EIGHTH EDITION

Volume One

Fitzpatrick's DERMATOLOGY IN GENERAL MEDICINE

DVD INCLUDED

Lowell A. Goldsmith • Stephen I. Katz

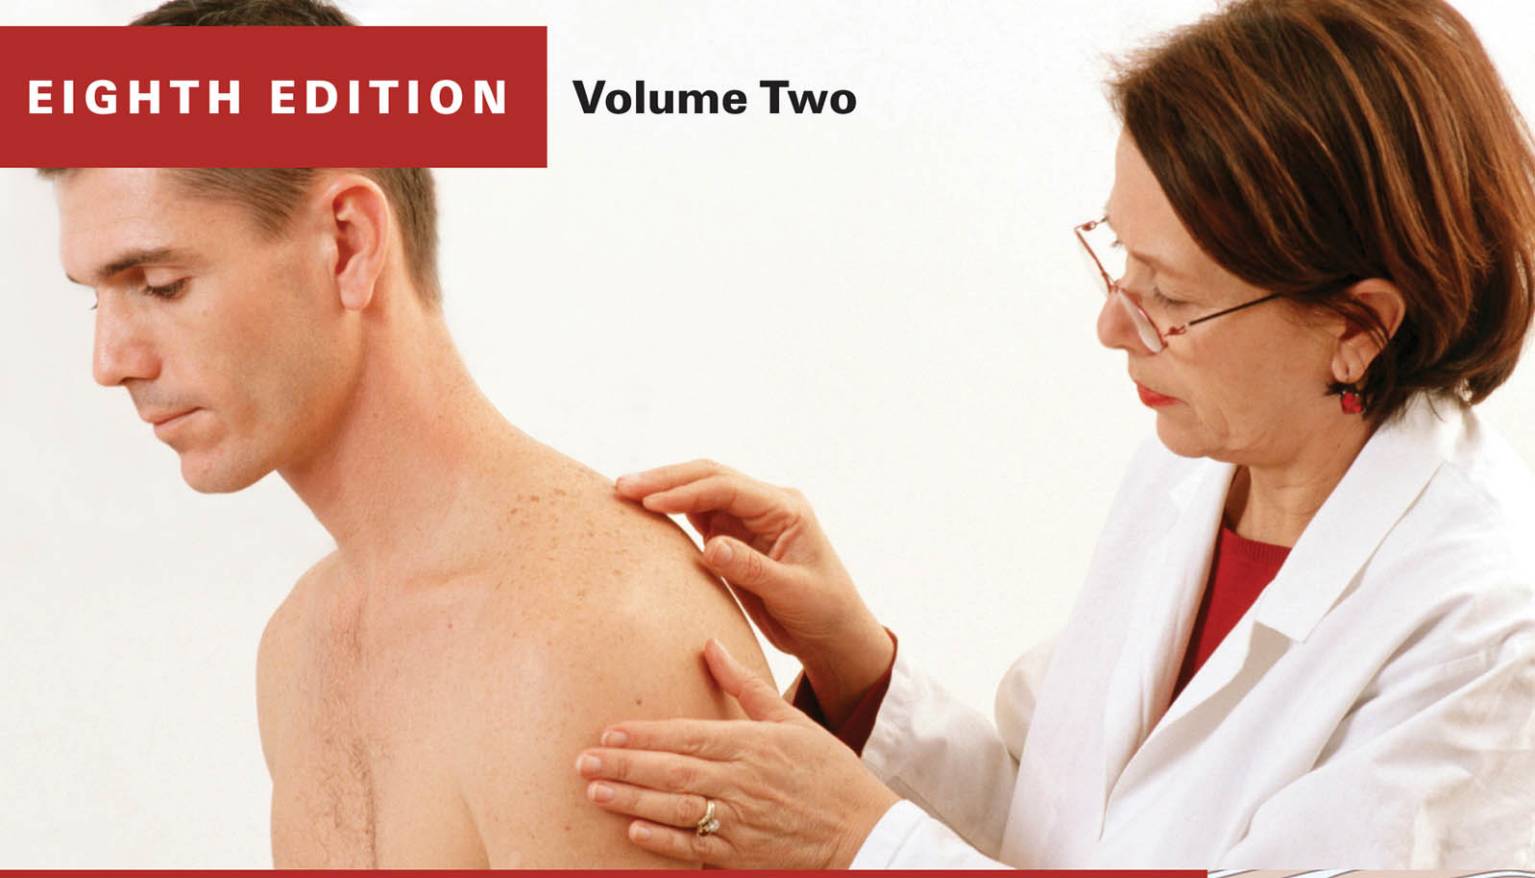
Barbara A. Gilchrest • Amy S. Paller

David J. Leffell • Klaus Wolff

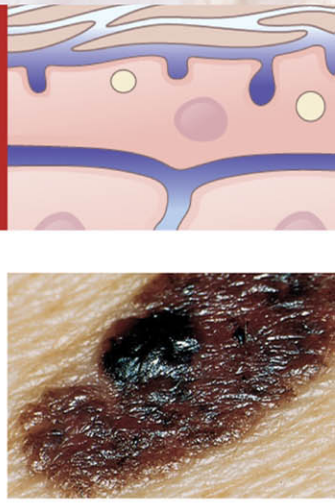
Mc Graw Hill

EIGHTH EDITION

Volume Two



Fitzpatrick's DERMATOLOGY IN GENERAL MEDICINE



DVD INCLUDED

Lowell A. Goldsmith • Stephen I. Katz
Barbara A. Gilchrest • Amy S. Paller
David J. Leffell • Klaus Wolff

Mc Graw Hill

Fitzpatrick's Dermatology in General Medicine

LOWELL A. GOLDSMITH, MD, MPH
Emeritus Professor of Dermatology
University of North Carolina School of Medicine
Chapel Hill, North Carolina
Dean Emeritus
University of Rochester School of Medicine and Dentistry
Rochester, NY

STEPHEN I. KATZ, MD, PhD
Fellow, American Academy of Dermatology
Schaumburg, IL;
Past President, Society of Investigative Dermatology
Cleveland, OH;
Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases
National Institutes of Health
Bethesda, MD

BARBARA A. GILCHREST, MD
Chair Emerita and Professor of Dermatology
Department of Dermatology
Boston University School of Medicine
Boston, MA

AMY S. PALLER, MD
Walter J. Hamlin Professor and Chair of Dermatology
Professor of Pediatrics
Feinberg School of Medicine
Northwestern University
