under a similar process, which resulted in publication of monographs establishing which ingredients may be "generally recognized as safe and effective" for various conditions.

IND Regulations

After the 1962 amendments, the FDA issued and implemented regulations concerning the investigational use of drugs; these regulations were updated and revised in 1987. The revisions were intended to "ensure FDA's ability to monitor carefully the safety of patients participating in clinical investigations, while also facilitating the development of new beneficial drug therapies." The regulations serve to "focus FDA's attention during the early phase of clinical research on protecting the safety of human test subjects and to give sponsors greater freedom to design, revise, and implement clinical research studies" and to "facilitate consultation between FDA and drug sponsors, once the preliminary human studies have been completed and a drug appears to have marketing potential, to help ensure that the design of major clinical trials is acceptable and will support marketing approval if the test results are favorable." And beginning in the mid-1970s, the FDA began giving advice on the kinds of studies and data that would be needed to support drug approval. Clinical guidances have been published, setting forth the data needed for drugs in various therapeutic categories.

PDUFA, FDAMA, and Pediatric Provision

Thirty years after the 1962 amendments, frustration over lengthy review times led to the passage of the Prescription Drug User Fee Act (PDUFA) of 1992, which charged fees for NDA review to facilitate the expansion of the FDA's review resources and, in return, ensured action on an application in a specified period of time. PDUFA was renewed with the passage of the FDA Modernization Act (FDAMA) of 1997, which further shortened review times and made additional changes in the review process. The authority to collect user fees was again reauthorized as part of the Public Health Security and Bioterrorism Preparedness Act of 2002 and the Food and Drug Administration Amendments Act of 2007 (FDAAA).

Among the provisions of FDAMA were the pediatric exclusivity provisions. These offered incentives, in the form of an additional period of protection from generic competition, to sponsors for fulfilling an FDA request for pediatric data on their products. In 2002, the Best Pharmaceuticals for Children Act (BPCA) was passed, providing further clarification of the pediatric exclusivity program and establishing a system for conducting studies through the National Institutes of Health for high-priority drugs that were already off-patent or for which the commercial sponsor declined to respond to the agency's request. In the first 10 years after the passage of FDAMA, over 150 submissions of data in response to written requests were evaluated to determine whether pediatric exclusivity should be granted. Among these were studies of a number of psychotropic agents, including antidepressants, antipsychotics, and anxiolytics. In many

cases, the results of the studies led to labeling changes stating that safety and efficacy in children had not been established; yet pediatric exclusivity is awarded even in these cases. In addition, under the provisions of the BPCA, upward of 50 drugs have been included on a priority list, including lithium (Eskalith), bupropion (Wellbutrin), and clonidine (Catapres).

Although FDAMA and BPCA established incentives for pharmaceutical companies to conduct pediatric studies, such studies remained optional. Subsequently, in 2003, the Pediatric Research Equity Act (PREA) authorized the agency to require sponsors to conduct pediatric studies as part of their development program. The requirements may be waived if the drug is not likely to be used in a substantial number of pediatric patients or does not represent a meaningful therapeutic benefit for pediatric patients. In addition, the agency may also waive the requirement if "there is evidence strongly suggesting that the drug or biological product would be ineffective or unsafe in all pediatric age groups," or on the grounds that the studies are impossible or highly impracticable. The agency may require that the pediatric studies are submitted as part of the initial application or may defer all or some of the pediatric studies until after the application is approved for use in adults.

The FDAAA of 2007 reauthorized PDUFA, PREA, and BPCA as well as creating new programs to enhance postmarketing safety surveillance and the FDA's ability to communicate safety information.

STRUCTURE OF THE FDA

There are five headquarters centers in the Washington, D.C., area: The Center for Drug Evaluation and Research (CDER), the Center for Biologics Evaluation and Research (CBER), the Center for Devices and Radiological Health (CDRH), the Center for Veterinary Medicine (CVM), and the Center for Food Safety and Applied Nutrition (CFSAN). Staff in these offices work primarily on product review and regulatory policy. In addition, a network of field offices throughout the United States focuses on inspection and surveillance, laboratory work, and public and industry education.

Most relevant to psychiatric treatment is the work of CDER, where drugs and therapeutic biological treatments are reviewed, and CDRH, which has jurisdiction over medical devices such as those used in ECT. This section will address the review of drugs and biological therapeutic products as undertaken in CDER.

NEW DRUG DEVELOPMENT

The development of a new pharmacological treatment of a psychiatric (or any other) disorder usually begins with exploration of a compound's actions in in vitro and animal investigations. These investigations may be carried out before involving the FDA. Indeed, initial safety testing in animals is required before beginning human studies that are subject to

FDA review. Most compounds are abandoned in these early stages of development. However, those that appear promising and are reasonably tolerated in animal safety studies may go forward in development.

Definition of a Drug

The Food, Drug, and Cosmetic Act defines drugs as:

1. Articles recognized in the official U.S. Pharmacopeia, the official Homeopathic Pharmacopeia of the United States, or the official National Formulary
2. Articles *intended for* [emphasis added] use in the diagnosis, cure, mitigation, treatment, or prevention of disease
3. Articles (other than food) intended to affect the structure or function of the body
4. Articles intended for use as a component of any article specified previously

Therefore, it is the *intended use* of the substance that defines it as a drug. As soon as a substance is intended for human use toward one of these objectives (i.e., when human studies begin), the substance is, by definition, a drug and is subject to regulation under the drug provisions of the Food, Drug, and Cosmetic Act.

Note that therapeutic biological products are a subset of drugs. Although the term "drug" is often used to designate a typical small-molecule product and the terms "biologic" or "therapeutic biologic" to designate the large, biologically derived substances used therapeutically such as monoclonal antibodies, both types of products are considered drugs outside the FDA. In this section, the term *drug* will be used to encompass all products meeting the statutory definition.

Phases of Drug Development

Drug development to support a commercial marketing application proceeds in somewhat overlapping phases. Nonclinical (also called *preclinical*) studies begin before human studies but continue throughout the clinical development period. Each phase of human testing is supported by animal tests that are appropriate to the extent of planned human exposure in the ensuing studies. Human studies proceed from basic characterization of the drug product to establishment of efficacy and elucidation of the adverse event profile in the intended population of use. Although the categorizations phase 1, phase 2, and phase 3 are used commonly, the development of a drug does not proceed linearly through these phases. For example, studies of drug–drug interaction and studies of pharmacokinetics in renal or hepatic impairment are both considered phase 1 studies, but often occur late in drug development. Finally,

unanswered questions or new indications may be explored after the drug has been approved for marketing and are commonly called phase 4 studies.

Nonclinical Studies

Nonclinical studies that are sufficient to establish a tolerable dose and to identify the target organs of toxicity for a new drug must be conducted before first use of a new chemical entity in humans. A standard battery of animal studies and in vitro studies are required to support a marketing application, with the duration and timing of these studies related to the proposed duration of use of the drug in the clinical program. Thus, acute toxicology studies are needed to support single-dose human administration, whereas longer studies must be completed before using the drug in human studies involving chronic exposure.

Phase 1. Phase 1 studies represent the initial introduction of the new drug into humans. These studies, usually conducted in healthy volunteers, typically in closely monitored (often inpatient) settings, serve to characterize the absorption, distribution, metabolism, and excretion of the compound, to identify overt toxicities associated with drug administration, and to establish a tolerable dose for use in further studies. In some circumstances, phase 1 studies may involve patients and may be designed to provide early indications of the drug's efficacy; examples include drugs intended as chemotherapeutic or anti-HIV agents. Phase 1 also includes studies in which investigational drugs are used as research tools to explore biological phenomena or disease processes. The objective of phase 1 in commercial drug development is to obtain sufficient information about the drug's pharmacokinetics and pharmacological effects to permit the design of well-controlled, scientifically valid, phase 2 studies. The total number of subjects and patients included in phase 1 studies varies with the drug but is generally in the range of 20 to 80.

Phase 2. Phase 2 includes the initial controlled clinical efficacy studies. These studies typically include carefully selected patients with the disease or condition under study and are usually well controlled, closely monitored, and optimized for the collection of efficacy data. In phase 2, exploratory work is undertaken to help determine the optimal doses of the drug. In conditions for which no standard outcome measures have been defined, studies may explore different approaches to capturing the effect of the drug. Safety data are collected in this phase to determine the common short-term side effects and risks associated with the drug.

Phase 3. After preliminary evidence suggesting effectiveness of the drug has been established in phase 2 trials, additional information about effectiveness and safety is needed to evaluate the overall risk to benefit

relationship of the drug and to provide an adequate basis for product labeling. Phase 3 studies provide this information. The inclusion and exclusion criteria in phase 3 studies are usually broader than in phase 2, in order to select a population that is more representative of the patients who will be exposed to the drug during marketing. Phase 3 studies may include from several hundred to several thousand subjects, including individuals with a broad range of typical comorbid conditions and concomitant medications seen in the target population.

Phase 4. Once the drug has been approved, subsequent postmarketing activities may be conducted in phase 4. Studies to elucidate specific issues about a drug, which are considered important for optimal use but not essential to know before drug approval, may be performed. Studies to support approval for additional indications (e.g., use in pediatrics, if not previously established) may also be conducted. Programs of active surveillance for adverse events may be undertaken, as well as the required passive collection of adverse event reports from patients, health care providers, and other sources, which manufacturers must report to the FDA periodically.

IND Review Process. Before beginning human studies, the commercial drug sponsor must submit a request for an IND exemption from interstate shipping laws, or an IND, for review by the FDA. Once the IND is submitted, the sponsor must wait 30 calendar days before initiating any clinical trials. During this time, the FDA has an opportunity to review the IND for safety to ensure that research subjects are not subjected to unreasonable risk.

REVIEW EMPHASIS AND PROCEDURES. According to the Code of Federal Regulations:

FDA's primary objectives in reviewing an IND are, in all phases of the investigation, to assure the safety and rights of subjects, and, in phases 2 and 3, to help assure that the quality of the scientific evaluation of drugs is adequate to permit an evaluation of the drug's effectiveness and safety. Therefore, although FDA's review of phase 1 submissions will focus on assessing the safety of phase 1 investigations, FDA's review of phases 2 and 3 submissions will also include an assessment of the scientific quality of the clinical investigations and the likelihood that the investigations will yield data capable of meeting statutory standards for marketing approval.

Thus, the reviewers pay close attention in all reviews in determining whether the risks of the study are appreciated, anticipated, communicated, and managed by the sponsor. For later phase studies, they also consider whether the study design is adequate to meet the scientific and regulatory objectives of the study. During the review of an initial IND submission (as

well as the review of subsequent submissions of additional protocols and amendments), the interdisciplinary review team approaches these issues from various angles including: clinical study results; chemistry/product quality; pharmacology/toxicology information; clinical pharmacology data; and biostatistics use and results.

Clinical Hold. If no concerns are identified by the interdisciplinary review team, the IND goes into effect, and the studies proposed in the initial submission are permitted to proceed. Once the IND is in effect, additional protocols, study results, and safety information are submitted. For each new clinical study proposed, the review process is similar, but the sponsor is not required to wait 30 days before initiating subsequent studies.

However, at the time of initial IND review or at any time during drug development, the FDA can place human studies under an IND on *clinical hold*. A clinical hold, according to the Code of Federal Regulations, is "an order issued by FDA to delay a proposed clinical investigation or to suspend an ongoing investigation. The clinical hold order may apply to one or more of the investigations covered by an IND."

Under the Code of Federal Regulations, the FDA may impose a clinical hold on an IND for any of the following reasons:

- Human subjects are or would be exposed to an unreasonable and significant risk of illness or injury.
- The clinical investigators named in the IND are not qualified by reason of their scientific training and experience to conduct the investigation described in the IND.
- The investigator brochure is misleading, erroneous, or materially incomplete.
- The IND does not contain sufficient information required under §312.23 to assess the risks to subjects of the proposed studies.
- The plan or protocol for a phase 2 or 3 study is clearly deficient in its design to meet its stated objectives. When a clinical hold is issued, a sponsor must address the issues that are the basis of the hold before the order is removed, and the study may proceed.

Marketing Application Submission and Review. The culmination of the development program is the submission of the NDA for a small-molecule drug product or a biologics licensing application (BLA) for a therapeutic biological product. FDA staff have 10 months (6 months for a drug designated as a priority application owing to its potential to offer a breakthrough in treatment) to assess thoroughly the raw data and to compare their own conclusions about the data to the applicant's conclusions presented in written reports. The objective is to determine

whether the sponsor (now called the *applicant*) has met the regulatory burden for marketing: Demonstrating efficacy through "substantial evidence" from "adequate and well-controlled investigations, including clinical investigations, by experts qualified by scientific training and experience to evaluate the effectiveness of the drug involved" and demonstrating safety through "all tests reasonably applicable." Therefore, in the course of review, FDA staff assess whether the clinical studies were indeed appropriately designed and conducted, whether the data support the conclusion that the drug is effective, whether the proper human and animal safety data ("all tests reasonably applicable") were collected and illustrate a favorable risk to benefit ratio, and whether the manufacturing methods and controls are sufficient to ensure consistency of identity, quality, purity, and strength of the product.

SAFETY REVIEW. The purpose of the safety review is twofold: First, to determine the adequacy of the extent of exposure and the specific tests carried out in the safety evaluation (such as laboratory tests, electrocardiograms [ECGs], and adverse event collection) and to assess whether it meets the standard of "all tests reasonably applicable." For example, approval of a drug in a class known to be associated with a prolongation of the QT interval might be withheld if safety review determined that the effects of the drug on cardiac conduction were not thoroughly evaluated. The second purpose is to characterize the safety profile, so that the risks of the drug may be weighed against the benefits identified in the efficacy review. Characterization of the safety profile includes identifying and estimating the frequency of common adverse events that are, or may be, causally related to the use of the drug; identifying factors that predict the occurrence of adverse events, such as age, gender, concomitant medication, or illness; and examining the data for events that suggest problems that are so serious that the use of the drug should be limited or approval withheld altogether. The clinical reviewer evaluates all available safety information and integrates it into an overall picture of the drug's effects.

EFFICACY REVIEW. The review of efficacy, conducted jointly or in parallel by the medical officer and biostatistician, uses raw data from the pivotal clinical trials in the application to confirm the applicant's conclusions about the study results. Any deviations from the protocol-specified study plan are evaluated for possible impact on the outcome of the studies. Reviewers analyze the applicant's assumptions about outcome for protocol violators, subjects who withdraw early from studies, or subjects with missing data. They test the impact of alternative assumptions on study outcomes. The objective of the efficacy review is to determine whether the studies submitted were "adequate and well controlled" and whether they

provide "substantial evidence" of efficacy. For the most important trials, the review also includes clinical trial site inspections by the Division of Scientific Investigation (DSI). By examining the trial site, documentation, source materials, and equipment, the DSI establishes whether there are important violations that call into question the results of the study. Such findings are unusual but do occur as a result of deliberate fraud, error, or incompetence.

Abuse Liability Assessment. For most psychotropics, the NDA also includes a section addressing the abuse potential of the product. Assessment of abuse potential is required for many drugs with CNS activity. This testing may include a battery of in vitro receptor-binding studies, various animal studies of the rewarding properties of the drug, and, if preliminary studies suggest the potential for abuse, human laboratory studies. Data from these studies, as well as other information concerning the chemical structure of the compound, and any other relevant data from literature or epidemiological reports are reviewed as part of the NDA and are considered in writing the relevant sections of the product package insert. Importantly, these data are also taken into consideration in preparing a recommendation concerning control of the substance under the Controlled Substances Act. This recommendation is prepared by a team within the Office of the Director of CDER at the FDA and is forwarded through the secretary of Health and Human Services to the Drug Enforcement Administration.

PHARMACOLOGY AND TOXICOLOGY. By the time that the NDA is submitted, the nonclinical data include a variety of animal studies. There should be both acute and multidose toxicity studies, the durations of which are determined by the intended use of the product. Also included are reproductive toxicology studies, mutagenicity studies, carcinogenicity studies for chronically used products, and any special toxicity studies (such as dermal sensitization studies for a transdermal product and blood compatibility studies for an intravenous [IV] product). There also should be studies of the absorption, distribution, metabolism, and elimination of the drug in animals, because these data are needed to compare the dose response in animals to the dose recommended for humans. In the course of review, the pharmacologist examines the results of these studies and also critically evaluates the study design and conduct to determine if the data may be accepted as valid.

CLINICAL PHARMACOLOGY. The clinical pharmacology reviewer examines data relevant to understanding all aspects of the absorption, distribution, metabolism, and excretion of the drug. This includes information on any important influences on these parameters, such as food effects, drug interactions, or effects of age, gender, or hepatic or renal impairment. This

information is included in the clinical pharmacology section of the label and often forms the basis for important precautions to ensure safe use of the product. Explorations of exposure–response relationships for efficacy and safety end points are also an important part of the clinical pharmacology review. Some pharmacogenomic analyses (analyses of genetically based differences in pharmacology), such as explorations of the role of metabolic polymorphisms, may also be undertaken.

CHEMISTRY/PRODUCT QUALITY. In reviewing an NDA, the chemistry reviewer examines the manufacturing information to determine whether there are appropriate specifications and test methods in place to ensure identity, quality, purity, and strength, as well as consistency from batch to batch. For a BLA, the quality reviewer, similarly, is responsible for ensuring the quality, safety, efficacy, availability, and security of therapeutic protein and monoclonal antibody products. The reviewer also evaluates information about stability, including the adequacy of the stability data to support product use, expiration dating, and any concerns about packaging or shipping that might affect stability. In addition, the reviewer takes into account the findings of inspections of the manufacturing facilities, which are undertaken to ensure adherence to the principles of good manufacturing practices. Reviewers of biological products participate in the actual preapproval and biennial facility inspections. The FDA may withhold approval if inspections show significant procedural problems at the facilities that are responsible for manufacturing or packaging the product.

REGULATORY DECISION. All of the discipline reviews are taken into consideration in making an assessment of whether the drug's benefits outweigh its risks for the intended use in the intended population. If a drug offers significant benefits for a narrowly defined population but carries significant risks, the FDA may decide to approve the drug subject to special conditions to ensure that physicians understand and comply with using the drug only for those in whom the anticipated benefits can be expected to be greater than the possible risks.

If there are unanswered questions or unresolved issues in an application or concerns about safety or lack of efficacy, the FDA may withhold approval. The applicant is issued a letter explaining the deficiencies precluding approval and instructions on how to address these deficiencies.

PRODUCT LABELING. For the physician and the patient, the most obvious product of the NDA review process (apart from the regulatory decision that makes the product available on the market) is the package insert or label. The multidisciplinary review team carefully examines language drafted by the NDA applicant and ensures that the statements throughout the label are supported by the submitted data. The format of the label is set forth in

the Code of Federal Regulations (21 CFR §201).

Postapproval (Phase 4). Despite careful premarket review, postmarketing surveillance of drug adverse effects is also essential. It is evident that all possible side effects of a drug cannot be anticipated based on preapproval studies. The total exposure to an investigational drug during its development depends, to some extent, on the novelty of the compound and on the presence of any specific safety concerns. However, for practical reasons, it is rarely possible to have sufficient premarket exposure to characterize the occurrence of rare adverse events. According to the current recommendations of the International Conference on Harmonization, for new chemical entities that are to be used chronically (or repeatedly but intermittently) in the treatment of conditions that are not immediately life threatening, the number of patients exposed should be sufficient to detect serious adverse events occurring at a rate of approximately 1 per 1,000 in short-term use. It is recommended that the safety database include at least 1,500 subjects. Of these, 300 to 600 should be treated for at least 6 months, and 100 should be treated for 1 year. Applying the so-called rule of three, if a particular serious adverse drug effect is not observed in the 100 subjects exposed for 1 year, this can provide reasonable assurance that the true cumulative 1-year incidence is no greater than 3 percent. However, this rule of three represents only 95 percent confidence limits. It must be noted that even a database of 3,000 subject exposures stands a 5 percent chance of missing events that occur at a rate of 1 per 1,000, and such a rate may translate into a significant number of occurrences when the drug is introduced into a population of hundreds of thousands.

Therefore, the FDA maintains a system of postmarketing surveillance and risk assessment programs to identify adverse events that did not appear during the drug approval process. The agency monitors adverse reactions reported by drug companies, consumers, and physicians and seeks out signals suggestive of drug-related events. The agency uses this information to update drug labeling, to identify unanticipated drug–drug or drug–disease interactions, to spot common medication errors and to take action to prevent them, and, on rare occasions, to re-evaluate the approval or marketing decision.

POSTMARKETING SAFETY. Due to practical limitations on how many patients can be studied in clinical trials for a new drug, it is inevitable that some safety concerns will come to light until after a new drug is used in a broader population after approval. Unlike Frances Kelsey, the modern FDA reviewer often does not have foreign postmarketing data available to supplement the clinical trial data submitted in the drug application since drugs are now frequently approved first in the United States. In the post-

PDUFA era, critics of the FDA raised concerns that the emphasis on bringing new drugs to market more rapidly had led to a failure to identify important safety issues. Several high-profile drug safety issues led the agency to examine its procedures and to launch several initiatives aimed at improving the safe use of medicines, including a dedicated Safety Policy and Communication staff that ensures that physicians, health provider groups, and patients are alerted to important new safety information in a timely manner. The Safety Policy and Communications staff includes a Drug Safety Oversight Board (known as the DSB) that was established to provide independent oversight and advice to the center's director on the management of important and emerging drug safety issues. The DSB provides perspective from scientists not involved in the initial review and approval of a particular marketing application and provides a venue for adjudicating organizational disputes concerning the management of drug safety issues. In 2007, the Safety Policy and Communications Staff launched a new tool for communicating safety issues, the FDA Drug Safety Newsletter, which is distributed electronically and viewable at the FDA's Web site.

FUTURE DIRECTIONS FOR FDA

In 2004, the FDA launched a new initiative known as the *Critical Path Initiative,* which is intended to "stimulate and facilitate a national effort to modernize the scientific process through which a potential human drug, biological product, or medical device is transformed from a discovery or 'proof of concept' into a medical product." By identifying key areas in need of attention and partnering with other agencies and organizations to initiate research, the FDA is working to improve the tools used to evaluate the safety and efficacy of human and veterinary products as well as the safety and nutrition of food and food ingredients. A list of areas representing high-priority opportunities for improvement was disseminated and work has been initiated in a variety of projects.

One project specific to psychiatry is an effort under the aegis of the *Biomarkers Consortium,* a public/private biomedical research partnership supported by the Foundation for the National Institutes of Health (FNIH). Among their first projects is an effort to identify genomic biomarkers for treatment response in major depressive disorder. Many other critical path projects are broadly relevant to psychotropic drugs, including work on examining the genetic basis of adverse drug events; work intended to broaden understanding of the biochemical and genetic basis of drug-induced liver injury; a database of digital ECGs collected in drug-approval studies to be used to improve methods of measuring drug effects on cardiac conduction; and efforts to identify nephrotoxic biomarkers that predict the effects of drugs on kidney function.

As drug development becomes more and more of a global endeavor, the

need for regulatory authorities in different countries and regions to interact and discuss regulatory issues and challenges becomes more important.

CONCLUSION

Drug development in every field has become increasingly complex, costly and challenging, and in no other therapeutic area is this more evident than in psychiatric conditions. The challenges are enormous in translating from the Gordian knot of poorly understood CNS pathophysiological processes and nonpredictive models into clinical trials that will have a good probability of success. Nevertheless, there are new technological and scientific approaches that provide a basis for increased hope as clinical trials for psychiatric conditions move into the 21st century. The goal is clear. Psychiatrists must discover, develop, and obtain regulatory approval for new medicines that will improve treatment of many unmet or poorly served medical needs in the psychiatric field. Patients are waiting.

▲ 34.3 Medication-Induced Movement Disorders

PHILIP G. JANICAK, M.D., AND KUMAIL HUSSAIN, M.D.

All antipsychotics can induce movement disorders. Thus, the *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition (DSM-5) continues to characterize these agents as "neuroleptics" in recognition of this property. Although controversial, these agents are categorized as first-generation (or typical) and second-generation (or atypical) antipsychotics with one potential differentiation being their propensity to produce movement disorders. In addition to antipsychotics, a variety of other psychotropic and nonpsychotropic agents can also produce these symptoms (Table 34.3–1). For example, lithium (Eskalith), anticonvulsants, or antidepressants can all induce tremors; dopamine-receptor agonists can induce dyskinesia; some antidepressants can induce akathisia or produce abnormal movements upon their discontinuation; and prochlorperazine (Compazine) or metoclopramide (Reglan) can induce pseudoparkinsonism. Based on the specific agent and type of movement problem, various strategies are employed to counter these adverse effects.

HISTORY

An important observation is that spontaneous movement disorders (e.g., blunted affect, psychomotor slowing, buccal–lingual–masticatory movements, catatonia, alogia) can occur in patients with schizophrenia even in the absence of exposure to antipsychotic medications. For example, one review found a 4 to 7 percent prevalence of dyskinetic movements in patients with schizophrenia not on an antipsychotic. This risk increases with age and illness chronicity. Thus, an association between psychotic illness and movement abnormalities was described years before the introduction of antipsychotics.

The first antipsychotic, chlorpromazine (Thorazine), entered clinical practice in 1952. As a specific and effective medication for psychosis, it revolutionized treatment for millions of patients who until then had received little beyond custodial care. Additional agents were synthesized in the phenothiazine class and eventually several other first-generation antipsychotics (FGAs) became available. All appeared equally effective if given in sufficient bioequivalent doses.

Problems with movement disorders went relatively unnoticed with the early FGA, low-potency agents. Symptoms such as sedation, anticholinergic effects, and hypotension, however, encouraged the development of more potent and specific dopamine 2 (D2) receptor antagonists, culminating with the introduction of haloperidol (Haldol) in 1968. Since this agent had

little effect on other receptors, previous troublesome adverse effects could usually be avoided or substantially reduced. Before the introduction of the second-generation antipsychotics (SGAs), a common strategy was to use higher doses of a high-potency FGA with the belief that optimal efficacy could only be obtained at the cost of some extrapyramidal symptoms (EPS). This approach resulted in an increased incidence of acute and late-onset movement syndromes (e.g., pseudoparkinsonism and tardive dyskinesia). Not surprisingly, adherence was compromised because patients often felt the benefit of treatment was outweighed by such adverse effects. Adjunctive agents (e.g., benztropine [Cogentin]) were often used to control these problems but possessed their own set of uncomfortable (or even dangerous) anticholinergic effects. Coming full circle, older, lower-potency FGAs were then used as an alternative approach to minimize acute movement syndromes. Some psychiatrists also maintained that weaker D2 antagonists could produce superior outcomes for certain patients while minimizing these risks. This position was supported with the release of the lower-potency D2 antagonist, clozapine (Clozaril) in 1990.

DIAGNOSTIC CRITERIA

The DSM-5 lists 10 categories under "Medication-induced Movement Disorders and Other Adverse Effects of Medication." Clinical syndromes are divided into those associated with antipsychotic (neuroleptic) use and those associated with other psychotropic and nonpsychotropic agents. Neuroleptic-related syndromes are divided according to the usual time of onset in relation to starting medication or increasing the dose. In general, SGAs cause less frequent and less severe movement disorders than their first-generation counterparts. In sensitive individuals, however, these symptoms also occur with SGAs. Further, the reduction in incidence and severity of abnormal movements may delay recognition when they do occur. The specific categories include neuroleptic or other medication-induced parkinsonism; neuroleptic malignant syndrome (NMS); medication-induced acute dystonia and akathisia; tardive dyskinesia; tardive dystonia and akathisia; medication-induced postural tremor; other medication-induced movement disorder; and antidepressant discontinuation syndrome.

The term "neuroleptic" (from the Greek word meaning to "clasp the neuron") includes existing antipsychotics, certain dopamine-blocking drugs used to treat gastrointestinal symptoms (e.g., metoclopramide) and amoxapine (Asendin), an antidepressant whose active metabolite has dopamine antagonist activity. The remaining categories include movement disorders such as tremor or parkinsonism induced by antipsychotics or other medications. Table 34.3–2 lists a brief description of the 10 categories provided in the DSM-5.

CENTRAL NERVOUS SYSTEM CONTROL OF MOVEMENT

Cortical motor areas, the cerebellum, basal ganglia, and related subcortical nuclei control normal movement. Other CNS areas which govern motivation are also important for the spontaneity and nature of movement. The classic antipsychotic-induced movement disorders are mediated primarily by their impact on D2 receptors located in the extrapyramidal tract. Agents with high D2 receptor affinity are associated with a greater risk of developing acute and late-onset movement disorders.

Table 34.3–2. DSM-5 Categories for Medication-Induced Movement Disorders

Neuroleptic or other medication-induced parkinsonism	Tremor, muscular rigidity, bradykinesia, or akinesia developing within a few weeks of starting or raising the dose of a neuroleptic medication or after reducing a medication used to treat extrapyramidal symptoms.
Neuroleptic malignant syndrome	Severe muscle rigidity, elevated temperature, altered consciousness, autonomic dysregulation, and other related findings (e.g., diaphoresis, dysphagia, incontinence, mutism, elevated or labile blood pressure, elevated creatine kinase levels) developing in association with the use of certain medications.
Medication-induced acute dystonia	Abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk developing within a few days of starting or raising the dose of certain medications or after reducing a medication used to treat extrapyramidal symptoms.
Medication-induced acute akathisia	Subjective complaints of restlessness accompanied by observed movements (e.g., movement of the legs, rocking from foot to foot, pacing, or inability to sit or stand still) developing within a few weeks of starting or raising the dose of certain medications or after reducing a medication used to treat extrapyramidal symptoms.
Tardive dyskinesia	Involuntary choreiform, athetoid, or rhythmic movements of the tongue, jaw, or extremities lasting at least a few weeks and developing in association with certain medications for at least a few months. May be for a shorter period of time in elderly individuals.
Tardive dystonia	Dystonia which occurs late in the course of treatment and persists for months to years.
Tardive akathisia	Akathisia which occurs late in the course of treatment and persists for months to years.
Medication-induced postural	Fine tremor which develops during attempts to maintain posture in association with the use of certain medications.

tremor	
Other medication-induced movement disorder	This category is for medication-induced movement disorders not explained by any of the disorders listed above. Examples include (1) parkinsonian, acute akathisic, acute dystonic, or dyskinetic movements associated with a nonneuroleptic medication; (2) a presentation that resembles NMS but is associated with a nonneuroleptic; and (3) tardive dystonia.
Antidepressant discontinuation syndrome	Movement symptoms which occur upon discontinuation or dose reduction of an antidepressant in use for at least one month.

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Association; 2013.

These adverse effects are categorized into *hypokinetic disorders* (e.g., akinesia, bradykinesia) which involve a paucity of movement; or *hyperkinetic disorders* (e.g., dyskinesia, akathisia) which involve excessive movement. Such disorders are primarily mediated by the basal ganglia which includes the corpus striatum (caudate nuclei, putamen), globus pallidus (internal, external segments), substantia nigra (pars compacta, pars reticulata), and the subthalamic nucleus.

These structures modulate motor activity by a set of complex mechanisms, ultimately balancing inhibitory and stimulatory impulses via dopamine, as well as other neurotransmitters. The latter include serotonin (5-HT), acetylcholine (Ach), GABA and glutamate (Glu). In this context, the optimal range of D2 blockade in drug-naive patients may be very narrow. For example, studies indicate that D2 receptor occupancy in the corpus striatum with FGAs exceeding 78 percent is associated with increased risk of EPS, while levels less than 65 percent are associated with suboptimal efficacy. An important finding is that these levels can be achieved in first-episode patients with haloperidol doses as low as 1 to 5 mg per day.

NEUROLEPTIC OR OTHER MEDICATION-INDUCED PARKINSONISM

Clinical Presentation

The clinical presentations of antipsychotic-induced parkinsonism and idiopathic primary Parkinson disease are indistinguishable. Further, patients with subclinical Parkinson disease often experience a worsening of the disorder when exposed to an antipsychotic. The classic triad of symptoms includes *muscular rigidity* which can be continuous ("lead pipe") or cogwheeling (a discontinuous, ratchet-like muscle motion); *akinesia or bradykinesia* which are characterized by psychomotor retardation, a minimization of spontaneous motor activity, slowed speech, decreased arm movements during walking, shuffling gait, and masked facies. A *resting tremor* usually presents with rhythmic oscillations (3 to 6 Hz) affecting the head, tongue, jaw, legs, and extremities in a unilateral or symmetrical fashion. Although all three symptoms may be present, only

one is required for the diagnosis. Symptoms can develop within days to weeks of starting or increasing the dose of medication or after reduction of agents used to treat EPS. Not included in the criteria are other parkinsonian symptoms (e.g., poor balance, micrographia, shuffling gait) which are often seen in more severe cases and mimic the progression of Parkinson disease in a dose-related fashion. Women are more susceptible than men and the incidence is higher for those older than 60 years. Symptoms are not better explained by a mental or generalized medical disorder or an adverse effect of another medication.

Pathophysiology

Drug-induced parkinsonism results from a decrease in nigrostriatal dopamine activity. This can be induced by various actions, including depletion of dopamine in presynaptic stores (e.g., reserpine); dopamine-blocking agents (e.g., antipsychotics); and the atypical calcium blocking agent (e.g., cinnarizine [Stugeron]).

Treatment Options and Implications

This syndrome usually subsides with dose reduction or medication cessation. Since this is not always an option, alternative strategies include switching from a high-potency D2 blocking agent (e.g., fluphenazine [Prolixin]) to a lower-potency FGA (e.g., perphenazine [Trilafon]) or to an SGA (e.g., quetiapine [Seroquel]; aripiprazole [Abilify], a partial D2 agonist). Adjunctive anticholinergic agents such as benztropine (Cogentin) in divided doses of 2 to 8 mg per day; trihexyphenidyl (Artane) in divided doses of 6 to 10 mg per day; or diphenhydramine hydrochloride (Benadryl) in divided doses of 25 to 100 mg per day are usually effective in ameliorating this syndrome. Dopamine agonists such amantadine (Symmetrel) in divided doses of 100 to 300 mg per day may also be helpful if anticholinergics are not tolerated or in elderly patients. Thus, adequate management is usually achieved by modification of the activity of dopamine, acetylcholine, or both. In addition, preliminary data indicate that the addition of oral dehydroepiandrosterone (DHEA) to existing antipsychotic regimens may also improve pseudoparkinsonism symptoms. After control of these adverse effects is achieved, the gradual withdrawal of antiparkinsonian medication may be achieved without recurrence of EPS in some patients.

NEUROLEPTIC MALIGNANT SYNDROME

Clinical Presentation

The core symptoms of NMS include a generalized “lead pipe” *muscle rigidity* and an *elevated temperature* which may range from modest to severe (e.g., 106°F). *Altered consciousness* and *autonomic system*

dysregulation are also common characteristics. These complications typically occur within days after exposure to an antipsychotic. NMS, however, can vary in terms of symptom presentation (e.g., core symptoms are not always present with certain SGAs); progression (e.g., rapid to delayed in onset); and outcome (e.g., full recovery to death, particularly in unrecognized cases). Thus, the disorder can exhibit rapid or gradual onset of the following symptoms:

- Autonomic instability:
  - Diaphoresis
  - Tachycardia
  - Elevated or labile blood pressure
  - Urinary incontinence
  - Pallor
  - Sialorrhea
- Other symptoms:
  - Dysphagia
  - Dysarthria
  - Trismus
  - Myoclonus
  - Akinesia
  - Tremor
  - Changes in the level of consciousness, ranging from confusion to stupor to coma
- Laboratory findings:
  - Leukocytosis
  - Metabolic acidosis
  - Evidence of muscle injury (e.g., creatine kinase elevation)
  - Liver enzyme elevation

NMS-like symptoms should not be due to a general medical (e.g., thyrotoxicosis, malignant hyperthermia [MH]) or neurological (e.g., parkinsonian hyperthermia) disorder; the effects of another type of medication (e.g., serotonin syndrome); or be primary to the underlying psychiatric illness (e.g., malignant catatonia) (Table 34.3–3).

Data from Zarrouf FA, Bhanot V. Neuroleptic malignant syndrome: don't let your guard down yet. *Curr Psychiatry.* 2007;6(8):89–94.

Pathophysiology

A hypodopaminergic state which interferes with temperature regulation is the postulated mechanism for the development of this syndrome. NMS is associated with dopamine antagonists, the abrupt discontinuation of antiparkinsonian medications and, rarely, the abrupt discontinuation of a dopaminergic agent. This suggests that fluctuation in dopamine binding may be important in its etiology. Because dopamine receptors are widely distributed in the CNS and spinal cord, it is likely that the various symptoms seen in NMS are accounted for by dopamine dysregulation in different areas. Thus, blockade of dopamine receptors in the corpus striatum causes muscle contraction and rigidity which then initiates heat generation; whereas blockade in the hypothalamus may lead to impaired heat regulation. The autonomic dysfunction commonly seen in advanced cases may be caused by dopamine blockade of spinal neurons. The fluctuations in mental status (e.g., delirium, coma) may be secondary to hyperthermia and/or effects on the mesocortical dopamine tract.

Abnormal calcium availability in muscle cells may also contribute, given the potential for muscle damage reflected by high creatine kinase elevations. There are no direct data which link NMS and MH, although cautious use of antipsychotics is urged in patients with a history of MH. NMS may also be due to a dysregulation of the sympathetic nervous system.

The occasional familial clustering of NMS leads to an analysis of genetic factors which may predispose to this condition. For example, the A1 allele of the dopamine D2 receptor gene was observed to be overrepresented in patients who develop NMS compared with those who do not. This allele reduces the density and function of the dopamine receptor in the striatum

and caudate nuclei, leading to reduced dopaminergic metabolism in those CNS areas with high concentrations of the neurotransmitter. By contrast, polymorphisms of the serotonin receptor gene did not appear to be associated with NMS but may increase the risk of developing acute EPS.

Treatment Options and Implications

NMS can be fatal or produce residual sequelae (e.g., cognitive or other neurological deficits). Therefore, management involves the aggressive use of supportive measures, as well as more specific interventions. Early identification is important and patients at higher risk should be carefully monitored. Factors which may increase the risk of developing NMS include:

- Concurrent medical and neuropsychiatric issues:
  - Dehydration
  - Psychomotor agitation
  - Exhaustion
  - Comorbid neurological disorders such as encephalitis and traumatic brain injury
  - Low serum iron levels
- Psychiatric diagnosis and symptom history:
  - Mood disorders
  - Pre-existing catatonia
  - History of NMS
- Medication-related:
  - Parenteral administration
  - High potency FGAs (e.g., haloperidol)
  - High doses of an antipsychotic
  - Dose increases or intermittent nonadherence
  - Adjunctive lithium treatment
- Demographic factors:
  - Male gender
  - Younger age

One easily treatable risk factor is dehydration. Thus, as a preventative measure, severely ill or catatonic patients on an antipsychotic should receive oral fluids or intravenous (IV) hydration. In addition, patients should avoid excessively high temperatures. Very mild cases of low-grade temperature increases or mild creatine kinase elevations may be treated in a psychiatric unit, while a rapid onset or worsening of symptoms requires transfer to a medical intensive care unit. Re-exposure to an antipsychotic can be considered after full resolution of the episode. While switching to an SGA (e.g., clozapine) is often recommended, NMS also occurs with these

agents. A past history of this syndrome is another reason patients are started or switched to SGAs. The relative risk of developing NMS between the two generations of antipsychotics, however, is difficult to compare.

Although NMS is one of the few life-threatening psychotropic-induced complications, its infrequent occurrence and severe nature make controlled studies impossible. The best available data support the following strategies:

1. *Prevention:* Antipsychotics should be used cautiously in patients with dehydration, catatonic symptoms, basal ganglionic disease, or a history of NMS.
2. *Early identification:* Patients with early signs should have their antipsychotic immediately discontinued, supportive measures initiated, and careful reintroduction of these agents considered only if absolutely necessary.
3. *Treatment:* The most important step is early recognition and prompt withdrawal of the offending agent. All cases require supportive interventions which may include IV hydration, temperature control and, in more severe cases, ventilator support or dialysis. In advanced cases, admission to an intensive care unit is required with a fatal outcome occurring in up to 20 percent of cases. A variety of other treatments may also help, including the use of dopamine agonists (e.g., bromocriptine, amantadine); muscle relaxants (e.g., benzodiazepines, dantrolene); and, in selected patients, ECT (Table 34.3–4). In patients who require an antipsychotic for their ongoing psychosis after an episode of NMS, several steps may reduce the chance of recurrence. These include waiting at least 2 weeks after symptoms resolve before reintroduction is attempted; resolving prior risk factors (e.g., dehydration, avoiding concomitant lithium); and considering alternative therapies when appropriate (e.g., mood stabilizers, ECT). If rechallenge with an antipsychotic is necessary, choosing an alternate agent, starting with low doses and titrating slowly can also reduce the risk of recurrence.

Table 34.3–4.
Neuroleptic Malignant Syndrome: Treatment

Intervention	Dosing	Effectiveness
Amantadine	200–400 mg/day by mouth in divided doses	Beneficial as monotherapy or in combination; decreases death rate
Bromocriptine	2.5 mg twice a day or three times a day by mouth; may increase to a total of 45 mg/day	Mortality reduced when used as a single agent or in combination; may worsen psychosis, reduce blood pressure; induce emesis
Levodopa/carbidopa	Levodopa 50–100 mg/day IV as continuous infusion	Case reports of dramatic improvement; may worsen psychosis, reduce blood pressure, or induce emesis
Dantrolene	1 mg/kg/day parenterally for 8 days;	Benefits may occur in minutes or hours

	continue by mouth for 7 additional days	as a single agent or in combination
Benzodiazepines	1–2 mg intramuscular as a test dose; if effective, switch to oral route; consider if catatonic symptoms are present	Has been reported effective when other agents fail
Electroconvulsive therapy	Reports of good outcome with both unilateral and bilateral treatment; response may occur in as few as three treatments	Effective when medications have failed; also may treat underlying psychiatric disorder; may worsen cognitive function
Supportive measures	IV hydration and oxygenation	Often effective as an initial approach early in the episode
	Cooling blankets	Can be used initially to lower temperature
	Ice packs	A second line measure if a more aggressive approach is needed to lower temperature
	Ice water enema	Another second line measure if a more aggressive approach is needed to lower temperature
	Antipyretics	May be used to reduce fever although its benefit is uncertain

MEDICATION-INDUCED ACUTE DYSTONIA

Clinical Presentation

Acute dystonia occurs in up to 10 percent of patients, especially young men receiving a high potency FGA. Up to seven different symptoms may occur, although only one is required for the diagnosis. These symptoms include abnormal positioning of the head and neck (e.g., torticollis; retrocollis); spasms of the jaw muscles (e.g., trismus); impaired swallowing, speaking or breathing; thickened or slurred speech; tongue protrusion or dysfunction; deviated eyes in any direction (e.g., oculogyric crisis); and abnormal positioning of limbs or trunk (e.g., opisthotonos). These symptoms are usually quite frightening to patients who may develop the syndrome within minutes of receiving parenteral, high-potency FGAs; more commonly, however, symptoms usually develop within days of starting or increasing the oral antipsychotic dose or reducing a medication used to treat EPS. Rarely, dystonia can be life-threatening if laryngeal muscles are affected.

Another complication with acute dystonic reactions is the frequent occurrence of long-term treatment nonadherence. After such an experience, patients commonly report being “allergic” to the offending medication. Careful history taking often reveals the true nature of the event, but patients are understandably reluctant to resume treatment with the implicated drug. Such a history may preclude future use of specific

agents unless considerable time and energy are spent educating the patient regarding the probable cause of the reaction and how it can be prevented with anticholinergic agents. If a patient has a history of acute dystonia, the prophylactic use of such medications should be considered, even with the use of less potent antipsychotics.

The risk of acute dystonia is increased in young males. Recent use of cocaine, which depletes dopamine, is also associated with an increased risk. Some patients who are covertly nonadherent to oral tablets or capsules may develop acute dystonia when they are switched to a liquid concentrate or parenteral formulation. The risk of dystonia diminishes quickly after a steady dose is reached and ongoing use of anticholinergic medication is usually not required. Patients at risk for developing dystonia, however, are also at risk for developing other forms of EPS which may require continued anticholinergic management. A family history of movement disorders, as well as a prior history of dystonia, is predictive of a higher rate of acute dystonia and other forms of EPS.

Pathophysiology

Although the mechanism of acute dystonia is not understood, the sudden onset of symptoms and its limitation to the initiation of treatment or dose increase suggest that acute saturation of D2 receptors plays a role. Preclinical studies suggest sigma-1 and sigma-2 receptors, found in the motor regions of the brain and involved in the control of posture and movement, may be involved in all forms of dystonia, including medication-induced.

Treatment Options and Implications

Patients should always be informed of the risk of muscle spasms associated with these drugs and encouraged to report such events immediately. With severe reactions or laryngeal dystonia which can compromise breathing, immediate recognition and treatment are essential. Parenteral (intramuscular [IM] or IV) benztropine (1 to 2 mg) or diphenhydramine (50 mg) typically produce rapid relief. Prophylactic use of oral anticholinergic medication, as well as the ready availability of the parenteral form, is strongly encouraged when use of a high-potency FGA is considered.

Anticholinergic medication has the greatest effect on antipsychotic-induced acute dystonia, less of an effect on tardive dystonia, and little effect on idiopathic dystonia. Because tardive dystonia can be a particularly disabling disorder, there is some support for the use of clozapine which may even improve this condition. Botulinum toxin (Botox) injections also offer symptomatic improvement for tardive dystonia. The prevalence of this adverse effect diminishes when acute agitation is treated with a

combination of intramuscular haloperidol (e.g., 2 to 5 mg) plus lorazepam (Ativan) (e.g., 2 mg). It is likely that both the lower haloperidol dose and lorazepam's sedative and peripheral muscle-relaxant effects contribute to attenuation of this painful and frightening event. Ziprasidone (Geodon), olanzapine (Zyprexa), and aripiprazole all have approved acute parenteral (1M) formulations which appear to carry a lower risk for acute dystonia and may be alternatives to haloperidol plus lorazepam.

MEDICATION-INDUCED ACUTE AKATHISIA

Clinical Presentation

Akathisia (from the Greek word meaning "never to sit down") usually develops after starting or increasing the dose of medication or after decreasing the use of medications used to treat EPS. The incidence is estimated to be between 20 and 45 percent for patients on an antipsychotic. This syndrome is also reported with various antidepressants, particularly the SSRIs, possibly mediated by serotonin agonism of the dopamine system. It is also associated with severe distress, suicidality, a higher risk for developing tardive dyskinesia, and a poor treatment outcome.

Acute akathisia typically occurs within weeks of starting a medication, lasts less than 6 months and is characterized by intense dysphoria and an inner sense of restlessness. In addition, at least one of the following observable movements should be present: fidgeting or swinging of the legs, rocking from foot to foot while standing, pacing, lifting the feet as if marching in place, crossing and uncrossing the legs when sitting, or the inability to sit or stand in one place for several minutes. *Chronic akathisia* involves persistent symptoms (i.e., 6 months or longer) after the introduction of or last change in medication dose. It is characterized by stereotypic movements often in the presence of limb or orofacial dyskinesias. *Tardive akathisia* is often associated with tardive dyskinesia and manifests with a delayed onset which may persist even after medication cessation. *Withdrawal akathisia* can occur within 6 weeks of switching or stopping an antipsychotic or upon stopping an anticholinergic agent. The most common metric used to assess for this problem is the Barnes Akathisia Scale (BAS) which quantifies both subjective and objective components.

Severe cases are easily recognized, whereas mild cases are more difficult to separate from symptoms of the primary psychiatric disorder, especially those in which anxiety and motor restlessness are prominent. Thus, patients who present with pacing or running may be misdiagnosed with manic excitement or psychotic agitation and receive additional doses of an antipsychotic, risking exacerbation of the movement disorder. By contrast, lowering the dose may unmask tardive akathisia. This adverse effect is also

more common with high-potency FGAs and may lead to inadequate adherence with future treatment recommendations. The symptoms of akathisia should not be better explained as part of a mental, neurological, or general medical disorder.

Pathophysiology

The pathophysiology of akathisia is uncertain. There is evidence, however, that decreasing dopamine tone in the ventral tegmental area and substantia nigra, which in turn alters interactions between the mesolimbic, mesocortial, and spinal dopamine/norepinephrine systems, is contributory. GABAergic, cholinergic, adrenergic, serotonergic, and neuropeptide mechanisms are also implicated. Risk factors can be divided into:

- Drug-related:
  - Higher doses
  - Rapid dose escalation
  - Higher potency agents
- Individual-related:
  - Older age
  - Female
  - Mood disorder
  - Preponderance of negative symptoms
- Symptom-related:
  - Iron deficiency
  - Cognitive dysfunction

Treatment Options and Implications

A slow dose titration schedule, dose reduction, or switching to a less potent FGA or an SGA are the preferred initial options. This should be done under close supervision to avoid exacerbation of psychosis or precipitating withdrawal symptoms, including akathisia. Clozapine may be an option for patients with chronic, persistent akathisia. In cases in which there is uncertainty, benzodiazepines are preferable to increasing the antipsychotic dose.

β-*Blockers* (e.g., propranolol [Inderal]) are the most commonly prescribed medication for this problem. Propranolol's mechanism of action may relate to its alteration of both noradrenergic and serotonergic inputs into the DA system. *5-HT2a/c antagonists* such as mirtazapine (15 mg per day), trazodone (100 mg per day), mianserin (15 mg per day), or cyproheptadine (8 to 16 mg per day) may produce benefits comparable to propranolol with better possible tolerability. *Anticholinergic* agents (e.g., trihexyphenidyl [2 to 10 mg per day]; benztropine [1 to 8 mg per day]) and

benzodiazepines (e.g., lorazepam at 1 to 2 mg per day) are second and third level choices, respectively.

In resistant cases, other *GABAergic agents* (e.g., gabapentin; 3,000 mg per day); *amantadine* (a weak glutamate receptor antagonist and DA-enhancing agent; 100 mg per day) or *clonidine* (a selective α_2-adrenergic agonist; up to 0.15 mg per day) may help. In two randomized controlled trials (RCTs), the addition of *vitamin B6* (1,200 mg per day) for 5 days significantly improved subjective and global subscales of the BAS.

TARDIVE DYSKINESIA

Clinical Presentation

Symptoms of tardive dyskinesia should develop after at least 2 months of exposure to a dopamine blocking agent (or 1 month if the patient is 60 years or older); while the patient is on medication or within 4 weeks of withdrawal from an oral agent (8 weeks from long-acting injectable medication); and be present for at least 4 weeks. The patient usually demonstrates involuntary movements of the tongue (e.g., twisting, protrusion), jaw (e.g., chewing), lips (e.g., smacking, puckering), trunk, or extremities. Patterns of movements may include rapid, jerky, and nonrepetitive movements (i.e., choreiform); slow, continuous, and sinuous movements (i.e., athetoid); or rhythmic movements.

Onset of the disorder may be gradual, occurring over a period of months to years. Symptoms are often seen in older patients who have poorly fitting dentures or other reasons for dyskinetic movements. In older patients (55 years or older), the onset of tardive dyskinesia is 25 percent after 1 year, 34 percent after 2 years, and 53 percent after 3 years. This rate of onset is three to five times higher than in younger patients. Patients with multi-infarct dementia and a psychiatric diagnosis are at greater risk than patients with Alzheimer disease or other organic mental disorders. Tardive dyskinesia may also occur in never-medicated patients with schizophrenia. Risk factors include increasing age, pre-existing parkinsonism, previous brain damage, antipsychotic treatment duration, and exposure to FGAs. These symptoms should not be due to a general medical or neurological disorder, or present as an adverse effect of another class of medication.

Pathophysiology

Sustained D2 receptor blockade resulting in receptor hypersensitivity is the most common hypothesis explaining the development of tardive dyskinesia. Clozapine's decreased propensity to induce tardive dyskinesia and its multiple neuroreceptor effects (e.g., binding to 5-HT1C, 5-HT2, and 5-HT3 receptors) suggest a role for serotonin as well. Serotonin-containing neurons interact with dopaminergic neurons in the substantia nigra and ventral tegmental areas. Genetic studies indicate a possible relationship

with polymorphisms in the DA2 receptor, DA3 receptor, dopamine transporter (DAT1), and the serotonin 2A receptor genes. Oxidative stress and cell death secondary to increased glutamatergic neurotransmission caused by blockade of presynaptic dopamine receptors is also postulated.

Treatment Options and Implications

Since the advent of SGAs, fewer episodes and less severe symptoms of tardive dyskinesia are now seen. For this reason, patients on FGAs are generally switched to a newer agent if possible. Further, there is evidence that agents such as clozapine may improve symptoms of tardive dyskinesia without causing progression of the disorder. For example, some studies of clozapine report reduced symptom severity in tardive syndromes by up to 50 percent. Patients on an FGA who develop tardive dyskinesia and are switched to an SGA have demonstrated improvement in their symptoms, but which specific agents are preferable is still unclear. Although a small percentage of cases progress to florid and potentially disabling or life-threatening intensity, others remain stable and some show spontaneous improvement.

Other strategies to address the problem include a *gradual discontinuation* in patients whose need for antipsychotic medication is not clearly established (e.g., a psychotically depressed patient who is maintained on an antipsychotic after apparent full recovery). Because a certain number of these patients will relapse, however, medication discontinuance requires close monitoring. Patients taken off high-potency FGAs usually require a cross-taper because tardive dyskinesia symptom exacerbation may occur after an abrupt change to a low-potency agent. *Discontinuance, dose reduction, or switch* to another agent may improve, stabilize, or worsen symptoms. Use of adjunctive agents is of limited benefit. These include *vitamin B6* and *procholinergic agents* (e.g., donepezil [Aricept]). *Ondansetron* (Zofran), a selective 5-HT3 receptor antagonist, may reduce symptoms of tardive dyskinesia and also exert a beneficial effect on psychotic symptoms. Preliminary studies indicate *cyproheptadine* (Periactin), a 5-HT and histamine antagonist, and *levetiracetam* (Keppra) may improve tardive dyskinesia. The use of *deep brain stimulation* (DBS) for severe and refractory tardive dyskinesia offers hope to those who are severely disabled. Systematic reviews and studies of galantamine (Razadyne), vitamin E, calcium channel blockers, benzodiazepines, lithium, estrogen, and essential fatty acids do not support their use for tardive dyskinesia.

MEDICATION-INDUCED POSTURAL TREMOR

Clinical Presentation

Motor tremors can develop after starting a medication such as lithium,

valproic acid (Depakene), α-adrenergic blockers, stimulants, dopaminergic agonists, caffeine, theophylline (Bronkodyl), an antipsychotic, or an antidepressant. Typically, it is a fine 8- to 12-Hz postural tremor affecting the limbs, head, mouth, or tongue. Other medical causes should be excluded and the tremor should not be part of an antipsychotic-induced pseudoparkinsonism which usually occurs at rest, is slower and, unlike true parkinsonian tremor, tends to worsen with movement.

Pathophysiology

The hypothesized mechanism of medication-induced postural tremor varies based on the class of drug implicated. For example, stimulants may cause tremors due to the resulting hyperadrenergic state.

Treatment Options and Implications

This diagnosis is commonly associated with the use of mood stabilizers such as lithium. For example, tremor is often present, may be dose related and can herald the onset of early lithium toxicity. Thus, checking the lithium plasma level and looking for other signs of toxicity is advisable. If the tremor is an isolated finding not associated with toxicity, it may improve with time. Although the dose of lithium may also be reduced, this may compromise its therapeutic effect. Tremor is often worsened by emotional factors such as anxiety, stress or fatigue; medical issues such as alcohol withdrawal, hypoglycemia, thyrotoxicosis, pheochromocytoma, or hypothermia; or by the addition of other medications. In cases where a pre-existing tremor worsens with the addition of a medication, the diagnosis of other medication-induced movement disorder should be considered. *Reduction of dose or switching* to another agent in a different class may help. In some cases, a *benzodiazepine or β-blocker* can ameliorate the tremor.

TARDIVE DYSTONIA/TARDIVE AKATHISIA

Clinical Presentation

Tardive dystonia and tardive akathisia are movement symptoms which arise later in treatment with an antipsychotic and may persist for months or years despite the reduction or discontinuation of the patient's medication. Young male patients have a higher risk. This syndrome is differentiated from acute dystonia and acute akathisia based on the time to onset. Both tardive dystonia and akathisia are associated with a higher incidence of tardive dyskinesia.

Pathophysiology

There is little known about the pathophysiology of tardive dystonia and

tardive akathisia. Tardive dystonia appears to involve impairment of the basal ganglia and tardive akathisia may involve dysfunction of the pontine region of the brain.

Treatment Options and Implications

Both of these movement disorders are preventable with the use of SGAs (e.g., clozapine; quetiapine). If the patient has symptoms while on or after discontinuing an antipsychotic, an increase in its dose or immediate reintroduction of the agent may be necessary to increase dopamine blockade. Such interventions can achieve short-term relief.

One potential treatment for refractory tardive dystonia is DBS. In one report, 60 patients with symptoms of various types of dystonia underwent DBS with leads placed in the globus pallidus pars interna. Using the Burke–Fahn–Marsden Dystonia Rating Scale (BFM), patients were assessed preoperatively, postoperatively, and for up to 5 years of follow-up. Improvement in the BFM severity and disability scores were 43 percent and 27 percent, respectively by 6 months and were sustained thereafter. Thus, DBS may be a potential option for patients with severe, treatment-refractory, medication-induced tardive dystonia.

OTHER MEDICATION-INDUCED MOVEMENT DISORDERS

Clinical Presentation

These disorders do not fit into more specific categories. For example, acute dystonia may occasionally follow the use of a benzodiazepine (e.g., midazolam) or antidepressants (e.g., amoxapine). Other forms of EPS which may occur as an idiosyncratic reaction to a nonantipsychotic medication are also coded under this category. NMS-like syndromes and tardive dystonia not associated with antipsychotic exposure may be coded under this category as well.

Pathophysiology

Genetic variability may account for idiosyncratic reactions seen in some patients. The ongoing research and rapid growth in knowledge about these variations in the CNS and their relationship to treatment response and adverse effects will help to clarify these questions.

Treatment Options and Implications

These disorders are infrequent and discontinuation of the offending agent is always the preferred option. Careful history taking and collateral information may reveal exposure to more typical causes of movement disorders (e.g., patient may have taken another's medication or is exposed to an antiemetic phenothiazine).

ANTIDEPRESSANT DISCONTINUATION SYNDROME

Clinical Presentation

While movement symptoms are not common withdrawal phenomena with antidepressants, abrupt discontinuation or rapid dose reduction may produce them. Usually, the patient is typically on the drug for a month or more and movement symptoms arise within days after discontinuation or tapering. This may occur with various classes of antidepressants, including SSRIs (e.g., citalopram, fluoxetine); serotonin and noradrenergic reuptake inhibitors (e.g., duloxetine, venlafaxine); TCAs (e.g., desipramine, imipramine); MAOIs (e.g., tranylcypromine, isocarboxazid); as well as other agents (e.g., mirtazapine). Common symptoms include *somatic* (e.g., dizziness, headache, nausea); *sensory* (e.g., numbness, ringing in the ears, "electric shocks," flashes of light); *mood* (e.g., anxiety, irritability); and *abnormal movements* (e.g., EPS). Some movement symptoms occur with all antidepressants, while others are specific to the class of agent and include:

- SSRIs:
  - Tremor
  - Akathisia
  - Parkinsonism
- TCAs:
  - Tremor
  - Akathisia
  - Parkinsonism
- MAOIs:
  - Catatonia
  - Myoclonic Jerks
- Serotonin and norepinephrine reuptake inhibitors (SNRIs):
  - Akathisia

Most of these symptoms occur upon discontinuation of an SSRI or TCA. The latter class has a higher tendency to cause parkinsonian symptoms which are managed with anticholinergics (e.g., benztropine) if a patient does not wish to restart their antidepressant. MAOIs, especially tranylcypromine, may cause more severe movement symptoms such as myoclonic jerks and catatonia which require acute management with benzodiazepines (e.g., lorazepam). Akathisia may occur with discontinuation from SSRIs, SNRIs, and TCAs and is managed with β-blockers (e.g., propranolol), anticholinergics, and in some cases, benzodiazepines.

Pathophysiology

While there are several hypotheses as to the cause of discontinuation symptoms with antidepressants, there is no clear consensus on their pathophysiology. There is agreement, however, that an increased propensity to develop these symptoms is associated with shorter half-life agents. For example, paroxetine is associated with the highest risk for the discontinuation syndrome.

Treatment Options and Implications

Reinstatement of the antidepressant typically resolves these symptoms. When no further treatment with an antidepressant is required, however, management of these symptoms depends on their severity. Mild symptoms often resolve spontaneously and require no treatment beyond counseling the patient. More moderate-to-severe symptoms may require reinstating the agent to quickly alleviate symptoms. The original antidepressant can be reintroduced or another antidepressant with a similar mode of action may be substituted. Once stabilized, a more gradual tapering is then initiated. It is important to take various factors into account such as the dose and type of antidepressant agent to determine the appropriate tapering duration.

While the symptoms of the discontinuation syndrome are manageable, they can be prevented by educating the patient on the importance of gradually tapering the dose of medication. It is also essential to educate patients on the importance of adhering to their medication and the potential for adverse events upon their cessation.

SUMMARY

The impact of medication-induced movement disorders should not be underestimated. These conditions are often debilitating, even life-threatening; diminish the effectiveness of treatment by precluding an adequate trial; contribute to nonadherence; simulate or accentuate

negative, cognitive or mood symptoms; and increase the risk for irreversible, later-onset abnormal movements. Also of concern is that some of these adverse effects (e.g., pseudoparkinsonism, tardive dyskinesia, akathisia) are associated with an increase in suicidality (e.g., ideation, behavior, attempt). As a result, the choice of antipsychotic is often based in large part on its potential to produce such adverse effects. Since SGAs usually produce fewer acute and chronic movement symptoms than FGAs, patients are more likely to initially receive one of these agents. Further, patients with concurrent movement disorders (e.g., Parkinson disease), significant drug-induced movement adverse effects, or who are at increased risk for developing tardive syndromes are often switched to an SGA. The substantial variation in the experience of such adverse effects, however, always requires an individualized risk–benefit assessment before choosing a specific agent. Figure 34.3–1 depicts the relative risk of acute EPS with these agents in comparison to high-potency FGAs.

Diagnosis, phase of the illness, age, gender, and race affect the likelihood of developing movement disorders. For example, individuals with first- or early-onset psychosis are at greatest risk for developing movement symptoms than more chronically ill patients; older white females with a mood disorder are at higher risk to develop tardive dyskinesia; younger black males are at greatest risk for developing acute dystonia; and more severe acute EPS in the context of catatonic symptoms may predispose to developing NMS.

The management of medication-induced movement disorders includes the appropriate prescription of antipsychotic agents (e.g., accurate diagnosis); optimal dosing; medication change; or adjunctive treatments (e.g., anticholinergic agents, benzodiazepines, and β-blockers which are most effective for antipsychotic-induced pseudoparkinsonism). Other agents may benefit NMS, including bromocriptine (Parlodel) and dantrolene (Dantrium). Management may also include the selection of an SGA with less likelihood of producing or even possibly improving these syndromes.

FUTURE DIRECTIONS

Medication-induced movement disorders require a careful consideration of the risk–benefit ratio when initiating antipsychotics or other potential offending agents, limiting their use, and encouraging the development of safer alternatives. Developments in the current understanding of brain function through advancements in neuroimaging and genetics will lead to safer and better tolerated agents. For example, pharmacogenetics and pharmacogenomics are increasingly helping to explain how the various alleles of receptor-related genes impact response and/or influence the development of acute and long-term medication-related adverse effects. Since medications which are life-saving for some patients but may be

disabling or even life-threatening for others, such advances will permit a better risk assessment and a better selection process from the increasing number of available agents. For now, predicting and minimizing drug-related movement disorders are primarily based on multiple clinical factors (e.g., diagnosis; phase of the illness; race; age). Although the recognition and management of medication-induced adverse effects are important, it is always better to avoid or minimize them with the judicious choice of treatment(s). The goal is to improve adherence, thus maximizing efficacy, functionality, and quality of life.

▲ 34.4 α2-Adrenergic Receptor Agonists: Clonidine, Clonidine Extended Release, Guanfacine, and Guanfacine Extended Release

ERIC HOLLANDER, M.D., AND JENNIFER N. PETRAS, M.D.

HISTORY

Clonidine (Catapres) was synthesized in the early 1960s and found to produce vasoconstriction mediated by α-receptors. The drug was initially developed as a topical nasal decongestant. During clinical testing it was found to cause hypotension, sedation, and bradycardia, and it was subsequently used as a centrally active antihypertensive. Due to its effects on norepinephrine and other neurotransmitter systems, and functioning of the prefrontal cortex (PFC), clonidine has been studied in several psychiatric disorders including tic disorders, ADHD, PTSD, and opiate, nicotine, and alcohol withdrawal. Guanfacine (Tenex) is also an α-adrenergic receptor agonist. It has a longer half-life and may have fewer side effects due to its differential affinity for certain receptor subtypes.

CHEMISTRY

Clonidine is an imidazoline derivative and exists as a mesomeric compound. Its chemical name is 2-(2,6-dichlorophenylamino)-2-imidazoline hydrochloride; the structural formula is shown in Figure 34.4–1. Clonidine hydrochloride is an odorless, bitter, white, crystalline substance soluble in water and alcohol. Its molecular weight is 266.56.

FIGURE 34.4–1. Molecular structure of clonidine.

The chemical name of guanfacine is *N*-amidino-2-(2,6-dichlorophenyl) acetamide monohydrochloride, and its molecular weight is 282.56. Guanfacine hydrochloride is a white to off-white powder sparingly soluble in water and alcohol and slightly soluble in acetone. Guanfacine's structural formula is shown in Figure 34.4–2.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption. Clonidine immediate release (CLON-IR) is well absorbed after oral administration and its bioavailability is nearly 100 percent. The plasma level peaks between 1 and 3 hours after an oral dose. Clonidine extended release (Kapvay) (CLON-XR) is well absorbed after oral administration with a bioavailability of about 90 percent, but is designed to be absorbed more slowly with peak plasma levels achieved at 6 to 7 hours. Due to differing pharmacokinetic characteristics, utilization of the same dose of CLON-IR and CLON-XR will result in different drug exposure. Comparisons across studies suggest peak plasma concentrations are 50 percent lower for CLON-XR compared with CLON-IR. Absorption of CLON-XR is not impacted by food intake. Guanfacine immediate release (GUAN-IR) is also well absorbed orally with a bioavailability of about 80 percent and peak plasma levels are seen in 1 to 4 hours. Guanfacine extended release (Intuniv) (GXR) has a relative bioavailability of 57 percent compared with the GUAN-IR formulation, therefore the XR and IR formulations are not interchangeable. GXR reaches peak plasma levels in 5 to 6 hours after oral administration. Absorption of GXR is significantly affected by food intake, with a 75 percent increase in peak plasma levels when administered with a high-fat meal. Administration with a high-fat meal should be avoided.

Distribution. Clonidine and guanfacine formulations cross the blood–brain barrier. Clonidine is present in breast milk. Clonidine is between 20 and 40 percent protein bound and has a volume of distribution of 2.1 L/kg. Guanfacine is approximately 70 percent protein bound and has a volume of

distribution of 6 L/kg, which suggests a high distribution of drug to the tissues. Clonidine is known to cross the placenta and is present in breast milk. It is not known if guanfacine crosses the placenta or is excreted in breast milk, although guanfacine has been shown to cross the placenta in rats.

FIGURE 34.4–2. Molecular structure of guanfacine.

Metabolism and Elimination. The elimination half-life (time required for the concentration of the drug to reach half its original value) of both the immediate-release and extended-release clonidine range from 6 to 24 hours, with a mean of 12 hours. After oral administration of clonidine, approximately 40 to 60 percent of the dose is present, unchanged in the urine. When renal function is severely impaired, the half-life can increase to approximately 41 hours. About 50 percent of the absorbed dose is metabolized in the liver. The elimination half-life of both guanfacine immediate release and guanfacine extended release is approximately 17 hours, and steady-state blood levels are reached within 4 days. Guanfacine is metabolized by hepatic cytochrome p450 (CYP) 3A4 microsomal enzymes. Exposure to guanfacine may potentially be increased by concurrent use of CYP3A4 inhibitors (clarithromycin, grapefruit juice, itraconazole) or decreased by concurrent use of CYP3A4 inducers (rifampin, St. John wort, phenytoin). Approximately 50 percent of the dose is eliminated in the urine as unchanged drug. In renal insufficiency clearance is reduced, but drug levels are only slightly increased. Guanfacine is poorly dialyzed. Both clonidine and guanfacine are metabolized more rapidly in children and, therefore, the half-life is decreased. When the clonidine transdermal patch is removed, plasma concentrations remain stable for approximately 8 hours and then decline gradually over a few days.

Pharmacodynamics

Mechanism of Action. The α_2-receptor is one of five adrenergic receptors (α_1, α_2, β_1, β_2, β_3). The α_1-receptors are located in the periphery, while the α_2-receptors are located centrally and peripherally. In the CNS,

they are located both pre- and postsynaptically. The α_2-receptors have three distinct subtypes (A, B, and C), each with its own area of anatomical predominance. The α_2A-adrenoreceptor is the most predominant and broadly distributed subtype being concentrated in the PFC, locus ceruleus (LC), amygdala, septum, hippocampus, and hypothalamus. The α_2B-adrenoreceptor is mainly restricted to the thalamus. The α_2C-adrenoreceptor is present in high densities in the hippocampus, the olfactory system, the striatum, and the cerebral cortex. Each of these subtypes is a Gi/Go protein–coupled receptor, which, on a cellular level, when activated by endogenous agonists (epinephrine) or exogenous agonists (clonidine), suppresses adenylyl cyclase activity which then leads to decreased production of cAMP. This in turn decreases feedforward cAMP–calcium signaling and prevents the opening of potassium channels. Continued exposure to α_2-agonists leads to downregulation of all three receptor subtypes.

Clonidine behaves as a partial agonist at all three α_2-receptor subtypes. Guanfacine is a selective α_2A-adrenoreceptor agonist that has a 15- to 20-fold increased selectivity for the α_2A-receptor over α_2B- and α_2C-receptor subtypes. The majority of the pharmacologic and physiologic functions are attributed to the α_2A-adrenoreceptor subtype.

Presynaptic α_2A-adrenoreceptor activation leads to an autoinhibition of norepinephrine release with activation of presynaptic α_2-receptors in the LC and cortex, and of α_2B-receptors in the thalamus likely accounting for the sedative effects of the α_2-agonists. Guanfacine is less sedating than clonidine, which is likely due to a weaker action at α_2B- and α_2C-receptors. The majority of α_2A-receptors are postsynaptic, including receptors on the dendritic spines of pyramidal cells in the PFC. Activation of these receptors and the resulting decreases in cAMP enhances prefrontal neuronal firing and strengthens prefrontal network connectivity, allowing for greater control of behavior including cognitive enhancing effects. The activation of this postsynaptic receptor also has a stimulatory effect on growth hormone secretion. Less is known about the effects of agonists on the α_2B- and α_2C-adrenoreceptors.

Clonidine, an imidazoline derivative, also binds to imidazoline-binding sites (IBS) located throughout the body and in the CNS. There are three subtypes of IBS: I1, I2, and I3. Clonidine has a greater affinity for the I1 IBS, which is involved in the control of blood pressure, and there is evidence to support that the hypotensive effect of clonidine is mediated via the IBS I1. Hypotensive side effects are less common with guanfacine, likely due to its weaker affinity at the IBS I1.

Blood Concentrations and Relation to Action. Concentrations of both

clonidine and guanfacine vary between individuals based on many factors, most notably age and renal function. A positive correlation between plasma concentrations of clonidine and its pharmacological effects has been demonstrated. In clinical practice, however, plasma levels are rarely obtained.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

The α_2-adrenergic receptor agonists have been evaluated in several psychiatric disorders with proposed underlying dysregulation of the adrenergic system or sympathetic nervous system. More recently, animal and neuroimaging research has led to further understanding of the neurobiology of PFC and the impact of the PFC and its connections on attention, emotion, and behavior. This has provided therapeutic targets to treat psychiatric disorders with a proposed underlying dysregulation of PFC. The design of clinical drug studies has been largely open studies, retrospective reviews, case reports, and small controlled studies. These studies have shown the α_2-adrenergic receptor agonists to have varying degrees of efficacy in the treatment of a variety of psychiatric disorders, including tic disorders, ADHD, PTSD, and opiate, nicotine, and alcohol withdrawal. Over the past 5 years, with the development of the extended-release formulations of clonidine and guanfacine, there have been multiple larger randomized, placebo-controlled studies. These studies have shown the extended-release α_2-agonists to be safe and efficacious for use in children and adolescents for the treatment of ADHD. In addition, the possible neuroprotective effects, especially in times of uncontrollable stress, of the α_2-adrenergic receptor agonists continues to be evaluated in humans because evidence of neuroprotective effects in animals has continued to expand.

EFFECT ON SPECIFIC ORGANS AND SYSTEMS

The α_2-agonists are active antihypertensive medications that directly affect the cardiovascular system by stimulating central α-adrenoreceptors, leading to reduced sympathetic nerve impulses from the vasomotor center to the heart and blood vessels. This results in a decrease in peripheral vascular resistance, renal vascular resistance, and a reduction in heart rate and blood pressure. Given these direct effects, measurement of heart rate and blood pressure prior to initiation, following dose increases and periodically while on therapy is recommended. Renal blood flow and glomerular filtration rate remain essentially unchanged. Normal postural reflexes remain intact; therefore orthostatic symptoms are mild and infrequent. Normal hemodynamic responses to exercise are maintained. Both clonidine and guanfacine acutely stimulate growth hormone release in both children and adults, but do not produce a chronic elevation of growth

hormone with long-term use.

THERAPEUTIC INDICATIONS

Clonidine extended release and guanfacine extended release are FDA approved in the treatment of ADHD as monotherapy and as adjunctive therapy to stimulant medication in children and adolescents. Immediate-release clonidine and guanfacine are FDA approved only for the treatment of hypertension, as monotherapy, or in combination with other antihypertensive medications. These medications are also used in a number of off-label uses for the treatment of numerous psychiatric conditions.

Tourette Syndrome and Other Tic Disorders

A tic is a sudden, rapid, recurrent, nonrhythmic motor movement or vocalization. Tourette syndrome (TS) is a neuropsychiatric syndrome characterized by both multiple motor and one or more vocal tics that may wax and wane in frequency but have persisted for more than 1 year since first tic onset, with first tic onset before the age of 18 years.

Clonidine and guanfacine are considered by many to be a first-line treatment for tics and TS, with multiple positive double-blind randomized placebo-controlled studies in the literature. Although haloperidol (Haldol) and pimozide (Orap) have been shown to be more effective than the α_2-agonists, concerns about their side-effect profiles, specifically NMS, tardive dyskinesia, and QTc prolongation (especially pimozide), have limited their use. Among the newer antipsychotics, the use of risperidone (Risperdal) has the strongest evidence for efficacy, yet its use is limited due to issues of weight gain, sedation, and risks of extrapyramidal symptoms and hyperprolactinemia. Preliminary data have shown clonidine and risperidone (Risperdal) to be equally efficacious. Preliminary data have also shown the clonidine transdermal patch to be an effective option for the treatment of TS and other tic disorders. When using clonidine for tics and TS it is important to note that there can be a delayed response, sometimes taking 2 to 6 weeks to have clinical effect.

Greater than 50 percent of children with TS have a comorbid diagnosis of ADHD. In this population, clonidine is considered first-line treatment. Several studies in this population report a significant improvement in impulsive-hyperactive symptoms as well as tic symptoms with both clonidine and guanfacine. In addition, there is evidence that the combination of clonidine and methylphenidate (Ritalin) is particularly efficacious and may not increase the severity of the tic disorder.

A standard titration of clonidine for the treatment of tics is 0.05 mg before bed, increasing by 0.05 mg every 3 to 7 days until the dose is 0.05 mg in the morning and midday, and 0.1 mg at bedtime. Total daily dose of clonidine for the treatment of tics is 0.1 to 0.3 mg. A standard titration of

guanfacine for the treatment of tics is 0.5 mg before bed, increasing by 0.5 mg every 3 to 7 days until the dose is 1 mg twice per day. In studies of tics or TS and comorbid ADHD, the dose range was 3 to 5 μg/kg per day. Measurement of heart rate and blood pressure prior to initiation, following dose increases and periodically while on therapy is recommended.

There are no published studies on the use of the extended-release formulations of clonidine and guanfacine in TS or tic disorders.

Attention-Deficit/Hyperactivity Disorder

Dysregulation of the central noradrenergic network has long been hypothesized to be an important aspect of the pathophysiology of ADHD. Ongoing structural and functional imaging studies along with neuropsychological studies have demonstrated delayed or inadequate maturation of the PFC, particularly in the right inferior regions needed for inhibitory control and executive cognitive functioning. Moderate levels of norepinephrine are critical for proper PFC function, while high and low levels may impair function. Action at presynaptic α_2-receptors in the LC leads to decreased cell firing and release of norepinephrine modulating and optimizing catecholamine influences to remediate symptoms of ADHD. Ascending norepinephrine afferent projections from the LC to the PFC enhance functional connectivity between the PFC and other brain regions. Guanfacine mimics norepinephrine at the postsynaptic α_2A-receptors.

The α_2-agonist clonidine has been used in the treatment of ADHD for more than 20 years. Yet, the effect size for stimulant medications in ADHD is larger than that for the α_2-agonists, and clonidine and guanfacine are therefore considered second-line agents for the treatment of ADHD. The α_2-agonists are most often used for augmentation of stimulants or when stimulant medications have been ineffective or poorly tolerated. There is also a particular interest in the use of α_2-agonists as monotherapy or in combination with stimulant medications for patients with comorbid ADHD and tic disorders. In these patients, data have shown moderate efficacy for some symptoms of ADHD with clonidine and guanfacine monotherapy, and with clonidine in combination with methylphenidate. For children with ADHD and comorbid oppositional defiant disorder or conduct disorder, there is increasing evidence that the addition of clonidine to ongoing psychostimulant treatment reduces symptoms of oppositional defiant disorder and conduct disorder, particularly symptoms of aggression.

The recent development and approval of the extended-release formulations of clonidine (CLON-XR) in 2010 and guanfacine (GXR) in 2009 has led to multiple positive randomized placebo-controlled studies as both monotherapy and adjunctive therapy for children and adolescents with ADHD. These trials support the efficacy and safety of extended-release α_2-receptor agonists for the symptomatic treatment of ADHD both as

monotherapy and adjunctive therapy with stimulant medication.

Highly comorbid with ADHD are oppositional symptoms such as anger, hospitality, irritability, arguing, and refusing to comply with adult directives. In studies of GXR, improvements in the oppositional subscales showed correlation with improvements in ADHD symptoms. Preliminary data of GXR plus a stimulant have shown significant reduction in oppositional symptoms, compared with placebo plus a stimulant in children and adolescents with ADHD and a suboptimal response to stimulant alone.

A standard CLON-IR dose for the treatment of ADHD is approximately 3 to 5 μg/kg per day, with a daily dose range of 0.1 to 0.3 mg per day. It is recommended to start with low doses and increase by 0.05 mg every 3 days. A standard dose of GUAN-IR for the treatment of ADHD ranges from 0.5 to 4 mg per day. The dose can be increased by 0.5 mg every 3 to 4 days. CLON-IR is administered on a schedule of three to four times a day, while GUAN-IR with its longer duration of action is generally administered on a twice a day schedule.

For CLON-XR as monotherapy for ADHD or as adjunctive therapy to a psychostimulant, dosing should be initiated with 0.1 mg at bedtime and adjusted in increments of 0.1 mg per day at weekly intervals until desired dose response is achieved. Dosing should consist of twice a day with either an equal split or the higher dosage at bedtime to a maximal total dose of 0.4 mg per day. For GXR as monotherapy for ADHD or as adjunctive therapy to a psychostimulant, dosing should be initiated once daily, either morning or evening with a dose of 1 mg per day and adjusted in increments of 1 mg per day at weekly intervals until desired dose response is achieved. Doses above 4 mg per day have not been systematically studied in controlled studies.

Concerns regarding the safety of the combination of stimulants and α_2-agonists remain after the sudden death of four children taking methylphenidate and clonidine was reported in 1995, although the specific contribution of clonidine in these deaths remains controversial. There have been no further reports of sudden death, and studies with children on this combination have been conducted with baseline, interval, and final visit ECGs and pulse and blood pressure monitoring. Before the initiation of an α_2-agonist, a cardiologist should evaluate patients with known cardiac problems or abnormal ECG. Measurement of heart rate and blood pressure prior to initiation, following dose increases, and periodically while on therapy is also recommended.

Opiate Withdrawal

Clonidine has been used for the treatment of opiate withdrawal since the 1980s and continues to be used in most detoxification protocols. Opiate

withdrawal is manifested by symptoms of irritability, anxiety, sweating, sniffling, rhinorrhea, nausea, diarrhea, lacrimation, abdominal pain, headache, muscular pain, and insomnia. During withdrawal, neural activity in the LC is greatly increased, and this surge is thought to be responsible for many of the symptoms seen during withdrawal. Clonidine's ability, through its preferential action on presynaptic α_2-neurons, to inhibit noradrenergic activity has been consistently shown to be effective in decreasing these symptoms by counteracting catecholamine release and decreasing the sympathetic hyperactivity in opiate withdrawal.

Clonidine has been used as a single agent in the treatment of opiate withdrawal and in combination with methadone (Dolophine), or buprenorphine (Buprenex), a partial opiate agonist. Clonidine is also used in rapid opiate detoxification under anesthesia (RODA), which is a procedure using opiate antagonists, such as naloxone/naltrexone (Narcan/Revia), under general anesthesia to rapidly reverse opioid dependence. Preliminary evidence finds that clonidine may be particularly effective in managing the gastrointestinal (GI) side effects associated with RODA. Some authors have suggested that withdrawal-induced diarrhea may be mediated through α_2-adrenoreceptors located on intestinal smooth muscles.

Although studies have shown clonidine to be effective in the management of opiate withdrawal, in comparison to methadone and buprenorphine, the treatment retention rate of patients treated with clonidine only is markedly lower. This is believed to be because patients treated with clonidine, as compared to methadone or buprenorphine, experience the most intense symptoms of opiate withdrawal earlier in the detoxification process. In addition, these patients experience and report greater medication side effects. These side effects are sedation, lethargy, fatigue, dry mouth, and hypotension. Withholding doses or decreasing the clonidine dose according to blood pressure changes usually manages the hypotensive side effects. Although the treatment retention rates and the percentage of patients who complete detoxification is higher when methadone, buprenorphine, or RODA is used, some recent work has suggested that at 6- and 12-month follow-up, the relapse rates with these other medications are equal to, or higher than, the clonidine only group. In adolescents, one study found buprenorphine with behavioral intervention to be significantly more efficacious than clonidine and behavioral treatment in the treatment of opiate withdrawal. In particular populations, such as prison inmates, where policies restrict opiate-assisted detoxification, surveys indicate clonidine is utilized in approximately 50 percent of jails. There is preliminary evidence that the use of standard clonidine protocols reduces inmate subjective symptoms of opiate withdrawal.

Several standardized protocols for the use of clonidine in opiate

withdrawal are commonly used. Generally, clonidine therapy is initiated at a dose of 0.1 to 0.2 mg orally up to six times per day and is titrated based on severity of symptoms and side effects. Maximum doses of clonidine are usually approximately 1 mg per day. The maximal doses are used for 2 to 3 days during the most acute withdrawal period. When the patient is stabilized, the clonidine is tapered over a 7- to 10-day period. Some protocols involve a slower taper or transition to a transdermal patch in order to address chronic symptoms of withdrawal such as sleep disturbance. Clonidine is usually withheld if the systolic blood pressure is less than 90 or if the patient shows marked bradycardia. Other regimens include basing the daily clonidine dose schedule on an as-needed basis and then decreasing the amount given over the next week.

Different formulations of clonidine are used in different protocols; RODA protocols use intravenous clonidine, although most protocols use tablets or a combination of tablet with a transition to the transdermal patch. Protocols using a combination of an opiate agonist, partial opiate agonist, or opiate antagonist along with clonidine have higher rates of completion of withdrawal.

At this time there are insufficient data available to make a conclusion regarding the efficacy of guanfacine in opiate withdrawal, but preliminary findings suggest that guanfacine may be as effective and associated with fewer side effects when compared with clonidine. In the comparison of clonidine and lofexidine (BritLofex), another α_2-receptor agonist, these drugs appear to have similar effectiveness in terms of reducing overall intensity of withdrawal, with those treated with lofexidine experiencing fewer side effects.

Nicotine Withdrawal

Clonidine is considered a second-line treatment for nicotine withdrawal. Although it has been shown to be effective in promoting smoking cessation, there is a high incidence of adverse effects, such as hypotension, dry mouth, and sedation. In light of these adverse effects, clonidine is typically reserved for smokers in whom sedation would be a desirable effect, such as in a smoker who experiences extreme agitation or anxiety during nicotine withdrawal. Clonidine also has a role in treating patients withdrawing from multiple drugs of abuse.

The recommended dose of clonidine for nicotine withdrawal from available studies is 0.1 mg twice a day with a titration to 0.4 mg daily as tolerated. Clonidine should be started 48 to 72 hours prior to cessation of nicotine use to allow time to reach steady state before the onset of nicotine withdrawal. Nicotine withdrawal symptoms may last 3 to 4 weeks after cessation of smoking, and then the clonidine dose is tapered gradually over several days in order to avoid clonidine withdrawal symptoms, such as

rebound hypertension.

Autism Spectrum Disorders

Results of surveys of medication prescribing patterns in children with autism spectrum disorders reveal that immediate release clonidine and guanfacine are being prescribed for between 10 and 15 percent of children with pervasive developmental disorders, and these rates have been increasing over time. In clinical practice, α_2-agonists are considered a second-line treatment for managing symptoms of hyperactivity, inattention, impulsivity, aggression, explosive outbursts, self-injury, and sleep dysfunction in autism spectrum disorders.

Overall empirical support for the use of the α-agonists in autism spectrum disorders is limited. There are three published trials of guanfacine in children with autism spectrum disorders. Preliminary evidence supports the efficacy and safety of guanfacine in the treatment of hyperactivity, inattention, and aggression in particular subsets of the autism spectrum disorders population. Clonidine has been studied as a sedative agent for autism spectrum disorder patients undergoing electroencephalogram (EEG), as a treatment for hyperactivity and inattention, and for sleep disturbance in these patients. Transdermal clonidine has also been investigated in small studies for the treatment of impulsivity and hyperactivity in children with autism spectrum disorders. At this time larger, controlled studies in this population are required. Of note, the individuals with autism spectrum disorders are generally more sensitive to the side effects of irritability and sedation when treated with α_2-agonists. There are case reports of use of extended-release guanfacine in children with autism spectrum disorders for symptoms of inattention and hyperactivity.

Posttraumatic Stress Disorder and Other Anxiety Disorders

Increased and altered noradrenergic neurotransmission and reactivity in the CNS has been associated with a variety of hyperarousal symptoms and sleep disturbances in PTSD. Clonidine's action at the postsynaptic α_2-adrenergic receptors in the CNS reduces sympathetic activity, possibly reducing the arousal symptoms of PTSD. Guanfacine, with the same mechanism as clonidine, has also been used for treatment of the symptoms of PTSD, including nightmares. Clinically there are reports of effectiveness in child refugees and veterans, although there are no randomized, placebo-controlled trials of clonidine in PTSD, and there are reports that it loses its effectiveness over time. In an 8-week, double-blind, randomized-controlled trial, immediate-release guanfacine was found to be ineffective in treating PTSD in veterans. In a small 8-week open label study of extended-release guanfacine for traumatic stress, generalized anxiety, and functional

impairment in traumatized children and adolescents, significant differences compared to placebo were seen on all symptom severity measures suggesting need for further investigation of GXR for traumatic symptomatology in children and adolescents.

Clonidine has also been studied in other anxiety disorders. In patients with panic disorder, clonidine appears to have an acute anxiolytic effect that is transient. Some debate exists as to whether clonidine has anxiolytic effects by proxy of its sedative side effects. The α_2-agonists do not appear to be effective in OCD.

Cognition and Neuroprotective Effects

The relationship between the noradrenergic system and executive and memory functions has been extensively investigated in animal models with positive results. Investigations of the cognitive enhancing potential of α_2-agonists via its effects on the PFC in humans have been inconclusive, and more recent studies found no significant clinical effects on adult healthy controls. There is evidence for the use of clonidine and guanfacine to enhance cognition in patients with schizophrenia and Korsakoff syndrome; however, its use remains limited by issues of tolerability.

Research on the neuroprotective effects of α_2-adrenergic receptor agonists began approximately 20 years ago after studies in rats indicated a protective effect of clonidine after cerebral ischemia. These neuroprotective effects have also been seen with the α_2-agonist brimonidine (Alphagan P) in glaucoma. At this time, despite extensive animal research, minimal investigation has been done to evaluate the neuroprotective effects of these drugs in humans.

Other Disorders

Clonidine has been used in the treatment of alcohol withdrawal to target the symptoms thought to be secondary to adrenergic hyperactivity and CNS excitation. There is no evidence suggesting that these medications are effective in reducing the incidence of seizures or delirium associated with alcohol withdrawal, thus reducing their use to an adjunctive treatment to benzodiazepines and typical antipsychotics. Animal studies have also looked at clonidine in decreasing voluntary alcohol drinking. There are also reports of using low-dose clonidine (0.025 mg three times per day) in hallucinogen persisting perception disorder, where symptoms may resolve within 2 months of initiating treatment.

There has also been a positive small double-blind randomized placebo-controlled trial investigating the use of clonidine for hyperarousal symptoms in patients with borderline personality disorder with and without PTSD.

PRECAUTIONS AND ADVERSE REACTIONS

Adverse effects of clonidine include dry mouth (40 percent), drowsiness (33 percent), dizziness (16 percent), constipation (10 percent), and sedation (10 percent). There are also numerous, albeit less frequent, side effects that have been reported in which a causal relationship has not been established, including nervousness, agitation, sleep disturbance, impotence, loss of libido, weight gain, headache, nausea, and vomiting. There are isolated reports of transient abnormalities in liver function tests, urinary dysfunction, thrombocytopenia, transient elevation of blood glucose, muscle pain, and leg cramps. Abnormalities on ECG such as sinus node arrest, junctional bradycardia, high-degree AV block, and arrhythmias have also been reported. Marked bradycardia is observed in some patients. Localized contact dermatitis is an adverse reaction to the clonidine transdermal therapeutic system (TTS) for approximately 15 to 20 percent of patients, particularly when using the optional adhesive cover. This can be addressed by alternating the site of the patch. The clonidine TTS contains aluminum and therefore should be removed before undergoing magnetic resonance imaging (MRI). Adverse reactions with use of extended-release clonidine include somnolence (30 percent), fatigue (15 percent), constipation (5 percent), and nightmares (3 to 9 percent), although there is some variability depending on dose. For guanfacine, the adverse effects are similar to those for clonidine, although hypotension, sedation, and dry mouth are somewhat less frequent. Adverse reactions with the use of extended-release guanfacine include somnolence (35 percent), fatigue (14 percent), and hypotension (7 percent). For these medications, there is evidence that the severity of dose-dependent adverse effects lessen over time.

Clonidine is considered a class C drug in pregnancy, which means that the safety is uncertain and that well-controlled studies in humans do not exist. Clonidine is excreted in breast milk, and caution should be exercised when administering clonidine in pregnancy and during lactation. Studies have not found evidence to suggest carcinogenesis and mutagenesis as a result of clonidine. Guanfacine is considered a class B drug in pregnancy, meaning that studies in humans have shown no evidence of risk to the fetus, although there have been adverse findings in animal studies. The excretion of guanfacine in breast milk is unknown, but in light of the fact that most medications are eliminated in breast milk, caution is suggested.

Clonidine is known to have a withdrawal syndrome. With sudden cessation of clonidine there may be an associated increase in plasma and urinary catecholamines, and associated symptoms such as nervousness, restlessness, insomnia, headache, increased heart rate, sweating, increased salivation, nausea, and flushing. There can also be episodes of rebound hypertension upon cessation of the medication. This syndrome is more pronounced after abrupt cessation of long-term therapy, in patients on a

higher total dose, and in patients also receiving β-blockers. A taper of the clonidine is required when the duration of use has been greater than 1 week, with a reduction in dose of 0.05 mg every other day. When the duration of use has been longer than 4 weeks, the dose reduction should be every third day. If there are symptoms of withdrawal present, they can be alleviated with clonidine. There are fewer data regarding a withdrawal syndrome with guanfacine, and although it remains a possibility, its longer duration of action makes withdrawal less likely.

DRUG INTERACTIONS

Clonidine and guanfacine cause sedation, especially early in therapy, and when administered with other centrally active depressants, such as barbiturates, alcohol, and benzodiazepines, the potential for additive sedative effects should be considered and dose reduction may be required. Due to a potential for additive effects, caution is required in patients receiving agents known to affect AV node and sinus node conduction such as β-blockers, calcium channel blockers, and digitalis. This combination increases the risk of AV block and bradycardia. When utilized along with antihypertensive drugs, use caution as there is the potential for additive effects. Guanfacine is metabolized by CYP3A4 microsomal enzymes and plasma concentrations can be affected significantly by CYP3A4 inhibitors or inducers. Guanfacine does not significantly affect exposures of methylphenidate and lisdexamfetamine when coadministered.

LABORATORY INTERFERENCE

Neither clonidine nor guanfacine is known to interfere with any laboratory tests.

DOSAGE AND ADMINISTRATION

Clonidine is supplied in 0.1-, 0.2-, and 0.3-mg tablets. It is also available in TTS that delivers 0.1, 0.2 or 0.3 mg daily (TTS-1, TTS-2, TTS-3). The dosing for the TTS is equivalent to the total oral daily dose. Multiple patches can be used at one time in order to administer the required dose. When administered for the treatment of hypertension, clonidine is initiated at 0.1 mg twice daily with increases of 0.1 mg at weekly intervals until desired response is achieved. Therapeutic doses for the treatment of hypertension range from 0.2 to 0.6 mg per day in divided doses. The maximum effective daily dose is 2.4 mg. It is suggested to administer a larger portion of the oral daily dose at bedtime to minimize adverse effects of dry mouth and sedation. The clonidine TTS is applied once every 7 days to a clean, dry, hairless area of intact skin on the upper outer arm, chest, or back. In children, a new patch is applied every 5 days due to their more rapid hepatic metabolism. Each new application should be on a different

skin site from the prior patch. If the clonidine TTS becomes loose from the skin, the adhesive cover can be placed over the system to ensure adhesion.

Clonidine extended release is available in 0.1- and 0.2-mg tablets. The tablets must be swallowed whole and never cut, crushed, or chewed.

Guanfacine is supplied in 1- and 2-mg tablets. When administered for the treatment of hypertension, guanfacine is initiated at 1 mg at bedtime to reduce sedation. The daily dose may be raised to 2 to 3 mg after 3 to 4 weeks of therapy. For the treatment of hypertension, the most clinical effect is seen at the 1- to 3-mg dose range, although the maximum recommended dose is 6 mg daily.

Guanfacine extended release is available in 1-, 2-, 3-, and 4-mg tablets. The tablets must be swallowed whole and never cut, crushed, or chewed.

▲ 34.5 β-Adrenergic Receptor Antagonists

ROGER S. MCINTYRE, M.D.

INTRODUCTION AND HISTORY

The first nontoxic β-adrenergic receptor antagonist, propranolol, was isolated by the Scottish pharmacologist James W. Black, earning him the Nobel Prize in Medicine in 1988. β-Adrenergic receptors are ubiquitously distributed throughout the body including the heart, lung, autonomic, and CNS. Although β-adrenergic receptor antagonists are not currently FDA approved for use in any psychiatric disorder, these agents have been used to treat disparate psychiatric conditions such as performance anxiety, PTSD panic attacks, major depressive disorder, aggressive and violent behavior, behavioral symptoms associated with dementia, alcohol and cocaine withdrawal, lithium-induced postural tremor, antipsychotic-induced akathisia, and migraine.

The five β-adrenergic receptor antagonists most frequently studied for psychiatric application are propranolol (Inderal), metoprolol (Lopressor, Toprol XL), atenolol (Tenormin), nadolol (Corgard), and pindolol (Visken).

CHEMISTRY

Propranolol is chemically described as 1-(isopropylamino)-3-(naphthalene-1-yloxy)propan-2-ol. Its molecular formula is $C_{16}H_{21}NO_2$. Propranolol is a stable, white, crystalline solid that is readily soluble in water and ethanol. Its molecular mass is 295.34. Its molecular structure is shown in Figure 34.5–1.

Metoprolol tartrate is chemically described as (1-[4-(2-methoxyethyl)phenoxy]-3-propan-2-ylamino-propan-2-ol). It is a white, practically odorless, crystalline powder with a molecular mass of [267.36] 684.82. Its molecular formula is $C_{15}H_{25}NO_3$. It is very soluble in water; freely soluble in methylene chloride, chloroform, and alcohol; slightly soluble in acetone; and insoluble in ether. The molecular structure is shown in Figure 34.5–1.

Atenolol may be chemically described as benzeneacetamide, 2-[4-[2-hydroxy-3-(1-methylethylamine)propoxy]phenyl]ethanamide. The molecular formula is $C_{14}H_{22}N_2O_3$. Atenolol has a molecular weight of 266.34. It is a relatively polar hydrophilic compound with a water solubility

of 26.5 mg/mL at 37°C and a log partition coefficient (octanol/water) of 0.23. It is freely soluble in 1N hydrochloric acid (300 mg/mL at 25°C) and less soluble in chloroform (3 mg/mL at 25°C). The molecular structure is given in Figure 34.5–1.

Nadolol is chemically described as 2R,3S 5-[2-hydroxy-3-3(tert-butylamino)-propoxy]tetralin-2,3-diol. Its molecular formula is $C_{17}H_{27}NO_4$. Nadolol has a molecular weight of 309.40. It is a white, crystalline powder that is freely soluble in alcohol, propylene glycol, and ethanol; slightly soluble in chloroform and water; very slightly soluble in sodium hydroxide; and insoluble in acetone, benzene, ether, and hexane. The molecular structure is shown in Figure 34.5–1.

Pindolol is chemically described as 1-(1H-indol-4-ylox)-3-(1--methylethylamino)propan-2-ol. Its molecular formula is $C_{14}H_{20}N_2O_2$. Pindolol has a molecular mass of 248.32. Pindolol is a white to off-white crystalline powder with a faint odor. It is practically insoluble in water, slightly soluble in methanol, and very slightly soluble in chloroform. The molecular structure is shown in Figure 34.5–1.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

The pharmacokinetics of atenolol, metoprolol, nadolol, propranolol, and pindolol are listed in Table 34.5–1.

Absorption. Absorption of propranolol (>95 percent) and pindolol (~95 percent) is extensive. Atenolol (~50 percent) and metoprolol (~50 percent) are intermediate, while absorption for nadolol is variable, averaging approximately 30 percent.

Distribution. β-Adrenergic receptor antagonists are categorized on the basis of their lipophilicity. The ability of β-adrenergic receptor antagonists to traverse the blood–brain barrier increases as a function of their lipophilicity. Propranolol and metoprolol are highly lipophilic and as a result, have both potent central and peripheral effects. Pindolol is of intermediate lipophilicity; nadolol and atenolol are the least lipophilic and have minimal central effects.

Propranolol is largely bound to circulating proteins (>90 percent). Propranolol exhibits extensive first-pass metabolism, with approximately 25 percent of an orally administered dose reaching the systemic circulation. Metoprolol is extensively metabolized by cytochrome P450 enzymes of the liver. With repeated oral administration, increases in a dose-dependent fashion. Metoprolol exhibits approximately 50 percent first-pass metabolism and relatively low protein binding (10 to 15 percent).

Atenolol plasma levels are proportional to dose over the range of 50 to 400 mg with relatively low protein binding (5 to 16 percent). Pindolol exhibits substantial interindividual variation in plasma concentrations. Pindolol has relatively low protein binding (~40 percent). Pindolol undergoes extensive metabolism in animals and man. In man, 35 to 40 percent is excreted unchanged in the urine and 60 to 65 percent is metabolized primarily to hydroxy-metabolites, which are excreted as glucuronides and ethereal sulfates. Approximately 30 percent of nadolol in serum is reversibly bound to plasma proteins. Nadolol is not metabolized by the liver and is excreted unchanged principally by the kidneys.

Elimination. The β-adrenergic receptor antagonists exhibit considerable variation in elimination half-life (see Table 34.5–1).

PHARMACODYNAMICS

Mechanism of Action

β-Adrenergic receptor antagonists block the action of endogenous catecholamines (primarily norepinephrine, as well as epinephrine) on β-adrenergic receptors. There are three types of β-adrenergic receptors, each of which exhibits tissue selectivity. β_1-Adrenergic receptors are localized in the myocardium and kidney; β_2-adrenergic receptors are located in the gastrointestinal tract, lung, liver, uterus, and vascular smooth muscles; and β_3-adrenergic receptors are located in fat cells. Norepinephrine is produced in the CNS by neurons in the locus ceruleus, a phylogenetically old monoamine system located in the dorsal pons with diffuse projections to subcortical and cortical regions.

There are also three types of α_1- and α_2-adrenoreceptors. Both α- and β-adrenergic receptors are G protein–coupled receptors. α_1-Adrenergic receptors are located in smooth muscle, notably in skin, where they mediate vasoconstriction. α_2-Adrenergic receptors are located pre- and postsynaptically in nerve terminals, where they mediate synaptic transmission. α_1-Adrenergic receptors are located in both the sympathetic and CNS. Clonidine is a selective agonist at the inhibitory α_2-adrenergic autoreceptor, while yohimbine is a selective antagonist. Clonidine, by decreasing central noradrenergic neurotransmission, exerts a centrally mediated hypotensive effect.

β-Adrenergic receptor antagonists are categorized as selective or nonselective on the basis of their affinity for β_1 and β_2 receptors, respectively. For example, propranolol and nadolol are nonselective, whereas atenolol, pindolol, and metoprolol exhibit differential affinity for the β_1-adrenergic receptor. Pindolol also exhibits intrinsic sympathomimetic activity, which implies modest agonist activity at the β-adrenergic receptor. None of the β-adrenergic receptor antagonists used in psychiatry is considered mixed antagonist, which implies antagonism of both β_1- and α_1-adrenergic receptors.

The β-adrenergic system participates in the formation and consolidation of emotional memories in humans. Pre- and postlearning stimulation of the β-adrenergic system enhances memory for the events that trigger stressful experiences, whereas β-adrenergic receptor antagonists administered prior to learning may inhibit declarative stressful memories. Propranolol affects context conditioning but has less impact on the acquisition or retention of cued fear conditioning.

Blood Levels and Relation to Action

Both propranolol and metoprolol exhibit variations in plasma concentrations due to their hepatic clearance. The bioavailability of propranolol increases with food ingestion and long-term administration. The lower lipid solubility of nadolol, pindolol, and atenolol reduces their interindividual variation.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

β-Adrenergic receptor antagonists are used in psychiatry to treat a variety of conditions. They are most frequently used as treatment for performance anxiety, lithium-induced postural tremor, and neuroleptic-induced akathisia. β-Adrenergic receptor antagonists are also used occasionally as adjunctive agents for the treatment of major depressive episodes, anxiety disorders, notably performance-based anxiety and panic attacks, aggression, behavioral disorders in the elderly, posttraumatic stress, and alcohol and cocaine withdrawal.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The ubiquity of β-adrenergic receptors throughout the body implies a panoply of physiological effects on organs and systems (Tables 34.5–2 and 34.5–3). The systems most pertinent are cardiovascular, respiratory, and metabolic. Psychiatric populations commonly treated with β-adrenergic receptor antagonists (e.g., individuals with mood, anxiety, and psychotic disorders) are differentially affected by disorders in each of these systems. For individuals without pre-existing cardiovascular disease (e.g., hypertension), β-adrenergic receptor antagonists rarely cause hypotension

at doses prescribed. Individuals with pre-existing hypertension, however, exhibit an increased propensity to the hypotensive effects of β-adrenergic receptor antagonists.

β-Adrenergic receptor antagonists minimally affect pulmonary function in healthy persons, but they may result in severe life-threatening bronchoconstriction in patients with chronic obstructive pulmonary

disease and asthma. As β-adrenergic receptor antagonists may alter the metabolism of carbohydrates and lipids and mask the premonitory signs of hypoglycemia, they should be used with caution in individuals with diabetes mellitus.

TERATOGENIC EFFECTS

None of the available β-adrenergic receptor antagonists has been adequately tested with controlled trials in pregnant women. Perinatal complications (e.g., placental insufficiency and intrauterine growth retardation) are reported with propranolol. Some infants born to mothers administered propranolol during pregnancy exhibited hypoglycemia and/or bradycardia.

Propranolol is the most commonly employed β-adrenergic receptor antagonist during pregnancy and is not known to exert a teratogenic effect in humans. β_1-Selective adrenergic antagonists such as atenolol or metoprolol may be preferred as they interfere less with β_2 receptor–mediated uterine relaxation. There are reports associating β-adrenergic receptor antagonists to fetal bradycardia, hypotonia, hypoglycemia, and intrauterine growth retardation.

Both metoprolol and pindolol cross the placental barrier; they are excreted in breast milk in small amounts. Transplacental passage of atenolol also occurs in pregnant women; fetal drug serum levels equal to the mother have been reported. Patients administered atenolol in the third trimester of pregnancy are at risk for low–birth-weight newborns and placental insufficiency. Nadolol crosses the placenta and is distributed into breast milk.

THERAPEUTIC INDICATIONS

Indications for β-adrenergic receptor antagonists are listed in Table 34.5–4.

Lithium Tremor

Lithium may result in an action tremor at therapeutic nontoxic levels. A stable lithium tremor in the absence of toxicity may, however, be distressing and impairing to the individual and require intervention. Therapeutic guiding principles are to ensure adequate blood levels necessary to achieve efficacy and to ensure that no other concomitant agents are contributory.

Consolidation of the dosing regimen to once a day at night ensures maximum lithium concentration during nonwaking hours (and may also reduce lithium-induced polyuria). If tremor persists, propranolol is most often used at a dose of 20 to 160 mg per day given in b.i.d. or t.i.d. dosing. β-Adrenergic receptor antagonists that bypass hepatic biotransformation (e.g., nadolol) may be preferred in individuals with compromised liver function. Less lipophilic β-adrenergic receptor antagonists may also be effective in lithium-induced tremor.

Generalized anxiety disorder
Schizophrenia
Treatment-resistant depression
Panic disorder
Posttraumatic stress disorder

Major Depressive Disorder

Pharmacological blockade of 5-HT_{1A} autoreceptors is thought to mimic the effect of autoreceptor desensitization and hasten the antidepressant effect of SSRIs. Results from open and randomized controlled clinical trials indicate that pindolol may accelerate the onset of antidepressant action in individuals with major depressive disorder. Extant studies suggest that pindolol's efficacy as an adjunct to SSRIs may be limited to the first 2 weeks of treatment. Pindolol's efficacy in treatment-resistant major depressive disorder, however, is less consistent. One possible explanation for inconsistent efficacy with pindolol may relate to drug–drug interactions as a consequence of a patient's pharmacokinetic profile (i.e., slow vs. fast

metabolizer).

The possibility that pindolol dosing in resistant populations was suboptimal (i.e., at 2.5 mg t.i.d.) has not been excluded. It is presumed that pindolol's mechanism of action relates to its affinity for somatic 5-HT_{1A} autoreceptors. When combined with SSRIs, pindolol also increases rapid eye movement (REM) suppression, notably an increase in REM onset latency and reduction in slow-wave sleep.

For patients receiving ECT, β-blockers are often an administered agent as part of an anesthesia regimen. It has been reported that the use of β-blocker therapy during ECT may be effective in reducing cardiovascular responses, but may also in some cases, may shorten seizure duration.

Substance Use Disorders

Available data suggest that blockade of β-adrenergic receptors potentiates cocaine-induced elevation of dopamine transmission in the nucleus accumbens, which is associated with an increase in cocaine-induced motor activity and a decrease in cocaine self-administration. Propranolol may attenuate the responsitivity of noradrenergic neurons, resulting in decreased anxiety from abstinence from cocaine, alcohol, and benzodiazepines. Propranolol may also selectively block memories associated with arousal in humans, which is salient to cue-triggered relapses in substance use disorders. Propranolol is superior to placebo in reducing cocaine withdrawal symptoms, but is not reliably efficacious in promoting abstinence from cocaine.

β-Adrenergic receptor antagonists have been used adjunctively for alcohol withdrawal and relapse prevention. Preclinical data indicate that the combination of propranolol with prazosin, an α_1-adrenergic receptor antagonist, significantly reduced alcohol drinking during both alcohol withdrawal and following imposed abstinence when compared to either drug alone. The foregoing observation suggests that contemporaneous blockade of central α_1- and β-adrenergic receptors may be a more robust strategy to reduce alcohol intake. β-Adrenergic receptor antagonists do not replace benzodiazepines for alcohol withdrawal. Available evidence indicates that atenolol 50 to 100 mg per day may be effective. β-Adrenergic receptor antagonists are not administered during alcohol withdrawal in individuals with a heart rate of less than 50 beats per minute.

Violence

Results from case reports and randomized, placebo-controlled trials indicate that β-adrenergic receptor antagonists are modestly effective and well tolerated for individuals with impulsive violence and disruptive behaviors associated with impulsive control disorders, brain injury, neurodegenerative disorder, and general medical conditions affecting the

CNS. The noradrenaline system has been implicated in the pathophysiology of behavioral disorders in Alzheimer disease. For example, individuals with Alzheimer disease evince an increased concentration of cerebrospinal fluid and norepinephrine and its metabolites.

Stimulation of CNS norepinephrine release by yohimbine, the α_2-adrenergic antagonist, engenders disruptive behaviors in Alzheimer disease. Propranolol 30 to 120 mg per day in divided doses is more effective than placebo in improving disruptive behaviors as measured by the Neuropsychiatric Inventory (NPI). In individuals with psychological impairment and severe aggression, propranolol 40 to 600 mg per day in divided doses has frequently been used as an adjuvant to antipsychotics, anticonvulsants, and lithium.

Performance Anxiety

The use of propranolol for performance anxiety as part of social phobia is the most familiar application of β-adrenergic receptor antagonists in anxiety disorders. Performance anxiety includes symptoms of dry mouth, coarse voice, increased heart rate, difficulty breathing, tremor, weakness, and dizziness. The somatic features often predispose and portend anticipatory anxiety for subsequent events. Performance anxiety can be severely impairing to affected individuals. When appropriately dosed, the β-adrenergic receptor antagonists have minimal central side effects and may facilitate performance. Benzodiazepines may result in disinhibition and impair cognitive performance.

Single dosing of propranolol 10 to 40 mg per day given approximately 20 to 30 minutes before performance is most frequently employed. It is generally recommended to consider a test dose prior to the performance event. The mechanism of action of β-adrenergic receptor antagonists relates to their effect on the peripheral sympathetic nervous system. In keeping with that view, less lipophilic agents may also be effective.

Anxiety

It has been postulated that disturbances in β-adrenergic receptor activity are associated with several anxiety disorders, notably panic disorder. Moreover, the anxiety behaviors are subserved by neural structures and circuits that involve the locus ceruleus. Human volunteer studies using the International Affective Pictures paradigm indicate that propranolol decreases basolateral amygdala responses to facial expressions independent of their emotional valence. Several randomized, controlled trials have established the efficacy of β-adrenergic receptor antagonists in the treatment of disparate anxiety disorders. Most studies have included individuals with generalized anxiety disorder, panic disorder, and OCD. It is generally understood that β-adrenergic receptor antagonists are

differentially efficacious for the somatic-autonomic symptoms (vs. psychological symptoms). Pindolol 2.5 mg per day t.i.d. has been used successfully as an adjunct to SSRIs in the treatment of OCD. For generalized anxiety disorder and panic attacks, propranolol doses of 40 to 320 mg per day have been employed.

Posttraumatic Stress Disorder

Disruptions in the catecholaminergic system in stress models are a highly replicated preclinical observation. Moreover, it has been reported in preclinical models that β-adrenergic receptor antagonism indirectly targets protein synthesis implicated in the reconsolidation of fear memories. It is established that disrupting reconsolidation targets original fears, and as a consequence, prevents the return of fear. Notwithstanding, a recent Cochrane collaboration review had concluded that β-adrenergic receptor antagonists have insufficient efficacy for the prevention of PTSD in individuals who are identified as at-risk.

Neuroleptic-Induced Akathisia

β-Adrenergic receptor antagonists may be more efficacious than anticholinergics and benzodiazepines for medication-induced movement disorders such as akathisia. Adequately powered comparator controlled studies, however, have not been completed. β-Adrenergic receptor antagonists are not considered efficacious for other neuroleptic-induced movement disorders such as acute dystonia and parkinsonism. In some resistant cases, β-adrenergic receptor antagonists may be combined with benzodiazepines and anticholinergics. Propranolol 10 to 30 mg per day has been the most frequently reported dosage; nadolol may also be employed.

PRECAUTIONS AND ADVERSE REACTIONS

Symptoms of propranolol overdose include bradycardia, cardiac failure, hypotension, and bronchospasm. The introduction of selective β-adrenergic receptor antagonists with less affinity at β_2 receptors has decreased, but not eliminated, the hazard of bronchospasm associated with nonselective agents. For patients with asthma or chronic obstructive pulmonary disease, selective β_1-adrenergic receptor antagonists should be used. Depression of the myocardium leading to cardiac failure has also been described. Abrupt discontinuation of propranolol therapy has been associated with severe exacerbation of angina and the occurrence of myocardial infarction. Skin rashes and conjunctival xerosis are rarely associated with β-adrenergic receptor antagonists. Aggravation of congestive heart failure has also been described. β-Adrenergic receptor antagonists may mask clinical signs of developing or continuing hyperthyroidism, as well as block premonitory signs and symptoms of

acute hypoglycemia.

Other adverse events include CNS depression, fatigue, nightmares, insomnia, vivid dreaming, and hallucinations. β-Adrenergic receptor antagonists do not adversely affect cognitive function and may enhance performance in measures of memory, learning, and psychomotor speed. The probability that a β-adrenergic receptor antagonist exerts central side effects is a function of its lipophilicity and ability to readily cross the blood–brain barrier. The amount of β-adrenergic receptor antagonist absorbed into brain tissue, rather than cerebrospinal fluid concentration, may be more pertinent to the liability of central side effects.

The incidents of CNS side effects is lowest with the most hydrophilic agents (e.g., atenolol) and highest with pindolol and propranolol, while metoprolol is intermediate. Other side effects attributable to β-adrenergic receptor antagonists are sexual dysfunction and gastrointestinal disturbances; hypersensitivity reactions are rare. Incident depressive symptoms are hypothesized to be due to the inhibitory actions of β-adrenergic receptor antagonists on β-adrenergic and serotonin receptors in the CNS. Studies evaluating this association have produced divergent results, however, which may be related to methodological factors such as small sample sizes, nonrandomized data, and lack of controlled groups.

β-Adrenergic receptors are located on osteoblasts; conflicting evidence suggests that β-adrenergic receptor antagonists may increase bone mineral density and reduce fracture risk. Individuals with sinus bradycardia, congestive heart failure, greater than first-degree atrioventricular block, severe chronic obstructive pulmonary disease, and bronchial asthma should not be prescribed β-adrenergic receptor antagonists.

The predominant symptoms reported following β-adrenergic receptor antagonist overdose are lethargy, respiratory depression, wheezing, sinus pause, and bradycardia. Additionally, a common effect associated with overdose of any β-adrenergic blocking agent is congestive heart failure. Treatment should be symptomatic and supportive and directed to the removal of any unabsorbed drug by induced emesis or administration of activated charcoal. Further consideration should be given to dehydration, electrolyte imbalance, and hypotension by established procedures.

DRUG INTERACTIONS

Drug interactions between β-adrenergic receptor antagonists and other agents may be either pharmacokinetic or pharmacodynamic. Lipid-soluble β-adrenergic receptor antagonists (e.g., propranolol, metoprolol) are extensively metabolized and have a high first-pass hepatic clearance. Conversely, atenolol, nadolol, and pindolol are eliminated unchanged by the kidney. Coadministered drugs that induce hepatic oxidative enzymes may increase the clearance of propranolol and metoprolol. Individuals coadministered metoprolol with a cytochrome P450 2D6-inhibiting SSRIs,

or those who are slow metabolizers of debrisoquine hydroxylase, may exhibit elevated plasma concentrations of metoprolol.

Coadministered agents that alter hepatic blood flow are also predicted to increase plasma concentrations of orally administered metoprolol and propranolol. Agents that inhibit hepatic enzymes and/or reduce hepatic blood flow will exert an opposite effect.

β-Adrenergic receptor antagonists may alter pharmacokinetics of other agents by reducing hepatic blood flow and inhibiting hepatic oxidative metabolism. Propranolol may increase the blood concentration of chlorpromazine by inhibiting its metabolism. Propranolol may also inhibit the metabolism of coumarin anticoagulants.

Pharmacodynamic interactions with β-adrenergic receptor antagonists include cardiac depression effects and potentiation of postural hypotension with coadministered antiarrhythmics and vasodilators.

LABORATORY INTERFERENCE

Pindolol may elevate liver transaminases, alkaline phosphatase, lactate dehydrogenase, and serum uric acid; pindolol rarely reduces bilirubin. Cases of thrombocytopenia and leucopenia have been described with β-adrenergic receptor antagonists.

DOSAGE AND ADMINISTRATION

β-Adrenergic receptor antagonists that act peripherally may be safer with regard to CNS adverse events when compared to agents with both peripheral and central action. For disorders in which a central effect is desired (e.g., violence), a more lipophilic agent (e.g., propranolol) should be considered. For peripheral side effects associated with psychotropic medication use, less lipophilic agents should be considered.

Propranolol is usually initiated orally at 10 mg t.i.d. or 20 mg b.i.d. increasing by approximately 20 to 30 mg per day until the desired effect is achieved. The patient's pulse and blood pressure readings should be taken regularly and the agent should be withheld if pulse is less than 50 beats per minute, the systolic blood pressure is less than 90 mm Hg, or the patient manifests CNS symptomatology. Propranolol should be tapered by approximately 40 to 60 mg daily until 60 mg per day is reached, after which time the drug should be tapered 10 to 20 mg per day every 3 to 4 days. β-Adrenergic receptor antagonists should not be discontinued abruptly as severe exacerbation of angina and the occurrence of myocardial infarction have been reported in patients with pre-existing cardiovascular disease following abrupt discontinuation of propranolol therapy.

Pindolol is initiated at 2.5 mg t.i.d. and increase is tolerated up to a maximum of 60 mg per day. Nadolol is initiated at 40 mg per day, increasing to 80 mg per day as tolerated. Atenolol is initiated at 50 mg per day and can be increased to 100 mg per day. Rarely, an atenolol dose of up

to 200 mg per day is used. The effective dosing range of metoprolol is 100 to 450 mg. The initiation dose is 100 mg; dosing beyond 450 mg has not been studied.

▲ 34.6 Anticholinergics and Amantadine

SAMOON AHMAD, M.D.

HISTORY

Anticholinergics block the binding of acetylcholine to its receptor present in nerve cells and are used to treat numerous diseases like asthma, motion sickness, symptoms of Parkinson disease and incontinence, and many others. In nature, anticholinergic substances exist as alkaloids and are most commonly found in perennial herbaceous plants such as *Atropa belladonna* (deadly nightshade), *Mandragora officinarum* (mandrake), *Hyoscyamus niger* (henbane), and Datura species. The active agents in belladonna with anticholinergic properties include atropine, hyoscine (scopolamine), and hyoscyamine. Atropine is the most common muscarinic antagonist and is used in cosmetics, for medicinal purposes, homeopathy, and as a recreational drug. In addition to being hallucinogenic, *Atropa belladonna* is one of the most toxic plants found in the Eastern hemisphere.

Anticholinergics fall into two categories: the antimuscarinic and antinicotinic. Antimuscarinic agents affect both the central and peripheral nervous system with varying selectivity among different agents. Antimuscarinic agents that block central cholinergic activity are used as antiparkinsonian drugs while those with nonselective antagonism have various clinical uses including bronchospasm, antispasmodic, urinary incontinence, and in anesthesia. The prototype of these agents is atropine.

ATROPINE

Atropine is a tropane alkaloid extracted from *Atropa belladonna* and other plants of the family *Solanaceae*. The solubility varies from being highly soluble in ethanol to being insoluble in ethyl ether. It is a secondary metabolite of these plants and serves as a drug with a wide variety of effects. Being potentially deadly, it derives its name from *Atropos*, one of the three fates who, according to Greek mythology, chose how a person was to die. Atropine is used in ophthalmic examination for pupil dilation and has been historically used by Italian women (*Bella Donna* is Italian for beautiful lady) to dilate their eyes for aesthetic reasons. Atropine is also used to treat poisoning by cholinesterase inhibitors, reverses the effects of nerve agents, and has cardiac and GI effects. Small doses can cause a marked increase in heart rate. It plays an important role in reversing reflex vagal cardiac slowing or asystole caused by various agents. Atropine is also administered in small doses before general anesthesia to lessen oral and air-passage secretions. Its ability to reduce these secretions is also utilized

in several preparations commonly used for symptomatic relief of colds. It also acts as a specific antidote to rapid type of mushroom poisoning. Blockade of muscarinic receptors in the CNS by atropine can lead to restlessness and excitement, and large doses can cause hallucinations. At the same time, these drugs are found to be therapeutically useful in Parkinson disease.

Atropine also serves as an antidote for poisoning by organophosphate insecticides and nerve gases. Troops who are likely to be attacked with chemical weapons often carry autoinjectors with atropine, which can be quickly injected into the thigh (Fig. 34.6–1).

Other commonly used anticholinergics include benztropine mesylate (Cogentin), diphenhydramine (Benadryl), trihexyphenidyl (Artane), and procyclidine (Kemadrin).

ANTICHOLINERGIC AGENTS

Chemistry

Artane (trihexyphenidyl hydrochloride) is the substituted piperidine salt, 3-(1-piperidyl)-1-phenyl-cyclohexyl-1-propanol hydrochloride, which exerts a direct inhibitory effect on the parasympathetic nervous system. It is used in the treatment of parkinsonism and extrapyramidal disorders. It also exhibits a direct spasmolytic action and weak mydriatic, antisialogogue and cardiovagal blocking effects (Fig. 34.6–2).

FIGURE 34.6–1. Structure of atropine.

MOLECULAR STRUCTURE OF TRIHEXYPHEIDYL HCL

FIGURE 34.6–2. Molecular structure of trihexyphenidyl HCL.

Benztropine mesylate is designated chemically as 8-azabicyclo[3.2.1]octane, 3-(diphenylmethoxy)-*endo*, methanesulfonate. Its empirical formula is $C_{21}H_{25}NO \cdot CH_4O_3S$. It is a crystalline, white powder, very soluble in water, and has a molecular weight of 403.54. It possesses both anticholinergic and antihistaminic effects, although only the former has been established as therapeutically significant in the management of parkinsonism (Fig. 34.6–3).

Diphenhydramine hydrochloride is an antihistamine that occurs as a white, crystalline powder and is freely soluble in water and alcohol. It has a molecular weight of 291.82 (Fig. 34.6–4). It is used in the treatment of runny nose, sneezing, and itching of the nose or throat.

Procyclidine hydrochloride occurs as a white, tasteless, crystalline powder that is soluble in water. It is a synthetic antispasmodic compound useful for the symptomatic treatment of parkinsonism (paralysis agitans) and extrapyramidal dysfunction. Some find fewer side effects with this agent. The dose is begun at 2.5 mg per day and increased gradually to a maximum of approximately 30 mg per day. It is known chemically as α-cyclohexyl-α-phenyl-1-pyrrolidinepropanol hydrochloride. Its structural formula is shown in Figure 34.6–5.

Biperiden is an analog of trihexyphenidyl. It is approved for the treatment of parkinsonism and has greater pharmacological anticholinergic activity than trihexyphenidyl.

Pharmacological Actions

There is limited information available regarding pharmacokinetics of these drugs especially in the elderly and may limit the safe and effective use in this population. According to Goodman and Gilman's Pharmacological Basis of Therapeutics 8th edition, "There is surprisingly little information on the pharmacokinetic properties of these anticholinergic drugs." There are numerous factors contributing to this limited data including newer and more effective treatments, loss of patent for older drugs, and very low dosages used for treatment.

FIGURE 34.6–3. Molecular structure of benztropine mesylate.

FIGURE 34.6–4. Molecular structure of diphenhydramine HCL.

Absorption and Distribution. Anticholinergic agents are widely distributed after absorption and achieve significant levels in the CNS within 30 minutes to 1 hour, and this high concentration in brain tissue may be related to their high lipophilicity. In humans, the bioavailability of these drugs is not reported and plasma protein binding is also poorly understood. All of these drugs are extensively metabolized, and all unchanged drugs as well as metabolites are excreted in the bile and urine.

Trihexyphenidyl is rapidly absorbed from the GI tract. After oral administration, the onset of action occurs within 1 hour, peak effects last 2 to 3 hours, and the duration of action is 6 to 12 hours. It is excreted in the urine.

Benztropine is well absorbed by the GI tract. However, it exhibits a

more rapid onset of action when administered either by the intravenous (IV) or intramuscular (IM) route, although there is no difference in onset of action between these two parenteral routes. All of these agents readily cross the blood–brain barrier (BBB).

Pharmacodynamics

Anticholinergic drugs act by blocking acetylcholine receptors. Acetylcholine acts in the nervous system at two major classes of cholinergic receptors: nicotinic and muscarinic. Distribution is quite different with the muscarinic receptors being located in the CNS, smooth muscle, cardiac muscle, and parasympathetically innervated glands, such as the salivary glands. Nicotinic receptors are located on striated muscle at the neuromuscular junction (motor end plate), the autonomic ganglia, and in the CNS. The muscarinic receptors are G-protein–coupled receptors. There are numerous muscarinic receptor subtypes (M1 to M5), and all are present in the brain. These receptor subtypes have selectivity for various brain regions with M1 receptor being the most abundant subtype in the CNS, and are predominantly located in the neocortex, neostriatum, and hippocampus. The M2 and M3 receptors are also widely distributed throughout the brain, but M3 receptor has a relatively lower density. The M4 receptors are mostly present in the neostriatum, while M5 receptors are localized in the hippocampus and projection neurons of substantia nigra, pars compacta, and ventral tegmental nuclei. Anticholinergic medications, such as benztropine, trihexyphenidyl, procyclidine, and biperiden, act as competitive antagonists at muscarinic receptors. The beneficial effect of agents in Parkinson disease is mediated by CNS muscarinic receptor blockade.

FIGURE 34.6–5. Molecular structure of procyclidine HCL.

The anticholinergic activity is independent of the serum drug levels of anticholinergic medications because drug levels vary up to 100-fold, and hence, are not routinely measured. There is evidence that there is a

threshold serum level for anticholinergics, and once this threshold is achieved, it is unlikely for extrapyramidal side effects to occur. This threshold level is a result of muscarinic receptor blockade. Consequently, the decrease in extrapyramidal side effects is not related to the dose of anticholinergic medication nor the dose or serum level of antipsychotic medication, but only to the serum level of anticholinergic activity.

Clinical Studies

The antimuscarinic drugs cause wide variety of CNS side effects, and this depends on their ability to penetrate the BBB as well as the activity on the receptors. Only small lipid-soluble molecules are able to pass from capillary blood to brain tissue. The cognitive impairment associated with these drugs in particular memory loss, may result from antagonism of M1 and, to some extent, M2 or M4 receptors in the CNS. Clinical studies suggest that older patients are more vulnerable to these cognitive side effects especially those with early stages of dementia, pre-existing cognitive impairment, and age associated memory decline.

Many recent studies have looked at the impact of these agents on cognitive functioning. A double-blind, crossover trial showed that agents that decrease cholinergic transmission impair storage of new information into long-term memory, but have little effect on retrieval from memory or on tasks involving only immediate memory. Another study evaluated the effects of discontinuation of anticholinergic medication on cognitive functioning in a group of elderly chronic schizophrenia patients. Significant improvement was demonstrated in the cognitive total score, as well as in the ideational praxia and orientation subscales.

These agents have also been implicated in worsening psychoses. However, many recent studies challenge this hypothesis; other recent studies show great variability in the patient population studied. A few recent small double-blind, placebo-controlled crossover studies have looked at anticholinergic medications and their effects on both positive and negative symptoms of schizophrenia. These agents appear to have no effect on the positive symptoms of schizophrenia in a stabilized patient, possibly because the presumed dopamine hyperactivity has been corrected. In schizophrenic patients who are acutely ill, studies consistently find that anticholinergic medications worsen positive symptoms.

Limited data exist regarding the utility of serum anticholinergic levels. One study compared verbal memory and reaction time of ten schizophrenic patients at two different serum anticholinergic levels. Verbal recall was worse at higher drug levels, while reaction time tended to be improved by anticholinergic treatment.

The effect of anticholinergics on tardive dyskinesia is also a controversial subject. Though the exact mechanism is unknown research studies have postulated that tardive dyskinesia may be related to an

abnormal influence of dopamine on striatal dopaminergic receptors. In one double-blind, placebo-controlled study, 10 chronic schizophrenic patients with pronounced symptoms of tardive dyskinesia were withdrawn from anticholinergic medication. The severity of tardive dyskinesia decreased significantly in nine patients within 2 weeks; this improvement, most pronounced in the oral region, persisted during a 6-week placebo period. Furthermore, acetylcholine and dopamine exert opposite effects on the striatum and a delicate balance is necessary to maintain normal functioning. The neuroleptic-induced dopaminergic blockage is considered to be a chemical denervation and analogous to pathological anatomical denervation of idiopathic Parkinson disease. Studies have shown the incidence of tardive dyskinesia to be higher in patients receiving both neuroleptic and anticholinergic medications. This hypothesis suggests that anticholinergic medications may predispose patients to the development of tardive dyskinesia. It is recommended that the use of anticholinergic medications should be kept to a minimum in patients receiving long-term neuroleptic therapy, and discontinuation of anticholinergic medication is a possible therapeutic approach in patients with tardive dyskinesia.

Effects on Specific Organs and Systems

Central Nervous System. In the usual recommended dosages, these drugs have a mild stimulant effect and a slower, longer-lasting sedative effect. The initial central vagal stimulant effect causes bradycardia, but as the antimuscarinic effects take place, it is supplanted by tachycardia. These effects are a result of the effect these agents have on the vagal nucleus in the medullary center and the sinoatrial node. Scopolamine is used for motion sickness and produces drowsiness and can cause amnesia in sensitive individuals. Toxic doses can cause agitation, hallucinations, excitement, and coma.

Parkinson disease is a result of excess of cholinergic activity and a deficiency of dopaminergic activity. The centrally acting antimuscarinic agents reduce the tremor, and when used in combination with a dopaminergic drug (levodopa [Dopar]) can have more effective response.

Eye. These agents cause cycloplegia (paralysis of the ciliary muscle), leading to loss of accommodation and the inability of the eye to focus for near vision. These medications also block the response of the sphincter muscle of the iris, which causes dilation of the pupil.

Anticholinergic medications have little effect on intraocular pressure, except in patients with narrow-angle glaucoma, in whom the pressure may rise to dangerous levels.

Cardiovascular System. In the heart, the atria are innervated by the parasympathetic (vagal) nerve fibers. The anticholinergic agents cause

tachycardia when moderate to high therapeutic doses are used. In toxic doses, these agents can cause intraventricular conduction block.

Respiratory System. The secretory glands and the smooth muscle of the airways are innervated by the muscarinic receptors. These agents inhibit secretions of the nose, mouth, pharynx and bronchi, usually clinically manifesting as dry mouth.

Gastrointestinal Tract. The GI tract is innervated by both cholinergic and noncholinergic fibers and is also modulated by local hormones. The net effect of these agents is decreased motility via inhibition of parasympathetic control, which may result in constipation or paralytic ileus. These agents also cause dry mouth and delay the gastric emptying time.

Genitourinary Tract. Anticholinergics cause relaxation of the smooth muscle in the ureter and the bladder wall and are used in the treatment of spasm caused by inflammatory conditions. At the same time, this can lead to urinary hesitancy, particularly in elderly men with prostatic hypertrophy.

Therapeutic Indications

Central Nervous System

EXTRAPYRAMIDAL SIDE EFFECTS. Extrapyramidal side effects (acute dystonias, parkinsonism, and akathisia) are caused by neuroleptic blockade of dopaminergic nigrostriatal tracts, leading to an increase in cholinergic activity. Other mechanisms involved include decreased serum calcium levels, which affect the cholinergic and dopaminergic systems. Acute dystonic reactions usually appear early and may occur within 1 to 4 days of neuroleptic therapy, while parkinsonism and akathisia usually manifest within the first 3 months of treatment. Anticholinergics reduce cholinergic activity and restore the cholinergic and dopaminergic equilibrium, leading to improvement in extrapyramidal side effects.

Acute Dystonia. Acute dystonia is characterized by a spastic contraction of muscle groups and often affects the neck, eyes, and trunk and develops early in the treatment or after rapid dose escalation of antipsychotic medication. The various forms of dystonia include torticollis, retrocollis, trismus or lockjaw, grimacing, dysarthria, blepharospasm, oculogyric crisis, and opisthotonos. These involuntary muscle contractions that occur suddenly are frightening and painful to the patient and may, in rare cases, be life-threatening (e.g., laryngospasm). In most cases, this side effect occurs within the first couple of days of treatment. It can be effectively and rapidly treated with medication. Treatment of a dystonic reaction is

typically with benztropine (1 to 2 mg) or diphenhydramine (25 to 50 mg), either IM or IV. Onset of action of these medications, IM or IV, is rapid, with resolution of the symptoms often within 10 to 15 minutes. As dystonic reactions may recur, prophylaxis with oral medications such as benztropine (1 to 2 mg twice daily) or trihexyphenidyl (2 mg three times a day) is recommended. Tardive dystonia may develop after months or years of treatment with antipsychotic medications and usually does not respond rapidly to anticholinergic medication.

Akathisia. Akathisia is characterized by an internal sense of motor restlessness often described as an inability to resist the urge to move. The most common form of akathisia involves pacing and an inability to sit still and most often occurs during the first few months of conventional antipsychotic use. At times, patients may have difficulty explaining the sensation of akathisia and can be often misdiagnosed as agitated, leading to an increase in antipsychotic medication and hence worsening the akathisia. Anticholinergics have limited utility in the treatment of akathisia; they should be considered second-line therapy and used when first-line agents, such as adrenergic receptor antagonists (propranolol), either fail or are contraindicated.

Parkinsonism. Parkinson disease and parkinsonism secondary to the use of antipsychotics can be indistinguishable. The symptoms include generalized slowing of movement (akinesia), rigidity, resting tremor, hypersalivation, cog-wheeling, and masked facies. These symptoms are caused by a blockade of dopamine receptors of nigrostriatal neurons, which terminate in the caudate nucleus. These symptoms can be mistaken for the negative symptoms of schizophrenia. Parkinsonism is more common with the high-potency antipsychotics and is seen much less frequently with atypical antipsychotics. These symptoms may manifest any time during antipsychotic treatment, but usually begin within the first 3 months of treatment and can be managed by lowering the antipsychotic dose to the lowest effective dose.

Anticholinergics are found to be useful in treating the symptoms of neuroleptic-induced parkinsonism. The additions of benztropine (0.5 to 6.0 mg per day), trihexyphenidyl (2 mg, two to four times daily), procyclidine (5 to 20 mg per day), and biperiden (2 to 24 mg per day) have been found to be effective therapies.

Long-Term Use of Anticholinergics

Patients with schizophrenia often require long-term treatment with conventional antipsychotics. As noted above, these medications have serious adverse effects such as extrapyramidal side effects, including acute dystonic reactions, akathisia, parkinsonism, and tardive dyskinesia. Much controversy exists in the prophylactic use of anticholinergic medication to

reduce or minimize these adverse events. As mentioned before, earlier reports stated that long-term use of anticholinergics might predispose to tardive dyskinesia. Anticholinergics also have serious side effects: long-term use may affect memory, and cognitive impairment can be seen as early as 60 days if these medicines are taken continuously; overdose of these agents creates a dangerous condition with tachycardia, hyperthermia, mydriasis, hallucinations, seizure, and coma; and anticholinergics may be abused. These findings led to recommendations by the World Health Organization, which has released a consensus statement that "the prophylactic use of anticholinergics in patients on neuroleptic treatment is not recommended, and may be justified only early in treatment (after which it should be discontinued and its need should be reevaluated)." Based on the above, since many patients will not develop parkinsonism, they do not need these medications.

Later studies suggest that there is evidence to support the use of initial prophylaxis, especially in young men receiving high-potency antipsychotics and who remain at high risk for developing acute dystonia. They also reviewed the literature for continuing prophylactic treatment and concluded that continuing prophylaxis is helpful for many patients because a large number of patients will develop parkinsonism upon withdrawal of anticholinergic medication. The prophylactic use of these agents is not routinely indicated and should be used on a case-to-case basis for patients with high risk of developing acute dystonic reactions.

Precautions and Adverse Reactions

Anticholinergic medications have CNS as well as peripheral adverse reactions due to their widespread antagonism of muscarinic receptors in the periphery. These agents produce clinically meaningful effects on the cardiovascular, GI, autonomic, and urogenital systems. The major adverse reactions of these medications are summarized in Table 34.6–1.

Anticholinergic agents block muscarinic acetylcholine receptors throughout the body and produce system-wide side effects. At low doses, it causes dry mouth, but at higher dosages it can cause constipation, which can progress to intestinal pseudo-obstruction and bowel dilation. Effects on the bladder can result in urinary retention, especially in male patients. Nausea, drowsiness, abdominal cramps, and mild tachycardia can also occur. Dry skin and impaired sweating may lead to heat stroke. Anticholinergics are contraindicated in patients with closed-angle glaucoma. These drugs can cause confusion and memory loss, and in the more advanced and demented patients, hallucinations and disorientation can occur. Lowering or discontinuing the drug can treat the side effects.

Toxic doses or an overdose of anticholinergic medication may lead to an atropine-like poisoning, which may manifest as confusion, nervousness, psychosis, ataxia, dry mouth, blurred vision, tachycardia, elevated blood pressure, GI upset, anhidrosis, hyperthermia, and respiratory collapse. In general, supportive measures are used after an overdose. However, 1 to 2 mg of physostigmine salicylate (Antilirium), an acetylcholinesterase inhibitor, may be used to reverse the anticholinergic symptoms of overdose. If required, a second dose of physostigmine may be administered 2 hours after the first dose.

Anticholinergic Abuse. These agents have an abuse potential secondary to their euphoriant and hallucinogenic effects, especially when combined with other street drugs. The prevalence of anticholinergic abuse varies from 0 to 34 percent. The most common reason for abuse is the drug-induced euphoria. Trihexyphenidyl is the most commonly abused anticholinergic for the reason that it tends to be the most stimulating of all anticholinergics.

Drug Interactions

Any medication with anticholinergic or antihistaminic properties may be pharmacodynamically additive to the effects of anticholinergic medications and, thus, would predispose to side effects and toxicity. Pharmacokinetic interactions with these agents occur as well. For example, the coprescription of benztropine and digoxin (Digitek) has been reported to increase digoxin levels (Table 34.6–2).

Table 34.6–2.

Anticholinergic Preparations and Dosages

Generic Name	Brand Name	Preparations	Daily Oral Dose
Benztropine	Cogentin	0.5, 1.0, 2.0 mg tablets 1 mg/mL injection	0.5–2.0 mg b.i.d. or t.i.d.
Trihexyphenidyl	Artane	2, 5 mg tablets 2 mg/5 mL elixir	2 mg b.i.d. to q.i.d.
Biperiden	Akineton	2 mg tablets 5 mg/mL injection	2 mg t.i.d. to q.i.d.

Any medication with anticholinergic properties may also potentiate the anticholinergic effects of amantadine. Due to the renal clearance of amantadine, medications that decrease renal clearance may result in higher plasma concentrations, and consequently, a greater risk for side effects. These include triamterene hydrochlorothiazide (Maxzide), trimethoprim sulfamethoxazole (Bactrim), and quinidine.

Laboratory Interference

The anticholinergic medications and amantadine are not known to alter the results of any standard laboratory tests and values.

Dosage and Administration

Anticholinergic doses can vary widely among individuals and must be empirically determined. In general, prophylactic doses are the same as the doses usually needed to treat parkinsonism. For acute dystonias, an IM or IV medication such as benztropine (1 to 2 mg IM) or the antihistamine diphenhydramine (25 to 50 mg IM or IV) is usually given. The starting dose for trihexyphenidyl is 0.5 to 1 mg per day and the dose should be increased no faster than every 7 to 14 days. Dose increase of 1 mg per day is reasonable and a dose of 2 mg three to four times per day is the usual goal.

The dose of benztropine is begun at 0.5 mg per day and can be raised to 4 to 8 mg per day and requires dosing two to three times per day.

The dose of procyclidine is begun at 2.5 mg per day and increased gradually to a maximum of approximately 30 mg per day.

The starting dose of diphenhydramine is 25 mg per day, and it can be titrated to 150 to 200 mg per day in divided doses.

SCOPOLAMINE

Introduction and Chemistry

Scopolamine is a tropane alkaloid drug and a competitive acetylcholine antagonist with significant affinity for the M3 receptor and has minimal effect at nicotinic receptors. It has been in use in its plant-based form since prehistoric times but has only been used in its purified forms (including

hydrobromide, hydrochloride, hydroiodide, and sulfate) since 1880. It is more potent then atropine for its antimuscarinic effect on the eye and salivary glands and less potent on the heart, respiratory and intestinal smooth muscle (Fig. 34.6–6).

Pharmacological Actions

Scopolamine is well absorbed from the GI tract primarily from the upper small intestine. Its onset of action varies depending on the formulation but ranges from 15 to 30 minutes for an injectable form to 4 hours for the transdermal form. The therapeutic effects last up to a maximum of 72 hours with the transdermal patch. Scopolamine crosses the BBB as well as the placenta and is secreted in to the milk and is classified as a pregnancy category C drug. It is reversibly bound to plasma proteins and principally eliminated in the urine. The transdermal formulation has fewer side effects and longer duration of action compared to the oral form. It is also used preoperatively to inhibit gastric and respiratory tract secretions.

FIGURE 34.6–6. Molecular structure of scopalamine.

Dosage and Administration

Scopolamine can be administered orally, as a transdermal patch or injected IM, direct IV or sub-Q. The oral adult dosage ranges from 0.4 to 0.8 mg initially and up to three times daily as needed. The injectable dose ranges from 0.32 to 0.65 mg and can be repeated up to three times daily.

Therapeutic Indications

Scopolamine is mostly used for motion sickness and postoperative nausea and vomiting. Recent studies suggest its role in depressive disorders as well. Scopolamine is available in various forms including transdermal, injectable, and oral formulations.

Precautions and Adverse Reactions

CNS effects: Drowsiness, amnesia, disorientation, dizziness, and confusion.

Ocular effects: Possible increased intraocular pressure requiring monitoring and may require adjustment of therapy.

Idiosyncratic reactions: Acute toxic psychoses, somnolence, dilated pupils, delirium and dryness of the mouth, and increased pulse rate.

Other possible adverse effects: Decreased GI motility, possible urinary retention, and decreased bronchial secretions with formation of bronchial plugs.

Design and Interpretation of Clinical Drug Studies

During the last few years, the role of anticholinergic medications has expanded to include treatment of depressive disorders. Researchers initially proposed the idea of adrenergic cholinergic imbalance as early as 1972, and though initially ignored, most of the recent body of research is based on this hypothesis. It is well known that increasing cholinergic activity using physostigmine (an anticholinesterase inhibitor) may lead to exacerbation of acute depressive symptoms in patients with major depressive disorder (MDD). In addition, this cholinergic increase may also induce depressive symptoms in currently manic patients with bipolar disorder (BD). Numerous studies since then have shown depressive symptoms associated with increased cholinergic activity while the inverse is true for improvement in major depression. It is also well established that REM sleep changes are associated with MDD, and REM sleep deprivation as induced by anticholinergic medications leads to reduction in these symptoms.

Among the anticholinergic medications, scopolamine in particular has been shown to improve symptoms of moderate to severe depression. The first evidence of this finding was suggested in 1991 research conducted on a small group of patients with moderate depression using intramuscular scopolamine and showed a statistical difference. However, it was not until 2006 that investigators established the efficacy of scopolamine in depressive disorders while studying the cognitive effects of intravenous scopolamine and incidentally found antidepressant effects of this drug. To validate these findings the investigators designed two crossover randomized controlled trials, and showed a significant robust and rapid antidepressant response of intravenous scopolamine compared to placebo. A later study by the same researchers in 2010 validated these findings specifically in patients with unipolar depression.

Another study conducted at the National Institute of Mental Health enrolled patients with MDD who received multiple sessions of placebo or scopolamine hydrobromide (4 μg/kg) and were randomized to a placebo/scopolamine or scopolamine/placebo sequence of infusions 3 to 5 days apart. Patients were evaluated using the Montgomery-Asberg Depression Rating Scale and the Hamilton Anxiety Rating Scale to assess response to scopolamine. Patients showed reductions in depression and anxiety from baseline during scopolamine infusions compared to placebo infusions. The antidepressant and antianxiety effects occurred in less than

3 days compared to conventional antidepressants which may take up to 4 weeks. The group receiving scopolamine infusions first followed by placebo infusions continued to show response suggesting alternative mechanisms besides effect on neuroreceptors. This persistence of improvement in mood beyond the initial infusion period also negates the hypothesis of anticholinergic euphoria and suggests a sustained antidepressant response. This study showed a rapid antidepressant response to scopolamine in depressed patients that is well tolerated and safe relative to other rapid antidepressant treatments including ketamine and high-dose TCA therapy. Scopolamine has high affinity for M3 receptor and is 30 times more potent than amitriptyline.

Recognizing the fact that a significant number of patients with MDDs do not respond to antidepressant medications, the need for augmentation strategies from the beginning are being increasingly entertained. Considering the role of scopolamine as discussed above, it is no surprise that it may have a substantial role in such treatments. The major limitation of using scopolamine has been the intramuscular and intravenous route of administration, which has a limited utility in every day practice settings. To overcome this barrier and assess the tolerability and efficacy of oral scopolamine, investigators designed a randomized, placebo-controlled, double-blind, parallel-group study to evaluate the role of oral scopolamine as an adjuvant therapy to citalopram in moderate to severe MDD.

Forty patients were randomized into two groups, the active group receiving citalopram and scopolamine hydrobromide (containing 0.5-mg scopolamine) with the second group receiving citalopram and placebo. The total dose of scopolamine used was 1 mg/day (0.5 mg b.i.d.) while citalopram was adjusted from an initial dose of 20 mg in the first week to 40 mg/day for the next 5 weeks. The patients were assessed using 17-item Hamilton Depression Rating Scale (HDRS) for 6 weeks with assessments at day 4, 7, 14, 28, and 42. By week 6, all patients in the scopolamine group and most patients in the placebo group had achieved a 50 percent reduction in the HDRS while the remission rate by week 6 were significantly higher (65 percent) in the scopolamine group compared to the placebo group (20 percent). Another study at the National Institute of Mental Health showed that intravenous scopolamine had a significant effect in unipolar and bipolar depression.

The results of this study validated the role of scopolamine as an adjunct to antidepressant therapy when initiated from the beginning of the treatment with a high response and remission rate and few adverse effects. These studies suggest that scopolamine as monotherapy as well as when used as an adjunct is a safe and effective strategy in MDDs.

In recent years, the need for better treatment options has been directed to biomarkers to investigate rapid treatment response especially with antidepressants. Scopolamine has been shown to induce rapid

antidepressant response through its effect on the cholinergic system; a study in 2012 showed that neural responses in the visual cortex especially to emotional stimuli may be a potential biomarker for patients with favorable response to scopolamine. The study conducted at National Institute of Mental Health suggests differences in treatment response based on brain-based variables and requires a more personalized approach to treatment for depressive disorders.

Various theories abound regarding the antidepressant efficacy and precise mechanism of action of scopolamine in MDDs, and to date, none have been established. Some of these theories suggest alterations in type 2 and 3 muscarinic receptors as well as polymorphisms in type 2 muscarinic receptor gene, and determine that scopolamine has a high affinity for type 3 muscarinic receptor. Other possible mechanisms include a hypercholinergic system, REM sleep deprivation as well as hyperactivity of the glutamatergic system which has been implicated in the development of MDD. Scopolamine decreases the glutamatergic transmission, thereby alleviating depressive symptoms.

Scopolamine seems to be an appropriate treatment option for difficult to treat patients with major and bipolar depression. Its relatively simple dosing and minor side effect profile with no significant impact on cognition based on the low doses used in the studies suggest its place as an adjunct to antidepressant treatment. Moreover, it should be noted that combination therapy from the beginning of treatment results in greater improvement than monotherapy. Some early studies reported less robust antidepressant effects but those results may have been due to the uncontrolled nature of the studies as well as lower dose range utilized. Despite the positive implications of the studies, numerous limitations remain regarding its impact on cognition (confusion and delirium), dosing, and safety, and more research is needed to study its efficacy in the long term and rapid antidepressant response as an adjunct when added later in the treatment.

AMANTADINE

Amantadine (Symmetrel; 1-aminoadamantane hydrochloride) is an antiviral drug that was approved in 1976 for the prophylaxis and treatment of influenza A. It was by chance found to have antiparkinsonian properties and is now used to treat the symptoms of Parkinson disease, drug-induced extrapyramidal symptoms such as parkinsonism, akinesia, and the rabbit syndrome (focal perioral tremor of the choreoathetoid type).

Chemistry

Amantadine is a tricyclic symmetric amine and is a stable, white, or nearly white, crystalline powder that is freely soluble in water and soluble in alcohol and in chloroform. Its molecular weight is 187.71 with a molecular

formula $C_{10}H_{18}NCl$ (Fig. 34.6–7).

Pharmacological Actions

Absorption and Distribution. Amantadine is well absorbed orally. The peak plasma concentrations of 0.2 to 0.4 μg/mL are reached in 1 to 4 hours after an oral dose and are directly related to dose for doses up to 200 mg per day. It reaches steady state in 4 to 7 days. Doses above 200 mg per day may result in a greater than proportional increase in maximum plasma concentrations. It is approximately 67 percent bound to plasma protein.

Metabolism and Elimination. Amantadine is primarily excreted unchanged in the urine by glomerular filtration and tubular secretion. Increasing plasma concentrations can lead to toxicity, but no absolute values of amantadine concentrations associated with adverse effects have been fully established. Mean half-life ranges from 10 to 14 hours. One study involving 19 healthy volunteers showed the plasma half-life averaged 16 ± 6 hours (range 9 to 31 hours).

CHEMICAL FORMULA

$C_{10}H_{17}N$

FIGURE 34.6–7. Amantadine structure.

SPECIAL CONSIDERATION IN THE ELDERLY AND RENALLY IMPAIRED. In healthy elderly individuals age 60 and older, the oral plasma clearance of amantadine is reduced and the plasma half-life and plasma concentrations are increased. It is unclear whether these changes are due to decline in renal function or other age-related factors. In adult patients with renal insufficiency, the clearance of amantadine is significantly reduced, and the elimination half-life increases two- to threefold or greater when creatinine clearance is less than 40 mL/1.73 m^2 per minute. Acidic urine increases the excretion rate of amantadine, and urine-acidifying drugs may increase the elimination of the drug from the body. Amantadine is removed in negligible amounts by hemodialysis.

Pharmacodynamics

Mechanism of Action. The exact mechanism of action of amantadine in the treatment of Parkinson disease and drug-induced extrapyramidal reactions is not known. It has preferential selectivity for central catecholamine neurons and acts by potentiating the release of endogenous catecholamines and dopamine from presynaptic vesicles, blocking reuptake of dopamine and having an agonist effect on postsynaptic dopamine receptors. Amantadine is a weak, noncompetitive NMDA receptor antagonist, and some studies suggest that it may have direct and indirect effects on dopamine neurons. It has no anticholinergic activity, and though it is only 1/209,000 as potent as atropine, it does cause side effects like anticholinergics such as constipation, dry mouth, and urinary retention. When used alone or in combination for mild parkinsonism, many patients derive only transient benefit, if any at all.

Design and Interpretation of Clinical Trials

Amantadine has been used as an antiviral drug for more than 30 years; as early as 1976, positive effects of amantadine on neuroleptic extrapyramidal side effects have been described.

It is also used in Parkinson disease and parkinsonism, but its efficacy in this arena remains questionable. Many studies have compared the effectiveness of amantadine and anticholinergic agents, but to date, there are no conclusive data to establish its efficacy as a first-line agent. A double-blind study compared the effects of amantadine and biperiden in treating extrapyramidal side effects in 42 schizophrenic subjects treated with haloperidol (Haldol). Of note, the treatment effect of amantadine and biperiden was similar. This study supports the fact that amantadine is a useful alternative to anticholinergics. In another double-blind, placebo-controlled study, amantadine was compared to trihexyphenidyl in treating drug-induced parkinsonism. The study showed that amantadine not only produced far fewer adverse effects but also was equally effective as trihexyphenidyl and is a useful alternative to atropine-like drugs. Some case reports show that amantadine may alleviate symptoms of tardive dyskinesia. This is a controversial issue, and there are no controlled studies to replicate these results.

A new form of extended-release formulation of amantadine is currently under investigation and phase 2/3 clinical trials are underway to evaluate its efficacy in Parkinson disease. Preliminary data suggest that two of the tested doses resulted in a statistically significant reduction in dyskinesia. This study suggests that the extended-release formulation of amantadine is effective in decreasing motor fluctuations and has a side-effect profile similar to regular available form of amantadine. The new extended-release formulation is taken at bedtime and is slowly released into the bloodstream overnight. As a result, the peak levels of the drug are present when it is time to wake up.

Recent studies have also looked at weight loss potential, reversal of sexual dysfunction, and improvement in cognitive functioning by amantadine. One study assessed the weight loss potential of amantadine in patients who were treated with olanzapine (Zyprexa). Significantly fewer subjects taking amantadine gained weight, compared to the placebo group. Amantadine stabilized weight in patients treated with olanzapine but did not improve fasting insulin or lipid levels.

Amantadine has a predilection for the nigrostriatal dopaminergic system compared to the mesolimbic system and enhances the CNS dopaminergic activity. This can lead to delusion, paranoia, alterations and elevation of mood, confusion, and disorientation. A few case reports suggest psychotic decompensation in patients treated with amantadine. The vast majority who are treated for extrapyramidal symptoms show a lack of psychotic relapse. Clinicians should be alerted to the fact that patients treated with amantadine are vulnerable to psychotic decompensation.

A double-blind study showed that amantadine did not cause memory impairment in patients treated with the medication, and, therefore, it is a good alternative for the elderly who are more prone to these side effects.

Effects on Specific Organs and Systems

Amantadine relieves parkinsonian symptoms by increasing dopaminergic function and increasing the release of catecholamines. These effects can be manifold and manifest as adverse reactions. These include restlessness, depression, irritability, insomnia, agitation, excitement, and occasionally psychotic decompensation. Amantadine is excreted unchanged by the kidneys, and patients with renal dysfunction should be monitored closely.

Therapeutic Indications

Drug-Induced Extrapyramidal Reactions. Amantadine is indicated in the treatment of drug-induced extrapyramidal reactions, but there are no data that support the use of this drug as a first-line agent particularly for acute dystonic reactions. Some studies suggest that it is as effective as anticholinergics for extrapyramidal signs and symptoms but is not effective in treating tardive dyskinesia and akathisia. Although side effects have been noted with amantadine, the incidence of anticholinergic-type side effects is lower than that observed with the anticholinergic antiparkinsonian drugs. This is particularly useful in the elderly who are more sensitive to the anticholinergic effects, both in the CNS, such as anticholinergic delirium, and in the peripheral nervous system, such as urinary retention.

Parkinson Disease and Parkinsonism. The usefulness of amantadine in

the treatment of parkinsonism is controversial; its efficacy in comparison with the anticholinergic antiparkinsonian drugs has not yet been established. In a controlled trial of 17 patients with parkinsonism, amantadine hydrochloride in a dose of 100 mg b.i.d. showed a minor beneficial effect on physical signs but failed to demonstrate any significant effect on functional disabilities. This improvement in physical signs was only sustained for 8 weeks but numerous patients noticed deterioration in functional performance after 2 to 5 weeks of treatment.

Amantadine is less effective than levodopa but is indicated in the treatment of idiopathic Parkinson disease (paralysis agitans), postencephalitic parkinsonism, and symptomatic parkinsonism, which may follow injury to the nervous system by carbon monoxide intoxication. It is indicated in those elderly patients believed to have developed parkinsonism in association with cerebral arteriosclerosis.

Amantadine has been reported to be beneficial in the treatment of selective serotonin reuptake inhibitor–associated side effects, such as lethargy, fatigue, anorgasmia, and ejaculatory inhibition.

Brain Injury. Traumatic brain injury (TBI) is one of the leading causes of death and disability in persons between 15 and 30 years of age. Currently there are no interventions or treatment to change the prognosis of this condition, and it leads to chronic disability in more than 90,000 survivors of brain injury. The trauma to the brain usually impacts the frontal region, disrupting neurotransmitters, including dopamine, and causes frontal lobe dysfunction. This syndrome includes problems with aggression, disinhibition, attention, impulsivity, planning, perseveration, amotivation, apathy, memory deficits, mood dysregulation, and problem solving. Other causes of brain injury with similar sequelae include stroke, encephalitis, and aneurysm. The role of dopamine and lowered levels of its metabolites is well established in brain injury, specifically in the frontal lobe regions. Multiple studies have shown that dopamine is involved in the regulation of cognition, mood, and behavior. In patients with brain injury, there is deficiency and dysregulation of dopamine in the frontal lobes.

Amantadine was first used in 1988 in two patients for the treatment of TBI. Subsequently, a study assessed 30 patients aged 5 to 59 with TBI with behavior problems including agitation, mood lability, and inattention. Treatment with amantadine led to improvement in 63 percent of the patients. These positive results led to the hypothesis that since amantadine impacted the dopaminergic system (presynaptic and postsynaptic), it would be an appropriate treatment for patients with TBI with compromised dopaminergic systems. Numerous studies since then have validated these results, and amantadine is now considered safe and beneficial for arousal, agitation, and problems with executive functioning in patients with head injury. During the past 20 years, amantadine has been used frequently for

the treatment of head injuries.

Amantadine is one of the most frequently used medications for patients undergoing neurorehabilitation. Various authors have reported the use of amantadine alone or in combination therapy with positive response in patients with brain injury, specifically in the frontal lobe syndrome. Recent studies suggest that amantadine and other dopaminergic agents may substantially improve the level of executive functioning in these patients. The clinical effects can be seen within a few days to a week. In one study of 184 patients with TBI who were minimally conscious 1 to 4 months after the brain injury, amantadine use after 4 weeks showed a significantly faster recovery compared to the placebo group. Of note, despite the high risk of seizures in this population, amantadine did not increase the risk of adverse effects including any medical or neurological events.

Another study showed improvements in attention span, speed of information processing, learning, and alertness. Other studies have shown improvements in apathy, amotivation, and perseveration. Greatest improvements have been seen in reduction of agitation, physical aggression, distractibility, and mood swings. More recently, amantadine has shown promising results in improving clinical status in dementia patients. According to one report, it is also useful in treating fatigue and depression of multiple sclerosis. Despite the fact that these case reports show promising results, there are limitations to these small and uncontrolled studies, which underscores the need for double-blind, large, and controlled studies.

The exact mechanism of action remains unclear, but amantadine appears to act as an NMDA antagonist and indirect dopamine agonist. Amantadine may increase dopaminergic activity by increasing presynaptic release and blocking reuptake postsynaptically targeting the nigrostriatal, mesolimbic, and frontostriatal circuits. The final result is increased arousal, drive, and attention.

These results suggest that patients with severe TBI can be treated with amantadine safely at doses between 200 and 400 mg.

Treatment in Children

Head injury is a common problem in children: nearly 300 out of 100,000 children suffer TBI by the age of 18. Most children are able to survive these injuries yet are left with deficits including inattention, difficulties with executive functioning, and academic performance. The use of agents to treat these behavior disturbances secondary to head injuries in pediatric population is less well known, but a small number of studies suggest the use of amantadine. Despite the limited body of literature on the use of amantadine in pediatric population, it is a useful and beneficial treatment in children with head injury and symptoms of arousal and alertness.

Pathological Gambling and Drug Addiction

Pathological gambling (PG) is a persistent gambling behavior with devastating consequences and is identified as one of the substance abuse and addictive disorders. Despite significant research, there have been no FDA-approved treatments for this condition. Considering the fact that PG and addictive disorders may have similar clinical and biological underpinnings, it may be appropriate to use drugs for the treatment of PG that are used for drug addiction. Numerous studies suggest the role of dopamine in addictive, reinforcing, and rewarding behaviors. The pleasure and reward seeking behavior present in drug addiction is linked to hypodopaminergic state and may also be responsible for gambling behavior triggering the release of dopamine (DA) and consequently sense of pleasure. In addition, imbalance in glutamate (Glu) homeostasis may also be responsible for reward seeking behaviors.

One study suggested that amantadine may be effective in reducing PG and showed symptoms resolving after 4 days of treatment. Another case study of a male patient with PG, comorbid depression, and alcohol dependence showed that amantadine 100 to 150 mg daily had a 43 to 64 percent reduction in the Gambling Symptom Assessment Scale (G-SAS).

The data suggest that glutamatergic system may play an important role in PG, and amantadine could be a potential treatment option for this condition.

Amantadine exerts its effects on dopamine neurotransmission by increasing DA release, DA reuptake inhibition, and acts as an antagonist at NMDA glutamatergic receptors. These effects may explain its role as an antidepressant. Numerous studies have suggested that its dopaminergic properties may be beneficial in cocaine-dependent patients with withdrawal symptoms, but more studies are required to validate these results.

Precautions and Adverse Reactions

The most frequently reported CNS adverse reactions (5 to 10 percent) are insomnia, dizziness, and impaired concentration. Less frequently (1 to 5 percent) reported CNS side effects include restlessness, irritability, agitation, excitement, depression, anxiety, and confusion. More severe CNS side effects are seizures and psychotic symptoms, and overdose may produce acute toxic psychosis.

Patient treated with anti-Parkinson medications including amantadine may have increased sexual urges and to spend money uncontrollably, urges to gamble, and other intense urges. Medications that increase central dopaminergic tone like amantadine may impair a patient's ability to control such urges. Prescribers should routinely inquire about the development of these urges (gambling, sexual, uncontrolled spending or other urges) and

lower the dose of amantadine or completely stop the medication if a patient develops such urges.

Other less frequently (1 to 5 percent) reported adverse reactions are anorexia, dry mouth, peripheral edema, orthostatic hypotension, congestive heart failure, headache, somnolence, nervousness, dream abnormality, dry nose, diarrhea, and fatigue. Livedo reticularis of the legs (purple discoloration of the skin caused by dilatation of the vessels) may occur in patients and usually clears within a month after discontinuation of the drug.

Rare (less than 0.1 percent) occurring adverse reactions are instances of convulsion, leukopenia, neutropenia, eczematoid dermatitis, oculogyric episodes, suicidal attempt, suicide, and suicidal ideation.

Amantadine is relatively contraindicated in patients with known history of seizures or renal disease. It should also be used with caution in persons with congestive heart failure or edema. There is evidence to suggest that it is teratogenic, and hence, should not be used by pregnant women or women who are breastfeeding.

Amantadine should not be discontinued abruptly in patients with Parkinson disease, since a few patients have experienced a parkinsonian crisis (i.e., a sudden marked clinical deterioration upon abrupt cessation of this agent) (Table 34.6–3).

Deaths

Amantadine has been associated with deaths secondary to overdose in amounts as low as 2 g. Anticholinergics effects may be responsible for these deaths secondary to cardiac, respiratory, renal, or CNS toxicity.

Drug Interaction

Coadministration of amantadine with phenelzine (Nardil) or other MAOIs may result in a significant increase in blood pressure. There is an increased likelihood of side effects such as confusion, hallucinations, nightmares, dry mouth, and blurred vision if administered with anticholinergics. The coadministration with CNS stimulants can result in insomnia, irritability,

nervousness, and possibly seizures.

Laboratory Interferences

Amantadine is not known to alter the results of any standard laboratory tests and values.

Dosage and Administration

Adult. The usual starting dose of amantadine hydrochloride is 100 mg twice a day when used alone and can be cautiously increased to 200 mg twice a day in patients whose responses are not optimal. Amantadine has an onset of action usually within 48 hours.

The initial dose of amantadine hydrochloride is 100 mg daily for patients with serious associated medical illnesses or who are receiving high doses of other anti-Parkinson drugs. After one to several weeks at 100 mg once daily, the dose may be increased to 100 mg twice daily, if necessary.

Some patients experience a fall-off of effectiveness after a few months and may benefit by increasing the dose to 300 mg daily or temporarily discontinuing amantadine for several weeks, followed by reinitiation of the drug.

Dosage for Concomitant Therapy

When patients do not respond to monotherapy with anticholinergic anti-Parkinson drugs, switching to or concomitant therapy with amantadine may produce additional benefits. In some cases when amantadine and levodopa are initiated concurrently, the patient can exhibit rapid therapeutic benefits. Amantadine should be held constant at 100 mg daily or twice daily while the daily dose of levodopa is gradually increased to optimal benefit.

Dosage for Drug-Induced Extrapyramidal Reactions

The usual starting dose of amantadine hydrochloride is 100 mg twice a day. Occasionally, patients whose responses are not optimal with amantadine hydrochloride at 200 mg daily may benefit from an increase up to 300 mg daily in divided doses (Table 34.6–4).

Dosage for Impaired Renal Function

Creatinine Clearance (mL/min/1.73 m^2)	Amantadine Hydrochloride Dosage
30–50	200 mg 1st day and 100 mg each day thereafter
15–29	200 mg 1st day followed by 100 mg on alternate days
<15	200 mg every 7 days

The recommended dosage for patients on hemodialysis is 200 mg every 7 days.

▲ 34.7 Anticonvulsants: Gabapentin, Topiramate, Tiagabine, Levetiracetam, Zonisamide, and Pregabalin

PO W. WANG, M.D., AND TERENCE ARTHUR KETTER, M.D.

Newer anticonvulsants, marketed over the past two decades, have generally been developed to have enhanced tolerability, simpler kinetics, and fewer drug–drug interactions. Chemical structures (Fig. 34.7–1) and pharmacodynamic effects of these drugs are diverse. As some purported mechanisms of action include enhancing neuronal inhibition by increasing GABAergic function or decreasing neuronal excitation by decreasing glutamatergic function, these agents have potential psychotropic benefits, and these amino acid neurotransmitters have been implicated in psychiatric disorders. Thus, newer anticonvulsants appear to have not only distinctive efficacy profiles for the treatment of epilepsy but also diverse

psychotropic and analgesic effects. A few of these agents can provide psychotropic benefits, and have received FDA indications for acute mania (valproate and carbamazepine) and bipolar maintenance treatment (lamotrigine).

The FDA announced in 2008 a class warning regarding increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders based on data from diverse anticonvulsants, six of which are described in detail in this chapter (gabapentin [Neurontin], topiramate [Topamax], tiagabine [Gabitril], levetiracetam [Keppra], zonisamide [Zonegran], and pregabalin [Lyrica]) and five of which are not described in this chapter (carbamazepine [Tegretol], felbamate [Felbatol], lamotrigine [Lamictal], oxcarbazepine [Trileptal], and valproate [Depakote]). This warning has been applied to seven subsequent anticonvulsants, which are not described in this chapter (rufinamide [Banzel], lacosamide [Vimpat], vigabatrin [Sabril], esogabine [Potiga], clobazam [Onfi], perampanel [Fycompa], and eslicarbazepine acetate [Aptiom]). In the FDA's analysis, anticonvulsants compared to placebo yielded approximately twice the risk of suicidality (0.43 percent vs. 0.22 percent). The relative risk for suicidality was higher in patients with epilepsy compared to psychiatric disorders.

The FDA has also stipulated additional behavioral toxicity warnings for seven diverse anticonvulsants (gabapentin, topiramate, tiagabine, levetiracetam, zonisamide, esogabine, and perampanel), including for perampanel a boxed warning for treatment-emergent irritability and homicidal ideation. However, additional behavioral toxicity warnings are lacking for 11 other diverse anticonvulsants (carbamazepine, valproate, lamotrigine, felbamate, oxcarbazepine, pregabalin, rufinamide, lacosamide, vigabatrin, clobazam, and eslicarbazepine acetate). Thus, to date, anticonvulsants with FDA approvals for bipolar disorder (carbamazepine, valproate, and lamotrigine) all lack behavioral toxicity warnings.

GABAPENTIN

Introduction and History

Gabapentin (Neurontin), which has a biochemical structure similar to the inhibitory amino acid neurotransmitter GABA, was developed by Warner–Lambert in efforts to create an agent for the treatment of spasticity. Gabapentin proved to have greater efficacy as an anticonvulsant than antispasticity agent. Gabapentin was found effective in several animal models of epilepsy, developed as an antiepileptic drug, and marketed for the adjunctive treatment of partial seizures in the United States in 1994 by Parke–Davis.

Due to generally good tolerability, fewer clinically significant drug–drug interactions than older anticonvulsants, and initial, postmarketing, open,

uncontrolled clinical experience suggesting efficacy in a variety of neurological and psychiatric conditions, gabapentin became increasingly used in conditions other than seizure disorders. In fact, nonepilepsy uses substantially exceeded those in epilepsy. Double-blind, placebo-controlled studies later confirmed gabapentin efficacy for some, but not all, of the neurological and psychiatric conditions suggested in open studies. Specifically, gabapentin appeared effective in neuropathic pain and was marketed for the management of postherpetic neuralgia in adults. Gabapentin also appeared effective in anxiety disorders (social phobia and panic disorder), but not as a main intervention in mania or treatment-resistant mood disorders. Thus, gabapentin has emerged as a safe and effective agent in epilepsy and postherpetic neuralgia, and has more widespread use adjunctively to relieve symptoms and pain, and improving, anxiety, and insomnia in a dimensional fashion across diverse neurological and psychiatric conditions. Moreover, gabapentin enacarbil (a prodrug of gabapentin) was effective in moderate to severe restless legs syndrome. Finally, recent controlled data suggested that gabapentin could be effective for relapse prevention in people with alcohol dependence.

FIGURE 34.7–1. Chemical structures of selected anticonvulsants.

Chemistry

Gabapentin, 1-(aminomethyl)-cyclohexane acetic acid, is a novel amino acid derived from adding a cyclohexyl group to GABA (Fig. 34.7–1), with some structural similarity to other anticonvulsants that resemble GABA, such as valproate. Immediate-release gabapentin preparations currently marketed in the United States include: 100-, 300-, and 400-mg capsules; 600- and 800-mg tablets; and a 250-mg/5-mL oral solution. Generic

immediate-release gabapentin is available in comparable formulations. Extended-release gabapentin and gabapentin enacarbil (a prodrug of gabapentin) are available in 300- and 600-mg tablets.

Pharmacological Actions

Pharmacokinetics. Gabapentin is available in immediate-release (Neurontin™) and sustained-release (Gralise™) formulations. In addition, gabapentin enacarbil is available in an extended-release formulation (Horizant™). Immediate-release gabapentin has sublinear kinetics due to saturable gastrointestinal absorption, with oral bioavailability of about 60 percent with 300 mg three times a day that decreases to 33 percent with 1,200 mg two times a day. In practice, maximum individual doses of immediate-release gabapentin should be no more than 1,200 mg. Sustained-release gabapentin can be titrated up to 1,800 mg once daily with the evening meal. Gabapentin enacarbil was designed to have high capacity absorption compared to gabapentin, even in doses greater than 1,200 mg, but the recommended dosing is only 600 mg once or twice daily. Sustained-release gabapentin and gabapentin enacarbil are not interchangeable with other gabapentin products because of differing pharmacokinetic profiles that affect frequency of administration. Food only modestly affects the rate and extent of immediate-release gabapentin absorption, but more significantly affects absorption of sustained-release gabapentin and gabapentin enacarbil, which need to be taken with food. Gabapentin circulates in the blood largely unbound, with less than 3 percent bound to plasma proteins, and has a moderate volume of distribution of about 1 L/kg. In epilepsy patients, cerebrospinal fluid gabapentin concentrations are about 20 percent of plasma levels. Immediate-release gabapentin has a half-life of about 6 hours and thus is given in three divided doses in epilepsy patients. Sustained-release gabapentin and gabapentin enacarbil have an elimination half-life of approximately 6 hours, but due to differential absorption and indications, are dosed once daily and once to twice daily, respectively. Gabapentin is not appreciably metabolized in humans, is eliminated unchanged by renal excretion, and can be removed by hemodialysis. Gabapentin clearance correlates with that of creatinine, so dosage adjustments are required in patients with impaired renal function. Clearance may be increased in children under age 5 years and decreased in the elderly, requiring dosage adjustments.

Pharmacodynamics. Like most other anticonvulsants, gabapentin has multiple biochemical actions, and the relationships between these and direct clinical effects remain to be established. Although gabapentin is a structural analog of GABA, it appears to lack direct GABAergic actions. Gabapentin does appear to have indirect GABAergic effects, as both acute

and chronic gabapentin increase cerebral GABA in humans. Gabapentin may also have antiglutamatergic actions, mediated by inhibition of glutamate synthesis by branched chain amino acid aminotransferase. It also modulates (but does not directly block) sodium channels and increases human whole blood serotonin concentrations. Gabapentin has high-affinity regional (including neocortical and hippocampal) binding to $\alpha_2\delta$ subunits of voltage-activated calcium channels and thus may modulate calcium channels to reduce monoamine release. Several of these biochemical mechanisms may underlie gabapentin's psychotropic effects.

Gabapentin has antiseizure activity in maximal electroshock, pentylenetetrazole, amygdala kindled, and other animal models of seizures, antinociceptive effects in several animal models of neuropathic pain, antispasticity activity in several animal models, and anxiolytic-like effects in animal models of anxiety disorders such as the rat conflict and elevated plus-maze, and the mouse light/dark box paradigms. Gabapentin was not active in the behavioral despair model of depression, or the Sidman avoidance paradigm, which screens for antipsychotic activity.

Clinical Drug Studies

Seizure Disorders. Adjunctive immediate-release gabapentin was more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials involving adults and adolescents (age 12 years or more) with refractory partial seizures, and in one trial in children (age 3 to 12 years) with refractory partial seizures. In a small trial, immediate-release gabapentin monotherapy did not differ from placebo in children (age 4 to 12 years) with newly diagnosed absence epilepsy.

Postherpetic Neuralgia. Immediate-release gabapentin appeared more effective than placebo in two multicenter, double-blind, placebo-controlled trials in adults with postherpetic neuralgia, relieving pain and sleep interference, and improving mood and quality of life. Two more recent multicenter, double-blind, placebo-controlled trials with gabapentin extended-release formulation in adults with postherpetic neuralgia demonstrated efficacy. Moreover, gabapentin enacarbil, appeared more effective than placebo in three multicenter, double-blind, placebo-controlled trials in adults with postherpetic neuralgia.

Other Pain Syndromes. Gabapentin appears to have analgesic effects in other pain syndromes, particularly in neuropathic pain. Thus, immediate-release gabapentin was more effective than placebo in relieving pain and in some instances yielded benefits on other measures such as sleep, mood, and quality of life in diabetic neuropathy, trigeminal neuralgia, neuropathic cancer pain (when added to opioids), Guillain–Barré syndrome, fibromyalgia, painful human immunodeficiency virus (HIV)-associated

sensory neuropathy, and diverse neuropathic pain. Immediate-release gabapentin was also more effective than placebo in relieving postamputation pain (in one of two studies), postradical mastectomy pain, postlumbar discectomy pain (when added to fentanyl [Actiq] but not when added to morphine [Roxanol]), postabdominal hysterectomy pain (when added to rofecoxib [Vioxx]), and catheter-related bladder discomfort and postoperative pain in percutaneous nephrolithotomy patients. Immediate-release gabapentin was more effective than placebo in chronic masticatory myalgia, complex regional pain syndrome type one (formerly known as reflex sympathetic dystrophy), and in suppressing nausea and vomiting and postoperative rescue analgesic requirements in laparoscopic cholecystectomy patients. Immediate-release gabapentin compared to placebo reduced migraine frequency and intensity in migraine patients, relieved symptoms and improved function and quality of life in chronic daily headache patients, and may attenuate hypobaric hypoxia-induced headache (a syndrome commonly experienced by newcomers to high-altitude areas). However, immediate-release gabapentin was no better than placebo for chemotherapy-induced peripheral neuropathy.

Restless Legs Syndrome. Immediate-release gabapentin appeared more effective than placebo in one small cross-over design study of adults, reducing periodic leg movements, pain, sleep quality and sleep architecture, and overall clinical impression, and in another small cross-over design study of adult hemodialysis patients. More recently, gabapentin enacarbil was more effective than placebo in two multicenter, double-blind, placebo-controlled trials in adults with restless legs syndrome, relieving restless legs movements and improving sleep quality.

Other Neurological Disorders. Limited data suggest gabapentin may have efficacy in relieving symptoms of other neurological disorders. Immediate-release gabapentin compared to placebo relieved essential tremor in two of three studies, primary orthostatic tremor in one study, and impairment of spasticity in multiple sclerosis in one study. Also, compared to placebo, immediate-release gabapentin attenuated rigidity, bradykinesia, and tremor in Parkinson disease. Immediate-release gabapentin compared to no treatment improved lower but not upper extremity function in spinal muscular atrophy patients. However, compared to placebo, immediate-release gabapentin failed to slow the decline of arm strength in amyotrophic lateral sclerosis patients in two studies and failed to increase muscle strength in spinal muscular atrophy patients in another.

Other Syndromes. Immediate-release gabapentin was more effective than placebo in treating pruritus related to uremia (but not related to cholestasis) and in controlling hot flashes in healthy postmenopausal

women and in women with breast cancer.

Alcohol and Substance Use Disorders. Four randomized, placebo-controlled studies in alcohol use disorders have found immediate-release gabapentin efficacious as monotherapy or in combination with either flumazenil or naltrexone, specifically associated with more abstinence days and longer time to relapse. Efficacy in opiate use disorders was found in two randomized, placebo-controlled add-on (to methadone or buprenorphine) studies with less opiate use and less withdrawal symptoms, but not in one study of monotherapy gabapentin. Efficacy in stimulant (methamphetamine or cocaine) use disorders is not well established for gabapentin where only one randomized, placebo-controlled study adding immediate-release gabapentin to flumazenil had less drug use and cravings, but three controlled studies (monotherapy and add-on) found no difference from placebo. One randomized, placebo-controlled study of immediate-release gabapentin monotherapy for marijuana use disorder found less use and improved executive functioning on neuropsychological testing. Thus, gabapentin has the strongest evidence of efficacy for alcohol use disorders, with less robust evidence in other substances of abuse.

Anxiety Disorders. Controlled studies have confirmed immediate-release gabapentin utility in some anxiety disorders, with double-blind, placebo-controlled trials demonstrating efficacy in social phobia (social anxiety disorder), and in a post hoc analysis, in moderate to severe panic disorder. Efficacy of immediate-release gabapentin in other anxiety disorders as suggested by open reports remains to be confirmed in controlled studies.

Mood Disorders. Two controlled studies found immediate-release gabapentin was ineffective, despite early, open, uncontrolled reports suggested that adjunctive immediate-release gabapentin was well tolerated and may offer benefit in patients with refractory mood disorders. In a double-blind, placebo-controlled study of bipolar patients suffering from mania or hypomania while taking lithium (Eskalith), valproate, or lithium and valproate, adjunctive placebo tended to lower mania scores better than adjunctive immediate-release gabapentin. In treatment-resistant (primarily rapid-cycling bipolar) mood disorders, immediate-release gabapentin monotherapy was no more effective than placebo, while lamotrigine monotherapy was more effective than both immediate-release gabapentin and placebo. However, a small (25 patients), randomized clinical trial suggested that adjunctive immediate-release gabapentin compared to adjunctive placebo might provide some prophylactic benefit in patients with bipolar disorder. Although antidepressant efficacy of adjunctive immediate-release gabapentin in bipolar disorder patients has been

suggested in several open trials, controlled studies have not supported the primary use of gabapentin for mood disorders.

Therapeutic Indications

Seizure Disorders. Immediate-release gabapentin is indicated as adjunctive treatment of partial seizures with and without secondary generalization in epilepsy patients over age 12 years, and as adjunctive treatment of partial seizures in pediatric patients age 3 to 12 years.

Postherpetic Neuralgia. Immediate- and extended-release gabapentin and gabapentin enacarbil are indicated for the management of postherpetic neuralgia in adults.

Restless Legs Syndrome. Gabapentin enacarbil is indicated for the treatment of moderate to severe restless legs syndrome in adults.

Precautions and Adverse Reactions

In general, gabapentin's adverse effects are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. In adult epilepsy patients, the most common adverse effects with adjunctive immediate-release gabapentin were somnolence, dizziness, ataxia, fatigue, and nystagmus. In adult postherpetic neuralgia patients, the most common adverse effects with immediate-release gabapentin were dizziness, somnolence, and peripheral edema. In pediatric (age 3 to 12 years) epilepsy patients, the most common adverse effects with adjunctive gabapentin are viral infection, fever, nausea or vomiting, somnolence, and hostility. Interestingly, psychiatric adverse effects in pediatric epilepsy patients have been sufficiently troublesome that the immediate-release gabapentin United States Prescribing Information (USPI) includes warnings of the risks of (1) emotional lability or behavioral problems in 6 percent (vs. 1.3 percent with placebo); (2) hostility or aggressiveness in 5.2 percent (vs. 1.3 percent with placebo); (3) thought disorder, concentration, or academic performance problems in 1.7 percent (vs. 0 percent with placebo); and (4) hyperkinesia, restlessness, or hyperactivity in 4.7 percent (vs. 2.9 percent with placebo). As with other anticonvulsants, gabapentin has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders. Gabapentin can also cause driving impairment. Acute oral overdoses of immediate-release gabapentin (up to 49 g) have been associated with diplopia, slurred speech, drowsiness, lethargy, and diarrhea, but all patients recovered.

Gabapentin was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date not in

humans. Gabapentin was classified as "Probably Safe" for lactation, though it is excreted in breast milk, with nursing infants receiving about 1 mg/kg per day, so that gabapentin should be administered to women who are breastfeeding only if the potential benefits clearly outweigh the (unknown) risks.

Gabapentin is contraindicated in patients with known hypersensitivity to gabapentin or its ingredients.

Drug Interactions

Gabapentin bioavailability may decrease as much as 20 percent when administered at the same time as antacids (such as Maalox [Novartis]), so that gabapentin should be taken at least 2 hours following antacids. Hydrocodone and morphine may increase blood gabapentin concentrations. However, as gabapentin is renally excreted, it generally lacks clinically significant hepatic drug–drug interactions. In addition, gabapentin may not have major drug–drug interactions with renally excreted drugs. For example, chronic gabapentin did not appear to alter the single dose pharmacokinetics of lithium in subjects with normal renal function.

Dosage and Administration

The immediate-release gabapentin USPI recommends that adjunctive therapy in adolescents and adults with epilepsy should start at 300 mg three times a day and be increased up to 1,800 mg per day in three divided doses. However, in adults with epilepsy, immediate-release gabapentin has been generally well tolerated at doses as high as 3,600 and 2,400 mg per day in short- and long-term studies, respectively. Adjunctive immediate-release gabapentin in pediatric seizures is recommended to start with 10 to 15 mg/kg per day in three divided doses and to increase over three days to 25 to 40 mg/kg per day in three divided doses. A long-term epilepsy study suggested that immediate-release gabapentin doses up to 50 mg/kg per day may be well tolerated. Plasma gabapentin concentrations in epilepsy patients commonly ranged between approximately 12 and 20 μg/mL (70 and 120 μM/L), but did not appear to be systematically related to antiseizure effects and thus are not routinely monitored.

Immediate-release gabapentin for adults with postherpetic neuralgia or neuropathic pain is recommended to start with 300 mg on day 1, increase to 600 mg on day 2, 900 mg on day 3, and subsequently increase as needed to relieve pain up to 1,800 mg per day in three divided doses. Extended-release gabapentin for postherpetic neuralgia is started at 300 mg daily, increased to 600 mg on day 2, then further increased 300 mg every 4 days, with maximum dose of 1,800 mg. Gabapentin enacarbil for postherpetic neuralgia is started at 600 mg daily with food for 3 days, then increased to

600 mg twice daily, and for restless legs syndrome is started and maintained at 600 mg per evening with food.

In patients with renal impairment, gabapentin doses may need to be decreased 30 to 80 percent, depending on the degree of renal insufficiency.

Off-label gabapentin is typically used adjunctively with similar doses. In some (nonepilepsy) applications, clinicians may administer more of the dosage at bedtime to enhance sleep and decrease daytime somnolence. However, individual doses of immediate-release gabapentin above 1,200 mg are divided due to saturable absorption. In psychiatric outpatients, immediate-release gabapentin started at 300 mg at bedtime and increased by 300 mg every 4 days as necessary, initially targeting a dose of 1,200 mg at bedtime, is typically well tolerated. Occasionally, elderly patients or patients on complex combination therapies may need doses as low as 100 to 200 mg due to sedation. Final total daily doses tend to be between 1,200 and 2,400 mg per day, but may range as high as 4,800 mg per day.

TOPIRAMATE

Introduction and History

Topiramate (Topamax) was developed by R. W. Johnson Pharmaceutical Research Institute. After effectiveness was seen in several animal models of epilepsy, topiramate was studied as an antiepileptic drug, and then marketed for the adjunctive treatment of epilepsy in the United States in 1997 by Ortho–McNeil Pharmaceutical, Inc.

Double-blind, placebo-controlled studies revealed that topiramate was useful for some, but not all, of the neurological and psychiatric conditions reported in initial postmarketing, open, clinical studies. Topiramate appeared effective in migraine prevention and was approved for this indication. Also, topiramate appeared effective in obesity, bulimia, binge eating disorder with obesity, and alcohol dependence. In contrast, topiramate was not effective as a main intervention in mania in adults with bipolar disorder.

Chemistry

Topiramate, 2,3:4,5-bis-*O*-(1-methylethylidene)β-*D*-fructo-pyranose sulfamate, has a novel sulfamate-substituted monosaccharide structure (Fig. 34.7–1). Two oral topiramate preparations are currently marketed in the United States: 25-, 50-, 100-, and 200-mg tablets; and 15- and 25-mg sprinkle capsules, which can be swallowed whole or opened and sprinkled on food. Generic topiramate is available.

Pharmacological Actions

Pharmacokinetics. Topiramate has oral bioavailability of about 80 percent and linear kinetics that are not significantly altered by food.

Topiramate is only 15 percent bound to plasma proteins and has a moderate volume of distribution of about 0.8 L/kg. Topiramate is about 70 percent excreted unchanged in the urine, so in the absence of enzyme inducers, clearance does not extensively involve hepatic mechanisms. However, in the presence of hepatic enzyme inducers (such as carbamazepine or phenytoin), hepatic metabolism increases and renal clearance decreases about 50 percent. Topiramate has a half-life of approximately 24 hours with monotherapy; half-life decreases about 50 percent with enzyme inducers, so that topiramate is given in two divided doses. Topiramate clearance is generally about 25 mL per minute. Enzyme inducers can almost double clearance rates, and moderate to severe renal impairment decreases clearance rates by about 50 percent. Topiramate clearance may be also decreased in patients with hepatic impairment, requiring dosage adjustment. Thus, dosage needs to be increased with concurrent inducers, decreased with renal insufficiency, and possibly decreased in patients with hepatic impairment.

Pharmacodynamics. Like most other anticonvulsants, topiramate has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Topiramate is a state-dependent sodium channel blocker. Topiramate also has GABAergic effects; as it positively modulates $GABA_A$ receptors and both acute and chronic administration appear to increase cerebral GABA in humans. Topiramate has antiglutamatergic effects, as it blocks kainite and α-amino-3-hydroxy-5-methylisoxazole-4-proprionic acid (AMPA) receptors. Topiramate also weakly inhibits carbonic anhydrase CA-II and CA-IV isoenzymes.

Topiramate has antiseizure activity in maximal electroshock, amygdala kindled, and other animal models of seizures, cerebroprotective actions in several animal models of ischemia, activity in animal models of obesity, and some evidence of antinociceptive activity in animal models of neuropathic pain.

Clinical Drug Studies

Seizure Disorders. Topiramate was superior to placebo as initial monotherapy in adults and children 10 years of age and older with partial-onset or primary generalized seizures in a multicenter, double-blind, placebo-controlled trial. Adjunctive topiramate appeared more effective than adjunctive placebo in several multicenter, double-blind, placebo-controlled epilepsy trials including six multiple-dose and four single-dose trials in patients with partial-onset seizures, one trial in children age 2 to 16 years with partial-onset seizures, one trial in patients age 2 years or older with primary generalized tonic–clonic seizures, and one trial in patients age 2 years or older with Lennox-Gastaut syndrome.

Migraine Prevention. Topiramate was more effective than placebo in two multicenter, double-blind, placebo-controlled trials, decreasing frequency of migraine headaches. Topiramate also appeared to improve daily activities and patient functioning.

Pain Syndromes. Adjunctive topiramate was more effective than placebo in painful diabetic neuropathy in one of four studies and in chronic low back pain in one study.

Other Neurological Disorders. Adjunctive topiramate was more effective than placebo in attenuating essential tremor in two of three studies, but was ineffective in patients with amyotrophic lateral sclerosis.

Weight Loss, Obesity, Bulimia, and Binge Eating Disorder with Obesity. Topiramate has been associated with weight loss in controlled studies of patients with epilepsy, psychiatric illness, and obesity and has shown efficacy in the treatment of adiposity in women undergoing olanzapine (Zyprexa) therapy, bulimia, and binge eating disorder associated with obesity in controlled trials. In 2012, the combination of topiramate with phentermine was FDA approved as an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adults with obesity.

Alcohol Use Disorder. Topiramate was superior to placebo in patients with alcohol dependence in two studies.

Smoking Cessation. In a controlled trial, topiramate promoted smoking abstinence among alcohol-dependent smokers.

Substance Use Disorders. In a controlled trial, topiramate was not better than placebo in promoting methamphetamine abstinence in patients with methamphetamine dependence. However, a separate controlled study found that topiramate improved some (retainment in treatment) but not all measures (alcohol or cocaine use) in patients with comorbid cocaine and alcohol dependence.

Bipolar Disorders. Although early open reports were encouraging, four double-blind, placebo-controlled trials failed to demonstrate topiramate monotherapy efficacy in acute mania in adults. A similar trial in children and adolescents was inconclusive, perhaps due to premature termination. In a controlled trial, adding topiramate to lithium or valproate was no better than adding placebo in patients with acute manic or mixed episodes. In one small single-blind study, adjunctive topiramate and adjunctive sustained-release bupropion (Wellbutrin) had similar efficacy in bipolar depression, although topiramate appeared to yield more weight loss and

adverse effects.

Psychotic Disorders. Case reports and small case series in patients with treatment-resistant schizophrenia suggested that open topiramate added to antipsychotics may help attenuate clozapine (Clozaril) adverse effects such as weight gain and seizures. In a small controlled study, adjunctive topiramate compared to adjunctive placebo in patients with schizophrenia yielded greater improvement in general psychopathological symptoms, but not positive or negative symptoms. However, adjunctive topiramate failed to attenuate schizophrenia symptoms in one small case series and may have even yielded deterioration in another. In a small controlled study, adjunctive topiramate was no better than adjunctive placebo in patients with schizoaffective disorder, bipolar type.

Posttraumatic Stress Disorder. Open, primarily adjunctive topiramate appeared effective in chronic civilian PTSD. A small controlled study suggested topiramate monotherapy was superior on some outcome measures in patients with civilian posttraumatic stress disorder, but another controlled study in male veterans with PTSD did not show benefit with topiramate.

Therapeutic Indications

Seizure Disorders. Topiramate is indicated as adjunctive treatment for adults and pediatric patients ages 2 to 16 years with partial-onset seizures or primary generalized tonic–clonic seizures, and in patients age 2 years or older with Lennox–Gastaut syndrome. Topiramate is also indicated as initial monotherapy in patients 2 years of age and older with partial-onset or primary generalized tonic–clonic seizures.

Migraine Prevention. Topiramate is indicated for adolescents (age ≥12 years) and adults for the prevention of migraine headaches.

Precautions and Adverse Reactions

The most common adverse effects with topiramate 400 mg per day monotherapy in epilepsy patients were paresthesia, weight decrease, somnolence, anorexia, dizziness, and memory problems in adults (21 percent adverse effect discontinuation rate); and weight decrease, upper respiratory tract infection, paresthesia, anorexia, diarrhea, and mood problems in children (12 percent adverse effect discontinuation rate). The most common adverse effects with adjunctive topiramate at 200 to 400 mg per day in adult epilepsy patients were somnolence, dizziness, ataxia, speech problems, psychomotor slowing, visual problems, memory problems, paresthesia, and diplopia (11 percent adverse effect discontinuation rate). The most common adverse effects with adjunctive

topiramate at 5 to 9 mg/kg per day in pediatric epilepsy patients were fatigue, somnolence, anorexia, nervousness, concentration or attention problems, memory problems, aggression, and weight loss (0 percent adverse effect discontinuation rate). The most common adverse effects with topiramate monotherapy in migraine prevention trials were paresthesia, fatigue, nausea, anorexia, upper respiratory tract infection, taste perversion, and dizziness (25 percent adverse effect discontinuation rate vs. 10 percent with placebo). In many cases, topiramate adverse effects are mild to moderate, and can be attenuated by dosage rescheduling or decrease.

Topiramate can cause appetite suppression and weight loss in epilepsy, psychiatric, and obesity patients. Although this is clearly a desirable effect in overweight or obese patients, it may be problematic in underweight patients. However, in epilepsy studies, weight loss with topiramate was more evident in patients with higher baseline weights. In these studies, topiramate-induced weight loss was more evident in women compared to men with similar baseline weights.

The topiramate USPI includes a warning of the risk of hyperchloremic, nonanion gap metabolic acidosis (low serum bicarbonate without chronic respiratory alkalosis), which can occur in a dose-related fashion with topiramate and yield hyperventilation, fatigue, anorexia, increased risk of nephrolithiasis, nephrocalcinosis, and osteomalacia; decreased growth rate; and rarely cardiac arrhythmias and stupor. Measurement of baseline and periodic serum bicarbonate is recommended, and if metabolic acidosis is detected, decreasing or discontinuing topiramate or treating with alkali should be considered. Topiramate has been rarely associated with a syndrome of acute myopia with secondary angle closure glaucoma, characterized by acute onset of decreased visual acuity or ocular pain. Symptoms can occur in pediatric as well as adult patients, typically present within 1 month of starting topiramate, and reverse with discontinuation. Other warnings in the topiramate USPI include the risks of oligohydrosis and hyperthermia, unexplained death in epilepsy, visual field defects, hyperammonemia and encephalopathy with or without concomitant valproic acid, hypothermia with and without hyperammonemia during concurrent treatment valproic acid, and seizures after abrupt discontinuation in patients with or without epilepsy. As with other anticonvulsants, topiramate has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

An important warning in the topiramate USPI concerns the risks of cognitive or neuropsychiatric adverse events. These are common and include cognitive problems (confusion, psychomotor slowing, and concentration or attention, memory, speech, or language problems), psychiatric problems (depression, mood problems), sedation, and fatigue.

Topiramate has also been associated with the onset of psychosis in case reports.

About 1.5 percent of adults exposed to topiramate develop nephrolithiasis. Maintaining adequate fluid intake may help decrease the risk of nephrolithiasis. Topiramate is a weak carbonic anhydrase inhibitor and hence decreases urinary citrate excretion and increases urinary pH, perhaps contributing to the increased risk of nephrolithiasis with this medicine. Carbonic anhydrase inhibition may also contribute to the increased risk of paresthesias with topiramate.

In patients with or without a history of epilepsy, topiramate should be gradually withdrawn to minimize the potential for seizures.

Acute oral overdoses of topiramate have been associated with convulsions, drowsiness, speech disturbance, blurred vision, diplopia, impaired mentation, lethargy, impaired coordination, stupor, hypotension, abdominal pain, agitation, dizziness, depression, and severe metabolic acidosis. In most instances, clinical consequences were not severe, but deaths have been reported in polydrug overdoses involving topiramate.

Topiramate was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, and use during pregnancy may cause cleft lip and/or palate in humans. It is not known the degree to which topiramate is excreted in breast milk, so it was classified as "Safety Unknown" for lactation, and should be administered to women who are breastfeeding with caution only if the potential benefits clearly outweigh the (unknown) risks.

Topiramate is contraindicated in patients with known hypersensitivity to topiramate or its ingredients.

Drug Interactions

The large renal component of topiramate disposition yields it resistant to effects of enzyme inhibitors, yet the limited monotherapy hepatic metabolism component makes it susceptible to enzyme inducers. For example, in epilepsy patients, carbamazepine yields clinically significant decreases in topiramate serum concentrations, but topiramate does not yield clinically significant changes in carbamazepine serum concentrations. In contrast, valproate and lamotrigine do not appear to have clinically significant pharmacokinetic interactions with topiramate in patients with epilepsy. However, concomitant administration of topiramate and valproate has been associated with hyperammonemia with and without encephalopathy, and hypothermia (with and without hyperammonemia), most likely due to pharmacodynamic drug interactions. In view of its substantial renal clearance, topiramate could affect lithium levels. However, the clinical significance of such putative effects remains to be definitively established. Specifically, although topiramate at doses over 200 mg/day may affect serum lithium concentrations, the clinical importance of

this phenomenon remains to be adequately characterized. Nevertheless, the topiramate USPI recommends monitoring lithium concentrations when coadministered with high-dose topiramate. The effects of lithium on topiramate pharmacokinetics remain to be established. Although levetiracetam does not alter topiramate concentrations, the combination may yield adverse effects through a pharmacodynamic interaction. In addition, combination of topiramate with other carbonic anhydrase inhibitors, such as acetazolamide (Diamox) and zonisamide, is not recommended due to concerns about increasing the risks of metabolic acidosis, nephrolithiasis or heat-related problems (oligohydrosis and hyperthermia). Also, should topiramate cause metabolic acidosis, use of metformin is contraindicated. Topiramate is a mild enzyme inducer and can decrease blood concentrations of hormonal contraceptives, potentially compromising their efficacy. This effect may be less problematic at doses of 200 mg per day or less. Because of the potential of topiramate to cause CNS depression, as well as other cognitive and/or neuropsychiatric adverse reactions, combination with alcohol and other CNS depressants should only be done with caution.

Dosage and Administration

The topiramate USPI recommends that topiramate monotherapy in adults and children 10 years of age or older with epilepsy start with 25 mg twice daily for the first week, increase to 50 mg twice daily for week 2, 75 mg twice daily for week 3, 100 mg twice daily for week 4, 150 mg twice daily for week 5, and 200 mg twice daily for week 6 onward. In adult (age 17 years or older) epilepsy patients, topiramate adjunctive therapy is recommended to start with 25 to 50 mg per day and be increased by 25 to 50 mg on a weekly basis, up to 400 mg per day in two divided doses. In pediatric (age 2 to 16 years) epilepsy patients, topiramate adjunctive therapy is recommended to start with 1 to 3 mg/kg per day at bedtime and increase by 1 to 3 mg/kg on a weekly basis, up to 5 to 9 mg/kg per day. Plasma topiramate concentrations in epilepsy patients commonly range between 5 and 20 μg/mL (15 to 60 μM/L), but to do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. For migraine prevention, topiramate is recommended to start with 25 mg in the evening for the first week, increase to 25 mg twice daily for week 2, 25 mg in the morning plus 50 mg in the evening for week 3, and 50 mg twice daily for week 4 onward. Doses may need to be decreased by 50 percent in patients with moderate to severe renal impairment (creatinine clearance less than 70 mL/1.73 m^2 per minute), and doubled in patients receiving concurrent enzyme inducers such as carbamazepine and phenytoin. Topiramate doses may need to be decreased in patients with hepatic impairment.

Off-label topiramate is typically used adjunctively, starting with 25 mg at bedtime and increasing weekly by 25 mg, as necessary and tolerated.

Dosage increases of 25 mg per day every 2 to 4 weeks during initiation may sometimes improve tolerability. Unfortunately, tolerability may be a problem for some patients even with doses as low as 25 mg per day. Final doses in efforts to promote weight loss are often between 75 and 200 mg per day at bedtime. Lower doses appear to less consistently suppress appetite, and higher doses, at least early in therapy, tend to not be tolerated due to sedation or cognitive difficulties. However, continuing to gradually increase topiramate 25 mg per day on a monthly basis may allow some patients to eventually achieve doses of 400 mg per day. In some (nonepilepsy) applications, clinicians may administer most or all of the dosage toward bedtime to enhance sleep and decrease daytime somnolence.

TIAGABINE

Introduction and History

Tiagabine (Gabitril), a lipophilic derivative of nipecotic acid, was developed by Novo Nordisk. The addition of a lipophilic group to nipecotic acid (a hydrophilic GABA reuptake inhibitor that does not cross the blood–brain barrier) allowed tiagabine to more easily enter the central nervous system. Tiagabine was effective in several animal models of epilepsy. Abbott Laboratories developed it as an antiepileptic drug, initially marketed for the adjunctive treatment of partial seizures in the United States in 1997, and later marketed by Cephalon, Inc.

Limited, postmarketing, open, uncontrolled clinical experience suggested efficacy in some psychiatric conditions. Importantly, safety concerns were raised paradoxically for this antiepileptic drug concerning the risk of seizures in patients with bipolar disorder, particularly if the drug was dosed aggressively. Limited double-blind, placebo-controlled studies revealed that tiagabine may be useful for generalized anxiety disorder and primary insomnia. Safety concerns, along with a lack of controlled efficacy data, have limited the use of tiagabine in disorders other than epilepsy.

Chemistry

Tiagabine, (-)-(R)-1-[4,4-Bis(3-methyl-2-thienyl)-3-butenyl] nipecotic acid, is a lipophilic derivative of the hydrophilic cyclic amino acid nipecotic acid (comprising nipecotic acid linked to a lipophilic group by an aliphatic chain), which inhibits GABA reuptake in neurons and glial cells (Fig. 34.7–1). Tiagabine is available in 2-, 4-, 12-, and 16-mg tablets for oral administration.

Pharmacological Actions

Pharmacokinetics. Tiagabine is well absorbed with a bioavailability of about 90 percent, extensively (96 percent) bound to plasma proteins, and

has linear kinetics at doses between 2 and 24 mg per day. Giving tiagabine with meals decreases rate of absorption and delays and lowers peak plasma concentrations, but does not significantly affect extent of absorption. In monotherapy, tiagabine has a half-life of about 8 hours and clearance of about 110 mL per minute. In the presence of enzyme inducers (as in the pivotal epilepsy studies), the half-life decreased to about 4 hours and clearance doubled to about 220 mL per minute. Tiagabine is a CYP3A substrate and is extensively transformed into inactive 5-oxo-tiagabine and glucuronide metabolites, with only 2 percent being excreted unchanged in the urine. The remainder is excreted as metabolites in the feces (65 percent) and the urine (25 percent).

Pharmacodynamics. Tiagabine has a putative specific single major biochemical action (as opposed to multiple diverse actions with most other anticonvulsants) that may account for its clinical effects. Tiagabine acts on the GABA transporter, blocking reuptake of the inhibitory amino acid neurotransmitter GABA into neurons and glia, and thus enhancing the inhibitory action of GABA. Actions at both $GABA_A$ and $GABA_B$ receptors putatively yield anticonvulsant and antinociceptive effects, respectively. Tiagabine has antiseizure activity in the pentylenetetrazole mouse, amygdala kindled rat, and other animal models of seizures, but only has weak activity in the maximal electroshock mouse model. Tiagabine has antinociceptive activity in animal models of neuropathic pain and anxiolytic-like effects in the rat open field and elevated plus-maze models of anxiety.

Clinical Drug Studies

Seizure Disorders. Adjunctive tiagabine appeared more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials involving patients with refractory partial seizures who were taking at least one enzyme-inducing anticonvulsant, as well as in two small placebo-controlled crossover studies.

Pain Syndromes. Limited data suggest possible utility of tiagabine in bruxism and associated temporomandibular joint pain, painful tonic spasms in multiple sclerosis, chronic pain, and chronic painful neuropathy. Large controlled studies are needed to confirm these encouraging preliminary findings.

Mood Disorders. There are no controlled studies of tiagabine in bipolar disorders. Moreover, there is an apparent lack of compelling and consistent open data suggesting efficacy of tiagabine in bipolar disorders. Some experience with open low-dose tiagabine in bipolar disorders may have been encouraging, but other case series suggested significant

problems with both efficacy and tolerability. For example, rapid loading of open primarily adjunctive tiagabine, starting at 20 mg per day (five times the recommended starting dose) in eight acute mania inpatients not only was ineffective, but also yielded unacceptable adverse effects, with one patient having a seizure. This suggested not only inefficacy in mania, but also that loading or rapid dosage escalation should be avoided and caution exercised in using tiagabine, particularly in the initial titration phase. However, even more gradual initiation may be problematic. Thus, open primarily adjunctive tiagabine initiated at 4 mg per day and increased weekly as tolerated by 4 mg per day (mean dose 8.7 mg per day, mean duration 38 days) in outpatients with treatment-refractory bipolar disorder had limited efficacy and raised tolerability concerns, as 2 of 13 patients (15 percent) had seizures attributed as likely due to the medication. Thus, controlled studies are lacking and open studies have raised both efficacy and tolerability concerns regarding tiagabine in bipolar disorders.

Cocaine Use Disorder. Although preliminary studies were somewhat encouraging, in a larger controlled trial, tiagabine at 20 mg per day was no better than placebo as treatment for cocaine dependence.

Other Psychiatric Disorders. Limited controlled data suggested that low-dose (16 mg or less per day) tiagabine was generally well tolerated and yielded some benefit in primary insomnia. In three controlled trials tiagabine was no better than placebo for generalized anxiety disorder.

Therapeutic Indications

Seizure Disorders. Tiagabine is indicated as adjunctive treatment of partial seizures adults and adolescents 12 years of age and older with epilepsy.

Precautions and Adverse Reactions

In general, in patients with epilepsy who are also taking enzyme-inducing anticonvulsants, tiagabine adverse effects are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. In epilepsy patients, the most common adverse effects with adjunctive tiagabine were dizziness or lightheadedness, asthenia or lack of energy, somnolence, nausea, nervousness or irritability, tremor, abdominal pain, and thinking abnormally or difficulty with concentration or attention.

Importantly, the tiagabine USPI dosing recommendations were based on epilepsy patients taking enzyme-inducing anticonvulsants, which lower tiagabine plasma levels by approximately 50 percent. Administering tiagabine without enzyme inducers will approximately double tiagabine

plasma levels compared to those attained in the published epilepsy trials, which provided guidance for dosing. Thus, tiagabine given without enzyme inducers needs to have doses approximately 50 percent of those in the USPI. If this adjustment is not made, patients are at increased risk for adverse effects, some of which are serious.

The tiagabine USPI includes a boldface warning regarding the risk of seizures in patients without epilepsy. As noted above, rapid loading of open primarily adjunctive tiagabine in patients with acute mania, starting at 20 mg per day, yielded unacceptable adverse effects, with one patient having a seizure, and even more gradual initiation in outpatients with bipolar disorder at 4 mg per day and increased weekly as tolerated by 4 mg per day (mean final dose 8.7 mg per day) raised tolerability concerns, with 2 of 13 patients having seizures.

Other warnings in the tiagabine USPI include the risks of withdrawal seizures, cognitive or neuropsychiatric problems (impaired concentration, speech or language problems, somnolence, and fatigue), status epilepticus, and sudden unexpected death in epilepsy. As with other anticonvulsants, tiagabine has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

Acute oral overdoses of tiagabine have been associated with seizures, status epilepticus, coma, ataxia, confusion, somnolence, drowsiness, impaired speech, agitation, lethargy, myoclonus, stupor, tremors, disorientation, vomiting, hostility, temporary paralysis, and respiratory depression. Deaths have been reported in polydrug overdoses involving tiagabine.

Tiagabine was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date not in humans. It is not known the degree to which tiagabine is excreted in breast milk, so it was classified as “Safety Unknown” for lactation, and should be administered to women who are breastfeeding with caution only if the potential benefits clearly outweigh the (unknown) risks.

Tiagabine is contraindicated in patients with known hypersensitivity to tiagabine or its ingredients.

Drug Interactions

Tiagabine neither induces nor inhibits hepatic enzymes, but it is a target for pharmacokinetic drug interactions. Thus, enzyme inducers such as carbamazepine can yield clinically significant decreases in serum tiagabine concentrations, possibly by induction of CYP3A. Valproate does not yield clinically significant changes in serum total tiagabine concentrations, but appears to displace tiagabine from protein-binding sites, yielding an increase in free tiagabine, and thus potentially higher tiagabine toxicity. Tiagabine does not yield clinically significant changes in the pharmacokinetics of carbamazepine, phenytoin, and valproate. The

presence or absence of pharmacokinetic interactions between tiagabine and lamotrigine and tiagabine and lithium remains to be established. Tiagabine does not yield clinically significant changes in the kinetics of hormonal contraceptives.

Dosage and Administration

Most importantly, tiagabine should not be rapidly loaded or rapidly initiated due to the risk of serious adverse effects, namely potential seizures. The tiagabine USPI recommends that in adults and adolescents 12 years of age or older with epilepsy who were also taking enzyme inducers, tiagabine be initiated at 4 mg per day and increased weekly by 4 mg per day during the first month, and then increased weekly by 4 to 8 mg per day for weeks 5 and 6, yielding 24 to 32 mg per day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 4 to 8 mg per day to as high as 56 mg per day. Plasma tiagabine concentrations in epilepsy patients commonly range between approximately 20 and 100 ng/mL (50 and 250 nM/L), but do not appear to be systematically related to antiseizure effects, and thus are not routinely monitored.

In pivotal epilepsy trials, tiagabine was given with meals, which decreases the rate (later, lower peak plasma concentration) but not the extent of absorption. Thus, in order to limit the risk of adverse effects, the USPI recommends that tiagabine be given with meals.

If tiagabine is administered in the absence of enzyme-inducing anticonvulsants, the dosing needs to be even more conservative (50 percent lower doses) in order to limit the risk of adverse effects. Thus, it is prudent that tiagabine be initiated at no more than 2 mg per day and increased weekly by 2 mg per day during the first month, and then increased weekly by 2 to 4 mg per day for weeks 5 and 6, yielding 12 to 16 mg per day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 2 to 4 mg per day to as high as 28 mg per day.

Patients with hepatic impairment compared to those without may require up to 60 percent lower doses of tiagabine.

LEVETIRACETAM

Introduction and History

Levetiracetam (Keppra), developed in efforts to create second-generation nootropic (memory enhancing) medications, proved to be a potent anticonvulsant in the audiogenic-susceptible mouse model of epilepsy. In 1999, UCB, Inc. began marketing levetiracetam for the adjunctive treatment of refractory partial seizures in the United States.

Postmarketing, open, uncontrolled clinical experience suggested

potential benefit in patients with depressive symptoms with seizure disorders, bipolar disorder, and premenstrual dysphoric disorder. On the other hand, there also were reports of levetiracetam-related depression and aggressive behavior, and placebo-controlled studies did not find efficacy of levetiracetam for behavioral or overall clinical improvement in children with autism. Controlled studies have been lacking to assess the effects of levetiracetam in patients with bipolar disorder and other psychiatric disorders.

Chemistry

Levetiracetam, (-)-(*S*)-α-ethyl-2-oxo-pyrrolidine acetamide, is the (*S*)-enantiomer of the ethyl analog of the nootropic agent piracetam (Fig. 34.7–1) and has a structure unrelated to other anticonvulsants. Levetiracetam preparations currently marketed in the United States include: 250-, 500-, 750-, and 1,000-mg immediate-release tablets, 500- and 750-mg extended-release tablets; a 100-mg/mL oral solution; and a 100-mg/mL injectable intravenous solution. Generic immediate-release and extended-release levetiracetam are available.

Pharmacological Actions

Pharmacokinetics. Levetiracetam has a favorable pharmacokinetic profile, with absorption unaffected by food, bioavailability greater than 95 percent, binding to plasma proteins less than 10 percent, moderate volume of distribution of about .6 L/kg, linear elimination pharmacokinetics at clinically relevant doses (between 500 and 5,000 mg per day), half-life of approximately 8 hours, and clearance of 40 mL per minute. Levetiracetam is 66 percent excreted unchanged in the urine and is 24 percent hydrolyzed (in blood rather than in liver) to an inactive metabolite. Dosage may need to be decreased in patients with impaired renal function. However, levetiracetam has a low potential for pharmacokinetic drug interactions, because only a minor metabolic component involves hydrolysis (rather than CYP [cytochrome P450] oxidation or glucuronidation), and levetiracetam does not yield clinically significant changes in hepatic oxidation or glucuronidation.

Pharmacodynamics. Like most other anticonvulsants, levetiracetam has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Levetiracetam has GABAergic and antikindling effects, reduces voltage-dependent potassium currents, and binds to the synaptic vesicle protein SV2A. Levetiracetam lacks antiseizure activity in the pentylenetetrazole and maximal electroshock acute seizure models, but is potently active in chronic seizure models such as kindled seizures and genetic animal models. Levetiracetam also has antinociceptive

activity in animal models of neuropathic pain, and anxiolytic-like effects in animal models of anxiety disorders such as the rat conflict and elevated plus-maze.

Clinical Drug Studies

Seizure Disorders. Adjunctive levetiracetam appeared more effective than adjunctive placebo in three multicenter, randomized, double-blind, placebo-controlled trials involving adults with refractory partial seizures with or without secondary generalization; in one multicenter, randomized, double-blind, placebo-controlled trial in children (age 4 to 16 years) with refractory partial seizures; in one multicenter, randomized, double-blind, placebo-controlled trial in patients 12 years of age and older with juvenile myoclonic epilepsy; and in one multicenter, randomized, double-blind, placebo-controlled trial in patients 6 years of age and older with idiopathic primary generalized tonic–clonic seizures.

Other Neurological Disorders. In controlled pilot studies, levetiracetam appeared superior to placebo for migraine prevention, but was no better than placebo for essential tremor and Tourette syndrome.

Psychiatric Disorders. Levetiracetam was effective in an animal model of mania, and a series of uncontrolled case reports and case series suggested that levetiracetam may have efficacy in patients with bipolar disorder. In a small open-label study, patients with premenstrual dysphoric disorder had some improvement with levetiracetam. However, in controlled pilot studies, levetiracetam was no better than placebo in patients with social anxiety disorder and autism. Furthermore, there are reports of levetiracetam-related depression and aggressive behavior. Adequately powered controlled studies are lacking to assess the effects of levetiracetam in psychiatric disorders.

Therapeutic Indications

Seizure Disorders. Levetiracetam is indicated as adjunctive treatment of (1) partial-onset seizures in adults and children 4 years of age and older with epilepsy; (2) myoclonic seizures in adults and adolescents 12 years of age and older with juvenile myoclonic epilepsy; and (3) primary generalized tonic–clonic seizures in adults and children 6 years of age and older with idiopathic generalized epilepsy.

Precautions and Adverse Reactions

Levetiracetam is generally well tolerated but can cause somnolence and fatigue, coordination problems, and mood, anxiety, or behavioral adverse effects. In adult epilepsy patients, somnolence was seen in 14.8 percent (vs.

8.4 percent with placebo), asthenia occurred in 14.7 percent (vs. 9.1 percent with placebo), and coordination problems were evident in 3.4 percent (vs. 1.6 percent with placebo). In adult epilepsy patients, psychosis occurred in 0.7 percent (vs. 0.2 percent with placebo), and other behavioral problems were seen in 13.3 percent (vs. 6.2 percent with placebo). Behavioral problems included aggression, agitation, anger, anxiety, apathy, depersonalization, depression, emotional lability, hostility, and irritability. Behavioral adverse effects occurred early in treatment (often in the first month of therapy), and led to discontinuation in 1.7 percent (vs. 0.2 percent with placebo). Suicide attempts occurred in 0.5 percent (vs. 0 percent with placebo).

In pediatric epilepsy patients, somnolence was seen in 22.8 percent (vs. 11.3 percent with placebo), and asthenia occurred in 8.9 percent (vs. 3.1 percent with placebo). In pediatric epilepsy patients, behavioral problems were seen in 37.6 percent (vs. 18.6 percent with placebo). Behavioral problems in pediatric epilepsy included agitation, anxiety, apathy, depersonalization, depression, emotional lability, hostility, hyperkinesia, nervousness, neurosis, and personality disorder, leading to discontinuation in 10.9 percent (vs. 6.2 percent with placebo).

Levetiracetam-related behavioral problems appeared more common in patients with epilepsy than in patients with cognitive or anxiety disorders.

As with other anticonvulsants, levetiracetam has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders. Acute oral overdoses of levetiracetam have been associated with somnolence, agitation, aggression, respiratory depression, and coma.

Levetiracetam was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date not in humans. Levetiracetam was classified as “Probably Safe” for lactation, though it is excreted in breast milk, so that levetiracetam should be administered to women who are breastfeeding only if the potential benefits clearly outweigh the (unknown) risks.

Levetiracetam is contraindicated in patients with known hypersensitivity to levetiracetam or its ingredients.

Drug Interactions

Levetiracetam’s high degree of renal clearance and hydrolytic metabolism yield a low potential for pharmacokinetic drug interactions. Hence, levetiracetam does not appear to have clinically significant pharmacokinetic interactions with valproate or lamotrigine in epilepsy patients. Levetiracetam does not significantly alter serum concentrations of carbamazepine or carbamazepine epoxide in epilepsy patients; however, levetiracetam plus carbamazepine may still yield adverse effects through pharmacodynamic interactions. Carbamazepine (Tegretol) may decrease

serum levetiracetam concentrations, but with variable reports of potential clinical significance. Oxcarbazepine (Trileptal) may also modestly decrease serum concentrations of levetiracetam. Levetiracetam does not appear to have clinically significant pharmacokinetic interactions with gabapentin or topiramate in epilepsy patients, although the levetiracetam plus topiramate combination may yield adverse effects through a pharmacodynamic interaction. Levetiracetam does not yield clinically significant alterations in serum concentrations of phenytoin (Dilantin), phenobarbital (Bellatal), or primidone (Mysoline) in epilepsy patients. Despite both being renally cleared, levetiracetam and lithium pharmacokinetic interactions remain to be established. Levetiracetam does not yield clinically significant changes in the metabolism of hormonal contraceptives.

Dosage and Administration

In adult epilepsy patients, adjunctive levetiracetam is commonly started at 500 to 1,000 mg per day and increased as necessary and tolerated every 2 weeks by 1,000 mg per day, up to a maximum 3,000 mg per day in two divided doses. In pediatric epilepsy patients, adjunctive levetiracetam is commonly started at 20 mg/kg per day and increased as necessary and tolerated every 2 weeks by 20 mg/kg per day, up to a maximum 60 mg/kg per day in two divided doses. Plasma levetiracetam concentrations in epilepsy patients commonly range between approximately 6 and 20 μg/mL (35 and 120 μM/L), but to do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In view of the substantive renal clearance, levetiracetam dosage needs to be adjusted in patients with impaired renal function, based on the degree of renal insufficiency.

ZONISAMIDE

Introduction and History

Zonisamide (Zonegran) was synthesized by Dainippon Pharmaceutical Company while screening arylsulfonamides for anticonvulsant effects, putatively related to carbonic anhydrase inhibition. Although zonisamide only weakly inhibited carbonic anhydrase, it proved effective in several animal models of epilepsy. Zonisamide was subsequently developed as an antiepileptic drug, and marketed for over a decade in Japan and South Korea prior to being marketed for the adjunctive treatment of partial seizures in the United States in 2000 by Elan Pharmaceuticals, and more recently by Eisai, Inc.

Limited, open, uncontrolled clinical experience and controlled trials suggest potential efficacy in some other neurological and psychiatric conditions. Large controlled trials are needed to assess these encouraging

preliminary findings.

Chemistry

Zonisamide, (3-[sulfamoylmethyl]-1,2-benzisoxazole), is a 1,2-benzisoxazole-3-methanesulfonamide, which is structurally different from other marked anticonvulsants (Fig. 34.7–1). Zonisamide is available in 25- and 100-mg capsules for oral administration. Generic zonisamide is available.

Pharmacological Actions

Pharmacokinetics. Zonisamide has generally favorable pharmacokinetic properties, with good (close to 100 percent) bioavailability, only 40 to 60 percent binding to plasma proteins (but extensive binding to erythrocytes), a clearance of 20 mL per minute, and a moderate volume of distribution of 1.5 L/kg. Zonisamide has linear pharmacokinetics between 200 and 400 mg per day, but has disproportionate serum concentrations at 800 mg, presumably related to saturable binding to carbonic anhydrase in erythrocytes. As monotherapy, zonisamide has a half-life of 60 hours, which decreases to 30 hours if administered with enzyme inducers. Zonisamide is reduced to 2-sulfamoylacetylphenol (SMAP), primarily by CYP3A4, but is also 30 percent excreted unchanged in the urine. Marked renal impairment (creatinine clearance less than 20 mL per minute) increases plasma zonisamide concentrations by 35 percent.

Pharmacodynamics. Like most other anticonvulsants, zonisamide has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Zonisamide blocks sodium channels, reduces T-type calcium currents, facilitates dopaminergic and serotonergic neurotransmission, and is a weak carbonic anhydrase inhibitor. Although zonisamide binds to the GABA/benzodiazepine receptor complex, it does not alter chloride currents and does not appear to have major GABAergic activity. Zonisamide has antiseizure activity in the maximal electroshock, pentylenetetrazole (against maximal but not minimal seizures), fully kindled seizure, and several other animal models of seizures and antinociceptive activity in animal models of neuropathic pain.

Clinical Drug Studies

Seizure Disorders. Adjunctive zonisamide appeared more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials in patients with refractory partial seizures, with and without secondary generalization.

Diabetic Neuropathy. Zonisamide was no better than placebo for diabetic neuropathy in a small pilot study.

Other Neurological Disorders. A multicenter, randomized, double-blind, placebo-controlled study suggested adjunctive zonisamide had efficacy in treating motor symptoms in patients with Parkinson disease. However, zonisamide was no better than placebo for essential tremor in a small pilot study.

Eating Disorders. In controlled trials, zonisamide was superior to placebo for obesity and for binge eating disorder associated with obesity.

Bipolar Disorder. Open, uncontrolled reports suggest that zonisamide may have some utility in bipolar disorder, including for treatment of weight gain. Controlled trials are needed to assess these preliminary findings.

Therapeutic Indications

Seizure Disorders. Zonisamide is indicated as adjunctive treatment of partial seizures in adults with epilepsy.

Precautions and Adverse Reactions

In epilepsy registration trials, adverse effects with adjunctive zonisamide were generally mild to moderate, commonly attenuated by dosage rescheduling or decreases, and did not typically require discontinuation (adverse effect discontinuation rate 12 vs. 6 percent with placebo). The most common adverse effects with adjunctive zonisamide in epilepsy trials were somnolence, anorexia, dizziness, headache, nausea, and agitation or irritability. The appetite suppression effect of zonisamide has been used to therapeutic advantage in patients with obesity and binge eating disorder.

In patient populations other than epilepsy, zonisamide tolerability may be more challenging, with reports of higher adverse effect discontinuation rates in patients with binge eating disorder with obesity (27 vs. 13 percent with placebo), diabetic neuropathy (38 vs. 0 percent with placebo), essential tremor (30 vs. 0 percent with placebo), and bipolar disorder (32 percent due to worsening mood symptoms with open treatment).

Zonisamide has been associated with nephrolithiasis in approximately 4 percent of patients (but only symptomatic in approximately 1 percent of patients), presumably due to carbonic anhydrase inhibition. Zonisamide increases serum creatinine and blood urea nitrogen by approximately 8 percent, but does not appear to alter glomerular filtration rate (GFR) or yield progressive renal damage. Zonisamide is not recommended in patients with renal failure (GFR less than 50 mL per minute) due to toxicity risks. Sudden unexplained death in epilepsy, status epilepticus, and rare

creatine phosphokinase elevation and pancreatitis have been reported.

The zonisamide USPI includes a warning regarding the risks of severe reactions (Stevens–Johnson syndrome, toxic epidermal necrolysis, fulminant hepatic necrosis, agranulocytosis, aplastic anemia, and other blood dyscrasias) seen with sulfonamides, so if signs of such reactions occur, zonisamide needs to be discontinued immediately. Rash was seen in 2.2 percent of patients taking zonisamide in pivotal trials and resulted in discontinuation in 1.4 percent of patients. Other warnings include the risks of metabolic acidosis and nephrolithiasis, oligohydrosis and hyperthermia in pediatric patients, withdrawal seizures, teratogenicity, cognitive or neuropsychiatric problems (depression, psychosis, psychomotor slowing, impaired concentration or speech, language, word finding), somnolence, fatigue, and rare serious hematological events (two cases of aplastic anemia and one case of agranulocytosis in the first 11 years of marketing in Japan, and no case of aplastic anemia but two cases of agranulocytosis in the United States, European, and Japanese development programs). As with other anticonvulsants, zonisamide has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

Experience with zonisamide overdose is limited. Acute oral overdoses of zonisamide have been associated with coma, bradycardia, hypotension, and respiratory depression.

Zonisamide was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date not in humans. It is not known the degree to which zonisamide is excreted in breast milk, so it was classified as “Safety Unknown” for lactation, and should be administered to women who are breastfeeding with caution only if the potential benefits clearly outweigh the (unknown) risks.

Zonisamide is contraindicated in patients with known hypersensitivity to zonisamide or its ingredients. In addition, zonisamide has a sulfonamide functional group, so is contraindicated in patients with sulfa drug allergies.

Drug Interactions

Zonisamide does not inhibit CYP450 isoenzymes, does not induce its own metabolism, and is a target rather than an instigator of drug interactions. Carbamazepine decreases serum zonisamide concentrations, while zonisamide does not appear to yield clinically significant changes in carbamazepine pharmacokinetics. Zonisamide and valproate and zonisamide and lamotrigine do have clinically significant pharmacokinetic interactions in patients with epilepsy. The presence or absence of pharmacokinetic interactions between zonisamide and lithium remains to be established. Phenytoin and phenobarbital decrease serum zonisamide concentrations. Combination of zonisamide with other carbonic anhydrase inhibitors such as acetazolamide and topiramate is not recommended due

to concerns about increasing the risk of nephrolithiasis or heat-related problems (oligohydrosis and hyperthermia). Zonisamide does not alter hormonal contraceptive pharmacokinetics.

Dosage and Administration

In patients with epilepsy, adjunctive zonisamide is started at 100 mg per day, and increased every 2 weeks (no faster due to a 60-hour half-life) as necessary and tolerated by 100 mg per day, with final doses commonly ranging between 300 and 600 mg per day in two divided doses. Adverse effects were more common at doses of 300 mg per day or more. Plasma zonisamide concentrations in epilepsy patients commonly range between approximately 10 and 38 μg/mL (45 and 180 μM/L) but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In controlled studies, mean final zonisamide doses were 160 mg per day for essential tremor, 427 mg per day for obesity, 436 mg per day for binge eating disorder with obesity, and 540 mg per day for painful diabetic neuropathy. As zonisamide undergoes both hepatic metabolism and renal excretion unchanged, patients with hepatic or renal disease may require more conservative dosing and titration and more frequent monitoring.

PREGABALIN

Introduction and History

Pregabalin (Lyrica) was developed in a fashion similar to that of gabapentin, as a compound with structure similar to the inhibitory amino acid neurotransmitter GABA that could easily cross the blood–brain barrier. Although these agents lacked direct GABAergic effects, they were effective in animal models of pain and epilepsy (with pregabalin being more potent) and developed as analgesic and antiepileptic drugs. Pregabalin was marketed for the treatment of neuropathic pain associated with diabetic peripheral neuropathy in the United States in 2005 by the Parke–Davis division of Pfizer, Inc. Pregabalin subsequently received approval for the treatment of postherpetic neuralgia, adjunctive treatment of adults with partial-onset seizures, for the treatment of fibromyalgia, and for the treatment of neuropathic pain associated with spinal cord injury. Pregabalin also appeared effective in controlled trials for generalized anxiety disorder and social anxiety disorder, but as of late 2014, had not been approved for these indications.

Chemistry

Pregabalin, *S*-(+)-3-isobutylGABA, is a novel amino acid derived from GABA (Fig. 34.7–1), with a structure and mechanisms that overlap those of gabapentin and some structural similarity to other anticonvulsants that resemble GABA, such as valproate. Pregabalin is currently marketed in the

United States as an oral preparation in 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules, and as a 20-mg/mL oral solution.

Pharmacological Actions

Pharmacokinetics. Pregabalin appears to have generally favorable pharmacokinetic properties, similar to gabapentin. Pregabalin is not bound to plasma proteins, has a moderate volume of distribution of 0.5 L/kg, a half-life of 6 hours (requiring twice daily dosing), is greater than 95 percent excreted unchanged in urine, and has clearance of 80 mL per minute that varies with creatinine clearance. Pregabalin clearance is highly dependent on renal function, and dosage reduction may be necessary in patients with renal impairment. Pregabalin lacks hepatic metabolism, does not induce or inhibit hepatic metabolism, and lacks metabolic drug interactions. Unlike gabapentin, pregabalin has higher (greater than 90 percent) bioavailability and absorption that is proportional to dose, without the gastrointestinal absorption saturation of gabapentin. Food has no clinically relevant effect on pregabalin absorption.

Pharmacodynamics. Like most other anticonvulsants, pregabalin has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Pregabalin, like gabapentin, is a structural analog of GABA, but these agents appear to lack direct GABAergic actions. However, both of these agents have selective inhibitory effects on voltage-gated calcium channels containing the $\alpha_2\delta$ subunit, reducing depolarization-induced calcium influx at nerve terminals, resulting in decreased release of excitatory neurotransmitters such as glutamate and noradrenaline. In rat forebrain, these drugs acutely decreased cellular glutamate but did not alter GABA or glutamine concentrations.

Pregabalin has antiseizure activity that is more potent than gabapentin in the maximal electroshock, pentylenetetrazole, hippocampal kindled, and other animal models of seizures. Antinociceptive activity is more potent than gabapentin in animal models of neuropathic pain. Pregabalin has anxiolytic-like effects in the rat conflict and elevated plus-maze animal models of anxiety disorders.

Clinical Drug Studies

Seizure Disorders. Adjunctive pregabalin was more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials in adults with partial-onset seizures.

Postherpetic Neuralgia. Pregabalin was more effective than placebo in three multicenter, double-blind, placebo-controlled trials in adults with

postherpetic neuralgia. Interestingly, mood, sleep, and quality of life measures improved, in addition to improved pain problems.

Diabetic Peripheral Neuropathy. Pregabalin was more effective than placebo in three multicenter, double-blind, placebo-controlled trials in adults with diabetic peripheral neuropathy. Similar to postherpetic neuralgia, pain, mood, sleep, and quality of life measures all improved.

Neuropathic Pain Associated with Spinal Cord Injury. Pregabalin was more effective than placebo in two multicenter, double-blind, placebo-controlled trials in adults with neuropathic pain associated with spinal cord injury. Similar to postherpetic neuralgia, pain, mood, sleep, and quality of life measures all improved.

Fibromyalgia. Pregabalin was more effective than placebo for fibromyalgia in one 14-week multicenter, double-blind, placebo-controlled trial (with superior relief of pain, disturbed sleep, and fatigue), and in one 6-month randomized withdrawal study.

Other Pain Syndromes. Pregabalin was effective for central neuropathic pain associated with spinal cord injury, improving pain, sleep, anxiety, and overall patient status. Pregabalin appeared effective for pain associated with chronic pancreatitis, postoperative mastectomy, and neuropathic pain from severe burns. Pregabalin was not found to be more effective than placebo for pain associated with prostatitis and HIV.

Other Neurological Disorders. In a pilot, double-blind, controlled, randomized trial, pregabalin was superior to placebo in the treatment of essential tremor.

Anxiety Disorders. In eight randomized, double-blind, placebo-controlled trials, pregabalin was effective for adult and older adult patients with generalized anxiety disorder and social anxiety disorder in short- and longer-term treatment.

Therapeutic Indications

Diabetic Peripheral Neuropathy. Pregabalin is indicated for the treatment of diabetic peripheral neuropathy.

Postherpetic Neuralgia. Pregabalin is indicated for the treatment of postherpetic neuralgia.

Neuropathic Pain Associated with Spinal Cord Injury. Pregabalin is indicated for the treatment of neuropathic pain associated with spinal cord

injury.

Seizure Disorders. Pregabalin is indicated for the adjunctive treatment of adults with partial-onset seizures.

Fibromyalgia. Pregabalin is indicated for the treatment of fibromyalgia.

Precautions and Adverse Reactions

In general, pregabalin adverse effects are mild to moderate, can be attenuated by dosage rescheduling or decreases, and do not typically require discontinuation. In diabetic neuropathy patients, the most common adverse effects with pregabalin were dizziness, somnolence, peripheral edema, dry mouth, and asthenia. In postherpetic neuralgia patients, the most common adverse effects with pregabalin were dizziness, somnolence, peripheral edema, infection, and headache. In partial-onset seizure patients, the most common adverse effects with adjunctive pregabalin were dizziness, somnolence, ataxia, weight gain, blurred vision, diplopia, and accidental injury. In fibromyalgia patients, the most common adverse effects with pregabalin were dizziness, somnolence, headache, weight gain, blurred vision, and dry mouth. The pregabalin USPI includes warnings regarding the risks for several of the above adverse effects (dizziness, somnolence, peripheral edema, weight gain, and blurred vision), as well as angioedema, hypersensitivity, withdrawal symptoms, tumorigenic potential (hemangiosarcoma in mice), elevated creatine kinase, thrombocytopenia, and PR interval prolongation. As with other anticonvulsants, pregabalin has a warning of increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders.

Pregabalin is a schedule V controlled substance, with abuse and dependence potential concerns, based on the potential to yield euphoria, and the potential for withdrawal reactions.

There are limited data regarding the clinical consequences of acute oral overdoses of pregabalin.

Pregabalin was classified as pregnancy category C, as fetal loss and teratogenicity have been demonstrated in animals, but to date not in humans. It is not known the degree to which pregabalin is excreted in breast milk, so it was classified as “Safety Unknown” for lactation, and should be administered to women who are breastfeeding with caution only if the potential benefits clearly outweigh the (unknown) risks.

Pregabalin is contraindicated in patients with known hypersensitivity to pregabalin or its ingredients.

Drug Interactions

Like gabapentin, in view of the absence of hepatic metabolism, pregabalin lacks metabolic drug interactions. Thus, in patients with epilepsy, pregabalin lacks clinically significant pharmacokinetic drug interactions with carbamazepine, valproate, and lamotrigine. The presence or absence of pregabalin pharmacokinetic interactions with lithium remains to be established. In patients with epilepsy, pregabalin lacks clinically significant pharmacokinetic drug interactions with gabapentin and topiramate. Although tiagabine does not affect pregabalin pharmacokinetics, the presence or absence of a pregabalin effect on tiagabine pharmacokinetics remains to be established. The presence or absence of pregabalin pharmacokinetic interactions with oxcarbazepine, levetiracetam, and zonisamide remains to be established. Pregabalin does not yield clinically significant changes in the kinetics of hormonal contraceptives.

Dosage and Administration

The pregabalin USPI recommends that therapy in diabetic neuropathy, postherpetic neuralgia, fibromyalgia, partial-onset seizures, and neuropathic pain associated with spinal cord injury should start at 150 mg per day in two to three (two for fibromyalgia and neuropathic pain associated with spinal cord injury) divided doses, and be increased within 1 week (based on efficacy and tolerability) to 300 mg per day in two or three (two for fibromyalgia and neuropathic pain associated with spinal cord injury) divided doses. Patients with insufficient efficacy may be further increased to 450 mg per day in divided doses for fibromyalgia, and 600 mg per day in divided doses in partial-onset seizures, postherpetic neuralgia, and neuropathic pain associated with spinal cord injury. Plasma pregabalin concentrations in epilepsy patients do not appear to be systematically related to antiseizure effects and thus are not routinely monitored. In controlled trials, pregabalin doses have ranged from 150 to 600 mg per day in generalized anxiety disorder and social anxiety disorder, though pregabalin lacks a specific indication for anxiety disorders. In patients with renal impairment, pregabalin doses may need to be decreased, depending on the degree of renal insufficiency.

NEWEST ANTICONVULSANTS

The seven newest anticonvulsants (rufinamide, lacosamide, vigabatrin, esogabine, clobazam, perampanel, and eslicarbazepine acetate) also have diverse efficacy and safety/tolerability profiles, but detailed review of these agents is beyond the scope of this chapter. Thus, a few anticonvulsants may yield efficacy for some psychiatric and pain disorders. Clinicians may also find adjunctive uses for anticonvulsants, such as for managing weight gain. Knowledge of these differences, combined with familiarity with the pharmacodynamics, dosing, pharmacokinetics, drug interactions, adverse

effects, and their management for these agents can help clinicians provide safer and more effective therapeutics when newer anticonvulsants are used in the management of not only epilepsy, but also psychiatric and pain disorders.

▲ 34.8 Antihistamines

ROGER S. MCINTYRE, M.D.

HISTORY

Histamine is a phylogenetically old amine widely distributed throughout the CNS across many species. In the early 1900s, histamine's role in immunomodulation and smooth muscle relaxation was originally described. Charles Best and colleagues were the first to isolate histamine (H-substance) in 1927. The antihistamines were first discovered by the Swiss-born Italian pharmacologist Daniel Bovet in 1937. The first nontoxic histamine-blocking drug, pyrilamine (Poly-Histine-D), was discovered in 1944. In the 1950s, diphenhydramine (Benadryl) and tripelennamine (Pyribenzamine) were introduced as highly effective histamine antagonists. The sedative and anticholinergic activity of antihistamines provided the basis for their frequent prescription for a panoply of psychiatric symptoms. The more recently introduced nonsedating antihistamines are less frequently prescribed in psychiatric practice.

CHEMISTRY

With approximately 50 H_1 antihistamines currently available worldwide, antihistamines are among the most widely utilized class of agents in the world (Table 34.8–1; Fig. 34.8–1). H_1 antihistamines have been reclassified as inverse agonists rather than competitive antagonists. Antihistamines are classified into six chemical classes: Phenothiazines (e.g., promethazine [Phenergan]), piperidines (e.g., cyproheptadine [Periactin]), ethanolamines (e.g., diphenhydramine), piperazines (e.g., hydroxyzine HCI [Atarax]), ethylenediamines (e.g., pyrilamine), and alkylamines (e.g., chlorpheniramine [Chlor-Trimeton). Although the antihistamines are structurally unrelated, they share a common ethylamine moiety. The typology, first- and second-generation antihistamines, refers to sedating and nonsedating agents, respectively. More recently, nonsedating (i.e., they are substrates of P-glycoprotein) antihistamines with less arrhythmogenic potential (e.g., fexofenadine [Allegra], loratadine [Claritin], desloratadine [Clarinex], and cetirizine [Zyrtec]) have been referred to as third-generation antihistamines.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Some general properties of important histamine antagonists are shown in Table 34.8–1.

Absorption

The first-generation H_1 antagonists are readily absorbed via the GI tract. Most agents achieve maximum plasma levels within 1 to 3 hours (T_{max}).

Distribution

Antihistamine binding of plasma protein varies from approximately 50 to 98 percent. The H_1 antihistamine's volume of distribution varies more than 100-fold from 0.33 L/kg (i.e., levocetirizine [Xyzal]) to greater than 100 L/kg (i.e., loratadine). Sedating antihistamines are widely distributed in the body and CNS. The antihistamine CNS adverse event profile is a consequence of its relative ability to traverse the BBB. Factors that influence BBB permeability are lipophilicity, molecular weight, and recognition by the P-glycoprotein efflux pump expressed on luminal surfaces of nonfenestrated endothelial cells in the vascular wall of the CNS. Radioligand studies utilizing carbon-11 doxepin [Sinequan] indicate that first-generation H_1 antihistamines occupy approximately 50 to 90 percent of the H_1 receptors (H_1R) in the frontal and temporal cortices, hippocampus, and pons. Second-generation H_1 antihistamines occupy approximately 0 to 30 percent of CNS H_1R_5 receptors largely due to their minimal lipophilicity and affinity for P-glycoproteins.

[a]Unless otherwise indicated, results are expressed as means ± SD or as a range of values. Parentheses denote active metabolites.

[b]T_{max} denotes time from oral intake to peak plasma concentration.

[c]Onset and duration of action are based on wheal-and-flare studies.

[d]Studies were performed decades after some of these drugs were introduced. Empirical dosage regimens persist.

[e]Second-generation H_2 antihistamines were not available in the United States at the time of publication.

[f]Fexofenadine should not be administered within 15 minutes after the ingestion of antacids that contain aluminum and magnesium as it may decrease absorption.

METABOLISM

Most antihistamines are subject to phase I metabolism via hepatic cytochrome P450 systems. In vitro studies evaluating human liver microsomes transfected with CYP2D6 complementary deoxyribonucleic acid (cDNA) indicate that several antihistamines (e.g., diphenhydramine, chlorpheniramine, clemastine [Dayhist-1], perphenazine [Trilafon], hydroxyzine, tripelennamine) inhibit the metabolism and are hepatically biotransformed by CYP2D6 and CYP3A4. Second- and third-generation

antihistamines are neither potent inhibitors nor inducers of the cytochrome P450 system. The H_1-antihistamine terminal elimination half-life ($t_{1/2}\beta$) ranges from approximately 2 to 27 hours. Pediatric populations rapidly metabolize antihistamines; individuals who are slow metabolizers may exhibit drug accumulation.

ELIMINATION

Most antihistamines are excreted largely unchanged in the urine and feces.

PHARMACODYNAMICS

Histamine is a pleiotropic, low–molecular-weight amine synthesized endogenously in diverse cell types from L-histidine by the enzyme histidine decarboxylase. Histamine is produced in the CNS in neurons of the tuberomammillary nucleus of the posterior hypothalamus with projections to both cortical and subcortical regions. Although no precise topographical organization of the histaminergic projection field has been elucidated, the cerebral cortex, amygdala, substantia nigra, and striatum receive moderate to dense histaminergic innervation. Innervations to the hippocampus, thalamus, retina, and spinal cord are variable. Histaminergic networks interact and modulate classical monoamine networks. Afferent projection to tuberomammillary neurons includes infralimbic cortex, lateral septum, preoptic nucleus, and brainstem (from adrenergic cell group C1 to C3, noradrenergic group A1 to A3, and serotonergic group B5 to B9).

In addition to histamine, the tuberomammillary neurons also contain GABA–synthesizing enzyme, glutamic acid decarboxylase (GAD), galanin, thyrotropin-releasing hormone, proenkephalin-derived peptides, substance P, and adenosine deaminase. The CNS histamine pool is also comprised of mast cells, glial cells, and vascular endothelium, which are activated by inflammatory effectors.

H_1 and H_2 receptors exert mostly excitatory actions on neurons, while H_3-receptor activation results in autoinhibition of tuberomammillary neurons and reduced neurotransmitter release. H_1-histamine receptors participate in synaptic plasticity and long-term potentiation (LTP) via their effect on intracellular Ca^{2+} and protein kinase C (PKC). H_2-receptor activation potently stimulates the cAMP pathway; a critical substrate for late-phase NMDA receptor-dependent LTP. H_2-receptor activation also participates in the induction of mossy-fiber LTP. High histamine concentration in the CA1 region of the hippocampus facilitates the induction of LTP in the presence of H_1 and H_2 antagonists, suggesting direct action at the NMDA receptors.

FIGURE 34.8–1. Molecular structures of antihistamines used in psychiatric practice.

Histamine plays a critical role in CNS arousal. Lesioning of the posterior hypothalamus results in hypersomnia and decreased psychomotor activity. Histamine also regulates cortical activity by stimulating cholinergic neurons of the basal forebrain and serotonergic neurons of the dorsal raphe nucleus. The wakefulness-promoting effects of orexins may be mediated by increased histamine release as inactivation mutations of the H_1R decrease the orexin-mediated arousal effect. Histamine is also involved in vasopressor effects, temperature regulation, and analgesia.

Histamine regulates energy homeostasis via effects on leptin networks. Central administration of leptin increases histamine turnover in the hypothalamus. Leptin-induced suppression of food intake and upregulation of uncoupling protein 1 expression in brown adipose tissue is attenuated in H_1R knockout mice. H_1R as well as POMC-MC4-R regulate energy homeostasis in the brain. Histamine's effect on drinking behavior and osmotic homeostasis is mediated by its stimulatory effect on vasopressin-producing neurons in the supraoptic nucleus. Histamine also regulates neuroendocrine systems (e.g., prolactin, growth hormone, adrenocorticotropin, and thyrotropin-releasing hormone).

Unlike other aminergic systems, histamine and the level of its metabolites increase in the CSF as a function of age. In Alzheimer disease, neurofibrillary tangles occur prominently in the tuberomammillary nucleus, with a corresponding decrease in the number of tuberomammillary neurons. Histamine levels and histidine decarboxylase

activity are diminished in brain regions affected by Alzheimer disease and Down syndrome. In Parkinson patients, histamine levels are selectively increased in the putamen, substantia nigra, and external globus pallidus. Levels of tele-methylhistamine (t-MeHA), the primary metabolite of histamine, are unchanged in substantia nigra. In contradistinction, t-MeHA is elevated in the CSF of individuals with schizophrenia, particularly those with prominent negative symptoms. These observations indicate that increased histamine release and turnover are pathophysiological features in schizophrenia, providing the basis for evaluating the efficacy of H_2-receptor antagonists. Interestingly, results from relatively small placebo-controlled clinical trials in schizophrenia indicate that adjunctive famotidine was superior to placebo in reducing overall objectively measured negative symptom severity. In addition, global psychopathology in famotidine-treated subjects may exhibit significantly greater reduction when compared to placebo treatment.

During the past two decades, the human H_1-, H_2-, H_3-, and H_4-histamine receptors have been cloned and characterized, each differing in structure, function, localization, and pharmacology. Immunocytochemical studies have isolated H_3 receptors throughout the CNS. Conformationally, the histamine receptor is a heptahelical protein that exists in both active and inactive forms in dynamic equilibrium. Several isoforms for each of the histamine receptors have been identified with reverse transcription polymerase chain reaction. The four major histamine receptors transduce extracellular signals via G proteins to intracellular second-messenger systems. Histamine receptors are constitutively active and capable of independent signaling from agonists both in vitro and in vivo.

The human H_1R have approximately 45 percent homology with muscarinic receptors. Inactivation mutations of the H_1-receptor gene result in abnormal learning, memory, immunological abnormalities, and locomotor activity. The H_1R also mediate the increased permeability of small vessels seen in allergic responses. Extravascular smooth muscle (e.g., bronchiole smooth muscle) contraction is also mediated by H_1R. H_3 receptors are presynaptic autoreceptors on histamine-containing neurons; they mediate the synthesis, release, and inhibition of histamine. H_3 receptors are also involved in modulating the release of several other monoamines and neuropeptides.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

A substantial body of evidence has established the efficacy of H_1 antihistamines for allergy-related conditions as well as motion sickness. There are no contemporary studies that have established the efficacy of H_1 histamine antagonist for any *Diagnostic and Statistical Manual of Mental*

Disorders (DSM-5)–defined mental disorders. H_1 antagonists are frequently prescribed to achieve ataraxia and to reduce psychomotor agitation and sleep latency. The anticholinergic effects of H_1 antihistamines have provided the basis for prescribing these agents in Parkinson disease and for antipsychotic-induced movement disorders. Equivocal evidence supports the use of H_2-antihistamine receptor antagonists in the treatment of schizophrenia, Alzheimer disease, medication-associated weight loss, anxiety disorders, and autism.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The effects of H_1 antihistamines are a direct consequence of their pharmacological activity at their canonical receptors. First-generation H_1 antihistamines result in sedation, somnolence, and decreased reaction time. In some cases, paradoxical excitation characterized by restlessness, agitation, and nervousness has also been reported. The stimulating effects of H_1 antihistamines have been particularly apparent in tasks that require a high level of attention (e.g., divided attention tasks, vigilance tasks, and driving tasks). In some cases, the stimulating effects of antihistamines are dose-dependent. The precise biochemical mechanism subserving the excitatory effects has not been elucidated; it is hypothesized that neurotransmitters such as dopamine and GABA are salient or that the effect is mediated by the H_3-histamine receptor.

Antihistamines also have prominent autonomic nervous system effects. They exert a drying effect on mucous membranes in the respiratory system, and their effects on smooth muscles result in bronchodilation and the inhibition of vasoconstriction. H_1 antihistamines do not significantly affect blood pressure; parenteral administration of antihistamines results in transient lowering of blood pressure.

THERAPEUTIC INDICATIONS

Histamine's critical role in immunomodulation provides the basis for its clinical application in allergic rhinoconjunctivitis, asthma, urticaria, and other allergic or immunological disorders. H_1 antihistamines are widely prescribed in the treatment of insomnia, analgesia, akathisia, serotonin syndrome, anxiety, motion sickness, vertigo, antiemetic, and for bruxism. For example, preliminary evidence suggests that hydroxyzine may be superior to placebo at reducing overall severity of bruxism in children. They are often included in many over-the-counter preparations. Benzodiazepines and other classes of psychotropic agents that reduce anxiety and improve sleep efficiency have largely replaced antihistamines in clinical practice.

The rationale for considering antihistamines is supported by evidence

that the histaminergic systems are critical to wakefulness promotion. Doxepin, a TCA, is FDA approved for the treatment of insomnia. Doxepin's principle pharmacodynamic mode of action in insomnia relates to its potent antihistaminergic effects. Doxepin (and diphenhydramine) have been reported to induce non-REM sleep by blockade of H_1R. A highly replicated body of evidence indicates that low-dose doxepin's beneficial effect on sleep maintenance and duration has a medium effect size in comparison to placebo.

Diphenhydramine

Oral diphenhydramine is efficacious in the treatment of antipsychotic-induced movement disorders. Diphenhydramine is indicated by the FDA for the treatment of antipsychotic-induced parkinsonism, allergic and anaphylactic reactions, as well as motion sickness. When prescribed for parkinsonism, diphenhydramine is often combined with other anticholinergic agents. The parenteral availability of diphenhydramine provides for it a viable treatment for Parkinson patients with difficulty swallowing and in the treatment of acute dystonic reactions. Diphenhydramine has historically been prescribed as a nonspecific sedative for children and the elderly. Reports of paradoxical excitation as well as cognitive impairment (e.g., anticholinergic effect) reduce its therapeutic index.

Hydroxyzine

Hydroxyzine is indicated for the short-term treatment of anxiety and tension due to psychological factors. Although hydroxyzine's efficacy in the treatment of generalized anxiety is supported with comparator- and placebo-controlled trials, there is a paucity of rigorous, controlled studies in DSM-IV-TR–defined generalized anxiety disorder. Hydroxyzine is also indicated for use as an antipruritic and as a sedative as part of a premedication regimen in conjunction with general anesthesia.

Promethazine

Promethazine is indicated before or after surgery and as an antiemetic in postoperative patients. Like diphenhydramine, it is also used for allergic reactions and to treat motion sickness. Promethazine is indicated for sedation in both pediatric and adult populations. It is also used as an adjuvant for analgesia.

Cyproheptadine

Cyproheptadine is indicated for allergic reactions. Cyproheptadine is used for disparate purposes in psychiatric practice (e.g., to reverse antidepressant-associated sexual dysfunction or stimulant-induced weight

loss or insomnia), and for the symptomatic treatment of schizophrenia, autistic disorders, and serotonin syndrome.

H_2-Receptor Antagonists

H_2-receptor antagonist use in psychiatric practice has primarily been for weight loss in overweight individuals and persons experiencing antipsychotic-associated weight gain. Initial studies indicated that the H_2-receptor antagonist nizatidine (Axid) was efficacious as a secondary prevention strategy for olanzapine (Zyprexa)-associated weight gain. Subsequent placebo-controlled studies with this agent as a primary or secondary prevention strategy for olanzapine and quetiapine (Seroquel)-associated weight gain have produced more equivocal results. The mechanism mediating nizatidine's modest weight loss effect is hypothesized to be via central appetite–regulating centers. Pharmacological managements related to weight gain from psychotropic agents are likely best treated with other better proven strategies (e.g., metformin).

Ecological studies suggested that H_2-receptor antagonists could possibly decrease incident Alzheimer disease. Subsequent randomized, double-blind, placebo-controlled trials with nizatidine, however, failed to demonstrate a therapeutic effect in the treatment of cognitive deterioration as part of Alzheimer disease. Notwithstanding, several lines of preclinical evidence suggest that antihistaminergic therapy may facilitate reduction in amyloid-beta neuropathology and prevention of autophagic failure.

PRECAUTIONS AND ADVERSE EVENTS

The most common side effect of first-generation H_1-antagonist receptors is CNS depression, manifesting as sedation, somnolence, cognitive impairment, and reduction in psychomotor activity. Simple and complex tests of psychomotor performance indicate that second-generation antihistamines are less impairing than first-generation antihistamines. Although second- and third-generation antihistamines are less sedating, when coadministered with other agents that alter P-glycoprotein function, their propensity for CNS adverse events is increased.

The coadministration of alcohol, benzodiazepines, or other CNS depressants may result in additive sedation, requiring dose adjustment. Other reported CNS side effects include cognitive impairment, blurred vision, nervousness, and tremors. Other non-CNS side effects associated with antihistamines are dry mouth, increased appetite, nausea, vomiting, diarrhea, or constipation. H_1-receptor antagonists also have anticholinergic side effects such as dry mouth and blurred vision and should be used with caution for individuals with bladder neck obstruction or enlarged prostate.

Use of antihistamines in the elderly could result in confusion and

disorientation. Pediatric populations and individuals overdosing with H_1-receptor antagonists are at risk for excitatory effects. Excitatory symptoms include ataxia, agitation, incoordination, and seizures. Other features seen in overdose resemble atropine poisoning and include flushed face, dilated pupils, tachycardia, and fever. Treatment of overdose is generally through supportive medical therapy.