Chicago, IL

DAVID J. LEFFELL, MD
David Paige Smith Professor of Dermatology and Surgery
Chief, Section of Dermatologic Surgery and Cutaneous Oncology
Department of Dermatology
Yale University School of Medicine
New Haven, CT

KLAUS WOLFF, MD, FRCP
Professor of Dermatology
Chairman Emeritus
Department of Dermatology
Medical University of Vienna
Vienna, Austria

Fitzpatrick's Dermatology in General Medicine

Eighth Edition

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

This is a copyrighted work and The McGraw-Hill Companies, Inc. (“McGraw-Hill”) and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill’s prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED “AS IS.” McGRAW-HILL AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Acknowledgments xxxiii

Volume One

PART 1 INTRODUCTION

SECTION 1. GENERAL CONSIDERATIONS

1 The Epidemiology and Burden of Skin Disease 1
Martin A. Weinstock, MD, PhD & Mary-Margaret Chren, MD

2 Evidence-Based Dermatology 9
Michael Bigby, MD, Rosamaria Corona, DSc, MD, & Moyses Szklo, MD, MPH, DrPH

3 Global Health in Dermatology 15
Roderick J. Hay, DM, FRCP, FRCPath, FMedSci

4 Public Health in Dermatology 21
Hywel C. Williams, MSc, PhD, FRCP, Sinéad M. Langan, MRCP, MSc, PhD, & Carsten Flohr, BM, BCh (Hons), MA, Mphil, MRCPCH, MSc, PhD