Of particular concern with H_1 antihistamines is the possibility of cardiotoxicity, particularly in overdose or when coprescribed with other agents. The arrhythmogenic potential of several second-generation H_1 antihistamines is mediated by nonhistaminergic receptors. Reports in the late 1980s of cardiac arrhythmia associated with intentional overdose and therapeutic use of terfenadine (Seldane) drew attention to the hazards of drug–drug interactions via P450 (CYP) oxidative enzymes. The first-generation H_1 antihistamines exhibit both muscarinic and α-adrenergic blocking effects as well as dose-dependent prolongation of QT intervals.

Originally introduced second-generation H_1 antihistamines astemizole (Hismanal) and terfenadine are known to block the rapid component of delayed rectifier potassium current (I_{Kr}) with 50 percent inhibitory in nanomolar range: This results in prolongation of the monophasic cardiac action potential and QT interval, engendering early depolarization and dispersion increasing risk for torsades de pointes. Terfenadine is similar in potency to quinidine at inhibiting the delayed rectifier potassium channel in cardiac tissue. Subsequently introduced second-generation antihistamines exhibit less potency in blocking the I_{Kr}, bestowing these agents with less cardiac toxicity potential.

Unintentional or intentional overdose of antihistamine can be fatal. The abuse liability of H_1 antihistamines is generally low, although some first-generation agents may be used for recreational purposes (e.g., dimenhydrinate [Dramamine]). Some first-generation H_1 antihistamines have been associated with sudden infant death syndrome. Other adverse events include fixed-drug eruption, photosensitivity, fever, hepatotransaminase elevation, and agranulocytosis. Some first- and second-generation H_1 antihistamines are FDA category B, while others are category C, indicating they should generally be avoided if possible.

DRUG INTERACTIONS

Pharmacodynamic drug interactions are not uncommon and usually have additive CNS depressant and anticholinergic effects. Many over-the-counter agents contain antihistamines. Coprescribing antihistamines with MAOIs may enhance anticholinergic effects.

LABORATORY INTERFERENCES

Promethazine has been reported to interfere with pregnancy tests and increase glucose levels. Hydroxyzine may falsely elevate urinary 17-hydroxycorticosteroid levels. All available H_1-receptor antagonists may interfere with allergic skin tests, resulting in a false-negative test.

DOSAGE ADMINISTRATION

Table 34.8–2 outlines the dosing of commonly prescribed first-generation H_1-receptor antagonists. Superficial administration of intramuscular formulations may result in local irritation, hence deep injection is recommended. Most antihistamines are prescribed in divided doses throughout the day; when used as a hypnotic, a single evening dose is recommended.

Table 34.8–2.
Dosage and Administration of Common Histamine Antagonists

Medication	Route	Preparation	Common Dosage
Diphenhydramine (Benadryl)	Oral	Capsules and tablets: 25 mg, 50 mg	Adults: 25–50 mg three to four times per day
		Liquid: 12.5 mg/5.0 mL	Children: 5 mg/kg three to four times per day, not to exceed 300 mg/day
	Deep IM or IV	Solution: 10 or 50 mg/mL	Same as oral
Hydroxyzine Hydrochloride (Atarax)	Oral	Tablets: 10, 25, 50, and 100 mg	Adults: 50–100 mg three to four times daily
		Syrup: 10 mg/5 mL	Children younger than 6 yrs of age: 2 mg/kg per day in divided doses
			Children older than 6 yrs of age: 12.5–25.0 mg, three to four times daily
	IM	Solution: 25 or 50 mg/mL	Same as oral
Pamoate (Vistaril)	Oral	Suspension: 25 mg/mL	Same as dosages for hydrochloride
		Capsules: 25, 50, and 100 mg	
Promethazine (Phenergan)	Oral	Tablets: 15.2, 25.0, and 50.0 mg	Adults: 50–100 mg three to four times daily for sedation
		Syrup: 3.25 mg/5 mL	Children: 12.5–25.0 mg at night for sedation
	Rectal	Suppositories: 12.5, 25.0, and 50.0 mg	
	IM	Solution: 25 and 50 mg/mL	
Cyproheptadine (Periactin)	Oral	Tablets: 4 mg	Adults: 4–20 mg/day
		Syrup: 2 mg/5 mL	Children 2–7 years of age: 2 mg two to three times daily (maximum of 12 mg/day)

	Children 7–14 years of age: 4 mg two to three times daily (maximum of 16 mg per day)

IM, intramuscular; IV, intravenous.

▲ 34.9 Barbiturates and Similarly Acting Substances

STEVEN L. DUBOVSKY, M.D.

HISTORY

Stories of substances that produce sleep or unconsciousness date back to antiquity. The first commercially available sedative–hypnotics were the bromides, which were introduced in 1853 and were frequently taken in overdose. In 1864, Adolph von Baeyer discovered barbituric acid. The name barbituric acid comes from a combination of uric acid and the name Barbara. It is believed that the name Barbara was picked either because it was the name of a close friend of von Baeyer or because he celebrated discovering the new compound by visiting a tavern on St. Barbara's Day. Barbituric acid had no sedative or hypnotic properties, but diethylbarbituric acid or barbital was introduced in 1903 as the first sedative barbiturate. Many other barbituric acid derivatives were subsequently developed, beginning with phenobarbital (Luminal) in 1912, followed by a number of related compounds such as chloral hydrate (Aquachloral, Noctec) and paraldehyde (Paral).

The barbiturates were widely used as sedative–hypnotic agents in the first half of the 20th century. However, by the 1950s and 1960s, these medications became the most common agents in successful suicides, as was publicized in the deaths of celebrities such as Marilyn Monroe and Judy Garland. After additional problems such as high addiction potential and a narrow therapeutic index became apparent, "safer" alternatives such as methyprylon (Noludar), glutethimide (Doriden), ethchlorvynol (Placidyl), and methaqualone (Quaalude) were introduced. These drugs turned out to have the same problems, however, and the entire group of agents was eventually supplanted by the benzodiazepines, the first one of which (chlordiazepoxide [Librium]) was synthesized in 1955 and marketed in 1960. Glutethimide, methaqualone, and other derivatives were withdrawn from the market because of significant toxicity and risks of misuse. Barbiturates are still occasionally used, mostly in anesthesia, including for ECT, for detoxification from alcohol or other sedative–hypnotics, and as anticonvulsants.

CHEMISTRY

Modern barbiturates are derivatives of barbituric acid (2,4,6-trioxo-hexahydropyrimidine), the structure of which is illustrated in Figure 34.9–1. Barbituric acid itself has no CNS depressant properties, but the presence of an alkyl or aryl group at position 5 confers sedative–hypnotic and anticonvulsant activity and various side chains alter lipophilicity, potency, and elimination. For example, a sulfur group at position 2 produces

thiobarbiturates, which have different lipid solubility and therefore a different duration of action, latency of action, metabolism, and potency.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption. The barbiturates are administered orally when used as sedative–hypnotics and chronic anticonvulsants, and parenterally when used for anesthesia and for the treatment of status epilepticus. Oral doses of barbiturates are rapidly and completely absorbed from the small intestine. Onset of action ranges from 10 to 60 minutes, depending on the preparation and stomach contents. Barbiturates that are more lipid soluble, more protein bound, and have a high pK_a have a more rapid onset and shorter duration of action. When administered intravenously (IV), barbiturates have an immediate onset of action.

Distribution. Barbiturates are widely distributed and readily cross the placental barrier. Barbiturates vary in their lipid solubility and their binding to plasma proteins. More lipophilic compounds such as thiopental (Pentothal) and methohexital (Brevital) are highly protein bound (80 percent), whereas less lipophilic compounds (such as phenobarbital) are only 20 to 40 percent protein bound. More lipid-soluble barbiturates are more rapidly distributed to the brain, resulting in a rapid onset of action. Rapid efflux from the brain along a concentration gradient then leads to a short duration of action. Some weak acids, such as warfarin (Coumadin) or aspirin may displace barbiturates from plasma proteins, thus augmenting their CNS effects.

FIGURE 34.9–1. Molecular structure of barbiturates that are currently available in the United States.

Metabolism and Elimination. Most barbiturates are metabolized almost completely in the liver by cytochrome P450 microsomal enzymes. However, a significant amount of phenobarbital is excreted unchanged by the kidney. Urinary excretion of phenobarbital, which has a low pK_a, can be increased five- to tenfold by alkalinization of the urine. This approach will

not work for short-acting barbiturates because they have higher pK_as, more protein binding, and more metabolism to inactive products in the liver.

The most important biotransformation that is responsible for the termination of barbiturate activity is the oxidation of radicals at C5. N-glycosylation is also an important metabolic pathway and, in some instances, yields active metabolites. Metabolism and elimination are more rapid in young people than in the elderly, infants, and pregnant women. Metabolism is slowed, and the half-life is increased, in chronic liver disease. Elimination half-lives for some barbiturates are summarized in Table 34.9–1.

Many barbiturates induce their own metabolism as well as the metabolism of other drugs. The elimination half-life may therefore decrease significantly with repeated administration. Phenobarbital induces CYP2 isoenzymes, resulting in substantially increased metabolism and decreased effect of β-blockers, corticosteroids, doxycycline (Vibramycin), estrogen, phenothiazines, tricyclic antidepressants and some newer antidepressants, quinidine, and other anticonvulsants.

Pharmacodynamics

Mechanism of Action. Through a separate binding site allosterically linked to other binding sites on the ion channel, barbiturates increase the duration of opening of the chloride ion channel in the γ-aminobutyric acid type A receptor ($GABA_A$) complex, whereas benzodiazepines increase the frequency of channel openings. These receptors are pentameric structures surrounding a chloride ion channel on postsynaptic membranes (see Section 31.10). There are three families of receptor subunits: α, β, and γ. Most sedative–hypnotics bind to $GABA_A$ receptors containing the α_1 subunit, but etomidate (Amidate) produces sedation at the β_2 subunit and anesthesia at the β_3 subunit. Barbiturates, etomidate, and propofol (Diprivan) inhibit NMDA and amino-3-hydroxy-5-methyl-4-isoxazol-propionic acid (AMPA) receptors and reduce glutamate release and increase presynaptic glutamate reuptake. Barbiturates and related drugs inhibit excitatory nicotinic cholinergic receptors by acting at binding sites in the desensitized state of the receptor. At higher concentrations used for anesthetic purposes, barbiturates appear to reduce repetitive firing of neurons by inhibiting voltage-dependent Na^+ channels and, possibly, K^+ channels. Barbiturates and related drugs may also affect binding of other drugs for their binding sites. For example, propofol potentiates the effect of pentobarbital (Nembutal) on the $GABA_A$ receptor.

Blood Concentrations. Although barbiturates have greater effects at higher plasma concentrations, tolerance to these drugs is common; therefore, the same plasma level may produce drastically different actions

at different times in the same individual or from one person to another. Tolerance to barbiturates is associated with downregulation and desensitization of receptors, structural changes in receptors, and uncoupling of the drug from the receptor in addition to declining serum levels due to autoinduction of metabolism. Tolerance to anesthetics such as thiopental may occur within minutes. Tolerance may not have a linear relationship to dose. The Mellanby effect is acute tolerance that results in more clinical effect when serum levels are increasing than when they are decreasing. Cross-tolerance of all drugs acting on the $GABA_A$ receptor is common. For example, tolerance to benzodiazepines is associated with decreased affinity of barbiturate-binding sites.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Because barbiturates were mostly used for insomnia and anxiety before modern protocols for diagnosis and treatment response, there are few reliable controlled studies of these indications. Although extensive clinical experience indicates that barbiturates are effective as sedative–hypnotics, the rapid development of tolerance, frequent rebound insomnia and REM sleep rebound, multiple interactions, and narrow therapeutic index make these drugs poor initial choices for insomnia. Barbiturates and related compounds are only approved for short-term treatment of insomnia and are at best second- or third-line treatment for severe acute insomnia after the benzodiazepines and nonbenzodiazepine $GABA_A$ agonists and possibly sedating antidepressants or antipsychotic drugs.

Although the sedative effect of barbiturates may reduce anxiety, there is little empirical evidence of a reliable antianxiety effect from controlled studies in any specific anxiety disorder. Benzodiazepines and antidepressants, especially the SSRIs, are generally recommended as first-line agents in the treatment of anxiety disorders.

There is variable evidence supporting the use of barbiturates in the treatment of a number of neurological conditions.

Phenobarbital is considered a safe, economical, and effective treatment for generalized tonic–clonic seizures and simple and complex partial seizures. Several studies have shown that barbiturate therapy reduces intracranial pressure (ICP), and it is therefore sometimes used in the management of acute head injury. However, a systematic review found no evidence that reduction of ICP by barbiturates is associated with reduction of morbidity or mortality. In addition, hypotension caused by the barbiturates can reduce cerebral perfusion pressure. Barbiturate-containing analgesic products are often prescribed for headaches (including vascular, tension, and mixed migraines) as well as premenstrual and postpartum pain. A Canadian review of the literature found that there was no evidence of a clinically important enhancement of analgesia by adding a barbiturate to an established analgesic, and the risk of dependence and withdrawal outweighs any benefit from sedation caused by the barbiturate. In addition, use of barbituates 5 days or more per month is associated with progression of migraines due to rebound headaches.

Barbiturates are still routinely used to induce anesthesia. Methohexital is the most frequently utilized agent for anesthesia for ECT. Propofol, etomidate, and thiopental have also been found to be effective for this indication. Propofol has increasingly been used for outpatient anesthesia

(e.g., for colonoscopy), but this application requires careful monitoring and benzodiazepines such as midazolam may be safer. Fentanyl appears to be an equivalent anesthetic agent to propofol, but it is associated with better postoperative pain control.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Barbiturates depress the activity of all excitable tissues. The CNS is more sensitive to these effects than are peripheral tissues. Barbiturates produce varying degrees of CNS depression, from mild sedation to general anesthesia. Although all barbiturates have anticonvulsant properties at anesthetic doses, only phenobarbital and mephobarbital (Mebaral) have anticonvulsant properties at subhypnotic doses. Barbiturates depress the sensory cortex, decrease motor activity, alter cerebellar function, and produce drowsiness, sedation, and sleep. At subanesthetic doses, barbiturates may increase the reaction to painful stimuli by suppressing inhibitory pain centers.

Barbiturates decrease sleep latency and the number of awakenings, and they increase total sleep time, but they also decrease REM sleep as well as stages III and IV sleep. Tolerance develops to the hypnotic effect, often within a few days. Within 2 weeks of continued use, the effects of barbiturates on prolonging sleep are virtually eliminated and doses must be increased to obtain the same effect. Abrupt discontinuation of barbiturates results in insomnia, increased dreaming, and increased nightmares (REM rebound).

In the peripheral nervous system, barbiturates selectively inhibit transmission in autonomic ganglia and reduce nicotinic excitation. This results in reduction in blood pressure, at times with clinically significant hypotension.

Respiratory drive and mechanisms for sleep rhythms are depressed by barbiturates. At therapeutic doses, the neurogenic drive for wakefulness is only reduced to that seen during normal sleep. However, at three times the hypnotic dose, the wakefulness drive is virtually eliminated. These doses also appear to reduce the hypoxic drive for breathing, exacerbating sleep apnea. Protective reflexes are not depressed until a level of sedation is reached that is associated with severe respiratory depression; this results in one of the most serious complications of barbiturate anesthesia, namely laryngospasm. These mechanisms may have contributed to the death of the entertainer Michael Jackson after escalating unmonitored self-administration of propofol in an attempt to suppress tolerance, rebound and withdrawal.

Barbiturate effects on the cardiovascular system are generally mild. At sedative–hypnotic doses, barbiturates produce a slight decrease in blood pressure and heart rate but usually no more than that seen during normal sleep. This reduction in blood pressure and heart rate can be exaggerated in

patients with congestive heart failure or hypovolemic shock. IV barbiturate administration may increase the incidence of ventricular arrhythmias.

The primary effect of barbiturates on the liver is induction of microsomal enzymes. Induction of cytochrome P450 isoenzymes inhibits metabolism of a number of medications and substances, including many anticonvulsants, antidepressants, antipsychotic drugs, and steroid hormones. In addition, autoinduction of P450 enzymes results in acceleration of metabolism of the barbiturates themselves.

THERAPEUTIC INDICATIONS

Many barbiturates, including amobarbital (Amytal), butabarbital (Butisol), aprobarbital (Alurate), pentobarbital, and secobarbital (Seconal), are indicated for oral use as sedatives or hypnotics. However, their use in insomnia should be limited to 2 weeks or less because they lose much of their effectiveness after this period of time. Secobarbital and pentobarbital are also approved as preanesthetics. Methohexital has been approved for use in ECT anesthesia.

Seizure Disorders

Barbiturates are standard anticonvulsants in the prophylaxis of seizures and the treatment of status epilepticus. These medications inhibit epileptic foci and reduce the spread of abnormal activity. Phenobarbital is the most commonly used barbiturate and is often administered along with other anticonvulsant classes.

Phenobarbital is effective in treating simple and complex partial seizures, as well as generalized tonic–clonic seizures. For status epilepticus, benzodiazepines and phenytoin (Dilantin) are first-line treatments. However, if those treatments fail and seizure activity continues, IV phenobarbital (20 mg/kg) at a rate no faster than 100 mg/min may be administered. IV benzodiazepines may also be effective. If status epilepticus continues, the patient may be anesthetized with pentobarbital. Because it raises the seizure threshold, ECT can be used for refractory status epilepticus.

Electroconvulsive Therapy

In general, the brief duration of ECT requires shorter-acting agents. Methohexital is usually the first-line agent for anesthesia during ECT. The rapid onset and offset of action of etomidate make it an appropriate choice. Thiopental is longer acting and its anticonvulsant properties can interfere with induction of therapeutic seizures. Propofol may also shorten seizure duration. The proconvulsant action of ketamine (Ketalar) makes it useful when seizures are difficult to induce, and ketamine may have acute antidepressant effects but it can cause psychosis and it may have

cardiovascular side effects. A randomized comparison of etomidate, propofol, and thiopental found all to be relatively free of important cardiovascular effects in otherwise healthy patients undergoing ECT. Etomidate raises the seizure threshold less than propofol, and its use is associated with a requirement for a lower stimulus dose to produce adequate seizures.

Cerebral Lateralization

The intracarotid amobarbital procedure (IAP or Wada test) is used to determine lateralization of memory and language in order to predict the risks of amnesia and aphasia following epilepsy surgery. Usually, amobarbital (100 to 200 mg) is administered directly into the internal carotid artery first contralateral, and then on the next day ipsilateral, to the epileptic focus. When one hemisphere is anesthetized, all functions that localize to that hemisphere are temporarily interrupted, and emergence of aphasia or memory impairment on tests such as naming, repeating, following commands, and remembering objects indicates that such functions are localized to that hemisphere. By comparing the effects of the two injections, it can be determined whether surgery on the side of the focus is likely to interrupt these functions. A recent study suggested that intracarotid methohexital was not as reliable for this purpose.

Narcoanalysis

Since the 1930s, interviews with amobarbital have been performed to distinguish between psychogenic and neurological symptoms and to elicit a better history. The amobarbital interview has been used as a diagnostic tool in cases of mutism, stupor, and suspected malingering or conversion disorder. The procedure involves administering IV amobarbital slowly in doses up to a maximum of 500 mg. Initial responses include dizziness, blurred vision, and fatigue, followed by drowsiness and mild euphoria. It is during this phase that the interview may be most fruitful. If the dose is increased further, the patient is likely to fall asleep. Controlled studies of the amobarbital interview are difficult to conduct, but clinical experience suggests that it may help an uncommunicative patient provide a history or clarify confusing psychogenic symptoms. The amobarbital interview should only be performed if personnel and equipment for resuscitation are present and increased ICP is not suspected.

Diagnosing Withdrawal from Sedative–Hypnotics

Since CNS depressants are cross-reactive through actions at different sites on the $GABA_A$ receptor, the barbiturate tolerance test can be used to determine the extent of tolerance to barbiturates, related drugs, benzodiazepines, and alcohol alone or in combination. This procedure

involves a test dose of 200 mg of pentobarbital or 30 to 100 mg of phenobarbital for patients who are thought to be experiencing CNS depressant withdrawal (and therefore will be tolerant to the barbiturate. If the patient is grossly intoxicated an hour later, tolerance is not significant and a withdrawal syndrome is unlikely. For less marked intoxication after the test dose (e.g., dysarthria and ataxia without depressed consciousness), further doses are administered every 1 to 2 hours for pentobarbital, or every 1 to 4 hours for phenobarbital, until signs and symptoms of withdrawal are suppressed, distinct intoxication emerges, or until a maximum dose (e.g., 480 mg of phenobarbital or 500 mg of pentobarbital) is reached. The substituted drug is then administered in divided dose and the dose is decreased by about 10 percent per day as determined each day by emergence of signs of toxicity (e.g., sedation, nystagmus) or withdrawal (e.g., hypertension, hyperreflexia) charted before and after each dose of barbiturate. Because it is available in an injectable form and it has a longer duration of action, phenobarbital is preferred as the withdrawal agent (with 30 mg of phenobarbital being roughly equivalent to 100 mg of pentobarbital), whereas either drug can be used to diagnose tolerance.

Delirium Tremens

Oral or IV phenobarbital, sometimes in doses as high as 1,500 to 2,000 mg in the first day, have been used as alternatives to benzodiazepines in the treatment of alcohol withdrawal delirium. Propofol in doses up to 4 mg/kg/hr has been used for severe intractable withdrawal delirium, especially if the patient is intubated. In such severe cases, ECT might also be considered.

Neuroprotection

Because they reduce neuronal electrical activity and energy demands and antagonize NMDA and AMPA receptors, barbiturates alone or with hypothermia have been used for years to protect the brain during surgery and sometimes following CNS injury, especially intraoperative stroke. If damage is not severe brain oxygen levels are increased by pentobarbital. However, any protective action is short term because these medications also have systemic immunosuppressive properties related to inhibition of T-cell calcineurin/calmodulin function, and their use for this purpose has been supplanted by newer anesthetic agents such as isoflurane (Forane). Barbiturates are used in many settings to reduce ICP following TBI, but these medications can also cause hemodynamic instability that reduces cerebral perfusion. Data on improved outcomes after barbiturate treatment following TBI have not been robust. Animal studies suggest that propofol and related medications may reduce beta amyloid-induced mitochondrial dysfunction and improve cognition. However, demented patients may be

more susceptible to adverse cognitive effects, although they appear not to have increased vulnerability to respiratory depression after anesthesia. By combining nucleic acid bases, heterocyclic amines, and barbiturate derivatives, a group of nucleobase-based barbiturates have been developed that appear to have antioxidant properties that protect against DNA damage in laboratory studies.

PRECAUTIONS AND ADVERSE REACTIONS

Barbiturate overdoses can be dangerous: 1 g (10 pills) causes serious toxicity and 2 g or more may be fatal. Acute overdose is manifested by dysarthria, ataxia, incoordination, CNS depression, and respiratory depression with respiratory acidosis, tachycardia, hypotension, hypothermia, and oliguria. Overdoses of specific drugs are associated with additional features. For example, chloral hydrate and ethchlorvynol produce unique odors; meprobamate (Miltown) and chloral hydrate cause cardiac arrhythmias; methaqualone, propofol, and etomidate induce myoclonus; chloral hydrate and methaqualone can cause GI bleeding; and glutethimide produces anticholinergic signs. Intravenous overdoses additionally produce toxicity associated with the material in which the drug is diluted. Propylene glycol in intravenous formulations of etomidate (and lorazepam [Ativan]) causes hypotension, hyperosmolar states, and metabolic acidosis.

Because death from barbiturate overdose is caused by cardiorespiratory collapse, treatment involves supporting airway, oxygenation, and cardiovascular function. Volume expansion is used to treat severe hypotension, with vasopressors only used when this approach does not work or causes volume overload. β-Adrenergic antagonists may be helpful for tachyarrhythmias. Activated charcoal with a protected airway can be helpful, although controlled research does not necessarily confirm the benefit of this practice. Hemodialysis is used for patients with chloral hydrate overdoses with life-threatening arrhythmias and in cases of prolonged intubation after ingesting large quantities of phenobarbital. The benzodiazepine receptor antagonist flumazenil (Romazicon), which can reverse benzodiazepine overdose, is not useful for overdoses of barbiturates, which act on a different receptor on the GABA receptor chloride ion channel complex. Severe barbiturate overdose can be successfully treated with hemodialysis.

The elderly, children, and those with brain damage may develop paradoxical excitation in response to barbiturates and other CNS depressants. Cases have been reported in which phenobarbital caused or exacerbated hyperactivity when used chronically in younger children, and the hyperactivity did not remit when the medication was withdrawn.

As noted earlier, barbiturates are often prescribed in combination with analgesics, but they may exacerbate pain in some patients. There is little

evidence of an analgesic effect of this class of medication. On the other hand, headache preparations containing butalbital are clearly implicated in medication overuse headaches. In this syndrome, which usually involves migraine headaches, continued use of the medication results in rebound headaches, which are then treated with more self-administered medication. Discontinuing the medication can be a challenge, since rebound headaches may persist for some time after detoxification and relapse of medication use is common.

Hypersensitivity reactions can occur with the use of barbiturates. These reactions are most likely to occur in patients with asthma, urticaria, or angioedema. Allergic reactions range from local swelling to exfoliative dermatitis. Bullous lesions have occasionally been caused by phenobarbital, more frequently but not exclusively in comatose patients.

Barbiturates are contraindicated in patients with porphyria variegata or acute intermittent porphyria because they enhance porphyrin synthesis and aggravate the illness.

Barbiturate Dependence

Barbiturates rapidly induce tolerance and dependence. Dependence is most common with shorter-acting agents such as pentobarbital and secobarbital. Pre-existing substance use increases the risk of barbiturate dependence. The risk of dependence on barbiturates increases with higher doses taken for longer periods of time (e.g., 400 mg per day of secobarbital equivalent taken for 90 days or more). Patients who have become dependent on barbiturates take on average 1,500 mg per day.

Rapid discontinuation of barbiturates induces withdrawal syndromes that include anxiety, tremor, myoclonus, dizziness, nausea, vomiting, insomnia, and hypotension, progressing in more severe cases to delirium, seizures, coma, and death. Withdrawal begins within a few hours of discontinuation and lasts days; signs and symptoms appear and abate more rapidly after discontinuing shorter-acting agents. As was described earlier, withdrawal of barbiturates with or without other CNS depressants acting at the $GABA_A$ receptor complex can be diagnosed with the barbiturate tolerance test.

Teratogenicity

Barbiturates inhibit progesterone synthesis by inhibiting cholesterol transport, and they could be risky to the pregnancy itself. Because barbiturates readily cross the placental barrier, caution should be used in prescribing them to pregnant women. There is some evidence that maternal consumption of barbiturates is associated with fetal abnormalities, especially cardiac anomalies. Moreover, newborns of mothers who use barbiturates in the third trimester may have withdrawal

symptoms after birth. Barbiturates are excreted in breast milk and may produce sedation and withdrawal syndromes in nursing infants. Concerns have been expressed about potential adverse effects of barbiturate and related anesthetics during pregnancy, but exposure is brief, and any risk is balanced by adverse effects of the condition for which anesthesia is administered.

Psychomotor Impairment

As is true of benzodiazepines, barbiturates can impair driving in addition to causing sedation and an intoxicated feeling. The degree of impairment is similar to that with alcohol.

DRUG INTERACTIONS

Complications from the concomitant use of barbiturates and other medications most often result from additive CNS depressant effects or from the induction of hepatic microsomal enzymes. Additive CNS depression occurs with alcohol, antihistamines, benzodiazepines, and other sedative–hypnotics. Metabolism of vitamins D and K is accelerated by barbiturates, which may reduce calcium absorption. Induction of hepatic metabolism may decrease the effectiveness of oral anticoagulants such as warfarin, corticosteroids, and estrogen. The latter effect may result in failure of oral contraceptives. Phenobarbital interferes with oral absorption of griseofulvin (Grifulvin V), thereby decreasing blood levels and possibly decreasing therapeutic response. Phenobarbital induces metabolizing enzymes for doxycycline, phenytoin, TCAs, and neuroleptics. Valproate (Depakote, Depakene) may decrease barbiturate metabolism, thus reducing the dose of barbiturate needed, while MAOIs may prolong the effects of barbiturates by inhibiting their metabolism. In view of frequent induction of CYP450 enzymes, it is important to look for altered efficacy of medications to which barbiturates are added.

LABORATORY INTERFERENCES

Routine toxicology screening does not identify barbiturates. Barbiturates have been reported to produce a false-positive phentolamine (Regitine) test result. Phenobarbital accelerates metabolism of dexamethasone (Decadron), resulting in a false-positive dexamethasone suppression test. Induction of metabolism of metyrapone by barbiturates may also produce false-negative responses in the metyrapone (Metopirone) test resulting from decreased levels of the test medication.

DOSAGE AND ADMINISTRATION

Dosages and routes of administration are given in Table 34.9–1. Table 34.9–2 lists some doses of preparations that contain barbiturates in

combination with other medications.

NONBARBITURATE, NONBENZODIAZEPINE SEDATIVE–HYPNOTIC AGENTS

Chloral Hydrate

Chloral hydrate was introduced in 1832. It was widely used in the late 19th century as a sedative and hypnotic. Chloral hydrate was also used to treat many psychiatric illnesses, such as anxiety, psychosis, and mania, until more effective treatments were introduced. Soon after its introduction, there were reports of overdose deaths and by 1910, it was considered to be more dangerous than heroin or opium. The routine use of chloral hydrate as a sedative–hypnotic has mostly been replaced by benzodiazepines and related medications, but it is still used regularly to sedate children for medical procedures. In addition, some clinicians prefer to prescribe it because it is relatively inexpensive, and it is a schedule IV medication. Probably as a matter of tradition, chloral hydrate is also often used as a hypnotic agent during industry sponsored clinical trials of novel psychotropic drugs.

Chemistry. Chloral hydrate is formed by attaching a water molecule to the carbonyl group of chloral,2,2,2-trichloroacetaldehyde. The hypnotic effect of chloral hydrate is attributable to its first active metabolite, trichloroethanol.

Pharmacological Actions

PHARMACOKINETICS. Chloral hydrate is rapidly and completely absorbed from the GI tract after oral administration, but it causes GI irritation. It is rapidly converted by hepatic dehydrogenase to trichloroethanol, which has an elimination half-life of 4 to 12 hours and is metabolized by alcohol and aldehyde dehydrogenases to the inactive trichloroacetic acid; it is also conjugated with glucuronide to urochloralic acid, which is excreted by the kidney. About 10 percent of the total chloral hydrate dose is excreted

unchanged. Plasma concentrations reach their peak in 30 to 60 minutes. Chloral hydrate and trichloroethanol are highly lipid soluble, readily penetrate the BBB and the placenta, and are excreted in breast milk. In newborns, the half-life of trichloroethanol is around 28 hours, and it drops to 10 hours in toddlers. Repetitive dosing in infants causes drug accumulation, and trichloroacetic acid has been detected 6 days after administration to infants is discontinued.

PHARMACODYNAMICS. Most of the pharmacological action of chloral hydrate is attributable to trichloroethanol. Trichloroethanol acts through the $GABA_A$ receptor complex in a manner similar to barbiturates, increasing chloride ion influx and reducing neuronal excitability.

Design and Interpretation of Clinical Drug Studies. Chloral hydrate was used at one time to treat alcohol withdrawal, but this use was never supported by controlled trials. Comparisons of chloral hydrate and benzodiazepines suggested equivalent efficacy for short-term treatment of insomnia, but the benefits of chloral hydrate diminished after 2 weeks due to tolerance.

Chloral hydrate is often used as a sedative during pediatric procedures such as echocardiography, MRI, and other radiological procedures. A randomized study found that chloral hydrate was as effective as midazolam (Versed) in producing adequate sedation during pediatric echocardiography.

Effects on Specific Organs and Systems

CENTRAL NERVOUS SYSTEM. The CNS depressant action of chloral hydrate produces drowsiness, sedation, lightheadedness, malaise, ataxia, and nightmares. Hangover effects seen with other hypnotics are rare with chloral hydrate. Chloral hydrate has few analgesic properties and is occasionally associated with agitation in the presence of pain. CNS effects of overdose of chloral hydrate are similar to overdose of other CNS depressants.

CARDIOVASCULAR SYSTEM. Chloral hydrate and trichloroethanol reduce myocardial contractility, shorten the refractory period, and increase sensitivity of the myocardium to endogenous catecholamines. As a result, most deaths from chloral hydrate poisoning are caused by cardiac dysrhythmias that are refractory to standard antiarrhythmics. β-Adrenergic blocking agents may be helpful in this setting.

RESPIRATORY SYSTEM. In typical clinical doses, there is little effect of chloral hydrate on respiration. However, overdose may cause respiratory depression.

GASTROINTESTINAL SYSTEM. Chloral hydrate may cause GI irritation, resulting in nausea and vomiting. This is most common when the medication is ingested on an empty stomach. Overdoses can cause hemorrhagic gastritis and occasionally gastric or intestinal necrosis with perforation, as well as esophagitis with stricture.

Therapeutic Indications

INSOMNIA. Chloral hydrate is indicated for the short-term treatment of insomnia. Most patients respond to a dose of 500 to 1,500 mg, with sleep taking place within 1 hour. Chloral hydrate may be effective in patients who are medically ill, the young, and elderly patients who become agitated or confused with a benzodiazepine.

SEDATION FOR PEDIATRIC PROCEDURES. Chloral hydrate is used in children undergoing a variety of diagnostic and minor surgical procedures. It can be administered orally or rectally, and the onset of its effects is rapid. Generally, 25 to 100 mg/kg is used in children, up to a maximum of 1 g per dose. In children younger than 2 years of age, chloral hydrate appears to be less effective. The dose of chloral hydrate may be repeated, but the child must be monitored until fully awake.

PREOPERATIVE USE. Chloral hydrate can be used preoperatively to reduce anxiety associated with surgery and to induce sleep without depressing respiration or the cough reflex if the dose is not excessive.

Precautions and Adverse Reactions

CENTRAL NERVOUS SYSTEM. Chloral hydrate can cause sedation, dizziness, lightheadedness, confusion, and, occasionally, paradoxical excitement. The CNS depressant effects of chloral hydrate may be additive to those of other CNS depressants, especially barbiturates and alcohol.

ABUSE AND DEPENDENCE. Similar to many other CNS depressants, chloral hydrate may be habit forming, particularly in those who have a history of alcohol or other drug dependence. Tolerance and physiological dependence may develop if chloral hydrate is used for long periods of time on a regular basis. Sudden withdrawal of chloral hydrate can precipitate a syndrome that is similar to barbiturate withdrawal and can be diagnosed and treated using the barbiturate tolerance test described above.

OVERDOSE. Signs and symptoms of overdose are similar to those seen in barbiturate overdose. Symptoms of overdose begin with ataxia and lethargy and may progress to stupor or coma. Initially, pupils may be constricted but then dilate as coma deepens. Toxic doses for adults are approximately 10 g. Treatment of overdose includes gastric lavage and supportive

measures. Hemodialysis may be effective in promoting the clearance of trichloroethanol.

ALLERGIC REACTIONS. Allergic skin reactions have been reported with chloral hydrate, including hives, eczematoid dermatitis, and urticaria. Occasionally, its use has been associated with leukopenia and eosinophilia.

GASTROINTESTINAL SYSTEM. Chloral hydrate can irritate the GI system, particularly when taken on an empty stomach. Symptoms can include nausea, vomiting, diarrhea, and an unpleasant taste.

PORPHYRIA. There have been reports of chloral hydrate precipitating attacks of acute intermittent porphyria, and, therefore, it should not be used in patients with porphyria.

CARCINOGENICITY. There have been several laboratory studies suggesting carcinogenicity of chloral hydrate. However, there is currently no evidence that chloral hydrate is carcinogenic in humans.

Drug Interactions. Chloral hydrate competes with ethanol for alcohol dehydrogenase, resulting in an increase of the half-life of ethanol by concurrent chloral hydrate administration. At the same time, ethanol inhibits the conversion of chloral hydrate to trichloroethanol as well as the conjugation of trichloroethanol. The combination of ethanol and chloral hydrate is known as a Mickey Finn (knockout drops) and produces rapid unconsciousness. Chloral hydrate has an unpredictable effect on warfarin use and may cause excessive hypoprothrombinemia. Patients who also take furosemide (Lasix) may experience vasomotor instability due to the displacement of furosemide from protein-binding sites resulting in increased free drug. Symptoms may include vasodilation, flushing, tachycardia, sweating, and hypotension.

Laboratory Interference. Because it is radiopaque, chloral hydrate may be detected on abdominal x-ray. Chloral hydrate may interfere with copper sulfate tests for glycosuria. It may also interfere with tests for urine catecholamines or urinary 17-hydroxycorticosteroid determinations.

Dosage and Administration. Chloral hydrate is available in an oral form, as well as a suppository. Chloral hydrate capsules are formulated in 250- or 500-mg strengths. Chloral hydrate syrup is available in a 500 mg per 5 mL concentration. The oral syrup should be mixed with 4 to 8 oz of water or juice to reduce GI upset. Suppositories are formulated in 325- and 650-mg strengths.

The usual adult dose for insomnia is 500 to 1,000 mg taken approximately 15 to 30 minutes before bedtime. Single, daily, adult doses

should not generally exceed 2 g. Pediatric doses vary from 25 to 100 mg/kg per dose, with a maximum dose of 1 g.

OTHER SEDATIVE–HYPNOTICS

Over the years, a number of medications with varying structures have been used as sedative–hypnotics. Glutethimide was introduced as a substitute for barbiturates. Its absorption was erratic and it had more than 14 metabolites, some contributing to toxicity. In addition, recirculation in the enterohepatic circulation contributed to fluctuating, prolonged toxicity. Glutethimide was unique in causing anticholinergic side effects, leading to thick bronchial secretions that further compromised respiration after overdose. Psychosis, seizures, peripheral neuropathy, and ataxia were associated with prolonged use. Glutethimide therefore was withdrawn in the United States.

Meprobamate was introduced in 1950 as a muscle relaxant. Carisoprodol (Soma), which was introduced 5 years later, is metabolized to meprobamate. Both of these propanediol carbamates have actions on the $GABA_A$ receptor and on NMDA receptors similar to the barbiturates. Meprobamate is more likely than other drugs in the group to cause euphoria. Meprobamate pills can agglutinate in the stomach to form concretions, leading to recurrent toxicity after overdose. Paraldehyde was used parenterally for agitation in alcohol withdrawal, but this approach caused sterile abscesses and the drug was withdrawn. Ethchlorvynol caused severe withdrawal syndromes and was particularly lethal after overdose.

Anesthetic Agents

Propofol. Propofol is a $GABA_A$ agonist. It also induces presynaptic release of GABA and dopamine (the latter possibly through an action on $GABA_B$ heteroreceptors on dopaminergic neurons) and is a partial agonist at dopamine D_2 and NMDA receptors. Because it is very lipid soluble, it crosses the BBB readily and induces anesthesia in less than 1 minute. Rapid redistribution out of the CNS results in offset of action within 3 to 8 minutes after the infusion is discontinued. It is well tolerated when used for conscious sedation, but it has a potential for acute adverse effects including respiratory depression, apnea, and bradyarrhythmias, and prolonged infusion can cause acidosis and mitochondrial myopathies. The carrier used for the infusion is a soybean emulsion that can be a culture medium for various organisms. The carrier also can impair macrophage function and cause hematological and lipid abnormalities and anaphylactic reactions. Recent concerns about unmonitored outpatient use for indications other than anesthesia were mentioned earlier.

Etomidate. Etomidate is a carboxylated imidazole that acts at the β_2

and β_3 subunits of the $GABA_A$ receptor. It has a rapid onset (1 minute) and short duration (less than 5 minutes) of action. The propylene glycol vehicle has been linked to hyperosmolar metabolic acidosis, as has been the case for parenteral lorazepam (see Chapter 34.10). It has both proconvulsant and anticonvulsant properties, and it inhibits cortisol release, with possible medical consequences after long-term use.

▲ 34.10 Benzodiazepine Receptor Agonists and Antagonists

STEVEN L. DUBOVSKY, M.D.

HISTORY

Alcohol has been used as a sedative since biblical times. Bromides were introduced as hypnotics in the mid-19th century. Barbital, the first barbiturate, was introduced in 1903, and phenobarbital (Barbita) was synthesized in 1912. Along with the later introduction of related drugs, such as meprobamate (Equanil), the barbiturates were the mainstays of the pharmacological treatment of anxiety and insomnia until the benzodiazepines were developed in the late 1950s.

The first benzodiazepine to be introduced was chlordiazepoxide (Librium), which was synthesized in 1959 at Roche Laboratories. In 1963, diazepam (Valium) was developed in the same laboratory. Over the next three decades, superior safety and tolerability helped the benzodiazepines replace the older antianxiety and hypnotic medications. Barbiturates and related medications are now rarely, if ever, used for anxiety and only occasionally used for insomnia, whereas 10 to 15 percent of the US population takes benzodiazepines in a given year. Recently, antidepressants, especially the SSRIs, have been used in place of benzodiazepines for some chronically anxious patients, and sedating

antidepressants, such as trazodone (Desyrel) and mirtazapine (Remeron), have replaced benzodiazepines, to some extent, as hypnotics.

Studies of the actions of the benzodiazepines and barbiturates have led to the elucidation of the structure and function of their primary target, the GABA–benzodiazepine receptor complex. This research has led to the development of other medications that act on this complex as agonists, antagonists, and inverse agonists. Understanding benzodiazepine receptors and their interaction with linked receptors makes it straightforward to predict the actions of a diverse group of medications.

GABA–Benzodiazepine Receptor Complex

GABA, the major inhibitory neurotransmitter in the CNS, interacts with inotropic GABA type A ($GABA_A$) heteroreceptors located on neurons in arousal and motor systems to decrease excitability of these neurons. The pentameric GABA receptor complex is a member of the nicotinicoid superfamily and includes six subunit families (α, β, γ, ρ, δ, θ) and 16 specific subunits that are encoded by separate genes and are allosterically linked to form a chloride ion channel. Interaction of the $GABA_A$ receptor with GABA increases chloride channel openings as described below, allowing more negative charges into the neuron, hyperpolarizing it (Fig. 34.10–1A,B). A $GABA_B$ receptor, which is linked by a G protein to calcium and potassium channels, is a presynaptic autoreceptor that modulates release of GABA, glutamate, and monoamines. A structurally and functionally distinct $GABA_C$ (also called $GABA_P$) receptor has recently been identified in the retina, spinal cord, superior colliculus, pituitary, and gut. These receptors appear to be involved in the regulation of vision, memory, and the sleep–wake cycle. The balance between inhibitory GABAergic, inhibitory glycinergic, and excitatory glutaminergic systems is fine tuned to set the responsiveness of the CNS to a host of neurotransmitters and neuromodulators.

The benzodiazepine receptor is contiguous to the $GABA_A$ receptor and is located at the interface between the α and γ subunits. Occupancy of this receptor does not affect the chloride ion channel directly but changes the conformation of the GABA receptor to increase its affinity for GABA. Benzodiazepine receptor agonists therefore have the effect of increasing the action of each available molecule of GABA in enhancing chloride ion influx and hyperpolarizing neurons on which the receptor complex is located (Fig. 34.10–1C). A picrotoxin site associated with the benzodiazepine–GABA receptor complex reduces GABA receptor affinity, reducing chloride ion influx and tending to depolarize the same neuron. A number of other substances, including inhaled and intravenous (IV) anesthetics, barbiturates, neurosteroids, and alcohol, alter $GABA_A$ receptor affinity at various binding sites, not all of which have been identified.

FIGURE 34.10–1. Benzodiazepine (BZD) receptor actions. The BZD receptor is allosterically linked to a γ-aminobutyric acid (GABA) type A receptor; both receptors outline a chloride ion (Cl^-) channel **(A)**. When they are stimulated by their agonist, GABA receptors increase Cl^- channel openings and hyperpolarize neurons **(B)**. Interaction of the BZD receptor with an agonist increases the affinity of GABA receptors, resulting in more Cl^- channel opening for each molecule of GABA **(C)**.

Three major benzodiazepine receptor subtypes have been described, two of them called central benzodiazepine receptors and one called a peripheral benzodiazepine receptor (PBR). Benzodiazepine-1 (Ω-1) receptors contain the α1 subunit and are located throughout the CNS. These receptors are thought to mediate the sedative, hypnotic, and antianxiety effects of benzodiazepine receptor agonists. Benzodiazepine-2 (Ω-2) receptors, which are a heterogeneous group of receptors containing α2, α3, or α5 subunits, are located in the cortex, hippocampus, striatum, and spinal cord and on pyramidal neurons, and mediate anxiolysis, muscle relaxation, CNS depression sedation, and psychomotor impairment and contribute to the anticonvulsant effect.

Benzodiazepine-3 (Ω-3) receptors (PBRs) are 18-kDa proteins with a structure and function distinct from that of the central (i.e., benzodiazepine-1 and benzodiazepine-2) receptors. PBRs are found on glial and other brain cells as well as throughout the body. These receptors, which bind benzodiazepines and the endogenous inverse agonist, are primarily located in the outer mitochondrial membrane and may contribute to tolerance and withdrawal. They are also involved in a number of complicated processes, including synthesis of neurosteroids implicated in some psychiatric disorders, and regulation of apoptosis. The mitochondrial PBR is linked to a mitochondrial permeability transition pore (MPTP) consisting of a nonselective ion channel, which alters the transmembrane potential, leading to release of proapoptotic proteins from the mitochondrion and other actions. The PBR plays an important role in protecting neurons from oxidative damage, which is implicated in Parkinson disease, Alzheimer disease, and negative schizophrenia. At micromolar concentrations at the receptor, PBR ligands may promote apoptosis, whereas nanomolar concentrations may, under some circumstances, interfere with it. An agonist effect at this receptor could

protect against oxidative damage, whereas an inverse agonist effect could play a role in cancer chemotherapy, which enhances apoptosis. Carbamazepine (Tegretol) binds to PBRs in lymphocytes, which may contribute to altered chemotaxis by these cells in carbamazepine-treated patients.

Benzodiazepine Receptor Ligands

Compounds that bind to the benzodiazepine receptor can have five different kinds of action. Nonselective full agonists (e.g., benzodiazepines) cause all benzodiazepine receptors to increase affinity of GABA receptors, which increases the frequency of chloride channel openings and hyperpolarizes neurons. Selective full agonists (e.g., zolpidem [Ambien]) have the same effect, but this action is selective for the benzodiazepine-1 receptor. Clobazam (Frisium) is the only benzodiazepine with more affinity for benzodiazepine-2 than for benzodiazepine-1 receptors. Partial agonists bind to all benzodiazepine receptors, but they are less effective than full agonists. If low levels of an endogenous agonist for a receptor are present, partial agonists occupy the receptor and stimulate it, although less so than the full agonist. If levels of the endogenous agonist are high, a partial agonist competes for receptors but is less effective than the full agonist, essentially reducing activity at the receptor. In the case of the benzodiazepine receptor, partial agonists have a less pronounced therapeutic effect at the receptor than full agonists, but they also have fewer adverse effects.

Inverse agonists occupy receptors in the same manner as full agonists, but they have the opposite effect. An inverse agonist of the benzodiazepine receptor binds to the same site as the benzodiazepines and reduces GABA receptor affinity, decreases the frequency of chloride channel openings, and depolarizes neurons. Inverse agonists produce arousal and anxiety and sometimes cause seizures and psychosis. Antagonists occupy a receptor without affecting its activity, thereby blocking the action of agonists and inverse agonists. Flumazenil (Romazicon) is a benzodiazepine receptor antagonist used to treat benzodiazepine overdose.

A number of medications and substances that depress or activate the CNS act on the benzodiazepine–GABA receptor complex, and many of these agents are cross-reactive. For example, picrotoxin binds to the chloride channel pore and reduces chloride channel openings to induce seizures. Alcohol and barbiturates have direct effects on GABA receptors and chloride channels and possibly on the picrotoxin site, and the reduction of cortical and limbic neuronal activity results in sedation and psychomotor impairment. Valproate (Depakene, Depakote) enhances GABA release, and gabapentin (Neurontin) has unclear actions on GABAergic transmission. Propofol (Diprivan), an IV anesthetic discussed in Chapter 34.9, acts at a site other than the benzodiazepine receptor to

increase GABA affinity synergistically with benzodiazepines at higher doses. Unidentified constituents of valerian, an herbal preparation used for centuries as a hypnotic and anxiolytic, seem to be GABA receptor agonists. Zopiclone (Imovane), which is widely used in Europe, and eszopiclone (Lunesta), which is available in the United States, are nonbenzodiazepines that act as partial agonists on a site close to the benzodiazepine receptor, with effects that are virtually the same as but less marked than those of direct benzodiazepine receptor agonists. The anticonvulsant tiagabine (Gabitril) inhibits GABA reuptake, increasing GABA action at all GABA receptors, and the anticonvulsant vigabatrin (Sabril) reduces GABA degradation. Baclofen (Lioresal) is a $GABA_B$ agonist that reduces spasticity via an action on presynaptic receptors on excitatory spinal cord neurons. This section reviews medications that act primarily on the benzodiazepine receptor on the $GABA_A$ receptor complex.

BENZODIAZEPINES

Chemistry

Benzodiazepines contain two benzene rings and a seven-member diazepine ring (Fig. 34.10–2). Because all benzodiazepines in clinical use contain a 5-aryl substituent ring and a 1,4-diazepine ring, they are 5-aryl-1,4-benzodiazepines. A fused triazolo ring at positions R1 and R2 on the diazepine ring in triazolobenzodiazepines such as alprazolam (Xanax), triazolam (Halcion), and estazolam (ProSom), increases potency; the same is true of a fused imidiazo ring at these positions in midazolam (Versed). Replacement of ring C with a keto substituent in position 5 and a methyl substituent in position 4 confers benzodiazepine antagonist features to flumazenil. Clobazam, the only 1-5-benzodiazepine, is not yet approved in the United States.

Pharmacological Actions

Absorption. All benzodiazepines except clorazepate (Tranxene) are completely absorbed after oral administration and reach peak serum levels within 30 minutes to 2 hours. Metabolism of clorazepate in the stomach converts it to desmethyldiazepam, which is then completely absorbed. Intramuscular (IM) absorption of benzodiazepines other than lorazepam (Ativan) is slower than oral absorption. The onset of action is nearly immediate with IV administration of high-potency benzodiazepines, such as midazolam.

Distribution. All benzodiazepines are lipid-soluble, but the degree of lipid solubility varies considerably between drugs. Benzodiazepines and their active metabolites bind to plasma proteins, the extent of binding being proportional to their lipid solubility. The amount of protein binding varies from 70 to 99 percent.

Distribution, onset, and termination of action after a single dose are determined by benzodiazepine lipid solubility. Preparations with high lipid solubility, such as diazepam and alprazolam, are absorbed rapidly from the GI tract and distribute rapidly to the brain by passive diffusion along a concentration gradient, resulting in a rapid onset of action. However, as the concentration of the medication increases in the brain and falls in the bloodstream, the concentration gradient reverses itself, and these medications leave the brain rapidly, resulting in fast cessation of drug

effect. Drugs with longer elimination half-lives, such as diazepam, may remain in the bloodstream for a substantially longer period of time than their actual pharmacological action at benzodiazepine receptors with single or intermittent dosing because the concentration in the brain falls rapidly below the level necessary for a noticeable effect. In contrast, lorazepam, which has a shorter elimination half-life than diazepam but is less lipid soluble, has a slower onset of action after a single dose, because the drug is absorbed and enters the brain more slowly. However, the duration of action after a single dose is longer because it takes longer for lorazepam to leave the brain and for brain levels to fall below the concentration that produces an effect. In chronic dosing, some of these differences are not as apparent because brain levels are in equilibrium with more consistent steady-state blood levels, but additional doses still produce a more rapid but briefer action with diazepam than with lorazepam.

Benzodiazepines are distributed widely in adipose tissue. As a result, some of these medications may persist in the body after discontinuation longer than would be predicted from their elimination half-lives. In addition, the dynamic half-life (i.e., duration of action on the receptor) may be longer than the elimination half-life.

Metabolism. Some benzodiazepines (e.g., oxazepam [Serax]) are conjugated directly by glucuronidation to a water-soluble form and are excreted. Most benzodiazepines are oxidized first by cytochrome P450 (CYP) 3A4 and CYP 2C19, often to active metabolites (Fig. 34.10–3). These metabolites may then be hydroxylated to another active metabolite. For example, diazepam is oxidized to desmethyldiazepam, which, in turn, is hydroxylated to produce oxazepam. These products undergo glucuronidation to inactive metabolites. A number of benzodiazepines (e.g., diazepam, chlordiazepoxide) have the same active metabolite (desmethyldiazepam), which has an elimination half-life of more than 120 hours. Flurazepam (Dalmane), a lipid-soluble benzodiazepine used as a hypnotic that has a short elimination half-life, has an active metabolite (desalkylflurazepam) with a half-life greater than 100 hours. The duration of action of a benzodiazepine therefore may not correspond to the half-life of the parent drug.

Because administration of medications more frequently than the elimination half-life leads to drug accumulation, medications such as diazepam and flurazepam accumulate with daily dosing, eventually resulting in increased daytime sedation. Clorazepate, halazepam (Paxipam), and prazepam (Centrax; no longer available in the United States) are not pharmacologically active but are prodrugs for desmethyldiazepam (nordiazepam). In contrast, temazepam (Restoril), oxazepam, and lorazepam are conjugated directly and do not have active metabolites. Unlike barbiturates, benzodiazepines do not induce their own

metabolism.

The combination of lipid solubility, potency, and elimination half-life (Fig. 34.10–4) predicts onset and duration of action in clinical settings as well as optimal frequency of drug administration. Benzodiazepines that are high in lipid solubility and potency and have a short half-life have a rapid onset but a brief duration of action and produce more intense and abrupt discontinuation syndromes. For example, midazolam, a high-potency and highly lipid-soluble nonselective full agonist with a short elimination half-life, has an almost immediate onset of action when used IV for conscious sedation or anesthesia. Sedation diminishes rapidly and is followed by withdrawal symptoms (usually amnesia) in approximately 70 percent of patients after a single dose. This profile makes midazolam useful in anesthetic practice but impractical for chronic treatment. Alprazolam, which is high in lipid solubility and potency, reduces anxiety rapidly but can produce interdose withdrawal when it is administered in accordance with its intermediate half-life (three to four times per day), because it leaves the brain more rapidly than it is eliminated from the body. In contrast, chlordiazepoxide is low in lipid solubility and potency and has a long elimination half-life. This medication has a slow onset of action after a single dose and is administered less frequently in chronic treatment. Withdrawal from long half-life, low-potency, low lipid-soluble benzodiazepines such as chlordiazepoxide results in discontinuation syndromes that begin later after discontinuation and are less intense but more prolonged than discontinuation syndromes produced by withdrawal of alprazolam.

Pharmacodynamics

Mechanism of Action. The affinity of clinically active benzodiazepines for the benzodiazepine receptor raises the question of whether there is a naturally occurring agonist for this receptor. An endogenous agonist (endozepine) has been identified, but mammals cannot synthesize it and they probably obtain it from plants. Conversely, a gene has been identified for a mammalian endogenous inverse agonist called diazepam-binding inhibitor (DBI). DBI may serve to upregulate the gain on the CNS by lowering the threshold for depolarization in arousal systems. DBI levels are increased in refractory epilepsy, suggesting that this could be a mechanism of uncontrolled gross neuronal activation. Along with cortisol, increased DBI activity during spontaneous labor (as opposed to caesarian section with anesthesia), indicating that this may be a mechanism of arousal during any kind of stress. One cause of chronic anxiety may be excessive activity of DBI, which is antagonized when benzodiazepines compete for benzodiazepine receptor occupancy and have a hyperpolarizing, rather than a depolarizing effect through opposite effects on the GABA receptor and, hence, on chloride ion influx. However, even if anxiety is caused by excessive excitability of arousal systems that is primary or that is secondary to some other influence, such as a hyperactive suffocation response, which has been demonstrated in panic disorder, benzodiazepines can reduce anxiety by enhancing hyperpolarization of systems that underlie anxiety and arousal.

The same action that results in the therapeutic action of benzodiazepines on benzodiazepine-1 receptors causes adverse effects when it is too pronounced and when benzodiazepines act on other receptors. For example, actions of benzodiazepines on benzodiazepine receptors in the cortex can cause cognitive and psychomotor impairment. Actions on pyramidal benzodiazepine receptors have an anticonvulsant effect and can also cause muscle relaxation and incoordination. Benzodiazepine hypnotics act on receptors in the reticular activating system, but if suppression of this system is prolonged, daytime sedation results. Suppression of the reticular activating system can induce delirium in demented patients and aggravate delirium if it is already present. However, benzodiazepines do not produce the same degree of CNS depression as do the barbiturates.

FIGURE 34.10–4. Potency, lipid solubility, and half-life (T-1/2) of some benzodiazepines.

Blood Concentration and Relation to Action. Concentrations of benzodiazepines in the CSF are equal to plasma concentrations of the free drug. Because of the complex metabolism of long-acting benzodiazepines, serum levels vary considerably between individuals. Levels of parent compounds have not been correlated with therapeutic response, and, because many of these medications have active metabolites, it is unlikely that such a correlation exists. Although many shorter-acting benzodiazepines do not have active metabolites, a correlation between blood levels and clinical response has not been demonstrated for these preparations either. There may be a correlation between levels of alprazolam and both adverse effects and efficacy for panic attacks, with response more likely at plasma concentrations around 20 to 40 ng/mL, which correspond to doses of 1.5 to 6.0 mg per day. However, such levels are rarely measured in clinical practice, and levels would be expected to fluctuate substantially between doses, making the optimal time to measure the trough level difficult to identify. On the other hand, undetectable levels in an agitated patient who has been taking benzodiazepines raise the suspicion of a withdrawal syndrome. The primary uses of serum levels therefore are for toxicology screening and identification of abstinence syndromes.

Design and Interpretation of Clinical Drug Studies

Studies of acute situational anxiety are difficult to control because exogenous stresses vary, as do past histories and medical and psychiatric comorbidities of acutely anxious patients. The fluctuating nature and high placebo response rate of primary anxiety disorders, such as GAD, social phobia, and panic disorder, require placebo controls and longer trials to

establish drug effectiveness. A number of well-validated diagnostic and assessment instruments exist that facilitate blinded outcome ratings in such trials. Studies of the usefulness of benzodiazepines as hypnotics are more difficult and expensive because ratings of amount and quality of sleep are not reliably correlated with objective sleep measures. Clinical experience suggests that factors listed in Table 34.10–1 predict a good response in the treatment of acute anxiety.

Placebo-controlled trials have clearly established the efficacy of benzodiazepines in the treatment of generalized anxiety. Multicenter, double-blind studies have also demonstrated that alprazolam is effective for panic disorder. Smaller studies indicate that, in equivalent doses, other benzodiazepines can also reduce the frequency of panic attacks, although such doses are much higher than ordinary doses for generalized anxiety. For example, 60 mg of diazepam would be equivalent to the reported antipanic dose of alprazolam of close to 6 mg per day in a pivotal multicenter trial. Although patients report significantly prolonged sleep with benzodiazepine hypnotics and these medications shorten sleep onset in the sleep laboratory compared to placebo, total sleep time is increased by an average of only 30 minutes with these drugs.

One factor that can complicate interpretation of studies of therapeutic and adverse effects of benzodiazepines is that anxious patients and normal subjects differ in their sensitivity to both effects. For example, without any difference in pharmacokinetics, alprazolam produced more of an impact on mood and EEG but fewer adverse effects in patients with panic disorder than in normal controls.

Effects on Specific Organs and Systems

The primary action of benzodiazepines is on the CNS, where they have an anticonvulsant and anxiolytic effect and produce muscle relaxation and CNS depression. Decreased depolarization of neurons in the brainstem can cause respiratory depression, primarily at high doses. Diazepam increases coronary blood flow and has negative inotropic effects. Other benzodiazepines used as preanesthetics reduce peripheral vascular resistance, thereby decreasing blood pressure and increasing heart rate.

Benzodiazepines cross the placenta and enter breast milk.

Benzodiazepines such as diazepam also bind to PBRs. The therapeutic potential of these interactions has not been extensively explored, but it is possible that stabilizing the mitochondrial ion channel could reduce neurotoxicity in some degenerative disorders.

Therapeutic Indications

Benzodiazepines have largely replaced the older barbiturates and related medications as anxiolytics and hypnotics. However, concerns about addiction have led to unwarranted regulation of these medications and declining use for chronic anxiety disorders in some settings. The year after a requirement for special prescribing procedures for benzodiazepines was introduced in the New York State in 1989, benzodiazepine prescriptions decreased by 60 percent while prescriptions for the more dangerous meprobamate, chloral hydrate (Aquachloral), and butabarbital (Butisol) increased by 125 percent, 136 percent, and 30 percent, respectively. Not surprisingly, overdoses of the latter drugs also increased.

Although they have clear advantages of effectiveness for most forms of anxiety, generally good tolerability, and ease of prescription, benzodiazepines (and other medications) have the potential to reinforce a passive approach to symptom relief in which one relies on something outside oneself for symptom relief and does not necessarily acquire an internal sense of mastery of stressful situations. For chronic anxiety, behavioral therapies such as cognitive behavior therapy and desensitization should therefore be considered along with or as alternatives to benzodiazepines. Benzodiazepines can facilitate exposure to phobic and other anxiety-provoking situations, resulting in more enduring benefit.

Generalized Anxiety Disorder. Benzodiazepines are clearly effective for GAD. Despite the chronic and relapsing nature of this condition, experts frequently recommend that benzodiazepines be taken for brief periods of time. This approach frequently results in relapse of anxiety, which is mistaken for drug dependence. Antidepressants, especially the SSRIs, have increasingly been used as replacements or supplements for benzodiazepines in the treatment of GAD. However, a significant number of patients require ongoing therapy with benzodiazepines.

Panic Disorder. As was mentioned previously, alprazolam has been found to be superior to placebo in reducing the frequency of panic attacks, usually in doses higher than those used to treat generalized anxiety. Other benzodiazepines appear to be equally effective in equivalent doses. Antidepressants other than bupropion (Wellbutrin) are equally effective for this condition and are probably better tolerated in chronic use. Some patients do best on combinations of antidepressants and benzodiazepines.

Other Anxiety Disorders. Benzodiazepines are used as adjuncts to reduce arousal in PTSD and are sometimes used intermittently to reduce social anxiety, although chronic treatment with SSRI and MAOI antidepressants is more effective. β-Blockers are more useful acutely for performance anxiety than benzodiazepines because they are less likely to impair psychomotor function and they directly reduce autonomic arousal that interferes with performance. Benzodiazepines are appropriate initial treatments for acute situational anxiety, especially in settings in which physiological arousal could be dangerous, such as in a patient with a damaged myocardium on the coronary care unit who will be vulnerable to the arrhythmogenic effects of catecholamines released in response to anxiety.

Major Depressive Disorder. Alprazolam has been found to have some antidepressant properties, although monotherapy with this benzodiazepine is not as effective as antidepressants for severe depression. Alprazolam might be considered for a depressed patient who could not tolerate any antidepressant and who did not respond to established psychotherapies and who refused or was not a good candidate for ECT or another instrumental therapy. Antidepressants frequently increase anxiety acutely in patients with primary anxiety disorders and with mixed anxiety and depression because of an initial increase in noradrenergic activity, even with medications that are purely serotonergic in the laboratory. To block early excessive activation by antidepressants, benzodiazepines are often prescribed first. Once anxiety and other symptoms of arousal are suppressed, the antidepressant is better tolerated. Eventually, noradrenergic alerting systems are down-regulated by the antidepressant, at which point the benzodiazepine can be withdrawn. In some cases of mixed anxiety and depression, both medications are continued.

Conventional wisdom holds that benzodiazepines other than alprazolam aggravate or cause depression. A Cochrane Review meta-analysis of nine randomized, controlled studies involving 679 unipolar depressed patients found that patients treated with combinations of an antidepressant and a benzodiazepine were significantly more likely than those treated with an antidepressant alone to respond during the first 4 weeks of treatment. In these studies, adding a benzodiazepine to an antidepressant conveyed as much additional benefit as chlorpromazine (Thorazine) over placebo for acute schizophrenia and almost as much as an SSRI over placebo for major depression or lithium (Eskalith) over placebo for mania. Much of the benefit was a function of fewer early dropouts among patients receiving a benzodiazepine, probably because of more rapid reduction of anxiety and more tolerability of the antidepressant. After 6 weeks of treatment, there was no longer any difference between those taking and those not taking benzodiazepines along with antidepressants.

Adverse benzodiazepine effects did not outweigh the therapeutic benefit. One comparison of diazepam, the MAOI moclobemide (Manerix), and placebo found the benzodiazepine to be superior to the antidepressant, as well as the placebo, for anxious depression. Conversely, a prospective study of elderly (mean age 85 years at baseline) patients suggested that those taking benzodiazepines were more likely to develop new depressive symptoms and had slightly higher depression rating scale scores. No controlled data are available about the development of a new episode of major depression in nondepressed patients taking benzodiazepines.

Insomnia. Benzodiazepines increase quality and length of sleep, decrease sleep latency, and slightly reduce REM sleep. However, tolerance develops to the hypnotic effect after 1 to 2 months. Efficacy can be retained by intermittent use. Gaboxadol, an experimental nonselective extrasynaptic $GABA_A$ agonist, reduces sleep latency and increases slow wave sleep. Sedating antidepressants, especially trazodone, and the atypical antipsychotic drug quetiapine (Seroquel), are currently used more frequently than benzodiazepines to treat chronic insomnia. Benzodiazepines are useful for insomnia caused by acute stress, such as hospitalization. Hospitalized patients should be asked if they would prefer a sleeping pill rather than routinely prescribing these medications. In many cases, chronic insomnia is probably better treated with a sedating antidepressant.

Flurazepam itself has a short elimination half-life, but its major active metabolite, desalkylflurazepam, has a half-life longer than 1 day. Persistence of the drug effect makes this medication most useful for patients with daytime anxiety, and high lipid solubility can also result in a rapid onset of action. Accumulation with repeated dosing often leads to daytime sedation. The relatively slow onset of action of temazepam, which is related to its lower lipid solubility, combined with an intermediate half-life make it most appropriate for patients with middle or terminal but not initial insomnia. Triazolam, on the other hand, has a rapid onset of action and a short elimination half-life, making it useful for patients who have difficulty falling asleep who want to avoid daytime impairment. However, the same features lead to a high frequency of withdrawal symptoms, especially amnesia, the next morning. In addition, concerns have been raised about the efficacy of lower doses (0.125 mg) and the safety of higher doses (0.5 mg).

Gamma-hydroxybuturate (GHB, Xyrem), which is approved for the treatment of narcolepsy and improves slow wave sleep, is also an agonist at the $GABA_A$ receptor, where it binds to specific GHB receptors. GHB has the capacity both to reduce drug craving and to induce dependence, abuse, and absence seizures as a result of complex actions on tegmental dopaminergic systems. Such adverse effects, as well as reports of drug misuse,

substantially limit use of this drug. The application of other nonbenzodiazepines acting on the benzodiazepine receptor in the treatment of insomnia is discussed later in this chapter.

Benzodiazepine and other sleeping pills are often used to treat or prevent jet lag and work shift-related sleep phase changes. However, the sleep–wake cycle is more effectively shifted by exposure to bright light at the time of waking up than by the time of falling asleep. If a hypnotic agent is used, it should be combined with getting out in the sunlight or using artificial bright light the next morning. Melatonin, or ramelteon (Rozerem), a melatonin M1 and M2 receptor agonist, is more likely to shift the onset of sleepiness than is a primarily sedating medication.

The decision to promote a particular benzodiazepine receptor agonist as an anxiolytic or a hypnotic is based on marketing strategies and the kinds of studies that the manufacturer chose to perform to obtain FDA approval, not the pharmacology of the drug. There is no reason, for example, why preparations with similar onset and duration of action (e.g., temazepam, lorazepam, oxazepam) could not be used for the same indication.

Bipolar Disorder. Clonazepam (Klonopin) is frequently used for anxiety and insomnia in patients with unstable bipolar mood disorders. Although some authorities hold that a mildly serotonergic action of this medication could contribute to an antidepressant effect, clinical experience suggests that it may induce depression or at least oversedation with chronic use. Lorazepam, with or without antipsychotic drugs, is still used frequently as an adjunctive treatment for mania. In view of the risk that antidepressants can destabilize mood in bipolar disorder, benzodiazepines other than alprazolam (which has antidepressant properties) are safer anxiolytics for patients with bipolar illness.

Schizophrenia. Perhaps as a result of GABAergic inhibition of dopamine release, benzodiazepines have been found somewhat useful as adjuncts to antipsychotic drugs, primarily in reducing agitation and anxiety, but not as monotherapy for positive symptoms of schizophrenia. A Cochrane Review of 31 studies involving over 2,000 patients concluded that there are insufficient data to recommend benzodiazepines alone or as adjuncts in the treatment of schizophrenia.

Catatonia. Lorazepam, sometimes in low doses (less than 5 mg per day) and sometimes in very high doses (12 mg per day or more), is regularly used to treat acute catatonia, which is more frequently associated with bipolar disorder than with schizophrenia. Other benzodiazepines have also been said to be helpful. However, there are no valid controlled trials of benzodiazepines in catatonia. Chronic catatonia does not respond as well to benzodiazepines. The definitive treatment for catatonia is ECT.

Seizure Disorders. Because they reduce neuronal hyperactivity in cortical and pyramidal cells, all benzodiazepines have anticonvulsant properties. Its longer duration of action makes clonazepam the most frequently used benzodiazepine for adjunctive chronic seizure control. IV diazepam, lorazepam, and midazolam are used for status epilepticus. However, the longer a seizure persists, the more likely it is to become resistant to the anticonvulsant effect of the benzodiazepine, as has also been reported with barbiturates. Animal studies suggest that cannabinoid receptor antagonists may not exhibit rapid development of tolerance in the treatment of status epilepticus. Clobazam, which is approved in 100 countries for the treatment of Lennox-Gastaux syndrome, a form of intractable childhood epilepsy, is undergoing phase III testing in the United States. A group of 2,3-benzodiazepines that are also noncompetitive antagonists of the excitatory amino acid α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor are being investigated as antiepileptic and neuroprotective agents. As noted earlier, anticonvulsants such as valproate and tiagabine alter GABA dynamics rather than acting on the benzodiazepine receptor. The same appears to be true of pregabalin and gabapentin.

Acute Agitation. A rapid onset of action with minimal residual impairment has made IV midazolam useful for control of severe acute agitation in the emergency department. Life-threatening agitation caused by delirium or other neurological conditions can be controlled with a few doses of IV lorazepam, which is often combined in the same syringe with haloperidol (Haldol), and ECT is also rapidly effective for this purpose. Nonspecific agitation is treated in many centers with a combination of intramuscular lorazepam and haloperidol, but the advantage of this combination over either drug alone is limited to remaining asleep longer, and midazolam acts more rapidly with less residual sedation. A Cochrane Review of 11 studies with a total of 648 patients found no difference between haloperidol plus lorazepam and lorazepam alone in improvement, need for additional medication, or incidence of extrapyramidal side effects. Lorazepam is used as an adjunctive treatment to reduce excitement, improve sleep in manic patients, and treat agitation in schizophrenic patients. Although benzodiazepines can reduce the dose of antipsychotic medications in agitated manic and schizophrenic patients, there is no evidence that they have an adjunctive antipsychotic effect. Increased use of atypical antipsychotic drugs, which are better tolerated than the older neuroleptics, has reduced the need for adjunctive benzodiazepines.

The parenteral form of lorazepam contains a small amount of propylene glycol that is not problematic for isolated doses but can cause metabolic acidosis if given in high enough doses for a long enough period of time, especially in patients with renal or hepatic impairment. Doses greater than

0.1 mg/kg/hr over 1 to 2 days, which may be used as a continuous infusion for sever alcohol withdrawal, can result in propylene glycol levels of 25 mg/dL or more.

Alcohol Withdrawal. Half of people with alcohol use disorders develop withdrawal syndromes when they decrease or discontinue drinking; delirium tremens and/or seizures complicate 3 to 5 percent of cases of alcohol withdrawal. Benzodiazepines are standard treatments for alcohol withdrawal because they reduce arousal and act at a different site on the same receptor complex. No single benzodiazepine has been found to be superior to any other. Benzodiazepines with low lipid solubility and long elimination half-lives, such as chlordiazepoxide, are most frequently used because the blood level slowly declines after a decreasing dose administered over several days. Clorazepate, which has an intermediate half-life, is also used because it is a prodrug with a long half-life active metabolite. Lack of hepatic metabolism of lorazepam, which can be increased by alcohol, make this an appealing choice, but more frequent dosing is necessary because of its shorter elimination half-life.

In the treatment of delirium tremens, very high benzodiazepine doses may be needed. For example, as much as 2,000 mg of diazepam (Valium) on the first day, or 2,800 mg of midazolam over 50 days, have been used in ICU settings. One protocol recommends up to 8 mg of lorazepam (Ativan) orally, IM or IV every 15 minutes, followed by 10 to 30 mg/hour after a final 8-mg bolus. Such dosing usually requires careful monitoring in a hospital setting.

Addiction. Baclofen, a $GABA_B$ agonist, reduced the reinforcing effects of substances and food in animal studies. This or another agonist could prove useful for smoking cessation.

Neuroleptic Side Effects. Benzodiazepines are more effective than antiparkinsonian drugs in treating akathisia, but they are not as useful for parkinsonism. There is some evidence from a single study of 24 patients that benzodiazepines may reduce manifestations of tardive dyskinesia, but pooled data from other studies indicate no benefit.

Anesthesia and Conscious Sedation. Midazolam is frequently used for brief anesthesia and for conscious sedation. Other highly lipid-soluble benzodiazepines, such as diazepam, are used adjunctively for conscious sedation.

Acute Agitation and Violence. Medications that improve agitated and aggressive behavior do so primarily as a result of sedation. Even psychotic agitation is ameliorated by sedative effects of antipsychotic drugs, since

reduction of psychosis itself is not immediate. IM lorazepam (Ativan) in doses of 0.5 to 2 mg and sometimes as high as 4 mg, often in combination with 5 mg of haloperidol, is commonly used to treat acute agitation in the emergency room and in psychiatric inpatient settings. In most studies, 2 mg of lorazepam has been found to be as effective as 5 mg of haloperidol, primarily as a function of sedation. Clonazepam has also been found to be equivalent to haloperidol, although it is not available in an IM form. IM midazolam in a dose of 5 mg is very appealing as monotherapy for agitation because it has a rapid onset of action. Oversedation is not as significant a concern because of the rapid offset of action and the short half-life of midazolam; the same features may require more frequent dosing. In general, benzodiazepines are preferable to antipsychoptic drugs for most forms of agitation, because they do not cause neurological side effects or QT prolongation. The latter is an important consideration in emergency settings, where an electrocardiogram that could reveal pre-existing QT prolongation cannot realistically be performed. They are obviously useful for agitation caused by CNS depressant withdrawal, but they may aggravate other forms of delirium.

Antispasmodic, Chronic Pain and Tinnitus. Baclofen is commonly used to treat spasticity. It is also effective for pain, but tolerance develops rapidly. A small single-blind study reported significant reduction of severe disabling tinnitus of cochlear origin by benzodiazepines and other GABAergic drugs compared to placebo.

Infectious Disease. Benzodiazepines may inhibit the respiratory syncytial virus, an action that seems attributable to the S-enantiomer. The in vitro action of benzodiazepines for leishmaniasis is equivalent to the standard treatment for this illness, sodium stibogluconate.

Precautions and Adverse Effects

Most adverse effects of the benzodiazepines involve the CNS.

Sedation. Although some benzodiazepines (e.g., alprazolam) are less sedating than others (e.g., chlordiazepoxide), all benzodiazepines are CNS depressants and can cause intolerable sedation. Tolerance often develops to this side effect if the dose is raised slowly. Respiratory depression can occur as a result of depression of the central respiratory drive in high doses or in patients with liver disease. This mechanism, along with the muscle relaxant effect, makes nighttime benzodiazepine use risky for patients with sleep apnea and chronic obstructive pulmonary disease.

Cognitive and Psychomotor Impairment. Retrograde amnesia, caused by withdrawal from short-acting, high-potency benzodiazepines such as

triazolam and midazolam, can occur after a single dose. Withdrawal probably also accounts for amnesia following a dose of the high-potency lipid-soluble "date rape drug" flunitrazepam (Rohypnol), especially when it is combined with alcohol. All benzodiazepines can cause anterograde amnesia and can interfere with new learning, although they do not usually interfere with memories that are already acquired.

All patients taking benzodiazepines should be warned about the risk of impaired psychomotor performance. Impairment of driving caused by a single 10-mg dose of diazepam is equivalent to impairment caused by a blood alcohol level sufficient to qualify for a citation for driving under the influence. Patients whose driving is impaired often are not aware of the problem. Tolerance to psychomotor impairment does not occur as readily as does tolerance to sedation.

At one time it was thought that an endogenous benzodiazepine receptor ligand caused hepatic encephalopathy. However, a careful study of controls and cirrhotic patients with and without encephalopathy found that increased concentrations of benzodiazepine receptor ligands in encephalopathy patients were entirely explained by administration of benzodiazepines for sedation or endoscopy.

In some cases, persistent delirium associated with alcohol withdrawal or mixed CNS depressant use is caused by benzodiazepines, especially those with longer durations of action. This condition can be diagnosed by improvement with the benzodiazepine receptor antagonist flumazenil if delirium has persisted for 5 days. Flumazenil can precipitate benzodiazepine withdrawal if benzodiazepine use has continued.

Aggravation of Dementia. Cognitive side effects of benzodiazepines can exacerbate the cognitive deficits of dementia. Interference with balance and psychomotor performance can also lead to falls, which can be devastating in elderly, frail, patients. These medications therefore should be used with great caution if at all in elderly patients, and in 2012 the American Geriatrics Society included benzodiazepines in its list of drugs that are inappropriate for older patients because of cognitive side effects. If a benzodiazepine is indicated, preparations with shorter half-lives and simpler metabolism such as lorazepam or oxazepam in lower doses are preferable. Nevertheless, a recent study found that benzodiazepine use increased from 2.6 percent of the population aged 18 to 26 years to 8.7 percent of those aged 65 to 80 years, with 24 percent of all benzodiazepine users taking long-acting preparations, especially when nonpsychiatric physicians prescribed them.

Concern about the risk of Alzheimer disease in patients taking benzodiazepines was raised by a recent case-control study of 1,796 patients with Alzheimer disease who had been followed prospectively for at least 6 years prior to diagnosis, and 7,184 matched controls (age >66 years). After

controlling for relevant risk factors and anxiety, insomnia, and depression, Alzheimer disease was 1.32 times more likely in patients taking benzodiazepines for 3 to 6 months and 1.84 times more likely in patients taking benzodiazepines for more than 6 months; less than 3 months use of a benzodiazepine was significantly associated with Alzheimer disease. The association was stronger for long half-life (1.70 times increase) than for short half-life benzodiazepines (1.43 times increase). Although not all research has supported this finding, another study found a 50 percent increased risk of Alzheimer disease within 15 years after starting a benzodiazepine. Such results could indicate that benzodiazepine use reduces cognitive reserve sufficiently for Alzheimer disease to be expressed earlier, that using a benzodiazepine for extended periods of time is a marker of an as yet unidentified risk factor for Alzheimer disease, or that benzodiazepines themselves increase the risk of Alzheimer disease through an unclear mechanism.

Disinhibition. Demented patients may become more confused when they take benzodiazepines because further depression of the reticular activating system induces delirium. These patients become agitated as a direct result of the reduced organizing function of brainstem structures and because they become more confused and frightened. Some hypervigilant individuals become more suspicious or agitated when their ability to keep track of their environment is impaired by a benzodiazepine.

Abuse and Dependence. A 1990 population survey found that 10 to 15 percent of the population used benzodiazepines during the previous year, and 2 percent used benzodiazepines chronically. Benzodiazepine dependence and abuse are more prevalent in individuals who abuse other substances. By contrast, misuse of benzodiazepines is considered rare in medical practice, occurring primarily in people with a history of misusing these or other substances. However, a Canadian study of more than 400,000 hospitalizations of elderly patients who had not previously taken benzodiazepines found that 1.5 percent had new chronic use of benzodiazepines that were started in the hospital. The likelihood of new chronic benzodiazepine use was highest in women, patients admitted to the intensive care unit or nonsurgical wards, those with longer hospital stays, patients with more comorbidity, a prior diagnosis of alcoholism, and patients taking more medications. Benzodiazepine use by narcotic addicts increases complexity and refractoriness of the substance use disorder.

A comprehensive interview study of 33 primary care physicians found them to be reluctant to address discontinuing long-term benzodiazepine use with elderly patients because they felt unskilled in doing so and because the patients usually resisted the change. Similarly, a study by the same group of elderly chronic benzodiazepine users in primary care practice

found them to be unwilling to consider discontinuing or tapering the medication because they felt that it reduced stress and in some cases even prolonged life. Conversely, a Spanish study found that with biweekly follow-up and a standard withdrawal schedule, patients taking benzodiazepines chronically were almost five times as likely to discontinue or substantially reduce benzodiazepine use as they were with usual practice (number needed to treat = 3). Most studies demonstrate that gradual taper of benzodiazepines is more likely to result in successful discontinuation than rapid withdrawal. There is not enough research to determine the efficacy of the common practice of switching to a long-acting benzodiazepine before withdrawing short-acting benzodiazepines, but this practice may result in fewer dropouts. It is important to distinguish between a desire to prevent relapse and ongoing excessive benzodiazepine misuse before embarking on discontinuing benzodiazepines. For patients who need ongoing benzodiazepine use but should not be exposed to the continued risk of these medications (especially older patients), adding an antidepressant first may facilitate discontinuation of the benzodiazepine. It should at least be possible to cross over to a benzodiazepine with a shorter half-life in older patients.

In studies of addict ratings of the degree to which a particular drug would be sought and emergency department admissions for drug abuse or dependence, diazepam, alprazolam, and lorazepam have been judged to be most prone to misuse. This finding probably reflects the high potency and lipid solubility of the first two medications, resulting in a rapid onset of action perceived as a high, and interdose withdrawal leading to escalation of the dose. Lorazepam does not have a rapid onset of action, but the combination of high potency and a short elimination half-life can lead to dosage escalation to avoid withdrawal.

Dysphoria. Patients who feel intensely anxious may find the rapid onset of high-potency lipid-soluble benzodiazepines to be reassuring. Those who are afraid of losing control may become dysphoric when they feel rapidly calmed or sedated by the same medication and may feel more in control with the slow onset of action of less lipid-soluble preparations.

Pregnancy and Lactation. Benzodiazepines readily cross the placenta. Concerns have been raised that exposure to benzodiazepines in utero causes cleft lip and palate, but a large case-controlled study of diazepam and chlordiazepoxide found no teratogenicity and a case control study of more than 38,000 pregnancies found no association of teratogenicity with any of five benzodiazepines. A critical review of the literature on the teratogenic risks of benzodiazepines during the first trimester of pregnancy from 2001 to 2011 found no evidence of congenital malformations and noted that studies were limited by lack of detailed data about

benzodiazepine use during pregnancy, possible recall bias, and lack of control for confounding factors. The authors recommended diazepam and chlordiazepoxide as first choices during pregnancy. All benzodiazepines are excreted in breast milk, in which concentrations are close to serum concentrations for more lipid-soluble preparations. Although the total dose of benzodiazepine at any time to the nursing infant is low, sedation, hypotonia, and decreased feeding may occur. Some infants chronically exposed to benzodiazepines may develop discontinuation syndromes when the mother stops taking the benzodiazepine or stops breastfeeding.

Discontinuation Syndromes. Three types of syndromes have been clearly described when benzodiazepines are discontinued. All are more pronounced when the medication is withdrawn more rapidly and with shorter half-life, high-potency, and lipid-soluble preparations.

RELAPSE. Return of symptoms of the condition that the medication was treating is called *relapse*. Relapse of anxiety disorders begins over weeks to months and lasts indefinitely with fluctuating severity unless it is treated again because most anxiety disorders are chronic or recurrent.

REBOUND. *Rebound* refers to an intensification of the original symptoms. Rebound symptoms, which are worse than was the case before treatment began, start within days to weeks of drug discontinuation and last from days to weeks. The level of symptomatology then returns to the baseline (i.e., rebound is replaced by relapse). Rebound anxiety may occur between doses of highly lipid-soluble, high-potency, short half-life benzodiazepines, such as alprazolam. Taking such medications every 2 to 3 hours is not necessarily a sign of misuse and may simply reflect the rapid onset and termination of drug effect.

WITHDRAWAL. *Withdrawal* syndromes involve new autonomic signs and symptoms (Table 34.10–2) that are not components of the original disorder. Withdrawal begins within hours to days of discontinuation of short-acting benzodiazepines but may not occur for 1 to 2 weeks after abrupt discontinuation of longer-acting preparations. Withdrawal typically lasts for a few days for shorter-acting medications to 1 or 2 weeks for longer-acting drugs, but attenuated withdrawal symptoms have been observed 1 year after discontinuation of long half-life benzodiazepines. Slow downward taper of the benzodiazepine dose reduces the risk of withdrawal symptoms but does not prevent them. Some patients experience interdose withdrawal in addition to rebound with high-potency short-acting benzodiazepines. Withdrawal may occur after 4 to 8 months of treatment with typical benzodiazepine doses or after half that duration of treatment with higher doses.

Signs and Symptoms of Benzodiazepine Withdrawal

Withdrawal can probably best be understood as a natural consequence of benzodiazepine receptor adaptation to chronic benzodiazepine use. Benzodiazepine receptors downregulate when presented with a large number of benzodiazepine molecules. At the same time, the inverse agonist DBI is upregulated to compensate for depression of CNS excitability. When the benzodiazepine is abruptly withdrawn, there are more DBI molecules than there are benzodiazepine molecules competing for fewer benzodiazepine receptors. This results in a shift of the benzodiazepine receptor toward inverse agonism, causing decreased, rather than increased, GABA receptor affinity and reduced, rather than enhanced, chloride influx. CNS excitability increases abruptly, resulting in manifestation of arousal ranging from jitteriness and tremor to myoclonus and seizures. Slower benzodiazepine withdrawal allows the benzodiazepine receptor to upregulate, while DBI is gradually downregulated, but the unpredictability of this accommodation may lead to withdrawal symptoms with a slow taper or even with a reduction in benzodiazepine dose. An additional contributing factor to rebound insomnia after discontinuation of long-term benzodiazepine hypnotic use may be dysregulation of endogenous melatonin rhythms.

Withdrawal from benzodiazepines, as well as many other CNS depressants, is treated by reinstituting the previous dose and withdrawing the medication more slowly or by substituting a longer-acting benzodiazepine or another CNS depressant with a known pattern of withdrawal, preferably one that acts at the same receptor complex. A barbiturate tolerance test with phenobarbital or pentobarbital (Nembutal) can be used to more precisely determine the dose of CNS depressant necessary to suppress withdrawal, as described in Chapter 34.9. Standardized withdrawal protocols using one of these barbiturates can then be applied. In a recent study, addition of 2 mg of sustained-release melatonin was superior to placebo in promoting withdrawal of benzodiazepine hypnotics in 19 of 24 patients who were able to discontinue the benzodiazepine and were able to maintain good sleep quality without return to benzodiazepine use. However, patients were then maintained on melatonin.

As chronic doses of alprazolam are reduced below approximately 1 mg,

the benzodiazepine receptor undergoes paradoxical downregulation, which can cause rebound and withdrawal symptoms, even with an extremely slow taper. Some clinicians find that substitution of clonazepam facilitates withdrawal of the final 1.0 to 1.5 mg, but others have found that clonazepam does not reliably suppress alprazolam withdrawal.

A confusing clinical picture may emerge when alcohol-dependent patients who have also been taking long-acting benzodiazepines are admitted to the hospital. The onset of withdrawal seizures or alcohol withdrawal delirium may be postponed up to several weeks because it is prevented by the benzodiazepine, which has a longer duration of action at the GABA–benzodiazepine receptor complex. When the serum level of the benzodiazepine eventually declines, typical alcohol withdrawal emerges, sometimes complicated by benzodiazepine withdrawal. The late onset of symptoms may result in withdrawal delirium being mistaken for postoperative psychosis or a complication of a medical illness.

Drug Interactions

Antacids may reduce GI absorption of benzodiazepines. Otherwise, benzodiazepine interactions may be pharmacokinetic or pharmacodynamic. Inhibitors of CYP 3A4, such as erythromycin (E-Mycin), ketoconazole (Nizoral), cimetidine (Tagamet), estrogen, disulfiram (Antabuse), verapamil (Isoptin), nefazodone (Serzone), and grapefruit juice, increase benzodiazepine levels, whereas carbamazepine and St. John wort, which induce this enzyme, lower benzodiazepine levels. These are not issues for benzodiazepines with minimal hepatic metabolism, such as oxazepam and lorazepam.

Pharmacodynamic interactions mainly involve additive CNS depression with other sedating agents, such as antihistamines and sedating antidepressants. Combining benzodiazepines and alcohol results in additive psychomotor impairment. Adding benzodiazepines to clozapine can produce respiratory and cardiovascular depression. There are some reports of respiratory arrest in patients taking buprenorphine and parenteral benzodiazepines, but this interaction does not seem to have been as important with lower doses of oral benzodiazepines.

Laboratory Interferences

Benzodiazepines do not affect most laboratory tests.

Dosage and Administration

Usual benzodiazepine doses for the treatment of anxiety are summarized in Table 34.10–3. Even medications with long elimination half-lives are often given in divided doses to avoid oversedating peak levels. In chronic treatment, especially at higher doses, it is sometimes necessary to

administer alprazolam frequently (e.g., every 2 to 3 hours) to avoid interdose withdrawal and rebound anxiety. An alprazolam sustained-release preparation (Xanax XR) has acceptable steady-state kinetics with three daily doses. Slow absorption of temazepam administered at bedtime makes this approach most useful for patients who have no trouble falling asleep but wake up early. To reduce sleep latency, this medication should be taken 1 to 2 hours before bedtime.

The common approach of withdrawing benzodiazepines after 2 months of treatment usually results in relapse in chronic and relapsing anxiety disorders, such as GAD and panic disorder. However, it is often possible to suppress anxiety initially with a benzodiazepine and then add an antidepressant, which is better tolerated when arousal has been controlled acutely with the benzodiazepine. It may then be possible to withdraw the benzodiazepine. Some patients who have been taking stable doses of benzodiazepines for years without evidence of impairment or misuse and who cannot tolerate other treatments should simply continue the benzodiazepine rather than undergo multiple unsuccessful attempts at drug discontinuation.

PARTIAL AGONISTS AND SELECTIVE BENZODIAZEPINE RECEPTOR FULL AGONISTS

Chemistry

Zolpidem (Ambien), an imidazopyridine, and zaleplon (Sonata), a pyrazolopyrimidine, are not benzodiazepines in that they lack a diazepine ring (Fig. 34.10–5). Although it is technically accurate to describe these medications as nonbenzodiazepines, they act on benzodiazepine receptors, and their clinical effect can be blocked by the benzodiazepine receptor antagonist flumazenil. However, they are selective for the benzodiazepine-1 receptor and have no significant effect on other benzodiazepine receptor subtypes at usual doses (Table 34.10–3); at higher doses, they are less selective. Zolpidem has an elimination half-life of approximately 2 hours, with a bioavailability of 70 percent; ingestion with food slows absorption. Zolpidem is oxidized to inactive metabolites. Zaleplon is rapidly absorbed and has a half-life of just 1 hour, with a 30 percent bioavailability because of extensive presystemic metabolism. Zaleplon is almost entirely metabolized to inactive metabolites. Alpidem (Ananxyl) is a selective benzodiazepine-1 agonist that is not available in the United States and is used as an anxiolytic.

[a]Not available in the United States.

The hypnotic drug quazepam (Doral) is selective for the benzodiazepine-1 receptor, but it is metabolized to desalkylflurazepam, a nonselective benzodiazepine metabolite of flurazepam that accounts for 40 percent of total drug activity. With chronic dosing, this medication therefore is similar to other long-acting benzodiazepine hypnotics.

Zopiclone is a benzodiazepine receptor partial agonist that is in widespread use in Europe but is not available in the United States. Its S-enantiomer, eszopiclone (Lunesta), is marketed in the United States. Eszopiclone is extensively metabolized by CYP 3A4 and 2E1; less than 10 percent of an orally administered dose is excreted in the urine, mainly as racemic zopiclone. It does not appear to stimulate or inhibit any CYP450 enzymes.

FIGURE 34.10–5. Selective benzodiazepine-1 receptor agonists.

Pharmacological Actions

Zolpidem is rapidly absorbed after oral administration and reaches peak plasma levels in 2 to 3 hours. Zolpidem has an elimination half-life of 2 to 3 hours and has no active metabolites. As a result, in most cases, a bedtime dose is completely eliminated during the night, and there is no daytime hangover. The pharmacology of zolpidem therefore predicts greater usefulness for difficulty falling asleep than for interrupted sleep and early morning awakening. A controlled release preparation (Ambien CR) has a more prolonged duration of action and may help patients stay asleep. Zaleplon, which reaches peak plasma levels 1 to 2 hours after dosing and has an elimination half-life of approximately 1.5 hours, is primarily useful for difficulty falling asleep and usually does not cause a hangover.

Selectivity for the benzodiazepine-1 receptor results in hypnotic and some anxiolytic action without muscle relaxant or anticonvulsant effects for zolpidem and zaleplon. Lack of effects on benzodiazepine-3 receptors appears to result in a lower incidence of withdrawal and rebound symptoms, although these may occur especially at higher doses and with more chronic treatment. Eszopiclone is rapidly absorbed from the GI tract. Its elimination half-life is 5 to 7 hours. About 50 to 60 percent is weakly bound to plasma protein.

Therapeutic Indications

Comparisons of zolpidem and eszopiclone to cognitive behavior therapy

(which includes sleep hygiene) find the latter to be more effective, with more prolonged benefit, than medications. Medications may be more appropriate initial choices for acute insomnia associated with a time limited stress, but behavioral approaches should be considered for chronic insomnia.

The "Z drugs," zolpidem, zaleplon, and eszopiclone, are primarily used to treat insomnia. Zolpidem improves sleep latency and total sleep time to an extent similar to benzodiazepines, without reduction of REM or delta sleep or other changes in sleep architecture. Zolpidem accounts for approximately one-third of all hypnotic prescriptions, having eclipsed benzodiazepines because of its more favorable side-effect profile. An extended release (Ambien CR) and a formulation in which the drug is released longer after ingestion (Intermezzo) have been released for patients with difficulty remaining asleep. A sublingual tablet (Edluar) and oral spray (Zolpimist) are also available. As is true of other hypnotics, it is usually recommended that zolpidem not be administered for more than 2 to 8 weeks. However, one study showed no tolerance during 6 months of treatment.

Zaleplon in a 10-mg dose reduces sleep latency to an extent similar to 0.25 mg of triazolam. Usual doses increase total sleep time by approximately 42 minutes. At higher doses (40 to 60 mg), slow wave sleep increases and REM percentage decreases. Eszopiclone improves sleep efficiency, sleep latency, number of awakenings, total sleep time, and quality and depth of sleep in adults and elderly patients, in whom it also decreases the number of daytime naps. Because the manufacturer chose to conduct 6-month studies, eszopiclone is approved for long-term treatment of insomnia. Sales of this medication have increased substantially as a result of this indication and extensive advertising.

The "Z drugs" are frequently used to treat jet lag and to facilitate shift changes. However, all sleeping pills do is induce sleep; they do not reset the sleep–wake cycle. The time of waking up generally determines the time of falling asleep, and the most effective cue for a sleep–wake cycle that is out of phase with the environment is exposure to bright light at the time of waking up. Therefore, the best approach to preventing jet lag and work shift sleep changes is to take melatonin at the desired time of going to sleep at the new location or shift, and to go outside or have 30 minutes of exposure to artificial bright light at an intensity of 10,000 lux at or near the desired time of waking up.

Precautions and Adverse Reactions

A survey of British primary care physicians found that despite any evidence supporting the belief, the majority believed that the "Z drugs" were safer and more effective than the benzodiazepines. Although tolerance, withdrawal, and rebound insomnia have been found to be rare with

zolpidem, this finding is based on short-term studies. Clinical experience suggests that tolerance can develop, and rebound insomnia can occur after chronic use. Because of its short elimination half-life, zolpidem usually does not produce much daytime impairment. However, memory impairment similar to that seen with triazolam occurs approximately 1.5 hours after dosing, and complex automatisms including driving and eating, during sleep have been reported with amnesia for the behavior, reflecting the peak plasma level of the drug. Adverse effects are more common at doses exceeding 20 mg. Zolpidem is excreted in breast milk and may cause sedation in nursing infants. Concerns about adverse effects and withdrawal have led to reduction in the recommended dose of zolpidem to 5 mg for the immediate release form and 6.25 mg for the extended release form.

In doses up to 10 mg, zaleplon has been found to cause dizziness, headache, and somnolence. Psychomotor impairment has also been reported. However, these side effects are usually not problems during the day because they wear off within 2 to 3 hours as a result of the short half-life of the drug. At doses of 60 mg, psychomotor impairment persists for 25 hours. Abuse potential of zaleplon and zolpidem is low.

In addition to expected side effects such as somnolence and dizziness, eszopiclone can also cause a bitter taste. An Irish study found that almost one-fourth of patients in a methadone maintenance program were abusing zopiclone, often along with benzodiazepines. Abuse of eszopiclone has been reported at doses two to four times the recommended maximum. Although tolerance and rebound insomnia have been rare in clinical trials, rebound insomnia is more common than other discontinuation syndromes with eszopiclone.

Drug Interactions and Laboratory Interferences

Zolpidem, zaleplon, and eszopiclone can have additive sedative effects with other CNS depressants. L-type calcium channel blockers and ritonavir (Norvir) may increase zolpidem effects. No effects on laboratory tests have been described.

Dosage and Administration

The initial dose of zolpidem, sublingual Edluar, and oral spray Zolpimist is 5 mg. The dose can be increased to 10 mg at bedtime. The controlled-release formulation of zolpidem is started at a dose of 6.25 mg, and the dose can be increased to 12.5 mg for males if necessary. The initial dose of Intermezzo is 1.75 mg for women and 3.5 mg for men. Zaleplon is started at a dose of 5 mg, and the dose can be increased to 10 to 20 mg. The short duration of action of zaleplon makes it applicable for patients who have to get back to sleep after waking up in the middle of the night. Eszopiclone is started at a dose of 1 mg, and the dose is increased as needed to 2 to 3 mg at

bedtime.

BENZODIAZEPINE RECEPTOR ANTAGONISTS

Antagonists occupy receptors but have no effect on receptor signaling. They are most frequently used to block the action of a pharmacological agonist, usually a benzodiazepine. The only benzodiazepine antagonist in common use is flumazenil, which has a benzodiazepine structure.

Pharmacological Actions

Flumazenil is only used IV because extensive presystemic metabolism results in low bioavailability after oral dosing, and effective oral doses are too high to tolerate. With IV use, flumazenil has an elimination half-life of approximately 15 minutes. Flumazenil is metabolized to a free acid and a glucuronide, which are excreted in the urine. The drug is completely eliminated within 72 hours. Age and gender do not affect pharmacokinetics, but liver disease slows metabolism and prolongs half-life and action of flumazenil.

Flumazenil reverses CNS depression caused by benzodiazepines. Although alcohol and barbiturates act on the same complex, their primary action is not at the benzodiazepine receptor, and sedation and other signs of CNS depression caused by these substances are not antagonized by flumazenil. The effects of opioids, which act at an entirely different site, are not affected by flumazenil. Emergency treatment of a mixed overdose therefore may require opioid as well as benzodiazepine receptor antagonists.

Therapeutic Indications

Flumazenil is primarily indicated for reversal of benzodiazepine-induced CNS depression caused by intentional overdose or excessive administration during anesthesia. It has also been used experimentally to treat hepatic coma.

Precautions and Adverse Reactions

Common adverse effects include nausea, vomiting, dizziness, agitation, cutaneous vasodilation, headache, agitation, visual problems, memory impairment, and emotional lability. Benzodiazepine withdrawal may be precipitated abruptly, especially in patients who are tolerant to benzodiazepines. When administered to patients taking benzodiazepines, especially if they already have epilepsy, seizures may occur. Seizures can also be precipitated by flumazenil in patients who have had overdoses of TCAs.

Drug Interactions and Laboratory Interferences

The primary interaction of flumazenil is with benzodiazepines. In overdoses that include benzodiazepines and other medications, reversal of sedation from the benzodiazepine may uncover symptoms of intoxication of the other substances. If substances that induce seizures have been ingested along with the benzodiazepine, flumazenil may reverse the anticonvulsant, as well as the depressant, effect of the benzodiazepine, resulting in the emergence of seizures.

No interferences of flumazenil with laboratory tests have been reported.

Dosage and Administration

The starting dose of flumazenil is 0.2 mg (2 mL) given IV over 30 seconds. A 0.3-mg (3-mL) dose is added if the patient does not regain consciousness within 1 minute. This dose can be repeated up to a maximum total dose of 5 mg over approximately 5 minutes. If unconsciousness is not reversed with this dose, it is probably not caused by benzodiazepines, and further treatment with flumazenil is not likely to be of any additional benefit.

INVESTIGATIONAL DRUGS

Abecarnil is a beta-carboline benzodiazepine receptor partial agonist that has anxiolytic and anticonvulsant actions with minimal sedation and psychomotor impairment. This medication appears useful in treating GAD and uncomplicated alcohol withdrawal. Withdrawal symptoms have occurred after 3 to 6 months of treatment with higher doses, but abuse liability appears to be low. Abecarnil has not been released in the United States. Bretazenil, an imidazobenzodiazepine partial benzodiazepine receptor agonist, was found to be effective as monotherapy or adjunctive treatment in reducing symptomatology of severe refractory chronic schizophrenia. The antipsychotic effect was not a function of sedative or antianxiety actions. There was no evidence of withdrawal when the medication was withdrawn.

A benzodiazepine S-enantiomer, (S)-1-(2-fluorophenyl)-3-(2-oxo-5-phenyl-2,3-dihydro-1H-benzo[e][1,4]-diazepin-3-yl)-urea, or 17b (RSV604), was found to inhibit respiratory syncytial virus, a common cause of lower respiratory tract infections, and is now in clinical trials.

Naturally occurring flavones bind to the benzodiazepine receptor, and multiple synthetic flavonoids have been designed to have agonist and inverse agonist effects. The flavonoid 6-bromo-3′-nitroflavone, which has a structure derived from plants used in folk medicine as tranquilizers, is a high-affinity partial benzodiazepine receptor agonist that is ten times as potent as diazepam as an anxiolytic in animal studies. Sedation produced by this preparation occurs at doses much higher than doses that reduce anxiety, suggesting that it could be a well-tolerated antianxiety medication at lower doses. Perhaps because of differential affinities for

benzodiazepine-1 and benzodiazepine-2 receptors, it seems to have minimal muscle relaxant and amnestic effects.

Studies of point mutations of $GABA_A$ receptor subunits are beginning to identify targets for more specific drug action. For example, L838,417 acts on α2, α3, and α5 subunits of the benzodiazepine-$GABA_A$ receptor complex, possibly conveying an antianxiety effect without sedation.

Experimental ligands of the PBR receptor may prove useful as adjuncts in the treatment of illnesses in which enhancement or suppression of apoptosis may be useful. Micromolar concentrations of RO54864 and PK11195 have been found to enhance apoptosis induced by other agonists of the PBR site in a variety of tumor cell lines. Conversely, nanomolar concentrations of the same ligands were found to interfere with apoptosis induced by tamoxifen (Nolvadex) in breast cancer cells with and without estrogen receptors. This discrepancy may reflect differing effects (e.g., agonist vs. inverse agonist) at different concentrations, differential effects in different cancers, or variations in method. However, research is consistent in suggesting that medications that act as antagonists of the PBR may enhance apoptosis and may play an eventual adjunctive role in the treatment and possibly the prevention of cancer. An agonist effect at the PBR could help protect the brain from oxidative damage and could possibly reduce progression of some neurodegenerative diseases.

Indiplon, which is selective for the benzodiazepine-1 receptor, may prove useful for insomnia. Ocinaplon is a full agonist at benzodiazepine-1 receptors and a partial agonist at benzodiazepine-2 and -3 receptors that is in development as a treatment for GAD. It has fewer of the usual sedative side effects, but it may cause hepatotoxicity. ELB139 is a benzodiazepine-3 selective agonist with potential applications in anxiety disorders. Pagoclone is a cyclopyrroline that is a full agonist at benzodiazepine-3 receptors and a partial agonist at benzodiazepine-1 and -2 receptors that is well tolerated and is effective for panic attacks. SGS742 is an experimental $GABA_B$ agonist under study for improvement of cognition in Alzheimer disease and for absence epilepsy. Conversely, based on observations that baclofen causes cognitive impairment, $GABA_B$ antagonists are under development as potential cognitive enhancers. SGS742 is one such compound that is in phase II clinical trials for mild cognitive impairment, and CGP36742 has been found to improve cognitive function in animal studies. Results of phase II studies have not yet been reported for either compound. In human and animal studies, $GABA_B$ agonists have reduced substance craving, suggesting an interesting direction for new drug development.

▲ 34.11 Bupropion

CHARLES DEBATTISTA, M.D., AND ALAN F. SCHATZBERG, M.D.

Originally introduced in the 1980s bupropion (Wellbutrin) is one of the more commonly prescribed antidepressants in the United States. As a result of a unique pharmacology, bupropion is often used as an alternative to SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs). In addition to its FDA approval in the treatment of depression, bupropion is also approved for smoking cessation and is the only antidepressant to receive FDA approval for the preventive treatment of seasonal affective disorder (SAD). Additionally, bupropion is used for numerous off-label indications including the treatment of ADHD, sexual dysfunction, obesity, and fatigue related to nonpsychiatric medical condition. Currently, all formulations of bupropion are generically available and the major metabolite of bupropion, hydroxybupropion, is being investigated as a potential antidepressant.

PHARMACOLOGY

Pharmacodynamics

The pharmacodynamics of bupropion remains in debate. Although frequently described as a noradrenergic agonist/dopamine reuptake inhibitor, the human in vivo effects of bupropion on dopamine appear rather modest. Animal studies have indicated that bupropion is associated with an increase in nucleus accumbens dopamine concentrations and it appears to inhibit the reuptake of dopamine more potently than do tricyclics. However, human studies have not consistently shown a dopamine effect. For example, some PET studies have shown that bupropion increases occupancy of the dopamine transporter as a dopamine reuptake inhibitor should but others have shown no effect. Likewise, concentrations of homovanillic acid (HVA), a major metabolite of dopamine, do not appear to rise in clinical responders, although they may rise in nonresponders.

The effects of bupropion on noradrenergic activity appear more consistent than its dopamine effects. Bupropion reduces the 24-hour excretion of norepinephrine and its metabolites. Bupropion and its active metabolites, hydroxybupropion, erythrobupropion, and threohydroxybupropion, inhibit the reuptake of norepinephrine in rat cortex, although much less potently than does imipramine. Downregulation of beta-adrenergic receptors and decreased firing of norepinephrine cells in the locus ceruleus have been reported in animal studies. In addition, chronic administration of bupropion appears to modestly inhibit the

tyrosine hydroxylase activity.

Bupropion became the focus of investigation by medicinal chemists in the 1960s when it appeared to be effective in standard screening models of antidepressants but lacked many of the properties of the TCAs and MAOIs that make both classes problematic to use. These include muscarinic side effects, tyramine pressor effects, hypotension, and so forth. Bupropion is not a significant inhibitor of serotonin reuptake, an agonist of 5-HT_{1A} receptors, or an antagonist of 5-HT_2 receptors. The lack of significant serotonergic effects is thought to be the major factor in bupropion's lack of sexual side effects and its general lack of efficacy in anxiety disorders.

Pharmacokinetics

Bupropion is a racemic mixture of enantiomers and is rapidly absorbed. This absorption is not substantially affected by concurrent food of anticholinergic administration. The peak blood level occurs within 2 hours of administration, and bupropion is tightly bound to protein (80 to 90 percent). Protein binding for hydroxybupropion is similar to bupropion, while the other metabolites are about half as tightly bound as bupropion.

Elimination of bupropion is biphasic, consistent with what has been referred to as a "two compartment model," that is, after distribution serum levels are in equilibrium between the intravascular and extravascular compartments. The terminal mean half-life is about 21 hours, while the distribution phase half-life is about 4 hours. Hydroxybupropion may have a half-life as long as 45 hours.

Bupropion undergoes extensive first-pass metabolism with only 1 percent of the drug excreted unchanged in the urine. Most elimination is fecal. Bupropion is a substrate for the CYP450 2B6 isoenzyme, which is not commonly inhibited or induced by other drugs. Oncology agents such as thiotepa (Thioplex) for meningeal neoplasms are among the rare potent inhibitors of 2B6, while barbiturates, such as phenobarbital (Bellatal), may induce the enzyme.

CLINICAL USES

Depressive Disorders

Bupropion has long been known to be an effective antidepressant. It appears to be comparable in efficacy to both TCAs and SSRIs. Most studies with bupropion have involved outpatients with mild to moderate depression. However, inpatient studies with more severely depressed patients have also indicated benefit. Small open-label studies in children and adolescents suggest benefit of bupropion in pediatric depression, but no controlled studies are available. Geriatric depression studies indicate that bupropion in lower doses may be effective and well tolerated. Case reports suggest occasional worsening of psychotic features in patients with

delusional depression.

Unlike most antidepressants, the efficacy of bupropion in treating MDD with concomitant anxiety or anxiety disorders is not well established. Some studies in depressed patients have reported comparable anxiolytic effects of bupropion to SSRIs. However, most studies of bupropion in the treatment of panic disorder have failed to show benefit. Likewise, no controlled trials have been completed that demonstrate clear benefit of bupropion monotherapy for GAD, PTSD, or other anxiety disorders. On the other hand, anxiety may be a consequence of bupropion treatment on occasion.

Among the most common applications of bupropion is in the augmentation of response to other antidepressants. Thus, it is frequently combined with SSRIs, SNRIs, or mirtazapine in patients who have shown inadequate responses to monotherapy. It makes intuitive sense that the combination of a noradrenergic and perhaps dopaminergic molecule such as bupropion might.

Among the largest trials to evaluate the efficacy of bupropion augmentation to date is the Sequenced Treatment Alternatives in Resistant Depression (STAR*D) trial. In that study, patients who had failed citalopram (Celexa) treatment could opt to be randomized to either buspirone (BuSpar) or bupropion augmentation. Both treatments were equally effective with about 30 percent of patients achieving remission after failing citalopram monotherapy. Bupropion was somewhat more effective than buspirone in overall reduction of depressive symptoms. However, the lack of a placebo arm makes it difficult to determine whether either augmenting strategy was more effective than would be longer treatment with citalopram alone.

Given the low remission rates to monotherapy of major depression with antidepressants, attempts have also been made to initiate combined treatment with bupropion and an SSRI as a way of enhancing the speed of onset and remission rates. A randomized controlled study of 245 MDD patients compared the combination treatment with escitalopram and bupropion to monotherapy with either escitalopram or bupropion. No advantage was found for the combination treatment with bupropion to either monotherapy in speed of response or overall remission rates.

Bupropion is commonly used adjunctively with antidepressants to treat SSRI-induced sexual side effects. Again, the rationale for using a dopaminergic agent, even a modest one, to impact sexual side effects appears sound. Stimulants and other dopamine-enhancing agents enhance libido. Although case reports and open studies supported the use of bupropion, several placebo-controlled trials have not demonstrated substantial benefit in depressed patients. Two studies at 150 mg per day of bupropion sustained release (SR) added to an SSRI did not report significant benefit over placebo in treating sexual side effects; one study at 300 mg per day did demonstrate mild efficacy. The benefit of adding

bupropion to a serotonergic antidepressant may be more evident in women than men. A randomized controlled study of 218 women with antidepressant-induced sexual side effects found that 300 mg per day of bupropion added to an existing antidepressant was significantly more effective than placebo in increasing libido, and to a lesser extent, arousal. Switching from a serotonergic antidepressant to bupropion also appears to be an effective strategy to reduce sexual side effects in both men and women.

Bupropion was approved for the preventive treatment of SAD in 2006. In a series of three trials, 1,042 patients who met criteria for SAD were treated in the autumn while they were still well. Patients were randomized to receive either 150 to 300 mg per day of bupropion extended release (XL) or placebo and then followed through the spring. On average, patients had 13 previous seasonal depressive episodes. Patients on placebo were significantly more likely to experience fall/winter depressive episodes than were bupropion-treated patients. Placebo-treated patients were also more likely to have a recurrence of depression sooner than were those on bupropion. To date, no other antidepressants have received an indication in the treatment of SAD.

Bupropion has been favored as an adjunctive treatment for bipolar depression secondary to the perception that it might be less likely to induce switches into mania or more rapid cycling. This perception, however, is based on very few data. Few large prospective studies have evaluated the utility and safety of bupropion in bipolar depression. The largest study to date to evaluate bupropion in bipolar disorder was a part of the NIMH-funded Systematic Treatment Enhancement Program for Bipolar Disorder (STEP BD) study. In that study, patients with bipolar depression on a mood stabilizer were randomized to the addition of bupropion or paroxetine (Paxil) versus the addition of placebo. Patients were treated for 26 weeks and evaluated to determine if they had at least 8 weeks of recovery. Neither bupropion nor paroxetine was significantly better than placebo on achieving a durable recovery from the bipolar depressive episodes. In fact, on some measures placebo-treated patients fared somewhat better. The rate of switches into mania also did not differ between bupropion, paroxetine, and placebo in patients on therapeutic doses of standard mood stabilizers. A study supported by the Stanley Foundation likewise showed relatively low switch rates of bupropion in an acute bipolar trial. The response rate in this study was about 50 percent with about a 10 percent switch rate. Thus, the utility of bupropion in bipolar depression is still uncertain, but switch rates of bupropion when combined with standard mood stabilizers appear low.

Smoking Cessation

Beyond the treatment of depression, the only other FDA indication for

bupropion (SR) is for the promotion of smoking cessation. Early conceptualization about the mechanism for its efficacy in nicotine withdrawal and cravings included bupropion's effects on dopamine reuptake and an influence on reward mechanisms in addictive states. Indeed, there is evidence that dopamine polymorphisms have some predictive value in determining the efficacy of bupropion in smoking cessation. However, more current thinking is that bupropion may have significant, although indirect, effects on nicotine receptors. For example, bupropion may mimic nicotinic effects on dopamine and norepinephrine, which may attenuate withdrawal symptoms. In addition, there is some evidence of direct antagonism of nicotine receptors, which might prevent relapse by diminishing the reinforcing properties of nicotine. In addition, bupropion appears to act as a noncompetitive α3β4 nicotinic antagonist. Despite additional understanding, the mechanism in bupropion for smoking cessation remains unclear, but bupropion appears unlike the nicotine-specific therapies such as the nicotine substitutes (nicotine patch/gum) or the partial nicotine receptor agonist varenicline (Chantix). There is evidence that the major metabolite of bupoprion, hydroxybupropion may mediate the smoking cessation effects of drug. Since there are polymorphisms for the CYP2B6 isoenzyme that is responsible for the metabolism of bupropion to hydroxybupropion, slow metabolizers of CYP2B6 may require higher doses to achieve a serum level of 0.7 mcg/mL as these doses may predict better response to bupropion therapy for smoking cessation.

Overall, bupropion appears to be about twice as effective as placebo in reducing acute nicotine withdrawal symptoms, nicotine cravings, and maintaining abstinence. For example, bupropion has been associated with less mood instability and weight gain after acute withdrawal of tobacco. In one pivotal trial, only 27 percent of patients experienced nicotine cravings 1 month after smoking cessation on bupropion 300 mg per day versus 56 percent of those on placebo. About 30 percent of patients on bupropion are able to quit after 1 to 3 months versus about 15 percent of placebo-treated patients. After 1 year of treatment, patients who remain on bupropion are about 1.5 times as likely to remain abstinent as placebo-treated patients. Bupropion also appears effective in specific populations with nicotine addictions including those with chronic obstructive pulmonary disease (COPD), cardiovascular illness, concurrent alcoholism, schizophrenia, and those with comorbid depression.

Direct comparisons with nicotine-specific therapies are few. Bupropion appears to be at least as effective as nicotine replacement with a nicotine patch, but the combination of bupropion and the nicotine patch may not offer benefit over either therapy alone. For example, the addition of bupropion to a nicotine patch did not offer benefit over the addition of placebo in a 26-week study of smoking cessation in adolescents. At least

two head-to-head comparisons with varenicline tartrate 1 mg twice daily indicated that varenicline may be somewhat more effective in the acute and long-term management of smoking cessation. The combination of varenicline and bupropion may be more effective than either treatment alone.

The usual starting dose of bupropion SR for smoking cession is 150 mg per day, with a target dose of 300 mg per day within 7 days. An acute course of bupropion tends to last 8 to 12 weeks with tobacco stopped within the first 2 to 3 weeks of treatment. Responders may continue bupropion treatment chronically to prevent relapse.

Obesity and Eating Disorders. The FDA approved the combination of bupropion and naltrexone for the treatment of obesity in 2014. Four large registration trials involving over 4,500 patients were completed in overweight BMI >27 to obese BMI >30 patients (mean BMI = 36). The general design of these studies was 3 weeks of dose titration followed by approximately 1 year of treatment. Subjects were randomized to the combination of naltrexone (15 to 60 mg) and bupropion (300 to 400 mg) along with dietary modifications (e.g., reducing daily calories by 500 kcal/day), behavioral counseling, and an increase in exercise or physical activity versus the control group included with these interventions with a placebo instead of the active drug. In all four trials, subjects randomized to the active group were more likely to lose clinically meaningful amount of weight defined as >5 percent or >10 percent of total body weight. In addition, subjects on the combination of bupropion (mean dose 360 mg per day) and naltrexone (mean dose 32 mg per day) lost about 5 percent more of total body weight versus subjects in the control group.

A large percentage of patients in both the active and control groups of the naltrexone/bupropion obesity studies dropped out before completing the 1 year end point. In fact, approximately 45 percent of both groups dropped out early with subjects in the active group twice as likely to drop out as subjects in the control group (24 percent vs. 12 percent). The most common side effects leading to discontinuation of the combination treatment were nausea, headache, and vomiting. Other common side effects of the combination of naltrexone/bupropion constipation,

Bupropion alone also has mild anorexiant effects that have been evaluated in nondepressed obese patients. Approximately 25 percent of patients in acute depression trials lost 5 lb or more while taking bupropion. Several controlled studies have evaluated 300 to 400 mg per day of bupropion in the treatment of obesity. These studies have indicated that bupropion-treated patients tend to lose 1.1 to 4.5 kg at 6 to 12 months, and this is significantly greater than placebo-treated patients. Bupropion has also been investigated in the treatment of binge eating disorder. The largest randomized, placebo-controlled trial to date (n = 61) did not find the

bupropion to reduce binging or to improve weight loss in women with the disorder.

Other Clinical Uses

In addition to the FDA-approved indications in the treatment of major depression and for smoking cessation, bupropion has been clinically tested for a number of other conditions. For example, as with other noradrenergic antidepressants such as nortriptyline (Aventyl), bupropion may be useful in the treatment of adult ADHD. In pediatric populations, the only large controlled trial did not show significant benefit of bupropion on the primary outcome measures. However, in this trial, teachers rated the bupropion-treated children as less aggressive and hyperactive relative to placebo-treated children. Clinicians and parents did not observe a significant difference. There a few direct comparisons of bupropion with stimulants; however, these studies revealed that bupropion is either about as effective or somewhat less effective. A small randomized trial (n = 44) comparison of bupropion and methylphenidate found that both drugs were equally effective and well tolerated. Studies of bupropion in adults with ADHD have been more consistently positive. For example, in a study of 162 adults with ADHD 53 percent of patients responded to bupropion XL versus 31 percent of placebo-treated patients. Benefits over placebo were noted as early as week 2, and bupropion, with an average dose of 450 mg per day, was well tolerated.

Finally, bupropion has been suggested to be of benefit in a number of small studies and case series for a broad spectrum of conditions. These have included sexual dysfunction in nondepressed patients, fatigue in cancer patients, the treatment of amphetamine addiction, lowering tumor necrosis factor-α, and improving concentration in patients without ADHD.

SIDE EFFECTS

The pharmacodynamics effects of bupropion result in a side-effect profile different from most antidepressants. Many of the adverse events reported with bupropion are associated with its noradrenergic, and to a lesser extent, dopaminergic effects. For example, CNS activation is associated with bupropion treatment. Insomnia is one of the common side effects of bupropion, affecting at least 11 percent of patients in clinical trials. Anxiety and agitation may occur as treatment emergent effects. At least 6 percent of patients in clinical trials also experienced a mild to moderate tremor. Treatment emergent psychotic symptoms have rarely been reported in depressed patients.

The risk of seizure with the immediate release (IR) formulation of bupropion became evident in studies of eating disorder patients initially and lead to withdrawal of the drug in 1986. Patients in the eating disorder

trials were treated with up to 600 mg per day of bupropion. Analysis of data sets revealed an enhanced risk of seizure in patients with a history of eating disorders, head trauma, or previous seizure disorder. Also, doses above 450 mg per day or 200 mg at one time (for the IR formulation) enhanced the risk of seizure. For extended-release formulations at doses of 450 mg per day or less, the seizure risk is estimated at 0.1 to 0.2 percent, which is comparable to the rates reported with SSRIs and may be less than the rates reported with some TCAs and maprotiline (Novo-Maprotiline).

Other common side effects reported in trials included nausea, dry mouth, excessive sweating, tinnitus, and rash. The most common reasons patients discontinued bupropion in acute clinical trials in depression were nausea and rash.

Bupropion has a favorable cardiovascular profile with few cardiac effects. Bupropion is not known to have clinically significant effects on blood pressure, heart rate, or cardiac conduction. Thus, bupropion is commonly used in patients with known cardiac pathology. However, there have been rare reports of significant hypertension associated with bupropion in patients with and without a pre-existing history of high blood pressure.

Side effects common to many antidepressants (including sexual side effects and weight gain) appear uncommon with bupropion. As noted earlier, bupropion has been associated with weight loss, and there are many reports of improved sexual functioning, including increased libido and arousal, with the drug.

Other side effects such as hepatoxicity, hematopoietic changes, and severe headaches occur rarely in bupropion-treated patients. Thus, the side-effect profile makes bupropion an important alternative to many patients who cannot tolerate other antidepressants.

DRUG INTERACTIONS

The limited cytochrome P450 interactions of bupropion contribute to its few drug interactions. Since bupropion and hydroxybupropion are metabolized via the cytochrome P2B6, there is a theoretical risk of an interaction between oncology agents such as IV thiotepa and the muscle relaxant orphenadrine (Norflex). Hydroxybupropion is a weak to moderate inhibitor of cytochrome P450 2D6 and has been associated with increasing serum levels of some 2D6-dependent drugs such as venlafaxine (Effexor) and desipramine (Norpramin). Rare seizures that have occurred in combination of fluoxetine (Prozac) and bupropion have sometimes been attributed to inhibition of the metabolism of hydroxybupropion by 2D6 inhibitors, but seizures can occur independent of these potential interactions, so it is unclear whether this mechanism was at play.

Since bupropion may lower the seizure threshold, particularly when the IR form is used in higher doses, combination with other drugs that lower

the seizure threshold, such as some tricyclics, amoxapine (Asendin), clozapine (Clozaril), and theophylline (Elixophyllin), have sometimes been associated with seizures.

As with other antidepressants, the concurrent administration with MAOIs is contraindicated. However, there have been few reports in the literature of serious interactions with MAOIs. Oral selegiline (Carbex) at doses of 10 mg per day or less have sometimes been combined with bupropion without incident.

OVERDOSE

Bupropion has rarely been associated with fatalities in monotherapy overdoses. Overdoses of bupropion as low as 10 g have sometimes been associated with deaths. Causes of death in these overdoses have included complications of status epilepticus and arrhythmias. Although therapeutic doses of bupropion are rarely associated with cardiovascular effects, overdoses have sometimes been associated with tachycardia, intraventricular conduction delays, and QRS complex widening. Treatment for overdoses includes lavage, seizure treatment or prophylaxis, cardiac monitoring, and vital sign support. Most patients who overdose on bupropion recover.

DOSING AND FORMULATIONS

Bupropion hydrochloride is available in IR, SR, and XL forms. As of 2006, all of these formulations had become available as generics in the United States. The usual starting dose in all formulations is 150 mg per day taken in the morning, but the IR form was often started at 100 mg twice a day. The average therapeutic dose of bupropion for the treatment of depression is 300 to 450 mg per day. Doses above 200 mg at once are associated with greater seizure risk in the IR form. Thus, at maximum doses, compliance to bupropion IR prescriptions was somewhat difficult when dosed at 150 mg three times a day. In contrast, the typical therapeutic dose of the SR form was 150 or 200 mg twice a day. The XL form could be taken all in one morning dose, which was said to have more consistent blood levels and perhaps less sleep disruption. A cellulose coating in XL formulation allowed for slow absorption.

In smoking cessation, bupropion SR is typically started at 150 mg per day and then increased to the target dose of 300 mg per day.

▲ 34.12 Buspirone

MOLLY M. MCCARTHY, D.O., AND REGINA M. CARNEY, M.D.

INTRODUCTION AND HISTORY

The azapirones are a unique pharmacological class of medications that includes buspirone, an azaspirodecanedione derivative, and its second-generation compound gepirone. Two other related compounds are ipsapirone and tandospirone. Since its synthesis in 1968 in the laboratories

of Mead Johnson, this class of medications has been studied for its potential antidepressant and anxiolytic effects. Although it was initially developed as an antipsychotic drug thought to act primarily on dopamine receptors, buspirone was later found to exert its clinical effects by working on the serotonergic system, specifically on the serotonin 1A ($5\text{-}HT_{1A}$) receptor subtype. Studies conducted in the 1970s revealed that a single dose of buspirone improved aggressive behavior in rhesus monkeys. Furthermore, buspirone showed marked anxiolytic effects in behavioral models of anxiety in rodents in the early 1980s. Eventually, a phase II study in patients with DSM-II anxiety disorder showed improvement in symptoms with treatment of buspirone as compared with placebo, leading to FDA approval for generalized anxiety disorder (GAD) in 1986. By that time, the newest DSM classification system, DSM-III, had replaced anxiety neurosis with the diagnostic category of GAD. FDA approval for the treatment of GAD with buspirone reflected this change. This drug was the only nonbenzodiazepine medication approved by the FDA for treatment of the disorder. Other potential clinical uses have since been explored, such as treatment for other anxiety disorders (e.g., social anxiety disorder, OCD, PTSD, panic disorder), depressive disorders, eating disorders, and attention-deficit/hyperactivity disorder (ADHD). To date, buspirone has been indicated for the treatment of GAD and anxiety associated with depressive symptoms.

PHARMACOLOGICAL ACTIONS

Buspirone hydrochloride (BuSpar) belongs to a group of compounds known as the azaspirodecanediones and has been shown to act on two types of receptors: Serotonin (5-HT) and dopamine (D). It has high affinity for the $5\text{-}HT_{1A}$ serotonin receptor, acting as an agonist or partial agonist, and moderate affinity for the D_2-dopamine receptor, acting as both an agonist and antagonist. The approved indication for this psychotropic drug is for the treatment of GAD. It was initially believed to be a better alternative to the benzodiazepine drug group since buspirone does not exert strong sedative effects and does not possess the same potential for dependence. However, it is more currently believed that although the azapirones, including buspirone, are better tolerated than benzodiazepines, combined evidence reveals that they are not more effective.

PHARMACOKINETICS

Absorption

Buspirone undergoes extensive first-pass metabolism when ingested orally, with an absolute bioavailability of 4 percent. A 20-mg dose of buspirone led to peak plasma concentrations of 1 to 6 μg/L (C_{max}) from 0.7 to 1.5 hours

following administration (T_{max}). Studies in humans have shown that buspirone exhibits linear pharmacokinetics over the 10- to 40-mg dose range. Outside of this dosing range, buspirone no longer holds this relationship. Taking buspirone with food affects bioavailability, increasing the area under the plasma concentration-time curve (AUC) by 84 percent and the C_{max} by 116 percent. Patients with hepatic impairment, defined by the Child–Pugh classification system, had a 13-fold increase in AUC.

Distribution

Following first-pass metabolism, the remaining drug enters the systemic circulation. The volume of distribution is 5.3 L/kg following intravenous (IV) administration. Buspirone and its major active metabolites 6-OH-buspirone and 1-pyrimidinylpiperazine (1-PP), all readily cross the BBB. A recent in vivo study demonstrated that its active metabolite 6-OH-buspirone localized in the hippocampus and the dorsal raphe nucleus. Buspirone and its metabolites have also been reported in the lungs and kidneys. In vitro studies have indicated that 86 to 95 percent of the drug is bound to plasma protein. In vivo studies in rats have indicated that both buspirone and its metabolites are found in maternal milk and cross the placenta, although it is not known to what extent both these events occur in humans.

METABOLISM AND ELIMINATION

Buspirone is metabolized through oxidation by cytochrome P450 3A4 (CYP3A4). CYP3A4, the most abundant form of cytochrome P450 in the human adult liver, is polymorphic and thus shows wide interindividual variation in its activity. Main metabolic pathways include hydroxylations on the 6′-position on the spiro ring system (6-OH buspirone) and the 5′-position on the pyrimidine ring of the drug complex (5-OH buspirone), as well as a *N*-dealkylation of a butyl side group, forming 1-PP. Approximately 26 percent of buspirone was found to be converted to 1-PP, and this metabolite had a 49-fold greater AUC than that of buspirone but conversely had 25 percent of the potency of the parent compound.

Another major active metabolite is 6-OH-hydroxybuspirone. This metabolite was found to have 12 times greater mean AUC in the brain compared to the parent compound. Similar to the parent compound, 6-OH-hydroxybuspirone had four times greater affinity for presynaptic 5-HT_{1A} receptors in the dorsal raphe nucleus compared to postsynaptic 5-HT_{1A} located in the hippocampus. As expected, given that CYP3A4 is polymorphic, the mean half-life ($t_{1/2}$) of buspirone varied greatly between healthy individuals, with a minimum of 2 to 3 hours and a maximum of 11 hours after a single dose of 10 to 40 mg. The mean half-life of 1-PP was 6 hours following a 20-mg dose. In subjects with renal impairment, defined

as improper creatinine clearance, the half-life of buspirone increased, on average, by 2 hours.

PHARMACODYNAMICS

Mechanism of Action

Buspirone has a unique mechanism of action from other anxiolytics, such as the widely used benzodiazepines, as it does not bind to the GABA receptor. Although the exact mechanism of action is not fully understood, it is thought to involve a combination of systems, mainly, the serotonergic and dopaminergic systems.

Serotonin System

Buspirone functions as a full agonist at presynaptic 5-HT_{1A} autoreceptors, as a partial agonist at postsynaptic 5-HT_{1A} receptors, and as a weak antagonist at 5-HT_{2C} receptors. The activation of somatodendritic 5-HT_{1A} autoreceptors in the midbrain raphe nuclei has been demonstrated to decrease the synthesis of serotonin (5-HT) in rats. This is believed to be the mechanism of action that may explain buspirone's therapeutic effect. Moreover, activation of postsynaptic 5-HT_{1A} receptors located in the hippocampus resulted in decreased neuron excitability, which could explain the antidepressant effects of buspirone. A combination of buspirone and the SSRI citalopram (Celexa) was observed to cause a downregulation in 5-HT_{2A} and 5-HT_{2C} and may be the source of the effectiveness of buspirone in augmentation therapy for nonresponders to SSRI treatment.

Dopaminergic System

The dopaminergic system is another site of action of buspirone. Buspirone has been categorized as both an agonist and antagonist to the D_2 subtype of the dopamine receptor. Buspirone acts as an antagonist to presynaptic dopamine antagonist autoreceptors, but some evidence has also pointed to the involvement of postsynaptic DA receptors. The activation of these receptors increased dopamine antagonist synthesis and metabolism in the striatum and nucleus accumbens. Other studies have suggested that buspirone can function as a full dopamine agonist and could also antagonize D_1-dopamine receptors.

GABAergic System

As previously mentioned, buspirone has no affinity for the benzodiazepine-binding site on the GABA receptor, nor does it affect the binding of this drug group or the binding of the GABA receptor to its natural ligand.

Despite this fact, there has been some suggestion that buspirone can indirectly affect the GABAergic system, as buspirone was found to increase the level of binding of flunitrazepam in an in vivo model. Further studies are needed to explore the implications of this effect.

Norepinephrine System

Administration of buspirone in humans has been found to interact with both the α_1-adrenergic and β-adrenergic systems, with plasma levels of noradrenaline increased significantly along with a decrease in systolic blood pressure and heart rate. One of the major metabolites of buspirone, 1-PP, has antagonistic properties to α_2-adrenergic receptors.

Cholinergic System

Binding evidence has shown that buspirone has no binding affinity for muscarinic cholinergic receptors, but some evidence indicates the possibility of an indirect relationship with this system. Administration of buspirone caused an efflux of acetylcholine in the rat hippocampus, which led to a modest increase in motor activity and was observed to have a trophic effect on septal cholinergic-containing neurons.

Blood Concentration and Relation to Action

There is no evidence tightly linking plasma concentrations to the therapeutic effects of buspirone.

CLINICAL TRIALS

Generalized Anxiety Disorder

Several double-blind, randomized, placebo-controlled trials have established the anxiolytic efficacy of buspirone. Most monotherapy studies have focused on the treatment of GAD, with the majority of trials finding buspirone to be significantly associated with greater reduction in anxiety symptoms compared to placebo. Standard outcome measures of severity of anxiety symptoms (Hamilton Anxiety [HAM-A] scale) and global improvement (Clinical Global Impressions [CGI] scale) were generally employed. A recent clinical trial examined the use of buspirone or placebo in conjunction with anxiety management therapy (AMT) or nondirective therapy (NDT). All four treatment groups exhibited a significant reduction in anxiety symptoms, but there was no significant difference between any of these groups. Although each of these trials required a diagnosis of GAD, it is worthwhile to note that the definition of GAD has shifted over time, with the required duration of anxiety symptoms lengthened from 1 month (third edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-III]) to 6 months (DSM-III-R, DSM-IV). Early buspirone clinical

trials used DSM-III criteria for GAD, while more recent clinical trials utilized DSM-III-R or DSM-IV criteria for GAD. It is possible that those initial studies may have had many subjects with an anxiety disorder that would not have been sufficiently chronic to be currently classified as GAD. Early studies found buspirone to be statistically inferior or equivalent to benzodiazepines in the acute reduction of anxiety symptoms in GAD. One clinical trial found buspirone to have significantly less anxiolytic efficacy than either lorazepam (Ativan) or alprazolam (Xanax). However, another study did not find any statistical difference between buspirone and alprazolam with respect to reduction of anxiety symptoms and the same conclusion was reached in a trial between buspirone and diazepam (Valium). It has also been demonstrated that recent benzodiazepine treatment negatively predicts treatment response to buspirone. This study found no significant difference in response to buspirone or diazepam in patients with no prior exposure to benzodiazepines, but that diazepam was significantly more effective than buspirone at reducing anxiety symptoms in patients with recent exposure to benzodiazepines. These buspirone versus benzodiazepines studies all made use of the DSM-III criteria for GAD. There have been no recent studies comparing buspirone to benzodiazepines. A recent study found no statistical difference between buspirone and venlafaxine XR (Effexor XR) in reducing anxiety symptoms in GAD. Serotonergic antidepressants are often used as first-line treatments for GAD, and the paucity of studies comparing buspirone to SSRI antidepressants is a large gap in the available literature. Further trials are required to compare the use of standard treatment for GAD (i.e., SSRIs) with buspirone to adequately understand the role of buspirone for this indication. An interesting recent study found no statistical difference between buspirone and kava-kava with respect to reducing anxiety symptoms in GAD. Kava-kava is an herbal medication with constituents that putatively act both as a monoamine oxidase B (MAO-B) inhibitor and as a norepinephrine reuptake inhibitor. Another trial found buspirone to be equivalent to hydroxyzine (Vistaril) in reducing anxiety symptoms in GAD. Hydroxyzine is a first-generation antihistamine of the piperazine class that acts via antagonism of the H_1 receptor. Further data comparing buspirone to other alternative pharmacological and nonpharmacological interventions are warranted.

Other Anxiety Disorders

Several clinical trials have also examined the role of buspirone in the treatment of other anxiety disorders such as panic disorder OCD, and PTSD. Double-blind, randomized, placebo-controlled trials found that buspirone was not significantly superior to placebo in treating patients with panic disorder. In addition, one of these trials also found alprazolam to be

superior to buspirone and placebo with respect to its antipanic and anxiolytic effects. With respect to PTSD, smaller, open-label trials found buspirone to be effective in alleviating symptoms such as anxiety, insomnia, flashbacks, and depressive state. In one of these studies, seven of eight patients exhibited a significant reduction in symptoms as measured by the Structured Inventory for PTSD (SI-PTSD) and the Beck Depression Inventory (BDI) after usage of buspirone as a monotherapy. In another trial, 12 combat-related PTSD patients exhibited a 40 percent reduction in reexperiencing symptoms after usage of buspirone as an adjunct therapy.

The promising results from these smaller, open-label trials highlight the need for larger, placebo-controlled studies. Several double-blind, randomized, placebo-controlled trials have evaluated buspirone augmentation of antidepressant treatment for patients with OCD. These trials found no significant improvement in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores associated with the addition of buspirone. Two trials added buspirone to SSRI therapy (fluoxetine [Prozac] and fluvoxamine [Luvox]), and another used buspirone as an adjuvant therapy to the TCA clomipramine (Anafranil). The use of buspirone as adjunct treatment for OCD is therefore not supported by the current evidence.

Major Depressive Disorder

Several large, double-blind, randomized, placebo-controlled trials have examined the efficacy of buspirone in treating patients with MDD. These clinical trials have generally shown buspirone to be significantly superior to placebo in reducing depressive symptoms. One study compared buspirone to placebo as adjunct therapy to citalopram in patients who were treatment refractory to this SSRI. This trial found buspirone to be significantly more effective at reducing depressive symptoms in these patients than placebo. Most of these trials used the HAM-D scale as the standard outcome measure of severity of depressive symptoms, although the Montgomery-Asberg Depression Rating Scale (MADRAS) was also employed in this capacity. More recent studies have evaluated buspirone as augmentation to SSRI treatment for MDD. The NIMH-sponsored Sequenced Treatment Alternatives in Resistant Depression (STAR*D) trial included an arm of the study in which patients who did not remit during a treatment course with citalopram were treated with the addition of either bupropion sustained release (SR) (Wellbutrin XL) or buspirone. Although there was no significant difference between response to buspirone and bupropion SR, both adjuvant therapies exhibited a clinically meaningful reduction in HAM-D scores in these treatment-refractory MDD patients, with remission rates of 30.1 and 29.7 percent, respectively. Table 34.12–1 provides a summary of clinical trials of buspirone.

Other Uses

Alcohol and Cannabis Dependence. Buspirone usage has also been examined in alcoholism. One clinical trial found that while buspirone reduced anxiety symptoms in male veterans, this change was not significantly different from the reductions associated with placebo. In addition, that study also found buspirone to be statistically equivalent to placebo with respect to standard measures of alcohol consumption, such as time to first drink and number of standard drinks per drinking day. Similarly, a meta-analysis of five double-blind, RCTs concluded that buspirone was not statistically significantly superior to placebo in reducing alcohol consumption. That report did, however, highlight the positive effects of buspirone on treatment retention and anxiety. The authors suggested that while buspirone did not affect alcohol consumption, it may mediate associated psychopathological symptoms. Given its favorable side-effect profile and lack of interaction with alcohol, buspirone may have a role as an adjunct therapy in the treatment of comorbid anxiety and alcoholism.

Treatment of cannabis (marijuana) dependence with buspirone was compared to placebo in a single study of 50 individuals titrated to a target dose of 60 mg daily and treated for 12 weeks. There were no significant differences between the buspirone-treated individuals and those receiving placebo on self-reported and urine drug detection measures of cannabis use. Secondary outcome measures (time to first negative urine drug screen result, summary measures of self-reported use, and measures of marijuana craving/withdrawal symptoms and anxiety) suggested a trend toward faster time to first negative urine drug screen and a reduction in overall positive urine drug screens for those individuals in the buspirone-treated group.

Smoking Cessation. The efficacy of buspirone as a means of promoting smoking cessation has been evaluated in open-label trials and a small number of RCTs. The evidence of efficacy remains inconclusive. A comparison between buspirone and nicotine transdermal patches found both treatments had similar cessation rates, while another study looking exclusively at buspirone found that the greatest improvement was observed in patients who had high anxiety. In a more recent study, buspirone coadministered with sertraline (Zoloft) was found to lead to improved abstinence rates (43.5 percent for the drug group compared to 17.3 percent for the control) at 26 weeks following smoking cessation (n = 98).

NS, no significant difference; (+), significantly greater improvement in primary efficacy measure for buspirone arm; (−), significantly greater improvement in primary efficacy measure for comparator arm; NK, not known (unpublished).

Agitation. The possible role of buspirone in the management of behavioral and psychological symptoms of dementia (BPSD), in the context of Alzheimer disease (AD), has been examined. Buspirone was compared to trazodone (Desyrel) and placebo in AD patients with behavioral symptoms (n = 10) in a 12-week study. Only subjects taking trazodone, not buspirone, showed improvement compared to placebo. In another study looking at an AD population, buspirone (n = 12) was compared to haloperidol (Haldol) (n = 14) for the treatment of agitation. Subjects taking buspirone demonstrated a near-significant drop in tension when compared to subjects taking haloperidol (11 percent reduction in tension scores for buspirone versus 1.6 percent for haloperidol).

Psychosis. Buspirone has not demonstrated any clear efficacy in the treatment of psychosis. In the context of schizophrenia, efficacy has not been observed in the treatment of either positive or negative symptoms. An RCT using a population with a diagnosis of schizophrenia found that patients taking buspirone (n = 30) had a significantly greater improvement

in cognitive scores compared to placebo (n = 29) following 6 months of treatment, although no significant improvement in psychotic symptoms was observed. A number of open-label studies in the schizophrenic population have shown contradictory evidence, where a 6-week trial found that subjects taking buspirone (n = 20), in addition to a stable dose of an antipsychotic, demonstrated significant improvement in outcome scores, while showing no worsening of tardive dyskinesia and akathisia. Conversely, a smaller study (n = 7) found no benefit and worsening of akathisia.

Somatic Dysfunction. Fibromyalgia patients (n = 22) were found to have an augmented prolactin response compared to healthy controls (n = 14) when challenged with a single dose of buspirone. The researchers concluded that dopaminergic neurotransmission was altered in fibromyalgia via the D_2 receptor and that the onset of this disease may be associated with anxiety. Buspirone has also been investigated in its role for altering colonic sensorimotor function in healthy subjects. In a randomized control study (n = 60), buspirone was compared to venlafaxine XR and placebo in its ability to alter colonic function. It was found that individuals taking buspirone had no significant changes in colonic compliance, tone, and sensation when compared to those on placebo.

Sexual Dysfunction. It has been previously reported that in patients with GAD suffering from decreased sexual function, an improvement in sexual dysfunction was seen after 4 weeks of buspirone. Sexual dysfunction is a common side effect experienced by antidepressant users. Buspirone has been previously investigated in order to determine if this side effect could be reversed. Subjects who met the criteria for a major depressive episode (MDE) and were on a stable dose of an SSRI for at least 4 weeks were given either buspirone or placebo to determine if an improvement in sexual function would occur. Only women in weeks 1 and 3 had a significant improvement in sexual function. An 8-week RCT in females with an MDE being treated with fluoxetine compared buspirone to the antiviral medication amantadine (Symmetrel) and found that neither drug significantly improved sexual dysfunction compared to placebo.

Premenstrual Syndrome. Buspirone has demonstrated some benefit in the treatment of premenstrual syndrome (PMS) in two RCTs. The first RCT compared buspirone (n = 19) to nefazodone (n = 22) and placebo (n = 22) in subjects suffering from premenstrual dysphoria, and found that subjects taking buspirone had a greater global improvement and improvement in irritability compared to placebo. The second RCT demonstrated that subjects on buspirone (n = 17) had a significant improvement in PMS-related symptoms, including aches and pains, cramping, impaired social

interaction, and irritability.

Sleep Apnea. Buspirone as a treatment option for sleep apnea has been studied but no benefit has been observed. One randomized control trial (n = 5) found that patients on buspirone scored less on the Apnea Hypopnea Index (AHI); however, this difference did not reach significance. One animal model study demonstrated efficacy of buspirone in the treatment of apnea, where morphine-induced apnea was reversed with the IV administration of buspirone.

Attention-Deficit/Hyperactivity Disorder. An open-label study of children and adolescents (n = 50) with a diagnosis of both ADHD and oppositional defiant disorder (ODD) were given buspirone for a minimum of 6 months. Eighty-three percent of the study population improved moderately or better with symptoms related to ODD, reducing irritability, aggression, and temper outbursts. An RCT (n = 57) administering buspirone via a transdermal patch did not observe a significant decrease in ADHD-related symptoms in the buspirone group compared to placebo.

Withdrawal from Other Medications/Substances of Abuse. An RCT looking at the withdrawal of opiates found that buspirone had similar efficacy to methadone in alleviating withdrawal symptoms in patients discontinuing heroin. Another RCT looking at the discontinuation of long-term benzodiazepine use in patients with panic disorder, comparing imipramine (Tofranil) to buspirone, found that buspirone did not significantly decrease withdrawal symptoms compared to placebo. A recent open-label study looking at withdrawal from marijuana found that patients on buspirone (n = 11) had a significant decrease in both cravings for drug and irritability.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Nervous System

The most frequent adverse events affecting the nervous system reported by buspirone users included dizziness, headache, drowsiness, lightheadedness, insomnia, fatigue, nervousness, decreased concentration, abnormal thinking, excitement, depression, confusion, vivid dreams, and hostility. Less frequent events included noise intolerance, euphoria, fear, apathy, seizures, and suicidal thoughts.

Gastrointestinal System

Users of buspirone report instances of nausea, GI distress, diarrhea, and vomiting. Less frequent events include anorexia and rectal bleeding.

Cardiovascular System

Tachycardia or palpitations was the most frequently listed cardiovascular effect with the use of buspirone. Less common adverse events included syncope, hypotension, and hypertension. Rare cardiovascular effects include congestive heart failure, cerebrovascular accident, myocardial infarction, cardiomyopathy, bradycardia, and ECG change.

Dermatological Effects

The most frequent dermatological side effect reported with buspirone use was skin rash, while facial edema, easy bruising, blisters, hair loss, and dry skin were reported infrequently. Rare events included acne and thinning of nails.

Endocrine System

Patients taking buspirone reported, infrequently, the following adverse events: change in libido, change in weight, and menstrual irregularity.

THERAPEUTIC INDICATIONS

The FDA has approved buspirone for the management of anxiety disorders or for short-term treatment of anxiety-related symptoms. It is recommended for use in individuals who present symptoms that correspond with GAD based on the DSM criteria, for at least 1 month. There are no data available pertaining to the long-term (greater than 4 weeks) use of buspirone.

PRECAUTIONS AND ADVERSE REACTIONS

Patients with a hypersensitivity to buspirone should not take this medication. Pharmacological studies have indicated that liver and kidney impairment affect drug metabolism and drug clearance, respectively. As such, patients with either condition should receive less than the recommended dose. Buspirone is not recommended for patients with severe liver or kidney impairment. In vivo animal studies have indicated a lack of teratogenic, carcinogenic, and fetal impairment effects of buspirone administration, but similarly well-controlled studies in humans have not been performed, resulting in a current classification by the U.S. Food and Drug Administration of Pregnancy Category B. In rats, buspirone and its metabolites are found in maternal milk and cross the placenta, although it is not known to what extent both these events occur in humans.

The most commonly listed adverse reactions to buspirone that were significantly higher when compared to placebo included dizziness, nausea, headache, lightheadedness, excitement, and sweating or clamminess. A study in a child and adolescent population found that the most frequently reported side effects were lightheadedness, headache, and dyspepsia, while

studies in geriatric populations found no difference in adverse events reported in comparison to a younger population. Rare side effects include congestive heart failure, bradycardia, slurred speech, claustrophobia, tingling of limbs, burning tongue, and photophobia.

DRUG INTERACTIONS

Buspirone is a substrate for CYP3A4. Concurrent use of buspirone and MAOIs) has been associated with a significant increase in blood pressure. Verapamil (Verelan), an inhibitor of CYP3A4, was found to increase the AUC and C_{max} of buspirone by 4.1- and 5.0-fold, respectively. Erythromycin (ERY-C), an inhibitor of CYP3A4, increased both AUC and C_{max} by 19- and 16-fold, respectively. Rifampiin (Rifadin), an inducer of CYP3A4, decreased the C_{max} and AUC by 84 to 90 percent and the half-life from 2.8 to 1.3 hours. With the coadministration of haloperidol and buspirone in subjects with Schizophrenia, buspirone increased the plasma concentration of both haloperidol and its metabolite, although this study did not examine the concentration of buspirone in the presence of haloperidol. Grapefruit juice, an inhibitor of CYP3A4, increased the AUC and C_{max} of buspirone by 9.2- and 4.3-fold, respectively. Other known inducers or inhibitors of CYP3A4 that may affect buspirone plasma concentration include ketoconazole (Nizoral), dexamethasone (Decadron), phenytoin (Dilantin), phenobarbital (Bellatal), and carbamazepine (Tegretol). Concurrent use of certain drugs has been found to change the percentage of protein-bound buspirone. Acetylsalicylic acid (ASA) increased plasma levels of free buspirone by 23 percent, while flurazepam (Dalmane) decreased levels by 20 percent. Other drugs that alter the free plasma level of this drug include desipramine (Norpramin), diazepam, ibuprofen (Advil), propranolol (Inderal), thioridazine (Mellaril), and tolbutamide (Orinase).

DOSAGE AND ADMINISTRATION

Buspirone is available as an oral tablet and is provided in the following strengths: 5, 10, 15, and 30 mg. The recommended initial dose listed by the FDA is 15 mg daily (7.5 mg twice a day). Patients may be titrated to an optimal dose within 2 to 3 days by increasing the dose by 5 mg daily. The maximum daily dose should not surpass 60 mg.

▲ 34.13 Calcium Channel Inhibitors

STEVEN L. DUBOVSKY, M.D.

HISTORY

The complex psychobiology of mood disorders is unlikely to be explained by changes in a single neurotransmitter or receptor. Intracellular messengers, however, regulate multiple aspects of neuronal function, and abnormal regulation of one messenger can have multiple downstream effects on affective, cognitive, and behavioral systems directly and through actions on gene expression. The intracellular calcium ion is particularly interesting in this regard because it regulates activity of multiple neurotransmitters, such as serotonin and dopamine, and has a biphasic action (Fig. 34.13–1). Moderate increases in free intracellular calcium ion concentration ($[Ca^{2+}]_i$) stimulate cellular activity, whereas greater elevations inhibit the same functions and even higher levels within a physiologic range induce apoptosis. A hyperactive intracellular Ca^{2+} signal that contributes to the activation of mania at the same time that it suppresses behavioral and other affect regulation systems depending on the sensitivity of those systems to increased intracellular signaling could explain why so many bipolar patients have rapid fluctuations between mania and depression or experience both states at the same time. The same explanation could apply to observations that hyperparathyroidism can induce both depression and mania. The contribution of excessive intracellular calcium signaling to programmed cell death could be a component of the neuronal loss that has been observed with recurrent affective episodes, and hyperactive calcium signaling in other cellular systems could play a role in the susceptibility of patients with bipolar mood disorders to hypertension and cardiovascular disease. Correction of hyperactive intracellular calcium signaling could explain why treatments such as lithium (Eskalith) can improve both mania and bipolar depression.

FIGURE 34.13–1. Intracellular calcium ion signaling. Intracellular calcium ion concentration ($[Ca^{2+}]_i$) is increased by entry into the extracellular space and by release from intracellular stores. Calcium enters the cytosol through receptor operated (e.g., *N*-methyl-D-aspartate) and potential-dependent ion-specific channels, as well as in exchange for intracellular sodium. Stimulation of a variety of G-protein–associated receptors (e.g., serotonin type 2 and dopamine type 2) activates turnover of the membrane phosphoinositol system, with production of inositol triphosphate (IP_3) and diacylglycerol (DG). IP_3 releases calcium ions from intracellular stores, and DG draws protein kinase C (PKC) to the cell membrane, where it is activated by Ca^{2+}. Moderate increases in $[Ca^{2+}]_i$ stimulate cellular processes by activating PKC and a variety of other enzymes that are activated by the calcium–calmodulin (CaM) complex; greater increases suppress the same processes. CBZ, carbamazepine; CCB, calcium channel blocker; Li, lithium; NL, neuroleptic; PIP_2, phosphatidylinositol biphosphate; PLC, phospholipase C; TCA, tricyclic antidepressant.

Free intracellular Ca^{2+} concentration is normally regulated tightly at approximately 100 nM, or 0.0001 of the Ca^{2+} concentration in the extracellular fluid. Compared with controls, elevations of resting ($[Ca^{2+}]_B$) free intracellular calcium ion concentration have been found in affectively ill patients with bipolar disorder in blood platelets, lymphocytes, B-lymphoblast cell lines (BLCLs), olfactory neurons, and neuroblastoma cells, as well as elevations of intracellular calcium ion concentration stimulated by agonists ($[Ca^{2+}]_S$) including thrombin, platelet-activating factor (PAF), serotonin, dopamine, thapsigargin, and various mitogens. Most studies that demonstrate increased resting and/or agonist stimulated $[Ca^{2+}]_i$ in bipolar disorder have reported similar elevations in mania and bipolar depression. When bipolar I and bipolar II disorders have been compared, the results have been similar in some if not all studies. These changes tend to normalize with euthymia after treatment with various medications or ECT (Fig. 34.13–2). There are a few reports of greater serotonin-stimulated $[Ca^{2+}]_S$ in unipolar depressed patients than in controls, with blunting of the excessive intracellular signal by serotonin reuptake inhibitors, possibly because these samples included patients with unrecognized or subsyndromal bipolar disorder. This possibility is supported by the finding in 53 patients who had a diagnosis of unipolar depression with melancholia and who had elevated platelet $[Ca^{2+}]_S$ in response to serotonin that levels were significantly higher in 7 patients whose diagnosis was changed over the next 8 to 10 years to bipolar disorder. Hyperactive intracellular Ca^{2+} signaling appears to be specific to bipolar disorder and is not found in schizophrenia. This finding is not a function of psychosis, which is common in bipolar disorder, as $[Ca^{2+}]_B$ and $[Ca^{2+}]_S$ are found in nonpsychotic as well as psychotic bipolar disorder.

The same finding with different agonists in different cells from patients with bipolar disorder suggests that hyperactive intracellular Ca^{2+} signaling is not a function of a specific receptor but a primary change in intracellular calcium ion dynamics. The impression of a diffuse change in cellular function rather than an effect of a circulating factor such as cortisol is strengthened by the finding of lack of increase in $[Ca^{2+}]_i$ in control platelets after incubation with a plasma ultrafiltrate from bipolar disorder patients with elevated platelet $[Ca^{2+}]_i$.

The immediate source of increased $[Ca2+]_i$ in bipolar disorder has been thought to be increased release from intracellular calcium stores promoted by inositol triphosphate (IP_3), a product of membrane phosphoinositide (PI) turnover. Proposed mediators of increased release of stored intracellular calcium include increased PI turnover; hyperactivity of the calcium-binding protein neuronal calcium sensor-1 (NCS-1), which is activated by IP_3; a hyperactive G-protein, mitochondrial dysfunction;

increased production of protein kinase C (PKC) from membrane PI turnover; secondarily altering Ca2+ efflux from intracellular stores; and decreased expression of the antiapoptotic and neurotrophic B-cell CLL/lymphoma (Bcl-2) gene, the product of which reduces intracellular Ca2+ release by IP_3.

FIGURE 34.13–2. Elevated platelet intracellular calcium ion concentration in bipolar disorder and normalization by lithium (Eskalith). Resting ($[Ca^{2+}]_B$) and, in this figure, stimulated ($[Ca^{2+}]_S$), as well as interindividual variability, are increased in mania and bipolar depression. Hyperactive intracellular calcium signaling is normalized by in vitro incubation with therapeutic concentrations of lithium, and bipolar patients who are euthymic after treatment with lithium or anticonvulsants have mean $[Ca^{2+}]_S$ levels that are statistically the same as in controls.

Heterozygous Myshkin (Myk/+) mice, which have a missense mutation of the neuron-specific sodium/potassium ATPase, exhibit mania-like behavior such as hyperambulation, altered sleep–wake cycle, and increased reward preference. The manic-like behavior, which is reduced by lithium and valproate, is associated with increased release of Ca^{2+} from intracellular stores in cortical neurons via activation of IP_3 receptors, as well as increased glutamate-induced Ca^{2+} currents. In humans, polymorphisms of the CACNA1C gene, which encodes the alpha subunit of the calcium channel Cav1.2, have been associated with bipolar disorder in a number of studies. Such results suggest that altered intracellular calcium homeostasis could be involved in the actual pathophysiology of bipolar disorder and implies that this might be a target of effective thymoleptic treatments.

Lithium has a number of effects on intracellular Ca^{2+} signaling. For example, it inhibits a crucial step in membrane PI turnover (inositol-1-monophosphatase), which could reduce production of IP_3, thereby decreasing calcium mobilization from intracellular stores; this possibility is suggested by the findings that lithium-treated bipolar patients, but not controls, have reduced platelet phosphatidylinositol biphosphate (PIP_2), that lithium increases accumulation of IP_1, and that lithium reduces concentrations of myoinositol in the frontal cortex of bipolar patients. Since lithium is an uncompetitive inhibitor of this enzyme, its inhibitory activity increases with higher rates of PI turnover. Another recently demonstrated action by which lithium could dampen hyperactive intracellular calcium signaling is antagonism of the intracellular calcium-binding protein NCS-1, which enhances IP_3 calcium channel activity, promoting efflux of Ca^{2+} from intracellular stores to the cytosol. Lithium may also interfere with calcium channel activity or it may enhance calcium efflux, perhaps through an effect on sodium countertransport. Additional relevant lithium actions include antagonism of the hyperactive G protein by competition for magnesium ion binding required for G protein dissociation, induction of Bcl-2, and inhibition of glycogen synthase kinase-3β, an effect that enhances membrane stability. Inhibition of PKC, a ubiquitous protein activated by intracellular Ca2+ that is increased in bipolar disorder, may be another mechanism relevant to calcium signaling. Carbamazepine (Tegretol) inhibits Ca^{2+} currents in a variety of models, and the time course of suppression of calcium-dependent potentials is comparable to that produced by the calcium channel inhibitor verapamil (Calan, Isoptin). In vitro incubation with lithium or carbamazepine lowers platelet and lymphocyte $[Ca^{2+}]_i$ significantly in ill bipolar patients but not in controls or euthymic bipolar patients (Fig. 34.13–2). Lamotrigine (Lamictal), another medication that has been found useful in bipolar disorder, also has calcium channel blocking properties, as do valproate

(Depakote), gabapentin (Neurontin), and pregabalin (Lyrica), although these effects are not nearly as prominent as with lithium and carbamazepine. Attenuation of hyperactive intracellular calcium signaling by antimanic drugs may have a number of different mechanisms (Fig. 34.13–1). Findings of elevated intracellular Ca^{2+} activity in mania and bipolar depression that is attenuated by established mood stabilizing medications warrant investigation of medications that act primarily on intracellular Ca^{2+}.

CHEMISTRY

Verapamil, the first calcium channel antagonist to be introduced, was synthesized in 1962. A phenylalkylamine derivative of papaverine (Pavarine), verapamil was found to have negative inotropic effects that, in 1967, were postulated to be due to reduction of excitation–contraction coupling caused by inhibition of calcium influx into cardiac cells. Three additional classes of calcium channel inhibitors were subsequently identified, with significantly different structures (Fig. 34.13–3), leading to differential activity in various tissues depending on their binding site on the calcium channel. In addition to the phenylalkylamine verapamil, currently available calcium channel blocker (CCB) classes include benzothiazepine (diltiazem), and dihydropyridine (nifedipine, nimodipine, amlodipine, felodipine, isradipine, nicardipine, and nisoldipine). Because of their heterogeneity of structure and action, these medications are not interchangeable. However, they all have the capacity to reduce excessive excitability of diverse cellular systems.

Verapamil and diltiazem (Cardizem) are crystalline powders that are soluble in water and chloroform. Nifedipine (Procardia) is insoluble in water, but it is soluble in ethanol. Nimodipine (Nimotop), a 1,4-dihydropyridine (DHP) that is insoluble in water but is highly lipophilic, has two closely related congeners: isradipine (DynaCirc) and amlodipine (Norvasc). Amlodipine is a white crystalline powder that is slightly soluble in water and ethanol.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption. The CCBs are nearly completely absorbed after oral administration, but bioavailability is decreased by extensive first-pass hepatic and probably intestinal metabolism. First-pass metabolism also results in considerable interindividual variability in blood level at a given dose. As noted in Table 34.13–1, oral bioavailability of the CCBs is generally less than that of other drugs used to treat mania, but effective concentrations for their primary indication are an order of magnitude lower. Optimal serum concentrations for mood disorders or any other

conditions have not been investigated.

Verapamil is metabolized by D-dealkylation and *O*-demethylation to at least 12 metabolites. One of these, norverapamil, has approximately 20 percent as much cardiovascular activity as the parent drug in animal models and a half-life of 10 hours. Diltiazem, which is metabolized by *O*-deacetylation or *N*-demethylation, has active metabolites that do not appear to be clinically important. Nifedipine, nicardipine (Cardene), and most of the other dihydropyridines have inactive metabolites. The majority of people are rapid metabolizers of nifedipine and possibly other DHPs; approximately 17 percent are slow metabolizers. Isradipine is metabolized to inactive monoacids and a cyclic lactone.

Carbamazepine (Tegretol)	70	74	1.4 ± 0.4	15.0 ± 5.0	4–12 µg/mL
Divalproex (Depakote)	100	93	0.2 ± 0.07	14.0 ± 2.2	50–125 µg/mL

Distribution. Peak plasma levels of the majority of CCB agents are

achieved within 30 minutes to 3 hours after oral dosing, but amlodipine does not reach peak plasma concentrations for 6 hours. All CCBs are extensively bound to plasma proteins (70 to 98 percent). Most CCBs are excreted in breast milk. Verapamil and norverapamil can be recovered from human cerebrospinal fluid (CSF) after oral administration, and the concentration of phenylalkylamines in the brain is sufficient to be protective after cerebral ischemia in rats. However, the more lipophilic nimodipine crosses the blood–brain barrier more readily.

As noted in Table 34.13–2, L-type channels are distributed in multiple organ systems, whereas many of the other calcium channels are found primarily in neurons. Since all of the CCBs that have been used for psychiatric indications bind to L-type channels, their actions are not limited to the CNS, and central actions can be accompanied by cardiovascular and other effects that may be troublesome.

Elimination. Most CCBs have elimination half-lives in the range of 1.3 to 6.0 hours, except for amlodipine, which has a half-life of 35 to 50 hours. Although amlodipine can be given once daily, the short half-lives of most CCBs require multiple daily doses. However, because repeated administration saturates hepatic metabolizing enzymes, bioavailability and half-lives increase with chronic administration, and the dosing interval can be increased. For example, verapamil is administered four times per day initially, but after 1 to 2 months the dosing interval can often be reduced to twice a day. Intestinal and hepatic metabolism of many CCBs by CYP3A4 enables increased bioavailability by 3A4 inhibitors such as grapefruit juice.

Pharmacodynamics

Mechanism of Action. Calcium ions enter the cytosol through receptor-operated channels gated by receptors for hormones and transmitters, such as some catecholamines and the excitatory amino acids, and through potential-dependent channels (PDCs or voltage-gated channels), which are gated by membrane potential. In the brain, potential-dependent calcium channels are localized in regions rich in synapses, perhaps because high $[Ca^{2+}]_i$ must be produced rapidly to regulate neurotransmitter release. Additional pathways for calcium entry include leakage through an ungated channel and exchange of extracellular calcium ions for intracellular sodium ions (Na^+) (Fig. 34.13–1). Under physiological conditions, PDCs can be regulated by receptor-mediated events, such as the production of IP_3, and receptor-operated channels can be gated by voltage dependent events. In addition, extracellular Ca^{2+} entering the cell may release calcium ions from intracellular stores, and trigger amounts of calcium ions released from intracellular stores may facilitate calcium channel opening. Even subtle alterations of the function of one kind of calcium channel can therefore

have significant effects on the overall balance of calcium-dependent cellular activity.

CCB agents interact with the PDC. This type of channel consists of five allosterically linked subunits: α_1, α_2, β, γ, and ε; the α_1 channel has a hydrophobic region that spans the cell membrane and outlines and gates the actual calcium pore (Fig. 34.13–4). The α_1 subunit has at least four and possibly seven or more separate binding sites for different CCB classes. Thus far, four separate genes coding for the L-channel α_1 subunit have been identified, producing different versions of CCB-binding sites. The other subunits, and possibly other endogenous circulating factors, can alter the conformation of the α_1 subunit, changing the affinity of the L-channel for a given CCB. Endogenous regulators unrelated to neurotransmitters appear to modulate PDC gating and CCB binding and may be altered in disease states.

Six types of potential-dependent calcium channels have been characterized (Table 34.13–2). The L (for long-lasting) channel requires significant depolarization for Ca^{2+} entry and inactivates slowly. L-type calcium channels do not participate directly in neurotransmitter release, but they play an important role in determining neuronal excitability. Currently available CCBs bind to L-channels, which are found in the cardiovascular, endocrine, and nervous systems, and in muscle. Because of the widespread distribution of L-channels, these medications have multiple effects. The T (transient) channel is activated by small depolarizations and inactivates rapidly. T-type calcium channels may be involved in the action of ethosuximide (Zarontin), valproic acid (Depakene), and divalproex (Depakote) in the treatment of absence seizures. The N (neither L nor T) channel, which is primarily found on CNS neurons, is unresponsive to CCBs. Levetiracetam (Keppra), an anticonvulsant used for refractory epilepsy, antagonizes N-type channels. This action does not appear to be associated with reduction in elevated $[Ca^{2+}]_i$ in platelets of bipolar disorder patients or clinically with a mood stabilizing effect. Ziconotide (Prialt), a peptide toxin used for chronic pain, also antagonizes N-channels. A rapidly inactivating P (Purkinje cell) channel identified in cerebellar Purkinje cells is insensitive to the DHP CCBs. Q and R channels, like N and P channels, participate in neurotransmitter release.

[a]Most currently available calcium channel blockers bind to the L-channel but do not have binding sites on other channels.

FIGURE 34.13–4. Structure of the calcium channel blocker–binding site. BP, benzodiazepine-binding site; DHP, 1,4-dihydropyridine-binding site; DPP, diphenylpiperazine-binding site; O, other calcium channel blocking agent binding sites; PA, phenyl alkylamine–binding site.

In addition to binding to L-channels, nimodipine, nicardipine, methoxyverapamil, flunarizine (Adalat), and cinnarizine (Sturgeon) may also antagonize T-channels, and a phenylalkylamine-binding site exists on the inner mitochondrial membrane. Variations in CCB structure produce variations in potency at different L-channels in different tissues, and depending on the distribution of binding sites for a given chemical class of CCBs, that class may be more or less active in a particular tissue or region. For example, dihydropyridines are more selective for vascular tissue, whereas verapamil and diltiazem have more prominent antiarrhythmic properties. In animal studies, nifedipine, diltiazem and verapamil blocked the effect of subconvulsive doses of pentylenetetrazole (PTZ) to the same extent as valproate, and diltiazem enhanced the anticonvulsant effect of valproate. In other studies, nifedipine, verapamil, and diltiazem increased the threshold for PTZ-induced clonic seizures, and amlodipine blocked PTZ-induced seizures in mice. However, verapamil did not improve epilepsy control in phenobarbital-resistant canine epilepsy. Possibly as a result of T-channel antagonism, nimodipine has more of a potential for anticonvulsant actions.

Several additional features of the calcium channel contribute to activity

profiles of CCBs of different structure. Along with allosteric regulation and the influence of circulating modulators, membrane potential determines the conformation and, therefore, the affinity of CCB-binding sites. Dihydropyridine binding is enhanced by membrane depolarization, the CCB stabilizing the channel in an inactivated state. Most DHPs are uncharged at physiologic pH and easily gain access to the receptor through the cell membrane if it is sufficiently depolarized. Charged DHPs, such as amlodipine, have slower onsets of action because of interactions with negatively charged phosphate head groups in the cell membrane. Verapamil and diltiazem, which are also charged at physiological pH, gain access to the receptor through open channels and therefore are more active when channel openings are more frequent. The activity dependence of charged and uncharged CCBs makes these drugs much more potent in hyperactive tissue than in normal tissue. As a result, actions measured in normal cell preparations may not reflect activity in pathological states, a point emphasized by the finding that lithium attenuates elevated $[Ca^{2+}]_i$ in platelets of bipolar disorder patients but has no significant effect on $[Ca^{2+}]_i$ in normal platelets.

Several objections can be raised to the hypothesis that attenuation of excessive rises in $[Ca^{2+}]_i$ is a primary mechanism of action of CCBs in bipolar illness. First, as noted previously, L-channels do not appear to be involved in the action potential-dependent release of neurotransmitters, and calcium channel subtypes that are more specific to the CNS are not affected by L-type CCBs. However, neurotransmitters activate L-channels, making them an important component of neuronal signaling, and it is not certain that neurotransmitter dysfunction is the primary pathophysiology of mood disorders anyway. Similarly, low concentrations of CCBs do not affect neurotransmitter release or neuronal Ca^{2+} currents, because depolarization in these cells is normally too brief to permit sufficient binding of the CCBs, but higher concentrations of CCBs may alter neuronal activity in other fundamental ways, and CCBs have greater effects on neurons with prolonged or marked depolarization. Reduction in tonic calcium influx may reduce the intracellular pool from which more immediate release results in rapid neuronal activation.

It could be argued that it is the anticonvulsant property of some CCBs and not their effect on Ca^{2+} currents that accounts for their antimanic activity, and there is some overlap between intracellular calcium dynamics in epilepsy and bipolar disorder. For example, mutations of the CACNA1A calcium channel gene have also been associated with idiopathic epilepsy, and prolonged elevations of $[Ca^{2+}]_i$ can contribute to the development and maintenance of seizure disorders through changes in GABA receptor recycling, gene transcription, protein synthesis, and neuronal sprouting. Nimodipine, a CCB with anticonvulsant properties, seems particularly

useful in the treatment of mood disorders, although this may be more a function of its high lipid solubility and penetration into the CNS. The finding noted earlier that levetiracetam, which is clearly an anticonvulsant, does not normalize increased $[Ca^{2+}]_i$ in bipolar disorder and has little efficacy in this condition, could indicate that a combination of anticonvulsant and calcium antagonist properties may be associated with a mood stabilizing effect. Some CCBs also antagonize nicotinic cholinergic receptors, and some reduce dopamine D2 receptor signaling, which could also contribute to their clinical effects. Inhibition of PKC may be an additional independent action of CCBs relevant to an antimanic effect, as suggested by studies demonstrating an antimanic effect of tamoxifen, which has PKC inhibitory properties.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

The first type of calcium antagonist used in psychiatry was calcitonin (Cibacalcin), which lowers $[Ca^{2+}]_i$ by driving Ca^{2+} into intracellular storage sites. John Scott Carman and Richard A. Wyatt found that three manic patients had temporary reduction in agitation after injections of subcutaneous salmon calcitonin (Calcimar) but not after administration of placebo. In a subsequent trial, a group of nine patients with "chronic psychopathological suffering" accompanied by depression or anxiety but no formal diagnoses felt tranquillized and demonstrated a reduction in Brief Psychiatric Rating Scale scores after receiving an unspecified dose of salmon calcitonin for 20 days.

The first report of the use of a CCB in the treatment of mania was a double-blind, placebo-controlled trial of verapamil in a single manic patient. The rationale for choosing this particular CCB was that it was the only CCB that the manufacturer would make available at a time at which none of these medications had yet been approved for use in the United States. Based on initial positive experience in case reports and open trials, double-blind studies of verapamil in bipolar disorder have been conducted. Because of lack of interest of CCB manufacturers in psychiatric applications of the CCBs, there have not been any large, multicenter trials of any of these medications in mood disorders.

In initial studies, verapamil was superior to placebo and no treatment in mania, and two studies reported equivalent antimanic efficacy with lithium. A 2-week open trial of diltiazem in seven manic patients, a 3-year follow-up of a bipolar patient for whom flunarizine was successfully substituted for lithium, a 1-week trial of nimodipine, and a prolonged double-blind follow-up of three bipolar patients receiving high doses of nimodipine suggested possible antimanic applications of these medications. In 10 manic patients who did not respond to 3 weeks of treatment with lithium, switching to verapamil for 3 weeks did not produce

better results, but another 3 weeks of treatment with the combination of lithium and verapamil led to a robust response.

Verapamil has been noted to prevent antidepressant-induced hypomania. Extended controlled follow-up after acute treatment demonstrated the usefulness of nimodipine as maintenance therapy in bipolar illness, and verapamil also has been found effective in the clinical setting in preventing affective recurrence. Careful longitudinal observations have suggested possible usefulness of nimodipine for ultradian cycling and recurrent brief depression. Blinded monotherapy with nimodipine was more effective than placebo for 10 of 30 patients with refractory, highly recurrent bipolar and unipolar mood disorders; augmentation of nimodipine with carbamazepine substantially improved the status of 4 of 14 partial nimodipine responders. The highly refractory nature of these patients' illnesses and the careful evaluation of response using Post's life-charting method increase confidence in the results, even though the sample was small.

In one of two negative trials of verapamil in mania, single-blind lithium produced significantly more improvement in mania rating scales than verapamil in a 28-day randomized trial of 40 manic patients. However, doses and frequency of administration of verapamil were lower than are usually effective, and both groups were still quite symptomatic at the end of the trial. The second negative study was a random assignment trial of 32 acutely manic patients, most of them psychotic, to placebo or verapamil given three times per day. Both groups had similarly slight and statistically insignificant reductions in mania and depression rating scale scores. However, patients only remained in the treatment for a mean of 9.3 (verapamil) to 13.3 (placebo) days, a duration of treatment that would not be considered adequate for any antimanic drug. Most patients in clinical practice with psychotic mania would be treated with antipsychotic drugs along with or before an antimanic drug. In addition, although the authors stated that verapamil doses could be adjusted to as much as 480 mg per day, actual doses received were not noted, and verapamil may not have been administered frequently enough to achieve a steady state acutely. Finally, no data were presented to determine whether patients had been refractory to lithium or other treatments; patients who have responded to verapamil monotherapy in most studies have also been responsive to lithium.

Most antimanic and mood-stabilizing medications are effective for some patients and not others, and negative studies have been published of all currently used mood stabilizers. Possibly because CCBs have not been popularized by manufacturers to the same extent as anticonvulsants and some atypical antipsychotic drugs, the two negative antimanic trials of verapamil led to conclusions by some authorities that the entire class of CCBs is ineffective for bipolar disorder, a generalization that would not be

applied to other medication classes and that is not justified for verapamil, given the limitations noted previously. It is also worth noting that studies supporting the thymoleptic properties of popular medications such as the atypical antipsychotic drugs have utilized sample enrichment, while CCB studies have enrolled more heterogeneous samples of patients who have not been demonstrated a priori to respond to the experimental treatment before a randomized trial is conducted.

As is true of lithium, the usefulness of CCBs in the treatment of depression is not as clear as their potential applications in mania. Nifedipine reduces immobility in the behavioral despair test, which is believed to be an animal model of antidepressant activity. Flunarizine was thought to reduce depressive recurrences in one patient, and one patient with recurrent brief depression responded to blind trials of nimodipine and verapamil. Verapamil may have acute antidepressant properties in some bipolar and psychotically depressed patients. However, a Czech study found that overall verapamil was no more effective than placebo and was inferior to amitriptyline (Elavil) in the treatment of depression, although a few patients did seem to have a genuine antidepressant response to verapamil in this study and in a previous report by the same authors. As the investigators did not differentiate between bipolar and unipolar depression, it is possible that, as would be expected with lithium, those with bipolar depression were more likely to respond to verapamil than were those with unipolar depression. Verapamil appeared to augment the antidepressant action of imipramine (Tofranil) in a patient with unipolar depression who had previously responded to lithium augmentation; when imipramine was discontinued 6 months later, the patient remained euthymic on verapamil alone. Compared to placebo, treatment with nicardipine during ECT resulted in a better antidepressant response to ECT. Conversely, investigators thought that nifedipine caused depression itself or resistance to antidepressants in five unipolar depressed patients. In a blinded protocol involving 10 patients with bipolar depression generally of more than 6 months duration, acute treatment with isradipine resulted in significant improvement in 6 patients and remission in two.

For several reasons, CCB studies have been considerably smaller than studies of other putative antimanic and mood-stabilizing agents. Manufacturers have not been particularly interested in possible psychiatric implications of these medications. In addition, clinical testing of hypotheses of actions on second messengers and other intracellular processes has not been of as much interest as studies of neurotransmitter, receptor, and anticonvulsant hypotheses and development of “me too” products. These conceptual and financial limitations on clinical studies of CCBs have constrained the data available to reliably assess the place of CCBs in the treatment of bipolar disorder.

As is true of other medications used to treat bipolar mood disorders,

insufficient numbers of patients with different bipolar subtypes have been studied to understand which patients are most likely to benefit. The scatter in actual levels of $[Ca^{2+}]_i$ in bipolar patients (Fig. 34.13–2) undoubtedly reflects the biological and clinical heterogeneity of the disorder, and patients with hyperactive calcium signaling may be more responsive to CCBs than those without this finding. This possibility is suggested by findings in a few small studies that bipolar patients with elevated $[Ca^{2+}]_i$ had a better response to lithium than those with normal levels. The possibility remains that CCBs may be more effective in bipolar disorder accompanied by elevated $[Ca^{2+}]_i$.

Another issue to consider is that the heterogeneity of CCB-binding sites provides for different spectra of action of various CCBs. Just as patients with one bipolar variant may do better with CCBs than those with another variant, it is possible that patients who do not respond to one CCB class may have a good response to another. Combinations of CCBs with each other and with other antimanic drugs could also produce additive effects on Ca^{2+}-dependent and other systems to make them useful in complex treatment-resistant states. However, such possibilities have not been investigated formally.

Bearing these limitations in mind, the available data suggest that verapamil is most likely to be useful for mania and hypomania in patients who are responsive to lithium but cannot tolerate it, whereas patients who do not respond to lithium seem less likely to respond to verapamil. The only available data on combinations of verapamil and other medications involve a few case reports and small studies suggesting that addition of verapamil to lithium was helpful to some patients who did not respond to lithium alone. Nimodipine seems to have potential for treating refractory and complex bipolar disorder, especially in combination with other thymoleptic medications, and there are fewer drug–drug interactions with nimodipine than verapamil. In addition, nimodipine may be useful in bipolar depression. However, larger controlled studies are necessary to assess its precise role. The few small studies of isradipine suggest that this medication, which is closely related to nimodipine, may have similar applications. Verapamil does not appear to be predictably useful for depression, and some CCBs may inhibit an antidepressant response in unipolar depression. However, a single study suggested that verapamil could be a useful adjunct in panic disorder.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Animal studies and clinical experience with verapamil when it is used to treat premature labor and fetal arrhythmias suggest that it is relatively safe in pregnancy, at least in later trimesters. Reports have been published of three patients for whom verapamil was effective for mania during

pregnancy without any evidence of teratogenicity. A study of 28 pregnant women with acute episodes of mania or bipolar depression and nine euthymic pregnant women who switched to verapamil maintenance from another mood stabilizer found no complications of pregnancy, as well as a 100 percent response rate in mania, a 77 percent response rate in mixed states, and a 39 percent response rate in depression; six of eight patients who continued verapamil maintenance therapy remained well. A few case reports of similar outcomes with nimodipine during pregnancy have emerged, and nimodipine and isradipine have been used to treat or prevent pre-eclampsia without adverse effects on the mother or newborn. Obviously, such experience is insufficient to ensure its safety in this setting, but thus far evidence of teratogenicity has not emerged. There is not enough information about effects of other CCBs during pregnancy.

In a prospective study, elderly patients taking short-acting CCBs, especially dihydropyridines like nifedipine, had a greater risk of myocardial infarction (MI) than patients taking other antihypertensives. However, as severity of hypertension was not controlled, and CCBs are usually used as second-line treatments of more severe hypertension, the possibility could not be excluded that patients treated with CCBs were more likely to have this complication because their hypertension was more severe. Although the investigators speculated that coronary vessel steal caused by diffuse vasodilatation accounted for the increased risk of MI, the large Danish Verapamil Infarction Trial (DAVIT) found that CCBs reduced the risk of recurrent MI when used prophylactically after an index MI.

A review of Medicare files of elderly patients treated for hypertension found a somewhat increased risk of a variety of cancers in patients taking short-acting CCBs compared with those taking other antihypertensives. The investigators argued that CCBs could interfere with apoptosis (programmed cell death), which is dependent on increased Ca^{2+} influx that activates proteolytic enzymes. However, cell growth is also calcium dependent and antihypertensive use was assessed years before the presence of cancer was recorded. Although carcinogenesis is a prolonged process, there was no way of knowing when cancer developed, whether antihypertensives were taken during carcinogenesis, or whether these medications were still being taken when cancer was initiated or diagnosed. Furthermore, the CCBs have been found to have potential applications in the treatment of cancer discussed below.

THERAPEUTIC INDICATIONS

Because of their capacity to reduce cellular hyperactivity without suppressing normally active cells, CCBs have been used to treat angina, hypertension, migraine headaches, Raynaud phenomenon, esophageal spasm, premature labor, and epilepsy; verapamil and diltiazem, but not the DHPs, have class IV antiarrhythmic activity and are used to treat

supraventricular arrhythmias. Several CCBs have been found to retard the development of atherosclerosis in animals. In view of the role of excessive elevations of $[Ca^{2+}]_i$ in apoptosis, nimodipine, which is used to block cerebral arteriospasm after subarachnoid hemorrhage, also has the potential to reduce anoxic brain damage. Preliminary studies suggested that this feature could slow progression of Alzheimer disease, but a large multicenter trial found no difference between nimodipine and placebo in this disorder.

In the few reported cases in which verapamil or diltiazem was administered to brain-damaged manic patients, the CCBs were well tolerated. CCBs might be considered in the presence of physical conditions in which other medications would be more dangerous (e.g., pregnancy) or in which a CCB might be helpful, such as hypertension, migraine headaches, tardive dyskinesia, Tourette syndrome, or supraventricular tachyarrhythmias. Since the CCBs usually do not cause weight gain or metabolic changes, they may be better tolerated by patients for whom such effects would be particularly troublesome. Lack of a need for blood tests is appealing to some patients.

Nifedipine chewed and placed under the tongue has been used to treat hypertensive crises associated with MAOIs. However, absorption of nifedipine is poor from the buccal mucosa, and this approach has been found not to be pharmacologically effective. A study of 18 normal subjects found that isradipine reduced the subjective response to methamphetamine and craving for the drug, suggesting that it could have applications in the treatment of stimulant abuse.

One mechanism of resistance to cancer chemotherapy is induction of the *MDR1* gene, which codes for P-glycoprotein, a drug extrusion protein that removes chemotherapy drugs from cancer cells. Verapamil, which inhibits P-glycoprotein, has been used to reduce chemotherapy resistance. Since cell proliferation is a calcium-dependent process, CCBs can inhibit tumor cell growth, and the ability of T-channels to generate rapid calcium currents at resting membrane potentials may account for findings that experimental T-channel antagonists reduce cancer cell proliferation in vitro. An epidemiologic study found an inverse relationship between the use of verapamil and the risk of prostate cancer.

PRECAUTIONS AND ADVERSE REACTIONS

The most common CCB side effects involve consequences of excessive vasodilatation, such as dizziness, headache, skin flushing, tachycardia, nausea, lightheadedness, weakness, and digital dysesthesia; aggravation of myocardial ischemia may rarely occur because of coronary steal, as discussed previously. Precapillary dilatation with reflex postcapillary constriction can increase capillary hydrostatic pressure and can cause peripheral edema. Verapamil and diltiazem are more likely than other

preparations to produce sinus bradycardia and atrioventricular block and may aggravate heart failure. Coughing, shortness of breath, wheezing, rashes, somnolence, constipation, seizures, and, rarely, depressed level of consciousness or psychosis may be caused by the CCBs. Possibly because of inhibition of calcium signaling in postsynaptic dopamine receptors, akathisia, parkinsonism, and delirium have occasionally been associated with use of calcium channel antagonists. Toxic serum concentrations of CCBs have not been defined. Possibly because of compensatory changes in calcium channels or CCB receptors, tachyphylaxis and withdrawal do not occur. CCBs do not alter exercise tolerance. Treatment of severe toxicity is with calcium, glucagon, volume expansion, and vasopressors.

Although inhibition of hyperactive intracellular calcium signaling may reduce a downstream effect of excitotoxicity in adult neurons, postnatal brain development involves increased intracellular calcium ion activity and animal studies suggest that CCBs that inhibit calcium signaling can injure neonatal neurons. The use of CCBs in very young children therefore requires caution.

DRUG INTERACTIONS

Adding CCBs to β-adrenergic blocking agents can result in additive cardiac slowing and atrioventricular block, whereas additive effects with α-adrenergic blocking agents may produce hypotension. Verapamil and nitrendipine increase plasma concentrations of digoxin (Lanoxin) and produce bradycardia, hypotension, or atrioventricular block when combined with quinidine (Cardioquin). Because verapamil and nifedipine inhibit cytochrome P450 (CYP) 3A4, they raise serum concentrations of CYP 3A4 substrates, such as carbamazepine and the triazolobenzodiazepines; this interaction can lead to carbamazepine neurotoxicity. Neurotoxicity also occurs occasionally when verapamil is combined with lithium. Additive suppression of the spontaneous rate of depolarization of the sinus node and of conduction through the atrioventricular node can increase the risk of bradycardia when lithium is combined with verapamil.

LABORATORY INTERFERENCES

As mentioned previously, verapamil raises serum levels of carbamazepine, digoxin, and other CYP 3A4 substrates. CCBs do not primarily affect other laboratory tests.

DOSAGE AND ADMINISTRATION

Verapamil is available in 40-, 80-, and 120-mg tablets. A 120-mg sustained release preparation used to treat hypertension was effective for mania in one report of three cases, but, because peak serum levels are not as high, it

generally is not as reliably effective for mood disorders as the immediate release forms. The usual daily doses of verapamil in the treatment of mania have been between 240 and 480 mg per day, although some patients may need higher doses because of low bioavailability. The short elimination half-life of verapamil requires three to four times per day dosing. Nimodipine is available only as a 30-mg capsule and is administered in doses of 90 mg per day for dementia and stroke. However, doses for bipolar illness have ranged from 360 mg to as much as 720 mg per day. The latter dose is substantially greater than the maximum dose approved by the FDA, although they are usually well tolerated. Nimodipine must be administered four to six times per day to sustain therapeutic levels. Isradipine, which is available as a tablet or capsule, is available in 2.5-, 5.0-, and 10.0-mg doses and is administered in doses of 2.5 to 20.0 mg per day in a frequently divided dose. Amlodipine, the only CCB that is effective when it is administered once daily, is available in 2.5-, 5.0-, and 10.0-mg tablets and is given in doses of 5 to 15 mg per day. However, there is little experience with this medication in mood disorders.

INVESTIGATIONAL DRUGS AND PREDICTION OF RESPONSE

Research into psychiatric applications of CCBs has been limited by relative lack of interest of manufacturers of these agents. Nimodipine and related dihydropyridine CCBs will probably turn out to have greater potential for psychiatric applications, because they cross the blood–brain barrier more readily than verapamil and they act on T- as well as L-type channels. Future development of CCBs for psychiatric indications will focus on antagonists of channels that are primarily expressed in the CNS such as N-channels, since such agents would not be expected to be limited by cardiovascular effects as could occur with high doses of L-channel antagonists. Such agents may be found to have applications in a variety of disorders characterized by neuronal hyperactivity. Investigations of medications with novel calcium antagonist properties may also prove fruitful. For example, as noted earlier, tamoxifen (Nolvadex), which is primarily used as an estrogen receptor antagonist in prevention of breast cancer, also inhibits PKC and has been found in preliminary trials to have antimanic properties.

Imaging of receptors for specific CCBs may prove useful in predicting which CCB might be effective for which patients. A study of 22 patients with bipolar or unipolar depression found that patients who responded to nimodipine had lower CSF somatostatin levels than patients who did not respond, and that nimodipine raised CSF somatostatin levels. However, this does not appear to be a practical approach to predicting treatment response. A positron emission tomography (PET) study finding that nimodipine responders had greater cerebral (including left insular) hypometabolism than nonresponders, whereas carbamazepine responders

had the opposite finding, may indicate a direction for further research into mechanisms of response but probably would not be used clinically. A 2-week trial in which manic patients received 360 mg per day of verapamil found a 61 percent reduction in manic symptoms and a correlation between the degree of improvement of mania and an increase in plasma calcium levels. A correlation has been suggested between the degree to which in vitro incubation with lithium lowered platelet $[Ca^{2+}]_i$ and predicted an antimanic action of lithium. Similarly, elevated platelet or lymphocyte $[Ca^{2+}]_i$ that is reduced by incubation with a CCB may turn out to be the best predictor of response to that class of medication.

▲ 34.14 Carbamazepine

ROBERT M. POST, M.D., AND MARK A. FRYE, M.D.

Carbamazepine (Tegretol) is an iminostilbene drug possessing some structural similarity to the tricyclic antidepressant imipramine (Tofranil), but having a very different clinical spectrum of efficacy. It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and for temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but, because of its atypical profile in a number of animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a first- or second-line mood stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained release formulation (Equetro) was approved by the FDA for the treatment of acute mania in 2002.

The structure and chemistry of carbamazepine are closely related to the more recently introduced anticonvulsant oxcarbazepine (Trileptal). As illustrated in Figure 34.14–1, whereas carbamazepine has a double bond in its middle ring, oxcarbazepine has a keto-oxygen attached. These differences result in very different routes and profiles of drug metabolism, yet, apparently, a generally similar clinical spectrum of efficacy in seizure, pain, and mood disorders. Oxcarbazepine is not FDA approved for acute mania. Although double-blind comparisons showed equal response to oxcarbazepine and haloperidol (Haldol) or lithium (Eskalith), these results were contaminated by the concomitant use of high potency benzodiazepines. One study suggested better efficacy of oxcarbazepine in less severe mania compared with more severe mania, while carbamazepine is effective in severe forms of mania.

CHEMISTRY

Carbamazepine is oxidized by cytochrome P450 oxidase of the 3A4 subtype to an active 10,11-epoxide metabolite that also possesses both anticonvulsant and antinociceptive properties. This epoxide is stable but can be further hydrolyzed to an inactive dihydroxy compound via an enzyme called epoxide hydroxylase. In contrast, oxcarbazepine is metabolized directly to its monohydroxy metabolite, which is also metabolically and physiologically active. Dissimilar from carbamazepine, neither oxcarbazepine nor its active monohydroxy metabolite is readily oxidized by P450 liver enzymes, resulting in a lesser number of pharmacokinetic interactions with other drugs than with carbamazepine. These and other differences are highlighted in Table 34.14–1.

Carbamazepine is highly insoluble in water and difficult to dissolve in most preparations. It is commonly given in preclinical studies to animals in a solution of ethanol and propylene glycol, but no clinically available intravenous formulation exists.

Two long-acting preparations are now available. One of these preparations, extended release carbamazepine, needs to be taken with food, as its absorption depends on normal gastrointestinal transit time, and it leaves a residual capsule ghost. Another long-acting preparation (Carbatrol or Equetro) uses a microtrol delivery system with 25 percent uncoated intermediate release beads, which are absorbed almost as soon as the pill is swallowed; 40 percent extended release beads, which dissolve gradually over a period of 8 to 12 hours because of a polymer coating that allows carbamazepine to diffuse slowly through tiny micropores; and 35 percent enteric release beads, which release the drug very slowly as a result of special pH-sensitive coating.

Such a formulation makes the long-acting forms suitable for single bedtime administration in affectively ill patients (although this is not recommended in epilepsy).

FIGURE 34.14–1. Comparative metabolism of carbamazepine and oxcarbazepine. Both parent and first metabolite are active anticonvulsants—the top two are potent enzyme inducers; the bottom two are not.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Carbamazepine is absorbed slowly and somewhat erratically through the gastrointestinal tract. Bioavailability is 80 percent, and the drug should not

be exposed to high humidity because this can decrease bioavailability. Peak plasma levels are reached 2 to 8 hours after a single dose. Carbamazepine is 70 to 80 percent bound to plasma protein. The average half-life after a single dose is 26 hours, with a range of 18 to 54 hours. However, with long-term administration in humans, the half-life decreases to approximately 12 hours (range, 10 to 25 hours). This change occurs with the induction of hepatic P450 3A4 enzymes, which increase the rate of metabolism of carbamazepine itself (autoinduction) and a variety of other agents, as referred to in Table 34.14–2.

The degree of carbamazepine autoinduction is somewhat dose dependent but is usually complete after 3 to 5 weeks of treatment. Thus, doses that are not initially tolerated may become so after several weeks, and blood levels usually fall despite the use of the same daily dose, necessitating later dose increases to maintain similar blood levels and clinical effect. Long-term use of carbamazepine is associated with a markedly increased ratio of the amount of the 10,11-epoxide to carbamazepine. The half-life of the 10,11-epoxide is approximately 6 hours.

Carbamazepine is metabolized in the liver and then excreted by the kidneys, as only 1 percent is eliminated by biliary excretion. Oxcarbazepine is a white to faintly orange crystalline powder and, like carbamazepine, is practically insoluble in ethanol, ether, or water. It is slightly soluble in chloroform, acetone, and methanol.

Because there is no or minimal autoinduction with oxcarbazepine, its half-life remains relatively stable over time. The half-life of oxcarbazepine is approximately 2 hours, and, because of the rapid conversion to the monohydroxide, which has a half-life of approximately 9 hours, the monohydroxide is responsible for most of the anticonvulsant activity. Dosing is usually twice or three times daily. There is an FDA approved long-acting preparation of oxcarbazepine (Oxtellar) for complex partial seizures, but efficacy in bipolar disorder has not been demonstrated. Oxcarbazepine is 96 percent absorbed and 60 percent bound to plasma proteins. Its monohydroxy derivative is 40 percent bound to plasma proteins. The monohydroxy derivative, eslicarbazepine, was FDA approved for seizures in 2013, although the results of earlier trials in mania have not been reported.

PHARMACODYNAMICS

Mechanisms of Antinociceptive, Antimanic, and Antidepressant Action

The onset of anticonvulsant and antinociceptive effects of carbamazepine is rapid and can occur after a single dose in appropriate animal model studies, or after 24 to 48 hours in most clinical studies of paroxysmal pain syndromes, such as trigeminal neuralgia (Fig. 34.14–2). Its antimanic actions can also be relatively rapid in onset, beginning within the first several days of treatment, but several weeks are typically required for maximum treatment response in patients. In contrast, the antidepressant effects of carbamazepine are often delayed, with 3 to 4 weeks required

before maximum effects are observed. However, because carbamazepine can be relatively sedating, an improvement in sleep may occur much earlier, yet as with other antidepressant modalities, the degree of improvement in sleep is not correlated with the degree of subsequent antidepressant response.

In assessing mechanism of action related to clinical effects, the actions of carbamazepine at clinically relevant blood levels and in the appropriate time frame should be considered, as schematized in Figure 34.14–2. Immediate effects would be more likely related to the anticonvulsant and antinociceptive profile of the drug, whereas effects requiring more chronic administration would be those more likely linked to the parallel time course of antidepressant effects of carbamazepine. The anticonvulsant effects of carbamazepine have been most closely linked to blockade of type 2 or batrachotoxin-sensitive sodium channels. When these channels are inactivated, they tend to decrease release of excitatory amino acids such as glutamate and inhibit sustained rapid neuronal firing in a variety of in vitro models. This action of sodium channel blockade is shared by oxcarbazepine, as well as a variety of other anticonvulsant compounds, including phenytoin (Dilantin), lamotrigine (Lamictal), and topiramate (Topamax), and, to a lesser extent, valproate (Depakene; Depakote). Although these are acute effects of the drug and are associated with decreased neurotransmitter release, Robert Belmaker and colleagues have postulated that the potency of sodium channel blockade is related to the antimanic efficacy of the anticonvulsant compounds as a group. This potential relationship, which is discordant for the time frame of clinical action and violated by topiramate (which is not antimanic), remains to be further investigated.

FIGURE 34.14–2. Schematic and time course of clinical and biochemical effects of carbamazepine. Seizure(s) and paroxysmal pain(p) syndromes respond rapidly to carbamazepine, whereas maximal effects in mania(m) and depression are delayed 2 to 3 weeks or more, respectively. The acute effects observed in animal and humans are probably related to anticonvulsant and antinociceptive efficacy, whereas chronic effects are more likely to be related to antidepressant mechanisms. Candidate mechanisms for each clinical effect are listed according to their occurrence at clinically relevant concentrations. Chr>A, chronic greater than acute; CSF, cerebrospinal fluid; DA, dopamine; GABA, γ-aminobutyric acid; HVA, homovanillic acid; l.c., locus ceruleus; NE, norepinephrine.

The acute anticonvulsant effects of carbamazepine have been closely linked to those that can be readily studied in a variety of animal models, including amygdala-kindled seizures. Carbamazepine appears to exert its actions on amygdala-kindled seizures through the so-called peripheral-type or mitochondrial benzodiazepine receptor. It is at this receptor that the peripheral-type ligand Ro 5-4864 is proconvulsant and an agonist, whereas PK1195 is anticonvulsant and an antagonist. Carbamazepine appears to share PK1195-like antagonist activities at the peripheral-type benzodiazepine receptor.

In contrast to the anticonvulsant effects of diazepam (Valium), which are reversed by a pure central benzodiazepine antagonist such as Ro 15-1788 or flumazenil (Romazicon), carbamazepine actions are reversed by Ro 5-4864 in a PK1195-blockable fashion, strongly implicating this peripheral-type benzodiazepine receptor in carbamazepine's anticonvulsant actions on amygdala-kindled seizures (as illustrated in Fig. 34.14–4A). Whether this peripheral-type effect is related to any of carbamazepine's psychotropic

properties remains to be further investigated.

The peripheral-type benzodiazepine receptors have been linked to cholesterol transport and calcium influx through mitochondrial membranes. Cholesterol is converted to pregnenolone in mitochondria, and this compound subsequently becomes transformed into neuroactive steroids allopregnanolone and allotetrahydro-DOC (which enhance γ-aminobutyric acid type A [$GABA_A$] receptors) and pregnanolone sulfate (which inhibits TBPS [t-(35)S]butyl-bicyclophosphorothionate] binding and voltage gated Ca^{++} channels, but enhances NMDA receptors) and dehydroepiandrosterone sulfate (which inhibit the barbiturate binding site). Thus, it remains possible that some of carbamazepine's actions initiated at peripheral-type benzodiazepine receptors may be achieved indirectly at other receptors through these effects on neurosteroid metabolism.

In addition to its blockade of glutamate release, carbamazepine is also potent at adenosine A_1 receptors. Its agonist properties at these receptors could account for not only some of its anticonvulsant properties but also its sedative properties.

It is also of interest that a variety of mood stabilizers beyond carbamazepine, such as lithium, valproate, and lamotrigine, are able to weakly block calcium influx through glutamate receptors of the NMDA subtype. Thus, the possibility remains that carbamazepine could exert relatively antiglutamatergic effects both by decreased release of glutamate and by relative decreases in glutamate's postsynaptic efficacy by inhibiting calcium influx. Glutamate NMDA receptor antagonist actions in general have been increasingly linked to potential antidepressant (ketamine) and possible mood-stabilizing effects (memantine), but further investigation of this possible linkage to carbamazepine's actions is required.

In common with both lithium and valproate, carbamazepine blocks inositol transport at the myoinositol transporter. Other common and differential effects of carbamazepine compared with lithium and valproate are illustrated in Figure 34.14–3.

The antinociceptive effects of carbamazepine have been most closely linked to effects at $GABA_B$ or baclofen-like receptors. Carbamazepine and baclofen share structural similarities, and the antinociceptive actions of both drugs are specifically inhibited by $GABA_B$ antagonists. It is also of interest that chronic but not acute administration of lithium, carbamazepine, and valproate are all associated with upregulation of $GABA_B$ receptors in the hippocampus, yielding this action as a potential convergent mechanism for mood stabilization. In contrast, unimodal antidepressants appear to upregulate $GABA_B$ receptors in frontal cortex.

Carbamazepine also exerts a variety of interesting effects on aminergic and indolaminergic systems. Carbamazepine is a very weak blocker of

norepinephrine reuptake, which is probably not clinically relevant, but it does decrease induced release of norepinephrine at clinically relevant concentrations. These preclinical findings converge with carbamazepine's ability to decrease CSF norepinephrine in manic patients.

Actions at noradrenergic α_2 receptors are of special interest in that the α_2 agonist in clonidine (Catapres) reverses some of carbamazepine's effects in some seizure models, whereas, paradoxically, the α_2 antagonist yohimbine reverses carbamazepine's anticonvulsant effects in other models. In epilepsy-prone animals, carbamazepine's ability to increase serotonin in the hippocampus appears to be important, as depletion of serotonin by several different mechanisms is associated with a loss of carbamazepine's anticonvulsant effects in this model.

Consistent with other mood-stabilizing drugs (lithium and valproate), carbamazepine is also able to decrease dopamine turnover, an action that could be related to its antimanic and mood-stabilizing properties. In contrast to the antipsychotics that directly block dopamine receptors, carbamazepine is not a direct antagonist at dopamine receptors and exerts its actions on the dopamine system through some other series of mechanisms. Dopamine levels have been reported to be increased in the prefrontal cortex after chronic carbamazepine administration. Carbamazepine does decrease levels of the dopamine metabolite homovanillic acid (HVA) in the CSF of affectively ill patients following probenecid administration, consistent with its ability to decrease dopamine turnover in animals.

Taken together, these data suggest that different mechanisms of carbamazepine's actions could be related differentially to its anticonvulsant efficacy in different seizure models. To the extent that this is clearly delineated in epilepsy research, as, for example, in relationship to α_2 receptors, it raises the possibility that different components of carbamazepine's actions could be related to different aspects of its efficacy and side effect profile in the affective disorders.

In addition to those mentioned above, carbamazepine's actions on a variety of neuropeptides appear to require chronic administration and, thus, could be pertinent to antidepressant actions. Chronic, but not acute, drug administration increases substance P levels and sensitivity in the striatum, findings of particular interest, as they are shared by lithium. Substance P antagonists have been studied in depression, but have a mixed record for effectiveness.

Carbamazepine decreases levels of somatostatin in CSF, in contrast to nimodipine (Nimotop; Nymalize), which increases CSF somatostatin. These differential effects of carbamazepine and nimodipine exist not only in terms of their blockade of calcium influx via NMDA type glutamate receptors versus L-type calcium channels, respectively, but also in terms of

their physiological effects on brain metabolism, as assessed by PET. Ketter and associates have found a differential relationship of metabolism in paralimbic areas, particularly in the left insula, to the degree of antidepressant response to carbamazepine, with higher baseline levels of activity being associated with better antidepressant response. In contrast, low levels of metabolism in the left insula are associated with better antidepressant response to the dihydropyridine calcium channel blocker nimodipine. In both instances, response to the drug was associated with a relative normalization of the baseline abnormalities in the activity of insula and related paralimbic areas of brain.

Carbamazepine's antidepressant effects may be mediated by those that are atypical of many other antidepressant modalities. For example, most antidepressants decrease β-adrenergic receptors in the prefrontal cortex, whereas carbamazepine upregulates them. Most antidepressants upregulate mineralocorticoid and glucocorticoid receptors and, thus, decrease cortisol, whereas carbamazepine increases plasma and urinary

free cortisol. This unusual profile of carbamazepine may explain why it is effective in some depressed patients with affective syndromes that are resistant to more traditional antidepressant modalities. A definitive link of carbamazepine to antidepressant response in depressed and PTSD patients with low basal cortisol or increased dexamethasone suppression has not been adequately studied, however.

As noted earlier, carbamazepine has both convergent and contrasting effects with other mood stabilizers, such as lithium and valproate (see Section 34.34, Table 34.34–1 in the section on valproate). Whereas lithium and carbamazepine block cAMP and G proteins, their effects on phosphoinositide turnover diverge. Lithium inhibits several inositol phosphatases, whereas valproate does not, and carbamazepine may enhance their activity. This contrasts with the common effects of the three drugs in blocking the inositol transporter and in decreasing arachidonic acid turnover. Carbamazepine, as well as the mood stabilizers lithium, valproate, and most antidepressant modalities increase BDNF. This action may be of considerable importance because the Val66 met allele of pro-BDNF and early life adversity can reduce hippocampal volume and yield low levels of BDNF in hippocampus and cortex in adulthood. Stressors, affective episodes (both mania and depression), and substances of abuse all can lower BDNF in hippocampus or serum of bipolar patients. As such, effective prophylaxis will indirectly prevent episode-related BDNF decrease, and mood stabilizer treatment may also directly increase BDNF and help correct persisting BDNF decreases.

Whereas lithium is a blocker of vasopressin effects via its inhibition of the second messenger cAMP, carbamazepine appears to exert indirect facilitatory effects at the vasopressin receptor. Therefore, because carbamazepine's effects are at the level of the receptor and lithium's blockade is below the receptor (in the transduction system), carbamazepine is unable to reverse the effects of lithium on the development of diabetes insipidus.

Carbamazepine, like phenytoin and lamotrigine, is not effective in blocking the initial developmental phase of electrical kindling of the amygdala, but is a highly effective anticonvulsant in the midphase of full-blown kindled seizures. Conversely, chronic treatment with carbamazepine does block the initial or developmental phase of pharmacological kindling with the local anesthetics lidocaine (Xylocaine) or cocaine. Chronic carbamazepine should thus make the development of cocaine-related seizures in humans less likely as well. This effect could contribute to carbamazepine's utility in helping with cocaine abstinence, an effect that has only been demonstrated compared with placebo in those with concomitant affective disorders.

Mechanisms of Tolerance Development

It is of interest that carbamazepine is acutely effective against completed amygdala-kindled seizures, but tolerance rapidly develops to this effect with repeated daily administration (Fig. 34.14–4A). This form of tolerance is called contingent tolerance as it develops only when the drug is given before the amygdala stimulation, but not when the drug is given immediately after the stimulation. In this way tolerance is contingent on having the drug present during the seizure-inducing stimulation and is clearly based on pharmacodynamics and not pharmacokinetic mechanisms. This tolerance that develops to the anticonvulsant effects of carbamazepine may provide an indirect but useful model for considering mechanisms potentially associated with clinical tolerance development in seizure and mood disorders and ways of slowing its development or reversing it once tolerance has occurred.

A gradual loss of efficacy after many years of successful treatment has been reported in a subgroup of patients via an apparent pharmacodynamic tolerance mechanism in patients with: paroxysmal pain syndromes such as trigeminal neuralgia, the prophylaxis of bipolar illness (Fig. 34.14–5), and to a lesser extent in clinical epilepsy syndromes. Some of the ways of slowing tolerance development in the preclinical seizure model could be tested clinically for their relevance to human therapeutics, either in epilepsy patients specifically or in other syndromes such as bipolar disorder as well.

FIGURE 34.14–4. **A:** Schematic illustration of contingent tolerance to carbamazepine (CBZ): development and reversal. In fully kindled animals (*open circles, squares*), carbamazepine treatment inhibits kindled seizures (*filled squares*). Repeated drug administration before (*filled squares*), but not after (*filled circles*), stimulation results in tolerance development. Tolerance induced in this matter (*filled squares*) can be reversed by a period of kindled seizures with drug administration after each seizure (*open squares, dotted lines*). **B:** Seizures enable carbamazepine's anticonvulsant effect. *Left side:* In fully kindled animals, CBZ was administered (15 mg/kg, i.p.) and produced complete seizure suppression (CBZ-first day). Animals were then divided into two groups that received either 13 daily amygdala-kindled seizures (at 800 μA [*open triangles*]) or no treatment. Following this, both groups of animals received 3 days of kindling stimulation preceded by CBZ administration on each day (15 mg/kg). The rats that did not experience seizures for the 13-day interval showed only a partial response to CBZ (*closed squares*), whereas the rats that underwent seizures again showed complete seizure suppression by CBZ. Both groups were then given repeated seizures (*open squares and triangles*) to reinstate the original CBZ effect. *Right side:* A crossover design was used to replicate the initial finding. Animals that previously were given no treatment now received 13 days of seizures (*open squares*) and vice versa. Again, and even more robustly, the animals that did not experience seizures for 13 days showed no anticonvulsant response to CBZ administration (day 14), whereas the animals experiencing seizures showed almost complete seizure suppression.

FIGURE 34.14–5. Life chart showing the phases in evolution and treatment response in a female patient with bipolar II disorder. This life chart illustrates the phenomena of illness progression, probable antidepressant-induced cycle acceleration (m 1981), lack of response to lithium in a rapid cycler (1984–5), response to the combination therapy of lithium and carbamazepine, development of loss of responsiveness to this treatment regimen via tolerance (1989), and cross-tolerance to valproate (1990). Key: Lithium (= = = =); carbamazepine (//////); valproic acid (VVVV); tricyclics (-.-.-.); benzodiazepines (–.–.–.); thyroid (TTTT); other (oooo). As noted above, the tolerance that develops to carbamazepine's anticonvulsant effects on amygdala-kindled seizures is not related to pharmacokinetics or a drop in carbamazepine blood levels. This can be demonstrated by the fact that tolerance develops only when the drug is given to the animal just before each amygdala stimulation, but not when the same dose of drug is administered immediately after each kindled seizure has occurred. Animals administered daily carbamazepine just after

each seizure has occurred (and drug levels again become negligible prior to the next stimulation the next day) never become tolerant. In this fashion, tolerance development is contingent on the drug's being in the brain concurrently with the amygdala stimulation. This type of contingent tolerance can be reversed either by a period off the drug (and the occurrence of seizures in the medication-free state) or, remarkably, by a period of continuing to give the drug daily, but now after (rather than before) each of a series of several once-daily seizures has occurred.

The neurobiology of this anticonvulsant tolerance development has been preliminarily explored in the kindled seizure model and appears to involve differential regulation of a variety of seizure-induced adaptations at the level of gene expression. Seizures ordinarily induce a variety of neurotransmitter and receptor effects that have been linked either to the primary pathology of kindled seizure progression or to more short-lived secondary compensatory or endogenous anticonvulsant effects (Table 34.14–3, left column). For example, thyrotropin-releasing hormone (TRH) peptide and its messenger ribonucleic acid (mRNA) are increased for approximately 4 days after an amygdala-kindled seizure. However, TRH does not increase after a seizure that occurs when animals are tolerant to carbamazepine.

TRH is likely an anticonvulsant adaptation based on the finding that its bilateral injection of TRH into the hippocampus decreases amygdala-kindled seizures. Further supporting this perspective are the observations that after a period of 4 or more days after the last amygdala-kindled seizure, endogenous TRH levels and other putative endogenous anticonvulsant adaptations dissipate and carbamazepine loses its anticonvulsant effectiveness (even in nontolerant animals) (Fig. 34.14–4B; day 14). These data suggest that TRH is one example of many endogenous substances that are induced postictally in an attempt to prevent further seizures from occurring and at the same time are also required for carbamazepine's efficacy. Thus, the failure of seizures to induce TRH and other anticonvulsant peptides in carbamazepine tolerant animals could be relevant to this loss of efficacy. TRH also has antidepressant effects when administered intravenously or intrathecally to depressed patients. Therefore, it remains a possibility to be further studied that loss of depressive-episode induced increases in TRH could be related to clinical tolerance development in the mood disorders.

Similarly, in carbamazepine-tolerant animals, the breakthrough seizures selectively fail to induce other endogenous adaptations, such as increases in $GABA_A$ receptors, but increases in benzodiazepine receptors continue to occur (Table 34.14–3, right columns). The inability of GABA receptors to show their normal increase after a seizure is also observed at the level of the $GABA_A$ receptor subunit mRNAs. The mRNA for the α_4 subunit is one of several subunits that ordinarily increases after seizures,

but it fails to do so in the carbamazepine-tolerant state. Thus, in addition to an anticonvulsant neuropeptide such as TRH, transient seizure-induced increases in other inhibitory neurotransmitter receptors, such as those of $GABA_A$, and its α_4 subunit are also selectively suppressed during carbamazepine tolerance, which could contribute to its loss of anticonvulsant efficacy. That is, some of the needed episode-induced adaptations fail to occur.

These are just two examples of several neural systems that are selectively impaired after seizures in carbamazepine-tolerant animals but are consistently induced by seizures in nontolerant animals that have been exposed to the same number of prior seizures and the same amount of carbamazepine (but given after the seizure has occurred) (Fig. 34.14–4A). Also, supporting this view that seizure-induced adaptations are important to carbamazepine's efficacy is the observation that carbamazepine again becomes effective in tolerant animals, after a series of seizures are given in the absence of medication (which then re-induce the full range of adaptive effects on gene expression).

Clinical case studies suggest that this renewal of efficacy may also be seen after a period of time off medications in the instance of clinical tolerance development in seizure or mood disorders, but it would be preferable to find a new treatment agent that did not show cross-tolerance to carbamazepine so as to avoid the necessity of experiencing further episodes while off medication.

In the preclinical model of anticonvulsant tolerance to carbamazepine on amygdala-kindled seizures, cross-tolerance is observed to the anticonvulsant effects of PK11195 (a peripheral type of benzodiazepine antagonist), lamotrigine, and, surprisingly, valproate and levetiracetam (Keppra), but not to diazepam or phenytoin. How these cross-reactivities for seizure tolerance in the rodent relate to those in the clinical condition of recurrent affective disorders remains to be further studied. Finding ways to address clinical tolerance development is potentially important because a substantial group of treatment-refractory patients (perhaps some 20 to 40 percent) who initially experience an excellent prophylactic response to carbamazepine begin to show breakthrough episodes consistent with a tolerance process, which often begins after a period of 2 to 3 years of effective treatment (see years 1986 to 1988 in Fig. 34.14–5).

Interestingly, as in the seizure model of cross-tolerance between carbamazepine and valproate, the patient illustrated in Figure 34.14–5 failed to respond to valproate when she was becoming tolerant to carbamazepine. Further exploration of ways to circumvent tolerance development and ascertain which drugs do not possess cross-tolerance is of considerable interest. A number of approaches have been examined that slow tolerance development in the amygdala kindled seizure model. These include using sustained higher rather than marginal and then increasing doses of drug, combining carbamazepine with valproate, treating earlier rather than later in the course of kindling, and reducing the stimulation intensity (or lowering illness drive). Whether some of these are also pertinent to slowing tolerance development during clinical treatment of seizure and mood disorders remains to be studied systematically, but they are listed here for their potential heuristic value.

CLINICAL DRUG STUDIES

Acute Mania

Numerous double-blind studies of various designs have compared carbamazepine to placebo or other active agents that indicate antimanic efficacy. Two large placebo-controlled, parallel-group design trials have recently revealed that the long-acting formulation of carbamazepine

(Equetro) was significantly more effective than placebo in acute mania. Similar acute antimanic effects of carbamazepine that roughly parallel those of lithium and antipsychotics are illustrated in Figure 34.14–6.

FIGURE 34.14–6. Time course of double-blind acute antimanic effects of carbamazepine compared to lithium and neuroleptics. The incidence and time course of antimanic effects of carbamazepine appear comparable with those achieved by neuroleptics, although several studies have suggested a slightly faster onset of efficacy of neuroleptics in the first 3 days of treatment, a difference that was gone by 7 days. Even patients requiring seclusion for acute, fulminant, psychotic manic episodes may rapidly improve after initiation of treatment to carbamazepine alone.

Moreover, acute antimanic responsivity has been documented in double-blind, off-on–off-on study designs as illustrated in Figure 34.14–7, in a patient who was a clear nonresponder to lithium, as revealed by a

breakthrough episode during carefully monitored lithium treatment upon hospital discharge. The patient was readmitted in a full-blown manic episode despite lithium treatment and showed a third excellent re-response to active carbamazepine and, subsequently, has been able to remain out of the hospital during long-term prophylaxis with carbamazepine as supplemented by other agents. Response to carbamazepine but not to valproate has also been seen in some patients (Figs. 34.14–3 and 34.14–9). Other patients with bipolar disorder have shown the opposite pattern of clear-cut responses to valproate, but not carbamazepine, emphasizing the principle that response to one anticonvulsant is not predictive of response to another.

Acute Depression

Fewer studies have addressed the acute antidepressant effects of carbamazepine, but several are highly suggestive of efficacy. One large parallel-group study of carbamazepine compared with placebo has been completed recently by Zhang and associates (Table 34.14–4). These authors found 50 percent reductions in Hamilton Depression Rating Scale scores in 34.8 percent on placebo ($N = 23$), 63.8 percent on carbamazepine ($N = 47$), and 84.8 percent on carbamazepine plus a Chinese herbal preparation (Free and Easy Wanderer Plus [FEWP]) ($N = 46$; $p < 0.05$), further supporting the acute antidepressant effects of the drug. Zhang et al. have also demonstrated acute antidepressant effects of carbamazepine compared with placebo in unipolar depression.

Moreover, the authors have observed that a group of 10 patients at the National Institute of Mental Health (NIMH) who were initial good acute antidepressant responders to carbamazepine on a double-blind basis subsequently relapsed on placebo and then re-responded during a second blind treatment trial with carbamazepine (Fig. 34.14–8). This off-on-off–on documentation of responsivity indicates that carbamazepine has unequivocal antidepressant effects in a subgroup of highly treatment-refractory depressed patients. While good acute antidepressant effects occurred in about one-third of patients exposed to carbamazepine, the percentage of antidepressant response to this agent and the particular characteristics and predictors of response remain to be further delineated.

Initial data summarized in Table 34.14–5 suggest that those with more severe episodic and less chronic depressions were among the best responders to the drug, as were those with low baseline CSF HVA, the

major metabolite of dopamine. Carbamazepine responders also showed a pattern of baseline hypermetabolism on PET scans that is unusual and contrasts with the more typical hypofrontality of major depression. Some data also suggest that those with a history of depression in association with prior alcoholism are among those who respond well to the drug. This is of considerable interest because carbamazepine can block the effects of alcohol withdrawal in experimental animals, and the drug is widely used in the acute and long-term treatment of those with alcohol-related dysphoria in Scandinavian countries.

FIGURE 34.14–9. Efficacy of carbamazepine (CBZ) in preventing manic and depressive episodes in a patient whose symptoms were previously refractory to lithium and antipsychotic treatment **(A).** CBZ administered on a blind basis acutely suppressed manic and psychotic symptoms. During periods of CBZ dose reduction or placebo substitution, exacerbation of manic and psychotic symptoms was consistently noted and reinstitution of active CBZ treatment led to improvement on three different occasions. Each rating circle is one hospital day **(B).** The prophylactic effect of CBZ during double-blind, clinical trials in a treatment-refractory, rapidly cycling patient who required seclusion 26 percent of the time (based on each 24-hour day) while taking placebo or 30 percent of the time while taking lithium, but only 4 percent of the time while taking CBZ (*n* = 540 days) at doses greater than 800 mg per day. The patient was not responsive to two other antiepileptic drugs, phenytoin (seclusion 77 percent) or valproic acid (seclusion 22 percent), but did exceptionally well and rarely required seclusion (1.6 percent) while treated with the combination of CBZ and haloperidol. *n,* number of days in treatment. **C:** Dose-dependent therapeutic effects of carbamazepine during a prolonged manic episode in the same patient.

Prophylaxis

More than a dozen partially controlled studies (involving either randomization or double-blind comparison with other agents such as lithium) reveal that carbamazepine is approximately as effective as lithium in the prevention of affective episodes, although several caveats remain. In these controlled studies of carbamazepine prophylaxis, 224 of 382 (59 percent) showed a moderate to marked response to carbamazepine. Similarly, lithium response in these same studies occurred in 241 of 395 patients (61 percent). However, in several studies, there was better antimanic efficacy of lithium compared with carbamazepine.

The German collaborative study indicated several different predictors of response to these two agents. Lithium was substantially more effective than carbamazepine in those with a classic bipolar I diagnosis, with euphoric mania, no thought disorder or comorbid substance abuse, as well as (in other studies) a positive family history of affective disorder. Conversely, there was a trend toward better prophylactic efficacy of carbamazepine in those with bipolar II illness, schizoaffective diagnosis, dysphoric mania, and substance abuse comorbidity (current or prior), as well as (in other studies) a negative family history of bipolar disorder in first-degree relatives.

Case studies performed in a double-blind fashion have also documented that some patients respond to carbamazepine and they fail to respond to divalproex sodium (Depakote) (Fig. 34.14–9B) or vice versa. These observations are consistent with the notion that response to the anticonvulsants does not occur as a class effect, and that further elucidation of the clinical and biological predictors of response to carbamazepine would be of great clinical importance.

It is noteworthy that within individual patients there appears to be dose-related antimanic and antipsychotic responsiveness (Fig. 34.14–9C). However, there is little evidence of a relationship between blood levels across individuals and the degree of clinical antidepressant or antimanic

response (Fig. 34.14–10).

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System

Typical of many anticonvulsant drugs, carbamazepine can exert a variety of untoward effects on CNS function. Most commonly these include dizziness, ataxia, and diplopia (characteristically occurring approximately 2 hours after a given dose of the regular immediate-release formulation). These common side effects can largely be avoided with slow upward titration of the dose to just below a patient's side-effects threshold, which can vary greatly, as illustrated in Figure 34.14–10. Given this wide range of individual proclivity to side effects (Fig. 34.14–11) and the lack of a clear anticonvulsant dose–response relationship, the importance of individualizing dose titration is emphasized as preferable to attempting to achieve a set blood level within the conventional 4 to 12 μg/mL "therapeutic" window.

In overdose, carbamazepine produces drowsiness, stupor, coma, sinus tachycardia, atrial ventricular conduction blocks, hypotension or hypertension, seizures, nystagmus, and hyporeflexia or hyperreflexia. Hypothermia, oral dyskinesias, and respiratory depression can also occur, yet few fatalities have been reported even after ingestion of as high as 10 to 20 g of carbamazepine.

In overdose, supportive techniques include gastric lavage and

instillation of activated charcoal (10 to 100 g and then 12.5 g per hour) until the patient is symptom free. Consideration of charcoal hemoperfusion before the patient becomes hypotensive has also been recommended. Although flumazenil (Ro 15-1788) has been recommended by some, the preclinical pharmacology noted above would not support such a suggestion. Instead, the $GABA_A$ receptor partial inverse agonist Ro 15-4513, which has been shown to reverse alcohol intoxication and is also effective in reducing the sedation and lethality of carbamazepine overdose in rodents, should be considered.

Carbamazepine's effects on memory and psychomotor performance have generally been minor, and improvement in a few indices has even been reported during treatment. However, higher doses or those that exceed an individual's toxic threshold can be associated with impairment. A similar range of side effects can occur with oxcarbazepine, although it is generally better tolerated than carbamazepine with the exception of an increased incidence of hyponatremia (Fig. 34.14–1).

Blood

As summarized in Table 34.14–6, the hematopoietic system is a major target of carbamazepine's benign and serious adverse actions. A statistically significant but usually clinically insignificant suppression of the white blood cell (WBC) count occurs in a substantial proportion of patients and is thought to be based on the drug's ability to inhibit colony-stimulating factor. Lithium enhances colony-stimulating factor and will reverse the benign WBC suppression of carbamazepine.

In contrast, the potentially life-threatening occurrence of agranulocytosis, pancytopenia, or aplastic anemia is a rare phenomenon and thought to occur in approximately 1 in 25,000 to 100,000 patients. Because of the rarity of these idiosyncratic events, many authorities recognize the inadequacy of routine blood count monitoring and suggest advising patients that, in the face of clinical signs of potential hematological dysfunction (such as fever, sore throat, rash, petechiae, bruising, or overt bleeding), they should immediately contact their physician. It may be wise to monitor the complete blood count (CBC) during initial phases of carbamazepine administration so as to assess the degree of benign white count suppression or any evidence of more problematic changes, such as drops in platelet or red cell counts, which deserve closer monitoring and attention.

In contrast to carbamazepine, the routine benign suppression of the WBC has not been reported with oxcarbazepine, and the incidence of more serious blood dyscrasias does not appear elevated over baseline. No hematological monitoring is required with this agent.

Hormonal Effects

Carbamazepine increases the 24-hour excretion of urinary free cortisol and notably induces a robust escape from dexamethasone suppression. These effects are thought to be not entirely related to heightened metabolism of steroid compounds (such as lowering of dexamethasone levels) and may suggest actions of carbamazepine that are contrary to those of more traditional antidepressants that downregulate the hypothalamic–pituitary–adrenal axis and increase glucocorticoid hormone receptors upon chronic administration. Whether this side effect of increasing cortisol could be clinically useful in the treatment of patients with PTSD who have abnormally low basal secretion of urinary free cortisol and show enhanced sensitivity to dexamethasone suppression compared with normal or depressed patients remains to be systematically explored.

Carbamazepine decreases circulating levels of thyroxine (T_4), free T_4, and triiodothyronine (T_3) without substantially altering thyroid-stimulating hormone. Studies indicate that it does not affect basal metabolic rate and that thyroid replacement is almost never required. In fact, patients with the largest decrements in T_4 or free T_4 showed the greatest degree of antidepressant response to carbamazepine in one series. For example, the degree of improvement in depression with carbamazepine was inversely related to the degree of decrease in free T_4 from baseline ($r = -0.56$; $N = 36$; $p = .0004$).

Renal Effects (Hyponatremia)

Carbamazepine has direct or indirect agonist-like effects at the vasopressin receptor, accounting for its occasional use in the treatment of diabetes insipidus. It will not reverse the lithium-induced variety of this syndrome, however. This carbamazepine-increased resorption of water predisposes patients to the development of hyponatremia and, in rare instances, water intoxication. Elderly patients, women, and those treated with high doses are more prone to this side effect. Several small case series suggest that carbamazepine-related hyponatremia can be prevented or reversed by the administration of lithium or demeclocycline (Declomycin).

Hyponatremia is the one area in which oxcarbazepine has a higher incidence of side effects than carbamazepine. Approximately 3 to 5 percent of patients treated with oxcarbazepine develop hyponatremia, and whether lithium or demeclocycline would be effective treatments is not known.

The elimination half-life of oxcarbazepine is prolonged in those with renal impairment.

Skin

Carbamazepine can induce a variety of dermatological syndromes—from a common benign macular papular pruritic rash typically emerging in the first 9 to 23 days after drug initiation to more serious conditions. Drug cessation usually results in regression of the rash, but, in rare instances, it can progress to exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome (SJS), or toxic epidermal necrolysis (TEN). Given the inability to distinguish which rashes might evolve toward these serious end points, most clinicians recommend stopping the drug in the face of even the benign presentation of a carbamazepine-related rash, which can be expected to occur in some 5 to 15 percent of individuals. However, a substantial group of patients re-exposed to carbamazepine will not have a re-emergence of the rash. The rash rate may be lower with the new extended release preparations.

In those individuals who appear to respond well to carbamazepine but not other agents, one can attempt to suppress the benign dermatological reaction with prednisone (Cordrol) (40 mg per day). However, several case reports have indicated that, in the face of evidence of more serious systemic allergy (such as fever, lymphadenopathy, and pneumonitis), such steroid co-treatment may not be successful.

Oxcarbazepine appears to have a reduced frequency of inducing both the benign and serious forms of rash. Moreover, the majority of patients who have a rash on carbamazepine, it will not recur on oxcarbazepine, but approximately 25 to 30 percent will show such a cross-sensitivity.

Considerable progress has been made in studying the pharmacogenomics of serious rash (SJS/TEN) on carbamazepine. The human lymphocyte antigen (HLA-B*1502 has been associated with this syndrome in patients of Asian descent (including Han Chinese, Thai, Malaysian, Filipino, and Taiwan) where the frequency of HLA-B*1502 is about 10 to 15 percent in the general population. If one has this antigen the odds ratio (OR) is 79.8. A direct interaction of HLA-B*1502 with cytotoxic T lymphocytes has been reported.

In contrast, in those of northern European decent, the risk of SJS/TEN is lower and of the order of 1 to 6 per 10,000 and is associated with HLA-A*3101 (which occurs in 2 to 5 percent of Europeans) with an OR of 25.9. 9 percent of Japanese have the HLA-A*3101 and it is associated with SJS/TEN OR = 10.8. In addition, preliminary evidence links HLA-B*1511 in

severe rash in Japanese. There is some controversy about the clinical utility of doing these genetic screens for potential carbamazepine-treated patients, but consensus is emerging that it would be worthwhile in those of Asian descent. In Thailand, the positive predictive value (PPV) was 1.92, while the negative predictive value (NPV) was 99.96.

There is another hypersensitivity syndrome (also called DRESS for drug reaction with eosinophilia and systemic symptoms) which occurs with a maculopapular rash (77 percent), increased liver enzymes (71 percent), eosinophilia (64.3 percent), fever (61 percent), lymphadenopathy (55 percent), and increased WBC (43 percent). Treatment with *N*-acetylcysteine (NAC) and/or intravenous immunoglobulin (IVIG) has anecdotally been reported effective as has treatment without the use of steroids. In those with the CBZ-induced hypersensitivity syndrome, CBZ-specific CD4(+) and CD8(+) T cells have been shown to persist some years after the resolution of the syndrome.

Liver

Like other anticonvulsants, carbamazepine has been associated with enzyme elevations. However, the outright appearance of hepatitis is extremely rare. As with oxcarbazepine, routine monitoring does not appear indicated.

Carbamazepine increases total serum cholesterol by an average of 20 points. It increases both high- and low-density lipoproteins, such that deleterious cardiovascular effects have not been unambiguously demonstrated. However, in those at high risk, preventive treatment with statins may be indicated. Homocysteine increases and folate decreases have been reported, so treatment with folate may also be helpful. Vitamin D levels may also decrease on carbamazepine with or without associated increases in osteoporosis.

Weight

In epilepsy patients, long-term treatment with carbamazepine is associated with small degrees of weight gain, which are significantly less than those observed on valproate. Oxcarbazepine is reported to be weight neutral. Carbamazepine decreases plasma levels of ghrelin, which also decreases with obesity.

Heart

The cardiac effects of carbamazepine are generally not prominent, although the drug does decrease atrial-ventricular conduction and is relatively contraindicated in patients with heart block. Carbamazepine has been used to treat digitalis-induced arrhythmias, including ventricular tachycardia. Bradycardia and syncopal episodes have been reported in rare instances,

with elderly women apparently at increased risk. Effects on blood pressure are typically minimal, and orthostatic hypotension is not a common accompaniment (as it is with several of the structurally related tricyclic antidepressants).

THERAPEUTIC INDICATIONS

Bipolar Disorder

Carbamazepine has been approved by the FDA for use in seizure disorders and trigeminal neuralgia. Like many treatments of bipolar disorder, carbamazepine is widely used in the treatment of acute mania and in long-term prophylaxis, but is only FDA approved as the long-acting preparation Equetro in acute mania. Carbamazepine is approved in many European countries, Japan, and Canada, however. It is considered a first- or second-line treatment in many guidelines and can be used as a substitute for lithium or as an adjunct to it for the partial responder (Table 34.14–4). Use in combination with lithium appears especially helpful in rapid cyclers.

Oxcarbazepine is thought to have effects similar to carbamazepine, but these have not yet been documented in large placebo studies and the drug is not FDA approved for bipolar illness. One study reported that that overall oxcarbazepine was no more effective than placebo, although it did exceed placebo in younger children with childhood-onset mania and not in adolescent-onset acute mania.

Carbamazepine can also be used in conjunction with unimodal antidepressants and antipsychotic agents, although several instances of drug–drug interactions are of some importance—for example, blood levels of nefazodone (Serzone), haloperidol, aripiprazole (Abilify), lurasidone (Latuda), and quetiapine (Seroquel) and lamotrigine are substantially reduced. Carbamazepine is not recommended for use in conjunction with the atypical antipsychotic clozapine (Clozaril) for fear of an additive risk of agranulocytosis, although the mechanisms for WBC suppression appear to differ. Use of carbamazepine in conjunction with valproate has not been as systematically explored in the refractory mood disorders as it has in seizure disorders. The combination usually requires a decrease in the dose of carbamazepine (because valproate displaces carbamazepine from its protein-binding sites and also increases the levels of the 10,11-epoxide by virtue of its inhibition of the epoxide hydroxylase). Case reports show efficacy of the combination of carbamazepine and valproate when either drug alone was not efficacious.

As antimanic effects are often observed within the first several days of treatment with carbamazepine, a several weeks' trial in acute mania is usually sufficient to ascertain whether the patient is going to be a responder. Longer periods of evaluation may be required to assess its potential antidepressant efficacy, however. Exploration of its potential

efficacy in long-term prophylaxis requires the observation of a consistent reduction of episode severity or the prevention of episodes for a duration several times longer than the previous usual "well interval." Thus, the faster the cycling at baseline, the more rapid can be the assessment of prophylactic effectiveness.

Although 4 to 12 μg/mL has been identified as a therapeutic anticonvulsant level, serum levels for antimanic efficacy have not been established, and there is no relationship of blood levels to the degree of acute antimanic or antidepressant response. One study suggested that 1,200 mg per day was associated with an antimanic response, although trough serum levels of 8 to 12 μg/mL are generally associated with good anticonvulsant and antimanic effects (Fig. 34.14–10).

Schizophrenia and Schizoaffective Disorder

A series of double-blind studies with few exceptions have indicated that the addition of carbamazepine to antipsychotics is more effective than placebo, particularly in those patients with more florid positive symptoms and problems with aggression and dyscontrol. It does not appear useful as an adjunct in chronic, negative, symptom-prominent schizophrenia. Carbamazepine is helpful in schizoaffective disorder, particularly in depressed phases. One study suggested that, in contrast to carbamazepine, oxcarbazepine was less effective in those with more fulminant psychotic manic symptoms.

Impulse Control Disorders

A very substantial case series literature indicates that carbamazepine is highly effective in a wide range of aggressive syndromes and impulse-dyscontrol disorders that can be manifest in those with diagnoses of borderline and other personality disorders, affective disorders, and schizophrenia. Its efficacy in these dyscontrol syndromes appears independent of the presence or absence of an associated EEG abnormality.

Other Disorders

Carbamazepine is as effective in acute alcohol withdrawal syndromes as diazepam, and it does not have the abuse liability of the benzodiazepines. Greater anxiolytic and global distress decreases have also been reported in withdrawing alcoholics treated with carbamazepine compared with benzodiazepines. In addition, placebo-controlled prophylactic studies of alcohol dependence have suggested greater relapse prevention of heavy drinking with carbamazepine. Although carbamazepine inhibits the development of cocaine-kindled seizures and their associated lethality in rodents, controlled clinical studies in cocaine abusers did not indicate that it is more successful in maintaining abstinence or drug-free urine than

placebo, except in a subgroup with concomitant mood disorder.

Open studies suggest the potential use of carbamazepine in the treatment of PTSD, particularly the paroxysmal recurrent components and the associated sleep disorder. Isolated case reports, but no controlled clinical trials, indicate its adjunctive use in other anxiety disorders and in OCD.

PRECAUTIONS AND ADVERSE REACTIONS

The *Physicians' Desk Reference* indicates that aplastic anemia and agranulocytosis occur in conjunction with the use of carbamazepine at a rate five to eight times greater than that in the general population. That incidence is approximately six patients per 1,000,000 of the population per year for agranulocytosis and two patients per 1,000,000 population per year for aplastic anemia. If, in the course of treatment, a patient exhibits low or decreased WBC or platelet counts, that individual should be monitored closely in the face of stable benign WBC suppression; the usual minimum safe total WBC count is approximately 3,000 and absolute neutrophil count approximately 1,000 to 1,500 neutrophils/mm^3. If there is a concomitant suppression of the red cell or platelet series or other indications of bone marrow depression, the drug should be stopped immediately.

Carbamazepine will increase the metabolism of estrogen in birth control formulations, resulting in occasional unwanted pregnancies. Therefore, a higher dosage form of the estrogen component or other contraceptive devices should be used.

Carbamazepine is a category D drug and should be avoided during pregnancy. There is a several percentage risk of spina bifida with the use of carbamazepine, and this appears to increase with anticonvulsant combination treatment. In one series, carbamazepine was reported to decrease head size and body length, although the developmental lag was completely compensated for after a period of several months. Although carbamazepine and its epoxide metabolite are transferred to breast milk during lactation, their concentrations are approximately 50 percent of those in maternal plasma. There are no adequate studies of the clinical effects of oxcarbazepine in pregnant women; given its similar structure to carbamazepine and evidence of problems in animal studies, so one should also consider it teratogenic in humans until more systematic data to the contrary are acquired.

DRUG INTERACTIONS

In contrast to oxcarbazepine, carbamazepine is a potent inducer of cytochrome P450 oxidase enzymes, particularly of the 3A4 category. This leads to its own autoinduction after 2 to 3 weeks, as well as a reduction in the levels of a variety of other compounds listed in Table 34.14–2.

If a patient is switched from carbamazepine to oxcarbazepine, deinduction of the 3A4 enzyme should be expected, and substances that would have their levels reduced by carbamazepine may increase. This is particularly important for lamotrigine, as carbamazepine approximately halves lamotrigine levels and substantial increases in lamotrigine levels would occur with carbamazepine discontinuation. This could also occur with dicumarol and warfarin (Coumadin), increasing proclivity for excess anticoagulant activity and increased bleeding.

Of potential importance for the generation of carbamazepine's toxicity are a series of agents that inhibit either cytochrome oxidase 3A4 or the epoxide hydroxylase, as schematized in Figure 34.14–12. Many commonly used agents markedly increase blood levels of carbamazepine (Table 34.14–7). These include the antibiotic erythromycin and all of its related congeners, as well as the calcium channel blockers verapamil (Verelan) and diltiazem (Cardizem), but not nifedipine (Adalat), nimodipine, or amlodipine (Norvasc). The antituberculosis drug isoniazid (Nydrazid) will also markedly increase carbamazepine levels, but more minor effects are observed with dextropropoxyphene (Darvon), fluoxetine (Prozac), and nicotinamide (Nicomide), and minimal effects occur with cimetidine (Tagamet).

FIGURE 34.14–12. Carbamazepine (CBZ) metabolism. *Bottom left:* Drugs that inhibit cytochrome P450 increase CBZ. ++, drugs that decrease the level of the active metabolite carbamazepine through induction of its oxidative metabolic pathway cytochrome P450; +, drugs that decrease the level of the active metabolite carbamazepine-10, 11-epoxide (CBZ-E) through induction of the epoxide hydroxylase and production of the inactive dihydroxy metabolite (CBZ-D); –, drugs that increase the level of carbamazepine-10,11-epoxide through blockade of the epoxide catabolism. Drug names in capital letters indicate common

or more important interactions.

There are fewer drug–drug interactions of importance for oxcarbazepine. However, strong inducers of cytochrome P450 enzymes (such as carbamazepine) decrease plasma levels of the monohydroxy derivative metabolite by 29 to 40 percent. As noted in Table 34.14–1, there is no autoinduction, and few major drug–drug interactions have been reported. However, oxcarbazepine reduces estrogen levels in oral contraceptives, and its use, as with carbamazepine, will necessitate higher dosage forms or alternative contraceptive devices.

Use of carbamazepine fell off in the 1990s after a decade of considerable use in the 1980s. One reason was the advent of valproate and the notion that it was easier to use. However, now that it is clear that some patients are relatively selective responders to carbamazepine, it becomes increasingly important to demystify some of the important details about its use. A primer employing a dozen key principles is included in Table 34.14–8.

Table 34.14–8.
CBZ in Bipolar Illness: A Brief Users Guide

Start with low (200 mg) H.S. doses in depression, euthymia; higher doses (600–800 mg/day in nighttime divided doses) in manic inpatients.

All H.S. dosing is reasonable with CBZ ER (Equetro) preparation.

Titrate slowly to an individual's response or side effects threshold (as there is no correlation with blood levels and degree of response).

Hepatic enzyme CYP 450 (3-A-4) induction and autoinduction occurs in 2–3 weeks; slightly higher doses may be needed/tolerated at that time.

Employ adequate birth control methods, including higher dosage forms of estrogen (as CBZ will lower estrogen levels).

Major increases in CBZ blood levels and potential toxicity are caused by erythromycin, verapamil, isradipine.

Warn regarding benign rash 5–10%; rare progression to severe rash, so drug should be discontinued. HLA-A*3101 predicts severe rash in northern Europeans and Japanese. HLA-B-1502 predicts in those of Asian descent.

Benign WBC decreases occurs regularly (and are usually inconsequential). Lithium will prevent or reverse these.

Rare agranulocytosis and aplastic anemia (several per million new exposures); warn regarding appearance of fever, sore throat, petechiae, bleeding gums, and to check with physician to obtain immediate CBC.

Avoid CBZ in pregnancy: Spina bifida 0.5%; other adverse outcomes about 8%.

Some people will response well to CBZ and not other mood stabilizers (lithium) or anticonvulsants (VPA).

Combination treatment often required to maintain remission and prevent loss of effect via tolerance.

H.S., nighttime or hours of sleep.

▲ 34.15 Cholinesterase Inhibitors and Memantine

ELIZABETH A. CROCCO, M.D., AND SAMIR A. SABBAG, M.D.

In 2010, the total number of people with dementia worldwide was 35.6 million. With the aging of the population, particularly in the United States, these numbers are expected to nearly double in the next 20 years. The incidence of Alzheimer disease (AD) increases with age. Epidemiological studies in the United States report its prevalence to be about 3 percent at age 65, which increases to greater than 30 percent by age 85. As the population ages, the prevalence of the disease will increase and significantly impact society and its health care systems.

Currently, cholinesterase inhibitors and memantine (Namenda) are the only medications approved by the U.S. Food and Drug Administration (FDA) for the treatment of AD and other dementias (Table 34.15–1). Since their introduction in the early 1990s, cholinesterase inhibitors were indicated only for mild to moderately ill patients with AD. Recently, their indication has expanded to include patients with moderate to severe AD and patients with dementia associated with Parkinson disease (PD). These agents are also being studied as potential treatment for other types of non-AD dementias, but they presently lack an FDA indication. Memantine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, has been approved for moderate to severe AD. It is routinely used with a cholinesterase inhibitor in clinical practice, as studies have demonstrated how this combination provides a potentially better response compared to monotherapy with a cholinesterase inhibitor.

Both the histopathology and clinical features of AD was first described over 100 years ago by Alois Alzheimer. Even today, its underlying pathophysiology and genetic basis continue to be investigated. Amyloid-β peptide and phosphorylated tau proteins make up the neuritic plaques and

neurofibrillary tangles seen in AD. These proteins play a central role in the two leading theories behind the pathogenesis of the disease. Additionally, loss of cholinergic neurons and impairment in cholinergic function have also been demonstrated in AD. Early subcortical changes occur in the nucleus basalis of Meynert, which provides cholinergic innervation to the hippocampus and cortex. Decline of acetylcholine in this area has been linked to the cognitive impairment seen in AD, and has been the basis for cholinergic therapies.

Currently, the most effective approach to increasing acetylcholine activity is achieved with the use of cholinesterase inhibitors. Cholinesterase inhibitors deter the activity of the enzymes that break down acetylcholine at the synapse. Two enzymes are known to hydrolyze acetylcholine: acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE). AChE has two binding sites—anionic and esteratic—and is present in several areas of the brain, as well as in erythrocytes, platelets, lymphocytes, and skeletal muscle. BuChE has a similar structure to that of AChE but lacks the peripheral anionic binding site. It is synthesized in the liver, secreted into the plasma, and found in the gastrointestinal tract and heart, comprising approximately 10 percent of the total amount of cholinesterase in the central nervous system (CNS) present in glial cells. In vitro studies indicate that cholinesterase inhibitors can selectively inhibit AChE and BuChE to varying extents. Currently, three cholinesterase inhibitors are available in the United States: donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). The first cholinesterase to be approved for treatment of dementia, tacrine (Cognex), was recently removed from the US market due to its high side-effect profile.

Table 34.15–1.
Medications Used in Neurocognitive Disorders

Drug (Brand)	Formulation	Indications	Starting Dose	Titration	Dosage Range
Tacrine (Cognex)	10-, 20-, 30-, 40-mg capsules	Mild to moderate AD dementia	10 mg 4 times a day	Increase by 10 mg 4 times a day (40 mg total daily) every 4 weeks	40–160 mg daily with 4 times a day dosing
Donepezil (Aricept)	5-, 10-, 23-mg tablets 5-, 10-mg disintegrated tablets	Mild to moderate and severe AD dementia	5 mg daily	Increase to 10 mg after 4 weeks. Increase to 23 mg daily after 3 months	10–23 mg daily
Rivastigmine (Exelon, Exelon	1.5-, 3-, 4.5-, 6-mg oral solution	Mild to moderate AD dementia Major	4 mg twice a day 8 mg daily	By 1.5 mg twice a day every 4	3–6 mg daily for oral preparation.

Patch)	4.6-, 9.5-, 13.3-mg transdermal patch	neurocognitive disorder due to Parkinson disease	extended release	weeks. Increase to 9.5 mg in 4 weeks and then to 13.3 mg after 4 weeks for transdermal patch	4.6 – 13.3 mg daily for transdermal patch
Galantamine (Razadyne, Razadine ER)	4-, 8-, 12-mg tablets 8-, 16-, 24-mg extended-release capsules 4-mg/mL oral solution	Mild to moderate AD dementia	1.5 mg twice a day 4.6-mg transdermal patch	Increase by 4 mg twice a day every 4 weeks. Increase by 8 mg every 4 weeks for extended release	4–12 mg in divided doses for oral preparation. 8–24 mg daily for extended release
Memantine (Namenda, Namenda XR)	5-, 10-mg tablets 7-, 14-, 21-, 28-mg extended-release capsules 10-mg/5-mL oral solution	Moderate to severe AD dementia	5 mg daily 7-mg extended-release formula	By 5 mg daily in weekly intervals. Increase by 7 mg daily extended-release formula	10–20 mg daily in divided dose for oral preparation. 7–28 mg daily for extended release
Memantine XR and donepezil combination (Namzaric)	14-mg memantine ER/10-mg donepezil capsules 28-mg memantine ER/10-mg donepezil capsules	Moderate to severe Alzheimer disease when patient already stabilized on memantine ER and donepezil	14-mg memantine ER/10-mg donepezil daily 28-mg memantine ER/10-mg donepezil daily in severe renal impairment		

Tacrine inhibits BuChE 18 times more potently than AChE, while donepezil inhibits AChE with higher selectivity. Rivastigmine inhibits both AChE and BuChE, and galantamine selectively inhibits AChE, while also producing allosteric modulation of nicotinic receptors. Although the actions of AChE have been thoroughly studied, the relevance of BuChE and nicotinic receptor modulation has become increasingly apparent to the overall function of cholinergic neurons. BuChE has been shown to be important in the development of amyloid plaques. When a polymorphic mutation of BuChE, known as the K variant, is combined with the apolipoprotein E4 (APOE4), this may result in an increased risk factor for developing AD. Nicotinic modulation results in increased ion channel

opening, enhancing cholinergic transmission independent of enzymatic inhibition. Nicotinic receptors are found in presynaptic and postsynaptic neurons. Presynaptic nicotinic receptors regulate the release of acetylcholine, glutamate, and γ-aminobutyric acid (GABA), while postsynaptic nicotinic receptors mediate cholinergic transmission in the hippocampus and cerebral cortex. Both receptor types play an important role in memory and learning.

Cholinesterase inhibitors can be classified into three categories: reversible, pseudoirreversible, and irreversible. These categories are based on the duration of enzyme inhibition. Reversible inhibitors bind to the enzyme for a very short time (seconds to minutes). Pseudoirreversible inhibitors bind for hours, but new enzymes are not developed to assist in the body's biochemical functions. Irreversible inhibitors bind to the enzyme and prevent further activity, prompting the body to synthesize new enzymes.

Prior to the appearance of medications for cognitive impairment, the estimated total direct and indirect costs for the treatment and care of Alzheimer patients in the United States was nearly $100 billion in 1990. Their introduction was associated with a reduction in costs of medical and social services, as well as a slight increase in functioning and a delay in nursing home placement. These medications helped bring to a lesser degree acute hospital visits, outpatient clinic encounters and unpaid caregiver time.

In addition to AD, there are other neurodegenerative disorders that can commonly lead to a major neurocognitive disorder. Major neurocognitive disorders due to PD, Lewy Body Disease (LBD), vascular dementia (VD), as well as frontotemporal dementia (FTD) have distinct pathophysiological mechanisms, although some overlap may occur. Dementia can occur in up to 40 percent of idiopathic PD patients who demonstrate decline in cholinergic function. The cholinesterase inhibitor, rivastigmine, is indicated by the FDA for the treatment of cognitive impairment in PD, and there is some evidence that other cholinesterase inhibitors like donepezil may also improve major neurocognitive disorder due to PD. Diffuse LBD, although a distinct illness clinically, has similar pathophysiological mechanisms to PD and may possibly benefit from cholinesterase inhibitors. VD may produce cerebrovascular damage causing cholinergic dysfunction. Additionally, the added presence of AD pathology rather than pure VD may explain why some studies demonstrate higher rates than others in improvement in VD with the use of cholinesterase inhibitors. Currently, there are no adequate randomized controlled trials (RCTs) showing efficacy of cholinesterase inhibitors in the treatment of FTD and similar dementias with tau neuropathology. Cholinesterase inhibitors are commonly used off-label in clinical practice in select non-AD dementia conditions, but tolerability and adverse reactions must be carefully taken into account.

Patients with mild neurocognitive disorders, including mild cognitive impairment (MCI), are a group of patients who display a modest decline in cognition. They do not meet criteria for dementia, as this decline does not preclude them from independent performance of everyday activities. These individuals pose a challenging dilemma, as cholinesterase inhibitors are not approved for the treatment of their illness, even though the annual conversion rate into a major neurocognitive disorder is approximately 10 to 15 percent. Trials with these medications have not been found to decrease the rate of progression to dementia, and at this time, there is weak support for using them in these conditions.

Very few studies have looked into the efficacy of cholinesterase inhibitors in treating behavioral and psychiatric symptoms, such as agitation, visual hallucinations or apathy in patients with AD. The evidence is limited due to methodological problems with these studies. Currently, despite not having FDA approval for treatment of behavioral or psychiatric problems, their use could be an alternative in the absence of other safe and effective options.

Cholinesterase inhibitors and memantine are moderately effective in treating the symptoms of AD including cognitive, functional, and behavioral impairment. Unfortunately, these agents are not disease-modifying and risks versus benefit must be carefully weighed by the clinician before starting treatment. Clinicians, caregivers, and patients should be made aware of and educated on realistic goals of therapy. The overall results of the pharmacological intervention should be to maintain for a longer period of time the patient's quality of life and functional ability. By detecting, diagnosing, and treating AD early during its development, there is an opportunity for clinicians and caregivers to optimize drug therapy and other psychosocial interventions that are important in the disease process. Cholinesterase inhibitors are indicated for all stages of the disease and early therapeutic interventions can maximize pharmacological efficacy with these agents.

TACRINE

The first cholinesterase inhibitor approved by the FDA for the treatment of AD, tacrine was introduced to the market in 1993. Tacrine is a reversible cholinesterase inhibitor that works by making intrasynaptic acetylcholine readily available in the brain of patients with AD. Despite being the first agent developed for AD, the use of tacrine was inconvenient due to its multiple daily dosing of three to four times a day and the likelihood of hepatoxicity, which required constant monitoring of liver function during its use. In 2013, tacrine was removed from the US market due to concerns with safety and is no longer available.

Chemistry

The molecular structure of tacrine is shown in Figure 34.15–1. It belongs to the family of the aminoacridines and consists of a 1,2,3,4-tetrahydro-9-acridinamine monohydrochloride monohydrate. This component is hydrolyzed to a variety of metabolites, including velnacrine maleate. This metabolite was under investigation as a possible treatment for AD, but studies were discontinued due to side effects, including elevation of transaminases. Other hydroxylated metabolites—2-OH and 4-OH—in tacrine possess weak cholinesterase inhibition activity.

Tacrine

FIGURE 34.15–1. Molecular structure of tacrine.

Pharmacological Actions

Pharmacokinetics. Tacrine possesses a low bioavailability (Mean [M] = 17 percent) despite being well absorbed from the gastrointestinal tract. Its time to peak plasma concentration ranges from 1 to 2 hours. Absorption rate and level of tacrine is decreased up to 40 percent by food intake, however food does not affect absorption if the medication is taken at least 1 hour before a meal. The elimination half-life of tacrine is 1.3 to 7 hours and reaches steady-state concentrations in 24 to 36 hours. Protein binding is at about 75 percent with a steady-state volume of distribution of 300 L. Tacrine is primarily metabolized by hepatic cytochrome P450 (CYP) 1A2 and to a minor extent, by CYP 2D6 isozymes. Its disposition is not affected by renal impairment and dose adjustments are not needed. There is a nonlinear relationship between tacrine dose and steady-state concentration. In women, plasma concentrations of the drug are almost twice as in men when comparable doses are given. This difference could be due to a lower CYP 1A2 activity in women. Smoking is a CYP 1A2 inducer that significantly lowers plasma drug concentrations in smokers compared to nonsmokers by 33 percent. Dose adjustments are not necessary when considering age, as this factor is not significant in tacrine pharmacokinetics.

Pharmacodynamics. Tacrine is a noncompetitive, centrally active reversible cholinesterase inhibitor that inhibits BuChE activity 18 times more than AChE activity in the cerebral cortex.

Design and Interpretation of Clinical Drug Studies

Two pivotal studies positioned tacrine as an effective treatment of mild to moderate AD, one study with a 12-week duration and the other one spanning 30. Both clinical trials found statistically significant differences between tacrine and placebo based on two primary outcome measures: the cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-cog) and the Clinician's Interview-Based Impression of Change (CIBIC).