SECTION 2. APPROACH TO DERMATOLOGIC DIAGNOSIS

5 Structure of Skin Lesions and Fundamentals of Clinical Diagnosis 26
Amit Garg, MD, Nikki A. Levin, MD, PhD, & Jeffrey D. Bernhard, MD, FRCP (Edin)

6 Basic Pathologic Reactions of the Skin 42
Martin C. Mihm Jr., MD, FACP, Abdul-Ghani Kibbi, MD, FAAD, FACP, George F. Murphy, MD & Klaus Wolff, MD, FRCP

SECTION 3. OVERVIEW OF BIOLOGY, DEVELOPMENT, AND STRUCTURE OF SKIN

7 Development and Structure of Skin 58
David H. Chu, MD, PhD

8 Genetics in Relation to the Skin 75
John A. McGrath, MD, FRCP & W. H. Irwin McLean, FRSE, FMedSci

9 Racial Considerations: Skin of Color 91
Kavitha K. Reddy, MD, Yolanda M. Lenzy, MD, MPH, Katherine L. Brown, MD, MPH, & Barbara A. Gilchrest, MD

PART 2 DISORDERS PRESENTING IN SKIN AND MUCOUS MEMBRANES

SECTION 4. INFLAMMATORY DISORDERS BASED ON T-CELL REACTIVITY AND DYSREGULATION

10 Innate and Adaptive Immunity in the Skin 105
Robert L. Modlin, MD, Lloyd S. Miller, MD, PhD, Christine Bangert, MD, & Georg Stingl, MD

11 Cytokines 126
Ifor R. Williams, MD, PhD & Thomas S. Kupper, MD, FAAD

12 Chemokines 142
Anke S. Lonsdorf, MD & Sam T. Hwang, MD, PhD

13 Allergic Contact Dermatitis 152
Mari Paz Castanedo-Tardan, MD & Kathryn A. Zug, MD

14 Atopic Dermatitis (Atopic Eczema) 165
Donald Y.M. Leung, MD, PhD, Lawrence F. Eichenfield, MD, & Mark Boguniewicz, MD

15 Nummular Eczema, Lichen Simplex Chronicus, and Prurigo Nodularis 182
Susan Burgin, MD

16 Vesicular Palmoplantar Eczema 187
Daven N. Doshi, MD, Carol E. Cheng, MD, & Alexa B. Kimball, MD, MPH

17 Autosensitization Dermatitis 194
Donald V. Belsito, MD

18 Psoriasis 197
Johann E. Gudjonsson, MD, PhD & James T. Elder, MD, PhD

19 Psoriatic Arthritis 232
Dafna D. Gladman, MD, FRCPC & Vinod Chandran, MBBS, MD, DM

20 Reactive Arthritis 243
John D. Carter, MD

21 Pustular Eruptions of Palms and Soles 253
Ulrich Mrowietz, MD

22 Seborrheic Dermatitis 259
Chris D. Collins, MD, FAAD & Chad Hivnor, MD

23 Exfoliative Dermatitis 266
Jane Margaret Grant-Kels, MD, Flavia Fedeles, MD, MS, & Marti J. Rothe, MD

24 Pityriasis Rubra Pilaris 279
Daniela Bruch-Gerharz, MD & Thomas Ruzicka, Prof. Dr. med. Dr. h.c.

25 Parapsoriasis and Pityriasis Lichenoides. 285
Gary S. Wood, MD, Chung-Hong Hu, MD & Rosemarie Liu, MD

26 Lichen Planus 296
Mazen S. Daoud, MD & Mark R. Pittelkow, MD

27 Lichen Nitidus 312
Mazen S. Daoud, MD & Mark R. Pittelkow, MD

28 Graft-Versus-Host Disease 316
Edward W. Cowen, MD, MHSc

29 Skin Disease in Acute and Chronic Immunosuppression 330
Benjamin D. Ehst, MD, PhD & Andrew Blauvelt, MD

SECTION 5. INFLAMMATORY DISEASES BASED ON NEUTROPHILS AND EOSINOPHILS

30 Regulation of the Production and Activation of Neutrophils 345
Steven M. Holland, MD

31 Regulation of the Production and Activation of Eosinophils 351
Kristin M. Leiferman, MD, Lisa A. Beck, MD, & Gerald J. Gleich, MD