The 12-week study included comparison groups taking placebo, 20, 40, and 80 mg of tacrine per day in an outpatient setting at 23 different centers. 468 patients participated in this study. Statistically significant differences were detected on both primary outcome measures in the group taking 80 mg/day when compared to placebo. Of note, reversible asymptomatic elevations of liver transaminases more than three times the normal value were seen in 25 percent of participants.

The 30-week double-blind, placebo-controlled trial, which involved 663 patients, evaluated tacrine effect at doses of 80, 120, and 160 mg/day. All groups started at 40 mg and the daily dose was increased at 6-week intervals in order to reach the desired goal. Those on the 120-mg group received this dose for the total final 18 weeks and the 160-mg group for the last 12 weeks. The groups using tacrine 120 and 160 mg/day demonstrated statistically significant improvement in the cognitive subscale of the ADAS-cog compared to the placebo group at 30 weeks. A similar finding occurred with the CIBIC scores with these doses. Forty percent of the tacrine 160-mg/day patients showed improvement in ADAS-cog scores by at least four points at week 30. Significant differences between the 80-mg/day group and placebo were not found.

Effects on Specific Organs and Systems

A dose-dependent effect appears to take place for therapeutic response, and the typical time frame necessary for response occurs after at least 12 weeks. Patients experienced elevated liver transaminases, sometimes up to 20 times the upper limit of normal, which represented a common cause for tacrine discontinuation. Several cases of liver toxicity have been reported, with elevated serum bilirubin, hepatitis, and liver failure as hallmarks. Most cases were reversible, but some deaths occurred. Constant liver function monitoring was necessary during treatment. Tacrine could potentially cause vagotonic cardiovascular effects and needed to be used with caution in patients with bradycardia and/or heart block. Due to increased cholinergic activity, tacrine can increase gastric acid secretion, placing patients at increased risk for developing ulcers. Patients who had a history of peptic ulcer disease or were taking nonsteroidal anti-inflammatory drugs (NSAIDs) needed monitoring of gastrointestinal symptom exacerbation when tacrine was being prescribed.

Therapeutic Indications

Tacrine was indicated for mild to moderate AD until it was removed from the market.

Precautions and Adverse Reactions

Clinical trials have reported frequent adverse side effects from tacrine, most notably increased liver transaminases, as mentioned in the effects on specific organs and systems section. These elevations were often asymptomatic but required monitoring, with some patients experiencing liver toxicity. Due to its hepatotoxic profile, tacrine was not indicated for patients who suffered from hepatic impairment. Gastrointestinal problems, including nausea, vomiting, and loose stools, were the second most frequent side effect observed.

Hepatic Monitoring and Rechallenge

Serum transaminase levels, specifically alanine transaminase (ALT), needed to be monitored every other week for 16 weeks, then monthly for 2 months, and then once every 3 months for patients without significant elevations. Dose adjustments were not needed until a value doubling the upper limit of ALT was reached. Weekly monitoring was recommended when two to three times the upper ALT limit occurred. When a level three to five times the upper limit of ALT was reached, tacrine dosage needed to be decreased by 40 mg/day with weekly ALT monitoring. If ALT levels normalized, dosage increase was resumed with every other week monitoring. If ALT level was greater than five times the upper limit, tacrine was discontinued and patients were monitored for symptoms of hepatitis. If jaundice or total bilirubin levels were greater than 3 mg/dL or there was presence of rash, eosinophilia, hepatitis, or fever, patients needed to permanently stop tacrine and not be rechallenged.

Drug Interactions

Being metabolized primarily via CYP IA2, drug–drug interactions could occur when given with agents that underwent the same metabolism. In conjunction with theophylline, tacrine increased its elimination half-life, doubling its concentration in plasma. Cimetidine coadministration results in tacrine increases of C_{max} and AUC by approximately 54 percent and 64 percent, respectively. Fluvoxamine is a potent CYP 1A2 inhibitor that decreased tacrine clearance by eightfold. Close monitoring was needed when prescribing fluvoxamine and tacrine together. Patients on theophylline demonstrated a 50 percent reduction in clearance when tacrine was taken at the same time. Tacrine could potentiate the effects of succinylcholine by inhibition of BuChE, the enzyme responsible for

succinylcholine breakdown. Women being prescribed estrogen replacement therapy (ERT) had enhanced clinical response to tacrine, which could have been due to increased tacrine plasma concentrations produced by ERT. Tacrine could also lengthen the action of succinylcholine-type muscle relaxants during anesthesia. All patients taking cholinesterase inhibitors need to be aware of concomitant use of anticholinergic medications, as they may interfere with their activity due to their mechanism of action.

Laboratory References

Elevation of the serum transaminase ALT is associated with the use of tacrine and occurred in about 28 percent of patients taking the drug. It does not interfere with complete blood counts, electrolytes, urinalysis, or other laboratory tests.

Dosage and Administration

Tacrine was available in 10-, 20-, 30-, and 40-mg capsules. Initial dosing was 10 mg four times a day, which was increased until a maximum of 40 mg four times a day was achieved, based on tolerance of adverse side effects. If liver transaminase elevation occurred, the dose was maintained or reduced. If tacrine was discontinued for longer than 4 weeks, the patient needed to be restarted at the initial dose of 10 mg four times a day with careful monitoring of liver enzymes. If gastrointestinal problems occurred, tacrine could be given with food, but this could result in a decrease in drug bioavailability.

DONEPEZIL

Originally developed in 1986, Donepezil was approved by the FDA in 1997 for its use in mild to moderate AD. It was later approved in 2006 for the treatment of severe AD as well. Unlike its predecessor tacrine, this medication immediately appealed to clinicians thanks to its once a day administration, lack of hepatotoxicity and not having to measure serum liver transaminase levels constantly.

Chemistry

Figure 34.15–2 shows the molecular structure of donepezil hydrochloride. It is a piperidine compound that consists of (±) –2,3 dihydro-5,6-dimethoxy-2-[[1-(phenylmethyl)-4-piperidinyl]methyl]-1H-inden-1-one hydrochloride.

Pharmacological Actions

Pharmacokinetics. Donepezil is not affected by food intake in its regular or oral disintegrating tablet presentations. The relationship between donepezil dose and its area under the plasma concentration time

curve (AUC) is linear at a dose range of 1 to 10 mg. It is bound to plasma proteins by approximately 96 percent (75 percent to albumin and 21 percent to α_1-acid glycoprotein). The donepezil 10-mg formulation reaches peak plasma concentration at approximately 3 hours, compared to 8 hours in the 23-mg tablet. Its volume of distribution at steady state is between 12 and 16 L/kg, reaching steady state after 2 weeks of use.

FIGURE 34.15–2. Molecular structure of donepezil.

Donepezil undergoes extensive hepatic metabolism by the CYP 2D6 and 3A4. 6-O-desmethyl-donepezil is its major active metabolite and possesses equal potency. It is also converted into an inactive *cis-N*-oxide metabolite and two glucuronide conjugates. The elimination half-life of donepezil is approximately 70 hours, allowing for once-daily administration. Age, gender, hepatic disease, and renal impairment have not been shown to affect donepezil disposition to any significant degree. Due to this, dose adjustments based on renal or liver function are not necessary. Donepezil is classified as a category C drug. There are currently no adequate trials of donepezil in pregnant women however, animal trials revealed that it may cause fetal harm. It therefore should not be used in pregnant women. It is unknown if it is excreted in breast milk.

Pharmacodynamics. Donepezil enhances cholinergic neurotransmission by increasing the concentration of acetylcholine through reversible, noncompetitive inhibition of AChE, the main enzyme involved in the hydrolysis of acetylcholine. Unlike tacrine, it is not highly selective for inhibition of butyrylcholinesterase (BuChE). It is a potent selective inhibitor that acts on the CNS, and it does not act on the peripheral nervous system.

Design and Interpretation of Clinical Drug Studies

A substantial number of randomized, double-blind, placebo-controlled studies have provided evidence of the effectiveness of donepezil as a treatment for AD at all of its stages. The results of these studies confirmed that donepezil was effective and well tolerated in treating the symptoms of mild to moderate AD, leading to its initial FDA approval. Additionally, the effectiveness of donepezil for the treatment of severe AD has been demonstrated by studies using both 10-mg daily doses and more recently,

23 mg.

To establish donepezil's effect on mild to moderate AD, two large multicenter clinical trials were conducted, both using similar study methods. One of them was a US study that took place during a 15-week period (12 weeks of active treatment followed by a 3-week blind placebo washout period), the other one a multinational study done during a 30-week period (24 weeks of treatment followed by a 6-week washout period). Patients were randomized into three groups: placebo, donepezil 5 mg, and donepezil 10 mg. In both studies, at the end of each treatment period (weeks 12 and 24), participants treated with placebo had a decline in their ADAS-cog score, while donepezil-treated patients showed statistically significant dose-dependent improvement. A scale measuring clinician's assessment of functionality with the help of information provided by a caregiver, called the Clinician's Interview-Based Impression of Change with caregiver input (CIBIC-plus), revealed scores at weeks 12 and 24 in each study that showed statistically significant improvement in the donepezil-treated groups. The 12-week study presented no difference between the 5-mg and 10-mg groups. On the other hand, the international study group demonstrated a statistically significant difference between the two doses, with the 10-mg donepezil group showing greater benefits in all outcome measures when compared to the 5-mg group. After the placebo washout periods, ADAS-cog scores declined in both donepezil-treated groups of the two studies, reaching scores that could not be differentiated from the placebo groups.

A 6-month randomized, double-blind, parallel-group, placebo-controlled study of 248 nursing home dwelling patients with severe AD (Mini-Mental State Examination [MMSE] score of 1 to 10), evaluated the effect of donepezil on cognition and daily functioning. Patients were assigned to donepezil or placebo. Donepezil dose was 5 mg/day for 30 days and then increased to 10 mg/day for the remainder of the study. The primary study end points were changed from baseline to 6 months on the Severe Impairment Battery (SIB) and the Alzheimer's Disease Cooperative Study–Activities of Daily Living–Severe Impairment Version (ADCS-ADL-SIV). The SIB uses a validated 40-item scale developed for the evaluation of the severity of cognitive dysfunction in more advanced AD patients. ADCS-ADL-SIV is a caregiver-based ADL scale composed of 19 items developed for use in clinical studies of dementia. When compared to baseline at 6 months, patients treated with donepezil displayed more improvement in SIB scores and less decline in the ADCS-ADL scores than placebo in severe AD subjects.

The use of donepezil 23 mg in moderate to severe AD was approved by the FDA in 2010, based on the conclusions of a multinational, randomized, double-blind study that included patients who were already being treated with a 10-mg dose for at least 3 months. 1,467 patients were randomly

assigned to receive either a 23 mg once a day dose of donepezil or a standard dose of 10 mg for 24 weeks. At week 24, changes in cognition and global functioning were assessed with the SIB and the CIBIC-plus, respectively. This study revealed a statistically significant benefit in cognition with the 23-mg dosing, but did not find significant change in global functioning. Side effects were also monitored, revealing increased incidence of gastrointestinal symptoms, which included nausea, vomiting, and diarrhea, in the higher 23-mg dose group.

One randomized placebo-controlled study was conducted over a 1-year period, evaluating the preservation of function in 431 patients with probable AD who received either placebo or donepezil. Participants randomized into the active treatment arm were started on 5 mg with a posterior dose increase to 10 mg on day 28. Function was assessed by evaluating basic activities of daily living (ADLs) and instrumental ADLs through the AD Functional Assessment and Change Scale. The results indicated that after 1 year, donepezil had a 38 percent reduction in the risk of functional decline when compared to placebo. Moreover, this study showed how donepezil delayed functional decline by 5 months in patients with AD. At 48 weeks, the probability of survival with no evidence of functional loss was 51 percent for those taking donepezil, compared to only 35 percent for those on placebo. These results demonstrated that continued use of donepezil benefits patients over a period of 1 year, and that untreated patients tend to decline in their functional ability.

Effects on Specific Organs and Systems

In the elderly, hepatic function is frequently decreased, leading to reduced tolerability of certain medications. Donepezil does not induce elevation of liver transaminases or causes hepatotoxicity and is, in general, well tolerated. Even though kidney function may also decrease with aging, donepezil may be safely administered in patients with moderate to severe renal impairment. This medication may produce vagotonic effects in the sinoatrial and atrioventricular nodes by acting on the muscarinic receptors, causing slowing of the heart rate. Like all cholinesterase inhibitors, it should be used with caution in patients with cardiac arrhythmias and significant cardiac dysfunction. Due to its increased cholinergic activity, donepezil may also augment gastric acid secretion in a dose-dependent fashion, causing gastrointestinal complications that potentially may increase the risk of gastric disease and gastrointestinal bleeding.

Therapeutic Indications

Donepezil is indicated for the treatment of mild, moderate, and severe AD. Additionally, select randomized, double-blind, placebo-controlled studies have demonstrated some benefit in cognition and functioning when

treating vascular dementia. Donepezil has not been approved by the FDA for this use, as there is concern for its safety in this population due to cardiovascular and cerebrovascular risks. Similarly, small studies have shown improvement of cognition in patients with LBD, but the use of donepezil in this population remains off-label.

Precautions and Adverse Reactions

The most common adverse reactions leading to discontinuation and poor tolerability of dose optimization in clinical settings include diarrhea, nausea, vomiting, insomnia, muscle cramps, fatigue, and anorexia. These side effects are usually mild and transient and have not resulted in a significant dropout rate during clinical trials with donepezil. Less commonly, donepezil can potentially cause more severe reactions such as seizures, cerebrovascular disease, or exacerbation of chronic obstructive pulmonary disease (COPD).

The incidence of gastrointestinal adverse side effects did not differ between patients with mild to moderate dementia when compared to severely ill patients. Patients who suffer from peptic ulcer disease, or are taking NSAIDs, need to be carefully monitored for gastrointestinal bleeding. Caution should also be exerted when using the 23-mg dose in patients who weigh less than 55 kg, as there have been increased reports of nausea, vomiting, and weight loss in this group. Due to donepezil's effect on cardiac conduction, donepezil should be used with caution in patients with cardiac arrhythmias, especially sick sinus syndrome. Patients may be at risk of developing bradycardia. It is recommended to titrate donepezil slowly to minimize the incidence of side effects. Additionally, donepezil is contraindicated in patients with known hypersensitivity to the drug or to piperidine derivatives.

Drug Interactions

Although metabolized mainly through the CYP 2D6 and 3A4, and highly protein bound at 96 percent, donepezil has minimal influence on drugs metabolized through these pathways. Pharmacokinetic studies have been conducted assessing the induction effects of donepezil on cimetidine, ketoconazole, risperidone (which is also metabolized through 2D6 and 3A4), warfarin and digoxin, and no effects have been observed on the pharmacokinetics of these drugs.

In vitro studies of inhibitors of CYP 3A4, such as ketoconazole, and 2D6, such as quinidine, have shown inhibition of donepezil metabolism. These studies have not translated into clinically significant drug–drug interaction. Phenytoin, carbamazepine, dexamethasone, rifampin, and phenobarbital, which are inducers of 2D6 and 3A4 pathways, can potentially increase donepezil's elimination rate. Donepezil is not affected

by the concomitant use of cimetidine or digoxin. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications, as donepezil may interfere with their activity due to its mechanism of action. Donepezil may also lengthen the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Donepezil has not been shown to interfere with any laboratory test including biochemical, urinalysis, or spectrometry.

Dosage and Administration

Donepezil is available in 5-, 10-, and 23-mg tablets and in an orally disintegrating tablet form of 5 and 10 mg. The recommended starting dose is 5 mg once a day at bedtime. After 4 to 6 weeks, the dose can be increased to 10 mg depending on tolerability. For mild to moderate AD, 5 and 10 mg are the recommended effective doses. In patients presenting with moderate to severe dementia, clinical trials have found doses of 10 and 23 mg effective. In the moderate to severe group, for those who are tolerating it well, the dose may be increased to 23 mg after a minimum of 3 months on a 10-mg dose. The medication should be administered at bedtime so that peak plasma concentrations occur during the night and potential adverse effects are minimized. As food intake does not affect its absorption, donepezil may be taken with or without food.

RIVASTIGMINE

Rivastigmine has been approved for the treatment of mild to moderate AD since 2000 by the FDA. It is also the only cholinesterase inhibitor approved, since 2006, for the treatment of mild to moderate dementia due to major neurocognitive disorder related to PD. Additionally, in 2013, rivastigmine was approved for severe AD. Rivastigmine is a second-generation cholinesterase inhibitor and has a different pharmacological profile in comparison to the earlier cholinesterase inhibitors, tacrine and donepezil.

Chemistry

Rivastigmine is composed of the chemical compound (S)-3-[1-(dimethylamino)ethyl]phenylethylmethylcarbamate. Its molecular structure is shown in Figure 34.15–3.

Pharmacological Actions

Pharmacokinetics. Rivastigmine is rapidly absorbed in its oral formulation, with a mean time to maximum plasma concentration (T_{max}) of

1 hour (range 0.8 to 1.7 hours). Additionally, it has a mean absolute bioavailability of 60 percent in comparison to intravenous drug administration. When ingested with food, its C_{max} is decreased by 30 percent and increases the total amount of drug in the body (AUC) by 30 percent. Because its bioavailability is unaffected, it is recommended that oral rivastigmine always be given with food to potentially prevent the drug's most common side effects, which are nausea, vomiting, and other forms of gastrointestinal distress. Rivastigmine is only 40 percent bound to plasma proteins with a volume of distribution between 1.8 and 2.7 L/kg. The relationship between drug dose and AUC is linear with a mean elimination half-life of 1.6 hours. The drug easily crosses the blood–brain barrier. Cerebrospinal fluid (CSF) rivastigmine concentrations are rapidly reached with a T_{max} of 1.4 to 3.8 hours, and it is quickly eliminated from the CSF with a half-life of 0.31 to 2.95 hours. Rivastigmine is converted after activity to an inactive metabolite which undergoes *N*-demethylation and sulfate conjugation prior to elimination. Rivastigmine is mainly eliminated through renal excretion, and it is not metabolized by hepatic oxidative CYP isozymes. Age, hepatic impairment, and renal insufficiency do not significantly affect rivastigmine disposition and dosage adjustments are not necessary in those individual patients. Additionally, the drug is not affected by inducers or inhibitors of CYP450 metabolism. There are currently no adequate trials of rivastigmine in pregnant women; however, animal trials have revealed no evidence of teratogenicity. It is unknown if it is excreted in breast milk.

FIGURE 34.15–3. Molecular structure of rivastigmine.

A rivastigmine transdermal patch (5 to 20 cm²) was developed and approved by the FDA in 2007. The 10-cm² patch pharmacokinetic profile is comparable to the oral 6 mg twice-daily dose, while the 20-cm² patch is similar to 9 to 10 mg twice-daily oral dose. The patch showed a 30 percent lower C_{max}, a longer T_{max} (8 hours vs. 1 hour), and a 1.8-fold greater

increase in AUC compared to the oral dose. Markedly less fluctuation in plasma drug concentrations between peak and trough levels were found with the patch. The 10-cm^2 patch showed adequate efficacy with fewer side effects than the 20-cm^2 patch, and therefore was initially recommended as the primary target dose in mild to moderate AD and major neurocognitive disorder due to PD. A higher, 15-cm^2 transdermal patch formulation is currently available and is the FDA recommended dose for patients with severe AD. Drug exposure is optimal when the rivastigmine patch is applied to the upper arm, chest, or back. These locations are the recommended application sites.

Pharmacodynamics. Rivastigmine is a noncompetitive, pseudoirreversible cholinesterase inhibitor due to its prolonged enzyme inhibition activity, where a single dose was shown to produce inhibition for as long as 10 to 12 hours. Rivastigmine displays equal potency in inhibiting both AChE and BuChE reported from both in vitro and in vivo data. This period of activity inhibition indicates that twice a day dosing is optimal. A linear relationship was reported between rivastigmine dose and AChE and BuChE inhibition measured in CSF. Plasma BChE inhibition rose slowly with the patch compared to two distinct peaks with the oral twice-daily dosing.

Design and Interpretation of Clinical Drug Studies

There have been a number of randomized, placebo-controlled, double-blind studies that have demonstrated the efficacy of rivastigmine in the treatment of AD. The majority of trials have been conducted on community dwelling subjects with mild to moderate AD, and were of 26-week duration or shorter. Doses ranged from 6 to 12 mg daily for oral doses and 5 to 20 cm^2 for the transdermal patch. The more efficacious oral dose was found to be 6 to 12 mg daily, higher doses demonstrating increased side effects and worse tolerability. For the transdermal patch, doses ranged from 5 to 20 cm^2, with 10 cm^2 having better tolerability than higher doses with significant clinical outcome. Moderate improvement in cognitive and functional scales occurred, as well as impression of improvement as assessed by the subjects' clinician. These improvements demonstrated equivalent efficacy with donepezil and other cholinesterase inhibitors.

Specifically for the oral drug form, two placebo-controlled multicenter clinical studies with rivastigmine (N = 1,424) were conducted prior to FDA approval. Subjects were randomized into placebo group, rivastigmine 1 to 4 mg/day, and rivastigmine 6 to 12 mg/day. Drug doses were adjusted weekly for the first 7 weeks as subjects reached the minimum assigned dose range. From weeks 8 to 26, subjects could be maintained on a flexible dose but in their assigned range to maximize therapeutic benefit and minimize side effects. Both studies showed a dose-dependent improvement effect on

ADAS-cog scores from baseline to the study end point. The placebo group showed a decline of two to four points in the ADAS-cog, while the rivastigmine 6 to 12-mg/day group had about a one-point increase in ADAS-cog score. The rivastigmine 1 to 4-mg/day group had approximately a one- to two-point decline in ADAS-cog scores. Both rivastigmine groups showed significant benefit in the CIBIC-plus scores compared to placebo.

Additionally, the subjects in one of these large trials continued into an open-label extension study where both, the placebo and rivastigmine groups, were treated with rivastigmine 6 to 12 mg/day for an additional 26 weeks. In this study, both the placebo and rivastigmine groups showed improvement at the study end point, compared to the projected rate of decline in untreated subjects. However, their scores were lower than the rivastigmine 6 to 12 mg/day group with about a three- to four-point decrease in ADAS-cog scores at week 52. Subjects treated with rivastigmine 6 to 12 mg/day had almost maintained their ADAS-cog scores from baseline with an approximate two-point decrease after 52 weeks. These results imply that with a 6-month delay in treatment or inadequate treatment with low doses, subjects may not be able to demonstrate that same level of improvement as patients with therapeutic treatment from the start. For maximum benefit, when a diagnosis of AD is established, treatment with cholinesterase inhibitors such as rivastigmine, when indicated, should be started as soon as possible. Dosing at suboptimal levels for extended periods can also hinder drug efficacy.

In a 24 week, randomized double-blind trial, patients with severe AD were randomized, receiving a 4.6 mg/24 hr patch versus a 13.3 mg/24 hr rivastigmine patch. There was an 8-week titration phase and a 16-week maintenance phase. As in the donepezil severe AD clinical trial, the SIB as well as the ADCS-ADL-SIV were used as clinical end points. Decline in both the SIB and the ASCS-ADL-SIV were both significantly less at 16 and 24 weeks for the 13.3 mg/24 hr dose.

In a 24-week, double-blind, placebo-controlled trial, rivastigmine with doses ranging from 3 to 12 mg was evaluated in 541 patients with PD dementia. Diagnosis was based on a 2-year or greater history of idiopathic PD before the onset of dementia, and patients did not meet criteria for other etiological causes of dementia. Based on ADAS-cog scores comparing baseline to week 24, rivastigmine-treated PD dementia patients had a mean improvement of 2.1 points, whereas the placebo group declined by a mean of 0.7 points. The Alzheimer's Disease Cooperative Study Clinical Global Impressions of Change (ADCS-CGIC) scores also showed benefit for rivastigmine, as 19 percent had improvement compared to 13 percent for placebo. Clinically meaningful worsening was reported to be only 13 percent for rivastigmine compared to a higher occurrence of 23 percent with placebo. Of note, the most frequent adverse side effects for rivastigmine were gastrointestinal, with nausea in 29 percent and vomiting

in 16 percent, as well as tremors in 10 percent of patients. Worsening tremor may signify increased clinical relevance in PD dementia patients and warrants closer monitoring with rivastigmine treatment.

Effects on Specific Organs and Systems

Rivastigmine does not produce hepatotoxicity or liver transaminase elevations, and therefore no monitoring of liver function tests are required with its use. Like other cholinesterase inhibitors, rivastigmine can produce vagotonic cardiovascular effects and should be used cautiously in patients with cardiac arrhythmias and cardiac conduction delays. Gastrointestinal problems can occur with all cholinesterase inhibitors, but is particularly seen with rivastigmine use in a more dose-dependent manner. Rivastigmine can also increase gastrointestinal acid production. Patients on NSAIDs, with peptic ulcer disease or other gastrointestinal illnesses should be carefully monitored, as they may be at greater risk of gastrointestinal bleeding.

Therapeutic Indications

Rivastigmine is indicated for the treatment of mild to moderate AD. It is also the only cholinesterase inhibitor with an FDA indication for mild to moderate dementia associated with PD. Similarly, rivastigmine has demonstrated benefits in LBD.

Precautions and Adverse Reactions

The most common adverse side effects with rivastigmine are typical of all the cholinesterase inhibitors. These include diarrhea, nausea, vomiting, insomnia, muscle cramps, fatigue, and anorexia. These side effects are usually mild and transient but in clinical trials, rivastigmine-treated groups had a higher drop-out rate than placebo, usually due to GI side effects. Additionally, in a study comparing rivastigmine with donepezil in AD patients, oral rivastigmine-treated participants had a significantly higher drop-out rate due to side effects. Gastrointestinal side effects with rivastigmine are not different when comparing mild to moderate individuals with those with moderate to severe AD. The transdermal patch formulation demonstrates much less gastrointestinal problems, most likely because of reduced plasma drug concentration, due to longer T_{max} and lower C_{max} when compared to the oral preparation. Less commonly, rivastigmine can potentially cause adverse reactions such as seizures, cerebrovascular disease or worsen COPD. It can also worsen urinary obstruction. Reanalysis of the electrocardiograph data from the clinical trial data revealed no significant differences between rivastigmine and placebo in heart rate, PR, QRS, and QTc interval. However, patients with cardiac conduction delays and significant heart disease should use

rivastigmine with caution, given the potential for bradycardia with cholinesterase inhibitors. The transdermal patch formulation reported skin erythema barely visible or mild that self-resolved within 24 hours. The upper back site, arms, and chest had a lower incidence of erythema compared to the abdomen and thigh sites.

Drug Interactions

Because rivastigmine is not metabolized by hepatic oxidative CYP isozymes, it does not interact with substrates of CYP450. Subsequently, there have been no drug interactions reported with digoxin, warfarin, diazepam, or fluoxetine. A retrospective analysis of the clinical trials did not find an increase in adverse side effects in patients who received various medications, including β-blockers, antihypertensives, and other drugs that may potentially produce pharmacodynamic interactions such as bradycardia. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications. Rivastigmine may also increase the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Rivastigmine has not been shown to interfere with any laboratory test, urinalysis, or spectrometry.

Dosage and Administration

Oral rivastigmine is available in 1.5-, 3.0-, 4.5-, and 6.0-mg capsules. Based on clinical trials, suggested dosage range is 3 to 12 mg/day. Patients should be initiated at 1.5 mg twice a day and gradually increased every 2 to 4 weeks by 1.5 mg daily until the maximum daily dose of 12 mg/day is reached or titrated to the patient's tolerability. It is highly recommended to take food with rivastigmine to minimize side effects. The transdermal patch preparation (5 to 20 cm^2) is able to be applied once a day due to its pharmacokinetic and pharmacodynamic profile for cholinesterase inhibition, reported to produce a slow and consistent release of the medication. The average exposure of transdermal patch dose of 10 cm^2 was comparable to an oral dose of 9.5 mg/24 hr. Patients should be initiated at a dose of 5 cm^2/4.6 mg daily and increased to 10 cm^2/9.5 mg in 4 weeks. Once this dose is maintained for 4 weeks and the patient tolerates it well, the maximum effective dose of 13.3 mg/day may be given. The slow release of rivastigmine from the patch should improve its gastrointestinal tolerability.

GALANTAMINE

Galantamine was approved by the FDA for the treatment of AD in 2001 and

is the fourth cholinesterase inhibitor made available in the United States. Galantamine is extracted from daffodils of the snowdrop plant *Galanthus nivalis* and is a phenanthrene alkaloid similar to codeine.

Chemistry

Galantamine is a (4aS,6R,8aS)–4a,5,9,10,11,12-hexahydro-3-methoxy-11-methyl-6H-benzofuro [3a,3,2–ef][2]benzazepin-6-ol hydrobromide compound. Its molecular structure is shown in Figure 34.15–4.

Pharmacological Actions

Pharmacokinetics. Galantamine immediate release (IR) has an 85 to 100 percent bioavailability in comparison of tablets to oral solution, and is readily absorbed with a T_{max} from 0.5 to 2.0 hours. C_{max} is decreased by 25 percent with a slight delay of T_{max} by 1.5 hours with food intake. Coadministration with food does not affect galantamine IR AUC. The volume of distribution at steady state was 2.6 L/kg with a very low protein binding of 18 percent. The elimination half-life of galantamine IR is about 7 hours. The bioequivalence of galantamine extended release (ER) 24 mg was reported to be within the 90 percent confidence intervals for AUC_{24} and C_{min} of galantamine IR 12-mg tablets twice daily. The mean time to peak plasma concentration was 4.4 hours with an elimination half-life of 8.3 hours after fasting and 8.0 hours after food intake. Galantamine ER formulation does not differ in its pharmacokinetic profile whether giving it with food or while fasting.

FIGURE 34.15–4. Molecular structure of galantamine.

Galantamine is mainly metabolized by hepatic CYP 2D6 and CYP 3A4 isozymes. Sanguinine (*O*-desmethylgalantamine) is formed by CYP 2D6 and accounts for 20 percent of the parent drug. Sanguinine is its major active metabolite and was shown to be three times more potent that galantamine in producing AChE inhibition. Other metabolites include galanthaminone and *N*-desmethylgalantamine, but they are much less

potent than sanguinine. Although a 25 percent decrease in drug clearance of galantamine IR was found between poor metabolizers and extensive metabolizers of CYP 2D6, and a 50 percent higher drug exposure in galantamine ER, these findings are probably not significant due to the large interpatient variability in galantamine disposition. The doses can be titrated to individual tolerability.

Age and mild hepatic impairment (defined as a Child–Pugh score of five to six) was shown not to affect galantamine pharmacokinetics. Patients with moderate hepatic impairment (Child–Pugh score of seven to nine) had galantamine AUC and elimination half-life increased by 30 percent. Patients with mild renal impairment had galantamine concentrations similar to Alzheimer patients without renal impairment. No dosage adjustments are needed for galantamine in elderly patients or in patients with mild hepatic impairment. A maximum dose of 16 mg/day is recommended for patients with moderate hepatic impairment. Galantamine is contraindicated in patients with severe renal (creatinine clearance less than 9 mL/min) and severe hepatic impairment (Child–Pugh score greater than nine). Galantamine is classified as a category C drug with no trials in pregnant women and animal trials revealing potential teratogenicity. Additionally, it is unknown if it is excreted in breast milk.

Pharmacodynamics. Galantamine is a competitive, reversible inhibitor that is significantly more selective for AChE over BuChE based on in vitro data. Galantamine also produces allosteric modulation of nicotinic receptors that are distinct from acetylcholine and nicotinic agonists or antagonists. Allosteric modulators upregulate or potentiate ion channel activity of nicotinic receptors in response to acetylcholine. This mechanism of action may play a unique clinical role as AD is associated with a deficit in nicotinic transmission. By enhancing the release of acetylcholine, this action can additionally modulate the release of other neurotransmitters such as GABA, serotonin, and glutamate.

Design and Interpretation of Clinical Drug Studies

A number of large, multicenter clinical trials with galantamine have been conducted. 978 subjects were evaluated in the main clinical trial that established the minimum effective galantamine dose. After a 4-week single-blind placebo treatment, patients were randomized into four treatment groups: placebo, galantamine 8, 16, and 24 mg/day. Patients were initiated on 8 mg/day and the dose was increased by 8 mg/day after 4 weeks until the target dose was achieved. The total study duration for the randomized groups was 5 months. All three groups showed improvement in ADAS-cog scores from baseline to the study end point when compared to placebo. During the intent-to-treat analysis, the 16- and 24-mg/day groups were found to be superior to placebo, but not the 8-mg group. The CIBIC-plus

evaluations showed that 64 to 68 percent of the patients in the 16- and 24-mg/day groups remained stable or improved after 5 months, versus 47 percent of the placebo group. The 8-mg/day group had only a 53 percent reported incidence of stability or improvement.

Several multicenter double-blind, placebo-controlled clinical trials have evaluated galantamine at higher doses of 18, 24, and 32 mg/day. Each study employed a different dosing strategy to reach these three dose groups, with a starting dose of 8 mg/day. Doses were either increased weekly or every 2 to 3 days until the assigned target dose was reached. The duration of the studies ranged from 12 weeks to 6 months. Each trial revealed that the 18- and 24-mg/day dose groups were superior to placebo. The 32-mg/day group also showed improvement compared to placebo, but did not reveal increased benefit when compared to the 24-mg group. The incidence of gastrointestinal adverse effects was highest in the 32-mg/day group, thereby limiting its usefulness. The results of these studies suggested that the optimal dose of galantamine is 24 mg daily.

One of these clinical trials reported a 6-month extension where patients assigned to the placebo group were placed on galantamine 24 mg/day. After the subsequent 6 months, the placebo/galantamine group had ADAS-cog scores that resembled the galantamine 32-mg group, which had its dose decreased to the 24-mg/day dose group, and above the projected rate of decline in untreated patients. The original 24-mg/day dose group at 6 months had ADAS-cog scores above baseline and at the 12-month time slightly decreased to baseline scores. The two other groups (placebo/galantamine and galantamine 32 mg or 24 mg) had ADAS-cog scores below the original 24-mg dose group at the 12-month time period. These results suggest that 24-mg dose is the optimal galantamine dose and that a delay of 6 months by the placebo group could worsen outcome in AD.

A 24-week double-blind, placebo-controlled study compared galantamine IR to galantamine ER in 971 patients with mild to moderate AD. Galantamine IR and ER were started at 8 mg/day and to 16, and then to 24-mg by 8-mg increments every 4 weeks as tolerated. The IR and ER were significantly better than placebo in regard to cognition, measured by the ADAS-cog, but not in global change (CIBIC-Plus), where they did not differ from placebo. Although these findings with CIBIC-Plus differ from the original IR studies, the secondary ADCS-ADL measure favored ER over placebo.

Effects on Specific Organs and Systems

Galantamine does not elevate hepatic transaminases and is not known to cause hepatotoxicity. As the other cholinesterase inhibitors, this medication may cause vagotonic cardiovascular effects and should be used cautiously in patients with cardiac arrhythmias. Gastrointestinal problems may occur in a dose-dependent manner, and patients with peptic ulcer

disease and other gastrointestinal problems should be carefully monitored.

Therapeutic Indication

Galantamine is indicated for the treatment of mild to moderate AD.

Precautions and Adverse Reactions

The most commonly reported side effects of galantamine are dizziness, headache, nausea, vomiting, diarrhea, anorexia, and weight loss. These side effects are mild and transient and did not produce a significant dropout rate during clinical studies. As previously stated, patients with renal and hepatic impairment may have substantially increased levels of galantamine. A maximum daily dose of 16 mg/day is the recommended dose for patients with moderate hepatic impairment. Galantamine is contraindicated in patients with severe renal and severe hepatic impairment. Less commonly, galantamine can potentially cause more severe reactions such as seizures, cerebrovascular disease, or exacerbation of COPD. The adverse side-effect profile of galantamine ER is similar to that of the IR formulation.

Drug Interactions

Galantamine is metabolized by hepatic CYP 2D6 and CYP 3A4 isozymes and could have significant drug–drug interactions. Galantamine AUC was reported to be increased by 40 percent when coadministered with paroxetine, 30 percent when given with ketoconazole, and 12 percent when erythromycin was coadministered. Patients should be monitored closely when known CYP 2D6 and CYP 3A4 inhibitors are given along with galantamine. As with all cholinesterase inhibitors, caution is advised when patients are taking anticholinergic medications, as galantamine may interfere with their activity due to its mechanism of action. It may also lengthen the action of succinylcholine-type muscle relaxants during anesthesia.

Laboratory Interferences

Galantamine has not been shown to interfere with any laboratory test, including urinalysis, spectrometry and biochemical.

Dosage and Administration

Galantamine IR is available in 4-, 8-, and 16-mg tablets. The suggested dose range is 16 to 32 mg/day given twice a day in a divided dose. It should be given with food. The 32-mg dose is less well tolerated than lower doses, and clinical trial data do not indicate significant benefit. If patients tolerate the 24-mg dose, an increase to the 32-mg dose can be warranted. The initial dose is 8 mg/day, and after a minimum of 4 weeks, the dose can be

increased. Further dose increases should be based on tolerability, with a minimum time period of 4 weeks on the previous dose. An oral solution is also available in a 4 mg/mL presentation. It should be taken as the IR form. Galantamine ER is available in 8-, 16-, and 24-mg tablets. The ER formulation should be taken with food with an initial dose of 8 mg daily in the morning and increasing the dose to 16 mg daily after a minimum of 4 weeks.

MEMANTINE

Memantine is the only noncholinesterase inhibitor indicated for the treatment of AD. It was first synthesized in the early 1960s as a possible hypoglycemic agent, but was found to be devoid of such activity. It was not until 2003, after multiple studies revealed its utility in dementia, that the FDA approved memantine for the treatment of moderate to severe AD. This agent is not indicated for mild to moderate AD as are the cholinesterase inhibitors.

Chemistry

Memantine is a 1-amino-3,5-dimethyladamantane hydrochloride, a derivative of amantadine (Symmetrel) (1-amino-adamatane). Its molecular structure is shown in Figure 34.15–5.

FIGURE 34.15–5. Molecular structure of memantine.

Pharmacological Actions

Pharmacokinetics. Memantine is absorbed completely from the gastrointestinal tract and achieves peak T_{max} within 3 to 7 hours. Protein binding is low from 42 to 45 percent and readily crosses the blood–brain barrier with a CSF serum concentration of 0.52. The elimination half-life of memantine is between 60 and 80 hours and is excreted unchanged in the urine. Steady-state conditions are reached in about 21 days. In a study

comparing 28 mg once daily of memantine XR to 10 mg twice daily of memantine, C_{max} and AUC0–24 values were 48 and 33 percent higher for the XR dosage regimen, respectively. Memantine is largely excreted unchanged in the urine and the remaining is converted to three minimally active polar metabolites. Memantine is a weak base with a pKa of 10.27, and urinary pH can affect renal clearance. Reduced renal clearance occurs at alkaline urinary pH (pH 8) and results in increased plasma concentrations of drug. Memantine has linear pharmacokinetics and with doses of 10 to 20 mg/day, has produced minimal inhibitions of CYP enzymes, having no significant interactions with CYP inhibitors. Pharmacokinetic studies in healthy young adults and AD patients indicate that memantine can be safely coadministered with cholinesterase inhibitors. With repeated administration, total serum concentrations reach 0.5 μM, which corresponds to the Ki value of memantine at the MK-801 binding site in the human frontal cortex, indicating that NMDA receptor antagonism occurs at therapeutic concentrations. There are currently no adequate trials of memantine in pregnant women, and animal trials have revealed minimal evidence of teratogenicity. It is unknown if it is excreted in breast milk.

Pharmacodynamics. The pharmacological effects of memantine are believed to result from the selective uncompetitive inhibitor blockade of the NMDA receptor class of glutamate receptors. Memantine does block the binding of glutamate to the receptor, but it blocks the ion current (Ca^{+2}, Na^{+}) through the receptor channel activated by glutamate. Memantine blocks the NMDA receptor with a strong voltage dependence and rapid blocking and unblocking kinetics, dissociating from the receptor in response to membrane depolarization. Blockade of the NMDA receptor channel during chronic, low-level excitation is thought to be the therapeutic benefit in neurodegenerative diseases such as AD.

Design and Interpretation of Clinical Drug Studies

Memantine indication for moderate to severe AD was based on two multicenter clinical trials. The first was a double-blind, placebo-controlled study comparing memantine 20 mg/day versus placebo in moderately to severely ill Alzheimer patients (N = 252). They had MMSE scores between 3 and 14 or a stage 5 or 6 on the Global Deterioration Scale (GDS). The study duration was 28 weeks, with an optional 24-week open-label extension phase. Patients receiving memantine had a significantly better outcome than placebo patients measured by the CIBIC-plus, ADCS-ADLsev and SIB at 28 weeks. The second study was a double-blind, placebo-controlled trial, but it had a single-blind, placebo lead-in period of 1 to 2 weeks to assess compliance. Afterward, patients were randomized to drug or placebo for the next 24 weeks. Memantine dose was initiated at 5

mg/day, with weekly increases to 20 mg/day at the beginning of week 4. The primary outcome measures were the SIB, CIBIC-plus, and the ADCS-ADLsev at week 24. Patients were allowed to remain on stable donepezil doses of 5 to 10 mg/day throughout the trial if medication was prescribed for at least 6 months prior to study entrance. The change in SIB, CIBIC-Plus, and ADCS-ADLsev outcome scores were all statistically significant in favor of memantine versus placebo. The SIB scores had a slight increase above baseline at week 12 and then remain above baseline by a mean of 1 point at 24 weeks. ADCS-ADLsev scores showed at gradual decline from baseline to 24 weeks for the placebo group, while the drug group displayed a slower rate of decline.

A 24-week open-label extension trial with moderate to severely ill patients reported continued benefit and a much slower decline in ADCS-ADL scores in those patients who were initially treated with memantine. Patients assigned to the placebo group were then placed on memantine. The newly treated patients showed less worsening of SIB, CIBIC-plus, and ADCS-ADL scores compared to the projected decline in untreated patients. At the end of 52 weeks, both groups had similar SIB, CIBIC-Plus, and ADCS-ADL scores and significantly higher scores than the projected scores for untreated patients. These findings indicate that memantine-treated patients continued to benefit from medication and had significantly delayed impairment compared to projections in untreated patients.

Although memantine is indicated only for moderate to severely ill patients, trials have been conducted on mild to moderate AD patients. These trials did not result in FDA indication for the mild stage of AD. A 24-week double-blind, placebo-controlled trial (N = 403) compared 20-mg memantine per day to placebo in mild to moderately ill AD patients, defined by MMSE scores of 10 to 22 points. The outcome measures included the ADAS-cog, CIBIC-plus, and ADCAS-ADL rating scales, comparing baseline to week 24. The study results indicated that only modest treatment effect in favor of memantine had occurred. The mean ADAS-cog score for the placebo group increased by 1.1 points, while the memantine group score decreased by 0.8 point (P = 0.003). The mean end point CIBIC-plus scores for placebo and memantine groups were 4.52 and 4.20, respectively (P = 0.004). A significant difference was not found in ADCS-ADL scores between the two groups.

Effects on Specific Organs and Systems

Memantine does not cause an increase in hepatic transaminases or hepatotoxicity. Memantine XR terminal elimination half-life increased by 16 percent in patients with moderately impaired liver function compared to controls. It is recommended that patients with severe hepatic impairment take memantine ER with extreme caution. Memantine is mainly excreted through the kidneys. Even though there is scarce data about renally

impaired patients taking memantine, drug doses should be reduced in patients with mild to moderate renal impairment. For patients with severe renal impairment, memantine is not recommended.

Therapeutic Indications

Memantine is indicated for the treatment of moderate to severe AD.

Precautions and Adverse Reactions

The most common side effects observed with memantine are constipation, dizziness, headache, and confusion. These effects are usually mild and transient and did not result in a significant dropout rate during clinical trials. With the use of memantine ER, the most common side effects are headache, diarrhea, and dizziness.

Drug Interactions

The use of memantine along with other NMDA antagonists such as amantadine and dextromethorphan has not been evaluated and this combination should be used with caution. In vitro studies with CYP substrates 1A2, 3A4, 2A6, 2C9, 2D6, 2E1, and 3A4 showed minimal inhibition by memantine. Therefore, no pharmacokinetic interaction by these enzymes should occur. Using memantine with donepezil did not affect the pharmacokinetics of either compound. The adverse side-effect profile of the combination of memantine and donepezil was similar to that of patients treated with donepezil alone. Memantine is eliminated by renal tubular secretion and, if administered with other drugs that are excreted through the same mechanism, the plasma concentration of both agents could be altered. Examples of these drugs include hydrochlorothiazide, triamterene, cimetidine, ranitidine, quinidine, and nicotine. Concomitant use of memantine, hydrochlorothiazide, and triamterene did not affect the disposition of memantine or triamterene, but the bioavailability of hydrochlorothiazide was decreased by 20 percent. Memantine clearance was reduced by 80 percent with alkaline urine conditions at pH 8. If the urine pH is altered, drug accumulation may occur. This condition could be caused by diet, drugs like carbonic anhydrase inhibitors and sodium bicarbonate, and medical conditions such as renal tubular acidosis. Memantine should be cautiously used in this situation.

Laboratory Interferences

Memantine has not been shown to interfere with any laboratory test, including biochemical, urinalysis, and hematology. No clinically significant electrocardiographic changes were noted during clinical trials.

Dosage and Administration

Memantine is available in 5- and 10-mg tablets, with a recommended starting dose of 5 mg daily. The recommended target dose is 20 mg/day. Drug is administered twice daily in separate doses with 5-mg increment increases weekly depending on tolerability. Memantine ER is available in 7-, 14-, 21-, and 28-mg capsules. Starting dose is 7 mg daily, with a target dose of 28 mg daily. The ER formulation should be increased no greater than 7 mg weekly. Patients with renal impairment should have a target dose of 14 mg daily. A drug is now available as a combination of memantine XR and donepezil (Namzaric). It is available in 14-mg/10-mg and 28-mg/10-mg formulations. It is only indicated for patients with severe AD already stabilized on memantine ER 14 or 28 mg and donepezil 10 mg.

FUTURE DIRECTIONS

In more recent years, drugs have been actively developed with different pharmacodynamic mechanisms to modify and delay the onset of AD. Multiple treatment trials, with the goal of slowing or even reversing the course of cognitive and functional decline among AD subjects are ongoing. They include secretase inhibitors, amyloid-β inhibitors, tau and amyloid-β-aggregation inhibitors as well as vaccines against amyloid-β and tau. These potentially disease-modifying therapies focus mainly on agents that will decrease amyloid-β content and tau hyperphosphorylation. To date, trials have not demonstrated any significant improvement in the decline of patients already suffering the full clinical picture of AD. Current research has shifted to better recognition of AD in its earliest clinical phases. The aim is to enlist those at risk populations with the mildest symptoms or even those still clinically asymptomatic into active clinical trials to potentially reverse or even prevent AD as well as other neurodegenerative disorders.

DISULFIRAM

History

The agent disulfiram was serendipitously discovered in 1937 for possible medical use by Dr. E. E. Williams, a physician to a rubber company. Dr. Williams observed that workers in the vulcanized rubber industry who were exposed to tetraethylthiuram disulfide became physically ill after alcohol consumption. The tetraethyl analog of the vulcanization chemical had also been used topically since 1942 to treat scabies. In 1945 while investigating this chemical to treat parasitic stomach infections, Erik Jacobsen and Jens Hald tested the compound on themselves only to become ill after drinking alcohol. They observed and reported symptoms such as nausea, vomiting, facial flushing, headache, and dizziness. Two years later, they collaborated with Dr. Oluf Martensen-Larsen and designed a study for disulfiram as a treatment for alcohol dependence. In 1951, it was the first medication approved by the FDA for that indication.

Over the years it has been recognized that the very same properties that constitute disulfiram's main therapeutic effect (i.e., the ability to produce unpleasant symptoms after alcohol intake also known as disulfiram–alcohol reaction) may also have potentially dangerous consequences. These are frequently related but not limited to dehydration and electrolyte imbalance secondary to vomiting, a symptom of the disulfiram–alcohol reaction. In the most severe cases serious clinical conditions such as respiratory depression, myocardial infarction, arrhythmias, heart failure, seizure, loss of consciousness, and death have been documented. These potential complications as well as the more recent development of alternative alcohol use disorder medications have been the limiting factors for a wider use of disulfiram.

Chemistry

Disulfiram, when it is in its pure state, is a white to off-white, odorless, almost tasteless powder, which is soluble in water and alcohol. Its chemical name is bis(diethylthiocarbamoyl) disulfide; its structural formula is shown in Figure 34.16–1.

Pharmacological Actions

Pharmacokinetics

ABSORPTION. After ingestion, disulfiram is rapidly converted to its diethyldithiocarbamate (DDC) copper complex. Subsequent absorption and distribution via the GI mucosa into the blood involves both the parent drug and the DDC copper complex. Absorption of disulfiram from the GI tract is rapid but incomplete (e.g., approximately 80 to 95 percent is absorbed through the GI tract). The concentration of disulfiram's active metabolite diethylthiocarbaminic acid methyl ester (Me-DTC) reaches its plasma peak about 4 hours after absorption. It is hypothesized that disulfiram tablets may be more bioavailable when taken with food. It can be crushed and mixed with water, coffee, tea, milk, soft drinks, or fruit juice.

FIGURE 34.16–1. Chemical structure of disulfiram.

DISTRIBUTION. Because of its high lipid solubility, disulfiram is widely distributed and accumulates in various fat deposits. Its safety during pregnancy has not been established, and it is labeled as a class C drug. In experimental animals, administration of disulfiram with ethanol potentiates the embryotoxic effects of ethanol. It is not clear whether the same potentiation occurs in humans. There are several case reports of normal pregnancy outcome in humans exposed to disulfiram without exposure to ethanol. It is not known whether it is excreted in breast milk.

METABOLISM AND ELIMINATION. Due to partial absorption, approximately 5 to 20 percent of disulfiram is excreted in the feces. In the blood, disulfiram is rapidly metabolized to DDC, which is partly excreted as carbon disulfide in the expired air and is partly metabolized in the liver to diethyldithiomethylcarbamate (Me-DDC). Further metabolic changes result in the formation of the active metabolite Me-DTC. This metabolic cascade is not appreciably affected by a mild to moderate decrease in hepatic function. Disufiram's metabolites are chiefly excreted with the urine and a part is expired as carbon disulfide. Overall elimination of disulfiram is slow, and up to 20 percent of a single dose may remain in the body for a period of 7 days or more.

Pharmacodynamics

MECHANISM OF ACTION. Disulfiram is a prodrug. It has been shown to inhibit the hepatic enzyme aldehyde dehydrogenase (ALDH) in vitro. However, in vivo the drug is too short-lived to inhibit the enzyme directly. The net effect of irreversible inhibition of ALDH is achieved by disulfiram's active metabolite Me-DTC.

The pharmacological action of disulfiram and its metabolites is based on the inhibition of enzymes involved in ethanol catabolism. Disulfiram is a sulfhydryl (-SH, thiol) group reagent and inhibits enzymes concerned with oxidation of active (-SH group) sites on enzymes' protein molecules. Normally, ethanol is metabolized to carbon dioxide and water, but in the presence of disulfiram the metabolic chain of reactions stops after the production of acetaldehyde, leading to the accumulation of this substance. The acetaldehyde concentration in the blood may increase to 5 to 10 times than occurring without disulfiram. Acetaldehyde is an important factor for the development of disulfiram–alcohol reaction, which occurs within the course of 10 to 30 minutes after the ingestion of alcohol. The clinical picture of disulfiram–alcohol reaction includes a number of unpleasant symptoms: intense flushing of the face, a feeling of difficulty in breathing, palpitations, a throbbing headache, nausea and vomiting. Ingestion of large amounts of alcohol may cause a significant fall of the blood pressure, resulting in fainting and the risk of cardiovascular shock.

Re-establishment of the ALDH enzymatic activity is dependent on new synthesis which occurs gradually during the course of up to 2 weeks. Although the plasma half-life of disulfiram's active metabolite Me-DTC is about 10 hours, its inhibiting effect on ALDH may last considerably longer, persisting for 7 to 14 days after discontinuation. Prolonged use of disulfiram does not result in the development of tolerance; conversely, it has been shown to produce a heightened sensitivity to alcohol.

In addition to its effect on ALDH, disulfiram and some of its metabolites (e.g., DDC) also inhibit the enzyme dopamine-beta-hydroxylase (DBH), thus reducing the synthesis of noradrenaline. This mechanism is suggested to play a role in the disulfiram–alcohol reaction. Disulfiram also diffuses readily into cells and raises intracellular -SH levels; therefore, it can affect intracellular oxidation reactions. Notably, disulfiram has been shown to inhibit the enzymes xanthine oxidase and succinoxidase. Disulfiram also possesses antithyroid properties as it reacts with free iodine to form a stable molecular complex.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. Plasma concentrations of disulfiram may vary between individuals due to a number of factors, most notably age and hepatic function. In general, the severity of disulfiram–alcohol reaction has been shown to be proportional to the amount of the ingested disulfiram and alcohol. However, disulfiram plasma levels are rarely utilized in clinical practice. Mild effects may occur at blood alcohol

concentrations of 5 to 10 mg per 100 mL. When alcohol levels reach 50 mg per 100 mL, symptoms will have fully developed. Unconsciousness may occur when alcohol levels reach 125 to 150 mg per 100 mL.

Design and Interpretation of Clinical Drug Studies

To date, the Veterans Administration Cooperative Study remains the largest disulfiram treatment study, conducted in a cohort of 605 males diagnosed with alcoholism. Participants were randomly assigned to three treatment arms: 202 participants received disulfiram 250 mg daily, 204 participants were administered disulfiram 1 mg QD, and 200 participants were prescribed riboflavin. After 1 year of treatment, there was no difference in the percentage of patients from the three groups in total abstinence, time to first drink, employment, or social stability. There was a significant relationship between adherence to any of the drug regimens and complete abstinence. Among those who did drink, those in the disulfiram 250 mg group reported significantly fewer drinking days. Also, in the subpopulation of patients who attended all the scheduled follow-up research appointments, treatment with disulfiram 250 mg daily significantly decreased drinking days when compared low-dose disulfiram and riboflavin. In this large trial, compliance with the study medication was a notable barrier, with only 19 percent of patients taking disulfiram consistently.

The first systematic meta-analysis of its disulfiram's effectiveness was published in 2011. Eleven randomized controlled trials were included with a total of 1,527 patients. Studies were published from 1979 to 2010 in India, Denmark, USA, Austria, Finland, and Italy. This review concluded that disulfiram had some short-term clinical benefits including short-term abstinence, number of drinking days, and days until relapse. However, possible confounds were related to the fact that five of the six efficacious studies also had supervised disulfiram administration and that all studies were short-term treatment protocols. Others have pointed to possible selection bias since the authors included one nonefficacy study while five eligible trials were absent.

Moreover, the aforementioned meta-analysis utilized both open and blind studies. This issue was addressed by a second meta-analysis that compared blind versus open-label studies of disulfiram. The analysis, which included 2,414 participants from 22 studies showed no difference between disulfiram and control groups. The authors explained this finding on the premise that the clinical effect of disulfiram is directly proportional to the expectation of a disulfiram–alcohol reaction, meaning a blinded placebo group has the same psychological threat as the treatment arm. Moreover, they point out that even in a blinded trial, the participants can unmask themselves easily with minimal alcohol. In the same meta-analysis, the results from only open-label studies indicate disulfiram is more

effective than naltrexone, acamprosate, and control group treatment conditions. Finally, the results suggested that disulfiram is significantly superior to placebo condition only with supervised administration.

There are only few long-term studies of supervised disulfiram administration and there have not been randomized controlled trials. The Outpatient Long-Term Intensive Therapy for Alcoholics (OLITA) study presents a biopsychosocial approach, including therapeutic elements like frequent participant contact, therapist rotation, support of social reintegration, aggressive aftercare, supervised use of disulfiram, and regular urine analysis for alcohol and other drugs of abuse. The group reported a main outcome of 52 percent cumulative 9-year abstinence rate.

By expert consensus, optimum disulfiram response is achieved when treatment is conducted in a specialized facility for substance use disorders. Aspects of care that can increase disulfiram efficacy by way of adherence include: use of incentives, contracting with the patient and a significant other, providing regular reminders, patient behavioral training, and social support networks. The need for adherence and supervised administration of this medication provides some framework to understand that disulfiram has documented superior efficacy over placebo in the treatment of alcohol abuse in adolescents or in combination with spouse-observed administration. This also helps conceptualize why court-ordered disulfiram therapy promotes efficacy by increasing adherence to the regimen. Additional research indicates that, in general, older med involved in a structured social network like AA, are more likely to remain compliant to treatment regimens, and thus, derive clinical benefit.

As aforementioned, spousal involvement can be advantageous in the utility of disulfiram. Several studies have documented the benefit of behavioral marital therapy as adjunct to disulfiram treatment. A pivotal component in this form of combined therapy is the disulfiram contract—a time-limited, renewable agreement by the couple to practice daily a behavioral interaction of observed disulfiram administration. It is believed that on individual level the contract aims to increase patient adherence to the medicine. On the couple's level, the goal is to restructure behaviorally the relationship dynamics of early sobriety, often characterized by negative emotions like distrust, shame, and occasionally violence. Several trials have evaluated the efficacy of this approach as the couples received the combined treatment for periods of 10 to 24 weeks and were followed as long as 104 weeks after that. Overall the combined treatment has been shown to produce greater disulfiram adherence, better drinking outcomes, higher marital satisfaction, and less domestic violence.

There are few comparisons between disulfiram and the other FDA-approved medications for the treatment of alcoholism, naltrexone, and acamprosate. Some of these trials are also potentially confounded by the nonspecific effects of frequent supervision with disulfiram but not the other

agents. One randomized, open-label trial aimed to compare the effects in alcohol-dependent patients of three pharmacotherapies, disulfiram, naltrexone, and acamprosate. It included 243 voluntary treatment-seeking alcohol-dependent adult outpatients. It had two phases: first, a 12-week continuously supervised medication phase, followed by up to a year of unsupervised medication. Participants were followed for up to 2.5 years. All treatment arms included a brief manual-based cognitive-behavioral therapy. The investigators found that all three medication interventions demonstrated a reduction in drinking, from baseline to the end of the study. Disulfiram was significantly superior to the other two agents (i.e., naltrexone and acamprosate) during the phase of supervised treatment; it demonstrated greater reduction in heavy drinking days, reduction in weekly consumption, abstinence days, and an increased time to the first drink. During the unsupervised period of the study, there were no significant differences between the groups in the heavy drinking days or time to first drink, although disulfiram displayed a significantly greater efficacy in the number of abstinence days.

Another study analyzed retrospectively collected data (i.e., from 2002 to 2007) in 353 outpatient alcohol-dependent individuals and compared the efficacy of acamprosate and disulfiram. Two groups were identified, individuals receiving three-time-a-week appointments for supervised disulfiram and once-weekly appointments for acamprosate. Both groups were individuals who had completed an inpatient detox prior to the medication intervention. They assessed abstinence by several means: breathylizer, self-report, urine and serum assays, and physician assessment. The investigators identified supervised disulfiram treatment to be more effective than the treatment with acamprosate, particularly in patients with a longer duration of alcohol dependence.

Efficacy of disulfiram has been also studied in individuals with addiction and co-occurring Axis I disorders (duel-diagnosis), including major depression, PTSD bipolar disorder, schizophrenia, and schizoaffective disorder. One study enrolled 254 patients with alcoholism and a co-occurring Axis I disorder and randomized participants into four groups: (1) naltrexone alone, (2) placebo alone, (3) disulfiram and naltrexone, and (4) disulfiram and placebo. There was open randomization to disulfiram or no disulfiram, and double-blind randomization to naltrexone or placebo. All patients were treated for 12 weeks in an outpatient setting. Participants treated with disulfiram had significantly more consecutive weeks of abstinence and less craving than those treated with placebo, but there were no significant group differences in other measures of alcohol consumption (percent of days abstinent, percent of heavy drinking days, achieving total abstinence). There was no advantage of the combination of both medications. Of note, individuals with psychotic spectrum disorders did not have a change in psychotic symptoms with the

intervention groups.

Disulfiram may be more effective in promoting short-term abstinence and treatment retention after detoxification, rather than long-term relapse prevention. As such, some have suggested that this medication be solely used to assist in the initial period of abstinence to facilitate the client's involvement in psychosocial interventions. Further, some experts dismiss disulfiram as a viable treatment option, considering the severe adverse effects from the disulfiram–alcohol reaction and also the potentially serious side effects from the drug itself. Others have questioned the effectiveness of disulfiram because the time between alcohol ingestion and the disulfiram–alcohol reaction can be up to 30 minutes and the reaction intensity can be variable. Patients with severely impaired judgment, significant cognitive impairment, or those who are highly impulsive may be inappropriate candidates for this treatment.

Effects on Specific Organs and Systems

Deaths from disulfiram treatment have become rare due to treatment with lower dosages and exclusion of patients with significant cardiac disease. Disulfiram has a black box warning to never administer to a patient who is in a state of alcohol intoxication or without the patient's full knowledge.

Adverse effects of disulfiram have been mostly documented on the gastrointestinal and nervous systems. Of particular clinical importance is the hepatotoxic effect of disulfiram. The symptoms of hepatotoxicity may be mild and reversible (e.g., jaundice, cholestasis, and altered liver function tests) or more serious such as acute hepatitis, hepatic necrosis, and hepatic failure that may require liver transplantation. These effects may occur after many months of disulfiram treatment and have been documented in both individuals with and without prior history of abnormal liver function. Estimates of disulfiram-induced hepatitis are between 1 in 25,000 and 1 in 30,000 patients treated per year.

Disulfiram effects on the nervous system may involve optic neuritis, resulting in eye pain or tenderness and changes in vision, as well as peripheral neuropathy (i.e., parasthesias—numbness, tingling, pain, or weakness in hands or feet). The latter is mainly reported in patients who have been maintained on relatively high dose of disulfiram (e.g., 500 mg daily). Peripheral neuropathy tends to improve with discontinuation of disulfiram treatment. More rare side effects include the antithyroid effect of disulfiram and skin eruptions that are usually controlled with antihistamine treatment.

Therapeutic Indications

Alcohol Use Disorder. In clinical practice disulfiram is recommended as an aid in the management of selected patients with alcohol use disorder.

It is emphasized that the selected patients should be highly motivated to maintain a state of sobriety. The agent has little effect on the long-term drinking pattern of the affected individuals. It has been found to be most appropriate and efficacious in the short-term after detoxification, to assist in the initial period of abstinence to facilitate the client's involvement in psychosocial interventions including psychotherapy. Optimum response to disulfiram seems to be achieved in facilities specializing in the treatment of substance use disorders.

The disulfiram–ethanol reaction is an aversive physiological state that functions through negative reinforcement and behavioral counterconditioning to extinguish an unwanted behavior (alcohol consumption). When an individual takes this medication, they acknowledge that possible alcohol consumption will entail such reaction and this knowledge is the motivation for abstinence. It is important that patients should be educated about the medication and informed consent should be obtained. Baseline blood tests include blood alcohol or breathalyzer (to confirm abstinence), liver function tests, a complete blood count, serum chemistries including blood urea nitrogen (BUN) and creatinine, and a pregnancy test. Follow-up liver function tests are recommended 10 to 14 days after therapy initiation, then monthly for a period of 6 months, to monitor for possible hepatic dysfunction. After the first 6 months, liver function testing should be obtained every 3 months. Monthly pregnancy tests are indicated for women of childbearing age. An ECG should be obtained at baseline if clinically indicated by a history of heart disease.

Disulfiram should be prescribed for individuals who are abstinent from alcohol for at least 12 hours. On occasions, patients who appear to be on adequate maintenance dose of disulfiram may report that they can consume alcohol without any negative reactions. In such cases the physician should presume that patient's compliance with the treatment has been compromised. Before the patient is observed to reliably administer the medicine (preferably crushed and mixed with water) it may not be concluded that disulfiram is ineffective.

Disulfiram Test Reaction. During the earlier use of disulfiram it was thought advisable to have patients experience at least one supervised disulfiram–alcohol reaction, a so-called "alcohol challenge." This practice is currently not recommended; moreover, it should never be considered for patients over the age of 50 years. At present it is believed that a clear, convincing, and detailed description of the disulfiram–alcohol reaction is considered sufficient.

Management of Disulfiram–Alcohol Reaction. The disulfiram–alcohol reaction is diagnosed when a patient with a history of disulfiram use and

possible exposure to ethanol presents with symptoms of the characteristic hypotensive flushing reaction. Blood disulfiram levels are not of value in diagnosis or treatment. Blood acetaldehyde levels may be elevated during the disulfiram–ethanol reaction, but this information is of little value in acute management. In a severe reaction, all measures should be taken to stabilize the patient's respiratory and cardiovascular systems, this may include supplemental oxygen, intubation, IV fluids, and/or pressor agents. Other interventions include intravenous use of vitamin C, ephedrine sulfate, and antihistamines. Since hypokalemia has been reported, potassium levels should be monitored, particularly in patients treated with digitalis. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver aminotransferases, and ethanol level. Some protocols include treating vomiting with metoclopramide. There is no specific antidote. Decontamination procedures are not likely to be of benefit once the reaction begins. Hemodialysis is not indicated for disulfiram overdose.

Management of Disulfiram Overdose (without Alcohol). Disulfiram overdose (without alcohol ingestion) is rare and its clinical presentation is one of neurological adverse effects from the medication: confusion, lethargy, headache, ataxia, seizures, and coma. Brain lesions in the basal ganglia have also been reported. A patient may also present with a garlic-like breath odor, vomiting, and hypotension. The diagnosis of overdose is made based on history and presenting symptoms. In some circumstances, activated charcoal may be clinically indicated. The treatment is focused on maintaining a patent airway, stabilizing the cardiovascular system, and treating seizures.

Other Disorders. Disulfiram is hypothesized to be potentially effective as a treatment for cocaine use disorder, as it inhibits dopamine-beta-hydroxylase resulting in an excess of dopamine and decreased synthesis of norepinephrine. Cocaine, on the other hand, increases dopamine through inhibition of the dopamine transporter, blocking reuptake. There is evidence that disulfiram could be efficacious for cocaine dependence alone and also for comorbid cocaine and alcohol dependence. Usually interventions were paired with some form of psychotherapy or 12-step program. A recent Cochrane review included seven controlled studies with 492 participants receiving disulfiram, a placebo, no pharmacological treatment, or naltrexone in addition to psychosocial treatment. The review showed "low evidence" in support of disulfiram for the treatment of cocaine dependence. Current investigations are examining safety profiles for the combination of disulfiram with alcohol and cocaine.

Some concern has been raised about the combination of the cardiovascular response to cocaine and the cardiovascular effects of a disulfiram–alcohol reaction. Safety trial data from few studies with small

sample sizes suggest that the severity of physiological effects is related to the doses of any of the three agents (e.g., disulfiram, alcohol, cocaine); however, cocaine does not appear to exacerbate the disulfiram–alcohol reaction. Disulfiram does inhibit the metabolism of cocaine, increasing cocaine plasma levels.

In nonalcohol-dependent individuals, several studies have demonstrated a benefit in reduction of cocaine use with comorbid opiate-dependent individuals receiving opiate agonist maintenance treatment (methadone and buprenorphine). However, one double-blind, randomized, placebo-controlled clinical trial in a population of methadone stabilized, cocaine-dependent individuals, reported that there may be a disulfiram dose-related benefit. The study found cocaine-positive urines increased in the 62.5- and 125-mg disulfiram groups. Disulfiram at 250 mg was similar to placebo. The authors suggest using higher doses of disulfiram (greater than 250 mg) in individuals with comorbid alcohol, cocaine, and opioid use disorders, which requires further investigation.

Precautions and Adverse Reactions

Precautions. All patients who are prescribed disulfiram should be fully informed of the disulfiram–ethanol reaction and cautioned against the possible consequences of taking alcohol either surreptitiously or unwittingly. Patients receiving disulfiram should be strongly advised not to use any alcohol-containing preparations, for example, certain cough syrups, sauces, vinegar, tonics, foods prepared with wine, and even should avoid the use of aftershave lotions and moisturizers containing alcohol. In addition, patients should be advised to obtain and carry an Identification Card describing the symptoms of disulfiram–alcohol reaction and containing contact information in cases of emergency. Disulfiram should not be coadministered with paraldehyde or metronidazole.

Candidates for disulfiram should be evaluated for hypersensitivity to other thiuram derivatives used in pesticides and rubber vulcanization. Concomitant conditions such as severe myocardial disease or ischemic heart disease, pregnancy, advanced hepatic and renal disease, psychotic states, and serious organic brain damage are contraindications for the use of disulfiram.

Adverse Reactions. Most common side effects associated with disulfiram include drowsiness, headache, fatigue, allergic dermatitis, stomach upset, dizziness, acneform eruption, halitosis, and impotence. Metallic or garlic-like aftertaste has been reported during the first 2 weeks of therapy. These complaints disappear spontaneously or by reducing dosage.

Sensorimotor peripheral neuropathy, frequently associated with combined treatment with metronidazole or isoniazid, may present with

numbness, tingling, pain, or weakness in hands or feet. In addition, symptoms of optic neuritis may occur, indicated by eye pain and changes in vision. Most of these symptoms improve when disulfiram is discontinued.

More serious but rare side effects include disulfiram-induced hepatitis with an incidence between 1 in 25,000 and 1 in 30,000 patient years of treatment. Varying degrees of hepatotoxicity have been reported including altered liver function tests, jaundice, and hepatic necrosis. Psychiatric side effects like mood liability and mental status changes (e.g., psychosis, mania, delirium) have also been reported with the administration of disulfiram.

Drug Interactions

Concomitant ingestion of antacids containing divalent cations as well as large doses of ferrous salts may reduce absorption of disulfiram. Other clinically salient drug–drug interactions of disulfiram may occur through several separate physiological mechanisms (i.e., inhibition of hepatic enzymes). For instance, disulfiram may affect the metabolic rate of other drugs, in particular phenytoin and theophylline. The concomitant use of disulfiram with either of these two agents should be used with caution since it may result in an elevated phenytoin or theophylline plasma level and possibly lead to phenytoin or theophylline toxicity. It is recommended that baseline phenytoin and theophylline levels be obtained before initiation of disulfiram with subsequent regular monitoring of phenytoin and theophylline levels.

Disulfiram may prolong prothrombin time when coadministered oral anticoagulants (e.g., warfarin), as disulfiram inhibits warfarin's metabolism and regular assessments of anticoagulation profiles are recommended.

Another clinical interaction with less clearly understood mechanism occurs between isoniazid and disulfiram. Their coadministration may cause ataxia and even mental status changes, both of which usually resolve after discontinuation of disulfiram. Another antituberculosis agent, rifampin, also interacts with disulfiram, resulting in inhibition of rifampin's oxidation and renal excretion. Mental status changes (e.g., psychosis and confusion) have also been demonstrated with concurrent use of metronidazole.

Disulfiram can differentially potentiate and prolong benzodiazepines' suppressing effect on the CNS—for instance this effect is more pronounced with coadministration of chlordiazepoxide and diazepam, but not oxazepam or lorazepam.

Animal research has documented that in the GI tract disulfiram may interact with nitrates and form nitrosamine in the GI tract, which has been shown to cause stomach tumors. The toxicity of certain centrally acting drugs (e.g., morphine, pethidine, amphetamine, and barbiturates) has been potentiated by disulfiram in rats; however, the importance of this

observation for humans is unclear.

Laboratory Interference

Disulfiram is not known to interfere with any laboratory tests.

Dosage and Administration

Dosing for the first 1 to 2 weeks is 250 mg in the morning or the evening (based on whether the patient has sedation). The average maintenance dose is 250 mg daily, with a range of 125 to 500 mg. The dose of disulfiram should never exceed 500 mg per day.

Disulfiram should be taken for 6 weeks to 6 months as required. A review of the effectiveness of therapy should be undertaken before continuation on a longer-term basis. A few patients would require higher doses of disulfiram and longer duration of treatment under close supervision.

Administration. Disulfiram should be taken preferably on waking, although in patients who experience a sedative effect, it may be taken at bedtime. Alternatively, to minimize the sedative effect, the initial dosage may be reduced.

ACAMPROSATE

History

Acamprosate was developed in response to a growing literature demonstrating that chronic alcohol consumption and withdrawal fundamentally change neurochemistry and electrophysiology. Consequently, a major therapeutic challenge in the treatment of alcohol use disorders is the maintenance of abstinence once it has been achieved and regaining sobriety after relapse. Over 30 years ago several European pharmaceutical companies started synthesizing amino acids neuromediators, with the hope of ameliorating the pathological hyperglutamatergic state that ensues from protracted alcohol use, thought to perpetuate alcohol use and contribute to relapse after abstinence. In collaboration with several universities in France, pharmaceutical companies investigated a number of taurine and homotaurine compounds in the 1980s. An animal model of alcohol relapse conducted at the University of Rouen in France supported the utility of calcium acetyl-homotaurinate in reducing alcohol consumption in dependent rats. This initial preclinical trial was again validated in another animal model, which revealed significant reduction in voluntary alcohol consumption.

These preclinical results catalyzed the first multicenter double-blind, placebo-controlled study in 569 detoxified alcohol-dependent male patients in Europe, again showing decreased alcohol consumption in patients

receiving calcium acetyl-homotaurinate compared to placebo. The compound was approved for the treatment of alcohol dependence in 1989 in France under the trade name Aotal. Extensive clinical studies involving over 4,000 subjects throughout Europe demonstrated the safety and efficacy of acamprosate across clinical settings. By 1996, the medication became available in all European Union countries for the treatment of alcohol use disorder, promulgating additional investigations into its utility in the pharmacological treatment of alcoholism.

In July 2004, the FDA approved acamprosate for the maintenance of abstinence from alcohol in detoxified patients with alcohol use disorder. It became available for use in January 2005 under the trade name Campral. Since its introduction in 1989, acamprosate has been used to treat over 1.5 million patients worldwide. It is now the most widely prescribed agent for the treatment of alcohol use disorders in the United States.

Chemistry

Acamprosate is the calcium salt of N-acetyl-homotaurine (Ca-AOTA), a synthetic analog of the endogenous amino acid taurine with additional carboxyl and methyl groups in its chain. Acamprosate calcium is a white, nearly odorless powder, which is readily soluble in water and practically insoluble in absolute ethanol. Its chemical name is calcium 3-acetylaminopropane-1-sulfonate and its structure is shown on Figure 34.16–2.

Pharmacological Actions

Pharmacokinetics

ABSORPTION. Acamprosate is a dimer of acetyl-homotaurine linked by a calcium salt, formulated to assist in its absorption across the GI tract. The amount of acamprosate actually absorbed is quite low, however, with a bioavailability of ~11 percent in the fasting state. Food consumption reduces acamprosate absorption but not sufficiently to justify dose adjustments. Acamprosate is so slowly absorbed that it acts as if it were a modified-release medication. Peak plasma concentrations are usually reached within 3 to 8 hours after dosing and steady-state levels are achieved by the fifth to seventh day of dosing. Its terminal half-life ranges from 20 to 33 hours subsequent to the administration of a standard 666 mg enteric-coated formulation.

FIGURE 34.16–2. Chemical structure of acamprosate.

DISTRIBUTION. The amount of acamprosate which is protein bound is negligible, such that the active drug that permeates the intestinal mucosa is entirely dissociated in plasma. While its volume of distribution following intravenous acamprosate administration is high, estimated to be 72 to 109 L (approximately 1 L/kg), its oral bioavailability is relatively low. Only 6.5 to 11 percent of what is ingested crosses the GI tract, which explains why it must be given in high doses. In contrast to orally administered acamprosate, its concentrations are quite high when administered intravenously, but its half-life is approximately 3 hours as compared to 20 to 33 hours when taken orally. This is an example of "flip-flop" pharmacokinetics in which the concentration and half-life are limited by the rate and extent of absorption rather than volume of distribution or excretion.

Acamprosate has been assigned a category C labeling in pregnancy. Teratogenicity has been demonstrated in rat and rabbit fetuses though there have been no large-scale studies in humans to date. It is also unknown whether the medication is excreted through breast milk.

METABOLISM AND ELIMINATION. Importantly, acamprosate bypasses the liver and is eliminated unchanged in the urine and the feces. The majority of the acamprosate does not permeate the intestinal mucosa, and is therefore removed through the feces. Once the medication is available via paracellular transport, renal clearance is expedient, occurring at approximately 6 mL/min. The portion of the drug that is absorbed (ranging from 6.5 to 11 percent) does not undergo metabolism and is excreted in the urine as acamprosate. There is a linear relationship between renal clearance and plasma half-life of acamprosate and creatinine clearance values when taken orally. No significant pharmacokinetic differences between male and female subjects have been found for acamprosate.

Pharmacodynamics

MECHANISM OF ACTION. Acamprosate bears structural similarities to several amino acids, including GABA, glycine, aspartate, and glutamate; its mechanism of action is therefore thought to be mediated, at least in part, through numerous neurotransmitter systems.

Initial studies focused on acamprosate's in vitro affinity for $GABA_A$ and $GABA_B$ receptors, which appears to decrease electrical excitability without changing the membrane potential of the neuron. It is postulated that the therapeutic effect of acamprosate is partially due to its potentiation of the GABA network, the main neuronal inhibitory system. Unlike other GABA agonists, however, acamprosate doesn't exert anxiolytic, hypnotic, or muscle relaxant properties.

Other research has shifted focus to the structural similarities between acamprosate and the excitatory neurotransmitter, glutamate. It has been proposed that acamprosate may decrease the excitatory effects of glutamate, especially during the period after abrupt discontinuation of alcohol. Since alcohol inhibits the activity of the NMDA receptors, chronic alcohol consumption leads to the overexpression of these receptors. Chronic alcohol intake also affects the release of glutamate—in order to compensate for the alcohol-induced inhibition at the NMDA receptors, the amount of glutamate released into the synaptic cleft increases over time. Thus, abrupt discontinuation of alcohol results in unopposed neuronal excitation due to supranormal levels of glutamate acting on upregulated NMDA receptors, which may contribute to the pathophysiology of the alcohol withdrawal syndrome, including delirium tremens and seizures.

Other research supports the hypothesis that acamprosate interacts with NMDA receptors in a more complex way; for example, studies show that the drug is an NMDA partial coagonist. This means that at lower concentrations, acamprosate activates NMDA receptors when receptor activity is low. Conversely, at higher concentrations and when NMDA receptor activity is high, acamprosate is inhibitory, thereby helping to restore equilibrium in this disrupted neuronal system. Furthermore, it has been shown that acamprosate induces the release of taurine, an inhibitory neuromodulator, which also decreases neuroexcitability. In early alcohol withdrawal, the drug also decreases dopamine hyperexcitability in the nucleus accumbens, as well as the expression of brain c-fos, a gene expressed during early alcohol withdrawal.

While it was previously thought that N-acetyl-homotaurine was the biologically active compound mediating acamprosate's effects, recent literature has demonstrated that calcium may be the moiety responsible for acamprosate's success in the treatment of alcohol use disorder. Studies have demonstrated that treatment with calcium-acamprosate decreases voluntary drinking, while sodium-acamprosate was not superior to placebo

in attenuating alcohol consumption after prolonged alcohol exposure. Further research showed no difference in the bioavailability of sodium and calcium-acamprosate, such that this finding cannot be explained by differential absorption. Other studies reveal that higher brain and plasma calcium levels correlate with acamprosate's efficacy in treating alcohol use disorder. Interestingly, studies on the use of calcium supplementation were conducted though never completed in the 1950s; initial findings of "intensive calcium therapy" resulted in fewer days hospitalized and better success during the transition of psychotherapy to sustain abstinence.

It is clinically important to emphasize that despite acamprosate's modulation of glutamate dysregulation in rodents, there is no clinical improvement in patients who begin acamprosate during acute detoxification. Acamprosate does not eliminate or diminish withdrawal symptoms and is not indicated for the treatment of delirium tremens. On the contrary, available research suggests that patients who receive acamprosate during the detoxification period drink statistically more alcohol in 10-week follow-up than those administered placebo.

Acamprosate is most beneficial in maintaining abstinence and helping patients regain abstinence after relapse. The medication is thought to alleviate the negative affect associated with early stages of alcohol withdrawal, reverse alcohol-related changes in sleep architecture and also to decrease alcohol cravings once abstinence is achieved. It additionally decreases cravings in response to conditioned environmental cues. Unlike disulfiram, which relies on decreasing alcohol use by inducing distinctly unpleasant effects or naltrexone, which decreases the pleasurable effects of alcohol, acamprosate's primary mechanism appears to lie in its neuromodulatory effect—its ability to normalize disturbed brain chemistry and electrophysiology during acute and protracted withdrawal. Some studies suggest that it may reduce the rewarding effects of alcohol.

The medication has not been associated with the development of tolerance or dependence following prolonged exposure and evidence suggests that it should be continued in the event that relapse occurs. Acamprosate does not cause alcohol aversion or produce a disulfiram-type reaction in the event of relapse.

Preclinical research provides evidence that acamprosate has neuroprotective properties in neurons exposed to alcohol. The hyperglutamatergic imbalance that takes place during alcohol withdrawal is associated with neuronal excitotoxicity, which acamprosate has been shown to mitigate. Results from cell culture and animal studies have demonstrated decreased cell death in alcohol-exposed neurons in the cerebral cortex and hippocampus. Research supports that excessive glutamate activity continues after acute withdrawal, inducing ischemia, as measured by lactate dehydrogenase levels. Furthermore, acamprosate has been shown to inhibit *trans*-ACPD, a metabotropic glutamate type receptor

(mGluR) agonist, responsible for some of the neurotoxicity that glutamate exerts. The hyperglutamatergic syndrome that occurs during alcohol withdrawal is also thought to be mediated by calcium entry into neurons, which acamprosate alleviates. The relevance of these finding for treatment in humans awaits further research.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. Plasma concentrations of acamprosate may significantly vary between individuals due to multiple factors, most notably individual rates of absorption. Pharmacokinetic studies indicate that the concomitant use of acamprosate and alcohol doesn't result in any noticeable changes in the pharmacokinetics of either substance. At least one double-blind, placebo-controlled randomized controlled trial in a sample of 56 patients seeking treatment for alcohol use disorder found a negative correlation between alcohol craving following a priming drink (i.e., first drink after 21 days of continuous acamprosate treatment) and acamprosate plasma levels. This suggests that higher acamprosate blood concentrations may increase the chances of regaining abstinence after mild relapse.

Design and Interpretation of Clinical Drug Studies

Since its inception, there have been more than 20 double-blind, placebo-controlled protocols investigating the utility and safety of acamprosate in the pharmacological treatment of alcohol use disorders. The length of any individual trial ranged from 12 to 52 weeks with some protocols offering additional follow-ups. With few exceptions, patients were detoxified prior to treatment, dosing was based on weight and ranged between four and six 333-mg tablets. Treatment took place in outpatient programs with concurrent psychosocial interventions. The subjects across trials were predominantly male and mean age fell in the fourth decade of life.

Cumulative sample size from a meta-analysis of eight positive randomized controlled trials was 2,430, sufficiently powered to support some clinically relevant conclusions. Six of these protocols followed patients for over 52 weeks, providing a relatively long duration to study adverse effects over time. Acamprosate treatment separated from placebo most consistently when acamprosate was initiated after the acute withdrawal phase and in patients receiving concurrent psychosocial interventions. Acamprosate outperformed placebo in terms of continuous abstinence duration (time to first drink) as well as cumulative abstinence proportion (number of days abstinent out of the total days patients were in treatment) measured at 6 months. These results support the notion that acamprosate may help patients achieve complete abstinence and regain abstinence if relapse occurs. Another meta-analysis assessed acamprosate in 27 studies across 7,519 subjects. Sample sizes ranged from 21 to 1,383, treatment durations were 12 to 52 weeks and mean age was in the 40s. The

participants met *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria for alcohol dependence and the majority of studies included concurrent psychosocial interventions. This meta-analysis found that the number needed to treat to prevent return to any drinking for acamprosate was 12, suggesting modest efficacy of acamprosate treatment.

In protocols that included patients who had not undergone detoxification or were acutely withdrawing from alcohol, acamprosate failed to demonstrate superiority over placebo. Further, in another study where patients initiated treatment 25 days after recovery from physical withdrawal symptoms, acamprosate was not more effective than placebo. One meta-analysis was designed to study differential outcomes as a consequence of duration of detoxification and abstinence prior to initiating treatment. Nineteen trials that used acamprosate alone and in combination with various other interventions (naltrexone with and without adjunctive psychotherapies) were analyzed. In the 5,559 subjects included in this part of the meta-analysis, detoxification prior to treatment was associated with larger medication effects. These data indicate that the outcome of acamprosate treatment is time sensitive and may depend on the timing of intervention in relation to acute detoxification.

Several studies have attempted to evaluate and compare the usefulness of different psychotherapies (e.g., dynamically oriented individual psychotherapy, cognitive-behavioral individual coping skills therapy, group therapy, or various brief interventions) in the treatment of abstinence from alcohol when used in combination with acamprosate. To date, it remains unclear whether any particular psychotherapy is superior to another. The literature does substantiate that acamprosate is more effective when administered concurrently with psychotherapy. Brief motivational enhancement therapy (MET) is readily learned and can be implemented in psychiatric and primary care settings alike. This intervention focuses on improving a person's motivation to achieve and sustain abstinence. Given that acamprosate has been shown to be more effective when abstinence is the goal of treatment, MET holds promise as a psychotherapeutic adjunct to acamprosate.

Additional studies have investigated the efficacy of acamprosate in comparison, or in conjunction with, naltrexone as compared to acamprosate alone, acamprosate and psychosocial interventions, and placebo. These studies have not shown any efficacy of acamprosate over placebo with or without psychotherapy. Results from a 16-week randomized controlled trial, including 1,383 recently alcohol-abstinent volunteers, demonstrated no evidence of efficacy of acamprosate alone or together with combined behavioral intervention (CBI) when compared to other treatments (e.g., naltrexone, CBI and placebo alone or in various combinations). The largest limitation of this study was that subjects were only given 4 days for detoxification in an outpatient program. Studies that

reported no additional benefit from the combined acamprosate and psychotherapy treatment had additional limitations including the following: (1) lack of randomization in one open-label naturalistic study of 753 alcohol-dependent patients and (2) presenting the participants with the option to be randomized to the no psychotherapy arm, which may have created a selection bias for participants with a particular interest in receiving psychotherapy as documented in one randomized, multicenter study of 248 patients.

Another protocol studied 426 subjects meeting DSM-IV criteria for alcohol dependence when the diagnosis was established using the structural clinical interview for DSM-IV and *International Statistical Classification of Diseases*, Tenth Revision (ICD-10). All subjects were recruited from inpatient wards for medical detoxification. Following a mean of 18 days' inpatient detoxification, eligible patients were treated for 12 weeks in the outpatient setting with acamprosate, naltrexone, acamprosate and naltrexone, or placebo in conjunction with brief psychotherapy. Exclusion criteria included dependence or abuse of another substance other than cannabis or nicotine, a comorbid psychiatric disorder for which subjects were receiving medication and unstable medical conditions. The study showed no effect on abstinence in those who received treatment as compared to those who received placebo. Limitations were related to higher acuity since participants were recruited from an inpatient setting, in addition to relatively long detoxification period followed by relatively short outpatient treatment duration. Furthermore, these data likely are not generalizable as patients with alcohol dependence often have comorbid psychiatric and medical conditions. Out of all the patients screened, for example, only 43 percent met inclusion criteria and only 31 percent of all eligible patients chose to participate, which is suggestive that selection bias may have influenced the results.

One study investigated the efficacy of acamprosate in respect to gender using gender-specific meta-analysis of individual patient data obtained from double-blind, randomized controlled trials with inpatients carrying diagnoses of alcohol dependence based on DSM-III or IV criteria. Records were obtained from 1,317 women and 4,793 men from 22 studies across 18 countries. Exclusion criteria were pregnancy, lactation, or refusal to use birth control in women of childbearing age and potential, significant comorbid psychiatric disorders for which patients were prescribed medication, medical disorders such and renal failure, and concurrent use of another pharmacological intervention for alcohol use. Fourteen trials had durations of at least 6 months and five lasted longer than 1 year. Patients needed to have at least one quantitative measure of drinking behavior to assess treatment efficacy. The four end points variables included percentage of abstinent days, percentage of no heavy drinking days, rates of complete abstinence and rates of no heavy drinking over the study's

duration. There was an incremental gain of 10.4 percent in percentage abstinent days, a gain of 11 percent in percentage of no heavy drinking days, an odds ratio of 1.9 for complete abstinence rates and an odds ratio of 1.9 for rate of no heavy drinking over the studies' durations. Importantly, outcomes in acamprosate efficacy, safety or tolerability did not differ between men and women.

These data are limited in that the randomized controlled trial with the highest power failed to demonstrate the medication's efficacy as compared to placebo or naltrexone and that many studies supporting acamprosate's efficacy are short. Taken cumulatively, however, acamprosate appears to be safe and effective adjunct to psychosocial alcohol rehabilitation programs. It is most useful for patients receiving concomitant psychotherapy and whose stated goal upon initiating treatment is abstinence.

Effects on Specific Organs and Systems

Most serious adverse effect of acamprosate may be related to the urogenital system since there have been several documented cases of patients developing acute renal failure while receiving acamprosate treatment. However, no causal relationship has been established between acamprosate and any specific physiological mechanism that may result in acute kidney impairment. Less severe but more frequent are acamprosate's effects on the cardiovascular (palpitation and syncope), respiratory (increased cough, rhinitis, dyspnea), digestive (diarrhea, nausea, vomiting, and abdominal pain), musculoskeletal (myalgias and arthralgias), nervous (somnolence, amnesia, tremor) and dermatological (pruritus) systems. Mild diarrhea or loose stool was the only statistically significant adverse event documented in a large meta-analysis. It is further estimated that up to 10 percent of patients may experience mild diarrhea; importantly, those who suffered from diarrhea were no more likely than their counterparts to discontinue the medication.

Therapeutic Indications

Acamprosate is an FDA-approved agent for maintenance of abstinence from alcohol in patients with alcohol dependence who are abstinent at treatment initiation. The efficacy of acamprosate in promoting abstinence has not been demonstrated in subjects who have not undergone detoxification and not achieved alcohol abstinence prior to beginning acamprosate treatment. The efficacy of acamprosate in promoting abstinence from alcohol in patients with polysubstance abuse has not been adequately assessed. Treatment with acamprosate should be a part of a comprehensive management program that includes psychosocial support.

Other Disorders. Acamprosate is only FDA approved for the treatment

of alcohol dependence. The literature on other uses for acamprosate over the last few years is expanding. The medication appears to hold promise in the treatment of fragile-X-syndrome (FXS)-associated autistic spectrum disorders (ASD) and tinnitus.

Excessive glutamatergic and deficient GABAergic neurotransmission is found in patients with both FXS and with idiopathic ASD. Extensive literature supports a correlation between excessive mGluR5 and deficient $GABA_A$ neurotransmission in FXS-associated ASD. Preliminary studies showed that three adults with FXS and ASD, who were treated with a mean dose of 1,221 mg/day of acamprosate for a mean duration of 21.3 achieved clinical and statistical improvement in communication. A subsequent 10-week prospective open-label trial of acamprosate in 12 patients (mean age 11.9 years old) with comorbid FXS and ASD showed improvement in social impairment and inattention/hyperactivity in 75 percent of the patients.

A derivative of amyloid-β precursor protein (APP), secreted APPα (sAPPα), has neuroproliferative effects and has been shown to be elevated in the plasma of persons with ASD compared to control subjects. A pilot study of 15 subjects treated with acamprosate for 10 weeks showed a significant decrease in sAPP-total and sAPPα in subjects with FXS-associated or idiopathic ASD ($p < 0.05$), proposing a mechanism by which acamprosate might treat these disorders on the molecular level. The largest limitation of this study was its very low power and that 13 of the patients enrolled were receiving other pharmacological therapies. There were no adverse effects reported in patients receiving acamprosate. The medication may benefit patients with FXS and ASD, though no high-powered randomized controlled trials have been conducted to date.

A prospective, randomized, placebo-controlled, double-blind, cross-over study investigated the use of acamprosate in treating 40 subjects with sensorineural tinnitus. The patients were randomized to receive three 333-mg tablets of acamprosate daily or placebo for 45 days, followed by a washout period of 7 days and then crossed over to acamprosate or placebo for another 45 days. 92.5 percent of subjects receiving acamprosate demonstrated objective and subjective improvement in tinnitus as opposed to 12.5 percent subjective improvement seen with placebo. Objective improvement of tinnitus was measured by tinnitus matching for loudness by decibel. On this objective measure of tinnitus, 80 percent of the treatment group showed improvement as compared to 0.0 percent of placebo group. Numerous case reports also reflect subjective improvement in tinnitus with acamprosate. Larger studies are needed for FDA approval, but evidence suggests some efficacy of acamprosate in the treatment of tinnitus.

There is insufficient data to determine acamprosate's utility in the treatment of other substance use disorders. This may be because the medication is relatively new and small pilot studies have failed to

demonstrate superiority to placebo in the treatment of stimulant (cocaine) use disorder while preliminary studies in rodents were promising. This topic awaits further research.

Precautions and Adverse Reactions

Precautions. The dose of acamprosate will need to be adjusted for patients with moderate renal impairment (i.e., creatinine clearance of 30 to 50 mL/min). Patients with severe renal impairment (creatinine clearance of ≤30 mL/min) should not be prescribed acamprosate. Because acamprosate does not rely on hepatic metabolism, it can be used in patients with mild to moderate hepatic impairment (Child-Pugh groups A and B). It has not been used in Child-Pugh C liver disease and is not approved for use in this population.

In placebo-controlled trials, adverse events such as suicidal ideation, suicide attempts, and even completed suicides were reported more frequently in acamprosate-treated patients than in patients who received placebo (1.4 percent vs. 0.5 percent in studies of 6 months or less; 2.4 percent vs. 0.8 percent in year-long studies). Completed suicides in the pooled acamprosate group were 0.13 percent (3 out of 2,272 patients) and 0.10 percent (2 out of 1,962) in the placebo group. Depression was reported at similar rates in both treatment groups. The interrelationship between alcohol dependence, depression, and suicidality is well recognized and complex, and since many of these adverse events occurred in the periods of addiction relapse, it was hard to determine any direct link between the clinical course of recovery from alcoholism and the emergence of suicidality. Patients with alcohol use disorders, regardless of whether or not they are treated with acamprosate, should be monitored for the development of symptoms of depression and suicidality since suicide attempts and completions occur more frequently in patients with alcohol use disorders.

Although the safety of acamprosate during pregnancy has not been determined, the agent has been shown to have a teratogenic effect on the fetus in rodents. Acamprosate is a category C drug during pregnancy. The benefit of acamprosate use during pregnancy should be carefully weighed against possible adverse effects. It is also not recommended for use in nursing mothers.

Adverse Reactions. More frequent and less serious side effects may include headaches, insomnia, stomach upset with nausea, vomiting, and abdominal pain, as well as sexual dysfunctions (e.g., decreased libido, frigidity, and impotence). In clinical trials the most commonly reported side effects were diarrhea and pruritus, though these adverse effects were usually transient and in recent meta-analyses, patients with these adverse effects are no more likely than those receiving placebo to discontinue the

medication. Those who developed anxiety and depression while taking acamprosate were most likely to discontinue the medication, but it is difficult to parse out whether these mood symptoms are directly attributable to acamprosate or to underlying untreated mood disorders or mood disorders that developed as a result of prolonged alcohol use. More serious side effects include allergic reaction to the drug, arrhythmias, and fluctuations of blood pressure.

Drug Interactions

Because acamprosate does not rely on hepatic metabolism, it has relatively few drug–drug interactions. Coadministration of benzodiazepines, disulfiram, antidepressants or alcohol do not change acamprosate's pharmacokinetic properties, which is fortunate and these medications are commonly prescribed in patients with alcohol use disorders. However, coadministration of acamprosate with naltrexone may result in a 33 percent increase in the C_{max} of acamprosate, which requires no adjustment of the dosage. Similarly, the pharmacokinetics of naltrexone and its major metabolite 6-beta-naltrexol are unaffected when given concomitantly with acamprosate. Patients taking acamprosate with antidepressants more commonly reported both weight gain and weight loss in comparison to patients taking either medication alone.

The absorption of several agents (tetracyclines, quinolones, levothyroxine, atenolol, iron, alendronate, sodium fluoride, and zinc) may be decreased by the calcium component of acamprosate during concurrent administration. The absorption of acamprosate can also be decreased by food. Acamprosate has shown no inhibiting or inducing potential both in vitro and in vivo on the enzymes of the cytochrome P450 system.

Laboratory Interference

Acamprosate is not known to interfere with any laboratory tests.

Dosage and Administration

Initiation of therapy should begin after alcohol detoxification has taken place and the patient has abstained from alcohol for 5 to 7 days. Just as it should not be initiated during acute detoxification, a review of the literature substantiates that it may not be superior to placebo if the medication is initiated more than 25 days postacute alcohol detoxification. Acamprosate treatment should not be interrupted if relapses occur and is recommended to proceed for 12 months.

Acamprosate is dosed by weight: patients >60 kg should receive 1,998 mg/day in divided doses with meals, while patients <60 kg should receive 1,332 mg/day in three divided doses with meals. The drug has not been sufficiently studies in pediatric and geriatric populations.

A.B. is a 54-year-old male with a life-long history of alcoholism. Through his involvement with Alcoholic Anonymous (AA) he managed to maintain abstinence for close to 2 decades before relapsing few months back. The current relapse was accompanied by increased feelings of loneliness and sadness along with self-isolation and binging episodes. Remarkably his work performance has been sustained, but he felt that "things will collapse soon" and self-enrolled in an outpatient 12-step based program. A.B. articulately participated in group sessions twice a week, but shared that "I have heard all of that many times before" referring to his prior experience with AA and felt that he is not "getting much out of it." Although he was able to maintain longer nondrinking intervals between relatively short-lived binges he was very concerned that "next big relapse is about to happen at any time with no warning" and continued to feel unable to enjoy some of his work-related successes. More specifically, he was recently offered a very high level position in a not-for-profit organization that was involved in a very high-end political fund-raising. On several occasions he stated that he cannot allow this opportunity to fail because of his inability to stay abstinent.

Within a month after A.B. joined the outpatient program he requested an appointment with the psychiatrist to discuss medication treatment in respect to his worsening depression and ongoing tendency to relapse on short-lived binges. He had used an SSRI medication for several years in the past and has stopped it about a year ago "because I did not need it anymore." He has considered restarting the medicine and was in agreement with such recommendation. He has also researched medications for alcoholism such as disulfiram (Antabuse), naltrexone (Revia) and acamprosate (Campral). He seemed concerned about Antabuse's "serious side effects" and decided on starting acamprosate (Campral). He found the treatment easy to tolerate and probably effective since he was abstinent for about 4 weeks until he had yet another relapse that he acknowledged was somewhat premeditated. Needless to say, A.B. felt very discouraged by his self-sabotaging behavior and possibly compelled to some extend by desperation decided to try disulfiram (Antabuse). To assure success he made a significant effort to be consistent with it on daily basis and shared that "as long as I take it I know I cannot drink." On a later date he inquired on the compatibility of disulfiram (Antabuse) and acamprosate (Campral) since the latter "seemed to have reduced the sudden and difficult to control urges to drink," which he found so distressing. About 2 months after he started Antabuse A.B. added Campral to his daily regimen. Ultimately the combination of disulfiram (Antabuse) and acamprosate (Campral) turned to successfully help A.B. in his motivation to consistently maintain sobriety.

▲ 34.17 First-Generation Antipsychotics

MARTIN T. STRASSNIG, M.D., AND PHILIP D. HARVEY, PH.D.

HISTORY

There is now emerging agreement that antipsychotic drugs should be differentiated based on their individual side-effect profiles in addition to their efficacy. Although 5-HT_{2A} and 5-HT_C inverse agonism (or antagonism) in addition to dopamine D2 antagonism has been a mainstay of dividing newer from older antipsychotics, several of the (older) first-generation agents (e.g., clozapine [Clozaril], thioridazine [Mellaril], melperone [Buronil], and cyamemazine) have considerable 5-HT_{2A} antagonism as well, making the distinction less useful. Moreover, it has become increasingly clear that SGAs differ among each other in many properties and are not a homogeneous class either.

The FGAs represent the first group of effective agents for schizophrenia and other psychotic illnesses. They include all of the antipsychotics in the following groups: phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindoles, and diphenylbutylpiperidines. Although the FGAs have gradually been replaced by the SGAs in the United States, the FGAs remain the most commonly prescribed antipsychotics in many parts of the world, and as cost considerations have become more prominent, FGAs remain frequently prescribed in the United States as well.

These agents are highly effective for nearly all disorders that result in

psychotic symptoms. However, these drugs have important limitations: they can cause acute and chronic neurological symptoms that, especially at higher doses, significantly limit their effectiveness; they are ineffective or only partially effective for a substantial proportion of psychotic patients; the minimally effective dosage has frequently not been determined and therefore patients may be over- or undermedicated; and they have limited efficacy for some of the most important signs and symptoms of the most common psychotic illness, schizophrenia. In higher dosages, the motor symptoms may induce "secondary" negative symptoms, such as akinesia, emotional blunting, apathy, and cognitive impairment.

Despite their limitations, FGAs have played an important role in the management of psychosis. The modern era of psychopharmacology began with the discovery of chlorpromazine (Thorazine), the first effective antipsychotic, in the early 1950s. The annual increase in state and county mental hospital beds in the United States that had occurred since the beginning of the 20th century reversed shortly after the arrival of antipsychotics. This occurred because most psychotic patients with schizophrenia and other psychotic illnesses became clinically stable enough to be discharged from hospitals after they received drug treatment. Moreover, patients with stabilized illnesses became candidates for psychosocial treatments and rehabilitation. There is also evidence suggesting that treatment with antipsychotics can improve the long-term course of schizophrenia.

The FGAs have wider applicability than for the treatment of schizophrenia only. They are effective for treating psychosis regardless of its cause. As a result, antipsychotics are standard treatments for many patients with psychoses associated with physical origins, bipolar illness, major depressions with psychotic features, and schizoaffective disorder.

The first phenothiazines were the first effective antipsychotic drugs. Drugs from this class were originally used as antihelminthics in veterinary medicine and as urinary antiseptics in humans. In 1950, Paul Charpentier, at the Rhóne-Poulenc Laboratories in Paris, synthesized chlorpromazine, a drug that appeared notable as a mild antihistaminic that was also sedating. Henri Laborit, a surgeon with an interest in drugs that would decrease preoperative anxiety and prevent postsurgical shock, convinced the Rhóne-Poulenc Laboratories of the importance of identifying compounds that would relax patients and make surgical shock less likely. Chlorpromazine appeared to fulfill these criteria, but it also appeared qualitatively different from other sedating drugs. Patients appeared indifferent toward the environment and more tranquil. These properties led Laborit to convince psychiatrists, including Jean Delay and Pierre Deniker, to administer chlorpromazine to patients with mania and schizophrenia. In 1952, these authors reported their observation that chlorpromazine was effective in treating mania and schizophrenia. Within a year, the atmosphere in Paris's

psychiatric hospitals had improved substantially. The discovery of chlorpromazine's effectiveness for psychosis represents the beginning of modern psychopharmacology in that it indicated that drugs could have specific effects on the symptoms of mental disorders that went beyond sedation. Moreover, the availability of drugs with direct effects on mental disorders became a powerful tool for laboratory studies with animals, leading to a greater understanding how drugs affect the brain and information about the nature of the illnesses that were affected.

The use of chlorpromazine was reported by Lehman and Hanrahan from Montreal in 1954 and it rapidly captured the interest of US psychiatrists. In 1955, Henry Brill, the assistant state mental health commissioner in New York, initiated the general use of chlorpromazine and reserpine in state hospitals in that state. Although reserpine was also an effective antipsychotic, its side effects led clinicians to prefer chlorpromazine and, as a result, it is no longer used for treating psychosis because of its side effects, such as depression, suicidality, dysphoria, and orthostatic hypotension.

In 1953, reports surfaced indicating that chlorpromazine could cause neurological adverse effects, predominantly parkinsonian symptoms. Although some individuals warned that these symptoms were evidence of neural toxicity, others suggested that the dosage should be increased until patients experienced a mild form of parkinsonism, termed the "neuroleptic threshold" dose. Later that year, clinicians noted that chlorpromazine could also result in forms of persistent dyskinesia, a syndrome that would later be called tardive dyskinesia (TD). Thus, information about the side effects of FGA medications has been available since their introduction.

The introduction of chlorpromazine was followed by the introduction of other phenothiazines including perphenazine (Trilafon) and fluphenazine (Prolixin). In 1958, the first effective butyrophenone, haloperidol (Haldol), was introduced by Paul Janssen from Janssen Pharmaceutica in Beerse, Belgium. The first thioxanthene antipsychotics were introduced the same year by Peterson and his coworkers. Although many other FGAs were introduced in subsequent years, most of these agents were similar in effectiveness and differed only in their propensity to cause side effects. The first long-acting antipsychotic, fluphenazine enanthate, was introduced in the early 1960s. Although this and subsequent long-acting agents, such as haloperidol decanoate, had similar effectiveness and side effects to other antipsychotics, they provided a method for administering an antipsychotic without requiring patients to take daily oral medication, improving treatment adherence and reducing relapse and rehospitalization rates.

CHEMISTRY

The FGAs have been referred to by a number of titles including neuroleptics, major tranquillizers, dopamine receptor antagonists, and

antipsychotics (typical or FGAs). The designation neuroleptic was suggested by Deniker who noted the tendency of these agents to have neurological side effects and thus appear to "take the neuron," based on the observation that neurological side effects are inevitably associated with antipsychotic activity. However, the effectiveness of drugs such as clozapine suggests that neurological side effects are not necessary to treat psychosis. Thus, referring to a side effect of these agents rather than the primary clinical effect may be misleading. The term *major tranquillizer* referred to the strange quietness or blandness (or *ataraxia,* Latin) that had been associated with those agents. However, the suggestion that these agents function by their tranquillizing effects is also misleading.

In this section, the dopamine receptor antagonists are subclassified according to their chemical structure. Another system for subclassifying this group is to use the antipsychotic potency of these agents (Table 34.17–1), dividing them into low-, mid-, and high-potency agents. This latter method is probably more useful to clinicians since this classification provides information about the amount of drug that is required for a clinical effect and the likelihood of important side effects. The antipsychotic drugs come from a number of chemical classes, each with somewhat different pharmacokinetic properties. The differences can have important effects on the clinical use of the drugs. The phenothiazines and the thioxanthenes share structural similarities and have a number of shared metabolic pathways. The same is true for the butyrophenones and the diphenylbutylpiperidines. This overview will focus on chlorpromazine and haloperidol as representative compounds. Since the pharmacokinetics of the long-acting agents differs substantially from the short-acting agents, they are discussed separately.

Phenothiazines

All of the phenothiazines have the same three-ring structure with different side chains joined at the nitrogen atom of the middle ring (Fig. 34.17–1). The activity of the group can be affected by substitutions at position 2 or 10. The phenothiazines are usually categorized into three classes based on substitutions at position 10. These substitutions have important effects on the pharmacological characteristics of the phenothiazines. Thus, substituting an *aliphatic* side chain results in a drug with relatively low antipsychotic potency such as chlorpromazine. These agents also tend to be sedating and to cause anticholinergic and hypotensive effects at their effective dosages. Chlorpromazine has a chlorine atom at position 2. If the chlorine atom is eliminated, the resulting drug is promazine (Sparine), a weak antipsychotic. Substituting a *piperidine* ring at position 10 leads to an effective group of antipsychotics characterized by thioridazine and mesoridazine (Serentil). These drugs have similar potency and side effects when compared with the aliphatic phenothiazines. Fluphenazine and

trifluoperazine (Stelazine) are representative antipsychotics with a *piperazine* group substituted at the 10 position. Piperazine phenothiazines have fewer anticholinergic and autonomic effects, but greater affinity for D_2 sites, and as a result produce more EPS. A number of piperazine phenothiazines have been esterified at a free hydroxyl group with ethanoic or decanoic acid to produce injectable long-acting antipsychotics.

Thioxanthenes

This group shares a similar three-ring structure with the phenothiazines, but has a carbon atom substituted for nitrogen at position 10. Chlorprothixene (Taractan) is an effective low-potency *aliphatic* thioxanthene agent with an antipsychotic potency and a side-effect profile similar to its phenothiazine counterpart, chlorpromazine. Thiothixene (Navane), clopenthixol (Sordinol), and flupenthixol (Depixol) are thioxanthenes with a *piperazine* substitution. Again, their clinical characteristics resemble those of their phenothiazine counterparts. As a result of their double bond at position 10, these agents have geometric isomers with the *cis* isomers demonstrating greater antipsychotic activity.

Butyrophenones

This class of antipsychotic drugs is characterized by a substituted phenyl ring, which is attached to a carbonyl group attached by a 3-carbon chain to a tertiary amino group. Most of the clinically useful butyrophenones have a piperidine ring attached to the tertiary amino group. Haloperidol is the representative drug for this class. It and other butyrophenones tend to be potent D_2 antagonists and have minimal anticholinergic and autonomic effects, as well as reduced sedation compared to phenothiazines. Haloperidol, a substituted piperidine, is the most commonly used (and oldest) drug from this class. Other important butyrophenones include droperidol (Dropletan), a short-acting, sedating compound that is commonly used to control agitation; and spiperone (Spiroperidol), an agent with very high affinity for D_2, 5-HT_{2a}, and 5-HT_{2b} receptors that is commonly utilized for labeling receptors in animal studies and in PET scanning.

Dibenzoxazepines

This class of antipsychotic drugs has a three-ring structure with a seven-member center ring. Loxapine (Loxapac), a dibenzoxazepine, is the only drug from this group that is available in the United States. Clozapine, a dibenzodiazepine, differs from loxapine in having a nitrogen instead of an oxygen atom in the middle ring, as well as differences in side chains.

Dihydroindoles

These derivatives are structurally related to serotonin, melatonin, and indole hallucinogens, such as dimethyltryptamine. The only dihydroindole available in the United States was molindone (Moban), the only antipsychotic agent without known weight gain liability. Molindone has

since been discontinued from the market in 2010.

Diphenylbutylpiperidines

This group of agents is similar in structure to the butyrophenones. Pimozide (Orap), the only diphenylbutylpiperidine available in the United States (indication for Tourette syndrome), is derived from the butyrophenone benperidol. It has a long half-life: 20 to 26 hours. Doses of 20 mg or higher are associated with seizure risk and QTc prolongation. This agent has been removed from the market for psychotic conditions because of those reasons. Penfluridol (Semap) and fluspirilene (experimental) are antipsychotics from this group that are not available in the United States.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Plasma concentrations of short-acting drugs rise rather rapidly during what is referred to as the absorption phase and then decline during a distribution, metabolic, and elimination phase. Each of these three phases is influenced by different factors related to the chemical structure of the agent (Table 34.17–2).

Absorption

In general, the FGAs are well absorbed when they are administered orally or parenterally. As with most drugs, oral administration leads to less predictable absorption than parenteral administration. Liquid concentrates are absorbed slightly more rapidly than pills. Plasma concentrations of the drugs usually reach peak levels 1 to 4 hours after ingestion and 30 to 60 minutes after intramuscular (IM) administration. In general, IM preparations reach their peak concentrations sooner than oral drugs and as a result have an earlier onset of action. For example, IM administration of most antipsychotics results in peak plasma levels in about 30 minutes with clinical effects emerging within 15 to 30 minutes. Oral administration of most FGAs results in a peak plasma level in 1 to 4 hours. A number of factors can interfere with the GI absorption of these drugs including antacids, coffee, smoking, and fatty foods.

Drugs usually reach steady state in about three to five half-lives. Thus, steady state levels for chlorpromazine, haloperidol, and most other FGAs are reached in about 3 to 5 days since their half-lives are about 24 hours. The bioavailability (i.e., the amount of drug reaching the systemic circulation) is substantially greater—as much as 10-fold—when FGAs are administered parenterally. This difference may result from the incomplete absorption of the drug in the GI tract and from extensive metabolism of oral drugs during the first pass mainly through the liver.

Distribution

The initial decline in the plasma concentration of an antipsychotic (or any drug) results primarily from drug distribution into various bodily compartments. Since antipsychotics are highly lipophilic, they tend to accumulate in tissues such as fat, lungs, and brain. Brain levels of antipsychotics tend to be substantially higher than plasma levels. Since plasma and brain levels are in equilibrium, measuring plasma levels is sufficient for estimating brain levels. However, behavioral effects may last substantially longer than the blood levels indicate. For instance, sexual side effects may last for several weeks after the last dose of chronic treatment.

Most FGAs are highly protein bound. For example, more than 90 percent of drugs such as fluphenazine and haloperidol are bound to plasma protein. The remaining unbound portion is the drug that is available for passing through the blood–brain barrier. In theory, conditions that alter the amount of plasma protein such as malnutrition will also alter the amount of bioavailable antipsychotic drug. This is potentially important for drugs that are protein bound for 98 percent or more.

Metabolism and Elimination

The metabolism of antipsychotic drugs is largely hepatic and occurs through conjugation with glucuronic acid, hydroxylation, oxidation, demethylation, and sulfoxide formation. The metabolism of the phenothiazines and thioxanthenes is particularly complex. For example, chlorpromazine has more than 100 different potential metabolites, with

some metabolites having significant amounts of pharmacological activity. The case of thioridazine, a substantial amount of the drug's activity, is from metabolites that may be more active than thioridazine itself. One metabolite, mesoridazine, is also marketed as an antipsychotic. However, haloperidol has only one major metabolite, reduced haloperidol, which has substantially less antidopaminergic activity than the parent compound. However, reduced haloperidol is converted back to the parent compound and in this manner may contribute to antipsychotic activity.

Most FGAs are metabolized by the cytochrome P450 2D6 and P450 3A subfamilies in the liver. Since these same isoenzymes also metabolize a number of drugs that are commonly combined with antipsychotics, a number of important drug–drug interactions are possible. These are discussed in the section on drug–drug interactions.

Patients demonstrate substantial differences in the extent to which they metabolize these compounds. This explains, in part, the marked differences among patients in the oral neuroleptic dosages required for treatment. This, along with differences in absorption, may also explain the 20-fold variation in plasma concentrations that can be found among patients treated with the same dosage of an antipsychotic.

The systemic clearance of FGAs is high as the result of a high hepatic extraction ratio. As a result, only negligible amounts of the unchanged drug are excreted by the kidneys. Phenothiazines, thioxanthenes, and their metabolites are excreted in the urine and the feces.

Pharmacokinetics of Long-Acting Antipsychotics

The pharmacokinetics of long-acting injectable antipsychotics differs markedly from those of short-acting oral and injectable drugs. Long-acting fluphenazine and haloperidol are administered as esters dissolved in sesame oil. The oil is injected into a muscle and the drug gradually diffuses from the oily vehicle into the surrounding tissues. The rate-limiting step appears to be the rate of diffusion, since once the drug enters the tissue it is rapidly hydrolyzed and the parent compound is released. Long-acting compounds, however, are absorbed continually during the interval between injections. Moreover, for patients who have received multiple injections, the drug will be absorbed from multiple injection sites simultaneously. As a result, it takes long-acting compounds much longer to reach steady state, and they are eliminated much more slowly than their oral counterparts. For example, the decanoate forms of haloperidol and fluphenazine each require about 3 months to reach steady state, and substantial plasma concentrations can be detected up to several months after therapy has been discontinued. This has consequences for prolonged side effects, and potentially for TD risk, even after discontinuation of therapy.

ELDERLY PATIENTS. Elderly patients require lower than usual dosages of

FGAs for a number of reasons. These include decreased renal clearance, decreased cardiac output, decreased liver size, and decreased CYP450 enzyme. In addition, elderly patients may be more sensitive to the parkinsonian side effects of the drugs. Recently, FGAs (and SGAs) have been associated with increased mortality risk in elderly patients with dementia.

PHARMACODYNAMICS

The pharmacodynamics of an antipsychotic describes its activity at important sites of action, particularly at its brain receptors. Recent findings in neuroscience have provided important information about the effects of FGAs at a number of different receptor sites, how these effects influence groups of neurons, and how activity at receptors is translated into intracellular events.

MECHANISM OF ACTION OF DOPAMINE RECEPTOR ANTAGONISTS

The Dopamine Hypothesis

The dopamine hypothesis states that antipsychotics reduce psychotic symptoms by decreasing dopamine activity. It was originally proposed by Arvid Carlsson from Sweden and other basic scientists based on the observation that haloperidol and chlorpromazine raised the levels of dopamine metabolites in dopamine-rich areas of mouse brain, interpreted as dopamine antagonism, and compensation of self-regulating systems by increasing dopamine production. Other investigators noted that FGAs inhibit the activation and stereotypical behaviors of rodents induced by amphetamine. This effect has been found to be a reasonably reliable predictor of antipsychotic activity in patients. Moreover, the dose–response relationships in animals provide information about the likely clinical dosage range for patients. These behaviors are thought to be mediated by dopamine and have been used as screening devices to identify compounds that are likely to have clinical efficacy as antipsychotics. Other evidence supporting a role of dopamine in psychosis comes from the observation that all drugs—at least to this date—capable of reducing psychosis are also dopamine antagonists, including partial dopamine agonists. Moreover, agents that are associated with increased dopamine activity such as amphetamine, methylphenidate, or cocaine tend to increase dopamine neurotransmission and also tend to worsen symptoms in patients with schizophrenia. At persistent high dosages, these drugs may cause psychosis in individuals without pre-existing psychiatric disorders.

A role for dopamine in the activity of antipsychotics, originally proposed by Carlsson, the Nobel laureate, was given strong support by the work of Solomon Snyder from Johns Hopkins University and Philip Seeman from the University of Toronto in the mid-1970s. Using similar receptor binding

methods, both found that the antipsychotic potency of a number of drugs was highly correlated with the drug's affinity for D_2 receptors. More recent studies, using highly selective D_2 receptor ligands and PET indicate that dopamine receptor antagonists are effective when approximately 80 percent of D_2 receptors in the striatum are occupied. Higher occupancy rates may be associated with more parkinsonian side effects without greater effectiveness. In contrast, clozapine is effective when only 40 to 60 percent of D_2 receptors are occupied (Table 34.17–3). Although it remains unclear why clozapine is effective at lower levels of D_2 occupancy, it has been suggested that activity at other receptors, particularly 5-HT_{2A} receptors, may contribute to clozapine's clinical activity, and to its major active metabolite, *N*-des-methyl clozapine (NDMC), which has partial $D_{2/3}$ receptor agonist activity in addition to being a strong 5-$HT_{2A/2C}$ inverse agonist (or antagonist). The 5-HT_{2A} antagonism by itself has been suggested to have antipsychotic effects, albeit not as strong as $D_{2/3}$ antagonism (Fig. 34.17–2). NMDA receptor agonism at the glycine site may increase its efficacy as well.

Several studies using PET scanning have found that there is no difference in D_2 receptor occupancy in the striatum between individuals who respond to an antipsychotic and those who do not. This finding suggests either that processes beyond the dopamine receptor affect response or that dopamine blockade in the striatum is not the mediator of behavior change.

The Effects of FGAs on the Dopamine System

Dopamine neurons with cell bodies in the ventral tegmental area (the A_{10} cell group in rat brain) project via the meso-limbo-cortical dopamine system to the nucleus accumbens, amygdala, and the neocortex. Dopamine cells in the substantia nigra (the A_9 cell group) project to the caudate putamen via the nigrostriatal system. It has been proposed that activity in the meso-limbo-cortical system explains the antipsychotic activity of drugs, whereas neurological side effects such as EPS and TD result from activity in the nigrostriatal system. Thus, drugs with preferential activity at meso-limbo-cortical sites would result in clinical effectiveness with fewer neurological side effects. However, the reason that the SGAs have fewer EPS has been attributed to having additional effects on the $5\text{-}HT_{2A}$ receptors, which increases dopamine turnover.

Advances in molecular biology have led to the cloning of a number of dopamine receptor subtypes. The discovery of these subtypes has raised the question of their possible role in the treatment of psychosis. Dopamine receptors can be classified into two groups: D_1-like (D_1 and D_5) and D_2-like receptors (D_2, D_3, D_4). Moreover, each of these receptor subtypes may have variants that have the potential for explaining heterogeneity in drug responses. As mentioned previously, the antipsychotic potency of dopamine receptor antagonists is highly correlated with their affinity for D_2 receptors. This relationship has not been established with other dopamine

receptor subtypes. Nevertheless, certain characteristics of receptor subtypes suggest that they may contribute to clinical responses. For example, a role for D_4 receptors has been suggested by clozapine's high affinity for this subtype. Unfortunately, multiple attempts to bring D_4 antagonists to the market have failed for lack of antipsychotic efficacy. The localization of D_3 receptors in limbic areas suggests that these subtypes may be clinically important for antipsychotic effects. In contrast, D_1 receptor blockade may be undesired, as D_1 stimulation in the cortex is associated with better cognitive functioning and D_1 antagonists have been reported to cause suicidality.

Studies of the dopamine system in animals and man have suggested important interactions between the subcortical and prefrontal dopamine systems that may affect responses to FGAs. Lesions in the prefrontal cortex of rats result in increases in dopamine activity in the striatum, suggesting that these two systems have important functional linkages. Similarly, increases in dopamine activity in the prefrontal cortex are associated with decreases in striatal activity. Also, a number of investigators propose that negative symptoms of schizophrenia are associated with decreased dopamine antagonist prefrontal activity, whereas psychotic symptoms are generated by subcortical increases in dopamine antagonist activity (temporal lobe). In this model, an effective antipsychotic would increase dopamine activity in prefrontal areas and decrease activity in subcortical areas.

Other clinical evidence for a role of dopamine in the antipsychotic effects of dopamine receptor antagonists comes from studies of homovanillic acid (HVA), a metabolite of dopamine. In these investigations, changes in plasma HVA on an antipsychotic are used as reflecting changes in dopamine activity in the brain. These studies indicate that plasma HVA rises soon after patients begin treatment with an antipsychotic and then falls below pretreatment levels in patients who improve. Moreover, a number of studies indicate that patients with high levels of plasma HVA prior to drug treatment are more likely to improve than those with lower levels. These findings suggest that improvement on an antipsychotic agent is associated with an overall reduction in dopamine activity. Since subcortical areas have the greatest contribution to dopamine activity in the brain, this finding may not reflect cortical dopamine activity.

Studies that monitor the intracellular firing rates of dopamine neurons have also contributed to an improved understanding of the effects of antipsychotics. Chiodo, Grace, and Bunney have reported that the administration of haloperidol to rats resulted in a short-term increase in the firing of midbrain dopamine neurons followed by a prolonged decrease in firing that has been referred to as “depolarization inactivation.” It has

been proposed that the antipsychotic effects of these drugs are associated with the decrease in firing rate. Taken together with the studies of plasma HVA, these findings suggest that for an antipsychotic response to occur, the blockade of D_2 receptors is an initial response that must be followed by a decrease in dopamine activity.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design

The FGAs were the first specific compounds for treating a major mental illness. Their effectiveness, conclusively proven, challenged the views of some clinicians who believed that psychosis was a psychological reaction related to early experiences and that only psychological treatment could have antipsychotic effects. This initial skepticism was valuable in that it helped inspire the development of controlled clinical drug trials aimed at demonstrating the effectiveness of antipsychotics. Early studies, such as those developed by the Department of Veterans Affairs (VA) and the National Institute of Mental Health (NIMH), were influential in establishing objective research methods. One principle, now widely acknowledged, is for an antipsychotic (or any other new drug) to be considered effective; it should yield a better outcome than a placebo. That principle controls for nonspecific improvement that occurs because of a number of factors, such as (1) spontaneous fluctuations in symptoms; (2) the rate of spontaneous improvement for the illness; (3) the expectation of improvement, which is related to starting a new drug; (4) the subject's protection from environmental and psychosocial stresses that may occur with hospitalization; and (5) other environmental factors such as the hospital milieu and psychological treatments that can lead to improvement.

Two other principles that reduce sources of bias are random assignment to a treatment group and double-blind evaluation methods. Random assignment ensures that differences in outcome between the groups (usually between those receiving a drug and those receiving a placebo or between two different active groups) are not attributable to patients with different expected outcomes or drug responses being assigned to one group. An example would be a study in which patients who are more severely ill are assigned to a particular group or if patients who are predicted to improve spontaneously are assigned preferentially to the drug group rather than the placebo group. Double-blind methods were developed to ensure that bias by patients or by those who evaluate the outcome does not influence the study. For example, a person who performs a clinical rating may be prejudiced toward rating patients who are receiving a drug as more improved than patients who are receiving a placebo. Double-blind methods also protect against bias in the manner in which treatment is administered. For example, a treating clinician may give more

attention to a patient who is receiving a certain drug.

A number of modifications in trial methods have been developed since the first studies of FGAs, although the principles of random assignment and blindness remain important. For example, treating acutely ill patients with schizophrenia with FGAs has become a standard of care and has led some to question the ethical use of placebos when effective treatments are available. Alternative methods for demonstrating the efficacy of a compound have included showing that it is as effective as an antipsychotic agent with proven efficacy or showing that a dosage thought to be subtherapeutic is less effective than a higher dosage. Since blindness is often difficult to preserve when a drug has known side effects, active placebos with side effects but without CNS effects have been used. However, inexperienced evaluators tend to overinterpret side effects as being secondary to active treatment rather than to placebo, which also is associated with similar side effects, even so less frequent. Recent research have indicated that high interrater reliability and centralized ratings may decrease variance even further, while increased number of sites and more rating scales and raters may increase variance and therefore decrease the likelihood of separation from placebo.

INTERPRETATION

Acute Psychosis

Numerous double-blind clinical trials have demonstrated that FGAs are more effective than placebo for reducing symptoms of psychosis. The initial studies were carried out in the 1960s by the NIMH, reviewed by Donald Klein and John Davis who concluded that compared more than one antipsychotic and found that with the exception of mepazine (Pacatal) and promazine, all of these agents were effective. These and subsequent studies also demonstrated that antipsychotics are effective for every subgroup of patients with schizophrenia. In 2009, the Schizophrenia Patient Outcomes Research Team (PORT) updated prior reviews and concluded that there is clear evidence that FGAs are effective for reducing positive symptoms during acute psychotic episodes. PORT recommendations also suggest that choosing antipsychotics should be based on individual preference, prior treatment response and adherence history, medical history and risk factors, the individual medication's side-effect profile, and long-term treatment planning.

Controlled clinical trials have demonstrated that antipsychotic medications are effective in reducing psychotic symptoms, such as hallucinations and paranoid ideation to a greater extent than anxiety and depression. Improvements individual patient experiences on these agents vary considerably. For many patients, FGAs can lead to a complete remission of psychotic symptoms. The early studies from the NIMH

indicate that 60 percent of drug-treated patients improved to the extent that they achieved a complete remission (albeit temporarily) or experienced only mild symptoms; the remaining 40 percent will continue to experience psychotic symptoms, and approximately 8 percent of them are not improved with drug treatment.

Positive psychotic symptoms, which include hallucinations and delusions, are more responsive to dopamine receptor antagonists than are negative symptoms, such as blunted affect, emotional withdrawal, and lack of social or vocational interest or disorganized symptoms, such as impaired attention and impaired communication. Although these latter two groups of symptoms are less responsive than psychotic symptoms, double-blind studies indicate that these symptoms improve to some degree. EPS can cause secondary negative symptoms, compounding symptom burden. Patients with parkinsonism may demonstrate fewer expressive gestures and diminished interest in their environment. Anticholinergic antiparkinsonian medications, aimed at mitigating parkinsonian and other EPS symptoms, sometimes recommended prophylactically when used with a (high potency) FGA, may impair memory in patients who require these drugs, while EPS may worsen cognitive test scores that require intact motor function.

The symptomatology of all forms and types of schizophrenia improves with FGAs. Although it was proposed that low-potency, sedating FGAs were more effective for agitated patients and high-potency, nonsedating drugs were more effective for more withdrawn patients, this has never been substantiated by controlled trials. As a group, women tend to respond better and to require lower dosages than men. Unfortunately, there are no biological or clinical indicators that can be used to predict treatment response other than the patient's prior responses.

Maintenance Therapy

A number of studies have compared FGAs to placebos for preventing relapse in patients who have been stabilized following a psychotic episode. These studies provide strong support for continuing FGAs when patients have recovered from a psychotic episode. A review of 24 double-blind studies of maintenance antipsychotic therapy found that in all studies many more patients relapsed when they were not receiving an active drug. A meta-analysis that included most of these studies reported that approximately 72 percent of patients will relapse in a year on placebo compared to only 23 percent on a conventional antipsychotic. A more recent review cited 66 studies in which antipsychotics were withdrawn. The mean relapse rate was 53 percent for patients withdrawn from medication and 16 percent for patients maintained on an antipsychotic. The more robust the remission prior to discontinuation (the lower the psychosis ratings) is, the longer the time until relapse.

A number of investigations have focused on the usefulness of continuing medication for patients who have recovered from a first episode of schizophrenia. Again, maintenance medication showed a substantial advantage, although relapse rates were lower for remitted first-episode patients when compared to multiepisode patients. Other studies indicate that patients who have been well and stable on an antipsychotic for years have a high likelihood of relapse when their medications are discontinued.

Earlier studies by Donald Johnson suggest other advantages for maintenance antipsychotics in schizophrenia. He found that patients who relapsed when they were receiving FGAs had episodes that were less severe than those in patients who had discontinued their drugs. Drug-maintained patients were less likely to have episodes with self-destructive behaviors, violence, and antisocial acts when compared with patients who were not receiving medication. Patients who were not receiving medication were also more likely to require involuntary hospitalization. Patients who discontinued their medications ended up, on the average, receiving more total medication because the dosage needed to treat acute relapses is much higher than the dosages usually prescribed for preventing relapse. Many of these findings have since been replicated. The common denominator is that maintenance therapy with antipsychotics benefits patients with schizophrenia. Antipsychotic maintenance treatment with both FGAs and SGAs substantially reduces relapse risk and reduces hospitalization rates. Depot antipsychotics appear to be more effective for relapse prevention than oral medications. This would suggest there is a more prominent place for depot antipsychotics in relapse prevention in schizophrenia, including haloperidol and fluphenazine decanoate. One recent study pointed out that there was no difference in relapse rates between the long-acting FGA haloperidol and SGA paliperidone over 24 months, although side effects rates differed. Haloperidol decanoate caused more and more frequent EPS, while paliperidone palmitate caused more hyperprolactinemia (McEvoy et al., 2014).

Medication compliance is a serious problem for patients with schizophrenia, with up to 50 percent of patients failing to comply with recommended (oral) treatments. Importantly, only a fraction of new patients adhere to their initial antipsychotic medication after their first hospitalization, or even collect their initial prescription; the initiation of both FGA and SGA depot antipsychotics during hospitalization significantly reduces rehospitalization rates as compared to oral antipsychotics.

A number of statistics also indicate the limitations of pharmacotherapy for chronic schizophrenia. Even among treatment responders, as many as 40 percent are permanently disabled, and most of the other patients fail to recover. In addition, more than 80 percent of patients are not fully employed and require public support. In large cities, individuals with

schizophrenia comprise 14 to 50 percent of the homeless. The rate of completed suicide is about 10 percent, with suicidal ideation and suicide attempts occurring in 70 percent or more of cases and the mortality rate is increased due to greater accident proneness.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Effects of FGAs on Motor Systems

Animals, administered high doses of a dopamine receptor antagonist, develop a syndrome consisting of immobility, increased muscle tone, and abnormal postures called catalepsy. In addition, these agents decrease spontaneous motor activity in rodents. These motor effects in animals and humans are caused by dopamine receptor blockade in the striatum and the substantia nigra.

In humans, all FGAs produce EPS, in line with their antipsychotic potency, including parkinsonism (i.e., stiffness, akinesia, bradykinesia, tremor, and shuffling gait), dystonia (i.e., abrupt onset, sometimes bizarre muscular spasms affecting mainly the musculature of the head and neck), and akathisia (with objective and subjective restlessness). These effects differ from antipsychotic effects in that they have a more rapid onset, and are potentially amenable to adjunct treatment. In addition, prolonged treatment with dopamine receptor antagonists can lead to the development of late appearing abnormal movements of TD. Both short- and long-term motor effects in patients are discussed in a later section.

Neuroendocrine Effects

Antipsychotic drugs influence the secretion of hormones in the pituitary and elsewhere mainly due to their blockade of dopamine receptors. Prolactin secretion is tonically inhibited by dopamine in the pituitary gland. As a result, dopamine receptor antagonists can increase serum prolactin concentration in the clinical dosage range, in line with their antipsychotic potency. This elevation sometimes produces gynecomastia, galactorrhea, and in men erectile dysfunction. FGAs also suppress levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These changes can lead to amenorrhea and inhibition of orgasms in women. There is also evidence indicating that FGAs can inhibit the release of growth hormone (GH).

Acute Psychotic Episodes in Schizophrenia and Schizoaffective Disorder

Schizophrenia is usually an illness that is characterized by periods of relapse and remission. Acute psychotic episodes are usually identified as periods during which patients demonstrate the emergence or worsening of positive or disorganized symptoms of schizophrenia such as hallucinations, delusions, and disorganized thoughts.

Attention has focused on whether SGAs should be considered the preferred antipsychotics for acute episodes of schizophrenia. This issue was considered by a group of experts who met in 2001 to consider important issues in the pharmacotherapy of schizophrenia. The consensus opinion at that time was that SGAs should be favored over FGAs for first-episode patients or when a history of drug responses was unavailable. The group supported the use of FGAs over SGAs for patients who have responded well to FGAs without experiencing EPS; for patients who have responded better to FGAs than SGAs; and for patients who respond better to depot forms of FGAs.

Between 2005 and 2007, the results of large multicenter clinical trials provided important information about the relative effectiveness and side effects of SGAs and FGAs. These results challenged the view of some that the newer agents were more effective and had fewer adverse effects than their predecessors. The most important studies were an NIMH trial known as CATIE (Clinical Antipsychotic Trial of Intervention Effectiveness), an open trial from the United Kingdom National Health Service known as CUtLASS (Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study), and EUFEST (European First Episode Schizophrenia Trial), another open trial completed in Europe. These trials are important because they were each relatively large for a nonpharmaceutical drug study and they were neither sponsored nor designed by pharmaceutical company sponsors.

The first phase of CATIE compared four SGAs, olanzapine (Zyprexa; 7.5

to 30 mg per day), quetiapine (Seroquel; 200 to 800 mg per day), risperidone (Risperdal; 1.5 to 6.0 mg per day), or ziprasidone (Geodon; 40 to 160 mg per day), to one FGA, perphenazine (8 to 32 mg per day), a midpotency phenothiazine. The subjects were 1,493 patients with schizophrenia who on average were in their 40s and who had been ill for more than 14 years. The primary outcome was the time that patients remained on their assigned drug. The results, reported by Jeffrey Lieberman and coworkers in 2005, demonstrated similar efficacy to the SGAs in terms of time to discontinuation. This finding was surprising to some, but consistent with a number of meta-analyses indicating that differences between first- and second-generation drugs were small if they existed at all. However, patients with TD were excluded from the perphenazine group, which may have given this agent an advantage. Patients treated with perphenazine were more likely to discontinue their medications for EPS. Patients receiving some SGAs, particularly clozapine and olanzapine, experienced weight gain and lipid elevations. Despite modest prolactin elevation, risperidone was the best tolerated antipsychotic. The trial was too brief to compare the risk of TD among the different agents.

CUtLASS randomized 227 patients to either an SGA or an FGA. Prior to randomization, the patient's psychiatrist selected the SGA or FGA that the patient would be assigned to. The results were published in a report by Peter Jones and coworkers. There was no significant difference in scores on the Quality of Life Scale, the primary outcome instrument. Moreover, there were trends suggesting advantages for the FGAs. However, 49 percent of patients in the FGA group received sulpiride (Meresa), an agent that is not available in the United States and differs substantially from other FGAs. Therefore, the results are more meaningful in settings such as the United Kingdom where sulpiride is available. The size of the sample was too small to compare the effectiveness of individual antipsychotics.

EUFEST compared several SGAs (amisulpride, olanzapine, quetiapine, ziprasidone) with a low dose (1 to 4 mg) of the high-potency FGA, haloperidol, in the treatment of first episode schizophrenia. The pragmatic trial found high discontinuation rates (highest with haloperidol), and symptom reductions and rehospitalization rates were virtually the same in all groups.

The results of these trials do not mean that older and newer antipsychotics are equivalent in their side-effect profiles. The differences in EPS liability may have been underestimated in CATIE. First, eliminating patients with evidence of TD may have excluded those who were most vulnerable to discomforting EPS side effects. Moreover, while there were no differences in EPS ratings for parkinsonism and akathisia between perphenazine and the SGAs, it is interesting to note that the higher rate of discontinuations for EPS among the perphenazine-treated patients

suggests that ratings may have not been adequately sensitive. However, most of the studies documenting large differences between FGAs and SGAs may have used what would now be considered excessive doses of haloperidol, a drug with an incidence of EPS, which may have exaggerated the difference between the two types of agents.

The current body evidence does not support the earlier belief that the SGAs are more effective than FGAs. However, the FGAs are more likely to cause EPS and, as noted below, are probably more likely to cause TD. Perhaps FGAs should be prescribed in lower dosages than traditionally has been done. If patients are treated with FGAs, they should be regularly monitored for EPS, particularly drug-induced parkinsonism and akathisia, and they should be assessed for the evidence of TD.

Maintenance Treatment in Schizophrenia and Schizoaffective Disorders

FGAs are effective for decreasing the risk of psychotic relapse in patients who have recovered from a psychotic episode. National and international guidelines indicate that after the acute phase of treatment for a first episode, treatment should continue for at least 1 year, but there is no consensus regarding the total duration of treatment if the patient remains symptomatic. In case of multiple episodes, maintenance treatment should be continued for at least 3 to 5 years, and often indefinitely.

Mania

Dopamine receptor antagonists are effective for reducing excitement and psychotic symptoms in mania. FGAs tend to have a more rapid onset of action than antimanic drugs including lithium (Eskalith), valproic acid (Depakene) (divalproex [Depakote]), and carbamazepine (Tegretol). This observation has led to the widespread practice of combining antipsychotic and antimanic drugs during the first days of treatment of severe excited states, before the antimanic compound has its onset of action. When the antimanic compound has become effective, the dosage of antipsychotic can usually be reduced or the drug can be discontinued. Although there is only limited evidence supporting the use of FGAs for the long-term management of bipolar mood disorder, it is common clinical practice to manage some patients with severe illness with maintenance antipsychotics combined with antimanic agents. Some studies indicate that patients with mood disorders are more vulnerable to developing TD than schizophrenia patients, suggesting the importance of using FGAs as briefly as possible and only when clearly indicated. The advent of the SGAs has preempted these arguments, because some of these agents are approved for acute as well as maintenance treatment of bipolar disorder.

Depression with Psychotic Symptoms

Patients with major depressive disorder may develop psychotic symptoms such as hallucinations or delusions. These patients tend to demonstrate a more robust improvement when an antipsychotic is added to an antidepressant agent. Although most studies have focused on perphenazine, fluphenazine, and haloperidol, there is no evidence that any single dopamine receptor antagonist is more or less effective than any other for this indication, barring side-effect considerations. The added benefits of FGAs are most apparent for those patients who are tormented by severe delusions. When the psychotic symptoms have remitted, the antipsychotic should be withdrawn.

Delusional Disorder

Delusional disorder is characterized mostly by nonbizarre delusions, that is, delusions that are within the realm of possibility for the patient. Moreover, patients rarely hallucinate and their behavior is rarely bizarre. Patients with delusional disorder will often demonstrate substantial improvement when they are treated with a dopamine receptor antagonist.

Borderline Personality Disorder

Borderline personality disorder is characterized by a pervasive pattern of instability that affects mood, interpersonal relationships, and self-image. Some patients with severe forms of this disorder may experience transient psychotic states particularly when they are under stress. These states may be characterized by suspiciousness, ideas of reference, impulsiveness, and aggressiveness.

Low dosages of thiothixene and haloperidol have been found to be effective in some of these patients, although there is no evidence indicating that other FGAs are less effective. Unfortunately, most trials have been relatively brief, and it is unclear how medications affect the overall course of this disorder and how medications interact with psychotherapeutic management that these patients usually require.

Substance-Induced Psychotic Disorder

A number of drugs including amphetamines, cocaine, alcohol, and phencyclidine can cause psychotic symptoms that occur while the patient is intoxicated or during drug withdrawal. These symptoms are usually time limited and remit within hours or days depending on the concentration of drug ingested and the rate elimination of the agent FGAs may reduce these substance induced psychotic symptoms, reducing dangerous behaviors or unusual suffering. Benzodiazepines may be helpful in calming the patient until psychotic symptoms remit. Some authors recommend prescribing benzodiazepines rather than dopamine receptor antagonists for phencyclidine intoxications. In some circumstances it may be helpful to

follow the patient's untreated course in order to differentiate drug-induced syndromes from schizophrenia or bipolar disorder.

FGAs are also useful for patients with hallucinations or delusions that occur with alcoholism, particularly for chronic alcoholic hallucinosis. Benzodiazepines are more appropriate than antipsychotics for uncomplicated alcohol withdrawal, and FGAs can be prescribed as adjunct if withdrawal delirium develops. FGAs should be prescribed carefully since these drugs may increase the likelihood of seizures that occur during alcohol withdrawal.

Impulse Control Disorders

There is a long-standing, but controversial, practice of prescribing dopamine receptor antagonists for individuals with extremely poor impulse control and a propensity for violent behavior. This practice is not supported by controlled clinical trials and may be appropriate only when other measures such as the use of SSRIs, carbamazepine, lithium, or β-blockers has failed. In such instances, nonweight gain–inducing SGAs may be more appropriate than FGAs.

Delirium and Dementia

Low of doses of high-potency FGAs, especially if administered intravenously, can be useful in the treatment of the psychotic symptoms and agitation associated with delirium that may be due to organic conditions. Interactions with the anticholinergic properties of low-potency drugs may exacerbate or prolong toxic deliriums caused by anticholinergic agents.

FGAs can be useful for reducing agitation and psychotic symptoms that are related to dementia, Wernicke syndrome, and Korsakoff syndrome. A number of carefully done double-blind studies have found that FGAs are superior to placebo for treating agitated elderly patients. A review by Janicak found that 66 percent of geriatric patients with "organic" psychosis improved on an antipsychotic compared to 35 percent who improved on a placebo. Low dosages of high-potency FGAs are usually preferable for elderly patients with dementia. Low-potency medications can result in orthostatic hypotension and falling episodes. In addition, the anticholinergic effects of low-potency FGAs can worsen cognitive and memory impairments. The treatment of elderly patients is complicated since many take multiple medications and are vulnerable to drug–drug interactions. Nevertheless, the adverse effects of these drugs should be weighed against the dangers of agitation in elderly patients. Clinicians should be aware that akathisia can present itself as agitation in these patients.

Childhood Schizophrenia

Schizophrenia infrequently has its onset during childhood (before age 17). Termed early onset schizophrenia (EOS) and associated with higher rates of premorbid abnormalities, children with schizophrenia may have symptoms that are similar to those in adults with schizophrenia, with similar thought disorder and perceptual abnormalities but less systematized delusions. Clinical experience indicates that children improve with antipsychotics, and there are a number of controlled trials available to demonstrate this effect. It is particularly important to treat children with the lowest effective dosage of an antipsychotic because of increased vulnerability to side effects. Children may are more prone to developing extrapyramidal symptoms associated with FGAs, but are also more likely to experience weight gain and metabolic abnormalities with SGAs. A brief, 8-week federally funded study comparing risperidone, olanzapine and molindone did not show differences in efficacy to molindone, an FGA, but weight gain was greater with the SGAs. Antipsychotic drugs may impair learning.

Pervasive Developmental Disorder

Patients with pervasive developmental disorders may demonstrate periods of hyperactivity, screaming, and agitation with combativeness. Although there are few controlled studies for this disorder, patients tend to improve with high-potency agents. Since these agents may impair learning, there is concern that they are overprescribed in some settings.

Tourette Syndrome

Tourette syndrome is a neurobehavioral disorder that is associated with motor and vocal tics. Motor tics may involve a single muscle group or several, thus appearing as purposeful movements. Similarly, vocal tics may involve an inarticulate sound or actual words. Often the words are socially inappropriate or even obscene. Milder tics may not require pharmacotherapy. However, when the tics are disabling, an antipsychotic medication can be effective in reducing the severity of both motor and vocal tics. Although haloperidol and pimozide are the most commonly used agents, there is little evidence indicating that other agents are less effective.

Huntington Disease

Huntington disease is a genetically transmitted disease that follows an autosomal dominant type of heritability with 100 percent penetrance. The median age of onset is 35 to 40 years, but childhood onset (high number of CAG repeats) and much later onsets also occur. Once the diagnosis is made, death will follow in 15 to 20 years. Patients who eventually develop Huntington disease may display psychiatric symptoms and cognitive

impairment years before the diagnosis of Huntington disease is made. The most common psychiatric symptoms are cognitive impairment, depression, irritability, apathy, obsessive–compulsive symptoms, and suicidality. These may progress to a psychotic delusional state or sometimes are followed by manic or hypomanic episodes. Some individuals may demonstrate symptoms that closely resemble schizophrenia with delusions and hallucinations (less than 10 percent).

Antipsychotics are believed to be useful during the early stages of the illness to reduce chorea. However, double-blind studies are lacking. They also may be effective in managing irritability, paranoia, hallucinations, violent tendencies, and bizarre behaviors. High-potency agents are usually preferred, but all agents appear to be effective. Clinicians should be aware of acute EPS, particularly in the rigid forms of the disorder. There is no dosing guidance. At present it is believed that the long-term benefit does not merit their use, particularly as TD, other EPS, and akathisia may resemble Huntington disease's later stage symptomatology. Recently, the FDA-approved tetrabenazine (Xenazine, an amine depletor, like reserpine) for the treatment of chorea in Huntington disease. Tetrabenazine should not be used to prevent the occurrence of choreoathetotic symptoms as there is evidence that tetrabenazine has no neuroprotective benefits. However, dysphoria, depression, suicidality, and dysphagia have been noted. No long-term studies are available.

Parkinson Psychosis and Lewy Body Disease

FGAs are contraindicated in these conditions, because they have the potential to worsen parkinsonian syndromes and may lead to precipitous dystonic reactions.

Psychiatric Disorders due to a Medical Condition

Dopamine receptor antagonists are effective for a broad range of medical conditions that result in psychosis. This category includes endocrinopathies and psychoses associated with temporal lobe epilepsy. FGAs are also helpful for patients with psychotic symptoms that can result from steroids.

Other Indications

Antipsychotics are also effective for treating ballismus, an illness characterized by abnormal activity of the axial and proximal musculature. Because of their antiemetic effects, dopamine receptor antagonists are sometimes prescribed for severe emesis associated with chemotherapy. Patients with intractable hiccups are sometimes aided by FGAs. Metoclopramide (Reglan), a dopamine receptor antagonist, is commonly prescribed for patients with gastroesophageal reflux and delayed gastric emptying. For obvious reasons, psychosis associated with Parkinson

disease, cannot be treated with these agents.

PRECAUTIONS AND ADVERSE REACTIONS

Neurological Side Effects

The most serious side effects of dopamine receptor antagonists are neurological and are largely confined to the extrapyramidal motor system (Table 34.17–5). These EPS are, in turn, separated into acute effects that occur in the first days or weeks of treatment and chronic effects that occur after patients have received medications for months or years.

Acute Extrapyramidal Syndromes

All of the dopamine receptor antagonists are associated with EPS. Since EPS, particularly parkinsonism, is believed to be caused by decreased dopamine activity in the basal ganglia, it suggests that this toxic effect is inescapable given that blockade of D_2 receptors is associated with the antipsychotic effect of these agents. Also, this relationship explains why the potency of FGAs for causing EPS is related to their affinity for D_2 receptors in the basal ganglia. Acute EPS, which include dystonia, akathisia, and drug-induced parkinsonism, have their onset relatively soon after the initiation of antipsychotic drug treatment. They remit soon after the drugs are discontinued. In contrast, tardive EPS syndromes occur after months of treatment and commonly persist after medications are discontinued.

Akathisia. Akathisia comes from the Greek word *akathizein,* which means inability to sit still. It is the most common acute manifestation of EPS and often the most distressing. One study found that 41 percent of patients treated with a dopamine antagonist had mild akathisia and an additional 21 percent had moderate to severe akathisia. The most common clinical manifestations consist of shifting the weight from foot to foot, walking on the spot, inability to keep the legs still, feelings of inner restlessness, and the shifting of body positions in a chair. Patients with akathisia may describe a compelling urge to walk or to initiate movement.

In mild cases, patients may experience a subjective feeling of restlessness, but not show increased motor activity. Akathisia may appear in the second or third day of antipsychotic treatment, but more frequently has its onset after 5 days.

Differentiating akathisia from behaviors that are related to the psychotic illness may be difficult. Feelings of restlessness or agitation may result in irritability or anxiety or even aggressive behavior. Psychotic patients with akathisia may appear more hostile or belligerent. This could lead clinicians to incorrectly conclude that the patient requires an increase in medication, which, in turn, could worsen this side effect. Akathisia is also thought to be a correlate of poor antipsychotic drug response. The use of these agents by inexperienced practitioners in nursing homes may lead to behavior deterioration.

Acute Dystonia. Acute dystonias consist of intermittent and sustained spasms of the muscles of the head and the neck, leading to involuntary movements. They can be experienced as the most frightening side effect of FGAs, particularly when patients experience the sudden onset of what may appear to be a form of paralysis.

Ten percent of drug-induced dystonias occur during the first hours of drug treatment, and 90 percent occur within the first 3 days. Common types of dystonia include opisthotonos, a rigid contraction of the back muscles with arching; retrocollis and torticollis of the neck; oculogyric crisis, a spasm in which an eye or both eyes are turned upward; macroglossia and tongue protrusion, which can lead to choking; and laryngeal dystonias. Rarely, dystonias of laryngeal or pharyngeal muscles can lead to sudden death.

Younger patients, particularly young males, are more likely to develop dystonias. They are more common when patients are treated with large dosages of high-potency FGAs. Dystonias almost always respond rapidly to antiparkinsonian medications and can usually be prevented by either pretreatment with antiparkinsonian medications or by limiting the antipsychotic dosage prescribed.

Drug-Induced Parkinsonism. Patients on dopamine receptor antagonists may experience all of the common motor symptoms of idiopathic parkinsonism including rigidity, bradykinesia, shuffling gait, and tremor. These side effects commonly occur during the first 5 to 30 days of treatment and may persist until the dosage is lowered, treatment is initiated, or FGAs are discontinued. Examination will usually reveal a positive glabella tap. The first evidence of drug-induced parkinsonism may be a diminished arm swing or decreased facial expressiveness. Risk factors for drug-induced parkinsonism include increasing age, dosage, a history of parkinsonism, and underlying basal ganglia damage (e.g., vascular insult).

In its milder forms, drug-induced parkinsonism may appear as a decrease in spontaneous gestures, a masked facial expression, apathy, unspontaneous speech, and difficulty in initiating usual activities, so-called akinesia. These symptoms may be difficult to distinguish from the negative or deficit symptoms of schizophrenia. Patients with akinesia may also appear to be depressed. The tendency of patients with akinesia to not cross their legs can be helpful in diagnosing this side effect.

Management of Acute Extrapyramidal Syndromes

Anticholinergic agents are the most effective treatment of EPS. For the acute dystonias, IM or intravenous (IV) diphenhydramine (Benadryl) (50 mg, 25 mg in children) or IM or IV benztropine (Cogentin) (0.5 to 2 mg IM or IV) or other anticholinergics alleviate this uncomfortable and often frightening side effect within minutes after the drug enters the bloodstream. Oral anticholinergic agents are usually prescribed for the management of parkinsonism and often for akathisia. Reducing the dosage of the antipsychotic is often effective, but it is common for patients to experience EPS at the minimum dosage that is needed to manage psychosis. Amantadine (Symmetrel), an antiviral agent that affects dopamine release, is also effective in reducing most EPS. This antiviral agent should not be used for this indication as a first-line agent. Direct dopamine agonists (e.g., bromocriptine [Parlodel]) and indirect dopamine agonists (e.g., levodopa [Dopar]) are not preferred, as they may aggravate psychotic symptoms.

Anticholinergics are frequently, but not always, effective for treating akathisia. β-Blockers, particularly propranolol (Inderal; 10 to 80 mg a day), have been found to be effective for treating akathisia and are preferred by many clinicians. The effectiveness of β-blockers may result from akathisia being a disturbance in the normal balance between dopamine and norepinephrine. Studies have been shown that 5-HT_{2A} antagonists can reduce haloperidol-induced akathisia.

Anticholinergic antiparkinsonian medications should be prescribed with caution in combination with low-potency FGAs and some antidepressants since the combined anticholinergic activity may lead to a number of side effects including hyperthermia and delirium. A sustained tachycardia may also occur. Further caution is warranted in the use of these agents in individuals with glaucoma, ileus, urinary retention, or with prostatic hypertrophy. Because many over-the-counter cold remedies, sedatives, and sleep aids contain anticholinergic agents and antihistamines, patients should be warned about the interaction between these agents and anticholinergic antiparkinsonian drugs.

Some controversy has arisen about the appropriateness of prescribing antiparkinsonian medications prophylactically when FGAs are started.

Reports indicate that 30 to 50 percent of patients receiving long-term treatment do not need anticholinergics. In 1990, the World Health Organization (WHO) published a consensus statement on the use of anticholinergics in patients receiving long-term antipsychotic treatment. The statement argued against the prophylactic use of these agents because of some of their side effects (e.g., the possible worsening of TD, the risk of anticholinergic toxicity, the impairment in memory, and the possible pharmacokinetic interactions with the primary treatment agent). The consensus group concluded that anticholinergics are overprescribed, that they should be given only as needed, and side effects should be treated first by lowering the antipsychotic dosage or by using other agents. However, reports indicate that anticholinergics may be helpful in managing forms of EPS that may not be obvious to the clinician and side effects. That is, milder forms of akathisia may appear as anxiety or irritability and milder forms of akinesia may appear as negative symptoms such as decreased motivation and a lack of affect. In these individuals, long-term anticholinergics may be useful for optimal pharmacotherapy.

There are other circumstances in which prophylactic antiparkinsonian medications may be helpful. Because of the discomfort and anxiety associated with acute dystonias, prophylaxis is prudent when there is a substantial risk of this side effect, for example, when young patients are treated with high-potency FGAs. Some patients and staff may interpret a dystonia as evidence that they are allergic to a particular drug, which may lead to drug refusal and an "allergy" label in the patient chart. Prudent practice may include using prophylactic antiparkinsonian drugs in high-risk patients, with gradual lowering of the dosage of this drug with regular evaluations for obvious and subtle manifestations of EPS over a 2- to 3-month period.

The availability of serotonin–dopamine antagonists provides an important alternative for patients with EPS. Symptoms of acute EPS who cannot be adequately controlled with dosage reduction or an adjunctive medication will probably improve if they are changed to an SGA.

Neuroleptic Malignant Syndrome. NMS is an uncommon but potentially fatal complication of FGAs. Its main clinical features include (1) hyperthermia; (2) severe muscular rigidity; (3) autonomic instability including hyperthermia, tachycardia, increased blood pressure, tachypnea, and diaphoresis; and (4) changing levels of consciousness. It usually presents as muscular rigidity and progresses to elevated temperature, fluctuating consciousness, and unstable vital signs. These symptoms are often associated with elevations in creatine phosphokinase (CPK) and aldolase. Less common are elevations in liver transaminases, leukocytosis, myoglobinemia, and myoglobinuria. Acute renal failure may also occur. Mortality in well-developed cases ranges from 20 to 30 percent and may be

higher when depot forms are used. More expedient early recognition of NMS has led to a substantially decreased mortality rate. Readers may find the Neuroleptic Malignant Syndrome Information Service (NMSIS) (nmsis.org) website helpful for specific questions or for their physician hotline to aid in the diagnosis of NMS.

NMS is more common when high-potency FGAs are prescribed in high doses and when dosage is escalated rapidly. The syndrome is twice as common in men as in women and is more likely to be present in younger patients. Clinicians should be concerned about any patient who demonstrates severe muscular rigidity and a rising body temperature, because early diagnosis and treatment can be life-saving.

Management of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive and symptomatic treatment should begin. This may include treating EPS with antiparkinsonian medications, correcting fluid and electrolyte imbalances, treating fevers, and managing cardiovascular complications such as hyper- or hypotension. Dantrolene (Dantrium) may be effective for treating severe NMS. Treatment begins with IV administration of 0.8 to 2.5 mg/kg every 6 hours, with a maximum of 10 mg/kg daily. When the symptoms subside and the patient can swallow, dantrolene is administered orally in dosages of 100 to 200 mg daily. Bromocriptine can then be added at doses of 20 to 30 mg daily in four divided doses. Amantadine may be helpful if the other agents are not sufficient. The course of treatment is commonly 5 to 10 days unless a long-acting injectable agent has been used.

Although NMS is considered by some to be an extreme form of EPS, its cause and biological risk factors are unknown. Most patients will require antipsychotic medications after they recover from NMS. Low-potency drugs may be preferable for patients who have previously had NMS. However, even clozapine has been demonstrated to be a potential cause of the syndrome. At this time there are no data available to indicate whether clozapine or other serotonin–dopamine antagonists are associated with a lower risk of NMS than SGAs.

CHRONIC EXTRAPYRAMIDAL SYNDROMES

Tardive Dyskinesia

TD is a movement disorder that can follow chronic treatment with antipsychotic medications. Patients with TD may have any or all of a number of abnormal movements, including mouth and tongue movements (lip smacking, sucking, and puckering) as well as facial grimacing. Other movements may include irregular movements of the limbs, particularly choreoathetoid-like movements of the fingers and toes; and slow, writhing movements of the trunk. Although seriously disabling TD is uncommon, a

small proportion may affect walking, breathing, eating, and talking.

The differential diagnosis of TD includes a number of disorders of the basal ganglia (including Huntington disease, Wilson disease, and Sydenham chorea), striatal hypercalcifications, hyperthyroidism, hypoparathyroidism, tardive Tourette disorder, and dyskinesias related to other drugs, such as L-dopa and amphetamines. Abnormal movements were also described in patients with schizophrenia before the introduction of antipsychotic medications.

Although antipsychotic medications will frequently suppress or reduce TD, dose increases are only appropriate when the movements are severe and incapacitating. If patients have their dosages of antipsychotic medication either decreased or discontinued, abnormal movements may worsen temporarily, or appear for the first time and then diminish, termed withdrawal emergent dyskinesias. Antiparkinsonian medications will often worsen TD. However, when patients suffer from combined TD and acute EPS, prescribing antiparkinsonian medication is often unavoidable.

Although the biological mechanism underlying TD is still controversial, it is likely that the disorder is related to an increased sensitivity of dopamine receptors in the basal ganglia. This is supported by the observation that drugs that block dopamine, such as antipsychotic medications, suppress TD, whereas dopamine agonists worsen the disorder. These observations are consistent with findings from preclinical laboratories indicating that blocking dopamine receptors can result in their upward regulation.

Approximately 10 to 20 percent of patients treated with FGAs for more than a year develop TD. In chronically institutionalized patients the prevalence of TD is between 15 and 20 percent, but increases with each year of treatment. Recent prospective studies indicate that approximately 4 to 5 percent of patients who are undergoing antipsychotic drug treatment will develop TD each year, with this risk markedly compounded in elderly individuals whose first treatment with antipsychotics is after age 65. Certain populations are at a greater risk than others for developing TD. Elderly women are particularly vulnerable. Moreover, TD in the elderly is less likely to remit when FGAs are discontinued. Patients with affective disorders may also be at a greater risk of TD when they are treated with dopamine receptor antagonists. Other possible risk factors for TD are the dosage of antipsychotic medications and the duration of treatment. There is also evidence indicating that the presence of acute EPS increases the risk of developing TD later.

TD does not appear to be a progressive disorder for most patients. The disorder seems to develop rather rapidly and to then stabilize, and often improves with time. The consensus of a number of long-term studies is that the severity of TD in most patients improves even if their FGAs are continued. Moreover, this improvement can be clinically meaningful in

some patients. Individuals who are most likely to remit are those with a recent onset and those with an onset prior to age 40. When FGAs are discontinued, a substantial proportion of patients with TD will demonstrate a remission. Reinstatement of antipsychotics does not mean an automatic reoccurrence. This is particularly likely for those with a rather recent onset of TD. Sometimes, this remission will take several months to occur.

Perioral Tremor

Perioral tremor is an uncommon side effect of dopamine receptor antagonists that appears after months or years of drug treatment. The peculiar tremors of the mouth have led to this disorder being called rabbit syndrome.

Management of TD. Patients receiving FGAs for more than 6 months should have regular and systematic evaluations for TD every 6 months. Although instruments such as the Abnormal Involuntary Movement Scale (AIMS) were originally developed as research tools, they also provide a structured system for evaluating and recording abnormal movements.

Once TD is diagnosed, the clinician should evaluate the need for continued antipsychotic treatment. This decision requires consideration of the dangers of both the psychotic illness and TD. It is a decision that, whenever possible, should be made in collaboration with the patient and his or her family. The results of this discussion should be documented in the patient's medical record. For most patients with chronic schizophrenia, the best decision will probably involve continuing the antipsychotic. If this is the case, there is some evidence that treating patients with the lowest effective dosage may minimize the risk of TD. Moreover, prescribing the lowest effective dosage of antipsychotic medication may also decrease the patient's risk of developing the disorder. Patients with severe TD may also be candidates for a trial of clozapine or other SGAs. Most clinical reports indicate that clozapine can suppress TD.

The American Psychiatric Association task force on TD recommended a number of steps for the prevention and management of the disorder, including (1) establishing objective evidence that antipsychotic medications are effective; (2) using the minimum effective dosage for long-term treatment; (3) exercising caution with children, the elderly, and patients with mood disorders; (4) examining patients on a regular basis for evidence of dyskinesia and noting the results of the examination in the medical record; (5) if TD is diagnosed, considering alternatives to antipsychotics, obtaining informed consent, and considering dosage reduction; and (6) if the dyskinesia worsens, considering the discontinuation of the antipsychotic, switching to a different drug, or considering a trial of clozapine.

In addition, there is substantial data indicating that clozapine and other

SGAs are less likely to cause the disorder than other antipsychotic medications, and, therefore, it is promising for the long-term management of patients who have developed TD. In addition, studies using animal models indicate that clozapine does not result in the increased sensitivity of striatal D_2 receptors, which is associated with typical neuroleptics and has been theorized to result in TD.

Table 34.17–6.
Behavioral Side Effects of Dopamine Receptor Antagonists

Dysphoric adverse effects
Secondary negative symptoms
Cognitive impairments

Current evidence suggests that SGAs are associated with a lower risk of TD than the FGAs. This has been proposed since the decreased tendency of these agents to cause acute EPS would predict a lower risk of TD. An accumulation of controlled and uncontrolled studies led a consensus group of experts in the pharmacotherapy of schizophrenia to conclude that SGAs were associated with a lower risk of TD. Because most of these studies were not designed to focus on TD, this remains a controversial issue. A Cochrane review did not find sufficient evidence to conclude that there was an advantage for SGAs, while other meta-analyses concluded that the available evidence supported an advantage. Still, despite high penetration of SGAs into clinical practice, the incidence and prevalence of TD appears relatively unchanged since the 1980s. Since it would be difficult to perform an adequate study of sufficient duration to prove that there is a difference, this issue remains unresolved.

BEHAVIORAL SIDE EFFECTS

FGAs may cause a number of subjective and behavioral effects that are not accompanied by obvious motor effects (Table 34.17–6). Subtle parkinsonian side effects may lead to decreases in emotional expressiveness, apathy, and depression. These symptoms can easily be confused with the negative symptoms of schizophrenia. In addition, subjective akathisia may cause feelings of restlessness that can cause anxiety or even agitation. High dosages of FGAs may also lead to cognitive impairment and attentional deficits. These behavioral symptoms can often be managed by decreasing the antipsychotic dosage.

CARDIOVASCULAR EFFECTS

Cardiac Side Effects

Animal studies have shown that antipsychotic agents may decrease cardiac contractility, disrupt enzyme activity in cardiac cells, decrease tissue levels

and increase circulating levels of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency agents, particularly chlorpromazine and thioridazine, can induce electrocardiogram (ECG) abnormalities, such as prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. QT prolongation is a particular concern since this can lead to a ventricular arrhythmia (known as torsades de pointes), which can progress to ventricular fibrillation and sudden death. There are indications that these arrhythmias have occurred in patients treated with thioridazine and chlorpromazine. A recent study monitored the QT interval in patients treated with a number of SGAs as well as haloperidol and thioridazine. The results led the FDA to conclude that thioridazine and mesoridazine (which is metabolized to thioridazine) were associated with substantial QTc prolongation and a risk of torsades de pointes, with subsequent high risk of sudden death. As a result, these agents are recommended for patients who are refractory to other agents. Clinicians should consider obtaining an ECG before and during treatment with thioridazine and mesoridazine. These agents should not be prescribed for patients with prolonged QTc intervals or those who are receiving other agents that have a tendency to prolong the QTc interval or that decrease the metabolism of such agents. Attempts are under way to identify patients at risk of QTc prolongation through pharmacogenomics. Recently the FDA and Johnson & Johnson have informed health care providers of a revision to the prescribing information for haloperidol, haloperidol decanoate, and haloperidol lactate to include a new cardiovascular subsection highlighting the risk of sudden death, QT prolongation, and torsades de pointes, particularly when given intravenously or at dosages higher than those recommended. Pimozide is also associated with QTc problems (and seizures) when given in doses of 20 mg or higher. Thioridazine (Mellaril) has the greatest risk of QTc prolongation among all currently available antipsychotics.

Elderly patients and those with dementia are at a greater risk of sudden cardiac death, presumably because of slower metabolism (higher blood levels) and concomitant polypharmacy for multiple aging related illnesses and symptoms. This polypharmacy may lead to drug–drug interactions.

OTHER DOPAMINE RECEPTOR ANTAGONISTS EFFECTS

Orthostatic (Postural) Hypotension

Low-potency dopamine receptor antagonists (e.g., chlorpromazine and thioridazine) may cause orthostatic hypotension particularly when these agents are first prescribed. This side effect can be dangerous when it results in fainting or falls. Both elderly patients and individuals with impaired balance should be monitored carefully for orthostatic changes. Since tolerance may develop gradually, patients should be initially treated with a

relatively low dose of these agents (e.g., 25 mg orally twice daily) and the dose should be titrated upward over several days until a target dose is reached. When appropriate, patients should be warned of this side effect and told to sit or stand up slowly, to sit with their feet outside the bed when arising, to wait for as long as a minute, and to sit or lie down if they feel faint, particularly during the first 2 weeks of treatment. Some patients, particularly the elderly, may have persisting orthostatic hypotension and, as a result, and may benefit from a change to a high-potency antipsychotic. Younger patients usually adapt to hypotension and may be asymptomatic, even though their blood pressure is low.

Orthostatic hypotension is more likely when low-potency agents are administered intramuscularly. Thus, clinicians should consider measuring the patient's blood pressure (both lying and standing) before and 1 to 2 hours after the first dose and before subsequent doses during the first days of treatment.

If hypotension does occur, even with higher-potency agents, it can usually be managed by having the patient lie down and instructing the individual to arise very slowly. Some patients may benefit from stockings, volume expansion, or pressor agents. The use of epinephrine paradoxically worsens antipsychotic-induced hypotension through β-stimulation and is, therefore, contraindicated. Pure α-adrenergic agents, such as metaraminol (Aramine), and norepinephrine, are the drugs of choice for this condition.

Sudden Unexplained Death

In spite of reports that dopamine receptor antagonists have been associated with sudden unexplained death, no evidence indicates that the incidence of such deaths changed in psychiatric patients after the introduction of antipsychotics. Similarly, no difference in sudden unexplained death is seen in patients on high-potency versus low-potency drugs. An American Psychiatric Association task force report concluded:

[Al]though a relationship between the use of antipsychotic drugs and sudden death has not been firmly established, it has also not been disproved. From a neurocardiologic perspective, these drugs have the potential for both increasing and decreasing the risk of sudden death. Ultimate outcome is probably determined by a multitude of interacting factors, and the role played by the drug in a given individual is difficult, if not impossible to determine.

Reports of sudden death in patients treated with antipsychotics could be explained by cardiac arrhythmias such as torsades de pointes secondary to QTc prolongation or other causes. For example, seizures, asphyxiation, heat stroke, malignant hyperthermia, and NMS could result in relatively sudden death. Individuals who may be more vulnerable to sudden death include the elderly, physically debilitated individuals, and agitated patients (particularly those who are physically restrained). Increasing evidence of

QTc prolongation caused by antipsychotic agents is surfacing, presumably responsible for torsades de pointes.

Gastrointestinal Tract

The most common GI side effects of dopamine receptor antagonists are related to their peripheral anticholinergic effects. These include dry mouth, constipation, occasional diarrhea, and urinary retention. Nausea and vomiting are less common. Anticholinergic effects are most prevalent with low-potency FGAs such as chlorpromazine or thioridazine and are uncommon with high-potency drugs. These effects can be exacerbated when other anticholinergic drugs such as tricyclic antidepressants are combined with a low-potency antipsychotic.

Patients who experience a severe dry mouth should be advised to rinse their mouth frequently and to chew sugarless gum or candy. Sugar-containing candies may lead to fungal infections in the mouth and increase the risk of dental caries. Constipation can be managed with stool softeners or laxatives. Clinicians should manage severe constipation carefully since it can progress to paralytic ileus, a potentially fatal condition.

Liver

Dopamine receptor antagonists may cause transient abnormalities in liver function tests. These are seldom of serious medical concern. Obstructive or cholestatic jaundice is a serious condition that was commonly associated with chlorpromazine treatment in the past. It is currently very uncommon.

Blood

Dopamine receptor antagonists may be associated with temporary and transient depression of leukopoieses. Mild leukopenia may occur for prolonged periods, although it is more common for the leukocyte to eventually return to normal. Agranulocytosis is rare with dopamine receptor antagonists, occurring in less than 1 in 10,000 cases. Thrombocytopenia and pancytopenia may also occur.

Kidney and Urinary Function

Chlorpromazine has weak diuretic effects. The anticholinergic effects of low-potency drugs may lead to urinary retention.

Skin and Eye Effects

Cutaneous reactions seen during the first weeks of antipsychotic drug treatment include urticarial, maculopapular, petechial, and edematous reactions. These reactions usually improve when drugs are discontinued, and sometimes clear even when drugs are continued. Patients receiving

low-potency FGAs, particularly chlorpromazine, may develop photosensitivity reactions consisting of severe sunburn or rash. Patients should be instructed to avoid direct sunlight or to use sunscreens.

Low-potency FGAs, especially chlorpromazine, are associated with an uncommon discoloration of the skin. Skin areas that are exposed to sunlight, particularly the face and neck develop blue–gray metallic discoloration. This skin reaction is usually associated with long-term treatment with high-drug dosages. Changing to a high-potency drug will usually lead to gradual improvement.

Patients receiving long-term treatment with chlorpromazine may develop granular deposits in the anterior lens and posterior cornea. These deposits, visualized on slit lamp examination, seldom affect the patient's vision. Changing the patient to another drug will usually result in a gradual improvement in the condition.

High doses of thioridazine—above 1,000 mg daily—can result in altered retinal pigmentation (retinitis pigmentosa). This condition can lead to serious visual impairment or blindness. Moreover, this condition may not remit when thioridazine is discontinued. As a result, thioridazine should not be prescribed at doses over 800 mg daily.

Endocrine Effects

Dopamine receptor antagonists elevate circulating levels of prolactin. In women, elevated prolactin can lead to breast enlargement, galactorrhea, and irregular menses, including anovulatory cycles and infertility, menses with abnormal luteal phases, or frank amenorrhea and hypoestrogenemia. The elevation of prolactin associated with FGAs may also suppress testosterone in men. Prolactin elevation occurs as a direct result of D_2 blockade in the tuberoinfundibular dopamine pathway and the pituitary. Since prolactin is under tonic inhibitory control by dopamine, blockade of dopamine receptors will elevate prolactin. Some patients, but not all, develop tolerance to the prolactin-elevating effects of these drugs after several weeks. Dosage reduction may relieve symptoms that are related to prolactin elevation.

Effects on Sexual Function

FGAs can have important effects on sexual functioning in both men and women. In men these agents can result in decreased libido, and ejaculatory and erectile disturbances. Erectile dysfunction has been reported to occur in 23 to 54 percent of men receiving an antipsychotic. This can be an important cause of medication noncompliance in men, and clinicians should inquire about it. Retrograde ejaculation has been reported with some FGAs, particularly thioridazine. In addition, these agents can affect ejaculatory latency and the quantity of ejaculate. Since sexual functioning is

affected by dopamine, serotonergic, and adrenergic systems, it is unclear how sexual dysfunction resulting from FGAs is mediated. Dosage reduction may be helpful in some individuals.

Women who receive dopamine receptor antagonists may experience decreased libido, anorgasmia, and decreased lubrication. Although reports indicate that a number of adjunctive medications have been reported, there is little evidence that any are effective. As with men, reducing the dosage of the antipsychotic may be helpful. Presumably agents with high 5-HT_{2A} blockade should be able to counter these effects.

Pregnancy

Although dopamine receptor antagonists cross the placenta, there is very little evidence to suggest that there is an association between prenatal exposure to an antipsychotic and an increased incidence of congenital malformations. A meta-analysis by Altshuler and colleagues found that the baseline incidence of congenital anomalies is 2 percent and the incidence with antipsychotics is 2.4 percent. This suggests that there is a very small additional risk to the fetus associated with these agents. This meta-analysis found no evidence that high-potency drugs increase the risk to the fetus.

Prenatal exposure to dopamine receptor antagonists in rats may lead to a decreased number of brain dopamine receptors. Other animal studies indicate that prenatal haloperidol exposure may raise cholesterol levels in offspring. It is unclear if these animal findings indicate risks in humans.

In developing a treatment of pregnant patients with schizophrenia, the relatively low risk of congenital abnormalities associated with antipsychotics should be weighed against the dangers of psychotic episodes. Clinicians may attempt to discontinue these medications during the first trimester if this is feasible and should consider carefully whether the risks of prescribing these drugs during the remainder of a patient's pregnancy are justified by the likely benefits. If patients have a history of relapse when FGAs are discontinued, the drugs are relatively safe. If FGAs are prescribed, high-potency compounds are probably safer.

Lactation

Dopamine receptor antagonists are secreted in low concentrations with lactation, suggesting that patients should be advised against breastfeeding during antipsychotic treatment.

Seizure Threshold

Dopamine receptor antagonists tend to lower the seizure threshold. As a result, they are associated with an increased risk of seizures. This risk is usually clinically important in individuals with a prior history of seizures. Low-potency drugs have a greater tendency to lower the seizure threshold.

Therefore, high-potency FGAs may be preferable for seizure-prone individuals.

Temperature Regulation

Some patients become poikilothermic, that is, they become hypothermic in the winter and overheat in the summer, with chlorpromazine and other low-potency agents. This indicates that special precautions should be taken for these patients during exposure to extremes in temperature.

Overdose

Overdoses with FGAs are usually characterized by exaggerations of their usual side effects. Thus, high-potency drugs are associated with severe extrapyramidal reactions, including dystonias and severe rigidity, as well as hypotension and sedation. Lower-potency drugs are more likely to be associated with CNS depression, sedation, anticholinergic effects, and hypotension. The clinical picture may also include agitation, restlessness, convulsions, fever, autonomic reactions such as dry mouth and ileus, ECG changes, and cardiac arrhythmias. In severe overdoses with FGAs the pupils are mydriatic, deep tendon reflexes are decreased and areflexia may occur, tachycardia and hypotension are present, and the EEG shows diffuse slowing and low voltage. This picture may progress to delirium and coma, with respiratory depression and hypotension.

The management of FGA overdose is symptomatic and supportive since overdoses with these agents are seldom lethal. However, the outcome may be unfavorable when these agents are combined with others, particularly CNS depressants such as alcohol, barbiturates, and benzodiazepines. If the overdose is recent, gastric lavage is helpful. If the patient can swallow, activated charcoal is indicated. Emetics should not be administered since their effects may be attenuated by the antipsychotic and because they are associated with a risk of aspiration pneumonia. Aspiration may be a serious risk if the patient develops a dystonic reaction of the head or neck. Forced diuresis and hemodialysis are not effective because FGAs are highly protein bound and lipophilic.

When hypotension occurs, standard measures for managing circulatory shock should be implemented. The hypotension may occur when, during α-receptor blockade, β-receptors are unopposed. Therefore, the clinician should consider norepinephrine or dopamine. Epinephrine is contraindicated.

Because of their quinidine-like effects, overdoses with thioridazine and mesoridazine may lead to heart block and ventricular fibrillation. Since these agents may have long half-lives, patients recovering from substantial overdoses may require cardiac monitoring for several days.

Tolerance, Dependence, and Withdrawal Symptoms

Some tolerance develops to the sedative, the anticholinergic, the hypotensive, and some other effects of FGAs. Tolerance does not develop to the antipsychotic effects. Some patients experience a decrease in EPS over time, suggesting tolerance to the motor side effects of these agents. Dopamine receptor antagonists are not addictive. As a result, most patients can be withdrawn from these agents without difficulty. Rapid withdrawal of low-potency FGAs can lead to symptoms related to their anticholinergic effects. These symptoms are commonly manifestations of "cholinergic rebound" including nausea, vomiting, and diarrhea. Other reported withdrawal symptoms include headache, sweating, restlessness, and insomnia. These symptoms tend to occur within 2 to 3 days of drug withdrawal and may last as long as 2 weeks. Most patients who are withdrawn from high-potency FGAs do not show withdrawal symptoms. These observations suggest that patients who are withdrawn from low-potency agents should be withdrawn gradually over 1 to 2 weeks or longer.

DRUG INTERACTIONS

Clinicians should be aware of several types of interactions (Table 34.17–7). These include drugs that interact with the metabolism of FGAs; age and gender, which may affect metabolic pathways; medical conditions, which may affect drug protein binding, absorption, and fecal or renal clearance; individuals who are dehydrated or malnourished or who have impaired liver and kidney function and are at risk of altered sensitivity and metabolism.

Factors Influencing the Pharmacokinetics of Antipsychotics

Age	Elderly patients may demonstrate reduced clearance rates
Medical condition	Decreased hepatic blood flow can reduce clearance Hepatic disease can decrease clearance
Enzyme inducers	Carbamazepine, phenytoin, ethambutol, barbiturates
Clearance inhibitors	Include selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, cimetidine, β-blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, ciprofloxacin, ketoconazole
Changes in binding protein	Hypoalbuminemia can occur with malnutrition or hepatic failure

Metabolism

FGAs may have clinically important interactions with drugs that are

metabolized by the same cytochrome P450 enzymes. For the conventional antipsychotics, particularly haloperidol, perphenazine, thioridazine, and others, this involves CYP 2D6. Since some SSRIs—particularly fluoxetine and paroxetine—are potent inhibitors of this enzyme, plasma levels of the dopamine antagonist are likely to be increased when an SSRI is added. This may result in an increase in a worsening of EPS. Other drugs that are substrates for 2D6, including heterocyclic antidepressants, β-blockers, and cimetidine (Tagamet), may also increase antipsychotic plasma concentrations.

Other drugs, particularly phenytoin (Dilantin), carbamazepine, and barbiturates, can reduce antipsychotic plasma concentrations by increasing the metabolism of the dopamine antagonist. Reports indicate that carbamazepine can reduce the plasma concentration of haloperidol by 50 percent. Cigarette smoking can also reduce the plasma levels of FGAs. Phenobarbital (Bellatal) has been shown to increase urinary excretion and to decrease the plasma levels of chlorpromazine.

There are other common interactions that should be of concern to clinicians. Antacids, activated charcoal, cimetidine, cholestyramine (Questran), kaolin, and pectin can decrease the absorption of antipsychotic from the gut. Increased absorption may occur with drugs that decrease GI motility such as digoxin (Digitek) and steroids.

Coffee and tea may precipitate FGAs. Although this has been demonstrated in vitro, its clinical significance is unclear. Trifluoperazine and chlorpromazine have been reported to precipitate with lithium citrate. The clinical relevance is unclear.

Antipsychotic drugs antagonize the effects of dopamine agonists or levodopa when these drugs are used to treat parkinsonism. Chlorpromazine, haloperidol, and thiothixene can block the antihypertensive effects of guanethidine (Ismelin). FGAs may also enhance the effects of CNS depressants such as analgesics, anxiolytics, and hypnotics.

FGAs may enhance the effects of oral hypoglycemics. Phenothiazines enhance the effects of oral anticoagulants, although haloperidol may decrease these effects. Cigarette smoking may lower dopamine antagonist blood levels by enzyme induction.

Side-Effect Interactions

Narcotics, captopril (Capoten), trazodone (Desyrel), heterocyclic antidepressants, hydralazine (Apresoline), and minoxidil (Rogaine) may increase hypotension. The combination of a low-potency dopamine antagonist and another sedating drug may lead to excessive sedation. Combining low-potency FGAs with other anticholinergic compounds can lead to peripheral anticholinergic symptoms such as dry mouth and urinary retention and central effects such as cognitive deficits and delirium

(atropine psychosis). Patients should be warned about the use of over-the-counter medications that contain anticholinergics.

Amoxapine (Asendin), fluoxetine, chloroquine (Aralen), and lithium may increase extrapyramidal symptoms. Hydroxyzine (Vistaril) potentiates thioridazine and mesoridazine toxicity. Diuretics and corticosteroids enhance cardiotoxic side effects through hypokalemia, and quinidine enhances the quinidine-like effects of these agents.

LABORATORY INTERFERENCES

Chlorpromazine and perphenazine may give false-positive or false-negative results on pregnancy tests. These drugs may also give inaccurate reports of bilirubin (with reagent test strips) and urobilinogen (with Ehrlich's reagent test). Phenothiazines may produce false-positive results in tests for phenylketonuria. Phenothiazines may also interfere with 17-ketosteroids (with the Haltorff-Koch modification of the Zimmermann reaction) and 17-OH corticosteroids (with the modified Glenn-Nelson technique).

DOSAGE AND ADMINISTRATION

Dopamine receptor antagonists are available in a wide range of formulations and dose sizes (Table 34.17–8).

TREATMENT OF ACUTE PSYCHOSIS

Initiation of Treatment

Treatment with an FGA is usually initiated soon after a diagnosis is made. Whenever possible, patients should receive a psychiatric evaluation including a history and physical examination and a laboratory evaluation that includes complete blood cell count; blood electrolytes; glucose, liver, renal, and thyroid function tests; and other appropriate evaluations (including ECG, pregnancy tests, and screens for alcohol and drugs). The results of this evaluation can be useful in confirming the diagnosis and establish a pretreatment baseline. Under most conditions, it is not necessary to delay treatment while awaiting the results from these tests. Moreover, because there are few contraindications to receiving FGAs, these evaluations can be postponed when patients refuse an evaluation or when treatment is urgent.

Choice of Agent

There is no evidence for differential effectiveness of FGAs, with the exception of clozapine, which is the most effective antipsychotic available. Tolerability may differ between FGAs, influenced by their potency. Low-potency FGAs may not have a higher EPS risk than their high-potency counterparts, but may not be as effective at low doses, and can be quite sedating at high doses. Since thioridazine and mesoridazine have been

associated with prolongation of the QT interval of the ECG, these agents should be reserved for patients who fail to respond to all other antipsychotics. The choice among the other FGAs is based on prior responses, both objective improvement and the patient's subjective response to the drug, available routes of administration and dosage forms, side-effect profiles, and cost.

The introduction of the SGAs (risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, iloperidone, lurasidone, zotepine, iloperidone, amisulpride at this time) has complicated the decision-making process. These agents, in themselves quite heterogeneous, have different side-effect profiles when compared with (especially high potency) FGAs. The most important advantage is that most SGAs cause substantially less EPS than high-potency FGAs. Patients who experience EPS at dosages of FGAs needed to treat their psychosis may or may not experience EPS with an effective dosage of an SGA. This was evaluated in a phase of the CATIE trial in which patients who discontinued perphenazine were subsequently randomized to risperidone, olanzapine, or quetiapine.

There is also evidence from a number of well-designed clinical trials indicating that patients who have only partial responses to an FGA due to lack of efficacy or side effects may improve if changed to an SGA. The evidence is compelling for clozapine, but there are also some reports supportive of other SGAs. However, most of the studies reporting this advantage of newer drugs were carried out in the late 1980s and 1990s when patients had only been exposed to FGAs. More recently, there are clinical reports of patients who had only received SGAs who improved when they were changed to an FGA. Moreover, cost considerations have become more important, especially in the United States. Many of the SGAs are patent protected and are considerably more expensive than SGAs which are usually available as generics. Risks and benefits need to be considered carefully when choosing antipsychotics, especially in light of the different TD risks with FGAs versus SGAs.

An additional advantage of some SGAs is that they are less likely to elevate prolactin. As a result, these agents may be helpful for women who experience galactorrhea and irregular menses with FGAs.

High-potency FGAs, such as haloperidol and fluphenazine, are more commonly prescribed than low-potency compounds. High-potency drugs are more strongly antidopaminergic and thus more likely to cause EPS than the low-potency medications such as chlorpromazine or thioridazine. However, EPS in some individuals may be easier to manage than the sedation and orthostatic hypotension associated with low-potency medications. High-potency medications can more readily be administered intramuscularly, since they seldom cause problems with blood pressure. In addition, because of sedation, orthostatic hypotension, and lethargy, the dosage of low-potency FGAs should be gradually titrated upward, whereas patients on high-potency medications can usually be treated with a therapeutic dosage within a day or two. Midpotency drugs such as loxapine and molindone are options for patients who have difficulty tolerating the side effects of high- or low-potency drugs.

Route of Administration

FGAs can be administered orally, or as short- or long-acting injectables (Table 34.17–9). Once patients are stabilized on a dosage, most patients can be managed with a single daily dose. Short-acting injectables are administered intramuscularly for calming acutely anxious patients or for administering a drug for patients who refuse oral medication. The clinical effects of an IM dose may appear as soon as 15 minutes after the injection. Since the FGAs are most effective when patients have reached a steady state for several days or even weeks, patients should be changed to oral administration as soon as possible.

FGAs can also be administered as long-acting injectables. In the United States, only two FGAs, haloperidol and fluphenazine, are available in long-acting formulations. Long-acting antipsychotics are usually prescribed in stabilized patients during maintenance treatment, after tolerance to the oral formulation has been established. It takes several months to reach steady state and oral supplementation may be necessary during that time. For these reasons, long-acting depot drugs better suited for long-term relapse prevention. They are cost-effective as well, but their TD risk may be higher.

Dosage

Patients demonstrate marked differences in the dosage of a dopamine receptor antagonist that is optimal. For example, some patients will find it difficult to tolerate the side effects from 1 mg of haloperidol, whereas others will tolerate 50 mg without suffering any side effects. Finding the best dosage for a dopamine receptor antagonist is both important and difficult. The importance stems from the tendency of FGAs to cause side effects at their effective dosages. Oftentimes the clinician must weigh the therapeutic advantages of a particular dosage against discomforting or disabling side effects. As many of the FGAs were developed prior to the required rigorous pharmacological methodology of today, a minimally effective or lowest dose has usually not been established. As a result, the most reasonable practice may be to treat a patient with a dosage that is likely to be effective and to wait an adequate amount of time, 4 to 6 weeks at most, to determine if the patient is responding.

Dosage comparison studies provide guidance to clinicians who are making decisions regarding the dosages of FGAs for most patients with schizophrenia or schizoaffective disorder. Doses below 300 mg of chlorpromazine (or 5 mg of fluphenazine or 2 mg of haloperidol) are likely to be too low for many psychotic patients. At the same time doses above 1,000 mg of chlorpromazine (or 10 mg of haloperidol or 20 mg of fluphenazine) are seldom necessary and may lead to substantial side effects and even fewer antipsychotic effects. In other words, most patients will respond to doses between 5 and 20 mg of fluphenazine or 2 and 10 mg of haloperidol or equivalent amounts of other FGAs. Studies that focused on haloperidol suggest that doses below 8 mg are adequate for most patients and that these doses are associated with less EPS than 20 mg doses. First-episode patients should be treated with lower doses, and children and elderly patients should be treated with much lower doses.

The issue of dosing was recently highlighted by the FDA when it added a "Black Box" warning to the use of SGAs in elderly patients with dementia (increased mortality risk). Similar increased mortality risk has been associated with FGAs. Whether this is secondary to higher blood levels and the use of polypharmacy in the elderly, exposing them to an increased risk of QTc prolongation, which may lead to torsades de pointes, arrhythmias, and subsequent death, has not been determined but seems likely. As with any condition that requires multiple medications, practitioners need to be aware of potential drug–drug interactions.

Some patients tolerate very high dosages of FGAs, particularly high-potency drugs, leading some clinicians to raise the prescribed doses in the hope that "more is better." This resulted in a substantial increase in the average dose of antipsychotic prescribed in the United States during the 1970s and 1980s. However, dosage comparison studies failed to support the routine use of higher doses. For example, when groups of patients were assigned to high doses such as over 2,000 mg of chlorpromazine or 40 mg of haloperidol, the commensurate improvements were no greater than in those assigned to more moderate doses. Moreover, these higher doses were associated with more EPS. Current evidence does not support the use of excessive doses of antipsychotic medications.

As-Needed Medication

Prescribing medication as needed is recommended only for the initial phases of treatment. Although FGAs can result in nearly immediate calming for agitated individuals, this response appears to differ from the true antipsychotic effect of these medications, which has a delayed onset. Treating excitement and agitation with the addition of benzodiazepines such as lorazepam (Ativan) has the advantage of calming patients without causing EPS.

Blood Levels and Clinical Activity

Drug response is an interaction between dosage and time on drug and individual pharmacokinetic and dynamic variables. Finding the best dosage of an antipsychotic for an individual patient often requires weeks or months of adjusted treatment. The clinician usually selects a drug dosage that is effective for most patients with the same illness or a dosage that has been effective for the patient at an earlier time. Once a decision is made about the dosage and the plan implemented, the clinician is forced to wait days or weeks until it is clear whether the dosage is effective, toxic, or ineffective. If measuring a patient's plasma or blood level enabled clinicians to select a drug dosage for an individual scientifically, this could decrease the amount of time it takes to arrive at an appropriate dosage.

Early studies of plasma levels indicated that patients who received the same dosage of a drug had large variations in their plasma levels. These findings suggested that studying individual differences in plasma levels would provide information that could be useful to clinicians. However, these early studies were limited to drugs such as chlorpromazine that have complex metabolisms. This creates a problem since some of the antipsychotic activity of these agents could result from metabolites rather than the parent drug. This and other problems including flawed research methods may explain why early studies failed to find a reliable relationship.

A number of more recent studies have focused on other dopamine receptor antagonists and have shown more promising results. Haloperidol has received the most attention for the study of relationships between plasma concentration and clinical response. An advantage of haloperidol for these studies is that its metabolism includes only a single important metabolite, reduced haloperidol, which does not have significant antipsychotic activity. As a result, measuring the plasma level of haloperidol may provide an accurate representation of the effective amount of the drug. At least five research groups, but not all, have reported a therapeutic window relationship between haloperidol levels and clinical response. Table 34.17–10 gives reported plasma concentration ranges for four commonly prescribed dopamine receptor antagonists. Although all of these ranges are supported by one or more high-quality study, the strongest evidence is for haloperidol.

Studies do not support the routine use of plasma level measurement with the exception of clozapine. Still, a level may be helpful in the patient who is receiving what appears to be an adequate drug dosage but who is not responding. A low level may suggest that the patient is not complying or that poor absorption or extensive drug metabolism is interfering with an adequate level. In other cases, the clinician may find it difficult to interpret anxiety or agitation and may consider whether psychotic agitation could come from an inadequate dosage or whether akathisia may result from an excessive dosage. A high or low plasma level could provide valuable information in these circumstances.

Plasma levels should only be obtained after steady-state levels have been reached, preferably during the late phase of the plasma level curve. This usually means after 5 days on a stable oral dose and 10 to 12 hours after the last dose.

Adjunctive Medications

Antipsychotic medications are frequently supplemented by other psychotropic medications. These are aimed at managing comorbid conditions that frequently occur with schizophrenia. There is substantial evidence indicating that depression is underdiagnosed and undertreated, while antidepressants may be effective for treating depressive symptoms in patients with schizophrenia and schizoaffective disorder. Mood stabilizing drugs including lithium, carbamazepine, and valproate (Depakote) are often used for patients with unstable moods. However, carbamazepine may induce the metabolism of antipsychotic agents, lowering plasma concentrations of the parent drug. Benzodiazepines are often effective for treating anxiety as well as agitation and excitement. Newer sleeping agents may assist patients to sleep better with lower risks than older medications.

MAINTENANCE TREATMENT

Duration of Treatment

During the maintenance phase of treatment, the treatment goals include preventing psychotic relapse and supporting treatments aimed at improving the patient's level of functioning and quality of life. Although

FGAs are effective in delaying or preventing relapse, they are also associated with short- and long-term side effects. For most patients with schizophrenia or schizoaffective illness, the analysis of costs and benefits will favor continuing the patient on an antipsychotic, including depot antipsychotics. Patients who have recovered from a single psychotic episode have a substantial risk of relapse if they are withdrawn from medications. As a result, first-episode patients should receive at least 1 year of maintenance therapy if asymptomatic. This is often a substantial point of contention with parents and their families, but the evidence is very clear that relapse will occur in 95 percent of patients eventually. Patients who have had multiple episodes should continue to receive antipsychotic maintenance for at least 2 to 5 years, potentially indefinitely. Present data indicate that there is a 10 percent relapse rate per year, often precipitated by nonadherence with medication, suggesting that continuous, moderate dosage maintenance FGAs afford the best chance of avoiding relapse in psychotic patients. Patients with a history of violent, aggressive behavior or serious suicide attempts should receive antipsychotics indefinitely. If a decision is made to discontinue medications, the dosage of medication should gradually be reduced and the patient should be carefully observed. However, as with many chronic medical diseases, patients do discontinue or take medications irregularly on their own.

Long-Acting Injectable Antipsychotics

There is substantial evidence indicating that long-acting injectable antipsychotics have advantages for patients, including first episode patients during the maintenance stage of treatment. Depot antipsychotics should be considered for each patient, starting early in the course of illness, because they have been shown to reduce relapse more than oral antipsychotics, potentially improving long-term prognosis as well as preventing both psychiatric readmissions and arrests. One advantage is that these agents are a partial solution to the problem of poor medication adherence in schizophrenia. Clinicians can administer a drug without depending on patients to take their pills. In addition, because depot drugs bypass variations in drug absorption and first-pass hepatic and gut metabolism, drug levels may be more consistent. A number of studies have compared the relative effectiveness of long-acting and oral drugs for preventing relapse in stabilized patients. Studies that closely resemble treatment in the community have found that patients are better protected by depot medications. A number of carefully controlled studies and meta-analyses have compared the risk of psychotic relapse in patients who were randomly assigned to receive either oral or depot medication, with depot antipsychotics reducing relapse rates to a greater extent than oral antipsychotics.

Treatment Strategies during Maintenance

Concerns about the side effects of antipsychotics and the risk of TD have led to a number of proposed strategies for safely managing patients on the lowest possible amount of a dopamine antagonist. A number of studies have found that patients can be safely managed with substantially lower dosages of a long-acting depot antipsychotic than are commonly prescribed. These studies found that most patients did well when their doses were reduced by 80 percent from doses that are usually prescribed for acute treatment. Patients treated with lower dosages experienced a small increase in the risk of relapse that was balanced in some studies by reductions in side effects, improved compliance, and suggestions of improved community adjustment.

Other studies have focused on a strategy called *targeted* or *intermittent therapy,* in which an antipsychotic is gradually reduced and eventually discontinued. Patients are monitored carefully for early or prodromal signs of relapse. The antipsychotic is reintroduced when these signs appear. A number of studies, including an NIMH collaborative study, have found that targeted treatment is associated with high relapse rates, indicating that this strategy is not advisable.

▲ 34.18 Lamotrigine

PO W. WANG, M.D., AND TERENCE ARTHUR KETTER, M.D.

HISTORY

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. The observations that folates could produce seizures in animals and some anticonvulsants such as phenytoin (Dilantin) and phenobarbital (Solfoton) could impair folate metabolism led to the hypothesis that folate antagonists could be anticonvulsants. Further research has failed to establish anti-folate as treatments for epilepsy in humans, nor has the exact role of folate in epileptogenesis been established. Lamotrigine also appears to lack clinically significant antifolate effects in humans. Nevertheless, lamotrigine did prove effective in several animal models of epilepsy. Burroughs Wellcome (later Glaxo Wellcome, and currently GlaxoSmithKline) developed lamotrigine as an antiepileptic drug, and it was marketed for the adjunctive treatment of partial seizures in the United States in 1995.

Initial, postmarketing, open, clinical experience suggested efficacy, coupled with generally good tolerability (aside from the risk of rash), in a variety of neurological and psychiatric conditions. Later double-blind, placebo-controlled studies revealed that lamotrigine was useful for some of the neurological and psychiatric conditions suggested in open studies. Lamotrigine demonstrated efficacy and was approved for maintenance treatment of bipolar I disorder in 2003. Lamotrigine also had some efficacy in acute bipolar depression, but the magnitude of the effect was only modest. Limited data also suggested lamotrigine had potential utility in rapid cycling bipolar disorder. However, lamotrigine did *not* receive approval for the treatment of acute bipolar depression nor rapid cycling bipolar disorder. Lamotrigine was *not* effective as a main intervention in acute mania. In summary, lamotrigine emerged as an agent that appears to "stabilize mood from below," such that it may maximally impact the depressive component of bipolar disorders and have some mood stabilizing effects as well.

CHEMISTRY

Lamotrigine, 3,5-diamino-6-(2,3-dichlorophenyl)-*as*-triazine, is a structurally novel phenyltriazine anticonvulsant (Fig. 34.18–1). Three oral lamotrigine preparations are currently available in the United States: 25-, 100-, 150-, and 200-mg immediate- or extended-release tablets and 50-, 250-, and 300-mg extended-release tablets; and 2-, 5-, 25-, 50-, 100-, and 200-mg chewable dispersible tablets. By mid 2016, generic formulations of

all of the above (with the exception of the 2- and 5-mg chewable dispersible tablets) were available.

FIGURE 34.18–1. Molecular structure of lamotrigine.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Lamotrigine has oral bioavailability of about 98 percent and linear kinetics that are not significantly altered by food. Lamotrigine is 55 percent bound to plasma proteins and has a moderate volume of distribution of about 1 L/kg. A large percentage (approximately 85 percent) of lamotrigine is conjugated to yield inactive glucuronide metabolites, with only about 10 percent excreted unchanged in the urine. In monotherapy its half-life is around 28 hours and clearance is about 40 mL per minute. Combined with hepatic enzyme inducers such as carbamazepine (Tegretol, Equetro) or phenytoin (Dilantin), lamotrigine's half-life falls about 50 percent to approximately 14 hours and clearance doubles to approximately 80 mL per minute. Estrogen-containing hormonal contraceptives also induce lamotrigine metabolism. Combined with the enzyme inhibitor valproate (Depakote), lamotrigine's half-life doubles to approximately 56 hours, and clearance falls approximately 50 percent to around 20 mL per minute. Thus, in patients with epilepsy immediate-release lamotrigine is given in two divided doses, unless valproate is present, which may allow single daily dosing. In bipolar disorder patients where stable blood levels are less critical, single daily dosing of immediate-release lamotrigine is used, unless an enzyme inducer (such as carbamazepine [Tegretol]) is present, in which case two divided doses are recommended. An extended-release formulation of lamotrigine has been approved for once daily administration in patients with epilepsy, but not bipolar disorder. Lamotrigine clearance is decreased with hepatic insufficiency, which may necessitate decreased dosage. Clearance is decreased to a lesser extent with renal insufficiency, but

dosage decreases may still be needed.

Pharmacodynamics

Like other anticonvulsants, lamotrigine has multiple biochemical actions, and the relationships between these and clinical effects remain to be established. Lamotrigine blocks voltage-sensitive sodium channels, modulating release of the excitatory amino acids glutamate and aspartate, and may have more limited effects on calcium channels. Lamotrigine also weakly blocks 5-HT_3 serotonergic receptors, has weak effects at σ-opioid receptors, and modestly inhibits serotonin uptake in human platelets and rat brain synaptosomes and noradrenaline and dopamine uptake in rat brain synaptosomes. In contrast, lamotrigine does not bind with high affinity to GABAergic, NMDA, glutamatergic, adrenergic, 5-HT_2 serotonergic, dopaminergic, cholinergic, histaminergic, adenosinergic, or κ-opiate–binding sites, and does not affect dihydropyridine calcium channels. Although lamotrigine inhibits dihydrofolate reductase in vitro, it does not appear to have clinically significant antifolate effects in humans.

Lamotrigine has antiseizure activity in maximal electroshock, pentylenetetrazol, amygdala-kindled, and other animal models of seizures; cerebroprotective actions in several animal models of ischemia; analgesic effects in animal models of neuropathic pain; and activity in the conflict animal model of anxiety.

Lamotrigine blood concentrations are not systematically related to antiseizure effects or efficacy in bipolar disorders. However, as other drugs may alter lamotrigine levels, monitoring of lamotrigine levels may have certain clinical uses.

CLINICAL DRUG STUDIES

Seizure Disorders

Immediate-release lamotrigine monotherapy appeared effective in a multicenter, double-blind controlled study of converting adults with partial seizures taking carbamazepine, phenytoin, phenobarbital, or primidone monotherapy to lamotrigine monotherapy. In a single study with less rigorous methodology, extended-release lamotrigine monotherapy also appeared effective for conversion to monotherapy in adolescents and adults with partial seizures. Adjunctive immediate-release lamotrigine appeared more effective than adjunctive placebo in three multicenter, double-blind, placebo-controlled trials in adults with refractory partial seizures, in one multicenter, double-blind, placebo-controlled trial in pediatric (age 2 to 16 years) partial seizure disorder patients, in one multicenter, double-blind, placebo-controlled study in adult and pediatric (age 3 to 25 years) patients with Lennox–Gastaut syndrome, and in one multicenter, double-blind, placebo-controlled trial in pediatric and adult patients with primary

generalized tonic–clonic seizures. Extended-release adjunctive lamotrigine appeared effective for primary generalized tonic–clonic seizures and partial-onset seizures in adolescents (age ≥13 years) and adults in multicenter, double-blind, randomized, placebo-controlled studies.

Pain Syndromes

Lamotrigine may have analgesic effects, as it was effective in placebo-controlled studies of posttransurethral prostatectomy pain, central poststroke pain, and HIV painful distal sensory polyneuropathy. In the latter study there was a higher rash frequency than seen in epilepsy studies. However, in placebo-controlled studies lamotrigine had inconsistent efficacy in diabetic neuropathy and was ineffective in neuropathic pain and spinal cord injury pain.

Other Neurological Disorders

Although open reports were encouraging, a double-blind, placebo-controlled study failed to show benefit in migraine. Lamotrigine was also ineffective in placebo-controlled studies in amyotrophic lateral sclerosis, Huntington disease, and Parkinson disease.

Bipolar Disorders

In two 18-month multicenter, randomized, double-blind, placebo-controlled trials (one after depressive episodes, one after manic or hypomanic episodes), both lamotrigine and lithium, compared with placebo, delayed time to intervention for any mood episode in bipolar I patients. Lamotrigine mood prophylaxis effect was driven by more robust delay of depression, so lamotrigine was predominantly effective against depressive relapse. Lithium mood prophylaxis was driven by more robust delay of mania, so lithium was predominantly effective against mania. Although an early double-blind, placebo-controlled study suggested lamotrigine monotherapy had some efficacy in the acute treatment of bipolar depression (based on a secondary outcome measure) four subsequent trials were negative. However, a meta-analysis including all five controlled trials suggested a statistically significant but only clinically modest efficacy in acute bipolar depression. One double-blind, placebo-controlled, industry-sponsored study suggested that the olanzapine (Zyprexa) plus fluoxetine (Prozac) combination compared to lamotrigine monotherapy had modestly superior efficacy for acute bipolar depression, but also more adverse effects. A small controlled trial suggested that adjunctive lamotrigine compared to adjunctive risperidone (Risperdal) might have utility in bipolar disorder patients who remained depressed despite taking a mood stabilizer plus an antidepressant. In treatment-resistant (primarily rapid cycling bipolar) mood disorder inpatients, about

50 percent responded to lamotrigine monotherapy, compared to only about 25 percent with gabapentin (Neurontin) monotherapy or placebo. In less treatment-resistant community sample of patients with bipolar disorder and rapid cycling course of illness, lamotrigine monotherapy appeared more effective than placebo bipolar II disorder, but not bipolar I disorder. Adjunctive (added to lithium) lamotrigine compared to adjunctive placebo was superior in acute bipolar depression, and also appeared to provide continued benefit in longer-term treatment. Adding lamotrigine to quetiapine yielded acute and longer-term benefit in patients with quetiapine-resistant bipolar depression. Lamotrigine monotherapy has not been shown efficacious in controlled studies of acute mania. In summary, these controlled studies support the notion that lamotrigine may "stabilize mood from below" in the sense that it may maximally impact the depressive component of bipolar disorders.

Major Depressive Disorders

There are fewer data suggesting lamotrigine efficacy in (unipolar) major depressive disorders. One of two double-blind, placebo-controlled monotherapy trials suggested possible efficacy. In a placebo-controlled study, adjunctive lamotrigine appeared to accelerate the onset but not degree of paroxetine (Paxil) response in depressed (mainly unipolar) patients. In another study, adjunctive lamotrigine compared to placebo yielded similar improvements in depression ratings, but better improvement in global (Clinical Global Impression) ratings, in (mainly unipolar) patients with depression nonresponsive to fluoxetine monotherapy.

Other Psychiatric Disorders

There are only limited data regarding the utility of lamotrigine in other psychiatric disorders. In controlled studies, chronic lamotrigine was no better than placebo in children with autism or adults with depersonalization disorder, and was only numerically but not statistically superior to placebo in adults with PTSD. Single-dose lamotrigine compared to placebo did not significantly attenuate the effects of acute cocaine or naloxone (Narcan)-induced opiate withdrawal. In hospitalized treatment-resistant schizophrenia patients on clozapine (Clozaril), adding lamotrigine compared to placebo reduced general psychopathological and positive (but not negative) symptoms. A subsequent similar trial of adding lamotrigine to conventional and atypical antipsychotics failed to replicate this in the primary (last observation carried forward) analysis, but was positive in a posthoc less rigorous observed case analysis. Interestingly, in a small controlled trial, lamotrigine appeared superior to placebo in the treatment of anger in women with borderline personality disorder. Lamotrigine was

also superior to adding placebo to SSRI treatment for Obsessive-Compulsive Disorder.

Obesity

A small controlled study in patients with obesity suggested that lamotrigine compared to placebo might yield modestly greater decreases in BMI, but not weight.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Lamotrigine has been associated with common benign rashes, uncommon serious rashes, and rare hypersensitivity reactions. Lamotrigine binds to melanin-containing tissues and thus has the potential to accumulate in the eyes. However, to date lamotrigine has not been associated with ocular problems. Lamotrigine inhibits dihydrofolate reductase in vitro but does not appear to have clinically significant antifolate effects in humans.

THERAPEUTIC INDICATIONS

Seizure Disorders

Immediate-release lamotrigine is indicated as adjunctive treatment for adults and children over age 2 years with partial seizures and for pediatric (over age 2 years) and adult patients with Lennox–Gastaut syndrome, and for conversion to monotherapy in adults with partial seizures who are receiving valproate or a single enzyme inducing antiepileptic drug such as carbamazepine, phenytoin, phenobarbital, or primidone in patients ≥16 years old. Extended-release lamotrigine is indicated in adolescents and adults as adjunctive therapy for primary generalized tonic–clonic seizures and partial-onset seizures, as well as for conversion to monotherapy in patients with partial seizures who are taking a single anticonvulsant.

Pain Syndromes

Emerging controlled data suggest lamotrigine may be effective in posttransurethral prostatectomy pain, diabetic neuropathy, central poststroke pain, and HIV painful distal sensory polyneuropathy. However, as of late 2016 lamotrigine lacked FDA approval for such uses.

Bipolar Disorders

Lamotrigine is indicated for the maintenance treatment of bipolar I disorder to delay the time to occurrence of mood episodes in patients treated for acute mood episodes with standard therapy. Limited controlled data suggested lamotrigine might have at least some efficacy in the acute treatment of bipolar depression and in rapid cycling bipolar disorder. In view of such data, lamotrigine was considered to be an important treatment

option for bipolar maintenance treatment and acute bipolar depression in the 2013 revision of the Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders' update of the CANMAT guidelines for the management of patients with bipolar disorder. However, as of late 2016, lamotrigine continued to lack FDA approval for the treatment of acute bipolar depression.

PRECAUTIONS AND ADVERSE REACTIONS

The prescribing information for lamotrigine includes a boxed warning due to the risk of serious rashes (including Stevens–Johnson syndrome) requiring hospitalization and discontinuation of treatment. The incidence of serious rashes was estimated in 1997 to be 1 percent in prospectively monitored pediatric (age less than 16 years) and 0.3 percent in premarketing clinical trials of adult patients. Rare cases of toxic epidermal necrolysis and rash-related death have been reported, but numbers are too few to allow precise estimates of rates. Other than age, possible factors increasing the risk of rash include factors that increase lamotrigine doses too quickly: concurrent administration of valproate (which doubles lamotrigine blood concentrations), exceeding the recommended initial lamotrigine dose, or exceeding the recommended lamotrigine dose escalation. Nearly all life-threatening rashes have occurred between 2 and 8 weeks after lamotrigine initiation, but isolated cases have been reported after prolonged treatment. If patients do not take lamotrigine for 5 days or more (approximately five times the half-life of lamotrigine), the drug needs to be reintroduced according to the gradual initial escalation regimen, as serious rashes can occur with rapidly restarting the medication.

Benign rashes can occur in as many as 10 percent of patients taking lamotrigine, and the prescribing information recommends that lamotrigine be ordinarily discontinued at the first sign of rash, unless the rash is clearly not drug related. Determination of the latter can contribute substantively to important clinical decisions. Thus, any rash in a patient on lamotrigine requires immediate evaluation. Some clinicians report that "dermatology precautions" and initial titration even slower than that described in the prescribing information may decrease the rate of benign rash. Dermatology precautions include not starting lamotrigine within 2 weeks of having a rash, viral syndrome, or vaccination, and during the first 3 months on lamotrigine to avoid ingesting other new medicines or new foods or utilizing new cosmetics, conditioners, deodorants, detergents, or fabric softeners, or stimulating their immune systems by developing sunburn or poison ivy/oak exposure. However, the utility of dermatology precautions was not confirmed in a controlled study. The utility of initial titration even slower than that described in the prescribing information remains to be established in a controlled study.

Any patient developing a rash accompanied by eye, mouth, or bladder

discomfort, fever, or lymphadenopathy should go immediately the emergency room for dermatological assessment; as such symptoms could herald the onset of a serious rash. Rashes with more benign presentations require medical evaluation as soon as possible (and before taking the next dose of lamotrigine) for assessment of the risk of continuing lamotrigine treatment. Rare hypersensitivity reactions with multiorgan failure/dysfunction have been reported, so that patients who develop fever or lymphadenopathy require emergent evaluation. Rare blood dyscrasias have been reported. In view of the potential risk of withdrawal seizures, lamotrigine should be tapered over a period of at least 2 weeks unless safety concerns require a more rapid lamotrigine discontinuation.

With the exception of the risk of rash, lamotrigine is generally well tolerated. Although transient difficulties with headache may be encountered during the initiation phase, other difficulties such as sedation, neurocognitive adverse effects, sexual problems, or weight gain are not typically seen.

The most common lamotrigine adverse effects during dose escalation (added to standard therapy) phase in adult bipolar disorder patients were headache, rash, dizziness, diarrhea, dream abnormality, and pruritus. In the lamotrigine monotherapy phase in maintenance treatment studies in adult bipolar disorder patients, the most common adverse effects were nausea, insomnia, somnolence, back pain, fatigue, rash, and rhinitis, and the adverse effects most commonly leading to discontinuation were rash and manic/hypomanic/mixed mood symptoms.

The most common lamotrigine monotherapy adverse effects in adult epilepsy patients were vomiting, incoordination, dyspepsia, nausea, dizziness, rhinitis, anxiety, insomnia, infection, pain, weight loss, chest pain, and dysmenorrhea. The most common adjunctive lamotrigine adverse effects in adult epilepsy patients were dizziness, ataxia, somnolence, headache, diplopia, blurred vision, nausea, vomiting, and rash. The most common adjunctive lamotrigine adverse effects in pediatric epilepsy patients were infection, vomiting, rash, fever, somnolence, accidental injury, dizziness, diarrhea, abdominal pain, nausea, ataxia, tremor, asthenia, bronchitis, flu syndrome, and diplopia.

In late 2008, the FDA announced a class warning regarding increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders for lamotrigine as well as 10 other anticonvulsants (carbamazepine, felbamate [Felbatol], gabapentin [Neurontin], levetiracetam [Keppra], oxcarbazepine [Trileptal], pregabalin [Lyrica], tiagabine [Gabitril], topiramate [Topamax], valproate, and zonisamide [Zonegran]). In the FDA's analysis, anticonvulsants compared to placebo yielded approximately twice the risk of suicidality (0.43 percent vs. 0.22 percent). The relative risk for suicidality was higher in the patients with epilepsy compared to psychiatric disorders. Acute oral overdoses of

lamotrigine up to 15 g have caused central nervous system and cardiac adverse effects, and some have been fatal.

Lamotrigine was classified as pregnancy category C. Although to date teratogenicity has not been definitively demonstrated in animals or humans, the ability of lamotrigine to inhibit dihydrofolate reductase in vitro has raised concerns regarding the risk of malformations. Limited data suggest the possibility of a modest association between lamotrigine and cleft lip or palate, but this remains to be definitively established. Specifically, the North American Antiepileptic Drug Registry found a higher risk of oral cleft, which was not found in other pregnancy registries. Lamotrigine is excreted in breast milk, considered as "unsafe" for lactation, and thus is contraindicated with breastfeeding.

Lamotrigine is contraindicated in patients with known hypersensitivity to lamotrigine or its ingredients. The lamotrigine prescribing information concludes with the recommended wording for a leaflet to provide to patients.

DRUG INTERACTIONS

Lamotrigine is mainly metabolized by glucuronidation with minimal involvement of oxidative metabolism, and is primarily a target rather than an instigator of drug–drug interactions. Thus, enzyme inducers such as carbamazepine, phenytoin, phenobarbital, primidone (Mysoline), rifampin (Rifadin), and estrogen-containing (but not progesterone) hormonal contraceptives can decrease blood lamotrigine concentrations by 40 to 50 percent. The carbamazepine derivatives, oxcarbazepine (Trileptal) and eslicarbazepine acetate (Aptiom), appear to less robustly decrease lamotrigine levels (so that dosage adjustment of lamotrigine administered with these agents is not recommended). The enzyme inhibitor valproate approximately doubles blood lamotrigine concentrations. Also, sertraline (Zoloft) may increase lamotrigine levels.

Lamotrigine appears to have at most modest effects on the pharmacokinetics of other drugs. For example, lamotrigine can yield modest (25 percent) decreases in valproate levels. Although lamotrigine can exacerbate the neurotoxic effects of carbamazepine, this may be due to a pharmacodynamic interaction, as only equivocal evidence suggests that lamotrigine could increase levels of the epoxide metabolite of carbamazepine. Lamotrigine does not alter lithium pharmacokinetics, which is important, given lamotrigine's utility in bipolar disorders. Lamotrigine does not appear to have clinically significant drug interactions with clozapine, olanzapine, risperidone, or aripiprazole, although a therapeutic drug monitoring database study suggested that lamotrigine might decrease quetiapine concentrations. Lamotrigine does not appear to have clinically significant antifolate effects in humans, although folate may interfere with the benefit of adding lamotrigine to quetiapine.

LABORATORY INTERFERENCES

Lamotrigine has not been associated with interference with laboratory tests.

DOSAGE AND ADMINISTRATION

It is crucial to gradually introduce lamotrigine in order to attenuate the risk of rash.

Because valproate increases and enzyme inducers (such as carbamazepine, phenytoin, phenobarbital, primidone, and rifampin) decrease lamotrigine blood a concentration, the lamotrigine prescribing information includes detailed instructions for gradual lamotrigine introduction (Table 34.18–1).

In maintenance treatment of adults with bipolar I disorder, when given without valproate or enzyme-inducing anticonvulsants, lamotrigine is started at 25 mg per day for weeks 1 and 2, increased to 50 mg per day for weeks 3 and 4, increased to 100 mg per day for week 5, and then increased to the 200 mg per day target dose. Some clinicians use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 25 mg per day for the first 2 weeks, increasing to 50 mg per day for the next 2 weeks, and thereafter increasing by 25 mg per day on a weekly basis.

When added to valproate, lamotrigine is started at 25 mg every *other* day (or 12.5 mg per day) for weeks 1 and 2, increased to 25 mg per day for weeks 3 and 4, increased to 50 mg per day for week 5, and then increased to the 100 mg per day target dose. Some clinicians use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 12.5 mg per day for the first 2 weeks, increasing to 25 mg per day for the next 2 weeks, and thereafter increasing by 12.5 mg per day on a weekly basis.

When added to enzyme-inducing anticonvulsants (such as carbamazepine), lamotrigine is started at 50 mg per day for weeks 1 and 2, increased to 100 mg per day in divided doses for weeks 3 and 4, increased to 200 mg per day in divided doses for week 5, increased to 300 mg per day in divided doses for week 6, and then increased to 400 mg per day in divided doses to the target dose. Some clinicians use even more gradual initial titration in efforts to further decrease the risk of rash, starting with 50 mg per day for the first 2 weeks, increasing to 100 mg per day for the next 2 weeks, and thereafter increasing by 50 mg per day on a weekly basis.

Based on controlled trials, the prescribing information describes target doses of 100 mg per day (with valproate), 400 mg per day (with enzyme inducers), and 200 mg per day (with neither), and does not recommend higher doses. However, some clinicians choose to gradually further increase doses as necessary and tolerated to about twice these figures. Although a therapeutic plasma concentration range has not been

established for lamotrigine for bipolar disorder or for epilepsy, if patients attain high doses (e.g., 400 mg per day without inducers), it may be helpful to assess a 12-hour trough lamotrigine level to determine if there is a pharmacokinetic cause to apparent nonresponse. To date, lamotrigine use in bipolar disorders has been limited in patients under age 16 years, due to the lack of an FDA indication and the potential for increased risk of rash.

Gradual Introduction of Lamotrigine in Adults with Bipolar Disorders

	Lamotrigine with Valproate (mg/day)	Lamotrigine with Enzyme Inducers (mg/day)	Lamotrigine with neither Valproate nor Enzyme Inducers (mg/day)
Weeks 1 and 2 dose	12.5	50	25
Weeks 3 and 4 dose	25	100	50
Week 5 dose	50	200	100
Week 6 dose	100	300	200
Week 7 and thereafter (FDA target dose)	100	400	200
Typical final dose range	100–200	400–800	200–400

Adapted from FDA, U.S. Food and Drug Administration.

In adults and adolescents over age 12 years with epilepsy taking valproate, adjunctive lamotrigine should start at 25 mg every *other* day for weeks 1 and 2, be increased to 25 mg per day for weeks 3 and 4, and increased every 1 to 2 weeks thereafter by 25 to 50 mg per day to 100 to 200 mg per day in one or two divided doses. In adults and adolescents over age 12 years with epilepsy on enzyme-inducing anticonvulsants (in the absence of valproate) adjunctive lamotrigine should start at 50 mg per day for weeks 1 and 2, be increased to 100 mg per day for weeks 3 and 4, and increased every 1 to 2 weeks thereafter by 100 mg per day to 300 to 500 mg per day in two divided doses. The prescribing information describes weight-proportional gradual adjunctive lamotrigine introduction in pediatric (age 2 to 12 years) epilepsy patients, with maintenance doses of 1 to 5 mg/kg per day (maximum 200 mg per day in one or two divided doses) in patients taking valproate, and 5 to 15 mg/kg per day (maximum 400 mg per day in two divided doses) in patients on enzyme-inducing anticonvulsants in the absence of valproate. The recommended lamotrigine monotherapy maintenance dose in epilepsy is 500 mg per day in divided doses.

Although estrogen-containing hormonal contraceptives can decrease blood lamotrigine concentrations by as much as 50 percent, no adjustment

to the lamotrigine dose escalation guidelines is recommended solely based on the use of estrogen-containing hormonal contraceptives. However, the maintenance dose of lamotrigine may need to be increased as much as twofold.

When estrogen-containing hormonal contraceptives are added to lamotrigine, lamotrigine doses may be increased by 50 to 100 mg per day on a weekly basis. If adverse effects related to increased lamotrigine concentrations such as dizziness, ataxia, and diplopia consistently occur during the week of inactive hormonal preparation (i.e., the "pill-free" week), it may be necessary to decrease the overall lamotrigine maintenance dosage, but dose adjustments confined to the "pill-free" week are not recommended.

When estrogen-containing hormonal contraceptives are discontinued, lamotrigine doses may be decreased by 25 percent the first week and by another 25 percent the second week.

In patients with hepatic impairment, lamotrigine doses may need to be decreased by 25 percent in patients with moderate to severe hepatic impairment without ascites, and 50 percent in patients with severe hepatic impairment with ascites. Lamotrigine dosage may need to be decreased in patients with impaired renal function.

If patients do not take lamotrigine for 5 days or more (i.e., for five times the half-life of lamotrigine or more), the drug needs to be reintroduced according to the gradual initial escalation regimen as serious rashes can occur with rapidly restarting the medication.

In conditions other than seizure disorders, lamotrigine is commonly given in one or two divided doses. Single daily dosing is convenient, enhances adherence, and in contrast to epilepsy, breakthrough symptoms due to the resulting lower trough blood concentrations are less of a concern. In some (nonepilepsy) applications, clinicians may administer most or all of the dosage in the morning or at bedtime if individual patients find the drug activating or sedating, respectively.

▲ 34.19 Lithium

CHARLES L. BOWDEN, M.D.

HISTORY

John Cade, a psychiatrist working in a psychiatric hospital in Australia, was the first person to treat a patient with lithium and observe its unequivocal beneficial effects in previously chronically manic patients. The clinical observations and associated publications by Cade were followed shortly thereafter by systematic clinical trials in Europe led by Schou, Baastrup, and Gershon in Australia which in turn led shortly thereafter to its approval by regulatory agencies for the treatment of mania. In the United States, the FDA approved its labeling for the treatment of mania in 1970. The only

other approval indication came in 1974 for maintenance therapy in bipolar patients with a history of mania. The story of its development therefore forms a major part of the foundation for the psychopharmacology revolution experienced in the last half of the 20th century.

CHEMISTRY

Lithium follows hydrogen and helium on the periodic table, making it the third simplest element (atomic number 3, atomic weight 6.94) and the first solid element. Whether lithium is essential to normal human growth and development has not been established. There is no evidence of a lithium deficiency state in humans. Experimentally produced lithium deficiency in goats and rats led to reduced fertility, retarded development, and reduced longevity.

PHARMACOLOGICAL ACTIONS

Lithium is rapidly and completely absorbed, with serum concentrations peaking in 1 to 1.5 hours with standard preparations and in 4 to 4.5 hours with slow and controlled-release forms. Unlike most psychiatric drugs, lithium has no clinically important protein-binding properties and no metabolites. It is excreted by the kidneys, although small amounts are also lost in sweat and feces. A substantial amount of filtered lithium is reabsorbed (primarily in the proximal tubules), so that renal lithium clearance is about one-fifth of creatinine clearance. The elimination half-life of lithium is about 18 to 24 hours, although it is considerably longer in the elderly because of the age-related decrease in GFR. Consequently, elderly patients generally need lower than usual doses to reach a given serum concentration and require a longer period to reach steady state. For example, thyroid and renal concentrations exceed serum level, whereas red blood cell, spinal fluid, and brain concentrations do not. Lithium enters and leaves the CNS slowly, which may explain why acute overdoses with relatively high blood levels are sometimes well tolerated and why clinical manifestations of chronic intoxications often persist long after blood levels have decreased substantially.

Pharmacodynamics

Li, acting via glycogen synthase kinase-3 (GSK3β) inhibition, induces the transcription and expression of neurotrophic and neuroprotective proteins linked to the activation of cell survival signaling cascades. Li has also been shown to have other important cell signaling effects related to abnormalities previously linked to bipolar disorder (BD) pathogenesis, several of which have been studied in lymphoblastoid cell lines: Li appears to decrease intracellular inositol levels, subsequently preventing the formation of inositol phosphate 3 (IP3) and diacylglycerol, thus blocking

transmembrane signaling. Particularly, through inositol depletion, lithium reduces IP3-mediated calcium release from endoplasmic reticulum. Li may decrease the phosphorylation of cAMP-response-binding-protein (CREB), which interferes with expression of the genes regulated by this transcription factor, and modulates protein kinase A and protein kinase C pathways. Additional evidence linking Li effects to signaling pathways comes from genome wide association studies reporting BD-associated SNPs in the diacylglycerol kinase gene, which encodes a key protein in the lithium-sensitive phosphatidyl inositol pathway.

Lithium has neurotropic and neuroprotective activity that may extend its spectrum of use beyond bipolar disorder. For example, it has been shown to increase levels of Bcl-2 in various areas of rat brain, to induce expression of BDNF, to stimulate neurogenesis in adult rat hippocampus, and to increase total brain gray matter volume (by 3 percent) in eight of ten bipolar patients after 4 weeks of treatment.

Design and Interpretation of Clinical Drug Studies

The history of lithium encompasses most of the history of clinical drug trials in psychiatry. The research that established its antimanic activity to the satisfaction of the FDA was meager compared to today's large, double-blind, placebo-controlled parallel design, multicenter trials. Although the response rate consistently favored lithium over placebo, early studies were small, short term, and of crossover design. Subsequently, however, large double-blind, placebo-controlled, parallel designs using lithium as an active comparator to divalproex (Depakote and Depakote ER), aripiprazole (Abilify), and quetiapine (Seroquel) more firmly established its effectiveness as an antimanic agent.

In the 1960s, open studies by experienced clinicians comparing episode frequency before and during lithium treatment did much to establish the long-term effectiveness of the drug. Citing lack of scientific rigor in the design of these studies, critics cast doubt on the conclusion and stimulated conduct of double-blind, placebo-controlled studies (both prospective and discontinuation designs) that convincingly established the long-term prophylactic efficacy of lithium in bipolar disorder. Recent maintenance studies of lithium and other drugs have used time to recurrence as the main outcome measure. Less examined, and often not at all, is whether treatment reduces episode frequency, duration, and severity.

In the first randomized, placebo-controlled, 12-month maintenance study of lithium and divalproex designed not to enrich either active drug the two drugs were non-significantly superior to placebo on time to recurrence of any mood episode. Median time to 50 percent survival without a mood episode was 40 weeks for divalproex, 24 weeks for lithium, and 28 weeks for placebo. Another study showed that the combination of lithium and valproate was superior to valproate and trended to be superior

to lithium alone.

THERAPEUTIC INDICATIONS

Bipolar Disorders

Mania. Lithium is an established, first line, antimanic drug with effectiveness greater than placebo. Currently it is but one of many FDA-approved drugs for treating manic episodes, but it continues to be listed among the first choices. Its onset of action is relatively slow, with clinical improvement usually occurring over the first 1 to 3 weeks of treatment. Although a small open study suggested that oral lithium loading might produce improvement in a few days, this approach has yet to be substantiated. Instead, the concomitant use of a benzodiazepine or an antipsychotic drug is often necessary during the initial phase of treatment. Among antipsychotics, second generation drugs have largely replaced conventional antipsychotic drugs in terms of preference and recognition of somewhat more benign adverse effects. Since disturbed sleep may ignite or fuel a manic episode, early treatment of insomnia may be useful.

As with other treatments, not all patients with acute mania respond equally well to lithium. Response rates of around 80 percent in initial research trials contrast with findings of less success when patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organic brain disorders are included. FDA-approved antimanic alternatives include divalproex, carbamazepine (Tegretol, Equetro), aripiprazole, olanzapine (Zyprexa), quetiapine, risperidone (Risperdal), and ziprasidone (Geodon). Combining lithium with any one of these is a common practice, supported by good evidence for divalproex, quetiapine, and olanzapine. In contrast, carbamazepine combined with olanzapine reduces olanzapine drug levels to therapeutically inadequate, therefore should be avoided. Whether another medication would be preferable to lithium as the initial treatment of mania, or at least for some subtypes of mania, has not been established in well-designed studies. Divalproex has become a preferred initial treatment of mixed mania.

Starting with the 1994, three arm study comparing valproate, lithium and placebo, most studies meet current methodological standards as comprehensively reviewed and published by the World Federation of Societies of Biological Psychiatry, whose expert guideline task force is international in membership. Lithium and valproate were significantly more effective than placebo in the 1994 study. Lithium was superior to placebo in studies for which quetiapine, topiramate, and aripiprazole were the investigational drugs. A meta-analysis of six randomized controlled trials including lithium reported a medium effect size for improvement with lithium of 0.4, which corresponded to a number needed to treat to see one patient significantly better than with placebo of 6 patients. In

secondary analyses of the studies that included valproate and quetiapine, lithium, valproate, and quetiapine were similarly superior to placebo, and to one another, in the subgroup of patients with psychotic symptoms.

Depression. Lithium is not approved by the FDA for the acute treatment of bipolar depressive episodes (in contrast to quetiapine, lurasidone and olanzapine/fluoxetine combination [Symbyax]). A large 2008 study did not show a difference versus placebo for low-dose lithium. A generally recommended approach for patients with bipolar depression who are already taking lithium is to increase dosage to the maximum tolerated level up to 1 mM/L either alone or, for more severe depressions, in combination with an antidepressant. This recommendation is mainly based on clinical experience. This strategy is to some extent contradicted by a study of Severus et al. indicating that high lithium serum levels are associated with an increased rate of relapse into bipolar depression. Treating bipolar depression with a conventional antidepressant alone does not protect against mania and may even precipitate mania or rapid cycling. Consequently, the presence of a mood stabilizer is a necessity in all but occasional low-risk bipolar II patients.

Antidepressants with some evidence for lower rates of worsening of manic symptoms include quetiapine, bupropion (Wellbutrin), lurasidone (Latuda), and MAOIs. Based on the results of one study (van der Loos et al., 2009), lamotrigine might be initiated if lithium optimization is unsuccessful.

If breakthrough depression occurs during lithium maintenance, lithium-induced hypothyroidism, poor compliance, and substance abuse must be considered as possible causes or contributors (Fig. 34.19–1). In the figure, derived from the two lithium, lamotrigine, placebo maintenance studies, note that patients taking lithium who required thyroid supplementation during the 18-month studies had essentially twice as high thyroid-stimulating hormone (TSH) levels as did lithium treated patients who did not require thyroid supplementation, whereas TSH was not elevated in subjects taking lamotrigine or placebo. If there is a margin of safety and tolerability, increasing the serum lithium level may be sufficient to bring the episode under control. Even if results of thyroid function testing are within normal limits, supplementing with thyroid hormone may be of value. There is some evidence that bipolar depression responds more slowly to antidepressant treatment in patients who have a lower free thyroxine index (FTI) and higher TSH levels, even within the range of normal. If optimizing the lithium blood level is ineffective, an antidepressant, a second mood stabilizer, or an atypical antipsychotic could be added. At present, many clinicians will follow the more conventional route and add an antidepressant, but others argue that two mood stabilizers might be preferable. One small short-term study found no

difference in response rates to bupropion or topiramate (Topamax) and no manic switches with either. In another small short-term study of patients on lithium or divalproex who had breakthrough depression, no difference in efficacy was found when either paroxetine (Paxil) or the alternate mood stabilizer (lithium or divalproex) was added. However, a placebo-controlled study of bipolar depression found no benefit from an antidepressant added to a mood stabilizer in maintaining 8 consecutive weeks of euthymia. All in all, the role that antidepressants should or should not play in the treatment of bipolar disorder remains a matter of debate. Since lamotrigine is beneficial for the prevention of recurrent bipolar depression with long-term treatment, combining it with lithium has appeal.

FIGURE 34.19–1. Elevated TSH levels from lithium predispose to development of depression. (From Frye M, Yatham L, Ketter TA, Goldberg J, Suppes T, Calabrese JR, et al. Depressive relapse during lithium treatment associated with increased serum thyroid-stimulating hormone: results from two placebo-controlled bipolar I maintenance studies. *Acta Psychiat Scan*. 2009;120(1):10–13.)

ECT is an effective treatment of bipolar depression, although it tends to be used only after medications have failed. Concern has been expressed that the presence of lithium during ECT increases the risk and severity of cognitive dysfunction, but whether this is true remains controversial.

Maintenance Therapy

Effective maintenance treatment, that is, reducing subsyndromal depression, mania and mixed states, along with preventing or minimizing the impact of new episodes, is the principal pathway to functional well-

being and productive lives for persons with bipolar disorders and all kinds of complications and disablement. Bipolar disorder ranks worldwide among the top ten of the most disabling disorders in adults.

Most long-term studies have used Kaplan–Meier (KM) survival analyses based on time to intervention. However, some studies use as study end point "any reason of failure" (inefficacy as indicated by new mood episodes or need for additional treatments or hospitalization, adverse events, withdrawal of consent, lost to follow up) as primary outcome. Some use discontinuation for emerging new mood episodes defined either by symptomatic *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria or/and by clinical rating scale thresholds. An intrinsic problem with KM survival analytic techniques is that they measure the occurrence of a predefined event, for example, intervention, discontinuation, only at two time points: baseline (absence of the event) and end point (occurrence of event). This might be suitable if between these time points there is only one state possible, for example, "absolutely healthy." This is not the case in bipolar disorder, where subsyndromal fluctuations of mood, impairing functionality and quality of life, are more the rule than exception. In addition, other clinically valuable information, for example, tolerability and impact of medication on physical health will not be fully captured. Another issue in survival analysis is that the risk of censoring should be independent of the risk of the event in question, which most often is not the case. One reason why survival analysis has gained popularity in pivotal trials is that it is more sensitive for measuring differences than the more traditional counting of failures.

Based on trials that used both CGI-BP and YMRS and MADRS, it appears that a cut-off score of <5 on the MADRS and <4 on the YMRS approximates a CGI-BP of 1 for a meaningful definition of remitted status. Clinical meaningful remission is rarely achieved in published controlled trials; for example, in the lamotrigine/lithium long-term studies, remission as entry criterion for the double-blind phase was defined as having a CGI-S score of ≤3 for 4 consecutive weeks.

Most recent maintenance studies have used enriched discontinuation designs wherein the patient's acute symptoms had to respond to the given medication during open label treatment to the point of syndromal remission before randomization, resulting in sample "enrichment" for responders to the open label treatments allowed.

Long-term treatment with lithium is an effective way to reduce the frequency, severity and duration of manic, and, to a lesser degree, depressive episodes in patients with bipolar disorder. More recent placebo-controlled studies compared lithium to divalproex, lamotrigine, or olanzapine and utilized survival analysis to evaluate outcomes. In the two lamotrigine studies, lithium was superior to placebo in time to intervention for a mood episode and in time to a manic episode, but it did not differ

significantly in time to a depressive episode. The olanzapine study, which lacked a placebo control, found no significant overall difference, while prevention of manic relapse favored olanzapine. Treatment response to lithium monotherapy is usually less than complete, and supplemental pharmacotherapies are often necessary either intermittently or continuously. Nonetheless, there is good evidence that long-term lithium therapy reduces mortality rates. In general, bipolar disorder carries with it an increased risk of premature death, particularly but not entirely from suicide. Most studies comparing mortality rates in lithium-treated patients to the general population, to patients following discontinuation of lithium, and to patients treated with alternative prophylactic medications support the mortality-lowering and suicide-reducing effect of lithium. A meta-analysis of 31 studies of major affective disorders found a fivefold reduction in suicides and attempted suicides during lithium treatment compared to those not taking the drug. In a retrospective study, patients at high risk of suicidal behavior were grouped into excellent, moderate, and poor lithium responders. No further suicide attempts occurred in 93.3 percent, 82.7 percent, and 48.8 percent, respectively, suggesting that the antisuicidal effect of lithium extends beyond its mood stabilizing property (the beneficial role of psychosocial support could also be a contributing factor).

Work by Grof and others to predict a favorable response to lithium maintenance found that the diagnosis of a mood disorder, an episodic course with euthymic intervals, and the absence of rapid cycling were the main predictors. Additional factors that have been associated with inadequate response to lithium in maintenance use include many prior episodes, poor interepisode functioning, comorbid substance abuse, and comorbid personality disorder. It is likely that such limitations apply to other mood stabilizing agents, not just lithium. A double-blind study without enrichment favoring either active agent found no significant difference in rates of all cause termination in the lithium–valproate–placebo trial. However, secondary outcome indices, for example, termination for depression or for intolerable adverse effects favored valproate assigned patients (Fig. 34.19–2). The decision to apply long-term treatment with lithium should not be a difficult one in most circumstances. One would expect some unequivocal benefit in an initial acute illness state, most likely mania or hypomania. Unless the patient is tolerating the lithium well, it makes no sense to plan on its long-term use. However, there is sufficient evidence that in aggregate samples higher range dosage of lithium provides mostly worse tolerability, not greater healthiness. Licht et al. conducted an unusual study of 5 years duration commencing with randomization to either lithium or lamotrigine, but subsequently allowing any psychiatrist determined adjunctive medication use. As shown in Figure 34.19–3, a large majority of patients assigned to either drug required additional medication, generally within the first 2 years of follow-up

treatment.

FIGURE 34.19–2. Months to a mood episode or early discontinuation in relationship to serum levels of valproate or lithium compared with placebo. (From Keck PE, Bowden CL, Meinhold JM, et al. Relationship between serum valproate and lithium levels and efficacy and tolerability in bipolar maintenance therapy. *Int J Psych Clin Pract*. 2005;9(4):271–277.)

The process of considering use of adjunctive or cotherapy for overall mood stabilization or for some bipolar illness aspect that is not within the spectrum of benefit of lithium is generally straightforward. If the symptom is outside the spectrum of benefit of lithium (or for that matter any other agent with which maintenance treatment is commenced), add what is. Even when exactly when to begin long-term lithium treatment has not been fully resolved, although most recommendations suggest earlier rather than later —possibly after only one episode of mania and certainly after two. Soft evidence suggests that episodes beget episodes (perhaps a form of kindling or behavioral sensitization), with each episode increasing the likelihood of the next and possibly shortening the interval to the next; hence, the recent trend toward earlier initiation of maintenance therapy. Obviously, many individual factors must be taken into consideration, including the abruptness, severity, and frequency of episodes; the presence of risk factors; and attitudes toward medication.

A patient had two manic episodes in 2 years, one resolving spontaneously and one with ECT, followed by 18 euthymic years without any treatment before the next episode occurred. Had she been treated with lithium after the second manic episode, the subsequent 18 years would have been considered a testimonial to the therapeutic effectiveness of lithium.

FIGURE 34.19–3. Early termination in 1 year randomized maintenance study. (From Bowden CL, Calabrese JR, McElroy SL, et al. A randomized, placebo-controlled 12-month trial of divalproex and lithium in treatment of outpatients with bipolar I disorder. Divalproex Maintenance Study Group. *Arch Gen Psychiatry*. 2000;57(5):481–489.)

The maximum benefits of lithium maintenance may not be immediate; with continued treatment, relapses sometimes become less severe and less frequent. Some patients appear to develop a tolerance to lithium after several years of successful use; this tolerance can sometimes be overcome by the addition of divalproex, carbamazepine, lamotrigine, or an atypical antipsychotic. Similarly, patients who are only partial responders to lithium maintenance may benefit from the addition of one of these drugs. Just as breakthrough depression may respond to a temporary increase in serum lithium concentration, so too may breakthrough mania. At such times, however, supplementing lithium with an antipsychotic drug or one targeted for sleep, anxiety control, or another discrete symptom will be desirable. A series of studies from 1983 through the present have consistently reported that serum lithium concentrations of 0.5 to 0.8 mmol/L range are at least as efficacious in maintenance as higher concentrations, and are much better tolerated and adhered to than higher ones. In a 6-month study (Fig. 34.19–4) among those randomized to lithium, only serum levels below 0.5 were associated with shorter time in study. No systematic, randomized study provides support for higher serum concentrations. Given the consistent evidence that lithium is frequently poorly tolerated, with consequent low adherence, attention to this strategy, particularly early in maintenance phase treatment should be routine.

The year 2000 valproate–lithium–placebo three arm study provides substantial clinically useful evidence consequent to its design, which per protocol allowed addition of a selective serotonin reuptake inhibitor (SSRI) if clinically significant depression occurred. The study shows the

proportion of patients who developed depression to have been highest with placebo and significantly less if receiving divalproex. The results or the study regarding profiles of maintenance benefit indicate that significantly fewer patients receiving valproate plus SSRI had early termination for any mood episode and for depression than occurred with placebo. Lithium resulted in nonsignificantly lower rates than placebo. This has been the only maintenance study to date that allowed treatment of breakthrough depression with an antidepressant (either sertraline or paroxetine). Valproate or lithium plus an SSRI provided longer time in study without discontinuation for depression than did placebo plus an SSRI. Fewer patients discontinued prematurely among valproate plus SSRI-treated patients than among placebo-treated patients. These results indirectly suggest that the combination of valproate and an SSRI in acute bipolar depression is more effective than SSRI monotherapy.

Both lithium and lamotrigine were associated with longer time in remitted status and lower time in subsyndromal mania. Lithium, but not lamotrigine, was also associated with significantly less time in syndromal and subsyndromal mania. Neither lithium nor lamotrigine reduced time

depressed compared with placebo. Neither lithium nor lamotrigine differed from placebo on the proportion of days with subsyndromal or syndromal depression or mixed states, which constituted almost one quarter of time in study for both drugs. This analysis by Multiple Outcome Assessment of Treatment methodology discussed earlier in this chapter also can be combined by latent class analysis with indices of tolerability to provide an aggregate measure of benefit and tolerability.

Lithium was associated with both significant benefit in time manic and worse tolerability compared to placebo. In summary, lamotrigine was associated with limited therapeutic benefit but not harm; lithium with both benefit and harm; and placebo with neither benefit nor harm.

The multi-state outcome analysis of treatments (MOAT) analytic approach that the authors developed to overcome limitations of survival analyses yielded the results displayed in Table 34.19–1. Both lithium and lamotrigine provided a significantly longer term in remitted status than did placebo. Lithium also provided significantly less time in a manic state. When syndromal and subsyndromal manic times were combined, the lithium superiority versus placebo continued. Lithium randomized patients did not differ for any facet of depressive time or time in a mixed state. Lamotrigine trended to less time manic but not after taking into account multiple comparisons.

Long-term treatment does not cure bipolar disorder. Following discontinuation of successful lithium therapy, the risk of recurrence increases substantially. For example, one review of discontinuation studies of patients with bipolar disorder found the risk of recurrence to be 23 times higher subsequent to discontinuing. In addition, rapid discontinuation of lithium appears to be associated with a rebound phenomenon characterized by increased risk of early recurrence, especially mania. One study found in the first year after stopping lithium that rapid discontinuation (1 to 14 days) was associated with twice as many manic and depressive episodes as was gradual discontinuation (15 to 30 days).

Major Depressive Disorder

Although episodes of major depressive disorder may respond to lithium alone, traditional antidepressant medications are considerably more effective and are the preferred treatment. The major value of lithium in major depressive disorder patients with acute depression is as an augmenting agent when antidepressants alone have been ineffective. Approximately half of patients respond when lithium is added to a wide variety of antidepressant drugs. Favorable responses have been described in both psychotic and nonpsychotic depression. Benefit has been reported with most all antidepressants, but evidence is most convincing with tricyclics. Although alternative explanations may apply in some situations (spontaneous remission), few negative studies for this use have been published. Experts disagree, however, as to where lithium augmentation should fall in the hierarchy of treatment resistance strategies.

Schou stated: "Doubt about the efficacy of prophylactic lithium treatment in unipolar illness seems almost exclusively a U.S. phenomenon." Indeed, most studies have found lithium to be more effective than placebo and as effective as antidepressant drugs for the long-term management of major depressive disorder. This may reflect the conceptualization that highly recurrent major depressive disorder and bipolar disorder are both components of manic-depressive illness. Lithium has not, however, demonstrated clear advantages over conventional antidepressant drugs, and since long-term treatment is most likely to involve the drug that ended the acute episode (an antidepressant), lithium maintenance for major depressive disorder is likely to be reserved for antidepressant treatment failures. However, a recent meta-analysis found support for antisuicidal effects of lithium in patients with recurrent major depressive disorder.

Schizoaffective Disorder and Schizophrenia

In general, the less affective and the more schizophrenic an illness is, the less likely it is to respond to lithium. The same cannot be said of an episode because the acute manifestations of mania and schizophrenia may be indistinguishable. Although not approved by the FDA for schizoaffective disorder or the revisions in DSM-5, lithium is generally accepted to be of value for treating this condition, especially in combination with antipsychotic drugs, and especially if the affective component is prominent.

Antipsychotic drugs remain the treatment of choice for schizophrenia, although patient response is often limited. The addition of lithium to an antipsychotic agent remains a treatment strategy for antipsychotic-resistant schizophrenia, although the availability of atypical antipsychotics such as clozapine (Clozaril), aripiprazole, olanzapine, quetiapine, paliperidone (Invega), risperidone, lurasidone, iloperidone, and ziprasidone makes this less necessary. In addition, while several small early studies suggested benefit from lithium augmentation of antipsychotic medication, more recent data have been less convincing. Should there be a coexisting mood disorder, lithium might play a more prominent role. A 2007 Cochrane Collaboration review concluded: "there is no evidence that lithium on its own is effective for people with schizophrenia or schizoaffective disorder. There is some evidence for the effectiveness of lithium as an adjunctive treatment to antipsychotic drugs, but this result was inconclusive."

Aggression

Lithium appears to have antiaggressive effects independent of its mood-stabilizing action. Several controlled studies have found reduced aggression in subjects recruited from prison populations. Behavioral dyscontrol and self-mutilation in intellectual disabled patients have also been successfully treated with lithium. However, lithium has not been used extensively to treat aggression associated with head trauma or epilepsy, and the results have been mixed. No work has been done to evaluate the effect of lithium in those patients defined by DSM-IV-TR as having intermittent explosive disorder. Aggressive outbursts are also treated with medications such as anticonvulsants, β-adrenergic receptor antagonists, benzodiazepines, buspirone (BuSpar), antipsychotics, and antidepressants. The relative ranking of lithium among those other drugs must be determined on an individual basis.

Alcohol-Use Disorders

Lithium's potential for treating alcohol dependence and abuse is based in part on the close association between mood disorders and alcohol-use disorders and in part on animal research that found reduced alcohol intake

in rodents receiving lithium. Efforts to establish lithium as a useful treatment of alcoholism have been largely unsuccessful. A large (N = 457), multicenter, double-blind, placebo-controlled 1-year study found that lithium did not alter the course of alcoholism in depressed or nondepressed alcoholics. Although not all research reports have been that discouraging, lithium is unlikely to play a major role in the treatment of alcoholism. Some patients may be exceptions, but clinicians have found no way to identify them prospectively.

Other Indications

The philosophy that "lithium is good for what ails you" led to its use in a wide variety of psychiatric (Table 34.19–2) and nonpsychiatric medical conditions (Table 34.19–3). In general, reports in these areas involve small numbers of patients in studies often lacking in scientific rigor. In such situations, both positive and negative outcomes may be inconclusive and even misleading. For example, two double-blind, placebo-controlled trials found lithium ineffective in OCD. Only 16 patients were involved and the treatment duration of 2 weeks was insufficient to evaluate the drug adequately. Two more recent well-designed, placebo-controlled studies of adequate duration found lithium to be ineffective in augmenting conventional drugs for OCD in treatment-resistant patients.

Efforts to establish lithium as a useful treatment of personality disorders have been largely unsuccessful. When favorable outcomes do occur, it is likely that a comorbid mood disorder has responded followed by indirect improvement in "personality." Following FDA approval of lithium for mania lithium was used with some success to treat inpatients with emotionally unstable character disorder. The findings were never replicated or extended to outpatients, and the disorder failed to appear in subsequent editions of DSM. Today, the substantial mood component of borderline personality disorder suggests a potential role for lithium in its treatment, but controlled trials have not been conducted.

[a]All the uses listed here are experimental and do not have FDA-approved labeling. There are conflicting reports about many of these uses, some have negative findings in controlled studies, and a few involve reports of possible adverse effects.

There has been considerable interest in lithium's potential for treating a wide variety of nonpsychiatric medical conditions (Table 34.19–3). The granulocyte-stimulating effect of the drug has been used to increase white blood cell count in conditions such as Felty syndrome, idiopathic neutropenia, chemotherapy-induced granulocytopenia, clozapine-induced neutropenia, and immunosuppressant drug-induced leukopenias. Lithium's antithyroid effects have been utilized investigationally to treat hyperthyroidism. Neurologists have found lithium useful as a treatment of chronic and episodic cluster headaches. The observation that lithium inhibits replication of DNA viruses such as human herpes virus 1 and 2 led to successful double-blind, placebo-controlled trials of both topical and oral preparations to treat herpes genitalis. Seborrheic dermatitis has also been shown in controlled studies to respond to a lithium-containing ointment that is marketed outside the United States.

PRECAUTIONS

Children and Adolescents

At least one-third of patients with bipolar I disorder have their first episode before the age of 20. This percentage may be even higher if age of onset is dated from first appearance of symptoms rather than from first well-defined manic or depressive episode or first hospitalization. Although adolescent onset is common, prepubertal onset is far less so, but its prevalence may be underestimated because of atypical presentations and reluctance to make the diagnosis in children.

In general, diagnostic criteria for bipolar disorder in the young are the same as in adults; however, atypical presentations (especially in younger children) and comorbidity, especially with attention-deficit/hyperactivity disorder (ADHD) and conduct disorder, may make recognition more difficult. Furthermore, extrapolating adult diagnostic criteria to youth may be problematic. Lack of a well-established longitudinal history further complicates the diagnosis and may contribute to miscategorizing first-episode psychotic mania as schizophrenia.

Another diagnostic issue is whether a first episode of depression will follow a bipolar or unipolar course. The following factors may be predictive of a bipolar outcome and influence early treatment with lithium or another mood stabilizer: (1) rapid onset with psychosis and psychomotor retardation, (2) family history of bipolar disorder, and (3) antidepressant-induced hypomania. One study followed 72 children diagnosed with prepubertal major depressive disorder into early adulthood and found that a third had bipolar I disorder and an additional 15 percent had bipolar II disorder or hypomania.

Despite a substantial literature on the use of lithium to treat children and adolescents with conditions such as bipolar disorder, aggression, and behavioral problems associated with intellectual disability and developmental disorders, there remains a paucity of well-controlled studies. Nevertheless, lithium is FDA-approved for treating mania in adolescents (ages 12 years and older). The range of serum lithium concentrations in adolescents is similar to that in adults (although its elimination half-life may be shorter) and the likelihood of responding appears the same. The adverse effect profile of lithium is also the same across age groups, although in view of adolescent concern about body image, adverse events such as acne and weight gain may be poorly tolerated. Also, nontoxic cognitive dulling induced by therapeutic amounts of lithium may adversely impact academic performance.

Whether to begin long-term lithium therapy is an even more difficult decision when treating young patients than when treating adults. The markedly disruptive effects of episodes in youth and the highly recurrent nature of bipolar disorder must be balanced against the potentially

deleterious adverse effects of long-term lithium.

Elderly Patients

In the absence of organicity and substance abuse, most evidence suggests that advanced age alone does not compromise responsiveness to lithium. However, the use of lithium in the elderly is complicated by factors that include associated medical illnesses and medications, special diets, age-related reduction in GFR, and increased sensitivity to adverse effects.

Whether the elderly as a group respond to lower serum concentrations of lithium than do their younger counterparts is not known. Increased sensitivity to adverse effects and toxicity confine many elderly patients to relatively low doses and blood concentrations, which may prevent them from benefiting from the drug. However, this is not always the case, as demonstrated in the case study presented here.

After 10 hospitalizations for mania and depression beginning at age 20, a 53-year-old woman was stabilized on 1,500 mg a day of lithium carbonate and remained on this regimen for the next 15 years with serum concentrations ranging between 0.6 and 0.75 mEq/L. It was only at age 68 that an increase in serum concentration led to a dose reduction to 1,200 mg daily, and at age 70 to a further reduction to 900 mg per day.

In general, elderly patients should be started on lower-than-usual dosages, with dosage changes occurring less frequently than in younger patients. The elimination half-life of lithium increases with age, and the time required to reach steady state is much longer in the elderly. If lithium is stopped, serum levels fall more slowly and the resolution of adverse effects and toxicity may be prolonged.

A 60-year-old man was treated with 900 mg a day of lithium carbonate. The dosage was continued unchanged for 10 years, despite laboratory evidence of gradually increasing serum lithium and creatinine concentrations. Even as clinical symptoms of toxicity were being reported, a thiazide diuretic was added to treat hypertension. Three weeks later, the patient was hospitalized with a serum lithium concentration of 4.2 mEq/L and marked neurological impairment that never fully resolved.

With appropriate monitoring and compliant patients, lithium use in the elderly can be both safe and effective. Unfortunately, there continues to be a lack of randomized controlled studies of any medication in elderly bipolar patients. Whether the putative neuroprotective effects of lithium would have practical utility in this population remains an open question.

Pregnant Patients

Lithium is in FDA pregnancy category D, which includes drugs for which there is evidence of human fetal risk, but whose potential benefits may outweigh the risk in some pregnant women. Almost three decades ago, the

International Register of Lithium Babies reported an 11 percent incidence of major malformations in babies exposed to lithium during the first trimester, with a disproportionate representation of cardiovascular malformations, especially Ebstein anomaly of the tricuspid valve. These data exaggerate risk because of the greater likelihood of reporting abnormal outcomes, failing to control for other medications and medical conditions, and failing to control for the effect of the illness itself on outcome. Recent studies have not confirmed such a high incidence of malformations, although there still appears to be an increased risk of cardiovascular anomalies in humans (the incidence of Ebstein anomaly is between 1 and 2 per 1,000 which is 10 to 20 times greater than in the general population). Although the teratogenic risk of lithium is still greater than that found in the general population, it is lower than that posed by carbamazepine and valproate. Fetal echocardiography is advised to screen for cardiovascular malformations in women exposed to lithium during the first trimester of pregnancy.

Physiological changes accompanying pregnancy alter maternal lithium metabolism. The GFR increases 30 to 50 percent over baseline, and plasma volume increases by 50 percent. The filtered sodium load increases markedly (5,000 to 10,000 mEq daily), as does the renal tubular reabsorption of sodium, resulting in cumulative sodium retention of close to 1,000 mEq. Complications of pregnancy, such as hypertension and edema and their treatments, may further complicate lithium therapy. Polyhydramnios in a pregnant woman taking lithium was ascribed to lithium-induced fetal polyuria. Following delivery, the altered renal physiology of pregnancy returns rapidly to normal. These factors and their variability among individual patients dictate that lithium use during pregnancy be closely supervised. Fetal and maternal blood concentrations are similar, so women should receive minimum effective dosages. To reduce the risk of toxicity in the newborn, clinicians should markedly reduce or possibly temporarily discontinue the drug shortly before delivery. In view of evidence that abrupt or rapid discontinuation of lithium is associated with a high risk of relapse (which may be increased further postpartum), dosage reduction rather than discontinuation may be more appropriate as delivery approaches. Full prophylactic concentrations should be re-established following delivery because this is a time of great vulnerability to recurrence. Because lithium appears in breast milk and in the blood of breast-fed babies, the American Academy of Pediatrics Committee on Drugs recommends that lithium be used with caution in nursing mothers. One study of 10 breastfeeding infants found serum levels to average 0.16 mEq/L (range 0.05 to 0.23). The merits of breastfeeding are considerable, and actual reports of infant lithium toxicity are limited to one or two cases; consequently, in some situations the benefits outweigh the risks.

Medically Ill Patients

The patient with bipolar disorder and coexisting medical illnesses presents a particularly difficult therapeutic challenge. Untreated or inadequately treated mania or depression can adversely affect a medical illness (e.g., mania and congestive heart failure) and decrease treatment adherence, and lithium may be more difficult or impossible to use in the presence of a medical illness (e.g., severe renal disease). Because medically ill patients are receiving other medications, their risk of adverse drug interactions is increased. Consequently, treatment of such patients requires close collaboration between psychiatric and nonpsychiatric physicians.

Such was not the case when an elderly woman became lethargic, confused, and anorectic after her internist prescribed a thiazide diuretic and her serum lithium level increased from 0.5 to 1.1 mEq/L.

Rapid Cycling Patients

Rapid cycling has been defined as four or more mood disorder episodes per year. Up to 20 percent of bipolar disorder patients experience rapid cycling, the majority of whom are women. Risk factors associated with rapid cycling include a depression-hypomania course, antidepressant drug therapy, thyroid abnormalities, and neurological disease. Rapid cycling appears not be a persisting condition in the majority of patients who experience it. Ultra-rapid cyclers have 24- to 48-hour cycles, and the concept of ultra-ultra rapid cycling has been introduced to describe patients with frequent mood shifts within a 24-hour period. Given increasing evidence that mood lability (also named affective lability) is increasingly recognized as a major symptom in bipolar disorder, some of what was previously labeled as rapid cycling subtype may be more fundamentally be viewed as a prominent bipolar symptom. Affective lability is closely associated with mixed states.

Overall, rapid-cycling appears to be more difficult to treat with most drugs and regimens, including lithium. Prior treatment with antidepressant drugs may predict a poorer response to lithium. Also, because antidepressants may induce rapid cycling, simply discontinuing the antidepressant agent may be sufficient to slow the cycling pattern (although at times worsening depression is the result). Correcting thyroid abnormalities is an important aspect of treating rapid cycling. Preliminary research suggests that hypermetabolic doses of thyroid hormone may be useful in dealing with treatment-resistant rapid cycling. If lithium alone is ineffective, treatment considerations include some anticonvulsants (particularly lamotrigine and valproate) either alone or combined with lithium. Atypical antipsychotics are additional considerations, as is ECT in more extreme cases.

ADVERSE REACTIONS

Adverse effects are to be expected during lithium therapy. Fewer than 20 percent of patients have no adverse effects, but only about 30 percent have more than minor complaints. The incidence of severe adverse effects may be underestimated, however, because patients who do not tolerate therapy may not be available for comment. Recognizing and minimizing adverse effects can do much to enhance compliance with lithium treatment (Table 34.19–4).

Neurological Reactions

Patients often complain of dysphoria, lack of spontaneity, slow reaction times, intellectual inefficiency, and impairment of memory. These complaints are a common cause of poor adherence. In assessing such complaints, psychiatrists should also assess for other contributors to cognitive impairment including depression, lithium-induced hypothyroidism or hypercalcemia, other illnesses, and other drugs. Single daily dosing at bedtime or a dosage reduction may be helpful, although switching to another mood stabilizer may be necessary.

After 19 years of successful lithium maintenance, a 37-year-old woman was switched to carbamazepine because of polyuria and proteinuria. Only in retrospect did she and her physician become aware of the cognitive dulling and impaired concentration that had been present during her many years on lithium.

Table 34.19–4.
Adverse Effects of Lithium

Neurological
Generally benign, nontoxic: Dysphoria, lack of spontaneity, slowed reaction time, memory difficulties
Tremor: Postural, occasional extrapyramidal
Toxic: Course tremor, dysarthria, ataxia, neuromuscular irritability, seizures, coma, death
Miscellaneous: Peripheral neuropathy, benign intracranial hypertension, myasthenia gravis-like syndrome, reduced creativity, lowered seizure threshold
Endocrine
Thyroid: Goiter, hypothyroidism, exophthalmos, hyperthyroidism (rare)
Parathyroid: Hyperparathyroidism, adenoma
Cardiovascular
Benign T-wave changes, sinus node dysfunction
Renal
Concentrating defect, morphological changes, polyuria (nephrogenic diabetes insipidus), reduced glomerular filtration rate, nephrotic syndrome, renal tubular acidosis
Dermatological
Acne, hair loss, psoriasis, rash
Gastrointestinal
Appetite loss, nausea, vomiting, diarrhea
Miscellaneous
Altered carbohydrate metabolism, weight gain, fluid retention

Tremor. The most common tremor associated with lithium use is a

postural tremor in the arms and hands. Because the tremor worsens during activities requiring fine motor control, it can be socially embarrassing and occupationally troublesome. Tremor sometimes improves spontaneously, but if it does not, benefit may be obtained from dose reduction, use of a slow-release lithium preparation, elimination of dietary caffeine, discontinuation of other medications, and treatment of associated anxiety. Medications useful in treating lithium tremor include β-adrenergic receptor antagonists such as propranolol (Inderal), as well as primidone (Mysoline), and possibly gabapentin (Neurontin). With long-term lithium therapy, a tremor with parkinsonian characteristics may occur occasionally. Worsening of tremor at any time during the course of lithium therapy may be an indication of impending lithium intoxication, and severe tremor should be considered due to lithium toxicity until proven otherwise.

Other Nontoxic Effects. Lithium use has been associated rarely with peripheral neuropathy, downbeat nystagmus, benign intracranial hypertension (pseudotumor cerebri), a myasthenia gravis–like syndrome, and lowering of the seizure threshold.

Lithium Intoxication

Lithium intoxication is primarily a neurotoxicity that can lead to death or permanent neurological damage (often cerebellar as characterized by dysarthric speech, tremor, and wide-based gait). Cardiovascular, gastrointestinal, and renal manifestations may also be present. Factors contributory to toxicity include, of course, excessive intake (accidental or deliberate), reduced excretion, kidney disease, low-sodium diet, drug interaction, reduced volume of distribution (dehydration), and individual sensitivity (e.g., elderly and the neurologically impaired). Absorption can sometimes be delayed substantially if slow-release preparations are involved.

A woman with lithium-induced nephrogenic diabetes insipidus was hospitalized for the treatment of a manic episode. Antipsychotic drug-induced sedation impaired her ability to replace fluids, and she quickly became lithium toxic and hypernatremic. Permanent cerebellar damage was the result.

Severe toxicity has been described in patients whose serum concentrations were within the so-called therapeutic range of .5 to 1.5 mEq/L. Some patients have tolerated high concentrations after deliberate overdoses without noticeable clinical consequences. In general, however, the higher the concentration and the longer the exposure, the more serious the intoxication. Early clinical manifestations include gastrointestinal upset, dysarthria, ataxia, and coarse tremor. Ominous findings include impaired consciousness, neuromuscular irritability

(fasciculations, myoclonus), seizures, and coma. Some cases of lithium intoxication have resembled Creutzfeldt–Jakob disease, nonconvulsive status epilepticus, or neuroleptic malignant syndrome.

Treatment is directed at the removal of lithium from the body. In mild cases, nothing more may be necessary than discontinuation of intake. After an overdose, gastric lavage is indicated and may have to be repeated. Although activated charcoal is not helpful following an acute lithium overdose, preliminary reports using polystyrene sulfonate (Kayexalate), a cation exchange resin, or whole bowel irrigation with polyethylene glycol solution (GoLYTELY) have been promising. In the presence of normal renal function, mild-to-moderate toxicity often responds to correcting dehydration and maintaining proper fluid and electrolyte balance. Whether forced diuresis provides additional benefit is open to debate. Hemodialysis is the treatment of choice for severe intoxication (peritoneal dialysis is considerably less efficient). Lithium is removed effectively by dialysis because it is water soluble, unbound to plasma protein, without metabolites, and of simple chemical structure (an element). Redistribution of lithium from tissues to blood after dialysis usually results in a rebound increase in its blood level; this may necessitate further dialysis. Hemodialfiltration has also been used, sometimes in conjunction with hemodialysis to minimize the likelihood of rebound. Because of lithium's tissue-toxic effects and gradual removal from the CNS, clinical improvement may lag several days behind the lowering of serum concentration.

Thyroid Impairment

Transient mild abnormalities in thyroid function testing are common early in the course of lithium treatment but are usually of little or no clinical consequence. Some patients, however, develop goiter or clinical hypothyroidism sometime during the course of treatment. Women, persons with pre-existing thyroid dysfunction, and those from iodine deficient areas are more than usually susceptible. Among lithium's many effects on thyroid function is its impedance of release of hormone from the gland. The goiter that has been described in about 5 percent of patients taking lithium (prevalence figures vary widely) is rarely of cosmetic or obstructive importance; however, an ultrasound study found thyroid gland enlargement in 44 percent of patients on lithium for 1 to 5 years in contrast to 16 percent of a control group.

Clinical hypothyroidism prevalence is directly associated with serum lithium concentration. Once diagnosed, it can be treated with supplemental levothyroxine (Synthroid) at a dosage that returns the TSH concentration to normal. Subclinical hypothyroidism (elevated TSH, normal free thyroxine) is considerably more common than clinical hypothyroidism. As noted earlier, elevated TSH predisposes to clinical depression. Substantial

elevations of TSH are likely to progress to clinical hypothyroidism and thus should be treated with exogenous thyroid hormone. Of course, the principal action warranted is reduction in lithium dosage. Subclinical hypothyroidism may contribute to reduced response to the treatment of bipolar depression.

Exophthalmos and hyperthyroidism have been described during lithium therapy. Whether these occur more often than in the general population is not established. Baseline assessment (including antithyroid antibody titers) and periodic monitoring of thyroid function (usually measurement of serum TSH concentration with or without triiodothyronine [T_3] and thyroxine [T_4] concentrations) is an integral part of lithium therapy. Whether it is done routinely (every 6 or 12 months) or only when clinical suspicion is aroused is a matter of preference.

Cardiovascular Reactions

Benign, reversible T-wave changes on the ECG are common during lithium therapy and are of no clinical consequence. Varying degrees of heart block and bradyarrhythmias as well as QTc prolongation and T-wave inversion have been reported during lithium intoxication and occasionally during its therapeutic use. Electrophysiological studies show that lithium can impair sinus node function, and sinus dysrhythmias, sometimes associated with syncopal episodes, have been reported in a few patients. Lithium does not have clinically important effects on blood pressure.

Although lithium is not contraindicated in the presence of cardiovascular disease, it should be used with caution. A pacemaker may be necessary if lithium is used in patients with clinically significant sinus node disease. Low-salt diets, certain diuretics, ACE inhibitors, angiotensin II receptor type-1 antagonists, fluid-electrolyte imbalances, and impaired renal function all predispose to lithium toxicity.

Renal Reactions

Lithium has complex effects on renal function. In the majority of patients, lithium impairs renal concentrating ability, which in itself is of no clinical importance. Nephrogenic diabetes insipidus occurs in around a third of patients taking lithium. The concentrating defect is not always reversible after lithium discontinuation, suggesting that both functional and structural changes have occurred in the distal tubules and collecting ducts.

Polyuria is the most clinically troublesome renal effect of lithium. Figures vary considerably, but a 24-hour urine volume of more than 3 L (1 to 2 L is normal) has been reported in as many as 35 percent of patients taking lithium. Lithium increases urine volume primarily by inhibiting the effect of antidiuretic hormone on the kidneys, although additional renal (including disruption of the aquaporin-2 shuttle) and CNS mechanisms

have been identified. When severe, polyuria can be socially and occupationally compromising; a cause of insomnia, weight gain (through consumption of high-calorie beverages), poor nutrition, and noncompliance; and potentially dangerous if dehydration occurs. Treatment considerations include (1) adequate fluid replacement, (2) use of the lowest effective dosage, and (3) counteractive medications such as thiazides or potassium sparing diuretics, or indomethacin (Indocin). Amiloride (Midamor) or an amiloride-hydrochlorothiazide combination (Moduretic) is preferred to minimize the risk of hypokalemia. Whether single-daily dosing is beneficial remains controversial, as do treatments such as inositol, potassium supplementation, and desmopressin (DDAVP). Polyuria does not always resolve following discontinuation of lithium.

Lithium can alter kidney morphology. The most common finding is a nonspecific interstitial fibrosis, although a lithium-distinctive microcystic lesion has also been described. In the absence of lithium intoxication and renal insufficiency, the morphological changes attributed to lithium tend to be mild, especially when compared with appropriately selected controls.

An issue not resolved is the extent to which nontoxic use of lithium is associated with eventual renal insufficiency. After correcting for age, one study of 142 patients on lithium for a minimum of 15 years found reduced GFR in 21 percent and increased serum creatinine in 12 percent. Another study of 114 patients on long-term lithium reported increased serum creatinine levels in 21 percent—the so-called creatinine creep. Both higher dosage and duration of treatment increase risk. Progression of renal insufficiency has been described despite discontinuation of lithium.

By age 62, a man successfully stabilized on lithium for 27 years had experienced a gradual increase in serum creatinine to 3.6 mg/dL (range of normal 0.6 to 1.3). A thorough evaluation by a nephrologist produced no other explanation, and lithium was felt to be the most likely cause. The drug was stopped, but over the next several years, kidney function worsened further and hemodialysis was started.

There have been occasional well-documented reports of lithium-related nephrotic syndrome and of incomplete distal renal tubular acidosis.

Regular monitoring of renal function is an essential part of long-term lithium therapy. For most patients, periodic measurement of serum creatinine, a urinalysis, and a clinical estimate of urine volume is sufficient. If clinically warranted, a 24-hour urine volume, protein, and creatinine clearance will provide more comprehensive information. Because there are many causes of impaired kidney function, consultation with a nephrologist is indicated if abnormalities are found.

Other Reactions

Weight gain is a common adverse effect of lithium and may be due to the

drug's complex effects on carbohydrate metabolism. Other possible causes include lithium-induced hypothyroidism, fluid retention, and increased caloric intake from thirst-quenching beverages.

Gastrointestinal adverse effects—including nausea, appetite loss, and loose stools—are common but usually mild. Severe gastrointestinal symptoms may portend impending lithium intoxication.

The most common hematological effect of lithium is a benign, reversible, and usually mild granulocytosis induced by stimulation of granulocyte production. An increase in platelet count is noted occasionally, but there are no clinically important effects on red blood cell count.

Dermatological adverse effects include the first occurrence or worsening of acne, psoriasis, and follicular keratosis, scattered reports of rashes of various types, and hair loss that is only occasionally related to lithium-induced hypothyroidism.

Through several possible mechanisms (antagonism of the calcium sensing receptor, direct stimulation of parathyroid hormone production, and decreased renal calcium excretion), lithium can cause hypercalcemia and hyperparathyroidism. Hypercalcemia is usually mild, but there have been reports of surgery being required to treat parathyroid hyperplasia or adenoma. Some authorities advise baseline and periodic monitoring of serum calcium levels.

Sexual dysfunction, including decreased libido and erectile difficulties, has been attributed to lithium, but well-documented cases are quite uncommon.

There is an inverse relationship between dietary sodium intake and serum lithium concentration. Low-sodium diets result in increased serum lithium concentrations and may cause lithium intoxication unless the dosage of lithium is reduced. Diets that severely restrict fluid intake place patients at risk of dehydration and subsequent lithium intoxication.

DRUG INTERACTIONS

Antipsychotics

Lithium and antipsychotic drugs have been used together safely and effectively for years; however, concern has been expressed that the combination may cause an encephalopathy in certain persons. Although the interaction has been reported most frequently with haloperidol (Haldol), a number of other antipsychotic drugs have also been implicated. A clear cause-and-effect relationship has not been established; nonetheless, caution is advised, and the simultaneous use of high doses of the two drugs should be avoided. The risk of extrapyramidal reactions may be increased as might the risk of neuroleptic malignant syndrome when lithium and antipsychotic drugs are combined.

Anticonvulsants

In treatment-resistant cases, lithium is often combined with another mood stabilizer such as divalproex, carbamazepine, lamotrigine, or oxcarbazepine. Neurotoxic interactions have been described but are usually avoidable with careful clinical management. When two drugs are used together, shared adverse effects may be more pronounced; for example, tremor and weight gain from lithium and divalproex. In addition, lithium offers some protection against carbamazepine-induced granulocytopenia, although whether it does the same for the rare agranulocytosis and aplastic anemia is unknown.

Antidepressants

In general, lithium and antidepressant combinations are safe and effective, although there have been occasional reports of a serotonin-like syndrome when lithium was combined with potent SSRIs. Serum lithium concentrations are not altered in any substantial way by antidepressant drugs.

Anti-Inflammatory Drugs

Most nonsteroidal anti-inflammatory drugs reduce renal lithium clearance and increase the serum lithium concentration in a way that is clinically important and potentially dangerous. Among the drugs that cause this interaction are indomethacin (Indocin), phenylbutazone (Butazolidin), diclofenac (Voltaren), ketoprofen (Orudis), meloxicam (Mobic), oxyphenbutazone (Tandearil), ibuprofen (Motrin, Advil, Nuprin), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and possibly sulindac (Clinoril) appear to be exceptions. The newer cyclooxygenase-2 (COX-2) inhibitors, such as celecoxib (Celebrex) and rofecoxib (Vioxx, no longer available), are no exception. Risk factors include high doses of the anti-inflammatory drug, increased age, and renal impairment. Because many of these drugs are now available without prescription, it is especially important that patients be aware of the possibility of an interaction.

Diuretics

Thiazide diuretics decrease renal lithium clearance and increase the serum lithium concentration. Lithium toxicity has been known to occur. If a thiazide is prescribed, lithium dosage reduction is often necessary. If a thiazide is discontinued, lithium dosage may need to be increased to avoid subtherapeutic levels. Although less well established, potassium-sparing diuretics may also cause lithium retention. However, loop diuretics such as furosemide (Lasix) do not reduce and may actually increase renal lithium clearance. Osmotic and xanthine diuretics (caffeine, theophylline [Theo-dur], and aminophylline) also increase lithium clearance. Because diuretics

are often given to patients who are medically ill with unstable fluid-electrolyte status, interactions with lithium may not be predictable, and close monitoring is advised.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Antagonists

Both of these drug classes are used extensively to treat cardiovascular disease, and both have been reported to cause lithium retention and toxicity in some patients. Package inserts note this in the precautions section.

Other Drug Interactions

Adverse interactions with varying degrees of substantiation have been reported between lithium and a number of other drugs (Table 34.19–5). These interactions may involve increases or decreases in serum lithium concentrations or neurotoxic symptoms in the presence of unchanged serum levels. Questions about potential interactions should be addressed by consulting a knowledgeable pharmacist, a handbook on drug interactions, a regional drug information center, or the Lithium Information Center at the Madison Institute of Medicine.

Table 34.19–5.
Drug Interactions with Lithium

Drug Class	Reaction
Antipsychotics	Case reports of encephalopathy, worsening of extrapyramidal adverse effects, and neuroleptic malignant syndrome. Inconsistent reports of altered red blood cell and plasma concentrations of lithium, antipsychotic drug, or both.
Antidepressants	Occasional reports of a serotonin-like syndrome with potent serotonin reuptake inhibitors.
Anticonvulsants	No significant pharmacokinetic interactions. Occasional reports of neurotoxicity; combinations helpful for treatment resistance.
Nonsteroidal anti-inflammatory drugs	May reduce renal lithium clearance and increase serum concentration. Toxicity reported (exceptions are aspirin and possibly sulindac [Clinoril]).
Diuretics	
Thiazides	Reduced renal lithium clearance and increased serum concentration. Toxicity reported.
Potassium-sparing	Limited data may increase lithium concentration.
Loop	Lithium clearance unchanged (some case reports of increased lithium concentration).
Osmotic (mannitol, urea)	Increase renal lithium clearance and decrease lithium concentration.
Xanthine (aminophylline,	Increase renal lithium clearance and decrease lithium concentration.

caffeine, theophylline)	
Carbonic anhydrase inhibitors	Increase renal lithium clearance (acetazolamide).
Angiotensin-converting enzyme (ACE) inhibitors	Reports of reduced lithium clearance, increased concentrations and toxicity.
Angiotensin II receptor type-1 (AT-1) antagonists	Reports of increased lithium concentrations and toxicity.
Calcium channel inhibitors	Case reports of neurotoxicity; no consistent pharmacokinetic interactions.
Miscellaneous	
Succinylcholine, pancuronium	Reports of prolonged neuromuscular blockade.
Metronidazole	Increased lithium concentration.
Methyldopa	Few reports of neurotoxicity.
Sodium bicarbonate	Increased renal lithium clearance.
Iodides	Additive antithyroid effects.
Propranolol	Used for lithium tremor. Possible slight increase in lithium concentration.

LABORATORY INTERFERENCES

Lithium does not appear to interfere in any clinically important way with other laboratory tests. A distinction must be made, however, between interfering with laboratory tests and causing alterations in laboratory tests. Lithium can cause alterations in a number of areas, including white blood cell count (increase), thyroid function (decrease), and serum calcium (increase). Those changes are induced by lithium rather than by an artifactual interference with the tests themselves. Serum lithium concentrations will be elevated spuriously if blood has been collected in a lithium–heparin anticoagulant tube.

Laboratory Monitoring

Lithium has been measured in virtually every body fluid, but only blood (serum or plasma) is used in clinical practice. Despite considerable research, red blood cell, saliva, and tear lithium measurements and ratios such as red blood cell to plasma have failed to gain widespread acceptance. Methods used to measure serum lithium include flame photometry, atomic absorption spectrophotometry, and ion-selective electrode analysis. Any of these methods in competent hands yields results that are acceptable for both therapeutic and toxic clinical situations. More recently, colorimetric assays have been developed. One uses finger stick blood and returns a plasma lithium level within minutes. The analyzers used in clinical

laboratories are usually not capable of measuring the low levels of naturally occurring lithium in the blood, but more sensitive measures such as flameless atomic absorption spectroscopy and mass spectrometry are available for that purpose. Promising research has been conducted using Li-7 magnetic resonance spectroscopy to measure lithium concentrations in human brain.

The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.5 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are less than 1.5 mEq/L. Clinical toxicity, especially in the elderly, has been well documented within this so-called therapeutic range.

The US package inserts for lithium products list effective serum concentrations for mania between 1.0 and 1.5 mEq/L (usually achieved with 1,800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1,200 mg of lithium carbonate daily). The dose–blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.5 mEq/L is usually outweighed greatly by the increased risk of toxicity, although rarely a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of debate. A prospective 3-year study found patients maintained between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those maintained between 0.8 and 1.0 mEq/L (mean 0.83). However, the higher blood concentrations produced more adverse effects and were less well tolerated. A reanalysis of these data concluded that lower maintenance levels per se were not responsible for the higher relapse rate, but rather that the risk of relapse was increased only in patients who were abruptly randomized from higher prestudy lithium levels to the lower level group. An international group of experts concluded recently that a good prophylactic effect can usually be obtained within the range of 0.4 to 0.8 mEq/L; unfortunately, trial and error is the only way to establish the minimum effective level for a given patient.

Essential to interpreting serum lithium levels is knowing the sampling interval (the time between the last dose and the drawing of blood), the dose form, and the dosage schedule. Blood concentrations obtained an hour or so after a dose are considerably higher than those obtained after a long sampling interval. The 12-hour interval that has been adopted as standard has been defined as follows: (1) the blood should be drawn in the morning, 12 hours (± 30 minutes) after the last dose; (2) a multiple-dose regimen should be used; and (3) a steady-state condition should exist (skipped or extra doses within 4 or 5 days should be avoided). There may be variations

in the 12-hour serum level when switching from immediate release to a slow or controlled release preparation. Although the effectiveness of lithium does not depend on the daily dosing schedule, 12-hour serum concentrations will be higher with single as opposed to multiple daily dosing. The difference may range between 10 and 30 percent and cannot be easily predicted. Consequently, treatment is usually initiated with at least twice-daily dosing, although switching later to single-daily dosing may have the advantage of improved compliance and fewer adverse effects.

Even when these guidelines are followed, the serum level may fluctuate from measurement to measurement, reflecting factors such as dietary sodium intake, mood state, activity level, body position, and improper sample collection (use of a lithium-heparin anticoagulant will increase the concentration by more than 1 mEq/L).

Dosage Prediction

In an effort to make lithium as therapeutically efficient as possible, investigators have developed several approaches to predicting the daily dosage required to produce the desired serum concentration. Dosage prediction techniques include giving a single dose of lithium carbonate and using the serum concentration after a given interval (usually 24 hours) to predict the maintenance dose; measuring renal lithium clearance; and the use of mathematical models. Thus far, prediction techniques have not been widely accepted, and most clinicians continue to adjust the dosage based on the patient's clinical condition and previous blood concentrations. Nonetheless, "loading" a drug to produce a more rapid onset of action has become more appealing because of economic pressures to minimize the length of hospital stay. Although two small studies found loading doses of 20 mg/kg per day and 30 mg/kg per day of slow-release lithium carbonate to be well tolerated, it remains to be determined whether lithium loading can safely reduce time to remission or duration of hospitalization.

DOSAGE AND ADMINISTRATION

The extent of medical evaluation necessary before starting lithium is determined by individual patient characteristics such as age, associated illnesses, and the presence of other drugs; consequently, a thorough medical history is essential. The history determines the need for and the extent of physical and laboratory evaluations. All patients, however, should have renal and thyroid function tested before beginning treatment. A pregnancy test would be appropriate for women of childbearing potential, as would an ECG in older patients.

In the United States, lithium preparations include immediate release generic lithium carbonate, slow release (Lithobid and generic lithium carbonate), controlled release (generic lithium carbonate), and lithium

citrate syrup. There are no parenteral forms. Both 300 mg of the carbonate and 5 mL of the citrate contain about 8 mEq (mmol) of lithium (Table 34.19–6). Elsewhere in the world lithium acetate, glutamate, gluconate, orotate, and sulfate preparations have been available or are currently available. Clinicians should be aware the *lithium* and *lithium carbonate* are not interchangeable (300 mg of lithium is equivalent to 1,597 mg of lithium carbonate).

Table 34.19–6.
Lithium Preparations Available in the United States

Lithium carbonate capsules	150, 300, 600 mg
Lithium carbonate tablets	300 mg
Lithium carbonate controlled-release tablets	450 mg
Lithium carbonate slow-release tablets	300 mg
Lithium citrate syrup	8 mEq/5 mL

Starting Dosage

Lithium therapy is initiated in divided doses. Once a patient is stabilized, single daily dosing is sometimes more convenient. In the presence of normal kidney function, a total daily dose of 1,200 to 1,800 mg of lithium carbonate generally produces an antimanic serum concentration of 0.8 to 1.2 mEq/L. Maintenance levels of 0.6 to 1 mEq/L can usually be attained with 900 to 1,200 mg daily. In general, a conservatively low dose is started, perhaps 300 mg two or three times daily, a serum concentration is obtained after steady state is reached (in 4 or 5 days), and the dose is adjusted accordingly. Patients vary widely in the dose required to reach a desired blood concentration, although the elderly usually require lesser amounts. Consequently, these figures must be considered guidelines rather than absolutes.

Maintenance Dosage

During maintenance therapy, patients must be evaluated clinically, lithium levels determined periodically, and appropriate laboratory tests performed at regular intervals. Monthly visits are common early in treatment if the clinical course is uncomplicated. Patients who have been stable for extended periods may be seen at intervals of 3, 4, or even 6 months. Patient education, including written materials and support programs, such as those by the Depression and Bipolar Support Alliance (DBSA) (formerly the National Depressive and Manic Depressive Association), plays an important role in ensuring safe, effective, and compliant long-term treatment.

Discontinuation

Lithium should be discontinued if it is ineffective or not tolerated. Patients may stop the drug for other reasons, such as a perceived or real loss in creativity, feeling cured, or a dislike for feeling controlled by a medicine. After a period of stability with maintenance therapy, a trial off lithium may be considered, although the risk of recurrence is substantial (especially if there have been several prior episodes), and there have been reports of failure to respond to lithium when treatment is reinstituted. Discontinuation should be gradual over many weeks because more abrupt discontinuation appears to be associated with a higher likelihood of early recurrence, especially of mania. Teaching patients and significant others to recognize early signs of recurrence is an important part of the discontinuation process.

▲ 34.20 Melatonin Receptor Agonists

SAMANTHA B. SALTZ, M.D., KAREN M. PADRON, M.D., PH.D., BRETT LLOYD, JR., M.D., PH.D., AND JEFFREY NEWPORT, M.D.

INTRODUCTION AND HISTORY

Insomnia is a debilitating condition affecting 34 percent of adults in the United States with chronic insomnia affecting 10 to 15 percent of the population. Insomnia disorder is characterized in *DSM-5* as difficulty initiating or maintaining sleep, or early morning awakening with an inability to return to sleep, occurring three or more nights per week for at least 3 months and resulting in significant psychosocial impairment. Historically, many classes of pharmacologic agents have been used to treat insomnia including classic benzodiazepines, other benzodiazepine receptor agonists (e.g., zolpidem), antihistamines, naturopathic agents, and even antidepressants and antipsychotics. Potential side effects of such drugs include residual daytime sedation, gait instability, memory impairment, weight gain and metabolic complications, and abuse and withdrawal potential (Lieberman, 2007). For this reason, safe, well-tolerated medications with low side-effect profiles for insomnia are imperative.

Although the pineal gland, as an anatomical structure, has been recognized since antiquity, its function remained a mystery until the 20th century. In 1917, McCord and Allen reported that the dermal pigmentation of tadpoles, when placed in water seeded with crushed bovine pineal gland, was altered. This provided initial evidence of the existence of the neurohormone now known as melatonin. Forty years would pass before *N*-acetyl-5-methoxytryptamine would be isolated and named melatonin. Nearly 40 additional years would elapse before melatonin receptors in the human were characterized.

Melatonin is released from the pineal gland in accordance with a circadian rhythm producing high nocturnal levels (400 pM) peaking at around 2 AM and low daytime levels (40 pM). It soon emerged that, in most vertebrate species, nocturnal melatonin secretion varies inversely with the length of day, thereby regulating, in some species, seasonal variations in reproductive behavior. It was not until nearly 1990 that the importance of melatonin in synchronizing not only seasonal but circadian rhythmicity became a focus of inquiry. It is now known that the suprachiasmatic nucleus (SCN) of the hypothalamus synchronizes melatonin synthesis to the light/dark cycle, transmitting neural signals from retinal neurons to the pineal gland.

With this realization, increased attention has been focused upon melatonergic dysfunction as a pathophysiologic mechanism underlying disruptions in the circadian sleep–wake cycle associated with insomnia, depression, and other disorders, and upon melatonergic ligands as pharmacologic agents to not only promote sleep but to normalize circadian rhythmicity.

Finally, within the last decade, medicinal use of melatonin, categorized in the United States as a nutritional supplement, has rapidly expanded and has been accompanied by the arrival of several melatonin receptor agonists with others in development. Agents currently approved for use in the

United States or Europe include melatonin, agomelatine, ramelteon, and tasimelteon.

CHEMISTRY

Melatonin is derived from serotonin within the pineal gland and other sites. As a result, the molecular structure of melatonin (Fig. 34.20–1) closely resembles that of serotonin, both molecules comprised of an indole aromatic ring (i.e., a 6-member benzene ring fused with a 5-member nitrogen-containing pyrrole ring) with a side chain at position 3. To form melatonin, the terminal amine group on serotonin's side chain is acetylated producing an acylaminoethyl side chain, and serotonin's hydroxyl group is methylated producing a methoxy group at position 5. These changes render melatonin a more lipophilic molecule that, unlike serotonin, readily crosses the blood–brain barrier.

All currently available melatonin receptor agonists are structurally similar to melatonin. Most similar is agomelatine, the only structural difference being replacement of melatonin's indole (fused benzene and pyrrole rings) aromatic ring with a naphthalene (two fused benzene rings) aromatic ring (Fig. 34.20–2). Ramelteon and tasimelteon preserve melatonin's acylaminoethyl side chain but replace the indole with a benzofuran aromatic ring in which a 6-member benzene ring is fused with a 5-member oxygen-containing furan ring (Figs. 34.20–3 and 34.20–4).

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Pharmacokinetic profiles for melatonin and the three commercially available melatonin receptor agonists are remarkably similar (Table 34-20–1). Each is readily and rapidly absorbed when administered orally, reaching peak plasma concentrations within an hour of administration. Concomitant food intake lowers absorption of tasimelteon (44 percent), ramelteon (22 percent), and melatonin (13 percent), but not agomelatine.

FIGURE 34.20–2. Molecular structure of agomelatine. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

FIGURE 34.20–3. Molecular structure of ramelteon. Light gray, nitrogen; gray, carbon; medium gray, oxygen; white, hydrogen.

Despite a uniformly high absorption rate (≥80 percent), absolute oral bioavailability is only 38 percent for tasimelteon, 15 percent for melatonin, and <5 percent for the others due to extensive hepatic first pass metabolism. All four are rapidly and extensively metabolized with elimination half-lives less than 2 hours and no more than 2 percent of the parent compound excreted unchanged in urine.

All four agents are primarily metabolized via hepatic oxidation, most extensively by the 1A2 cytochrome P450 isoenzyme. Ramelteon and tasimelteon are also substrates for the 3A4 isoenzyme, whereas melatonin, agomelatine, and ramelteon are substrates for the 2C9/C19 isoenzymes.

Renal impairment does not change the rate of drug clearance for any of the four melatonin receptor agonists. Conversely, mild and moderate hepatic impairment produces 70- and 140-fold increases in agomelatine exposure, respectively, and 4- and 10-fold increases in ramelteon exposure. Hepatic impairment is not associated with any changes in tasimelteon exposure or clearance. The effect of hepatic impairment upon the clearance of exogenous melatonin has not been formally evaluated; however, it has been reported that hepatic impairment reduces clearance of endogenous melatonin.

The pharmacokinetic profiles for melatonin, ramelteon, and tasimelteon are significantly affected by age, with elderly patients

exhibiting higher peak concentrations, diminished clearance rates, and longer elimination half-lives. Age-associated pharmacokinetic changes have not been observed with agomelatine.

There is a distinct gender difference in pharmacokinetic profile, with higher peak concentrations and/or longer elimination half-lives reported among women for all four agents. This is likely a consequence of estradiol's known inhibition of the 1A2 cytochrome P450 isoenzyme, the primary metabolic enzyme for all four. If so, reported gender differences are likely most pronounced among premenopausal women.

Finally, all of the agents are highly lipophilic compounds that readily traverse the blood–brain barrier. Of note, melatonin is less tightly protein bound (60 percent) than the three pharmaceutical agents.

Pharmacodynamics

Melatonin's physiologic activity is primarily mediated by two membrane-bound G protein–coupled receptors, melatonin receptor 1 (MT_1) and melatonin receptor 2 (MT_2), which are located in numerous brain regions and peripheral tissues. Both MT_1 and MT_2 receptors are found in the SCN of the hypothalamus, a region adjacent to the optic chiasm that is well recognized for its role in regulating circadian rhythms. Additional MT_1 receptors are located in the *pars tuberalis* of the pituitary. MT_2 receptors are also found in the hippocampus, cerebellum, and retina. Although their respective roles remain somewhat obscure, MT_1 receptors are thought to be involved in promoting sleep and inhibiting firing of the SCN, and MT_2 receptors are believed to play a major role in melatonin's resynchronizing activity. A purported melatonin receptor 3 (MT_3) has been demonstrated to be the enzyme quinone reductase 2 and may thus underlie the antioxidant properties of melatonin.

Other physiologic roles ascribed to melatonin include regulation of metabolic, cardiovascular, and immune systems with reported antioxidant, antinociceptive, and anticancer effects. These are likely mediated, at least in part, by activation of MT_1 and MT_2 receptors present in various peripheral tissues.

Melatonin and the other commercially available agents (i.e., agomelatine, ramelteon, tasimelteon) are all considered nonselective MT_1/MT_2 receptor agonists, albeit with distinct affinity profiles (Table 34.20–2). None has pharmacologically meaningful affinity for benzodiazepine, histaminic, or cholinergic receptors. The affinities of agomelatine, ramelteon, and tasimelteon for the so-called MT3 receptor are obscure. Among the current agents, ramelteon has the greatest MT_1 selectivity with six times melatonin's affinity for the MT_1 receptor. Tasimelteon, conversely, is the only current agent with greater affinity for

the MT_2 than the MT_1 receptor, theoretically underlying its particular utility in entrainment to remedy circadian rhythm disturbances.

Agomelatine, approved in Europe for the treatment of depression, is not only an MT_1 and MT_2 agonist but an antagonist at the serotonin-2C ($5HT_{2C}$) receptor. It remains a matter of debate whether the antidepressant efficacy of agomelatine is a consequence solely of its action on $5HT_{2C}$ receptors or of a synergy between its effects on MT_1, MT_2, and $5HT_{2C}$ receptors.

CLINICAL DRUG STUDIES

Numerous randomized clinical trials have demonstrated the beneficial effects of melatonin and other melatonin receptor agonists for sleep disturbances. For example, recent placebo-controlled trials of controlled-release melatonin (2 mg) in the treatment of primary insomnia have demonstrated significant improvements in self-reported quality of sleep in a study of 170 elderly subjects and reduction in sleep latency (–19 vs. –2 minutes) in 722 adults.

Ramelteon is approved in the United States for the treatment of insomnia characterized by difficulty with sleep onset. A meta-analysis encompassing 13 trials and 5,812 patients found ramelteon to improve sleep quality and reduce sleep latency by 4.30 minutes in a non–dose-dependent fashion with somnolence as the only significant side effect. A similar meta-analysis including eight trials, also found improvements in subjective and polysomnographic sleep latency, total sleep time, and latency to REM with ramelteon. Moreover, improvements in sleep latency produced by ramelteon may be enduring, with one study demonstrating reduced sleep latency compared to baseline at week 1, and months 1, 3, 5, and 6. Tasimelteon is approved in the United States for the treatment of non–24-hour sleep–wake disorder in blind adults. In a controlled trial of 84 non-24 patients, reported in ClinicalTrials.gov (NCT01163032), tasimelteon significantly outperformed placebo in synchronizing the master body clock to a 24-hour day (20 percent vs. 2.6 percent), increasing nighttime sleep time (50- vs. 22-minute change), and decreasing daytime nap time (–49- vs. –22-minute change). Moreover, a non-24 withdrawal study (NCT01430754) reported greater maintenance of 24-hour synchronization among those maintained on tasimelteon than those randomized to placebo (90 percent vs. 20 percent). Similar benefits have been observed for transient insomnia following a sleep-time shift. A pooled report (Rajaratnam et al., 2009) of phase II and phase III trials enrolling 39 and 411 patients, respectively, confirmed that tasimelteon improved sleep efficiency, reducing sleep latency and wakefulness after sleep onset. A clinical trial (NCT00548340) for primary insomnia (n = 321) demonstrated significantly reduced sleep latency times for both 20-mg and 50-mg

tasimelteon doses (−45 and −46 minutes) compared to placebo (−28 minutes).

Melatonin receptor agonists have consistently outperformed placebo in clinical trials of insomnia and other circadian sleep disturbances. Unfortunately, tolerance to these agents has not been systematically assessed, nor have they been scrutinized in head-to-head comparisons against other classes of hypnotic agents. Nevertheless, a recent meta-analysis reported that polysomnographically determined reductions in sleep latency and time awake after sleep onset for extended-release melatonin (2 mg) and ramelteon (16 mg) were less than that of benzodiazepines but comparable to changes produced by other benzodiazepine receptor agonists. The same meta-analysis reported that changes produced by ramelteon at an 8-mg dose were less than both benzodiazepines and other benzodiazepine receptor agonists. The utility of melatonin receptor agonists in the management of mood disorders has also been a focus of inquiry, albeit with mixed results. A controlled trial (NCT00705003) evaluating melatonin (3 mg) augmentation of buspirone for depression demonstrated no evidence of therapeutic efficacy. Similarly, a controlled trial of ramelteon (8 mg) augmentation of escitalopram for depression (NCT00642694) was terminated due to lack of efficacy. Finally, in an 8-week depression trial (NCT01428661) including 507 subjects, 20-mg tasimelteon failed to separate from placebo in reducing depressive symptom severity. Controlled trials of ramelteon (8 mg) augmentation for bipolar disorder have produced mixed results with one study reporting a significantly longer time to relapse than placebo (188 vs. 84 days, respectively) among euthymic patients with bipolar disorder but another reporting no difference from placebo in reducing manic symptoms or sleep disturbance in manic outpatients.

The strongest evidence for efficacy in the treatment of mood disorders is found with agomelatine, which, in Europe, is indicated for the treatment

of depression. It is suggested that the antidepressant efficacy of agomelatine stems both from its effects on mood and on circadian resynchronization. A recent meta-analysis incorporating 20 placebo-controlled agomelatine trials and 7,460 subjects demonstrated antidepressant efficacy, with an odds ratio for therapeutic response 1.25 [95 percent CI: 1.11–1.40]. A recent Cochrane review comparing agomelatine to SSRI antidepressants and venlafaxine found no advantage or disadvantage in achieving response or remission in unipolar depression. Interestingly, in a meta-analysis of 14 antidepressants, agomelatine was the only agent less likely to induce insomnia than placebo, yet it also had the third lowest rate of daytime somnolence.

The foundation for the role of chronobiotic therapies for mood disorders has largely emerged from the study of SAD. Most patients with SAD have a phase delay, or later secretion of dim light melatonin, due to the absence of early morning light during the winter months in the northern hemisphere. Both the dose and timing of chronobiotic administration are arguably keys to successful treatment. Proper treatment results in phase advancement with improvements in mood symptoms, while incorrect dosing or timing may actually worsen insomnia and mood disturbances.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Cardiovascular System

Endogenous melatonin is likely involved in the circadian regulation of the cardiovascular with decreases in cardiac output, blood pressure, and heart rate when melatonin levels are peaking during the evening hours. Rodent studies indicate similar effects of exogenous administration of melatonin.

Clinical trial data have not indicated any adverse effects upon cardiovascular function among the four commercially available melatonin receptor agonists. In fact, it has been posited that melatonin receptor agonists should be studied to identify possible beneficial cardiovascular effects.

Central Nervous System

As a group, the melatonin receptor agonists compare favorably to benzodiazepines and other hypnotics with respect to adverse effects on the central nervous system. Moreover, a risk of abuse liability for this class of medications has not been found in small cross-over trials.

Endocrine System

Preclinical studies indicate that supraphysiologic administration of exogenous melatonin may disrupt secretory profiles for numerous hormones including corticosteroids, gonadal steroids, luteinizing hormone,

insulin, prolactin, and thyroid hormone.

Two clinical trials have evaluated the endocrine effects of ramelteon administration. Neither study demonstrated an impact of ramelteon on adrenal or thyroid axis function. However, one of the studies indicated significant effects on reproductive endocrine function, increasing serum prolactin levels by 34 percent, particularly among females, following 6 months of ramelteon therapy.

Endocrine function has not been specifically examined in clinical trials of the other commercially available melatonin receptor agonists.

Hepatic and Renal Systems

There is no evidence that clearance of any of the four available melatonin receptor agonists is altered by pre-existing renal impairment. Nor is there evidence that these agents impair renal function. In fact, some preclinical studies suggest that melatonin may protect the kidneys from renal ischemia and reperfusion injury, exposure to carcinogens, hemorrhagic shock, or other injuries.

Agomelatine, unfortunately, has been associated with hepatic dysfunction. During clinical trials, 1.4 percent of patients receiving agomelatine 25 mg and 2.5 percent of those receiving agomelatine 50 mg experienced elevations in serum transaminase concentrations that were more than three times the upper limit of normal. Rare occurrences of hepatitis, increased γ-glutamyl transferase concentrations to three times the upper limit of normal, jaundice, and hepatic failure have been reported in association with agomelatine therapy. Hepatic injury has not been reported in association with any of the other three approved melatonin receptor agonists.

Ramelteon	Rozerem	Insomnia (sleep onset)	8	8-mg tablets
Tasimelteon	Hetlioz	Non–24-hour sleep–wake disorder	20	20-mg capsules

Respiratory System

In contrast to benzodiazepines and other hypnotics, melatonin receptor agonists appear to be devoid of respiratory depressant effects. For example,

in a study of patients with mild to moderate sleep apnea or chronic obstructive pulmonary disease, ramelteon did not adversely impact apnea–hypopnea indexes or arterial oxygen saturation levels.

THERAPEUTIC INDICATIONS

As shown, melatonin agonists provide a novel approach to the treatment of insomnia and other circadian sleep disturbances (Table 34.20–3). In addition to its effect on the circadian rhythm, melatonin has also been reported to possess anti-inflammatory, antitumor, vascular, retinal, antioxidant, neuroprotective, and pain modulatory effects. It has antiepileptic, antinociceptive, neurotrophic, antioxidant, and anxiolytic properties, perhaps providing other avenues for which to explore its therapeutic potential. For example, melatonin may be beneficial in promoting healing for tissue injury secondary to radiation exposure. Following radiation injury, TNF-α levels are elevated, resulting in increased levels of reactive oxygen species, which are scavenged by melatonin.

Melatonin receptor agonists also hold potential utility in the treatment of depression and other mental disorders associated with disturbances of circadian rhythmicity. Indeed, agomelatine is indicated for the treatment of major depression in Europe. It is unclear, however, the extent to which, if any, agomelatine's MT_1/MT_2 agonism contribute to its antidepressant efficacy.

Emerging evidence suggests that melatonin agonists may play an important role in the treatment and reduction of delirium. In a recent study, ramelteon was associated with a lower incidence of delirium when administered to older adults admitted to an acute care setting. Based on reviews of controlled trials and case series, melatonin may also be useful in the treatment of delirium in hospitalized older adults.

PRECAUTIONS AND ADVERSE REACTIONS

In many respects, the side-effect profile of the melatonin receptor agonists compare favorably to other sleep agents. Unlike benzodiazepine hypnotics, melatonin agonists have not been associated with prominent cognitive impairment, fall risk, or discontinuation-associated withdrawal syndromes, or rebound insomnia. The melatonin agonists are also devoid of prominent anticholinergic (e.g., dry mouth, constipation, blurred vision) or antihistaminic (e.g., carbohydrate craving, weight gain) side effects associated with other hypnotic agents.

Pregnancy. Endogenous maternal melatonin plays an important role during pregnancy. Although the fetal pineal gland does not yet produce melatonin (infant melatonin production does not begin until 2 to 3 months after delivery), there are more melatonin binding sites in both the fetal pituitary and fetal hypothalamus than in the adult. It is speculated that

maternal melatonin, which has been shown to cross the placenta, establishes periodicity and entrains the circadian pacemaker. For example, in evening deliveries, significantly elevated melatonin levels are detected via sampling of the umbilical artery or vein at birth. One hypothesis is that maternal melatonin might communicate important information about maternal sleep–wake cycles and entrain the fetal pineal gland, so that fetal circadian rhythms may be found as early as 3 months. Preclinical evidence suggests other roles for endogenous melatonin during fetal life including influencing the development of reproductive organs, regulating gonadal hormone activity, and protecting the fetal brain from oxidative damage during episodes of fetal hypoxia.

Despite the growing evidence that endogenous melatonin benefits the fetus, exogenous melatonin administration, which likely produces markedly higher fetal circulating concentrations, should not carry a presumption of safety. For example, a series of rodent studies, administering exogenous melatonin during pregnancy at doses as low as 2 to 10 times recommended human doses have demonstrated decreased luteinizing hormone levels, decreased ovarian and uterine size, and delayed vaginal opening in the offspring. Following delivery, offspring exposed to exogenous melatonin exhibit disruption in estrous cycles and blunted responses to testosterone, suggesting impairment in maturation of the hypothalamic–pituitary gonadal and prolactin axes.

There are no controlled clinical data addressing the reproductive safety of exogenous administration of melatonin or other melatonin receptor agonists.

In summary, there is no clear evidence of teratogenicity, though there is preclinical evidence that increased levels of melatonin may interfere with regulation of sex hormone levels and cycles, as well as delay sexual maturation. Pending further data, exogenous administration of melatonin and other melatonin receptor agonists should be avoided during pregnancy.

Lactation

Existing studies have examined levels of endogenous melatonin in breast milk but not at exogenous levels. Cyclic levels of melatonin in breast milk replicate maternal patterns including elevations in the evening and decreases with light with endogenous melatonin breast milk levels ranging from 35 to 80 percent of maternal serum levels. Circadian fluctuations in breast milk melatonin concentrations may dictate nursing schedules to the infant.

Agomelatine is detectable in breast milk with peak concentrations occurring 1 to 2 hours after the drug was administered and milk:plasma ratio equaling 0.19. Of note, 4 hours after the drug was administered, agomelatine was not detectable in breast milk. Clinical breast milk

excretion data have not been published for other melatonin receptor agonists.

In a recent edition of Hale's standard lactation reference, both melatonin and ramelteon are assigned a moderately safe (L3) rating.

DRUG INTERACTIONS

All currently available melatonin receptor agonists, including melatonin itself, are predominantly metabolized by the hepatic cytochrome P450 1A2 isoenzyme and to a lesser extent, the 2C9/2C19 and/or 3A4 isoenzymes. Thus, there are potential interactions with drugs that inhibit or induce the activity of these P450 isoenzymes (Table 34.20–4).

Of greatest concern are drug interactions mediated by the 1A2 isoenzyme. For example, coadministration with fluvoxamine, a potent 1A2 inhibitor, produces a 7-fold increase in total tasimelteon exposure, a 17-fold increase in melatonin exposure, a 60-fold increase in agomelatine exposure, and a whopping 160-fold increase in ramelteon exposure. By comparison, coadministration with ketoconazole, a potent 3A4 inhibitor, produces a 0.84-fold increase in ramelteon exposure and a 0.50-fold increase in tasimelteon exposure. Fluconazole, a potent 2C9 inhibitor, produces a 1.5-fold increase in ramelteon exposure and was not observed to alter agomelatine exposure.

[h]Macrolide antibiotics include clarithromycin, erythromycin, and telithromycin.

The magnitude of the drug interaction observed between fluvoxamine and the four melatonin receptor agonists raises concern for interactions with other agents that alter 1A2 activity. For example, coadministration with estrogen-containing compounds (e.g., oral contraceptives, hormone replacement therapies) may produce similar increases in levels of exposure to these agents. Unfortunately, no data are available to clarify the magnitude of this potential interaction. Tobacco, a known inducer of the 1A2 isoenzyme, may produce the opposite effect, that is, lowering exposure to the melatonergic agents. Indeed, smoking has been associated with a 3.7-fold lowering of cumulative exposure to agomelatine.

None of the four melatonergic agents, at therapeutic concentrations, have been observed to alter P450 enzyme activity; therefore, they seem unlikely to alter the clearance of other medications. However, in vitro research indicates that melatonin, at supratherapeutic concentrations, induces activity of the 3A4 isoenzyme. The clinical relevance of melatonin's impact of 3A4 activity, if any, is unknown. An additive impact upon psychomotor performance when taken with alcohol has been reported for the melatonin receptor agonists.

LABORATORY INTERFERENCE

None of the four approved agents (i.e., agomelatine, melatonin, ramelteon, tasimelteon) have been shown to have significant laboratory interferences. They also have not been shown to interfere with drug urine toxicology screens or to produce false-positive results.

DOSAGE AND ADMINISTRATION

Extended-release melatonin is administered using a 2-mg bedtime dose. Exogenous melatonin should not be administered to patients with moderate or severe hepatic impairment.

Ramelteon is usually administered at an 8-mg dose 30 minutes prior to bedtime, but there have been reports of efficacy between 4 mg and 64 mg

(Arendt, 2008). No dosing adjustment is needed for renal impairment. Ramelteon should not be administered to patients with moderate or severe hepatic impairment.

Tasimelteon is administered at a 20-mg dose at bedtime. There is no recommended dosing adjustment for renal or hepatic impairment.

Agomelatine is administered for depression using a 25-mg bedtime dose. No dose adjustment is needed for renal impairment. Agomelatine should not be administered to patients with even mild hepatic impairment.

INVESTIGATIONAL DRUGS

Two novel melatonin receptor agonists are currently in clinical trials. TIK-301, formerly known as LY-156735 and PD-6735, was initially developed by Eli Lilly and is currently licensed to Tikvah Therapeutics where phase III trials are on-going. The pharmacodynamic profile of TIK-301 is similar to agomelatine, a nonselective MT_1/MT_2 agonist (Table 34.20–3) as well as a $5HT_{2B}$ and $5HT_{2C}$ antagonist. It has potential utility for insomnia, circadian rhythm disorders, and depression.

Piromelatine, also known as Neu-P11, is a nonselective MT_1/MT_2 agonist and $5HT_{1A}/5HT_{1D}$ agonist under development by Neurim Pharmaceuticals for sleep and cognitive function in association with insomnia and Alzheimer disease. Piromelatine outperformed placebo in a 4-week phase II trial (NCT01489969) for insomnia. Preclinical research indicates that piromelatine may improve cognitive function in animal models of Alzheimer disease and prevent insulin resistance and metabolic derangements associated with sleep deprivation.

A number of other melatonin receptor ligands are in various stages of development and/or preclinical testing. Melatonin agonists in development exhibit one of four pharmacodynamic profiles: (1) nonselective MT_1/MT_2 agonists; (2) nonselective MT_1/MT_2 agonists with agonist or antagonist activity at one or more serotonin receptor subtypes; (3) MT_1 selective agonists; and (4) MT_2 selective agonists. By convention, a selective must display at least 50 times greater affinity for one receptor subtype.

Two MT_2 selective partial agonists, UCM765 and UCM924, have demonstrated antinociceptive efficacy in animal models of neuropathic pain. In other preclinical studies, UCM765 showed anxiolytic effects and promoted non-REM sleep. Production of MT_1 selective ligands has proven more challenging. Thus, progress toward development of MT_1 selective agonists is lagging.

▲ 34.21 Mirtazapine

RADU V. SAVEANU, M.D., MOUSA SOBHY AZER BOTROS, M.D., AND MICHAEL E. THASE, M.D.

Mirtazapine (Remeron) is a tetracyclic piperazinoazepine compound (Fig. 34.21–1) that was approved by the FDA in 1995 for the treatment of depression. Unlike most newer antidepressants, mirtazapine has virtually no effect on monoamine uptake. Rather, therapeutic effects are thought to be mediated by inhibition of α2-adrenergic receptors and blockade of postsynaptic serotonin type 2 (5-HT2) and type 3 (5-HT3) receptors. The former action diminishes the inhibitory effects of both α2-autoreceptors (located on presynaptic norepinephrine [NE] neurons) and α2-heteroreceptors (located on cell bodies of dorsal raphe 5-HT neurons). Inhibition of inhibitory cellular mechanisms thus increases the firing rates of noradrenergic and 5-HT neurons. This effect differs markedly from that of most other antidepressants, which tend to suppress cell firing rates until autoreceptors are downregulated.

Blockade of 5-HT2 and 5-HT3 receptors may enhance therapeutic effects directly (e.g., relief of insomnia or enhancement of appetite) or indirectly by dampening side effects attributable to disinhibited 5-HT release (e.g., agitation or nausea). Antagonism of 5-HT2 receptors also may enhance the availability of neurotransmitters to interact with serotonin type 1 (5-HT1) receptors. Mirtazapine is the only newer antidepressant that is a potent antagonist of histamine-1 receptors, which adds to sedative and appetite-enhancing properties. The sleep effects of mirtazapine in major depression have been studied. Mirtazapine therapy has been shown to lessen nocturnal awakenings and prolong total sleep time. Mirtazapine administration increased total slow wave sleep (SWS), REM latency, the duration of the first REM episode, and stage 3 sleep. It decreased the number of REM episodes. Simultaneously, it reduced wake time after sleep onset.

FIGURE 34.21–1. Chemical structure of mirtazapine (Remeron).

First synthesized in the early 1980s, mirtazapine is related to one older

antidepressant, mianserin (Tolvon). Mianserin is available throughout most of the world (although not in the United States or Canada). Mianserin is a more potent antagonist of α1-receptors than the newer compound, which is thought to explain why mianserin has less effect on 5-HT neurotransmission than mirtazapine.

PHARMACOLOGY

Mirtazapine has a half-life of approximately 30 hours and reaches steady state after 6 days of therapy. Linear pharmacokinetics is observed across the therapeutic dose range (i.e., 15 to 60 mg/day). Mirtazapine is essentially completely absorbed after oral dosing, and food has little effect on the rate or extent of absorption. Approximately 85 percent of circulating drug is bound to plasma protein.

Mirtazapine is metabolized in the liver via cytochrome P450 (CYP) 2D6, CYP 1A2, and CYP 3A4 pathways. The primary metabolite, *N*-desmethylmirtazapine, is substantially less active than the parent compound and has trivial pharmacological effects. Cimetidine, which inhibits CYP 2D6, CYP 1A2, and CYP 3A4, raises plasma levels of mirtazapine by more than 50 percent. Even greater increases in mirtazapine concentrations result from concomitant administration of the potent CYP 1A2 inhibitor fluvoxamine (Luvox).

The original formulation of mirtazapine is available in 15-, 30-, and 45-mg tablets. An alternate vehicle, an orally disintegrating tablet (ODT), was introduced in 2001 to facilitate compliance and to aid therapy for patients who have difficulty swallowing. The ODT is available in 30- and 45-mg strengths.

Antidepressant Efficacy

The minimum effective dose of mirtazapine in placebo-controlled clinical trials of major depressive disorder (MDD) is 15 mg/day. The maximum approved dose ranges from 45 mg/day (United States) to 60 mg/day (some European countries). There is some evidence of an ascending dose–response relationship for antidepressant efficacy, although this has not been definitively established.

The relative efficacy of mirtazapine has been established against older and newer antidepressants. Mirtazapine was found to be significantly more effective than trazodone (Desyrel) and as effective as the TCAs: amitriptyline (Elavil), doxepin (Sinequan), clomipramine (Anafranil), and nortriptyline (Aventyl). Therapy with the TCA, imipramine (Tofranil), was significantly more effective than mirtazapine treatment in one inpatient study. However, in this trial, dosages of both drugs were titrated in relation to plasma levels, which is a valid strategy for the TCA but of uncertain value for mirtazapine.

There are a number of published studies comparing mirtazapine and SSRIs, including citalopram (Celexa), paroxetine (Paxil), sertraline (Zoloft), fluvoxamine, and fluoxetine (Prozac). Several meta-analyses have been completed and have confirmed that, on average, the two types of antidepressants are comparably effective (less than 5 percent difference in response or remission rates) after 6 to 8 weeks of therapy, although patients treated with mirtazapine received earlier therapeutic benefit. It is not clear if this temporal difference is primarily due to a relatively nonspecific advantage in improving sleep and appetite or if it is attributable to the difference in mechanism of action.

Two studies have contrasted mirtazapine with the serotonin norepinephrine reuptake inhibitor (SNRI) venlafaxine (Effexor). In the first study, mirtazapine (mean dose: 50 mg/day) and the immediate release formulation of venlafaxine (mean dose: 255 mg/day) were compared in 157 depressed inpatients with melancholic features. Trends favored the mirtazapine-treated group on most outcome measures, but only the difference on the Hamilton Rating Scale for Depression (HAMD) sleep disturbance factor reached statistical significance at study endpoint. Significantly fewer patients did, however, withdraw from the mirtazapine group during the first 6 weeks of therapy because of side effects. The second study, which was conducted in 242 depressed outpatients, contrasted the ODT formulation of mirtazapine (45 mg/day) with the extended release formulation of venlafaxine (225 mg/day). Although the efficacy of the study drugs again did not differ at the end of the trial, results consistently favored mirtazapine therapy during the first 2 weeks of double-blind therapy, with significant differences in overall symptom improvement, response rates, and changes in sleep.

Combining SSRIs/SNRIs and Mirtazapine

Almost from the time of introduction, it was speculated that mirtazapine could be combined with SSRIs to obtain synergistic or additive effects. Subsequently, a number of studies have examined the clinical utility—both effectiveness and tolerability—of combining mirtazapine with other antidepressants, including SNRIs and bupropion as well as SSRIs.

The first RCT to evaluate mirtazapine in combination with other antidepressants (predominantly SSRIs) studied patients with a documented history of nonresponse to antidepressant therapy in the current depressive episode. In this pilot study, 26 outpatients were randomly assigned to 4 weeks of additional double-blind therapy with either active mirtazapine (15 to 30 mg/day) or matching placebo, in addition to ongoing therapy with the first antidepressant. The investigators found that the patient group receiving adjunctive therapy with active mirtazapine had significantly greater improvement in depressive symptoms than the group receiving adjunctive placebo. Although the difference in

remission rates was not statistically significant in this small study, the magnitude of the difference (45 percent vs. 13 percent)—if replicable in a larger study—would be clinically meaningful.

Another study tested the hypothesis that starting patients on the combination of mirtazapine and an SSRI would deliver a more rapid and/or larger response than monotherapy. This outpatient RCT randomly assigned 61 participants with MDD to 6 weeks of double-blind therapy with one of three options: (1) mirtazapine (30 to 60 mg/day) plus placebo; (2) paroxetine (20 to 40 mg/day) plus placebo; or (3) mirtazapine plus paroxetine. The group receiving combined therapy of mirtazapine obtained a significantly larger reduction in depressive symptoms than the groups that received mirtazapine and paroxetine monotherapy groups. The remission rate for the combined therapy group at week 6 was 43 percent, as compared to 19 and 26 percent for the mirtazapine and paroxetine monotherapy groups, respectively. Although again not statistically significant, such a difference in remission rates would be considered clinically significant if confirmed in a larger study.

A second study of the value of combining antidepressants from the outset of therapy randomly assigned 105 MDD outpatients to receive 6 weeks of therapy with one of four strategies. One group received fluoxetine (20 mg/day) plus placebo; this group served as the active comparator. A second group received fluoxetine (20 mg/day) in combination with mirtazapine (30 mg daily); this group directly tested the value of combining mirtazapine with the SSRI. Two other groups received mirtazapine (30 mg/day) in combination with either venlafaxine (225 mg/day) or bupropion (150 mg/day); these groups permitting a preliminary comparison of the utility of combining mirtazapine with other first-line antidepressants. This study again tested the hypothesis that patients receiving combination antidepressant therapy would show a more rapid or more complete remission than a monotherapy from the outset of therapy. At the end of 6 weeks of double-blind therapy, the fluoxetine plus placebo group had a remission rate of 25 percent. Across all outcome measures, trends favored the groups that received mirtazapine in combination with fluoxetine (52 percent remission rate), venlafaxine XR (58 percent remission rate), or bupropion (46 percent remission rate).

The combination of mirtazapine and venlafaxine was evaluated in two other studies. The first study was part of the massive STAR*D project. In this open label trial, 109 MDD outpatients who had not obtained adequate benefit from three rounds of antidepressant therapy were randomized to receive 12 weeks of therapy with mirtazapine (mean dose: 36 mg/day) and venlafaxine XR (mean dose: 210 mg/day) or the monoamine oxidase inhibitor tranylcypromine (mean dosage: 37 mg/day). Outcomes were assessed by self-report and by blinded independent evaluators. At study endpoint, neither group did particularly well, though the remission rate in

the mirtazapine plus venlafaxine XR group was twice that of the group that received the MAOI (14 vs. 7 percent). Patients receiving combination therapy were more likely to complete the trial and did show a statistically significant difference in improvement in depressive symptoms. A relatively few patients completed 12 weeks treatment with tranylcypromine at a therapeutic dose (i.e., at least 40 mg/day); one implication is that physicians in contemporary practice are better able to implement a trial of combined therapy than execute a successful switch to an MAOI.

A subgroup of the STAR*D investigators completed a second, larger study of the value of combining antidepressants at the beginning of treatment. This trial, known by the acronym COMED, randomized 220 MDD outpatients to 12 weeks of treatment with escitalopram plus placebo (i.e., the active comparison group), mirtazapine (mean dose: 18 mg/day) plus venlafaxine XR (mean dose: 178 mg/day), or escitalopram plus bupropion (i.e., an alternate widely used combination that had performed reasonably well in STAR*D). This trial found no evidence to support the routine use of antidepressant combinations from the outset of therapy, which reported significantly greater side effects.

Prophylactic Therapy

Two studies have evaluated longer-term treatment with mirtazapine. The first report examined the outcomes of patients who received extended therapy after responding to double-blind, acute-phase therapy with mirtazapine, amitriptyline, or placebo. Results indicated that patients who remained on mirtazapine had a significantly lower risk of relapse than patients who continued to take double-blind placebo. The amitriptyline-treated group had an intermediate outcome.

The second study was a formal relapse prevention trial in which 156 patients who had remitted during 8 to 12 weeks of acute-phase therapy were randomized to remain on active mirtazapine (N = 76) or to switch to placebo (N = 80). Across the subsequent 40 weeks of double-blind therapy, 44 percent of the placebo group relapsed, compared to 20 percent of the group receiving active continuation-phase therapy. The effects of continuation-phase mirtazapine therapy were of the same magnitude observed in studies of other effective antidepressants.

OTHER INDICATIONS FOR MIRTAZAPINE

Mirtazapine is not formally indicated for treatment of any other disorder. Nevertheless, mirtazapine may be useful for the treatment of insomnia, panic disorder, generalized anxiety disorder, PTSD, and OCD, as well as autism and other pervasive developmental disorders. A number of small studies and case series have evaluated the utility of mirtazapine in treating anxiety and depression in cancer patients. Blockade of 5-HT3 and

histamine receptors may have particularly useful effects in the symptomatic management of anxiety and depression in cancer patients. Improvements in pain, nausea, appetite, insomnia, depression, and anxiety have been reported.

A study of 12 adult outpatient subjects with comorbid MDD/alcohol dependence was recently conducted. Subjects were given 15 mg of mirtazapine for the first 2 weeks and 30 mg for the last 6 weeks of the medication trial. Mirtazapine improved depression on the Beck Depression Inventory (BDI), and decreased the number of alcohol drinks per week. These preliminary findings suggest that mirtazapine may be efficacious in reducing both depressive symptoms and excessive alcohol use in comorbid MDD and alcohol dependence. Two years later, 10 of the 12 patients who entered the acute-phase study participated in the follow-up study. The significant improvements initially observed in depressive symptoms (BDI), drinking, and sleep disturbance persisted at the follow-up evaluation. A study of depressed cocaine-dependent subjects who received either mirtazapine (11 subjects) or placebo (13 subjects) for 12 weeks suggested that mirtazapine is superior to placebo in improving sleep in patients with comorbid depression and cocaine dependence, but is not more effective than placebo in reducing cocaine use.

In another study, sixteen agitated patients with Alzheimer disease (AD) were enrolled in a 12-week open-label pilot study. Patients were given 15 to 30 mg/day of mirtazapine. The study found that agitated patients with AD could be treated with mirtazapine without significant adverse events or cognitive deterioration. Larger-scale studies are now warranted.

MIRTAZAPINE USE DURING PREGNANCY AND LACTATION

In a study of eight women who were taking a median dose of 38 mg of mirtazapine per day while breastfeeding, concentrations of mirtazapine or desmethylmirtazapine were measured in milk and plasma. All infants were clinically examined and four infants had blood drawn for analysis. No adverse effects were seen. Mirtazapine was detected in only one of four infants tested. The study suggested that mirtazapine use by lactating women is safe for the breast-fed infant. Nevertheless, each decision to breastfeed should always be made on the basis of an individual risk–benefit analysis.

It is not known whether mirtazapine may cause harm to the unborn baby but a study assessed the risks associated with exposure to this antidepressant. Pregnant depressed women taking mirtazapine were compared to pregnant women taking other antidepressants and pregnant women exposed to nonteratogens. About 100 pregnant women in each group were followed. Mirtazapine did not appear to increase the rate of major malformations. However, the rate of prematurity was higher in the mirtazapine group compared to pregnant women exposed to

nonteratogens.

TOLERABILITY, SAFETY, AND TOXICITY

Attrition from mirtazapine therapy because of adverse events generally was less than that observed in comparison groups treated with tricyclic antidepressants, but somewhat greater than that observed in comparative studies versus SSRIs. Mirtazapine and venlafaxine have comparable attrition rates in controlled studies. The specific side-effect profile of mirtazapine is quite different, however, from that associated with SSRIs and SNRIs.

The most common side effects reported during mirtazapine therapy are sedation, increased appetite, weight gain, and dry mouth. The drug's antihistaminic effects primarily cause these side effects. Approximately 50 percent of patients report sedation during the first week of mirtazapine therapy. This side effect can be clinically significant, as demonstrated in studies of reaction time or automotive driving performance. Sedation usually is not minimized by slow upward titration of the dose, and lower and higher starting doses of mirtazapine have similar rates of sedation. If early sedation can be tolerated, however, most patients adapt to this side effect without difficulty. When compared to SSRIs or SNRIs, mirtazapine therapy is associated with significantly lower rates of gastrointestinal disturbance and a lower incidence of treatment-emergent sexual dysfunction.

Mirtazapine provoked periodic leg movements (PLMS) in 67 percent of young healthy males. The effect was most pronounced in the first few days but gradually decreased in the first week. The indirect increase in central dopamine via 5-HT1A receptor activation may explain why mirtazapine-induced PLMS decreased over time. Further, diphenhydramine, another first-generation H1 antagonist, provoked PLMS during wake in subjects with restless legs syndrome, pointing to a possible antihistaminergic mechanism in the induction of PLMS.

Mirtazapine may cause withdrawal syndrome upon sudden discontinuation. Symptoms include depression, anxiety, restlessness, irritability, decreased appetite, insomnia, diarrhea, nausea, and vomiting. Therefore, reduction in dose should be gradual and slow.

Mirtazapine is not approved for use in children under the age of 18 years.

Perhaps 15 to 25 percent of patients gain an unacceptable amount of weight during mirtazapine therapy. This annoying adverse effect may occur more commonly among younger patients, and, interestingly, weight gain was not a problem in one study of depression in late life. The likelihood of problematic weight gain usually can be predicted within the first 4 to 6 weeks of therapy. A small study of seven women with MDD treated with mirtazapine for 6 weeks concluded that mirtazapine was associated with a

significant increase in body weight, body mass fat and leptin concentration. Interestingly, glucose metabolism remained unaffected in this study, in contrast to other psychotropic medications inducing weight gain.

The effects of mirtazapine and venlafaxine on leptin plasma levels were recently contrasted. After 28 days of treatment, mirtazapine treatment was strongly associated with an increase in leptin concentrations. There was also a significant effect on the leptin/body mass index (BMI) ratio elevated in mirtazapine-treated patients and slightly declining in venlafaxine-treated patients. Blockade of histamine synthesis may contribute to leptin resistance, as well as via possible histamine H1-receptor–mediated dysregulation of hypothalamic nuclei integrating central and peripheral signals relevant to energy balance.

The only significant effect of mirtazapine therapy on clinical chemistry profiles has been increased blood lipid levels. As this effect occurred with approximately twice the frequency seen in patients randomly assigned to treatment with amitriptyline, weight gain alone does not appear to be the cause.

The most controversial severe adverse effect possibly associated with mirtazapine therapy is agranulocytosis. Although concern has existed about this as a potential problem in the early (premarketing) studies, a definite association has not been established over the subsequent two decades.

Mirtazapine is remarkably safe in overdose. The principal problems following ingestion of as much as 5 g of mirtazapine are sedation, aspiration pneumonia, delirium, and tachycardia. No cases of seizure or abnormal heart rhythms have been reported. In the only reported fatal overdose, the patient also had ingested toxic levels of several other drugs.

FUTURE DIRECTIONS

Mirtazapine is distinctly different from the remainder of the newer antidepressants. It is at least as effective as the SSRIs, and most likely conveys earlier symptomatic benefit. It also differs dramatically from the SSRIs and venlafaxine with respect to tolerability. Virtually free from causing side effects commonly associated with 5-HT uptake inhibitors (e.g., gastrointestinal disturbances, insomnia, and sexual dysfunction), mirtazapine therapy is complicated by sedation (in as many as half of all patients) and weight gain (in as many as a fourth of all patients). Mirtazapine is increasingly used for treatment of older depressed people, for whom these effects are more likely to be therapeutic than problematic.

One study demonstrated that the interaction between HTR1A+272G>A and 5-HTT VNTR genotypes may be involved in the response to mirtazapine treatment in MDD patients. The response was greater for the combination than for individual genotypes. This observation should be replicated and further expanded in larger-scale studies.

▲ 34.22 Monoamine Oxidase Inhibitors

ETHAN F. KARSEN, M.D., AND PAUL E. HOLTZHEIMER, M.D., M.S.

INTRODUCTION AND HISTORY

Monoamine oxidase inhibitors (MAOIs) were among the first antidepressants found to be clinically effective in humans. Although MAOI use has declined over time due to the emergence of newer antidepressants with equivalent efficacy and more tolerable side effects, research interest in MAOIs has been rekindled by the development of selective MAOIs, new delivery systems, and the discovery of their neuroprotective role in neurodegenerative diseases.

Development of MAOIs

In 1957, at a regional meeting of the American Psychiatric Association (APA) in Syracuse, New York, two independent research groups presented findings showing that the antitubercular medication iproniazid had antidepressant effects in patients with tuberculosis and comorbid depression. These findings represented a culmination of years of laboratory and clinical research. Emil Fischer first isolated hydrazines, the class to which early MAOIs belong, in the 1870s. In the 1920s and 1930s, several research groups helped identify the enzyme monoamine oxidase (MAO), and showed that it is capable of metabolizing adrenaline through oxidation. In 1952, Albert Zeller demonstrated that iproniazid acts as an MAO inhibitor. The same year, physicians at Staten Island's Seaview Hospital observed that iproniazid had a more powerful stimulating effect than isoniazid in the patients they treated for tuberculosis. The first study of MAOI use in patients without tuberculosis was also presented at the APA meeting in 1957. The study showed substantial improvement of symptoms in 70 percent of a group of psychotically depressed patients taking iproniazid. By 1958, over 400,000 patients were being treated with iproniazid for depression, then marketed as Marsilid. The clinical use of iproniazid, however, was short-lived as reports of jaundice and hepatotoxicity accumulated, and in 1961 it was withdrawn from the US market.

While iproniazid was entering and leaving the market, pharmaceutical companies were developing several new MAOIs. Hydrazine derivatives similar to iproniazid included: isocarboxazid (Marplan), phenelzine (Nardil), nyalamide, mebanazine, and pheniprazine. Like iproniazid, many

of these agents showed hepatotoxicity and limited clinical use. In 1959, researchers discovered that tranylcypromine (Parnate), a cyclopropylamine structurally unrelated to the hydrazines, had MAOI action. Soon after its introduction, however, reports appeared of hypertensive crises and severe headaches associated, with subarachnoid intracranial hemorrhage. Barry Blackwell, a psychiatric resident at Maudsley Hospital in London, traced these effects back to ingestion of certain cheeses in patients taking MAOIs, thereafter known as the "cheese effect." Further investigation showed that food rich in amines, especially tyramine, could precipitate hypertensive crises in patients treated with MAOIs. Due to the concern for hemorrhage, tranylcypromine was briefly removed from the US market in 1964, only to be reintroduced a few months later after postmarketing analysis showed an incidence rate of less than 0.001 percent. Thereafter, all MAOIs included labeling to include precautions on adverse reactions and suggested dietary restrictions.

The first-generation MAOIs are irreversible inhibitors of MAO; they covalently bond to and inactivate the enzyme. After the discover of two isoforms of MAO, MAO-A and MAO-B (discussed in more detail later in this chapter), in the 1970s, researchers sought to synthesize MAOIs that would be reversible and selective inhibitors with fewer adverse effects. The use of platelets helped identify molecules selective for MAO-B, with evidence suggesting correlation between platelet MAO-B inhibition and antidepressant response to phenelzine. Pargyline was the first FDA-approved selective MAO-B inhibitor, although it did not show significant antidepressant effects in clinical trials and is no longer available. In 1972, researchers described L-deprenyl (Eldepryl), an irreversible but selective MAO-B inhibitor. However, in clinical trials L-deprenyl demonstrated antidepressant effect only at doses at which it loses its selectivity for MAO-B. This finding suggested that inhibition of MAO-A, alone or in combination with MAO-B inhibition, is necessary for antidepressant effect. Interestingly, experimental findings from the 1970s found L-deprenyl to be an effective adjunct to L-dopa in treatment of patients with Parkinson disease (PD). The FDA licensed the drug in 1996 and renamed it selegiline. Rasagiline (Azilect), with theoretically less adverse effects than selegiline, followed as another irreversible MAO-B inhibitor for use in PD.

Following the suggested association between MAO-A inhibition and antidepressive effects, researchers in 1979 identified clorgyline, an irreversible but selective MAO-A inhibitor. It proved effective for depression, but caused hypertensive crises as it irreversibly bound MAO in the gut. Moclobemide, initially developed for hyperlipidemia, became the first reversible and selective MAO-A inhibitor; it is currently available for use in depression in over 50 countries worldwide. Reversible inhibitors of monoamine oxidase type A (RIMA) are less likely to cause hypertensive crises because they are readily displaced by tyramine in the gut. There are

no RIMAs currently available in the United States (see Table 34.22–1 for MAOI drugs available worldwide). The five MAOIs currently available in the United States are isocarboxazid, phenelzine, tranylcypromine, selegiline, and rasagiline (Fig. 34.22–1).

CHEMISTRY

MAO is a flavoprotein enzyme system located on the outer mitochondrial membrane of both neurons and nonneuronal cells. In neurons, MAO metabolizes three major neurotransmitters: serotonin, dopamine, and norepinephrine. MAO also serves several other important roles, including the metabolism of trace amines in the brain, the peripheral inactivation of biogenic and dietary amines, phase I metabolism, and as an imidazoline

receptor.

MAO contains an intracellular active site that functions to metabolize amines through oxidation (Fig. 34.22–2). MAO transfers two hydrogen atoms to a flavin cofactor (FAD). The reduced flavin is reoxidized by oxygen producing hydrogen peroxide plus the imine, which spontaneously hydrolyzes to the aldehyde (or a substituted amine, in the case of secondary amines like adrenaline) plus ammonia. The aldehyde product is further metabolized for urine excretion.

MAO comes in two forms, MAO-A and MAO-B, encoded by separate genes on chromosome X, originally distinguished by their differing sensitivities to the inhibitors clorgyline and l-deprenyl. However, researchers did not publish structures of MOA-A and MAO-B (which share 70 percent DNA similarity) until 2005 and 2002, respectively.

Researchers have identified four polymorphisms in the gene coding for MAO-A as possible risk factors for psychiatric disorders. The most studied of these polymorphisms is MAO-A-uVNTR, which has been associated with depression in male patients, aggression and impulsivity levels, autism spectrum disorders, alcoholism and suicide attempts. Studies have also found polymorphisms in intron 13 and exon 14 of MAO-B to be associated with increased risk for PD.

In the central nervous system (CNS), both MAO-A and MAO-B serve to regulate the content of intracellular amine stores, terminate actions of amine neurotransmitters, and protect neurons from exogenous amines. In addition to MAO metabolism, neurotransmitter action may be terminated by catecholamine-o-methyl-transferase (COMT) or vesicular repackaging. Under normal conditions, neurotransmitters are preferentially stored in vesicles, where they are not exposed to MAO. As a result, MAO maintains low neurotransmitter concentration within the cytoplasm of neurons.

MAO-A preferentially deaminates serotonin and norepinephrine and predominates in catecholaminergic neurons in the substantia nigra, locus cerulerus, and periventricular regions of the hypothalamus. MAO-B preferentially deaminates phentylamine and benzylamine and predominates in serotonergic neurons in the dorsal raphe nucleus. Both forms metabolize dopamine, tyramine, and tryptamine. That MAO subtypes populate neurons with neurotransmitters of low affinity, suggests a role to prevent build-up of nonnative neurotransmitters.

In addition to the major monoamines, MAO also serves to metabolize other amines: phenylethanolamine, meta- and para-tyramine and octamine, which are found in the brain at lower levels and collectively known as trace amines. These trace amines can markedly affect uptake and release of catecholamines and serotonin at nerve endings. There has been increased research into the signaling roles of trace amines with the discovery of specific G-protein-coupled receptors for trace amines in the mammalian brain, which may help regulate activity of monoamine

transporters.

In the periphery, MAO serves to rapidly inactivate biogenic and dietary amines. The most well-known example is MAO-A's role in the intestinal tract. MAO-A inactivates ingested tyramine from the diet, preventing its release into the general circulation. When absorbed, tyramine causes significant release of norepinephrine for peripheral adrenergic neurons leading to vasoconstriction, increased heart rate, and elevated blood pressure. MAO also deactivates peripheral serotonin, epinephrine, and norepinephrine as it does in the CNS.

In addition to its role in amine regulation, MAO is involved in phase I metabolism of xenobiotics. Like the cytochrome P450 system, MAO can decrease bioactivity. For example, MAO-B in the liver oxidizes sertraline, citalopram, sumatriptan, and phenylephrine.

Finally, recent research has identified MAO as an imidazoline (I2) receptor (IR). The clinical relevance of this finding remains unclear, however there is some emerging evidence that it may play a role in depression. While IRs are found throughout the brain and on platelets, compounds that have I2-selectivity appear to allosterically inhibit both MAO isozymes, which may explain some anxiolytic and antidepressant effects seen in mice. Additionally, rat models show that chronic treatment with irreversible MAOIs reduces the density of I2 sites. Finally, studies found increased density of 45-kd I2 receptors in platelets of depressed patients and prefrontal cortices of suicide victims when compared to controls.

MECHANISM OF ACTION

The proposed mechanism of MAOIs efficacy in depression has evolved since their discovery and expanded with use in other neuropsychiatric disorders.

Several early observations led to the "catecholamine hypothesis" or "monoamine theory" of depression, including the effectiveness of MAOIs in depression, the nearly concurrent discovery of TCAs and their mechanism of norepinephrine reuptake inhibition, and reserpine's depressogenic effect via monoamine depletion. The theory postulates that depression in humans is caused by decreased levels of norepinephrine in the synaptic cleft, and that MAOIs alleviate depression by direct inhibition of MAO and an increase in catecholamines available within the synapse.

Monoamines, especially dopamine, serotonin and norepinephrine have long been known to play an important role in the behavioral regulation of mammals. For instance, in humans, low levels of amines in the brain are associated with hyperactivity and depression, and elevated amines are associated with risk-taking behavior. However, increased monoamine levels can be measured within hours after the first dose of an MAOI, while antidepressant effects take 2 to 4 weeks. Further studies suggest that secondary adaptations to long-term medication therapy may be responsible for the antidepressant effect including: reduced density of alpha-2, beta-adrenergic and 5-HT1 and 5-HT2 receptors; correction of hypothalamic–pituitary–adrenal (HPA) axis overactivation; increases in BDNF mediated signaling; and induction of hippocampal neurogenesis. There is also evidence that tranylcypromine at sufficiently high concentrations may act as a monoamine reuptake inhibitor and phenelzine may inhibit GABA transaminase, leading to increased levels of GABA within the brain.

Despite evidence questioning a simplistic monoamine deficiency model, recent imaging studies have renewed interest in the monoamine theory of depression. Researchers using positron emission tomography (PET) have shown increased MAO-A binding (suggesting decreased presence of monoamines) in the brains of medication-free patients during a major depressive episode compared with healthy controls. A follow-up study found that successful SSRI treatment did not result in normalization of MAO-A levels and that patients who experienced recurrent depressive episodes had increased MAO-A binding in the prefrontal cortex and anterior cingulate cortex compared to those who maintained remission. The authors go on to suggest an advanced monoamine model for depression that relies on chronic monoamine loss and associated changes as the primary mechanism.

As clinicians found use for selegiline in PD, researchers sought a mechanism of action different from that for depression. MAO activity is thought to have an important role in pathogenesis of PD. Postmortem studies have shown increased MAO-B activity in the substantia nigra in

patients with PD. It is postulated that heightened enzyme activity increases reactive oxygen species formed by metabolism of dopamine, leading to oxidative damage to neurons. Increased MAO-B activity also promotes aging of the brain by increasing hydrogen peroxide levels and activating other neurotoxins.

MAO-B inhibitors such as selegiline and rasagiline are thought to be effective for treating PD by enhancement of striatal dopamine activity, through antioxidation, and antiapoptotic activity. Chronic use of both selegiline and rasagiline has been shown to increase dopamine levels in rat striatum. The proposed mechanism is prevention of metabolism of B-phenylethylamine, a trace amine that stimulates release of dopamine and inhibits neuronal uptake. Selegiline and rasagiline may also protect neurons against damage from reactive oxygen species generated by hydrogen peroxide created by MAO-B metabolism of dopamine. Rasagiline may also possess added neuroprotective properties related to antiapoptotic pathways through activation of Bcl-2 and Bcl-X1 and preventing collapse of the mitochondrial membrane.

Finally, selegiline is metabolized to amphetamine compounds, which may explain its effectiveness in the treatment of attention deficit hyperactivity disorder (ADHD).

CLASSIFICATION

MAOIs may be classified according to chemical structure, reversibility, or selectivity (Table 34.22–1). Isocarboxazid and phenelzine are hydrazine compounds, containing a nitrogen–nitrogen pair on their side chain. All other MAOIs are classified as nonhydrazines. Irreversible MAOIs covalently bind to the enzyme, permanently inhibiting MAO function until new MAO can be produced, usually taking 2 to 3 weeks. Reversible MAOIs can be displaced by tyramine from the active site of MAO-B, allowing it to be metabolized. Tyramine is not present in high concentrations in the brain, and therefore does not inhibit MAOI effects on neurotransmitters. Nonselective MAOIs target both MAO-A and MAO-B, while selective MAOIs target a single isozyme.

Pharmacological Actions of Specific Agents

Tranylcypromine (Parnate). Tranylcypromine is Food and Drug Administration (FDA)-approved for use in major depressive episode without melancholia. Off-label uses include: other depressive disorders, panic disorder, social anxiety disorders, and post-traumatic stress disorder (PTSD).

PHARMACODYNAMICS

Mechanism of Action. Tranylcypromine is a irreversible and nonselective

nonhydrazine MAOI. It covalently binds to both MAO-A and MAO-B. Of note, as a nonhydrazine, its antidepressant effects tend to have more rapid onset.

PHARMACOKINETICS

Absorption. Tranylcypromine is readily absorbed from the GI tract.

Distribution. There is no clear data on distribution of tranylcypromine.

Metabolism and Elimination. Tranylcypromine has peak plasma concentrations 1 to 3 hours after ingestion. Its elimination half-life is 2.5 hours. Metabolites are excreted in the urine.

DOSING. Dosing generally starts at 10 mg twice a day (see Table 34.22–2). If there is no improvement within 2 to 3 weeks, then the dose can be increased by 10 mg every 2 to 3 weeks with a total maximum daily dose of 60 mg.

Tranylcypromine is contraindicated in patients with abnormal liver function tests, hepatic impairment, or a history of liver disease. Tranylcypromine is also contraindicated in patients with severe renal impairment. In patients with mild to moderate renal impairment, tranylcypromine should be used with caution due to the potential for accumulation of active metabolites.

Table 34.22–2.
Typical Dosage Forms and Recommended Dosages for Currently Available Monoamine Oxidase Inhibitors

Drug	Usual Dose (mg/day)	Maximum Dose (mg/day)	Dosage (Oral) Formulation
Tranylcypromine (Parnate)	20–60	60	10-mg tablets
Phenelzine (Nardil)	30–60	90	15-mg tablets
Isocarboxazid (Marplan)	20–40	60	10-mg tablets
Selegiline (Eldepryl)	10	30	5-mg tablets
Transdermal selegiline (Emsam)	6	12	6, 9 or 12 mg patch
Rasagiline	0.5–1.0	1.0	0.5- or 1.0-mg tablets

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

PREGNANCY AND LACTATION. Tranylcypromine is classified as FDA pregnancy risk category C. According to the manufacturer, tranylcypromine is excreted in human milk and the potential benefit of the drug should be weighed against the potential hazards to the mother and infant during breast-feeding.

COMMON ADVERSE EFFECTS. Agitation, anxiety, constipation, diarrhea, dizziness, headache, impotence, insomnia, loss of appetite, mania, nausea, orthostatic hypotension, somnolence, weight gain, and xerostomia.

Phenelzine. Phenelzine is FDA-approved for use in depressed patients clinically characterized as "atypical," "nonendogenous," or "neurotic." Off-label uses include: other depressive disorders, panic disorder, social anxiety disorder, and obsessive-compulsive disorder (OCD).

PHARMACODYNAMICS

Mechanism of Action. Phenelzine is an irreversible and nonselective hydrazine MAOI. It covalently bonds both MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Phenelzine is well-absorbed following oral administration.

Distribution. There is insufficient data on phenelzine's distribution.

Metabolism and Elimination. Peak levels are reached in approximately 2 to 4 hours. The mean half-life is approximately 12 hours. Phenelzine is eliminated in the urine as metabolites.

DOSAGE. Initial dosage of phenelzine is generally 15 mg two to three times per day. It may be increased rapidly, as tolerated, to a maximum dose of 30 mg three times a day. Many patients do not show response until treatment at 60 mg has been continued for at least 4 weeks. Historically, it has been recommended that after the maximum effect is achieved, the dosage should be slowly reduced to the lowest dose needed to maintain clinical effectiveness.

Due to the potential for drug accumulation and associated effects, phenelzine is not recommended in patients with hepatic disease or severe renal impairment.

PREGNANCY AND LACTATION. Phenelzine is classified as FDA pregnancy risk category C. According to the manufacturer, the safe use of phenelzine during breast-feeding has not been established, and the potential benefit of the drug should be weighed against the possible hazards to the mother and nursing infant.

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Constipation, disorder of ejaculation and/or orgasm, dizziness, edema, fatigue, headache, hyperreflexia, impotence, elevated values on liver function tests, orthostatic hypotension, sleep disorders, somnolence, tremor, weight gain, and xerostomia.

Isocarboxazid. Isocarboxazid is FDA-approved for use in major depressive disorder. Off-label use includes: panic disorder and social anxiety disorder.

PHARMACODYNAMICS

Mechanism of Action. Isocarboxazid is an irreversible and nonselective hydrazine MAOI. It covalently bonds both MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Isocarboxazid is readily absorbed from the GI tract.

Distribution. There is insufficient data on distribution of isocarboxazid.

Metabolism and Elimination. Isocarboxazid reaches peak plasma concentrations in 3 to 5 hours. The half-life is approximately 2.5 hours. It is metabolized by the liver and excreted as metabolites in the urine.

DOSAGE. Initial dose of isocarboxazid is 10 mg twice a day. The dose may be increased 10 mg daily up to maximum dosage of 60 mg total daily in divided doses. If therapeutic response is not seen in 3 to 6 weeks, it is unlikely to develop. After maximum benefit is achieved, the dose should be reduced to the lowest effective dose.

Isocarboxazid is not recommended in hepatic impairment or renal impairment.

PREGNANCY AND LACTATION. Isocarboxazid is classified as FDA pregnancy risk category C. According to the manufacturer, the amount of excretion of isocarboxazid and its metabolites in human milk have not been determined; therefore, isocarboxazid should only be used during breast-feeding if clearly needed.

MONITORING PARAMETERS. Complete metabolic panel at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Anxiety, blurred vision, constipation, dizziness, headache, insomnia, mania, somnolence, weight gain, and xerostomia.

Selegiline. Selegiline is FDA-approved for use in PD in combination with levodopa. Off label use includes: Alzheimer's disease, depression, and ADHD.

PHARMACODYNAMICS

Mechanism of Action. Selegiline is an irreversible and selective MAO inhibitor. At doses lower than 10 mg it covalently binds MAO-B. At doses above 10 mg it covalently binds both MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Selegiline is readily absorbed in the GI tract.

Distribution. Up to 85 percent of plasma selegiline is reversibly bound to proteins.

Metabolism and Elimination. Peak serum concentrations are found in 0.5 to 2 hours. At steady state, elimination half-life is approximately 10 hours. The drug is rapidly and completely metabolized to three active derivatives with the following half-lives: N-desmethyldeprenyl, 2 hours; 1-amphetamine, 17.7 hours; and 1-methamphetamine, 20.5 hours.

DOSAGE. Effective antidepressant doses of oral selegiline are not usually achieved unless doses in the range of 20 to 30 mg/day are used, at which point selegiline loses its selectivity and requires dietary monitoring

In PD, selegiline dosing is 5 mg after breakfast and 5 mg after lunch.

For ADHD, trials have used 2.5 mg twice a day for children under 5 years old, and 5 mg twice a day for children over 5 years old.

Specific guidelines for dosage adjustments of selegiline in hepatic impairment and renal impairment are not available.

PREGNANCY AND LACTATION. Selegiline is classified as FDA pregnancy risk category C. According to the manufacturer, it is unknown if selegiline is excreted into breast milk, and a decision should be made whether to discontinue the drug or discontinue breast-feeding, taking into account the importance of the drug to the mother.

MONITORING PARAMETERS. None.

COMMON ADVERSE EFFECTS. Nausea, dizziness, and insomnia.

Transdermal Selegiline. Transdermal selegiline is FDA- approved for use in major depressive disorder.

PHARMACODYNAMICS

Mechanism of Action. Transdermal selegiline is an irreversible and selective MAOI. At doses less than 6 mg it covalently binds MAO-B only. At doses above 9 mg it covalently binds MAO-A and MAO-B.

PHARMACOKINETICS

Absorption. Approximately 23 to 30 percent of the medication is absorbed through the skin over 24 hours.

Distribution. Once absorbed it is 90 percent protein bound, rapidly distributed throughout the body, and crosses the blood–brain barrier. Transdermal administration avoids first-pass metabolism and results in

much higher bioavailability (74 percent) compared to the oral form (4 percent).

Metabolism and Elimination. Selegiline is metabolized via N-dealkylation or N-depropargylation by several CYP450 enzymes (2A6, 2B6, 2C9, 3A4, and 3A5). Under steady-state conditions, the median elimination half-life increases to 10 hours. The half-life is approximately 18 to 25 hours. The final metabolites are methamphetamine and amphetamine, which are excreted in urine.

DOSAGE. Initial dose is 6 mg/24 hr. Although maximum dose is 12 mg, there is little evidence for doses above 6 mg. If clinically indicated, dose increases should be made in 3 mg increments every 2 to 3 weeks. In elderly patients, the recommended dose is 6 mg per 24 hours. At dose above 9 mg, the manufacturer suggests following a diet modified for reduced tyramine intake.

Dose adjustments for transdermal selegiline are not needed in patients with mild to moderate hepatic impairment or any degree of renal impairment.

PREGNANCY AND LACTATION. Transdermal selegiline is classified as FDA pregnancy risk category C. According to the manufacturer, it is not known if transdermal selegiline is excreted into human milk, and caution is advisable if administering selegiline to a nursing woman.

MONITORING PARAMETERS. None.

COMMON ADVERSE EFFECTS. Application site reaction, decreased systolic blood pressure, diarrhea, headache, indigestion, insomnia, orthostatic hypotension, weight loss, and xerostomia.

Rasagiline. Rasagiline is FDA-approved for use in PD as monotherapy or an adjunct to levodopa.

PHARMACODYNAMICS

Mechanism of Action. Rasagiline is an irreversible and selective MAOI. It covalently binds MAO-B.

PHARMACOKINETICS

Absorption. Rasagiline is rapidly absorbed and reaches peak levels in 1 hour.

Distribution. Plasma protein binding ranges from 88 to 94 percent.

Metabolism and Elimination. Rasagiline is metabolized by the cytochrome P450 system in the liver, predominately CYP1A2, and is mainly excreted via

urine.

DOSING. For monotherapy in PD, rasagiline may be started at 1 mg daily. In patients taking levodopa, the recommended initial dose is 0.5 mg daily, which if tolerated, may be increased to 1 mg daily if needed.

In patients taking a CYP1A2 inhibitor such as ciprofloxacin, dosages should not exceed 0.5 mg daily.

In patients with mild hepatic impairment, dosage should not exceed 0.5 mg daily and it should not be used in patients with moderate or severe hepatic impairment.

No dose adjustment is required for patients with mild or moderate renal impairment and it has not been studied in patients with severe renal impairment.

At recommended doses, rasagiline retains MAO-B selectivity and although the manufacturer does not recommend dietary restrictions, it suggests foods with high tyramine content may cause hypertensive cries.

PREGNANCY AND LACTATION. Rasagiline is pregnancy category C and there are no adequate studies of use of the medication in pregnant women. It is not known whether rasagiline is excreted in human milk.

MONITORING PARAMETERS. Liver function test at baseline, 1 and 3 months.

COMMON ADVERSE EFFECTS. Weight loss, orthostatic or postural hypotension, dry mouth, abnormal involuntary movements, and hallucinations.

Drug Level Monitoring

MAOI plasma levels may be measured but there is little evidence that levels correspond to treatment response and may be difficult to interpret given the short half life of MAOIs.

There is evidence that platelet MAO inhibition is a predictor of response, however its use is not recommended. Several studies have shown that patients taking phenelzine who have more than 80 percent platelet MAO inhibition after 2 weeks of treatment show higher response rates. However, researchers point out the moderate effect size means that this accounts for only 9 to 16 percent of treatment outcomes. MAO-B platelet inhibition is most likely an epiphenomenon as it has been shown in studies of selegiline that 100 percent inhibition can occur in the absence of antidepressant effects.

Laboratory Interference

Laboratory interference is not a major problem with use of MAOIs. They may lower blood glucose values. They have also been associated with a

minimal false elevation in thyroid function test results.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System

Commonly reported CNS effects include: dizziness, headache, drowsiness, sleep disturbance, fatigue, weakness, twitching, myoclonus, and hyperreflexia. Uncommon but serious CNS effects include: ataxia, shock-like coma, toxic delirium, acute anxiety reaction, psychosis, transient respiratory and cardiovascular depression following electroconvulsive therapy, confusion, memory impairment, hypomania, and mania. Rasagiline may cause increased impulsive or compulsive behaviors such as gambling, sexual activity, and binge eating.

Cardiovascular

Common side effects include: orthostatic and postural hypotension, syncope, palpitations, and tachycardia.

Skin

Adverse dermatological effects include rash, pruritus, and hyperhidrosis. Rasagiline may increase risk for melanoma and regular screening is recommended.

Gastrointestinal

Commonly reported GI effects include: constipation, diarrhea, nausea, xerostomia, and elevated hepatic enzymes. Severe but less frequent events include glottis edema, progressing necrotizing hepatocellular damage, and reversible jaundice, the last two more likely with hydrazine derivatives.

Genitourinary

Common urinary symptoms include urinary retention and hesitancy. Commonly reported sexual side effects include impotence, ejaculation dysfunction, and anorgasmia. Clinical experience shows less sexual side effects with tranylcypromine. There have been case reports of priapism in patients taking phenelzine. Impaired water excretion compatible with syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been associated with antidepressant use.

Optic

Glaucoma and blurred vision have been infrequently reported.

Hematologic

There are reports of rare occurrences of anemia, leukopenia, agranulocytosis, and thrombocytopenia.

Table 34.22–3.
Relative Restrictions in Food and Beverages with Irreversible MAOI Use

Restriction	Foods
Absolute (high risk)	Aged cheeses; aged and cured meats; banana peel; broad bean pods; improperly stored or spoiled meats, poultry or fish; Marmite; sauerkraut; soy sauce and soybean condiments; tap beer
Moderate (moderate risk)	Red or white wine; bottle or canned beer
Unnecessary (low to no risk)	Avocados; bananas; beef/chicken bouillon; chocolate; fresh and mild cheeses; fresh meat, poultry and fish; gravy; monosodium glutamate; peanuts; properly stored pickled or smoked fish; soy milk; yeast extracts other than Marmite

Neurologic

Tremor is a commonly reported side effect of phenelzine. Peripheral neuropathy, sometimes associated with a pyridoxine deficiency, has been reported in patients receiving phenelzine. There are case reports that suggest an association between MAOI use and pseudoparkinsonism with symptoms of bradykinesia, tremor, cogwheel rigidity, and dysarthria.

WARNINGS AND PRECAUTIONS

Food-Drug Interactions

Nonselective and irreversible MAOIs, when combined with food rich in tyramine, can cause increased release of catecholamines, resulting in hypertensive crisis characterized by an occipital headache, palpitations, nausea, vomiting, diaphoresis, and tachycardia. Severe reactions can lead to cardiac arrhythmias, stroke, and intracranial hemorrhage. Prior to recommendations on dietary restrictions, rates of hypertensive reactions were estimated to occur in 2.4 to 25 percent of patients treated with MAOIs.

After observation of hypertensive reactions in the 1960s, clinical use of MAOIs dropped dramatically. At the height of concern over drug–food interactions, more than 70 different types of food and beverages were on the list of foods to be avoided. However, over the past 20 years, critical review of reports of adverse effects and analysis of tyramine levels in food and beverages has refined the list of dietary restrictions (Table 34.22–3).

Drug–Drug Interactions

Hypertensive Crisis. In addition to tyramine-induced hypertensive crises, there are similar dangers in drug–drug interactions. Any medication

that increases adrenergic stimulation by a mechanism other than MAO inhibition can lead to hypertensive crisis (Table 34.22–4). The list includes decongestants that contain alpha-1 agonists, stimulants that increase release of norepinephrine, antidepressants that block norepinephrine reuptake, and appetite suppressants and analgesics with norepinephrine-reuptake inhibition.

Serotonin Syndrome. Concomitant administration of serotonergic agents with MAOIs, especially those with MAO-A inhibition, can result in dangerous levels of serotonin leading to serotonin syndrome. Increased activation at postsynaptic serotonin receptors causes a disruption in thermoregulation leading to a syndrome of fever, altered mental status, myoclonus, diaphoresis, and diarrhea. In extreme cases symptoms may include hypothermia, seizures, coma, cardiovascular collapse, permanent brain damage, and death. MAOIs should not be prescribed in combination with SSRIs, SNRIs, TCAs, certain narcotics, and other medications with serotonergic properties (Table 34.22–5).

Table 34.22–4.
Medications Contraindicated with MAOI Use due to Risk of Hypertensive Crisis

Decongestants: phenylephrine, oxymetazoline, ephedrine, pseudoephedrine, phenylpropanolamine
Stimulants: methylphenidate, amphetamines
Antidepressants: SSRIs, SNRIs, TCAs, bupropion, buspirone
Appetite suppressants: sibutramine, phentermine
Analgesics: tramadol
Centrally acting antihypertensives: guanethidine, methyldopa
Antiparkinson agents: levodopa

Table 34.22–5.
Medications Contraindicated with MAOI Use due to Risk for Serotonin Syndrome

Antidepressants: SSRIs, SNRIs, TCAs
Other TCAs: cyclobenzaprine, carbamazepine
Appetite suppressant: sibutramine
Cough suppressant: dextromethorphan
Opioids: meperidine, tramadol, methadone, propoxyphene
Antihistamines: chlorpheniramine, brompheniramine

In addition, care must be taken when changing antidepressants to or from MAOIs. A washout period of 2 weeks is required for all SSRIs prior to starting an MAOI, except for fluoxetine, which due to its long half-life, requires a 5-week washout period. A 2- to 4-week waiting period is also

required when switching from an MAOI to another antidepressant or when discontinuing an MAOI prior to ending the restricted diet. The selegiline patch loses its selectivity at higher doses, so the manufacturer recommends dietary restrictions with doses of 9 mg or higher and for 2 weeks following any discontinuation.

Weight Gain

In a retrospective review, weight gain occurred in 35.7 percent of patients taking phenelzine and 10.5 percent taking tranylcypromine.

Orthostatic Hypotension

All nonselective MAOIs may reduce blood pressure, likely due to central alpha-adrenergic agonist effects of increased norepinephrine levels. Rates of orthostasis may be higher in phenelzine. Hypotension usually develops gradually over first 2 to 3 weeks of treatment and correlates with peak plasma levels. The side effect may be reduced with divided dosing and resolves hours to days after discontinuation.

Insomnia

MAOIs, especially tranylcypromine, are associated with insomnia. MAOIs are known to reduce the time spent in REM sleep. Transdermal selegiline also shows this side effect in a dose-dependent relationship. Insomnia may be alleviated by avoiding evening dosing.

Application Site Reaction

The most common side effect to transdermal selegiline is an application site reaction, which occurs in a dose-dependent relationship, and occurs in 24 percent of patients.

Hepatotoxicity

Postmarketing monitoring showed increased risk for hepatotoxicity for hydrazine (isocarboxazid and phenelzine) MAOIs compared to the nonhydrazine (tranylcypromine). However absolute risk appears to be low (less than 1 in 30,000).

Psychosis

The combination of MAOIs and dextromethorphan has been reported to cause brief episodes of psychosis and bizarre behavior.

Overdose

Signs and symptoms of overdose include: dilated pupils, fever, diaphoresis, drowsiness, agitation, headache, hallucinations, trismus, opisthotonos,

seizures, coma, fever, tachycardia, hypertension, hypotension, respiratory depression/failure, shock, and death. Signs and symptoms may be absent or minimal during the initial 12-hour period following ingestion and may develop slowly, reaching a maximum in 24 to 48 hours. In some cases, symptoms may persist for 8 to 14 days. Disseminated intravascular coagulation, rhabdomyolysis, and acute tubular necrosis can also occur. Treatment of overdose is mainly supportive. Inducing vomiting or gastric lavage with charcoal may be helpful in early poisoning.

Withdrawal

Common withdrawal symptoms include nausea, vomiting, and malaise. Abrupt withdrawal for patients on long-term treatment with MAOIs can result in a withdrawal syndrome characterized by increased arousal, mood disturbance, psychosis, and convulsions within 24 to 72 hours after drug discontinuation.

Contraindications

Contraindications to MAOI use include cardiac disease, cerebrovascular disease, hypertension, headache, hepatic disease, pheochromocytoma, renal disease, and general anesthesia with certain opioid analgesics.

THERAPEUTIC INDICATIONS AND CLINICAL DRUG STUDIES

A significant number of studies on MAOIs occurred prior to publication of DSM-II, making interpretation difficult. Reviewed here are studies with clear inclusion criteria, and when possible, a control group. Limitations are noted where they arise. Meta-analyses are generally not used as they usually include RIMA studies. Evidence for efficacy of MAOIs that are not available in the United States, most notably moclobemide and brofaromine, is not discussed.

MAOIs were first used psychiatrically to treat patients with depression. However, given concerns over efficacy, side effects, drug–drug interactions, and dietary restrictions, MAOIs as a class generally fell out of favor. SSRIs have largely replaced MAOIs for psychiatric use. MAOIs are most commonly prescribed for atypical major depressive disorder and treatment-resistant depression. Less common uses include typical major depressive disorder, psychotic depression, dysthymia, bipolar depression, seasonal affective disorder, borderline personality disorder (BPD), eating disorders, social anxiety disorder, panic disorder, obsessive-compulsive disorder, and ADHD. Selective MAO-B inhibitors are used regularly in treatment of PD and Alzheimer disease (AD).

Atypical Depression

Early observations on groups of depressed patients who responded to

MAOIs but not to TCAs sparked interest in identifying the characteristics of this subset of depressed patients. Studies reported that these "atypical" patients had depressed mood with anxiety and phobia or reactive mood with reversed vegetative symptoms. Subsequent controlled trials by a group at Columbia codified patients with atypical features of depression, defining criteria as reactive mood plus at least two of four associated features: hyperphagia, hypersomnolence, leaden paralysis, and sensitivity to rejection. They also identified a second group characterized by depression plus panic attacks for which MAOIs also appeared to show advantage of TCAs. However replication studies by the same group failed to show a difference between MAOIs and TCAs in mixed depressive/anxiety states.

Acute Treatment. The Columbia group summarized their findings in a 1993 paper. From data of 269 patients, they compared response rates on Clinical Global Improvement scales for patients taking phenelzine (72 percent), imipramine (44 percent), and placebo (26 percent). They concluded that rather than enhanced response to MAOIs patients with atypical depression show substandard response to TCAs. Through stratification, they also demonstrated that presence of anxiety symptoms did not factor into response rates, despite previous suggestions of superior MAOI response in depression with anxiety.

Since that review, two controlled studies have been published, one comparing MAOI to cognitive-behavior therapy (CBT) and another to an SSRI. A 1999 study randomized patients with atypical depression to phenelzine, CBT, or placebo for 10 weeks. Response rates for phenelzine (58 percent) and CBT (58 percent) were equivalent to each other and superior to placebo (28 percent). Analysis found similar results for reduction in Hamilton Rating Scale for Depression (HAM-D) scores. Patients taking phenelzine had higher rates of marked side effects (92 percent) compared to placebo (53 percent).

The only trial that has compared an MAOI available in the United States to an SSRI is a randomized, double-blind, non–placebo controlled trial comparing fluoxetine and phenelzine. Forty patients with atypical depression randomized to fluoxetine or phenelzine showed no difference in response (80 percent vs. 85 percent) or remission (80 percent vs. 70 percent). The only patient who dropped out due to an adverse effect (confusion) was taking phenelzine. Dizziness, asthenia, arthralgias, somnolence, and blood pressure changes were more common in phenelzine group. Tremor and weight gain were more common in the fluoxetine group.

Maintenance Treatment. In addition to acute atypical depression treatment, there is one long-term study of relapse prevention in atypical depression. In this study, 60 patients who had improved with phenelzine or imipramine over 6 months were randomly assigned to same medication or

placebo for an additional 6 months. Recurrence rates were 23 percent for those receiving phenelzine, 41 percent for imipramine, 47 percent for those who switched from imipramine to placebo, and 87 percent for those who switched from phenelzine to placebo.

Treatment-Resistant Depression

Recently, the use of MAOIs in typical depression has been limited to treatment-resistant depression (TRD). Most controlled trials have focused on tranylcypromine after early case studies found benefit from tranylcypromine for patients with TCA-refractory depression. Response rates in these trials vary greatly, which may reflect the difficulty in defining this group, and it is a challenge to make firm conclusions about specific advantages to MAOIs in TRD.

In a 1988 study, 21 patients with major depressive disorder who had not responded to oxaprotiline of fluvoxamine were randomized to tranylcypromine or nomifensine. Compared to the nomifensine group, the tranylcypromine group showed statistically superiority in reduction on HAM-D scores but not response rate (45 percent vs. 10 percent) at 4 weeks.

A 1993 study compared brofaromine and tranylcypromine in 39 patients with major depressive disorder who had previously not responded to 4 weeks of maprotiline or nortriptyline. Of note, 12 patients had psychotic features and 23 melancholic features. There were no difference in response rates for brofaromine (45.5, 59.1 percent) and tranylcypromine (52.9, 58.9 percent) as measured by Hamilton Depression Subscale and Clinical Global Improvement, respectively. Melancholic features did not predict response. Brofaromine was better tolerated.

A second study in 1993 also compared brofaromine and tranylcypromine. In this case, 93 inpatients who had failed two classes of antidepressants were treated for 6 weeks. There were no differences between the two groups on reduction in HAM-D scores or response rates (nearly 74 percent for both groups). There were no differences in tolerability.

A 38-year-old divorced mother of two teenage daughters presented at the Mood Disorders Clinic with a history of failed antidepressant treatment trials. Two years earlier, she had become increasingly irritable, exhausted, and tearful after the breakup of her marriage. She could not tolerate fluoxetine (Prozac) or sertraline and discontinued each of these SSRIs after only a few days because of GI symptoms. Although she could tolerate desipramine (Norpramin) up to 300 mg daily, she felt no benefit after 4 months and was reluctant to continue this TCA medication because of adverse effects (weight gain and sweating, in particular). Because of her increasing fatigue, increasing sleep needs, and generally atypical profile, she was offered a trial of phenelzine. After 4 weeks, at a dosage of 60 mg daily, she reported significant improvement in her energy level, mood, and sleep pattern. Two years later, she continues to take 45 mg of phenelzine daily with some adverse effects (occasional insomnia and anorgasmia).

A 2004 study enrolled 77 patients who had failed either of two phases: (1) a double-blind randomized trial of imipramine or fluvoxamine, followed by augmentation with lithium or (2) an open trial with a TCA. They were randomized to either tranylcypromine or phenelzine for 5 weeks. Results showed no difference in response rate between tranylcypromine (44 percent) and phenelzine (47 percent) or remission rates (18 and 11 percent, respectively). About 21 percent of patients reported "severe" side effects including dizziness, agitation, and insomnia, though there were no differences between the two groups.

Level 4 of the STAR*D trial compared tranylcypromine versus extended-release venlafaxine plus mirtazapine in 109 patients who had not responded to three prior medication trials. The results showed no difference in response (13.8 percent vs. 15.7 percent) or remission (6.9 percent vs. 13.7 percent) between the two groups. Patients in the tranylcypromine group were more likely to exit the study (41.4 percent vs. 21.6 percent) and almost half had less than 6 weeks of treatment, suggesting that MAOI treatment may less tolerable than other antidepressant treatment. However, patients did not differ in ratings on side effect burden scales. Critics of the study point out that average tranylcypromine levels were only 36.9 mg, less than in similar studies, and may explain the lower response rates.

Finally, a crossover study compared selegiline to placebo in 16 treatment-resistant (failed at least two clinical trials of antidepressant) older patients with depression. Patients received selegiline 60 mg or placebo in two 3-week phases. During the active treatment phase, patients showed significant improvement in HAM-D scores. Overall 8 of 16 patients responded to treatment. Responders were more likely to be older, less depressed, less anxious, and more cognitively intact. Researchers also performed cognitive tests and with no changes during active treatment. There were no differences in side effect rates in each group.

Major Depressive Disorder

Early clinical observation, suggested that MAOIs tend to be more effective than TCAs in treatment of atypical depression and less effective than TCAs in melancholic or endogenous depressions. A particularly large and influential early study from the United Kingdom showed phenelzine 45 mg to be marginally inferior to placebo in a group of depressed inpatients of unspecified type. Subsequent trials with higher doses showed more equivalent efficacy for MAOIs to TCAs in treatment of endogenous or melancholic depression. Discussed here are trials investigating groups of patients with unspecified type of major depressive disorder or endogenous/melancholic subtype. Of note, there are no trials comparing MAOIs available in the United States with second-generation antidepressants.

Acute Treatment. Early studies of MAOI use in depression were characterized by limited size, short duration, and low dosages. A 1960 study crossed over 25 moderately or severely endogenously depressed patients to receive phenelzine 45 mg or placebo for 2 weeks each. Improvement rates were significantly higher for the second phenelzine group compare to placebo, but not the first. In a 1961 study, 21 consecutively admitted patients diagnosed with depression (13 with endogenous type) were given phenelzine or placebo for 3 weeks and then switched. On a seven-point improvement scale, a higher proportion of patients showed "complete recovery" or "marked improvement" in the phenelzine (50 percent) group versus placebo (15 percent). Fifty-three percent of endogenous depressed patients improved or remitted.

Later trials appear to show equivalence for acute depression, in endogenous or mixed groups, when comparing MAOIs to TCAs, without clear evidence of difference in side-effect burden. In 1981, researchers randomized 49 inpatients diagnosed with depression (33 nonendogenous) to phenelzine or imipramine for 3 weeks after a 1-week placebo-response period. Both groups showed an equal and statistically significant response as measured by the HAM-D. There was no subgroup analysis.

A 1986 study of 75 depressed patients over age 55 compared phenelzine and nortriptyline to placebo. Response rates found phenelzine and nortriptyline superior to placebo (59.1 percent vs. 60.0 percent vs. 10.7 percent) as measured by HAM-D. A majority of patients in each group had endogenous subtype but a subgroup analysis was not performed. Of note, only two patients from each active arm dropped out of the study due to side effects.

A 1987 paper investigated use of phenelzine or imipramine for 6 weeks after a 1-week placebo-response period in 83 patients with a diagnosis of major depression with melancholia or dysthymic disorder. In subgroup analysis for melancholia, reduction in scores on the HAM-D did not differ between phenelzine (58.2 percent) and imipramine (71.4 percent) treatment. Side effects were not reported.

Finally, two short-term studies established the efficacy of transdermal selegiline for major depressive disorder. A 6-week trial of 6 mg versus placebo showed significant results (9 vs. 6.5 point change on the HAM-D) and an 8-week trial with doses from 6 to 12 mg also showed significant changes (10.9 vs. 8.6 point changes on HAM-D). Oral selegiline has been found to be effective in treating depression only at doses higher than 20 mg daily, a dose where selective enzyme inhibition is lost, and tyramine-restricted diet required.

Maintenance Treatment. Few studies have investigated long-term use of MAOIs for the prevention of recurrent depressive episodes.

A 1991 study looked at maintenance on phenelzine versus placebo. After

acute unblinded treatment with phenelzine, responders were entered into a 16-week continuation phase followed by double-blind randomization to phenelzine 60 mg, phenelzine 45 mg or placebo for a 2-year maintenance phase. Forty-seven patients entered the maintenance phase. Both phenelzine doses showed significant protection against relapse within 3 months but not against recurrence (symptom onset beyond 3 months of continuation of treatment). Generalization from this study is limited as 36 percent of patients who initially responded to treatment discontinued during continuation therapy prior to enrollment in maintenance phase.

Fifty-two adults over 55 years old with depression who had responded to acute treatment with phenelzine or nortriptyline in the 1986 study were randomized to maintenance on the study drug or tapered to placebo. Results showed significantly less recurrence for patients taking phenelzine (13.3 percent) versus nortriptyline (53.8 percent) and placebo (65.2 percent) over 1 year. The phenelzine group had the only two dropouts due to side effects.

A 52-week study investigated relapse rates for 322 patients who had responded to acute treatment with transdermal selegiline 6 mg daily, who were randomized to continued treatment or placebo. Significantly fewer patients on transdermal selegiline (16.8 percent) relapsed compared to placebo (30.7 percent).

Psychotic Depression

It is unclear that patients diagnosed with psychotic depression in early trials would meet contemporary criteria, and these early trials found no efficacy for MAOIs in treatment of psychotic depression. There are no controlled studies. The only recent study is, an open-label trial examining use of phenelzine in depressed inpatients. The researchers classified patients into three groups: definitely psychotic, probably psychotic, and nonpsychotic. Response rates were 22, 43, and 68 percent, respectively. This inpatient study showed increased effectiveness for phenelzine in nonpsychotic versus psychotic patients. MAOIs are not usually considered for this indication.

Dysthymia

There is limited evidence for the use of phenelzine in dysthymic disorder. Three prospective studies have investigated the use of MAOIs for dysthymia, but only one used an MAOI available in the United States. A 1993 study comparing phenelzine to imipramine in dysthymic disorders over 6 weeks found superior response in the phenelzine group when measured by response on the HAM-D.

A retrospective analysis by the Columbia group studying atypical depression identified 37 patients meeting DSM-III criteria for dysthymic

disorder. The researchers found response rates of 22, 50, and 17 percent for phenelzine, imipramine, and placebo, respectively. However this study was limited by a small number of subjects, short duration of only 6 weeks for a chronic illness, and exclusion of patients with melancholic features. The same group found in a pooled group analysis that phenelzine was more effective than imipramine and placebo (83 percent vs. 45 percent vs. 21 percent) in double depression.

Bipolar Depression

There are three positive prospective studies for MAOI use in bipolar depression, one negative prospective study and one positive retrospective analysis.

A 1982 study on "anergic" depression, defined as depressed mood with motor retardation, fatigue, volitional inhibition, and reversed neurovegetative features, included 59 patients, 29 of which met criteria for bipolar disorder. The other 30 were classified as "pseudounipolar" or "borderline syndromes." Researchers randomized patients to tranylcypromine or placebo. They did not report subgroup analysis. Twenty of twenty-four patients on an active drug responded and only 4 of 31 on placebo. The same group, in 1991, conducted a double-blind study comparing tranylcypromine to imipramine for patients with anergic bipolar depression. Fifty-six patients were treated with either tranylcypromine or imipramine without a mood stabilizer over 6-week acute treatment phase and 10-week maintenance phase. Tranylcypromine outperformed imipramine in acute response (81 percent vs. 48 percent) and in sustained response (71 percent vs. 20 percent). Of note, 21 percent of tranylcypromine and 25 percent of imipramine patients developed mania or hypomania. Significantly more (7 vs. 2) patients taking imipramine dropped out than those taking tranylcypromine. They also conducted a crossover trial involving 16 patients who did not respond to original treatment. Nine of twelve patients who failed imipramine responded to tranylcypromine and had categorical improvement at similar rates to the original tranylcypromine group (75 and 81 percent). Two developed hypomania. Only one of four patients who crossed over to imipramine responded; two withdrew due to side effects and the other withdrew due to a mixed state.

The other prospective trial for bipolar disorder failed. Researchers compared tranylcypromine to lamotrigine in patients with bipolar depression who had previously failed a 6-week trial with an SSRI, TCA, venlafaxine, or bupropion added to an adequate dose of mood stabilizer. This study was severely limited by the number enrolled (20) and the number completed (11). However response, rates, though not statistically significant partly due to the small power of the study, were consistent with the response rates of trials discussed above: 62.5 percent for

tranylcypromine and 36 percent for lamotrigine. Two patients in the lamotrigine group developed mania.

Finally, a retrospective analysis of data from the Maintenance Therapies in Bipolar Disorder (MTBD) study compared the addition of MAOIs or paroxetine in 52 patients with bipolar depression who had already failed to respond on a mood stabilizer alone (usually lithium). Rates of durable recovery (defined as a period of 8 weeks of euthymia starting within the first 16 weeks of treatment) were significantly higher in the MAOI group (70 percent) versus the paroxetine group (33 percent). The authors did not report adverse events.

Seasonal Affective Disorder

In the only study of an MAOI for treatment of seasonal affective disorder, an open trial of tranylcypromine showed remission in 12 of 14 patients treated for "winter depression" as defined by the National Institute of Mental Health (NIMH).

Borderline Personality Disorder

Given overlapping symptoms with atypical depression, there has been some interest in the study of MAOIs for BPD. However only two prospective trials and a reanalysis have been completed. Overall there is weak evidence for use of MAOIs in BPD. The two prospective and one retrospective trial showed improvement on nonspecific or subscales only, without improvement on core borderline personality symptoms.

A 1988 placebo-controlled crossover study investigated four medications for the treatment of BPD: alprazolam, carbamazepine, trifluoperazine, and tranylcypromine. The study assigned 16 patients to complete 6-week trials of each medication. Completion rates were low, an average of 55 percent per arm. Tranylcypromine showed statistically significant improvement compared to placebo when measured by CGI, depression and anxiety subscales, but not on anger, rejection resistivity, impulsivity, suicidality, or behavioral dyscontrol. Tranylcypromine showed a nonsignificant trend toward increased number of physical side effects. The study is limited by its crossover design, short duration, and number of completers.

The second prospective trial, a 1993 study, compared phenelzine and haloperidol to placebo in 108 consecutively admitted patients with BPD over 5 weeks. Phenelzine was superior to placebo on a hostility rating scale but no difference was found on the Borderline Syndrome index, depression, atypical depression, anxiety, or anger scales. A follow-up paper described patients continuing on treatment for an additional 16 weeks. Results found phenelzine to be superior to haloperidol and placebo only on depression and irritability subscales.

Finally, the Columbia group reanalyzed data from their study on treatment of atypical depression with phenelzine, imipramine, or placebo. Diagnosis of comorbid BPD was made with a checklist. They found response rates on CGI for this group of phenelzine (89 percent), imipramine (38 percent), and placebo (20 percent). However, the measures did not include scales for borderline personality symptoms specifically.

Eating Disorders

Two controlled trials and a reanalysis have found efficacy of phenelzine and isocarboxazid in bulimia nervosa. Despite concerns about adherence to diet, the studies reported no hypertensive crises. There are no controlled trials of MAOI use in anorexia nervosa or binge eating disorder.

A 1986 crossover study compared isocarboxazid to placebo over 12 weeks in patients with bulimia nervosa. Isocarboxazid significantly decreased the number of binge episodes (7.0 to 2.8) compared to placebo (7.5 to 4.5). There were no adverse food or drug interactions but 40 percent experienced insomnia or hypotension.

A 1987 study enrolled 82 patients with bulimia to receive phenelzine or placebo over 8 weeks following a 2-week placebo washout phase. Twenty dropped out before randomization and another 12 did not complete at least 2 weeks of treatment. Although number of binges per week at study end did not differ between the two groups, the phenelzine group showed statistically significant reduction in change in binge frequency (64 percent) versus placebo (5 percent). A covariate analysis showed that this response was not related to antidepressant effects. Nine of thirty-one patients taking phenelzine did not complete the 8-week trial due to side effects. There were no reports of hypertensive crisis.

Finally, the Columbia group reanalyzed their data on treatment with phenelzine, imipramine, or placebo for atypical depression. They identified 24 patients who met criteria for comorbid bulimia. The study is limited by outcome measures that relied chart review for notes indicating at least a 50 percent reduction in bingeing and purging and the overeating question on the Hopkins Symptoms Checklist (SCL-90). Phenelzine was found to be statistically superior to both imipramine and placebo on both endpoints.

Posttraumatic Stress Disorder

There are two controlled trials, one positive and one negative, of MAOI use for PTSD. A 1987 study enrolled 13 patients with PTSD in a double-blind crossover trial comparing phenelzine and placebo. Response to phenelzine and placebo did not differ as measured by either PTSD Scale or Impact of Events Scale. Only 10 patients completed treatment and each phase lasted only 5 weeks. A second trial compared phenelzine and imipramine to placebo. At 8-week follow-up, phenelzine showed superiority to both

imipramine and placebo on the Impact of Events Scale, with 45, 25, and 5 percent reductions, respectively. Of note, PTSD was combat-related for all patients in this trial.

Social Anxiety Disorder

Until the introduction of SSRIs, MAOIs were widely considered to be the most effective medication for the treatment of social anxiety disorder. Four of five controlled trials have found positive results for use of phenelzine in social anxiety disorder or social phobia.

In a 1992 study, 74 patients with social phobia were randomized to phenelzine, atenolol, or placebo for 8 weeks. Response rates for phenelzine (64 percent) were statistically higher than atenolol (30 percent) and placebo (20 percent).

A study compared phenelzine and moclobemide to placebo over three 8-week phases. At week 8, both phenelzine and moclobemide showed statistically superior results compared to placebo on the Social Phobia Scale. During the next 8 weeks, mean scores continued to improve in both active treatments with no difference between the two with remittance rates of phenelzine (91 percent), moclobemide (82 percent), and placebo (43 percent). Finally in the last phase during which patients were randomized to continue active treatment or switch to placebo, relapse rates were significantly higher for those switched from either group to placebo. Finally, the phenelzine group showed highest side effect rates and had two severe adverse events, urinary retention and hypertensive crisis, that led to discontinuation of treatment.

The negative result came in a 1991 study that randomized 65 patients with social phobia to weekly cognitive-behavioral group therapy (CBGT) or alprazolam, phenelzine, or placebo with instruction for self-exposure to phobic stimuli for 12 weeks. On self-rating scales of social avoidance, no difference was found between groups. On physician-rated Work and Social Disability Scale, phenelzine and alprazolam were found to be superior to placebo (CBGT was not included as it could not be blinded).

Two more studies compared phenelzine to CBGT. A 1998 study randomized 133 patients with social phobia to CBGT, phenelzine, placebo, or education-supportive group therapy (ES) over 12 weeks. Independent ratings on the Social Phobic Disorders Severity and Change Form found response rates to be statistically significant for phenelzine (65 percent) and CBGT (58 percent) compared to placebo (33 percent) and ES (27 percent). On self-report measures, phenelzine was found to be superior on four of six anxiety rating scales with no difference between the other three groups. No serious adverse effects occurred. Researchers then continued responders in the phenelzine and CBGT group in 6 months of maintenance treatment and 6 months of treatment-free follow-up. Of 28 patients in the maintenance phase, relapse rates did not differ significantly between groups: phenelzine

(21 percent) and CBGT (14 percent). In the follow-up phase there was a nonsignificant trend toward less relapse in CBGT (0 percent) versus phenelzine (30 percent).

The same researchers followed up with a 2011 study that randomized 166 patients to one of four groups: phenelzine, cognitive-behavioral group therapy (CBGT), phenelzine plus CBGT, or placebo. Remission rates on the Liebowitz Social Anxiety Scale (LSAS) were measured at 12 weeks, and found that combined therapy (59.4 percent) was superior to placebo (11.1 percent), which also could not be distinguished from monotherapy phenelzine (20.0 percent) or CBGT (20.6 percent). Insomnia, light-headedness, dry mouth, weight gain, constipation, anorgasmia, and nervousness rates were all higher in patients taking phenelzine.

A 2003 meta-analysis of pharmacological treatment for social anxiety disorder combined results from the two phenelzine trials. The moderate effect size (0.66) was not statistically different from SSRIs, gabapentin, or clonazepam. Despite this equivocal result, the authors concluded that given SSRIs tolerability and safety they should remain first-line treatment for social anxiety disorder.

Obsessive-Compulsive Disorder

Early case reports described patients with OCD who responded to MAOI treatment, however TCAs emerged as the first-line treatment. Surprisingly, there are only two controlled studies, one comparing an MAOI and a TCA, the other an MAOI and an SSRI, with overall inconclusive results.

A 1992 study compared clomipramine to phenelzine without placebo control in 30 patients with OCD. No significant difference was found; each medication decreased OCD symptoms 40 to 50 percent over the 12-week trial period. A larger study of 64 patients compared phenelzine and fluoxetine to placebo. Fluoxetine was found to be superior to both on the Yale-Brown Obsessive Compulsive Scale but not the OCD Scale, NIMH OCD scale, or CGI. No difference was found between phenelzine and placebo on any scale.

Despite these inconclusive results, recently published guidelines on pharmacological management of treatment-resistant OCD list MAOIs as a third-line agent.

Panic Disorder and Agoraphobia

Early studies on MAOI treatment for panic disorder are difficult to interpret as they often clumped phobias together or examined mixed anxiety and depressive states. However the result of these early studies was that clinicians regarded MAOIs as more effective antipanic agents than TCAs.

The first prospective study on “endogenous anxiety” (characterized by

spontaneous panic attacks and agoraphobia) in 1980, compared imipramine and phenelzine to placebo. All three groups received supportive group therapy. At 12 weeks, results showed both active groups to be superior to placebo. The phenelzine group showed trends toward superiority on all measures and statistically significant improvement on Work and Social Disability Scale and Symptom Severity and Phobic Avoidance Scale.

A double-blind study compared four treatment conditions: phenelzine/exposure, phenelzine/no exposure, placebo/exposure and placebo/no exposure in a group of 40 patients with agoraphobia and social phobia. Exposure, with or without phenelzine, was found to be superior in reducing anxiety symptoms compared to no exposure groups.

The Columbia group compared response to phenelzine, imipramine, and placebo in 104 patients with atypical depression with and without spontaneous panic attacks. In patients with panic, response at 6 weeks was significantly higher for phenelzine (77 percent) compared to imipramine (2 percent) and placebo (15 percent) as measured by Clinical Global Improvement. It is unclear from the data whether response is related to decreased panic or depression, although stratified subgroup analysis suggests that response to phenelzine was independent of pretreatment anxiety levels.

Since the introduction in 1981 of panic disorder to DSM-III, there have been no published prospective trials on MAOIs. However, there are two studies that may provide some information.

A 1987 open-label study treated 40 patients with panic disorder or agoraphobia with phenelzine. Thirty-four of thirty-five patients who completed the study showed statistically significant response on the Hamilton-Rating for Anxiety. This study is limited by its open-label design and its high response rate suggests an unaccounted for confounder. Patients also showed significant adverse effects with postural hypotension (64.3 percent), insomnia (44.3 percent), dry mouth (42.9 percent), sexual dysfunction (27.3 percent men, 16.7 percent women), and weight gain (17.1 percent).

A 2010 study compared tranylcypromine 30 mg and 60 mg without placebo control in a group of patients with panic disorder and comorbid social anxiety disorder. Both doses reduced panic attacks about 70 percent from baseline, without statistical significance between the two. However, the higher dose reduced social anxiety symptoms by double the lower dose. Again, adverse effect rates were significant: orthostatic dizziness (58.8 percent), insomnia (47.1 percent), decreased libido (41.2 percent), and somnolence (35.3 percent).

Overall, the evidence is mixed, without clear antipanic effects from phenelzine. Studies are difficult to interpret, given inclusion of comorbidities and mixed treatment modalities. Still, guidelines suggest

MAOIs as third-line or fourth-line agents for panic disorder.

Attention-Deficit/Hyperactivity Disorder

As selegiline is metabolized to amphetamine and methamphetamine, there has been interest in its use for ADHD. Three randomized control trials show selegiline to be superior to placebo in treatment of ADHD and three drug–drug trials found MAOIs to be noninferior to stimulants.

A small crossover trial included 11 children with ADHD (nine with combined type). Each received selegiline 5 mg twice a day or placebo for 4 weeks and then crossed over. While on active treatment, children showed statistically significant improvement on attention and memory but not impulsivity tasks, and improvement on parent–teacher rating scales for inattention and hyperactivity but not impulsivity. There were no differences in side effects.

Another crossover design study used selegiline 5 mg twice a day and placebo in two 8-week periods for children with ADHD and Tourette syndrome. Active treatment showed benefit on ADHD scales only for the MAOI group in the first phase. There was a trend toward improvement in tics that was not statistically significant.

The efficacy of selegiline could not be reproduced for adults with ADHD. Twenty-four adults were randomized to selegiline 60 mg, selegiline 20 mg, or placebo. There was no difference found on ADHD measures after 6 weeks of treatment. Side effects were more frequent in the high-dose group.

Finally, two studies found no difference between selegiline and methylphenidate in treatment of ADHD in children. Importantly, selegiline was better tolerated than methylphenidate, the latter of which had increased rates of headache, decreased appetite, and insomnia. An earlier study also found tranylcypromine, which has similar amphetamine-like properties to selegiline, to be equally efficacious to dextroamphetamine in a crossover study of 14 children with ADHD.

Given positive results versus placebo and noninferiority to stimulants, selegiline appears to be an effective medication for ADHD in children. Importantly, it also is tolerated well. Use in adults is not yet supported. Though one study found tranylcypromine to be noninferior, selegiline has more evidence and is most likely a safer choice for children who do not respond to stimulants.

Neurodegenerative Disorders

Evidence for the use of MAOIs in the treatment of Parkinson and Alzheimer's disease will be covered in detail in another chapter. Please see Chen et al and Youdim et al in the reference section for two recent reviews.

FUTURE DIRECTIONS AND INVESTIGATIONAL DRUGS

Despite evidence for MAOI effectiveness in a number of psychiatric illnesses and consensus guidelines that continue to recommend their use as third- or fourth-line agents, MAOIs have fallen out of favor as SSRI use has increased. A population-based study in Ontario showed that from 1997 to 2007, only 348 older adults were started on an MAOI, accounting for only 1/500 older adults started on an antidepressant. Review of active clinical trials shows only one recently completed study on a RIMA for treatment-resistant depression (Efficacy, Safety, and Tolerability of CX157 in Treatment-Resistant Depression). There is no evidence that RIMAs will be approved for use in the United States.

Although MAOIs have fallen out of favor with prescribing clinicians, research continues in the area. Between 2012 and 2014, researchers filed 36 patents for compounds, with inhibitory effects on MAO. Recent clinical trials have focused on new indications for MAOIs including hair regrowth, prostate cancer, muscular dystrophies, negative symptoms in schizophrenia, and cocaine addictions. Though not covered in this chapter, selective MAO-B inhibitors continue to be investigated for use in Parkinson's disease, Alzheimer's disease, and other neurodegenerative disorders.

▲ 34.23 Nefazodone

AMIR A. KHAN, M.D., AND SUSAN G. KORNSTEIN, M.D.

Nefazodone (Serzone) was developed to improve the side-effect profile of the analogous, second-generation antidepressant trazodone (Desyrel) by using receptor-binding techniques. It has unique effects on the serotonergic system that are distinct from other antidepressants. It became available in the United States in early 1995. Following the issuance of a black box warning regarding rare but potentially life-threatening hepatotoxicity and the availability of generic nefazodone, the original manufacturer of Serzone (Bristol–Myers Squibb) discontinued the production of Serzone in June 2004, citing declining market share as a primary reason. Generic

nefazodone remains available in the US market though its clinical utilization continues to decline. Sales of nefazodone in Canada were discontinued in 2003.

Nefazodone is a phenylpiperazine compound, with some structural similarity to trazodone. It is structurally unrelated to other antidepressants. Nefazodone's mechanism of action is attributed to its antagonism of the 5-hydroxytryptamine, type 2A (5-HT_{2A}) receptor and inhibition of the serotonin transporter. It has limited affinity for the α_1-adrenergic receptor, hence the decreased incidence of postural hypotension compared with trazodone.

CHEMISTRY

Nefazodone is a synthetically derived phenylpiperazine antidepressant. The chemical name for nefazodone hydrochloride is 2-[3-[4-(3-cholorophenyl)-1-piperazinyl]propyl]-5-ethyl-2,4-dihydro-4-(2-phenoxyethyl)-3H-1,2,4-trizol-3-one monohydrochloride. The molecular formula is $C_{25}H_{32}CIN_5O_2$•HCl with a molecular weight of 506.5 (Fig. 34.23–1).

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption. Nefazodone is rapidly and completely absorbed after oral intake. The absolute bioavailability, however, is low at about 20 percent and variable because of its extensive metabolism. Presence of food in the GI tract delays the absorption and further reduces the bioavailability. The clinical significance of this finding is unclear and probably not important. Peak plasma concentration occurs in about 1 hour.

FIGURE 34.23–1. Molecular structure of nefazodone (Serzone).

Distribution. Nefazodone is widely distributed in the body tissues, including the CNS. The volume of distribution for nefazodone is 0.22 to 0.87 L/kg. It readily crosses the blood–brain barrier. Nefazodone is extensively (>99 percent) but loosely bound to plasma proteins. It does not tend to displace other protein-bound drugs when studied in vitro, but this

property in vivo is not well studied. It does decrease the protein binding of haloperidol by 5 percent, which is unlikely to be of any clinical importance.

Metabolism and Elimination. Nefazodone is extensively metabolized by n-dealkylation and aliphatic and aromatic hydroxylation. Less than 1 percent of the drug is excreted unchanged in urine. Nefazodone's three major pharmacologically active metabolites are hydroxynefazodone, meta-chlorphenylpiperazine (mCPP), and triazole-dione. Both nefazodone and hydroxynefazodone have a relatively short half-life (1.5 to 4 hours) and exhibit nonlinear kinetics. Compared to a single dose, multiple dosing as well as dosage increase produce a disproportional increase in the maximum concentration (C_{max}) of the drug. This property signifies greater-than-predicted accumulation of the drug and its hydroxy metabolite with multiple dosing. Nefazodone and its metabolites attain steady-state concentration within 4 to 5 days of initiation of BID dosing or changes in previous regimens.

The pharmacological profile of hydroxynefazodone is similar to that of nefazodone. mCPP is also somewhat similar to nefazodone, with the notable difference of possessing agonist activity at some serotonergic receptor subtypes. It has a half-life of 4 to 8 hours. The actions of triazole-dione are not yet well characterized, however it has a longer half-life of 18 hours.

Nefazodone should not be used in patients with hepatic disease. Pharmacokinetic studies have shown reduced drug clearance in patients with hepatic cirrhosis; a dose reduction should be considered in such patients, as the steady-state concentrations of nefazodone and hydroxynefazodone are 25 percent higher than in normal controls. Exposure to mCPP is about two- to threefold higher in patients with hepatic cirrhosis. Patients with renal dysfunction do not show a significantly different pharmacokinetic profile. Elderly patients show a 10 to 20 percent increase in steady-state plasma levels; therefore, the starting dose for older patients, particularly women, should be half the usual dose. Nefazodone does not utilize the CYP 2D6 metabolic pathway; hence, dosage adjustment for poor metabolizers is not required.

Pharmacodynamics

Nefazodone has a multimodal, complex mechanism of action. It inhibits neuronal uptake of serotonin and norepinephrine; however, its antidepressant effects are presumably exerted only through the serotonergic system. Presynaptically, it inhibits 5-HT reuptake, which increases the 5-HT level within the synapse and results in increased availability of serotonin. Postsynaptically, it occupies 5-HT_{2A} receptors as an antagonist, hence downregulating the receptor. The latter property is

believed to be responsible for the antidepressant action of nefazodone. Its ability to block 5-HT_{2A} receptors also provides a potential mechanism for the low likelihood of treatment-related activation and sexual dysfunction.

Hydroxynefazodone has an almost identical pharmacological profile to the parent compound and probably contributes to the antidepressant action of nefazodone. mCPP is a minor metabolite, but it appears to have important pharmacological properties. It binds potentially to all 5-HT_1, 5-HT_2, and 5-HT_3 receptors. It acts as an agonist at the 5-HT_{1A}, 5-HT_{2C}, and 5-HT_3 receptors and as a mixed agonist and antagonist at the 5-HT_{2A} site. It is believed to possess anxiogenic properties. Animal studies as well as the direct administration of mCPP to patients with anxiety disorders and normal controls generally support this finding.

Nefazodone has weak α_1-adrenergic antagonism that may cause postural hypotension, though this effect is much less pronounced compared to trazodone. Nefazodone does not have significant affinity for α_2-adrenergic, β-adrenergic, cholinergic, dopaminergic, 5-HT_{1A}, or benzodiazepine receptors. This receptor affinity profile offers distinct clinical advantages with regard to minimizing potential side effects.

THERAPEUTIC INDICATIONS

Nefazodone was approved for the treatment of major depression in the United States in 1994. This approval was granted based upon the results of five well-controlled premarketing clinical trials. Since its approval, many small and large scale studies including both inpatient and outpatient populations have documented its efficacy in the treatment of depression.

Major Depression

Nefazodone was evaluated in four phase III, double-blind, active (imipramine) and placebo-controlled trials to study its efficacy and safety as an antidepressant in outpatients with major depression. Primary efficacy measures were the 17-item Hamilton Rating Scale for Depression (HAM-D) and the Clinical Global Impression (CGI) scale. Three of the four studies showed nefazodone to be superior to placebo and comparable to imipramine in efficacy. The fourth trial failed to show a significant difference between both active drugs and placebo. The incidence of side effects and premature treatment discontinuation was higher with imipramine than nefazodone. Two dose-finding studies as well as other phase II/III studies determined the optimal treatment dosage range to be between 300 and 500 mg/day.

Nefazodone has been directly compared with the SSRIs in both short-term (6 to 8 weeks) and maintenance studies (up to 46 weeks). A meta-analysis of six studies reported that nefazodone (n = 523) and SSRIs (fluoxetine, paroxetine, and sertraline; n = 513) were comparable in efficacy

for the treatment of moderate to severe major depression. Differences were noted in the side-effect profile favoring nefazodone, particularly with regard to sleep disturbances, weight gain, and sexual dysfunction. An additional meta-analysis involving nine studies comparing nefazodone/trazadone with SSRIs for the treatment of major depression (n = 998) confirmed these findings.

There is considerable evidence for the efficacy of nefazodone in the treatment of various subtypes of depression. A meta-analysis of four clinical trials comparing nefazodone (n = 247), imipramine (n = 166), and placebo (n = 251) showed that nefazodone is effective for the treatment of severe depression as well as melancholic and recurrent depression. A placebo-controlled study evaluated the efficacy of nefazodone in 120 hospitalized patients with severe depression. Significant improvement was noted in patients treated with nefazodone compared to placebo (CGI-I response rates of 50 percent vs. 29 percent) in this 6-week study.

Nefazodone has been studied in direct comparison with psychotherapy and combination treatment in patients with chronic depression. In this study, 681 outpatients with chronic, nonpsychotic major depression were assigned to 12 weeks of treatment with nefazodone, The Cognitive Behavioral Analysis System of Psychotherapy, or their combination. In patients who completed the study (n = 519), the response rates were 55 percent in the nefazodone group, 52 percent in the psychotherapy group, and 85 percent in the combined treatment group. The response rates for the monotherapy groups are comparable to other studies of chronic depression. The level of response for combination treatment is the highest ever reported in this patient population. A subset of these patients who did not respond to the initial trial of either psychotherapy or nefazodone treatment showed improved response when treatments were switched (from nefazodone to psychotherapy and vice versa).

Other Mood Disorders

Nefazodone has not been systematically evaluated for the treatment of bipolar depression. One small open-label trial studied nefazodone as an add-on treatment for bipolar depression in 13 patients and showed positive results. The reason to use nefazodone, despite its well-known hepatotoxicity, was to study the underlying mechanism of postsynaptic 5-HT(2A) antagonism as a potential mechanism to develop future therapies for bipolar depression. There are several case reports of nefazodone-induced mania. Caution should be exercised in using nefazodone for the treatment of bipolar depression.

Two small open-label studies reported the efficacy of nefazodone in the treatment of premenstrual dysphoric disorder (PMDD). One small randomized, controlled trial compared its efficacy in PMDD versus buspirone and placebo. This study did not find significant efficacy for

nefazodone in the treatment of PMDD, except that it was modestly effective in controlling PMDD-associated irritability; however, the small sample size renders these findings inconclusive.

Symptoms of anxiety during depressive episodes are common. There is evidence from controlled trials that nefazodone helps the comorbid symptoms of anxiety in depressed patients. A meta-analysis of six randomized, controlled trials of nefazodone in patients with major depression showed that nefazodone produced earlier and more sustained improvement in the symptoms of agitation and somatic anxiety compared to imipramine and placebo. This finding was replicated by another retrospective analysis of over 300 patients with major depression. In this analysis, imipramine and nefazodone were both effective in alleviating depressive symptoms; however, nefazodone showed superior response for comorbid anxiety symptoms. Additional evidence from the nefazodone chronic depression study also supports this beneficial effect of nefazodone on comorbid anxiety, particularly early (first or second week) in the course of treatment.

Anxiety Disorders

Although a number of studies have looked at anxiety symptoms during an episode of major depression, there has been little study of nefazodone for the treatment of primary anxiety disorders. Most of the evidence available is from small, open-label trials.

A meta-analysis of six open-label trials consisting of 105 patients with PTSD (both civilians and combat veterans) showed that nefazodone was effective for a broad spectrum of PTSD symptoms at a dosage of up to 600 mg/day. This finding has been replicated in four additional, small, open-label trials. Randomized controlled trials are needed to determine if nefazodone is superior to placebo and comparable to other treatments for PTSD. An interesting finding in one of the open-label trials was that although patients with chronic PTSD reported improvement in the symptoms of nightmares and other sleep disturbance as well as depression and other PTSD symptoms, the objective, polysomnographic sleep measures did not change, which is in contrast to the sleep studies of depressed patients on nefazodone.

There are two open-label studies of nefazodone use in panic disorder and an additional study in panic disorder comorbid with depression. The total number of patients enrolled in these studies was 39, with study durations of 8 to 12 weeks. Two of the three studies found nefazodone to be beneficial for the treatment of panic disorder, with or without agoraphobia and with or without depression. However, one study reported that the response rate of nefazodone was lower compared to some other anti-panic medications such as paroxetine or low-dose venlafaxine.

A clinical case series of five patients suggested the potential efficacy of

nefazodone for the treatment of social phobia. An open-label study consisting of 23 patients reported a response rate of about 70 percent (n = 16) for social phobia. However, a recent double-blind placebo-controlled study for the treatment of social phobia (n = 102) reported no significant difference in response rate between nefazodone and placebo-treated patients. Another open-label trial of nefazodone was conducted in 21 patients with generalized anxiety disorder (GAD). Of 15 subjects who completed the trial, 12 were considered significantly improved. An open-label study of nefazodone in patients with depression and comorbid OCD did not report significant antiobsessional effects. Another retrospective study evaluated the efficacy of nefazodone for the treatment of nonparaphilic compulsive sexual behavior. Of the 14 subjects studied, 6 reported good control of sexual obsessions and compulsions and 5 reported remission of those symptoms.

In summary, nefazodone can potentially be useful for a variety of anxiety disorders; however, the existing evidence is not rigorous. If a patient fails the standard treatment, then nefazodone can be used as a second- or third-line treatment, with the understanding that the data regarding its efficacy are very limited.

Substance Abuse and Dual Diagnosis

There is one double-blind, placebo-controlled study of nefazodone in patients with comorbid major depression and alcohol dependence. This study enrolled 64 subjects who were actively drinking alcohol and had a history of at least one episode of depression when abstinent. Patients were randomized to receive 12 weeks of treatment with nefazodone or placebo. All patients continued once-weekly psychoeducational group therapy. The results indicated that nefazodone is efficacious for the treatment of depression in this population, but it did not show any advantage over placebo with regard to alcohol outcome. There was also an increased incidence of nonserious, drug-related side effects (sedation, visual trails, dizziness, and dry mouth). Another, larger study of 183 patients with alcohol dependence compared nefazodone with naltrexone and placebo. This study did not find any beneficial effects of nefazodone for the treatment of alcohol dependence. There is one case series reporting successful treatment with nefazodone for depression in four patients who were on methadone maintenance treatment and whose depression had not responded to other medications.

Two double-blind, placebo-controlled studies investigated the use of nefazodone in cocaine-dependent patients. The first study included 69 subjects with cocaine dependence and depressive symptoms, and the primary objective was to determine the efficacy of nefazodone in reducing cocaine use. The second study included 210 subjects. Both trials indicated no specific efficacy of nefazodone in treating cocaine dependence.

A recent double-blind study investigated the efficacy of nefazodone and bupropion-sustained release for treating cannabis dependence. Sample size was relatively small. The study did not show any specific benefit of nefazodone or bupropion for the treatment of cannabis dependence in the studied population.

From these reports, it can be concluded that nefazodone does not possess specific efficacy for the treatment of alcohol or substance abuse. However, it can be used for the treatment of comorbid depression in this population. Extreme caution should be exercised in using nefazodone for patients who have alcohol use disorders because of the rare but life-threatening adverse effect of liver failure.

Pain

One open-label study evaluated the efficacy of nefazodone for the treatment of chronic daily headaches in 52 patients. Most of the patients enrolled (n = 48) had a history of migraine, based upon the criteria established by International Headache Society. The remainder of the patients had chronic tension-type headaches. The median dose used was 300 mg/day. At the end of the 12th week, 71 percent of the patients showed at least a 50 percent improvement in their headache index. Patients who were depressed or anxious showed significantly greater improvement in their headache as well as in the symptoms of depression and anxiety. There is another small, open-label study of 10 patients with diabetes mellitus type II with painful diabetic neuropathy but who did not meet criteria for major depression. These patients received up to 450 mg/day of nefazodone for 8 weeks. At the end of the treatment period, the patients showed improvement in pain, parasthesias and numbness as well as slightly improved diabetic control. Both of these studies indicate a potential analgesic effect of nefazodone. However, whether this effect is independent of antidepressant action remains unclear.

Other Uses

There are case reports and small, open-label studies of nefazodone use for the treatment of mood disorders in children and adolescents. The results show that nefazodone is effective for the symptoms of depression in this population and is well tolerated. However, these studies also indicate that the pharmacokinetic properties of nefazodone in children and adolescents are highly variable.

There are also small open-label trials of nefazodone use as an adjunct treatment for schizophrenia, in patients who were on a stable dose of antipsychotic medication. There is also one study of nefazodone use in somatization disorder. These studies not only suffer from the limitations common to open-label trials, but they also do not have adequate power to

establish the efficacy of nefazodone independent of the comorbid depression present.

A recently published analysis of nefazodone and cognitive behavioral analysis system of psychotherapy trial showed an interesting finding supporting patient preference as a potent moderator of treatment response for patients with chronic forms of MDD (i.e., patients who preferred psychotherapy responded better to psychotherapy and patients who preferred medication treatment responded better to that intervention).

From the above discussion, it is reasonable to conclude that nefazodone is comparable to other treatments for major depression. However, there is clearly a need for randomized, controlled trials before nefazodone can be recommended for routine use for conditions other than depression.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

General

Premarketing clinical trials with nefazodone in almost 3,500 patients showed that it has a relatively low incidence of adverse events. In these trials, about 16 percent of participating patients discontinued treatment due to adverse experiences. The commonly observed adverse events that differed significantly from placebo were somnolence (25 percent vs. 14 percent), dry mouth (25 percent vs. 13 percent), nausea (22 percent vs. 12 percent), dizziness (17 percent vs. 5 percent), constipation (14 percent vs. 8 percent), asthenia (11 percent vs. 5 percent), light headedness (10 percent vs. 3 percent), blurred vision (9 percent vs. 3 percent), confusion (7 percent vs. 2 percent), and abnormal vision, consisting of scotoma and visual trails (7 percent vs. 1 percent). The most common reasons for treatment discontinuation were nausea, dizziness, asthenia, and agitation. The incidence of adverse events increases with the dosage of nefazodone. An analysis of three placebo-controlled trials in which two different dosage ranges were used (low ≤300 mg/day; high 300 to 600 mg/day) showed that the incidence of somnolence, nausea, dizziness, constipation, abnormal vision, confusion, and tinnitus was comparable to placebo in the low dosage range. However, the incidence of these adverse events increased significantly in patients treated at the higher dosage range (300 to 600 mg/day).

In 2004, FDA mandated that a boxed warning be placed on the labels of all antidepressants indicating an increased risk of suicidal thoughts and behavior in youth taking these medications and in 2006, added young adults age 24 years or less to this list. There are no data indicating a specific increase in this risk by nefazodone; however, caution should be exercised, particularly in children.

Central Nervous System

The most common adverse events pertaining to the CNS are somnolence, dizziness, confusion, insomnia, and light headedness. Less frequently reported events include memory impairment, paresthesias, flushing and feeling warm, abnormal dreams, ataxia, and tremors. There is at least one report of a nefazodone-induced acute dystonic reaction, which responded well to standard anticholinergic treatment.

There are reports of rare incidences of seizures after nefazodone administration, particularly in patients who have a seizure disorder, however a causal relationship has not been established. Controlled data for combining antidepressant drug therapy and ECT are sparse. In a case report from Australia, one patient with treatment-resistant dysthymia underwent ECT while taking 600 mg/day of nefazodone and 15 mg of midazolam without significant problems. There was no adverse outcome, and the patient showed a good response.

Sleep disturbance is one of the most frequent and distressing symptoms of depression. Many of the antidepressants tend to cause or worsen sleep disturbances. Their effects include decreased REM sleep, increased REM latency, increased stage I sleep, and decreased sleep efficiency. Nefazodone, on the other hand, appears to possess unique and potentially beneficial effects on sleep architecture. It shows minimal effects on REM sleep, decreases stage I sleep, and improves sleep efficiency. These effects have been observed in both normal as well as depressed subjects. In comparison with fluoxetine, nefazodone produced significantly greater improvement in sleep on both subjective and objective (sleep EEG) measures. The beneficial effects of nefazodone on sleep tend to appear early in treatment, during the first 2 weeks. The differences between nefazodone and SSRIs on sleep parameters have been shown to remain significant even after patients have responded to the antidepressant treatment. However, a recent study found no difference in subjective sleep improvement between nefazodone and paroxetine after 8 weeks of treatment.

Preclinical studies on human volunteers were carried out to determine the effects of nefazodone on daytime sleepiness, highway driving, and cognitive performance. Results of these early studies showed minimal impact of nefazodone on these measures. Clinical experience in patient populations shows that somnolence is frequently observed, particularly early in the treatment, however it does not appear to result in an actual increase in daytime sleepiness. The incidence of adverse events related to motor performance and cognitive tasks is also minimal but has a dose–response relationship and tends to increase for doses over 300 mg/day.

Cardiovascular System

Nefazodone has limited effects on the cardiovascular system. It can cause a slightly increased incidence of postural hypotension and hypotension. These effects are much less pronounced compared to the TCAs or

trazodone. In a pooled analysis of almost 800 patients, the incidence of postural hypotension with nefazodone was 4 percent, compared to 1 percent with placebo. In the same study, the incidence of hypotension was 2 percent.

There were no clinically significant ECG changes noted in placebo-controlled trials involving 1,153 patients taking nefazodone. Asymptomatic sinus bradycardia was noted in 1.3 percent of nefazodone-treated patients, compared to 0.4 percent of placebo-treated patients. The specific cardiac effects of nefazodone in patients with existing cardiovascular disease, particularly of recent onset, are not fully known. There is a potential for QTc prolongation if nefazodone is combined with terfenadine, astemizole, cisapride, or pimozide.

Genitourinary System

Antidepressant medications are often associated with treatment-related sexual dysfunction, including effects on desire, arousal, and orgasmic function. These side effects are particularly common with the SSRIs. In clinical studies, nefazodone has been associated with a low incidence of sexual side effects in both men and women. In one study comparing nefazodone and sertraline in depressed outpatients, 47 percent women on sertraline reported difficulty achieving orgasm compared to 17 percent of women on nefazodone. In the same study, significantly more men taking sertraline (67 percent) reported ejaculatory difficulty than did men taking nefazodone (19 percent). The incidence of sexual side effects reported with nefazodone was also low (3.5 percent) in a recent study of patients with chronic depression.

Priapism, a recognized side effect of trazodone, had not been reported with nefazodone until recently. There is one case report of nefazodone-precipitated clitoral priapism. The paucity of other case reports indicates that priapism is a possible but very rare adverse event associated with nefazodone use. It is believed that the relatively low affinity of nefazodone for α_1-adrenergic receptors is the reason for the low likelihood of treatment-related priapism or postural hypotension.

In premarketing clinical trials, the incidence of urinary frequency, retention, and infection was slightly increased with nefazodone compared to placebo. However, the overall incidence of these adverse events was low.

Gastrointestinal System

Rare cases of life-threatening hepatic failure have been reported in patients treated with nefazodone. The reported rate in the United States is about one case of liver failure resulting in death or transplant per 250,000 to 300,000 patient-years of nefazodone treatment. This rate is considered an underestimate by some because of potential under-reporting. This finding

prompted a mandatory black box warning by the FDA and a revision of the product labeling and patient information packet in 2002. This warning is based upon the postmarketing experience of over seven million patients in the United States. The reported rate represents about three to four times the estimated background rate of liver failure. Most liver failures were reported between 1 and 8 months after drug initiation. The common clinical symptoms of hepatotoxicity included jaundice and increases in ALT (10x), AST (10x), totalbilirubin (mostly conjugated), and prothrombin time. Dark urine and clay-colored stool were also reported. Available histological evaluations of livers demonstrated centrilobular necrosis and bile-duct proliferation with cholestasis. Inhibition of bile acid transport by nefazodone has been proposed as an indicator of potential hepatotoxicity in animal models. The radiochemical in vitro methods are available to detect and quantify covalent binding (CB) to liver proteins for a drug or its metabolites and are being studied to predict the risk of liver injury. The potential clinical application of these techniques remains to be seen. The risk factors for drug-induced hepatic injury include age and polypharmacy. Given the seriousness of hepatotoxicity, it is clinically important to obtain a complete pretreatment history of any underlying liver disease. Periodic serum testing of liver enzymes has not been shown to prevent serious liver injury, however, early detection of drug-induced hepatic injury and immediate withdrawal of the suspected drug is likely to improve the potential for recovery. Nefazodone should be discontinued in patients showing signs of hepatic toxicity. These patients should not be rechallenged with nefazodone.

More common GI problems associated with nefazodone use include dry mouth (25 percent), nausea (22 percent), and constipation (14 percent).

Other Systems

Nefazodone is generally considered to be weight-neutral. Evidence from both short-term and long-term studies comparing nefazodone with either placebo or other antidepressants supports this conclusion. A pooled analysis of six clinical trials comparing nefazodone (n = 523) and SSRIs (fluoxetine, sertraline, or paroxetine n = 523) as well as three trials comparing nefazodone (n = 224) with imipramine (n = 224) evaluated the impact of these antidepressants on weight. The criterion for clinically significant weight change was a 7 percent increase or decrease in weight from the baseline measurement. The results showed that in short-term trials, SSRI-treated patients showed more weight loss than nefazodone-treated patients; however, during long-term treatment, more patients gained weight on SSRIs compared to nefazodone. Imipramine was also found to be associated with more weight gain than nefazodone.

Abnormal vision, usually consisting of scotoma and visual trails (palinopsia), has been associated with nefazodone use. This adverse event

was noted in up to 10 percent of the patients taking nefazodone, compared to 2 to 3 percent of patients on placebo. It is generally considered benign and is probably dose-dependent. It can usually be managed by lowering the medication dose or changing the time of the day the dose is given.

In a recent, retrospective study, joint disorders were considerably more frequently reported adverse effects of 5-HT(2A)-blocking antidepressants, including nefazodone, than of other comparable drugs, suggesting a possible association between the use of 5-HT(2A)-blocking antidepressants and joint disorders.

PRECAUTIONS AND ADVERSE EFFECTS

Overdose

The limited information available regarding the effects of nefazodone overdose during premarketing trials consisted of seven reports of overdose ranging from 1,000 to 11,200 mg, alone or in combination with other drugs. Since its approval, one study has analyzed data on nefazodone from the American Association of Poison Control Centers. It contained over 1,300 human exposures to nefazodone overdose, after excluding patients with concomitant agent overdose. Commonly reported symptoms of overdose included drowsiness (17.3 percent), nausea (9.7 percent), and dizziness (9.5 percent). The most common serious clinical effect was hypotension (1.6 percent). None of these patients died. Most of them were treated with GI decontamination. The study concluded that nefazodone appears to be of low toxicity during poisonings.

There are rare reports of fatalities, predominantly in patients taking an overdose of nefazodone in combination with alcohol and/or other substances. There is no specific antidote available to treat a nefazodone overdose. The mainstay of treatment consists of supportive measures, including adequate airway management and monitoring cardiac rhythm and vital signs.

Used in medically compromised patients during premarketing trials, the pharmacokinetics of nefazodone and its metabolites were studied in a small number of normal healthy volunteers, both younger and older, as well as in patients with biopsy-proven hepatic cirrhosis and patients with impaired renal function. The results of these studies indicate that elderly or cirrhotic patients may require lower doses of nefazodone to achieve and maintain therapeutic effectiveness. Patients with mild to moderate renal impairment (based upon creatinine clearance) appear to tolerate the usual dose without difficulty.

There are no systematic studies of nefazodone treatment of depression in patients with compromised hepatic or renal function. Given the potential for life-threatening hepatotoxicity, nefazodone should be avoided in patients with existing liver disease. It should be used with caution in

patients with renal impairment and in patients on hemodialysis. There is one case report of the use of nefazodone to treat depression in a 59-year-old patient on hemodialysis who had not responded to an adequate trial of fluoxetine. Treatment was initiated with nefazodone at a dose of 50 mg BID, which was increased to 100 mg after 1 week and 150 mg after 4 weeks. This patient responded well to nefazodone treatment with minimal adverse events. Pre- and postdialysis nefazodone serum concentrations in this patient suggested that drug levels may be affected by this procedure. Additional studies are needed to confirm the efficacy and safety of nefazodone for the treatment of depression in such patients.

One open-label study evaluated the efficacy of nefazodone in 15 HIV-seropositive patients with major depression. Eleven patients completed the 12-week study. The results showed that HIV-seropositive outpatients respond well to nefazodone and comparably to other outpatient populations. Potential drug interactions with protease inhibitors should be considered before initiating nefazodone therapy in this patient population.

There are anecdotal reports of nefazodone use for depression in patients with cancer on chemotherapy and in patients with epilepsy and with cardiac problems, however systematic studies are not available. Aside from taking routine precautions, increased potential for drug–drug interactions as well as the need for lower dosage and slow titration should be important considerations in instituting nefazodone therapy in medically ill patients.

Use during Pregnancy and Lactation

Nefazodone is classified as a pregnancy category C medication. It has shown to increase early pup mortality in rabbits at a dose approximately five times the human dose. A decrease in pup weight was also seen at this dose as well as at lower doses. There are no systematic human studies evaluating nefazodone during pregnancy. Nefazodone should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus.

Very little information is available regarding the excretion of nefazodone in human breast milk. One small study of two lactating mothers reported that nefazodone is excreted in human milk; no metabolites were found. The levels of nefazodone in breast milk were not related to the maternal medication dose. Drug levels in the infants were not assayed; however, there was no indication of developmental difficulty in those infants. A case report of a premature, breast-fed infant described drowsiness, lethargy, poor feeding, and difficulty maintaining body temperature attributed to maternal use of nefazodone. Until more information becomes available, a careful risk–benefit analysis must be performed before recommending the use of nefazodone in lactating mothers.

Discontinuation Syndrome

Animal studies using monkeys trained for self-administration of cocaine as a reinforcer did not show this behavior when nefazodone was substituted for cocaine, suggesting that nefazodone has no abuse liability. Its potential for tolerance, physical dependence, or withdrawal has not been studied systematically in humans.

There are case reports suggesting possible withdrawal symptoms resulting from abrupt discontinuation of nefazodone. Typical symptoms reported include dizziness, nausea, vomiting, fatigue, insomnia, and paresthesias. Some unusual symptoms such as brief moments of disorientation and shock-like or electrical sensations have also been reported. Patients generally recover within a few days without any serious problems and the symptoms can usually be prevented by tapering the medication. The incidence of discontinuation symptoms with nefazodone appears to be much less common than with the SSRIs and venlafaxine. In a relapse prevention study of 259 patients who had been maintained on nefazodone treatment for 16 weeks and were randomly assigned to continuation treatment with nefazodone or placebo, there were no significant differences in new-onset or worsened adverse experiences between the nefazodone and placebo groups at 14 and 28 days after randomization.

DRUG INTERACTIONS

There are various mechanisms involved in the drug–drug interactions of nefazodone. Most of these interactions involve Cytochrome P450 (CYP) isoenzymes. Another potential mechanism involves drugs that are highly bound to plasma proteins, such as warfarin. Different metabolites of nefazodone also play a role in drug interactions; for example, the plasma concentration of mCPP is increased in individuals who have decreased activity of CYP2D6.

Psychotropic Agents

Nefazodone and its metabolites, hydroxynefazodone, mCPP, and trizoledione, inhibit CYP3A4, both in vitro and in vivo. This inhibition can result in increased bioavailability of medications metabolized by this pathway. Therefore, caution should be exercised when administering nefazodone with other compounds metabolized by CYP3A4. This interaction becomes even more important for drugs that are exclusively or predominantly metabolized by the CYP3A4 pathway. Two such benzodiazepines, alprazolam and triazolam, show a substantial and clinically important increase in blood levels when administered with nefazodone. When triazolam was coadministered with nefazodone, triazolam half-life increased by threefold, AUC increased by fourfold, and

peak concentration increased by 1.7-fold. Likewise, there was a 1.6-fold increase in peak concentration and a twofold increase in the AUC of alprazolam. Nefazodone plasma concentration was unaffected by either medication. Given these interactions, the manufacturer recommends that triazolam be avoided during nefazodone treatment in most patients. If alprazolam is used with nefazodone, a 50 percent reduction in the initial dose of alprazolam is recommended. This effect has not been observed with lorazepam.

One of the metabolites of nefazodone, mCPP, is present in relatively small quantities and is metabolized by the CYP2D6 pathway. When a patient is switched from an antidepressant that is an inhibitor of CYP2D6 (e.g., fluoxetine) to nefazodone, the metabolism of mCPP may be inhibited for some time. This can result in an increased level of mCPP, which is an anxiogenic compound, and may lead to increased anxiety and agitation. This problem can be minimized by using an adequate washout period before switching antidepressants. The interaction between nefazodone and MAOIs has not been systematically studied in humans or animals. The existing evidence with SSRIs or TCAs when combined with MAOIs suggests a potential for a serious, sometimes fatal, reaction. This serotonin syndrome consists of hyperthermia, rigidity, myoclonus, autonomic instability with rapid fluctuation of vital signs, and mental status changes that may include extreme agitation progressing to delirium and coma. This reaction has also been reported in patients who have recently discontinued an SSRI or TCA and have been started on MAOI. Some cases present with symptoms resembling neuroleptic malignant syndrome, including severe hyperthermia and seizures. Given the existing evidence with other antidepressants, it is recommended that nefazodone not be used in combination with an MAOI or within 14 days of discontinuing treatment with an MAOI. In addition, a minimum of 1 week should be allowed after discontinuing nefazodone before starting an MAOI.

Coadministration of lithium and nefazodone resulted in only a slight decrease in the concentration of two metabolites of nefazodone, mCPP and triazoledione, which was not clinically significant. The combination of nefazodone and carbamazepine, although well tolerated in small number of healthy volunteers, resulted in a very significant decrease in the steady-state C_{max} and AUC of nefazodone (86 and 93 percent, respectively), along with a similar but modest reduction in its metabolites. At the same time, the steady state C_{max} and AUC of carbamazepine were each increased by 23 percent, while the steady-state C_{max} and AUC of its metabolite, 10,11-epoxycarbamazepine, decreased by 21 and 20 percent, respectively. Because the decrease in nefazodone and its metabolites is likely to result in a loss of antidepressant efficacy, this combination should be avoided. There are no systematic studies to evaluate the impact of coadministration of

valproic acid and nefazodone. One case report suggested a potentially dangerous interaction of these two medications in a patient with bipolar disorder. This patient suffered from symptoms that were suggestive of serotonin syndrome. Whether this occurrence was incidental or represents a real interaction remains unclear. The impact of combining phenytoin and nefazodone has not extensively been studied. It appears that a single-dose administration of phenytoin with steady state nefazodone does not alter the pharmacokinetic properties of phenytoin. However, due to the nonlinear pharmacokinetics of phenytoin, this combination should be avoided if possible or the dose should be adjusted carefully, according to usual clinical practices.

Nefazodone tends to decrease the protein binding of haloperidol by 5 percent, however this interaction is unlikely be of any clinical significance. Human experience with clozapine and nefazodone in a small number of patients suggests that clozapine levels are increased by 4 percent and norclozapine levels by 16 percent. This relatively modest increase in levels is considered to be clinically insignificant. There are other small studies of concomitant antipsychotic and nefazodone use that have shown no significant difficulties. However, an important and potentially dangerous interaction may occur between nefazodone and pimozide resulting in a prolonged QT interval, as described in detail in the following section.

Other Medications

Terfenadine, astemizole, cisapride, and pimozide are metabolized via the CYP3A4 pathway. Drugs such as ketoconazole or erythromycin inhibit this enzyme and block the metabolism of terfenadine, astemizole, cisapride, and pimozide, resulting in increased plasma concentrations of these medications. Increased plasma concentrations of these four medications are associated with QT prolongation and rare cases of cardiovascular adverse events, including death, due principally to ventricular tachycardia of the torsades de pointes type. Nefazodone is a potent inhibitor of CYP3A4. Consequently, nefazodone must not be used in combination with terfenadine, astemizole, cisapride or pimozide. At the present time, terfenadine, astemizole and cisapride have been removed from the US market by the FDA.

Nefazodone was coadministered with digoxin to healthy volunteers who were genotyped as extensive CYP2D6 metabolizers. This combination resulted in an increased C_{max}, C_{min}, and AUC of digoxin by 29, 27, and 15 percent, respectively. There was no effect on the pharmacokinetics of nefazodone or its active metabolites. Since digoxin has a narrow therapeutic index, caution should be exercised in combining it with nefazodone. Plasma level monitoring of digoxin is also recommended. Coadministration of nefazodone and propranolol in healthy volunteers

resulted in a decrease in the level of propranolol, but did not impact the level of nefazodone or its active metabolites with the exception of mCPP, which was increased. Hence, initial dosage adjustment is not needed for either of the medications, however; subsequent dosage should be adjusted based upon the clinical response.

Simvastatin and atorvastatin are substrates of CYP3A4. When nefazodone was combined with either of these medications, it resulted in a 20-fold increase in the concentration of simvastatin and simvastatin acid and a fourfold increase in atorvastatin and atorvastatin lactone. This effect appears to result from the inhibition of CYP3A4 by nefazodone. Nefazodone did not significantly affect the level of pravastatin, another HMG-CoA reductase inhibitor. Metabolic interactions are unlikely between nefazodone and HMG-CoA reductase inhibitors such as pravastatin, fluvastatin, or rosuvastatin that undergo little or no metabolism by the CYP3A4 isoenzyme; therefore, dosage adjustment for these agents should not be necessary. However, dose adjustment is needed for simvastatin and atorvastatin because the increased concentrations of these medications might result in a greater risk of rhabdomyolysis and other adverse events associated with HMG-CoA reductase inhibitors.

There have been reports of increased blood concentrations of cyclosporin and tacrolimus into toxic ranges in patients who received concomitant nefazodone. These are immunosuppressive agents that are substrates of CYP3A4. If nefazodone is combined with either of these medications, the level should be monitored and the dose should be adjusted accordingly.

When nefazodone was administered with warfarin, there was no change in prothrombin or bleeding time despite a modest decrease in C_{max} of warfarin. This finding suggests a clinically insignificant interaction.

DOSAGE AND ADMINISTRATION

Nefazodone is indicated for the treatment of major depression. Based upon the results of clinical trials, the recommended starting dose of nefazodone is 200 mg/day in divided doses (BID). The effective dosage range is usually between 300 mg to 600 mg/day in divided doses. The starting dose can be increased by 100 to 200 mg/day at intervals of no less than 1 week. In order to minimize adverse events, it is preferable to start at 100 mg/day and then increase by 100 mg/day every week. The usual therapeutic dosage range is 400 to 600 mg/day. Doses higher than 600 mg/day are not recommended. As with all antidepressants, several weeks of treatment at a reasonable therapeutic dose are required for antidepressant response. As with other antidepressants, long-term study (up to 1 year) with nefazodone as a maintenance treatment suggests that the therapeutic dose should be continued as the maintenance dose. Once-daily dosing has been attempted in patients who were previously maintained on BID dosing as well as in

patients starting nefazodone. The results did not show significant differences with once- versus twice-daily dosing of nefazodone. Since these were open-label trials, this finding needs to be replicated in double-blind studies.

The recommended starting dose for elderly or debilitated patients is 50 mg BID. The increase in dosage should be slower and tailored to the individual patient's symptoms and side effects. The final therapeutic range in elderly patients may be similar to younger patients.

Nefazodone is supplied in 50, 100, 150, 200, and 250 mg strengths.

▲ 34.24 Opioid Maintenance Treatments: Methadone and Buprenorphine

ANDREW J. SAXON, M.D., AIMEE L. MCRAE-CLARK, PHARM.D., AND KATHLEEN T. BRADY, M.D., PH.D.

INTRODUCTION

It has long been recognized that after ongoing, regular use of opioids a use disorder including maladaptive use, functional impairment, withdrawal symptoms, and tolerance may develop. Commonly misused opioids include heroin, morphine, hydromorphone (Dilaudid), codeine, meperidine (Demerol), oxycodone, and hydrocodone (Robidone). The prevalence of opioid use and use disorder particularly in regard to prescription opioids has risen in recent years. The 2013 National Survey on Drug Use and Health reported that approximately 4.5 million Americans used prescription pain relievers for nonmedical reasons in the past month. Heroin use has also risen, with estimates of more than 4.8 million Americans having ever used heroin and 681,000 having used it in the last year. Sustained opioid-use disorder is associated with several negative outcomes, including early mortality, increased rates of hepatitis, HIV infection, sexually transmitted diseases, and other health problems, as well as criminal justice system involvement.

Physical Dependence and Withdrawal

If an individual is physiologically dependent on opioids, opioid discontinuation or diminution in the amount consumed often leads to the development of an opioid withdrawal syndrome. Physical signs and symptoms that frequently occur include sweating, piloerection, yawning, rhinorrhea, sneezing, lacrimation, pupillary dilation, nausea, vomiting, abdominal cramps, diarrhea, tremor, muscle aches or cramps, agitation, dysphoric mood, fever, and sleep disturbances. Although opioid withdrawal is not considered life threatening, it is highly physically and subjectively uncomfortable, such that an individual continues to use opioids to avoid withdrawal symptoms.

The goal of most medically supervised withdrawal (detoxification) protocols is to limit patient discomfort by decreasing or ameliorating withdrawal symptoms. Medications commonly used in the treatment of acute opioid withdrawal include the α_2-adrenergic agonist clonidine (Catapres), cyclobenzaprine (Flexeril) or benzodiazepines for muscle cramps, the antispasmodic dicyclomine (Bentyl), antidiarrheals such as loperamide, antiemetics such as prochlorperazine (Compazine) or ondansetron (Zofran), and sedatives such as zolpidem (Ambien) or

benzodiazepines. Another option is to convert the patient to an equivalent dose of another opioid, typically either methadone or buprenorphine and then to gradually reduce the dose to minimize withdrawal. If methadone is used, it must be done under the auspices of a federally licensed program, and if buprenorphine is used, it must be prescribed by a qualified, trained physician with a special Drug Enforcement Agency (DEA) number. If the goal is to expedite the withdrawal process, especially in the case of a long-acting opioid, administration of an opioid antagonist such as naloxone (Narcan) or naltrexone (Revia), hastens the onset of the withdrawal syndrome. Caution must be taken when using this approach because of the abrupt onset of symptoms that can appear in precipitated withdrawal. Again, adjunctive medications, such as clonidine, cyclobenzaprine, and dicyclomine, may also be used for the symptomatic treatment of some opioid withdrawal symptoms. The use of *ultrarapid opioid detoxification* which involves the administration of general anesthesia or heavy sedation in individuals undergoing withdrawal, although effective in reducing physiological dependence, has been demonstrated to lead to a greater number of serious adverse events than the other approaches without superior outcomes, and so it is not recommended. Once a patient has been completely withdrawn from opioids, naltrexone, an orally and parenterally active μ-opioid antagonist, may also be used to help prevent relapse. Prior to starting naltrexone, a naloxone challenge test should be performed to assure that no residual physiological dependence remains, or naltrexone could cause a prolonged, precipitated withdrawal episode. Oral naltrexone may be dosed at 50 mg/day or 100 to 150 mg two to three times a week. Positive results have been found with using naltrexone in highly motivated patients, but many opioid-dependent patients tend to drop out of naltrexone therapy. A long-acting injectable form of naltrexone (Vivitrol) that provides blockade of the μ-opioid receptor for about 30 days is also available for treatment of opioid-use disorder and may have a better efficacy profile than the oral form, but more research needs to be done to determine its efficacy.

Opioid Maintenance Therapies

Because outcomes for medically supervised opioid withdrawal are generally suboptimal, an alternative and generally preferred approach to the treatment of opioid-use disorder is opioid maintenance treatment. The goal of maintenance treatment is to provide a physician ordered or prescribed opioid (either methadone or buprenorphine) to deter and ideally eliminate the use of illicit opioids. Early researchers in this area speculated that an effective pharmacological treatment for opioid-use disorder must eliminate the euphoric appeal of heroin and the abstinence symptoms that draw addicts back to drug use; it must be sufficiently free from toxic dysphoric effects that patients will continue with treatment; it must be orally

effective, long-acting, medically safe, and compatible with normal performance at work and at school and with responsible behavior in society.

Methadone (Dolophine) which came into widespread use in the 1970s was the first medication to meet these requirements. Levomethadyl (ORLAAM) was available from 1993 until 2003 as an opioid maintenance therapy; however, production of levomethadyl was discontinued by the manufacturer due in part to reports of prolonged QT intervals and risk of torsades de pointes. In 2002, buprenorphine and buprenorphine/naloxone (Suboxone, Zubsolv, Bunavail) became the first opioid maintenance medications approved for office-based treatment of opioid-use disorder.

Among the more than 2 million current, long-term opioid users in the United States, as of 2013 only 330,308 were receiving methadone and 12,872 buprenorphine through federally licensed opioid treatment programs with an additional 35,276 receiving buprenorphine from other types of treatment programs. An undetermined number received buprenorphine through physicians' offices. Barriers to patients entering licensed opioid treatment programs include state and federal regulations for program admittance, treatment costs, and inadequate expansion of treatment centers since the 1980s. The social stigma associated with methadone treatment also may deter opioid-dependent individuals from entering treatment. Office-based treatment with buprenorphine, which appears to have nearly comparable effectiveness to clinic-based treatment, is making opioid maintenance therapy more accessible. As of 2014, 25,732 physicians had obtained waivers to prescribe buprenorphine. No clear data exist on the total number of patients treated since FDA approval, but it certainly exceeds 1,000,000. The following discussion reviews the history and current status of methadone and buprenorphine. A discussion on the use of opioid agonists in the treatment of chronic pain is also included.

METHADONE

History

In response to high rates of heroin-related deaths in the 1960s, researchers began investigating the feasibility of opioid maintenance therapy. Vincent Dole, Marie Nyswander, and Mary Jeanne Kreek evaluated several short-acting opioids as possible replacement medications but found that patients were overly sedated by the narcotic effects and still craved heroin. Moreover, patients required frequent dosing—every 4 to 6 hours—to prevent the emergence of withdrawal symptoms. Searching for a longer-acting alternative, the researchers administered methadone, which had been previously shown to be useful in heroin withdrawal. They discovered that, with methadone, it was possible to maintain a heroin-dependent individual "between the limits of narcosis and abstinence [where] there is a

functional zone."

Rapid expansion of methadone maintenance programs occurred in the 1970s during the presidency of Richard Nixon. At this time, politicians were concerned about the high rate of heroin-related crimes and were encouraged by the decrease in illegal activities reported by individuals receiving methadone. However, initial rapid expansion was soon curtailed by government regulation in an attempt to maintain some control over the distribution of methadone. Today, the DEA and the Center for Substance Abuse Treatment, which is part of the federal Substance Abuse and Mental Health Services Administration, both have roles in regulating licensed opioid treatment programs. There remains substantial community resistance to the placement and existence of these programs, which limits the availability of services in some areas. Critics often suggest that methadone maintenance is, in essence, trading one chemical dependency for another and is therefore not appropriate treatment. Finally, there is concern that methadone diversion may occur, further worsening opioid-use disorder epidemics or contributing to opioid overdoses. In reality evidence accrued thus far suggests that diverted methadone comes mainly from methadone prescribed to treat pain, not from methadone dispensed in licensed opioid treatment programs.

Chemistry

Methadone is a synthetic opioid of the phenylheptylamine class structurally unrelated to morphine (Fig. 34.24–1). Methadone consists of a racemic mixture; the *l*-isomer is responsible for the drug's analgesic and other opioid agonist effects. The *d*-isomer exhibits substantially less analgesic activity and does not have respiratory depression activity or addiction liability, but it does have antitussive effects.

Pharmacological Actions

Pharmacokinetics. Methadone is rapidly absorbed after oral administration. It is highly plasma protein bound, with an approximate volume of distribution of 4 L/kg. Methadone is demethylated in the liver by several cytochrome P450 (CYP) enzymes, primarily 3A4, and its inactive metabolite, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), is excreted in the urine. Of interest, women may metabolize methadone more rapidly than men. After oral administration, methadone has a biexponential half-life with an initial phase range of 12 to 24 hours and a secondary phase of 55 hours. Methadone obviously crosses the blood–brain barrier as well as the placenta and is found in maternal milk. The benefits of breastfeeding far outweigh concerns about exposing infants to the methadone in breast milk, and mothers on methadone maintenance are encouraged to breastfeed.

FIGURE 34.24–1. Molecular formula for methadone.

Pharmacodynamics. The major pharmacodynamic action of methadone is agonism at the μ-opioid receptor, but methadone, unlike most other opioids, also acts as an antagonist at the NMDA receptor and blocks serotonin and norepinephrine transporters. In addition, methadone inhibits the cardiac potassium channel, hERG, which can cause a prolonged QT interval on the ECG. There is often not a clear linear relationship between methadone blood levels and its clinical effects. Therefore, it is rarely necessary to obtain blood levels during clinical care of patients on methadone maintenance. Suggested minimally therapeutic trough serum levels of methadone range from 100 to 400 ng/mL. Peak serum levels of methadone vary considerably in stable patients. A peak-to-trough serum ratio of greater than 2:1 is often consider indicative of inadequate pharmacological coverage throughout the 24-hour dosing interval. Patients who display such a pattern may be rapid metabolizers of methadone who would ideally do best on a split-dosing regimen rather than on a higher single daily dose.

Design and Interpretation of Clinical Studies on Methadone

Although methadone maintenance treatment (MMT) was introduced in the 1970s, few randomized, controlled trials have evaluated its efficacy. Although these studies had small sample sizes and rarely followed patients for longer than 1 year, they reported positive results. The majority of data supporting the use of methadone maintenance comes instead from the many observational studies that have been conducted to evaluate this treatment modality. These studies support the findings of clinical trials in demonstrating that methadone treatment reduces heroin or other opioid use and criminal activity. Furthermore, MMT has been shown to decrease mortality among opioid-dependent patients. Mortality estimates indicate that heroin-dependent individuals in MMT are one-fourth as likely to die as dependent individuals not in treatment. MMT also appears to decrease drug use practices, such as needle sharing, that are associated with the transmission of HIV. Methadone treatment appears to be cost-effective, in that the cost per year of life saved is less than that incurred for other

common medical therapies such as coronary bypass surgery or renal dialysis. A review that included seven randomized controlled trials and two quasi-experimental studies of MMT from 1995 to 2012 confirmed all the benefits described above, particularly when the dose of methadone exceeded 60 mg/day and also confirmed improved maternal and fetal outcomes for pregnant women with opioid-use disorder when provided MMT.

Adverse Effects

General. Because methadone shares the adverse effects and toxic potential of other opioid agonists, the usual precautions of opioid agonist therapy should be observed. Common side effects of opioids include sedation, constipation, sweating, nausea, dizziness, and hypotension. During methadone maintenance, most adverse effects disappear over the course of several weeks. However, constipation and excessive sweating often persist even with long-term methadone administration. Recent case reports also indicate that, as noted above, methadone, especially in high doses, although occasionally in moderate doses, can impair cardiac conduction, prolong the QT interval, and in rare instances lead to torsades de pointes. Like other opioids methadone does suppress the hypothalamic–pituitary–gonadal axis and thus can cause hypogonadism with low testosterone levels in men and anovulation and lack of menstruation in women. A potential downstream effect of hypogonadism could be osteoporosis. Methadone does not cause chronic adverse effects on the heart, lungs, liver, or kidneys.

Overdose. Severe intoxication or overdose with opioids constitutes a medical emergency. Miosis (known as *pinpoint pupils*) is a recognized effect of most opioids and can be used to identify opioid intoxication. Of most concern in opioid overdose is potentially fatal respiratory depression from direct suppression of respiratory centers in the midbrain and medulla. For severe cases, the administration of the pure opioid antagonist naloxone in combination with general supportive measures is indicated. Owing to the long half-life of methadone, repeat administration of naloxone may be necessary. An overdose of methadone may also involve other sedative agents that may affect treatment decisions. In 2006, the FDA added a black box warning to the package insert for methadone emphasizing the risks of respiratory depression and QT prolongation. Naloxone is not effective orally but can be prescribed to patients on methadone maintenance either as an auto-injection device (Evzio), by a nasal spray device (Narcan), or in generic form for injection or by nasal spray for administration outside of the health care setting in the event of overdose.

Drug Interactions

Pharmacokinetic interactions are mainly related to methadone being a substrate for CYP450 3A4. Inducers of this enzyme such as the anticonvulsants, phenytoin and carbamazepine, the antituberculous medication rifampin, and antiretroviral medications, nevirapine, efavirenz increase the metabolism of methadone so that the patient could go into opioid withdrawal suddenly and become destabilized. Inhibitors of the enzymes such as the antidepressant fluvoxamine, the antibiotic, erythromycin, and antifungal medications, like ketoconazole have the potential to reduce methadone metabolism and lead to side effects or toxicity, though clinically meaningful effects are rarely observed with inhibitors. Pharmacodynamic interactions obviously can occur with opioid antagonists, such as naloxone or naltrexone, which would cause a patient on methadone maintenance to go into severe, precipitated withdrawal. Other opioids, sedative-hypnotics, and alcohol also have a pharmacodynamic interaction with methadone leading to additive excess sedation and greater risk of suppression of respiratory drive and overdose.

Laboratory Interference

None known.

Dosing

Federal eligibility requirements for MMT stipulate that individuals entering treatment have a minimum 1-year history of opioid-use disorder. The minimum age requirement is 18 years of age; however, individuals between 16 and 18 years of age may enter methadone treatment under certain conditions. There is no upper age limit on program entry. Pregnant women with opioid-use disorder may be accepted for methadone treatment, which is considered the standard of care for these women. Individuals with major medical conditions are also eligible for treatment, as are polydrug users who have opioid-use disorder as one component of their addictive disease.

Methadone dose determination should always be performed by an experienced physician based on his or her clinical assessment of the patient. Data indicate that adequate methadone doses are correlated with reduced illicit drug use and improved patient retention in treatment. A comparison by Eric C. Strain and colleagues of moderate daily doses of methadone (40 to 50 mg) and high doses (80 to 100 mg) showed significantly lower illicit opioid use in the high-dose group. Similar findings have been reported in regard to treatment retention, with one study showing that patients receiving 80 mg/day of methadone were twice as likely to remain in treatment as those receiving 60 to 79 mg, who were, in turn, twice as likely to remain in treatment as patients receiving less than 60 mg. The lowest effective dose of methadone is now widely accepted to be approximately 60 mg, with an optimum average dose for most patients of

approximately 80 mg (±20 mg), although some patients require a dose higher than this range.

In general, methadone can be initiated in an individual with well-established current physiological dependence at a dose of 20 to 30 mg. If there is any doubt as to the degree of an individual's tolerance to opioids, an initial dose of 10 mg is indicated. Under federal regulations the maximum allowable first dose is 30 mg, and the maximum total dose for the first day of treatment is 40 mg unless the physician documents the fact that 40 mg is insufficient to suppress withdrawal symptoms. Dose escalation should be done in small increments (usually 5 to 10 mg at a time) under close physician supervision until an optimum maintenance dose is achieved. Given methadone's long half-life, it is advisable to observe the patient for at least 3 to 4 days before an additional dose increase is provided. The optimum dose is achieved when (1) the patient evidences no withdrawal signs or symptoms throughout the 24-hour dosing period, (2) the patient reports an absence of craving for opioids, (3) adequate tolerance is obtained such that the patient experiences little or no reinforcement from use of other opioids, and (4) self-report and urine testing indicate the absence of illicit opioid use. Ideally these beneficial effects need to be balanced against side effects, so that small dose decrements may be required if unpleasant or intolerable side effects occur.

The duration of maintenance therapy may range from a few months to an indefinite period. In general, methadone maintenance should be continued as long as the patient is continuing to benefit from and wishes to remain in treatment. It should be noted that methadone administration should ideally be combined with comprehensive counseling and rehabilitative services.

BUPRENORPHINE

History

Reckitt and Coleman Ltd. developed buprenorphine in the 1970s as an analgesic because of the widespread interest in developing mixed agonist and antagonist opioid agents for pain relief. It was hoped that these agents would offer analgesia with greater safety and less abuse liability than the pure opioid agonists. Buprenorphine is available in many countries as an analgesic. It was first marketed in the United Kingdom in 1978 for injection and in 1981 as a sublingual tablet.

The potential for the use of buprenorphine in the treatment of opioid addiction was first recognized in the late 1970s when Donald Jasinski and colleagues demonstrated that buprenorphine substituted for morphine and suppressed opioid withdrawal while having few withdrawal symptoms. Human laboratory studies have demonstrated that buprenorphine suppresses heroin self-administration. A number of published clinical

observations have also supported the usefulness and general safety of buprenorphine in clinical settings. However, in clinical practice, buprenorphine has been widely used as an injectable analgesic, and intravenous (IV) buprenorphine has been reported as a significant drug of abuse in Europe, New Zealand, Australia, and the Republic of Georgia. In 2002, the FDA approved the use of buprenorphine for the treatment of opioid dependence. It is commercially available as a generic sublingual tablet containing buprenorphine only or a combination of buprenorphine and naloxone which can come as a sublingual tablet, a sublingual film strip, or a buccal patch. Only the sublingual formulation or the buccal patch, and not the parenteral or transdermal formulations, are approved for the treatment of opioid-use disorder. In 2016, the FDA-approved a subdermal formulation of buprenorphine requiring surgical implantation that has a 6 month duration of action. This formulation is approved for patients who have been stable on a dosage of sublingual buprenorphine of 8 mg daily or less for a minimum of 90 days.

FIGURE 34.24–2. Molecular formula for buprenorphine.

Chemistry

Buprenorphine is a semisynthetic derivative of the opioid alkaloid, thebaine (Fig. 34.24–2).

Pharmacological Actions

Pharmacokinetics. Because of extensive metabolism by the intestine and liver, buprenorphine is poorly absorbed by the oral route and is therefore best administered using IV or sublingual, buccal, or transdermal dosing. When administered by the IV route, buprenorphine is readily distributed into tissues, resulting in a large volume of distribution. The elimination is biphasic, with a rapid distribution phase ($T_{1/2}$ = 2 minutes) and a slower elimination phase ($T_{1/2}$ = 3 to 5 hours). The rate of absorption is slower by the sublingual route, with a time to reach maximum drug concentration (T_{max}) of approximately 60 minutes. It takes 3 to 5 minutes to dissolve, and sublingual bioavailability is approximately 55 percent. There is considerable between-subject variability in bioavailability, but the

data suggest greater bioavailability of buprenorphine/naloxone versus buprenorphine alone. Buprenorphine has a variable (range 3 to 44 hours) but typically long half-life. Following three-times-per-day dosing, steady-state levels of buprenorphine are reached at approximately 4 days. Buprenorphine is 96 percent bound to plasma proteins. Buprenorphine undergoes both glucuronidation and *N*-dealkylation, with *N*-dealkylation catalyzed by the liver enzyme CYP450 3A4 producing an active metabolite, norbuprenorphine. The main route of elimination for both parent drug and metabolites is fecal with lesser amounts excreted by the kidneys. Buprenorphine of course crosses the blood–brain barrier as well as the placenta and is found in maternal milk. The benefits of breastfeeding far outweigh concerns about exposing infants to the buprenorphine in breast milk, especially since buprenorphine has such low bioavailability by the oral route, so mothers on buprenorphine maintenance are encouraged to breastfeed.

Pharmacodynamics. Pharmacological studies have shown that buprenorphine combines a strong affinity for the μ-opioid receptor with low intrinsic activity. As such, it is considered a partial μ agonist. Buprenorphine is also an antagonist at the κ receptor. Because buprenorphine is a partial agonist, it has a considerable margin of safety with little chance of lethal overdose.

While blood levels of buprenorphine and norbuprenorphine are generally proportional to dose, to date no specific correspondence between blood levels and therapeutic effect has been demonstrated.

Design and Interpretation of Clinical Studies on Buprenorphine

A series of well-controlled clinical trials has clearly established the safety and clinical efficacy of buprenorphine. These trials have demonstrated the efficacy of buprenorphine, as compared to placebo, in decreasing illicit opioid use in opioid-dependent individuals. Subsequent trials have established the safety and efficacy of buprenorphine in maintenance treatment of opioid dependence in doses ranging from 2 to 32 mg/day.

Controlled clinical trials have demonstrated that buprenorphine and moderate-dose methadone (50 to 60 mg/day) have similar effects on retention and illicit drug use in maintenance programs. Comparisons of buprenorphine with higher doses of methadone suggest that high-dose methadone may have a slight advantage in terms of treatment retention and suppression of illicit opioid use. One recent study suggests that higher buprenorphine doses are associated with better treatment retention. Studies by Walter Ling and colleagues have demonstrated successful implementation and use of buprenorphine in private physicians' offices. Further studies have indicated that buprenorphine works as well or better for patients who primarily misuse prescription opioids as opposed to

heroin; that for patients without severe psychiatric illness outcomes for buprenorphine are as good with quality medical management alone as compared to addiction-focused counseling or psychotherapy added to medical management; and that outcomes with maintenance buprenorphine treatment are superior to outcomes when buprenorphine is tapered.

The Drug Addiction Treatment Act, which was signed into law in October 2000, marked the beginning of a process designed to allow qualified physicians to prescribe approved narcotic drugs for the treatment of opioid-use disorder in office-based settings. There are a number of approved training programs in place to teach physicians about the use of buprenorphine. This is the first time in modern medicine that physicians in the United States practicing in a variety of clinical settings, including office-based practice, are able adequately to treat opioid-use disorder with pharmacotherapy. This initiative has increased access to treatment for some individuals with opioid-use disorder, but in the face of an epidemic of prescription opioid and heroin use, a treatment gap still remains.

Adverse Effects

Because buprenorphine is a partial agonist rather than a full agonist at the μ receptor, and it is a weak antagonist at the κ receptor, this agent produces a milder withdrawal syndrome and has a wider margin of safety than the full μ-agonist compounds generally used in treatment. Buprenorphine has a ceiling effect beyond which dose increases prolong the duration of action of the drug without further increasing the agonist effects. Because of this, buprenorphine has a high clinical safety profile, with limited respiratory depression, therefore decreasing the likelihood of lethal overdose. Buprenorphine does have the capacity to cause typical side effects associated with opioids, including sedation, nausea and vomiting, constipation, dizziness, headache, and sweating. Buprenorphine may have the potential to suppress the hypothalamic–pituitary–gonadal axis, but this possible adverse effect requires further study. Buprenorphine does not cause chronic adverse effects on the heart, lungs, or kidneys. Some small early studies and case reports raised a concern that it could be hepatotoxic, but more recent, larger studies show no evidence of a hepatotoxic effect.

Drug Interactions

Theoretical pharmacokinetic interactions have been proposed mainly related to buprenorphine also being a substrate for CYP450 3A4. However, to the extent that these theoretical interactions have been studied in the human laboratory, no clinically meaningful effects have been observed, and no isolated clinical case reports have surfaced. It has been proposed that because buprenorphine has high affinity for and slow dissociation from the μ-opioid receptor, changes in plasma levels have little effect on efficacy.

Pharmacodynamic interactions obviously can occur with opioid antagonists, such as naloxone or naltrexone, although because of buprenorphine's high affinity and slow dissociation, there is competition for the receptor with likelihood of precipitated withdrawal being low. Other opioids, sedative-hypnotics, and alcohol could also have a pharmacodynamic interaction with buprenorphine leading to additive excess sedation and greater risk of suppression of respiratory drive and potential overdose. This risk is less than with full-agonist opioids, and overdoses in adults on buprenorphine alone are nearly nonexistent.

Dosing

To reduce the likelihood of abusing buprenorphine via the IV route, buprenorphine has been combined with the opioid antagonist naloxone for sublingual administration. Because naloxone is poorly absorbed by the sublingual route, when the combination drug is taken sublingually, there is no effect of the naloxone on the efficacy of buprenorphine. If an individual with opioid-use disorder injects the combination medication, the naloxone may precipitate a withdrawal reaction and/or block the intended effects of the buprenorphine being sought, therefore reducing the likelihood of illicit injection use of the sublingual preparation.

Inducting and stabilizing a patient on buprenorphine is analogous to inducting and stabilizing a patient on methadone except that, as a partial agonist, buprenorphine has the potential to cause precipitated withdrawal in patients who have recently taken full-agonist opioids. Thus, a patient must abstain from use of short-acting opioids for 12 to 24 hours prior to starting buprenorphine and from longer-acting opioids such as methadone for 24 to 48 hours or longer. The physician must assess the patient clinically and determine that the patient is in mild to moderate opioid withdrawal with objectively observable withdrawal signs prior to initiating buprenorphine. In most instances a relatively low dose of buprenorphine (2 to 4 mg) can then be administered with additional doses given in 1 to 2 hours if withdrawal signs persist. The goal for the first 24 hours is to suppress withdrawal signs and symptoms, and the total 24-hour dose to do so can range from 2 to 16 mg on the first day. In subsequent days the dose can be adjusted upward or downward to resolve withdrawal fully and, as with methadone, to achieve an absence of craving, adequate tolerance to prevent reinforcement from the use of other opioids, and ultimately abstinence from other opioids while minimizing side effects. Dose-ranging studies have demonstrated that doses of 6 to 16 mg/day are associated with improved treatment outcomes, as compared to lower doses of buprenorphine (1 to 4 mg). Sometimes patients seem to need doses higher than 16 mg/day, although there is no evidence for any benefit of doses beyond 32 mg/day. For the treatment of opioid-use disorder, a dose of approximately 4 mg of sublingual buprenorphine is the equivalent of a

daily dose of 40 mg of oral methadone. It has also been demonstrated that daily, alternate-day, or three-times-per-week administration have equivalent effects in suppressing symptoms of opioid withdrawal in physiologically dependent individuals. The buprenorphine/naloxone combination formulations are recommended for most clinical purposes, including induction and maintenance. The buprenorphine mono should be used only for pregnant patients or for patients who have a documented anaphylactic reaction to naloxone.

Newer forms of buprenorphine delivery including a long-acting depot intramuscular injection that provides therapeutic plasma levels for several weeks are being investigated. Such a delivery system, as well as the subdermal implants mentioned above, could obviate the need for taking medications daily while virtually eliminating the risk of medication nonadherence or diversion.

OPIOID AGONISTS IN THE TREATMENT OF PAIN IN INDIVIDUALS WITH ADDICTIVE DISORDERS

Opioid agonists are efficacious agents for the treatment of acute pain and possibly for some individuals with chronic pain syndromes, although their long-term use in chronic pain has never been demonstrated in randomized clinical trials, and the use of opioid agonists in the treatment of pain in individuals with substance use disorders is controversial. Untreated pain can be a powerful trigger for relapse. On the other hand, exposure to opioid analgesics for some individuals with addictive disorders could trigger reminders of past use and place them at risk for relapse. In addition, some of the physiological aspects of addictive disorders may make pain more difficult to treat in the addicted individual than in the nonaddicted individual. Finally, it can be difficult to distinguish distress related to pain from distress related to drug craving in individuals with opioid-use disorder. In spite of these potential problems, individuals with substance use disorders develop both acute and chronic pain disorders that warrant treatment, and total prohibitions against the use of opioids is neither practical nor good medical practice. However, pain management in individuals with addictions must attend to the treatment of both the pain and the addictive disorder to be successful. Ongoing support for maintaining recovery is essential for patients taking opioids for pain, including attendance at 12-step meetings and/or regular follow-up with a treatment professional who understands the issues involved in the treatment of pain in individuals with addictions.

Acute Pain Management

Undertreatment of pain associated with trauma and surgery has been demonstrated to increase morbidity and to lengthen hospital stays. In

individuals with addictive disorders, acute pain conditions increase distress and anxiety and may become a risk factor for relapse. Physicians treating patients in acute pain who have addictive disorders should reassure the patient that his or her addiction is not an obstacle to the appropriate and effective treatment of the pain condition.

For patients with opioid-use disorder, the physician should not consider tapering or discontinuing opioid medications until the acute pain situation is resolved. The use of nonmedication pain treatment approaches, such as ice or a transcutaneous electrical nerve stimulation (TENS) unit, should be optimized. When medications are necessary, it is best to use those least likely to alter mood or to produce physical dependence, if they are effective. Nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, anticonvulsants, and topical agents all have demonstrated efficacy in certain pain conditions. However, when opioid agents are necessary to manage pain conditions, they should be used effectively. In the management of moderate to severe acute pain, opioids are generally the mainstay of treatment in addicted or nonaddicted individuals. Scheduled administration of opioids is preferred to as-needed administration in individuals with addictive disorders, providing several advantages. If the patient needs to ask for medications, this may be misconstrued as drug-seeking behavior. In addition, when drug administration is time dependent rather than symptom dependent, reinforcement of pain symptoms is minimized.

Individuals on methadone maintenance or physically dependent on other opioids should have their baseline opioid requirements met in addition to the medications provided for pain treatment. At times these individuals require more opioid pain medication than the average individual because of their opioid tolerance and associated hyperalgesia. When possible, patients on methadone should receive a different opioid medication for the control of acute pain or have additional methadone prescribed on a three- or four-times-daily basis. Although an increase in methadone in divided doses throughout the day is generally effective in acute pain management, this strategy makes it easy to confuse issues of pain treatment with issues of addiction treatment. When the acute pain condition resolves, the taper of methadone back to the original maintenance dose can at times prove difficult for the patient.

The management of patients on buprenorphine who develop an acute pain condition is somewhat more complex, with less data and clinical experience to guide it. Although buprenorphine is an effective analgesic, it may not have the analgesic potency of a full-agonist opioid. There are essentially three options. One is to increase the dose of buprenorphine and give it in divided doses throughout the day. Another option is to try adding a full-agonist opioid to the regimen. It is unclear how efficacious a full agonist might be in the face of receptor occupancy by the partial-agonist

buprenorphine. A third option is to discontinue buprenorphine and switch temporarily to a full-agonist opioid during the time acute pain treatment is needed. When the acute pain subsides, the patient can be reinducted on buprenorphine, with care taken not to administer buprenorphine too soon after ingestion of the full agonist to avoid precipitating withdrawal.

Management of Chronic Pain

The treatment of chronic pain in individuals with addictive diseases also does not differ significantly from the treatment of these pain conditions in nonaddicted individuals. The goals of treatment are the reduction of pain, improvement in associated features, and restoration of function. Generally, these goals are approached initially through the use of nonpharmacological strategies, such as a TENS unit, peripheral nerve blocks, or trigger point injections. The mainstay of medication treatment for chronic, nonmalignant pain includes the nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, and anticonvulsants. Anticonvulsants (pregabalin) and antidepressant agents (duloxetine) have received FDA approval for specific chronic nonmalignant pain syndromes. There is now a Centers for Disease Control and Prevention Guideline for Prescribing Opioids for Chronic pain which emphasizes the importance of using a standardized approach so that decisions about the use of opioids and dose increases can be clearly justified. Clinicians should be aware that long-term opioid use may be associated with the development of abnormal sensitivity to pain or hyperalgesia, which can manifest clinically as needing increasing doses of opioids to maintain the same level of analgesia. However, dose escalation should be approached with caution, and ongoing assessment to determine whether the increased dosing is meeting the goals of treatment (decreased pain, improved functionality) is essential. Failure to meet goals requires reevaluation and change in treatment plan. Medication agreements may be a useful tool in the medication management of pain in individuals with addictions. A medication agreement is a written, signed statement that reinforces the patient's responsibility as a prerequisite for receiving controlled substance prescriptions and clarifies the boundaries of treatment. These can be useful in avoiding misunderstanding and clarifying decision points concerning opioid use in the treatment process.

Even when medications, including opioids, are deemed necessary in the treatment of chronic pain syndromes, the treatment plan should be multidimensional. Specifically, it should include a careful history of the development of the pain problem, factors that contribute to the patient's pain and distress, and a plan for dealing with each of these contributing factors. The treatment plan may include the physical treatments of pain mentioned previously (i.e., TENS unit, nerve blocks), as well as behavioral interventions, such as relaxation training, biofeedback, and changes in behavioral responses to pain. The use of long-term opioids as one

component in the treatment of chronic pain is generally a reasonable approach when other treatment regimens have failed. When opioids are used, it is important to document their benefit by observing that functional status is improving. The majority of chronic pain patients achieve relief of pain through multimodal approaches that do not include the use of opioids. Often, patients report that they feel better with the elimination of opioid use. For most patients, a trial period with the use of coordinated alternative treatments should be tried before long-term opioid therapy is used.

FUTURE DIRECTIONS

The efficacy of opioid agonist medications in the treatment of opioid dependence has been clearly established. In spite of the data demonstrating that maintenance programs are effective in decreasing opioid use, improving employment and prosocial behaviors, and enhancing public health and safety, only a small percentage of opioid-dependent individuals in the United States are in treatment. It is hoped that legislation making it possible to prescribe opioid agonist therapies in a variety of settings and the development of agonist agents with a greater margin of safety and less abuse potential will increase the number of opioid-dependent individuals receiving treatment.

▲ 34.25 Opioid Receptor Antagonists: Naltrexone and Nalmefene

SRINIVAS B. MUVVALA, M.D., SUCHITRA KRISHNAN-SARIN, PH.D., AND STEPHANIE S. O'MALLEY, PH.D.

INTRODUCTION AND HISTORY

Naltrexone, an opioid antagonist, was synthesized in 1965 by H. Blumberg and H. B. Dayton and proved to have a number of advantages over earlier opioid antagonists, including cyclazocine, nalorphine, and naloxone. Specifically, naltrexone had a relatively long half-life, was orally effective, was not associated with dysphoria, and could be administered once a day. Whereas earlier narcotic antagonists—principally naloxone—were used to reduce narcotic overdose, these characteristics of naltrexone made it suitable for use in preventing relapse to opiate use in detoxified opiate addicts. In 1984, naltrexone (under the original trade name Trexan) was approved for providing blockade of the effects of exogenously administered opiates in detoxified opiate addicts. Over the ensuing years, naltrexone has been tried for the treatment of a wide range of psychiatric disorders, including, among others, eating disorders, autism, self-injurious behavior, cocaine dependence, gambling, and alcoholism. Naltrexone (ReVia; Depade) was approved for the treatment of alcohol dependence in 1994. A number of generic formulations are also available. An extended-release, once-a-month injectable suspension (Vivitrol) was also approved in 2006 to treat alcohol dependence and in 2010 to treat opioid dependence. In

2014, FDA approved Contrave, which is a trade name for the combination of naltrexone hydrochloride and bupropion hydrochloride in an extended--release formulation, for treatment of obesity. Nalmefene (Revex) is indicated for the complete or partial reversal of opioid drug effects and in the management of known or suspected opioid overdose. An oral formulation of Nalmefene is available in some countries but not in the United States. Naloxone, an opiate antagonist, has been FDA approved for reversal of opioid overdose. It is an effective medication in reversing respiratory depression and preventing fatalities secondary to opioid overdose.

CHEMISTRY

Naltrexone, or 17-(cyclopropylmethyl)-4,5a-epoxy-3,14-dihydroxymorphinan-6-one hydrochloride, is a competitive opioid antagonist that was developed by substituting an *N*-methyl group on the opioid agonist oxymorphone with a methylcyclopropyl moiety. Naltrexone is available as a white, crystalline hydrochloride salt that is soluble in water, with a melting point of 275°C and a pKa of 8.13 at 37°C. Its molecular formula is $C_{20}H_{23}NO_4 \cdot HCl$. Nalmefene is a 6-methylene analog of naltrexone with a molecular formula $C_{21}H_{25}NO_3$, and it is also available as a hydrochloride salt with a pKa of 7.6 (Fig. 34.25–1).

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Naltrexone is rapidly and completely absorbed following oral administration of a 100-mg dose, with peak plasma concentrations of 19 to 44 mg/L being achieved within 1 hour. Oral bioavailability of naltrexone is 60 percent, with 20 percent of the drug being bound to plasma proteins. A single dose of naltrexone has a volume of distribution of 16.1 L/kg, which decreases to 14.2 L/kg following repeated administration.

Naltrexone is primarily recovered in plasma, urine, and feces as conjugated naltrexone and conjugated and unconjugated 6β-naltrexol along with minor quantities of 2-hydroxy-3-*O*-methyl-6β-naltrexol and 2-hydroxy-3-*O*-methylnaltrexone. Approximately 60 percent of the drug is recovered in the urine in 48 hours following oral administration and in 72 hours following intravenous administration. Naltrexone has a plasma half-life of 10.5 hours regardless of whether it is administered via the oral or intravenous route. Conjugated 6β-naltrexol has been shown to have a plasma half-life of 14 to 19 hours, which has been proposed to contribute to the longer duration of action of naltrexone. Studies indicate that after a 100-mg dose, naltrexone can be detected in plasma for 30 hours, whereas 6β-naltrexol can be detected for up to 125 hours. The extended-release injectable formulation (Vivitrol), containing 380 mg of naltrexone, was

created using Medisorb drug-delivery technology for once-a-month intramuscular (IM) injections. Following administration of this formulation, an initial peak is seen within 2 hours, followed by a second peak 2 to 3 days later, with a slow decline in concentrations after 14 days. Total naltrexone exposure is three- to fourfold higher than that observed with daily oral dosing over a 28-day period. The elimination half-life of both naltrexone and β-naltrexol in this form is 5 to 10 days.

FIGURE 34.25–1. Molecular structure of naltrexone (ReVia).

Nalmefene, following administration of a 1-mg intravenous dose, has a volume of distribution of 8.6 L/kg and a terminal half-life of 10.8 hours. Nalmefene is completely bioavailable following IM and subcutaneous (SC) routes, with time-to-peak plasma concentrations of 2.3 (±1.1) and 1.5 (±1.2) hours, respectively. Because of variability in the speed of absorption of IM and SC doses, repeated dosing should be done with great care. Nalmefene is primarily metabolized though glucuronide conjugation in the liver and is excreted in the urine. Both the glucuronide and the dealkylated metabolite (which is formed in trace amounts) have minimal pharmacological activity. Nalmefene when administered orally has a pharmacokinetic profile that is similar to that of naltrexone. A metabolite, nornalmefene, has been identified that also exists in glucuronidated and alkylated forms. Hepatic or renal impairment decreases clearance of both naltrexone and nalmefene.

Pharmacodynamics

Naltrexone is a nonspecific opioid antagonist that binds to all three opiate receptor sites (μ, κ, δ) as a function of dose administered. Naltrexone has minimal opioid agonistic effects, and its relative opiate antagonistic potency is 12 times that of nalorphine and 2.5 times that of naloxone or cyclazocine. The time course of action of oral naltrexone has been shown to be about three times longer than that of naloxone in rodents. No significant species differences in the binding of [^{3}H]naltrexone have been documented. An oral 100-mg dose of naltrexone was found almost completely to antagonize the subjective and objective responses of 25 mg of IV heroin.

Similarly, following a 1-mg IV dose, nalmefene blocks greater than 80 percent of brain opioid receptors within 5 minutes after administration. Whereas nalmefene has been shown to have greater antagonistic potency at the δ-opioid receptors, it has also been shown following oral administration of a dose of 20 mg to produce complete and prolonged blockade of the μ-opioid receptors.

Acute administration of 50 mg of naltrexone has been shown to precipitate an abstinence syndrome in morphine-dependent individuals, an effect that decreases with chronic use. This decrease is believed to be due to increases in the number and functional activity of brain opioid receptors with long-term naltrexone administration.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Naltrexone and nalmefene have demonstrated efficacy in blocking exogenously administered opiates and were used in protocols for rapid opioid detoxification. Both agents have also been extensively examined as aids in preventing relapse in patients with alcohol dependence. Both agents, particularly naltrexone have shown benefit in reducing heavy drinking in numerous studies. Extended-release formulations of naltrexone have been evaluated to prevent relapse in both alcohol and opiate use disorders. Naltrexone has also been evaluated as a treatment for self-injurious behavior and other autistic behaviors in patients with mental retardation and autism. Support for use in patients with mental retardation and autism is based only on small studies and case reports that have not been confirmed by larger, double-blind clinical trials. Case reports and small open-label trials have also examined naltrexone's utility in treating compulsive sexual behavior and kleptomania. Open-label and randomized, controlled trials using relatively small samples have examined the efficacy of naltrexone in reducing binge eating. Randomized placebo-controlled trials have evaluated the extended-release combination of naltrexone and bupropion for the treatment of obesity. Use of nalmefene and naltrexone for pathological gambling disorder is supported by some randomized clinical trials. Naltrexone has been evaluated for cocaine use disorders without much success. Although randomized clinical trials suggest the possible utility for naltrexone as adjunctive therapy for smoking cessation, the effects are inconsistent and may vary by gender.

THERAPEUTIC INDICATIONS

Alcohol Use Disorders

The efficacy of naltrexone was originally demonstrated in the 1990s in two double-blind, placebo-controlled trials of naltrexone in alcohol-dependent patients. In each of these studies, treatment with an oral dose of 50 mg daily was initiated following a minimum of 7 days of abstinence or

completion of medical detoxification and was provided with concurrent psychosocial interventions. In a combined analysis of these studies, naltrexone-treated patients were more likely to remain abstinent (54 percent vs. 31 percent), to experience fewer days of drinking (3.1 percent vs. 7.5 percent), and to report lower rates of relapse to heavy drinking (25 percent vs. 52 percent). Furthermore, participants who lapsed (i.e., were nonabstinent) were less likely to experience heavy drinking if they were taking naltrexone rather than placebo. The COMBINE Study, a large multisite trial combining pharmacotherapy and behavioral interventions, conducted in 11 academic sites across the United States showed that 100-mg dose of naltrexone, when given along with medical management was more effective than placebo in increasing percent days of abstinence and reducing heavy drinking days. In a recent meta-analysis of pharmacotherapies for alcohol dependence, 53 trials studied the efficacy of naltrexone (n = 9,140), and treatment duration ranged from 12 to 52 weeks. Naltrexone was shown to have benefit in various consumption outcomes. Naltrexone is particularly shown to have efficacy in preventing return to heavy drinking and reducing percent drinking days and percent heavy drinking days.

An extended-release formulation of naltrexone has also shown similar efficacy in reducing the rate of heavy drinking. A large multisite double-blind placebo-controlled study evaluated the efficacy and tolerability of 2 doses of intramuscular long-acting naltrexone injections (380 mg and 190 mg) versus placebo in alcohol-dependent patients. The long-acting preparation was well tolerated over a 6-month period and the 380-mg injectable naltrexone preparation showed 25 percent reduction in number of heavy drinking days. In the subset of patients who were abstinent 4 or more days prior to treatment initiation, the 380-mg preparation also prolonged abstinence and reduced the number of heavy drinking days and drinking days. Some research also suggests that naltrexone may have utility when used to control progression to heavier drinking behavior without a goal of abstinence.

Despite a substantial literature supporting the use of naltrexone for reducing drinking behavior, the efficacy of this agent is modest. This evidence has motivated researchers to examine predictors of response to naltrexone. Recent evidence suggests that the efficacy of naltrexone may be more pronounced in certain subgroups of patients, such as male drinkers, those with a positive family history of alcoholism, those who have antisocial traits, or smokers. Individuals with high levels of craving also seem to benefit from naltrexone. The predictive utility of the Asn40Asp polymorphism of the μ-opioid receptor (OPRM1) gene in treatment response is being debated with some studies showing a stronger effect of naltrexone in Asp40 carriers while others do not. As a result, the data are still insufficient to recommend using these moderators in predicting

response in clinical practice. Because of the good safety profile of naltrexone and support for its effectiveness in a range of patient populations, naltrexone should be offered as one of the treatment options to all patients with alcohol dependence who do not have contraindicating conditions.

Nalmefene is now approved by the European Medicines Agency for reduction of alcohol consumption in patients with high-risk drinking who do have alcohol withdrawal symptoms and who do not require alcohol detoxification. The studies supporting the approval tested nalmefene taken as need (i.e., in high-risk situations, when drinking is imminent, or as soon as possible after drinking) compared to placebo. Although there have been fewer studies of nalmefene, a recent meta-analysis concluded that nalmefene led to a reduction in heavy drinking days per month and the number of drinks per drinking day.

Several small trials have also examined the combined use of opioid antagonists with other agents. Preliminary small placebo-controlled studies suggest that combination of the 5-HT_3 antagonist ondansetron and naltrexone, when compared with placebo, may produce greater suppression of drinking outcomes in early-onset alcoholics. Combined use of naltrexone with disulfiram has shown modest efficacy in increasing abstinence rates in patients with concurrent axis I psychiatric disorders and alcohol dependence. A large, multisite trial indicated no significant advantage of using naltrexone in combination with acamprosate for the treatment of alcohol dependence. Combination of low-dose naltrexone and prazosin has shown some promise in patients with comorbid PTSD. Addition of gabapentin to naltrexone has shown to improve drinking outcomes than naltrexone alone in the first 6 weeks of abstinence possibly secondary to beneficial effects with symptoms such as insomnia and mood instability.

Narcotic Addiction

Although naltrexone was originally developed for the treatment of opiate addiction, the value of naltrexone for this indication has been limited primarily by two issues: (1) the need for opiate detoxification prior to induction and (2) poor adherence compared to agonist therapy. The newer extended-release formulations address to a large extent the issue of adherence at least for the 30 days between injections. The advantages and disadvantages of naltrexone for the treatment of narcotic addiction are discussed below.

As an opioid antagonist, naltrexone selectively competes with exogenous opioids for central nervous system (CNS) and non-CNS opioid receptors and blocks their activity. This blockade lasts for up to 72 hours after naltrexone administration and prevents patients from achieving sought-after reinforcement from opioid use and from resuming physical

dependence if prolonged opioid use is resumed. This blockade can have positive psychological consequences, including reduced craving related to reduced immediate availability of opioid effects and deconditioning of cue-related craving as patients are exposed to people, places, and things formerly associated with opioid use. The opioid antagonist properties of naltrexone do not appear to be subject to the development of tolerance because potency has been demonstrated after maintenance for 1 year or more. Naltrexone does not have opioid agonist properties, and patients do not obtain a psychoactive reward ("high") from using naltrexone. It is also not associated with significant withdrawal symptoms if use is discontinued. However, patients may be more sensitive to lower doses of opioids once naltrexone is discontinued due to the loss of tolerance to exogenous opiates.

In carefully selected patients who are motivated to take naltrexone, maintenance on naltrexone, an opioid antagonist, can be used as an alternative to maintenance treatment with opioid agonists, such as methadone or the partial agonist buprenorphine. As a nonscheduled medication without psychoactive or addictive properties, naltrexone can be administered as a maintenance treatment in a range of medical settings without any special licensing requirements. Because diversion is not an issue, take-home medications can be provided. As a drug without agonist effects that blocks the effects of opioids, naltrexone can be used only after completion of a 7- to 10-day period of complete opioid abstinence or after a rapid detoxification procedure to avoid precipitating opiate withdrawal. Hence, patients must start treatment with a goal of achieving total opioid abstinence and a willingness to undergo detoxification. Unlike patients maintained on opioid agonists, patients on naltrexone achieve no rewarding effects of taking medications and experience no withdrawal effects if doses are missed. Thus, there are no pharmacological barriers to dropping out of treatment. In addition, some patients continue to complain of at least mild side effects or opioid withdrawal effects throughout the first several weeks of treatment.

However, oral naltrexone has been associated with high rates of discontinuation. A Cochrane review of randomized controlled clinical trials of naltrexone maintenance treatments for opiate addiction suggested that oral naltrexone was not more effective than placebo or no pharmacological agent in preventing relapse mainly due to low adherence and retention rates. Greater success has been achieved with patients motivated by powerful contingencies such as opioid-dependent health care professionals for whom opioid abstinence is a condition for regaining medical licensure or incarcerated addicts for whom treatment is a requirement for probation or parole. Other strategies to enhance compliance include the use of voucher-based contingency management and the dispensing of naltrexone that is directly observed by either a medical professional or a significant

other. The importance of retention in therapy for opiate addiction is highlighted by a review of coronial data in Australia in which opiate agonist treatment was associated with lower opiate overdose deaths compared to oral naltrexone, likely due to better retention in treatment with agonist therapy.

Extended-release formulations, both injectable and surgically implantable, address some of the shortcomings of the oral naltrexone related to adherence and retention. The extended-release injectable formulation of naltrexone (XR-NTX) was approved by FDA in 2010 to treat and prevent relapse after patients with opioid dependence have undergone detoxification treatment. A double-blind placebo-controlled multicenter trial in Russia showed that XR-NTX in conjunction with psychosocial treatment is efficacious in preventing relapse on opiates in detoxified patients. The median proportion of weeks of abstinence was 90 percent in 380-mg extended-release naltrexone group versus 34 percent in the placebo group. In addition, treatment retention was much higher and opioid craving was much lower in the active medication group. The 1-year open-label extension phase of this study showed that 62.3 percent clients remained compliant out of which 50.9 percent patients remained abstinent from opiate use and the safety of use of XR-NTX is further established during this phase. A recent study demonstrated the usefulness of XR-NTX as a therapeutic option in the treatment of opioid dependence in individuals involved with the criminal justice system. XR-NTX patients were shown to have lower health care utilization costs and longer periods of medication refills than patients taking oral naltrexone or acamprosate. Opioid-dependent patients maintained on XR-NTX were shown to have both lower inpatient substance abuse–related utilization as well as total cost of treatment as compared to methadone. Newer sustained-release formulations have been developed such as naltrexone implants but further research is needed to establish their safety and efficacy in clinical use.

XR-NTX appears to be well tolerated and concerns about hepatotoxicity have not been realized. No differences have been found between XR-NTX and placebo on the proportion of patients showing elevations in liver enzymes and XR-NTX has been found to be safe in patients with mild to moderate chronic HCV and/or HIV infections. Opioid detoxification is key prior to naltrexone induction to avoid precipitating opiate withdrawal. This can be done by a gradual opioid or buprenorphine taper or by more rapid discontinuation with the help of adjunctive nonopioid medications for symptomatic relief. The latter is more suitable for patients with low physiological dependence. For patients who are at risk of moderate to severe withdrawal symptoms, detoxification is best carried out in an inpatient detoxification setting or a partial hospital program with inpatient backup.

Opiate Detoxification Protocols in Combination with Naltrexone

As a method for rapid detoxification, outpatient protocols have been developed combining naltrexone with clonidine, a selective α2-adrenergic antagonist initially used as an antihypertensive agent, and other adjunctive medication. This combined treatment allows patients to be completely opioid free from the first day of treatment, to have completed detoxification within 48 to 72 hours, and to be able to commence naltrexone maintenance at that time. In addition, as a method of initiating maintenance naltrexone treatment, this mode of detoxification removes the need for an unprotected 7- to 10-day opioid-free period prior to starting naltrexone, a time when vulnerability to relapse is high. Because blood pressure may be substantially lowered by clonidine administration, patients must be monitored for up to 8 hours on the initial detoxification day, limiting this procedure to settings in which treatment rooms and adequate nursing staff are available. As this procedure may result in significant withdrawal symptoms, this method is best used in patients with low level of physiological dependence to opiates.

A variant method of "ultrarapid" inpatient detoxification involves administering naltrexone to opioid-dependent patients who are placed under light sedation or general anesthesia (including mechanical ventilation) followed by detoxification using full doses of naltrexone. This method was associated with more incidences of life-threatening adverse events and therefore this form of "ultrarapid" detoxification cannot be recommended at this time.

Opioid Overdose Prevention

Deaths from opioid overdoses have reached epidemic levels in the United States. Naloxone hydrochloride (Narcan) a potent opioid antagonist has been widely used in various health care settings and by emergency medical personnel to reverse opioid overdose and the associated respiratory depression. Naloxone can be administered by multiple routes in a hospital setting, but it is available to be administered intramuscularly or intranasally in the community. Some community-based overdose prevention programs have been distributing naloxone to patients at risk of overdose since 1996. Subsequently, several agencies have been training clinicians to screen patients for overdose risk, and to educate them and their kin in recognizing and responding to overdoses. With increase in these initiatives focusing on naloxone distribution, there have been reports of thousands of overdose rescues in the United States. Many states have passed legislations permitting physicians to prescribe or dispense Narcan to prevent or reverse opioid overdose and for bystanders to administer Narcan in the event of an opioid overdose.

Cocaine Use Disorders

Based on preclinical studies showing that opioid antagonists can attenuate many effects of cocaine, including acquisition and maintenance of self-administration, a randomized, placebo-controlled clinical trial evaluated its efficacy in a 50-mg/day dose alone and in combination with relapse prevention therapy. Naltrexone was associated with modestly improved cocaine use outcomes only when combined with relapse prevention therapy. However, trials in patients with cocaine and alcohol dependence found no benefit of naltrexone in reducing cocaine use. A prior open-label study and another double-blind placebo-controlled study found disulfiram to be superior to naltrexone for patients with combined cocaine and alcohol abuse. Hence, the evidence does not justify a recommendation for naltrexone use in cocaine dependence.

Nicotine Use Disorders

Several lines of evidence suggest that the opioid system may be involved in nicotine dependence. Nicotine administration is known to stimulate the release of endogenous opioids and to attenuate the perception of pain via opioid mechanisms. Clinical laboratory studies examining the effects of opiate antagonists, including naloxone and naltrexone, on smoking behavior have been inconclusive, with some studies showing reductions in smoking and others finding no effect. Prior clinical studies suggested that naltrexone may reduce urges or the desire to smoke and may also reduce weight gain following smoking cessation. The clinical utility of naltrexone as an aid for smoking cessation is supported by two randomized clinical trials, both of which tested the efficacy of naltrexone when used in combination with the nicotine patch for smoking cessation. One study found preliminary efficacy for 50-mg naltrexone primarily in women. The other trial, which combined naltrexone (25 to 100 mg/day) with a 21-mg nicotine patch, found some advantage for the 100-mg dose of naltrexone as an augmentation strategy for smoking cessation. However, a recent meta-analysis of opioid antagonists for smoking cessation concluded that naltrexone alone or as an adjunct to nicotine replacement has no beneficial effect in short- or long-term smoking abstinence. The two clinical trials mentioned above found significant reductions in weight gain following smoking cessation, suggesting that naltrexone may have clinical utility as an adjunctive treatment for smokers who are concerned about weight gain following smoking cessation.

Self-Injurious Behavior

Naltrexone has been proposed as a treatment for self-injurious behavior and for autistic behaviors in patients with mental retardation and autism. Clinically significant symptom reduction has been reported from numerous

open case studies and trials with small sample sizes. Larger studies using more rigorous experimental designs have failed to replicate these reports. Hence, naltrexone's utility for these symptoms is not established.

Eating Disorders/Obesity

Numerous studies in rodents have suggested an association between altered endogenous opioid activity and obesity and other eating disorders. Exogenous and endogenous opioid administration increases food intake, whereas opiate antagonists block the increase in food intake. The clinical data on the use of opiate antagonists in eating disorders is controversial, and the literature is replete with studies that demonstrate differential effects of these agents based on the type of eating disorder. For example, a laboratory study demonstrated that naloxone reduces the consumption of sweet, high-fat foods in both obese and lean binge eaters compared with obese and lean nonbingers suggesting a role of the opioid system in binge eating but not in obesity. In bulimia nervosa, a handful of small sample-controlled clinical trials have been conducted, with some, but not all, reporting reductions in binge symptomatology. With regard to anorexia nervosa, naloxone infusion produced a 10-fold increase in weight gain per week, an effect that was ended when the naloxone infusion was stopped in patients who were also concurrently treated with the antidepressant amitriptyline Therefore, the role for naltrexone and other opiate antagonists in the treatment of eating disorders remains unclear, and larger, more definitive, controlled clinical trials are needed.

Naltrexone, when used alone has failed to produce clinically significant weight loss in controlled studies. However, in translational studies the combination of naltrexone and bupropion (NB) produced a synergistic reduction of food consumption in rodents. This was further proven by studies in overweight and obese individuals in which weight loss produced by the combination of bupropion and naltrexone was shown to be greater than the sum of individual monotherapies. A large, multicenter, randomized, double-blind, placebo-controlled trial showed that NB is a useful therapeutic option for treatment of obesity. The mean change in body weight was –6.1 percent in the sustained-release naltrexone 32 mg plus sustained-release bupropion 360-mg/day group (NB32) and –5 percent in the sustained-release naltrexone 16 mg plus sustained-release bupropion 360-mg/day group (NB16) as compared to –1.3 percent in placebo. Similarly, 48 percent of participants assigned to NB32 group and 39 percent of participants assigned to NB16 group had greater than 5 percent weight loss, as compared to only 16 percent in the placebo group. Another large 56-week, randomized, double-blind, placebo-controlled study in obese or overweight participants with dyslipidemia and/or hypertension compared NB32 to placebo. 55.6 percent of the participants treated with NB32 had greater than 5 percent weight loss as compared to

17.5 percent in the placebo group. This study also showed that NB32 produced greater improvement in weight-related quality of life, control of eating, and various cardiometabolic risk markers without any increase in depression or suicidality. Another double-blind placebo-controlled study in overweight/obese type 2 diabetics showed that NB was associated with improvements in glycemic control and select cardiovascular risk factors along with promoting weight loss. FDA recently, in 2014, approved the combination of naltrexone hydrochloride and bupropion hydrochloride in an extended-release formulation for the treatment of obesity.

Naltrexone showed promise in reducing long-term smoking cessation-related weight gain in women. In recent pilot studies naltrexone has shown promise in arresting antipsychotic-associated weight gain in patients with a diagnosis of schizophrenia and schizoaffective disorder. It is hypothesized that naltrexone could help reduce food cravings in this population by interacting with the dopamine–opioid system.

Pathological Gambling

Opioid antagonists have the ability to decrease dopamine release in the nucleus accumbens through the disinhibition of GABAergic input to dopamine neurons in the ventral tegmental area. As such, it has been hypothesized that these agents might be effective in the treatment of impulse control disorders in general and pathological gambling in particular. Two open-label case series and a moderately sized, placebo-controlled, randomized, double-blind study supported the efficacy of naltrexone in the short-term treatment of pathological gambling. In these studies, naltrexone was used at higher doses than generally used in the treatment of alcohol or opiate dependence. In the placebo-controlled, double-blind study, for example, the dose of 250 mg/day was targeted, and completers had an end-of-study dose of 188 mg/day. Consistent with the use of these higher doses, adverse effects were not infrequently reported, the most significant of which included elevated liver function tests (LFTs). An examination of the individuals experiencing naltrexone-induced increases in LFTs suggested that concurrent use of nonsteroidal anti-inflammatory drugs (ibuprofen, aspirin) was associated with LFT increase. A double-blind placebo-controlled trial demonstrated that 50, 100, and 150 mg doses of naltrexone were equally efficacious in reducing gambling urges and behavior in pathological gambling.

There has been more research examining the use of nalmefene for the treatment of pathological gambling. Two multicenter investigations suggested that the use of 25 mg of nalmefene daily may effectively reduce the severity of gambling in those with pathological gambling disorder; there was 59 percent improvement in those who received nalmefene versus 34 percent in those who received placebo. Higher doses of nalmefene (50 and 100 mg/day) were associated with intolerable side effects. Another

double-blind placebo-controlled showed that at doses of 20 and 40 mg, nalmefene was not superior to placebo in the treatment of pathological gambling.

Currently there is no FDA-approved medication for treatment of gambling disorder. A recent meta-analysis investigating the efficacy of pharmacological treatments found that opiate antagonists have small but significant benefit than placebo in treatment of pathological gambling. However, the study did not support the use of the opiate antagonists at this time citing that some of the studies have not adhered to intent-to-treat principles. Further studies are needed to examine the safety and efficacy of nalmefene and naltrexone in the treatment of pathological gambling, especially in individuals with co-occurring substance use disorders and also in combination with nonpharmacological treatment modalities.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Although this section is written specifically for naltrexone, the effects of nalmefene are similar except where noted.

Respiratory System

In opiate-dependent individuals, the administration of naltrexone has been shown to produce a variety of nasal symptoms, such as nasal congestion, sneezing, rhinorrhea, sore throat, cough, and shortness of breath. In clinical trials with the injectable formulation Vivitrol, one diagnosed case and one suspected case of eosinophilic pneumonia were observed.

Heart

Naltrexone has increased blood pressure in opiate-dependent individuals, and it can also produce palpitations and tachycardia. Naltrexone has also been shown to decrease fibrinogen levels in opiate addicts.

Smooth Muscles

Naltrexone has produced muscle tension, tremors, and twitching in opioid-dependent subjects. Incidences of back pain/stiffness, muscle cramps, and joint stiffness have also been reported with Vivitrol.

Liver

While naltrexone has not been shown to be hepatotoxic when administered in the recommended dose of 50 mg/day, hepatotoxic potential has been documented for a sixfold higher dose of 300 mg/day in obese individuals and in patients with Alzheimer disease. In an open-label safety study in which the typical dose was 50 mg, naltrexone was not associated with increased risk of hepatotoxicity in more than 500 alcohol-dependent patients treated for up to 12 weeks. However, in another trial, a daily dose

of 100 mg was associated with a small but statistically significant increase in the number of patients who experienced elevated liver function tests during a 16-week period. Thus, naltrexone is contraindicated in patients with acute hepatitis, liver failure, or significant liver disease. However, mild to moderate transaminase elevations associated with alcohol or drug use are not a contraindication. Similarly XR-NTX is reported to have lower likelihood of hepatotoxicity than previously suspected even in individuals with HIV and HCV co-infection. Moreover, naltrexone has also shown some utility in the treatment of pruritis observed in cholestatic patients.

Endocrine System

Changes in baseline levels of some hypothalamic, pituitary, and gonadal hormones have been reported with naltrexone. Naltrexone has been shown to produce significant increases in plasma luteinizing hormone (LH) and testosterone in opiate-dependent individuals and to reverse heroin-induced decreases in such individuals. In healthy adult men, naltrexone has been shown to increase plasma prolactin, LH, testosterone, adrenocorticotropin (ACTH), and cortisol levels.

Gastrointestinal Symptoms

Abdominal pain and cramps have been documented following naltrexone administration in both opiate-dependent and nondependent individuals. Some individuals also report feeling nauseated and/or vomiting and suffering loss of appetite, as well as diarrhea or constipation.

Carcinogenesis and Mutagenesis

Carcinogenicity studies with high doses in rats have documented a small increase in mesotheliomas and vascular tumors. No evidence of mutagenicity has been documented with naltrexone or nalmefene.

Pregnancy

Naltrexone, when administered at doses 140 times the therapeutic dose in humans, has been shown to decrease pregnancy rates in rats and to have an embryocidal effect in rats and rabbits. Doses of 100 mg per kg in rats and 60 mg per kg in rabbits have been shown to have similar effects. In preclinical studies, naltrexone has been shown to pass through the placenta to the fetus. There are no adequate or controlled studies of naltrexone in oral or injectable form in pregnant or nursing women. Similarly, preclinical reproduction studies with nalmefene indicate no evidence of impaired fertility or fetal harm. However, because there are no adequate trials in pregnant women, this drug should be used during pregnancy or in nursing women only if it is clearly needed.

Genitourinary

Less than 10 percent of individuals have reported increased frequency of or discomfort during urination, increased frequency of erections, or alteration in sexual interest.

Psychiatric/Neurological

Non–opiate-dependent individuals have reported feeling fatigued, tired, and listless following the administration of naltrexone. Some individuals have reported an increase in irritability, restlessness, mental confusion, and slowing following naltrexone administration. A recent meta-analyses of medications for alcohol use disorders found that both naltrexone and nalmefene have higher risk of withdrawal due to adverse events like dizziness, nausea and vomiting but the latter has a higher risk difference for incidence of dizziness as compared to placebo and also has higher rates of incidence of headache. Substance abusers have an increased risk of suicide, and this risk is not reduced by naltrexone.

Skin/Local Injection Site

Vivitrol (XR-NTX) injections can result in pain, tenderness, induration, swelling, erythema, bruising and pruritus at the injection site. Proper injection technique is essential as inadvertent subcutaneous administration may increase likelihood of severe injection site reactions.

General Problems

Some individuals have also reported blurred eyes and increased light sensitivity, as well as tinnitus.

THERAPEUTIC INDICATIONS

FDA-approved indications for naltrexone include the use of naltrexone as a maintenance treatment for detoxified patients with opioid dependence and to prevent relapse in patients with alcohol dependence. Naltrexone has established utility when combined with clonidine as part of outpatient detoxification protocols. Extended-release injectable formulation of naltrexone has been approved for maintenance treatment of both opiate and alcohol dependence. Fixed-dose combination of naltrexone and bupropion in an extended-release formulation has been approved for the treatment of obesity. Naloxone hydrochloride injection has been approved by FDA for opioid overdose reversal or for suspected acute opioid overdose.

PRECAUTIONS AND ADVERSE REACTIONS

One of the most important risks with this class of agents is the risk of precipitated withdrawal in those who have received high doses of opioids

for therapeutic purposes or in those who use opioids recreationally. As a result, patients should be abstinent from short-acting narcotics (e.g., heroin) for at least 5 to 7 days and from longer-acting opiates (e.g., methadone) for 10 days or more based on self-report and urine toxicology. If there is a question of occult opioid dependence in an individual who has a negative urine toxicology screen for opiates and is not showing signs of withdrawal, a naloxone challenge test is recommended in which the patient is observed for signs and symptoms of opiate withdrawal for 20 minutes following a subcutaneous injection of 0.8-mg naloxone. Otherwise, naltrexone is generally well tolerated, and the majority of patients who have no reaction to a test dose of naloxone report no side effects. The profile of reported side effects has considerable similarity to the symptoms of opioid withdrawal and includes gastrointestinal distress (nausea, vomiting, diarrhea, and abdominal pain), anxiety and restlessness, dysphoria, mild hypertension, headache, and insomnia. These side effects are most prominent in the first several days of use and improve rapidly for patients remaining in treatment. However, a substantial minority of those with a diagnosis of opiate dependence (5 to 10 percent) may refuse a second dose, and an additional 10 to 20 percent may discontinue medication in the first month of treatment, often citing continued discomfort reminiscent of opioid withdrawal throughout the first 1 to 3 weeks of treatment. Side effects can be minimized by ensuring an adequate interval between cessation of opioid use and initiation of naltrexone and by a graduated initial dose schedule starting with 12.5 or 25 mg daily for the first several days. A prior study which used naltrexone depot treatment showed that 32 percent of opioid-dependent patients discontinued treatment after the first injection. Six-month retention rates of oral naltrexone in opiate-dependent patients are generally less than 20 percent following induction. However, injectable naltrexone has been shown to have higher 6-month retention rates as compared to placebo in a recent large Russian study. Studies examining the medication refill persistence showed that injectable naltrexone is consistently associated with better adherence rates in alcohol-dependent patients as compared to the oral agents.

Patients should be advised that taking large quantities of exogenous opioids in an attempt to overcome the blockade provided by opioid antagonists can be extremely dangerous. Life-threatening opiate intoxication may result, including respiratory arrest or circulatory collapse. In addition, patients should be advised that once these agents are discontinued, they may be more sensitive to the effects of opioids due to loss of tolerance.

Among alcohol-dependent patients, nausea is the most common adverse reaction to naltrexone, can be mild to severe, and typically occurs within 90 minutes of administration. In a large multisite safety study, side

effects that occurred in more than 2 percent of patients included nausea (10 percent), headache (7 percent), dizziness (4 percent), nervousness (4 percent), fatigue (4 percent), insomnia (3 percent), vomiting (3 percent), anxiety (2 percent), and somnolence (2 percent). In a large clinical trial for alcohol dependence with a 100-mg daily dose of naltrexone a similar side-effect profile was observed. The effect of naltrexone on acute alcohol withdrawal has not been investigated. The rate of early termination due to adverse events has been somewhat higher in studies in which naltrexone was administered to actively drinking alcoholics. Women and younger patients appear to be at somewhat increased risk of side effects.

The potential for hepatotoxicity has been identified when naltrexone is administered at high doses. However, convincing reports of elevated liver function test results have been limited to patients treated for eating disorders with doses of 250 to 300 mg daily, which are five to six times higher than the recommended maintenance dose for opioid dependence. In a clinical trial of alcohol dependence with a 100-mg/day dose, a 2 percent rate of increases in liver enzymes (aspartate or alanine aminotransferases) to greater than five times the upper limit of normal was observed; this increase resolved on discontinuation of naltrexone. Therefore, as a precaution, patients should receive a full battery of liver function tests prior to receiving naltrexone, and naltrexone is contraindicated in patients with liver failure or acute hepatitis. The moderate transaminitis often seen in alcoholism and narcotic addition is not a contraindication; however, baseline bilirubin and serum transaminases and periodic monitoring of transaminases is indicated. If persistent elevations in liver enzymes occur, naltrexone should be discontinued. The possibility of medication noncompliance and continued alcohol or drug use should be ruled out when mild transaminase elevations (less than threefold) occur.

Because this class of agents is excreted through the kidneys and metabolized by the liver, caution should be used in patients with renal impairment or severe liver disease. Among patients with compensated and decompensated liver cirrhosis, a 5- to 10-fold increase in naltrexone levels has been found relative to individuals with normal liver function. The increased systemic availability of naltrexone, which is believed to be due to lower rates of conversion of naltrexone to 6β-naltrexol, appear to be related to the severity of liver disease.

Naltrexone has not been studied in pregnant or nursing women, and an embryocidal effect has been demonstrated in rats and rabbits when given dose approximately 140 times the human recommended dose. As a result, naltrexone should be used during pregnancy only when the potential benefit clearly outweighs the potential risks to the fetus. Similarly, there are no studies of nalmefene in pregnant women, and hence this agent should be used in pregnant women only when clearly needed.

DRUG INTERACTIONS

Because naltrexone and nalmefene are opioid antagonists, they block the pain-relieving effects of opioid analgesics. Therefore, in patients maintained on these agents, nonopioid pain medications or approaches should be tried first when possible. For elective surgery, cessation of oral naltrexone treatment 72 hours prior to surgery is recommended. Naltrexone does not reverse the effects of nerve root blocks or spinal anesthesia and does not antagonize agents used for general anesthesia. Intravenous nalmefene can be used to reverse respiratory depression produced by these agents without blocking the analgesic effects of subsequently administered opioids. In patients treated with opioid antagonists, if opioid medications are necessary for the treatment of severe pain, the blockade can be overridden with a rapidly acting analgesic, but treatment requires close monitoring in a setting equipped and staffed for cardiopulmonary resuscitation because the resulting respiratory depression may be deep and prolonged. Patients should be given a card identifying that they are on naltrexone to alert medical personnel in case of an emergency.

Recent trials of alcohol dependence have combined naltrexone and disulfiram without any significant increase in adverse effects or in hepatic dysfunction, and some clinicians use the two drugs concomitantly for brief periods of time. However, given the potential for hepatotoxicity with both these agents, frequent monitoring of hepatic function is recommended. Although formal drug interaction studies have not been conducted with antidepressant medications, the incidence of adverse events reported by patients who started naltrexone while on ongoing antidepressant therapy was similar to that of patients receiving naltrexone only in a large safety study. Simultaneous initiation of antidepressant therapy and naltrexone, however, has been found to result in higher rates of nausea than use of naltrexone alone. Increased lethargy and somnolence has been reported with the combined use of naltrexone and thioridazine. Combined use of high-dose naltrexone (e.g., 250 mg daily) with nonsteroidal anti-inflammatory agents (ibuprofen, aspirin) may be associated with elevations in liver function tests.

Intravenous nalmefene has been administered after benzodiazepines, inhalational anesthetics, muscle relaxants, and muscle relaxant antagonists administered in conjunction with general anesthetics without any adverse reactions. Care should be taken when using flumazenil and nalmefene together because both of these agents have been shown to induce seizures in preclinical studies.

LABORATORY INTERFERENCES

Thin-layer, gas-liquid, and high-pressure liquid chromatographic methods

used for the detection of opiates in the urine are not interfered with naltrexone. The potential for a false-positive urine for opiates using less specific urine screens such as enzyme multiplied immunoassay technique (EMIT) may exist, given that naltrexone and nalmefene are derivatives of oxymorphone.

DOSAGE AND ADMINISTRATION

Naltrexone is prepared in scored, 50-mg, capsule-shaped tablets. The recommended dose for adults is 50 mg/day for alcoholism and narcotic addiction. Lower initial doses can be considered over the first few days for patients at increased risk of adverse effects, with the dose increased as tolerated. In a large multisite study of alcoholism treatment, effect sizes for the 100-mg dose (compared to placebo) were not larger than those observed in earlier studies with a 50-mg daily dose. Morning administration is recommended for improved medication compliance.

Although daily oral administration is clearly effective for the treatment of alcoholism, there is some evidence that targeting naltrexone use to the days when drinking is anticipated may also be useful for some patients. The injectable formulation Vivitrol is available in single-use kits that contain 380 mg of Vivitrol microspheres and a diluent. The microspheres need to be suspended in the diluent provided prior to administration, and this agent is administered as an intramuscular gluteal injection once every 4 weeks or once a month.

Naltrexone should not be administered until there is no reasonable possibility of opiate use within the past 7 to 10 days or unless the patient has completed a detoxification and abstinence has been verified with urine testing for opiates. If there is a question about continued opiate use, opiate-free status should be confirmed by a negative response to an IM naloxone test dose of 0.8 mg. If substantial opioid withdrawal symptoms do emerge, initiation of naltrexone should be delayed at least 1 additional day. Nalmefene is available as a sterile solution for intravenous, intramuscular, and subcutaneous administration in two concentrations, containing 100 μg/mL or 1.0 mg/mL of nalmefene. The dose of this agent is titrated to achieve the desired reversal of the opioid effects. The oral form of nalmefene is not available in the United States. Naloxone hydrochloride injection is available to be administered intravenously, intramuscularly, or subcutaneously. An initial dose of 0.4 mg to 2 mg can be administered in adults, and may be repeated at 2- to 3-minute intervals to achieve reversal of opioid effects. If reversal is not achieved after administering 10 mg of naloxone, the diagnosis of opioid overdose should be questioned. Although it is not yet FDA approved, naloxone hydrochloride is also available in intranasal preparations for opioid overdose reversal.

INVESTIGATIONAL DRUGS

Naltrexone and nalmefene are nonspecific opioid antagonists that have been shown to dose dependently bind to all three types of opioid receptors. The highest antagonistic potency has been found to be at the μ receptor, which is 5 to 10 times greater than that at the δ receptor and 13 to 33 times greater than that at the κ receptor. Opioid antagonists that have specific affinity of specific opioid receptor types have been developed, which have enormous use as selective tools to identify specific receptor types involved in specific pharmacological endpoints. Most of the new specific opioid antagonists are nonpeptides that can easily penetrate the blood–brain barrier and therefore can be administered via peripheral routes. All of these are in the different phases of drug testing.

▲ 34.26 Selective Serotonin-Norepinephrine Reuptake Inhibitors

MICHAEL E. THASE, M.D., AND PIERRE BLIER, M.D., PH.D.

The term *serotonin-norepinephrine reuptake inhibitor* (SNRI) describes a group of medications that have therapeutic effects that are presumably mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine (NE) uptake transporters. The SNRIs are also sometimes referred to as *dual reuptake inhibitors*, a broader functional class of antidepressant medications that includes tricyclic antidepressants (TCAs) such as clomipramine and, arguably, imipramine and amitriptyline. What distinguishes the SNRIs from TCAs is selectivity, which in this context refers to a relative lack of affinity for other receptors, especially muscarinic, histaminergic, and the families of α- and β-adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older TCA dual reuptake inhibitors.

Clinical interest in the SNRIs has largely stemmed from the hypothesis that direct modulation of these two monoamine systems conveys greater antidepressant effects than exerted by medications that selectively enhance only 5-HT or NE neurotransmission. Greater therapeutic benefits could result from an acceleration of postsynaptic adaptation to increased neuronal signaling, simultaneous activation of two pathways for intracellular signal transduction, additive effects on the activity of relevant neuronal factors such as brain-derived neurotrophic factor or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine in comparison to the SSRIs, citalopram and paroxetine. A third report, which compared the results of a group of patients prospectively treated with the combination of the TCAs, desipramine and fluoxetine with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of TCAs and SSRIs yielded the

strongest evidence. Specifically, although the TCAs were found to have a modest overall advantage, superiority versus SSRIs was almost entirely explained by the studies that used the TCAs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine.

FIGURE 34.26–1. Chemical structures of the serotonin-norepinephrine reuptake inhibitors (SNRIs) venlafaxine, duloxetine, milnacipran, and desvenlafaxine.

There are currently five SNRIs approved for use in the United States: Venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (Pristiq), duloxetine (Cymbalta), milnacipran (Savella), and levomilnacipran (Fetzima). The racemic agent, milnacipran is indicated for major depressive disorder in a number of countries, including France and Japan, but in the United States only for fibromyalgia.

VENLAFAXINE AND DESVENLAFAXINE

Venlafaxine (Fig. 34.26–1) and desvenlafaxine are bicyclic phenylethylamine compounds that are structurally unrelated to other available antidepressants and anxiolytics. First synthesized in the late 1970s, venlafaxine was found to block uptake of 5-HT and NE in vitro, with a greater affinity for the 5-HT transporter. Unlike the TCAs, venlafaxine was found to have virtually no affinity for muscarinic, histaminergic, or α- or β-adrenergic postsynaptic receptors. Venlafaxine thus was predicted to exert antidepressant activity comparable to the prototypic dual reuptake inhibitors (i.e., amitriptyline and clomipramine), yet affording a safety and tolerability profile that was more similar to the SSRIs.

After efficacy was established versus placebo in the requisite phase II and phase III RCTs, the original immediate-release (IR) formulation of venlafaxine was approved by the FDA in 1994 for treatment of major depressive disorder. A microencapsulated extended-release (XR) formulation was introduced in 1997, which permitted once-daily dosing. Generic formulations of venlafaxine are now available. An extended-release formulation of the succinate salt of *O*-desmethylvenlafaxine (ODV), the principal active metabolite of venlafaxine (DVS; Pristiq), was approved by the FDA for treatment of major depressive disorder in early 2008.

Pharmacology

Venlafaxine and ODV inhibit neuronal uptake of 5-HT and, with significantly lower in vitro affinity, NE. In addition to a virtual lack of affinity for muscarinic, histamine 1 (H_1), and adrenergic receptors, neither the parent drug nor the metabolite affect sodium fast channel activity. Venlafaxine and ODV do not inhibit the activity of monoamine oxidases.

It is widely believed that the relative affinities of venlafaxine for inhibition of 5-HT and NE uptake underpin an ascending dose–response relationship. Specifically, venlafaxine is essentially an SSRI at the lowest therapeutic dose (i.e., 75 mg/day) and that noradrenergic effects increase progressively as the dose is advanced. Although supportive experimental and clinical data can be marshaled, this hypothesis cannot be tested definitively until a specific ^{11}C-ligand for NE transporters is developed so that in vivo studies correlating clinical response with NE transporter occupancy can be undertaken. Venlafaxine at higher doses has also been proposed to be a triple reuptake inhibitor on the basis of in vitro work documenting weak inhibition of dopamine reuptake. However, this effect is probably not clinically significant at usual therapeutic doses.