32 Acute Febrile Neutrophilic Dermatosis (Sweet Syndrome) 362
Philip R. Cohen, MD, Herbert Hönigsmann, MD, & Razelle Kurzrock, MD, FACP

33 Pyoderma Gangrenosum 371
Frank C. Powell, FRCPI, FAAD, Bridget C. Hackett, MB BCh, BAO, MRCPI, & Daniel Wallach, MD

34 Granuloma Faciale. 380
David A. Mehregan, MD & Darius R. Mehregan, MD

35 Subcorneal Pustular Dermatosis (Sneddon–Wilkinson Disease). 383
Franz Trautinger, MD & Herbert Hönigsmann, MD

36 Eosinophils in Cutaneous Diseases 386
Kristin M. Leiferman, MD & Margot S. Peters, MD

SECTION 6. INFLAMMATORY DISEASES BASED ON ABNORMAL HUMORAL REACTIVITY AND OTHER INFLAMMATORY DISEASES

37 Humoral Immunity and Complement. 401
Lela A. Lee, MD

38 Urticaria and Angioedema 414
Allen P. Kaplan, MD

39 Erythema Multiforme 431
Jean-Claude Roujeau, MD

40 Epidermal Necrolysis (Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis) 439
L. Valeyrie-Allanore, MD & Jean-Claude Roujeau, MD

41 Cutaneous Reactions to Drugs 449
Neil H. Shear, MD, FRCPC & Sandra R. Knowles, BScPhm

42 Pityriasis Rosea. 458
Andrew Blauvelt, MD

43 Erythema Annulare Centrifugum and Other Figurate Erythemas 463
Walter H.C. Burgdorf, MD

44 Granuloma Annulare 467
Julie S. Prendiville, MB, FRCPC

SECTION 7. DISORDERS OF EPIDERMAL DIFFERENTIATION AND KERATINIZATION

45 Epidermal Stem Cells 473
Rebecca J. Morris, PhD

46 Epidermal Growth and Differentiation 478
Pierre A. Coulombe, PhD, Stanley J. Miller, MD, & Tung-Tien Sun, PhD

47 Skin as an Organ of Protection. 486
Ehrhardt Proksch, MD, PhD & Jens-Michael Jensen, MD

48 Irritant Contact Dermatitis 499
Antoine Amado, MD, Apra Sood, MD, & James S. Taylor, MD, FAAD

49 The Ichthyoses 507
Philip Fleckman, MD & John J. DiGiovanna, MD

50 Inherited Palmoplantar Keratodermas 538
Mozheh Zamiri, BSc (Hons), MBChB, MRCP, MD, Maurice A. M. van Steensel, MD, PhD, & Colin S. Munro, MD, FRCP (Glasg)

51 Acantholytic Disorders of the Skin 550
Susan Burge, OBE, DM, FRCP & Alain Hovnanian, MD, PhD

52 Porokeratosis. 563
Grainne M. O'Regan, MRCPI & Alan D. Irvine, MD, FRCP, FRCPI

SECTION 8. DISORDERS OF EPIDERMAL AND DERMAL–EPIDERMAL ADHESION AND VESICULAR AND BULLOUS DISORDERS

53 Epidermal and Epidermal–Dermal Adhesion. . . 569
Leena Bruckner-Tuderman, MD & Aimee S. Payne, MD, PhD

54 Pemphigus. 586
Aimee S. Payne, MD, PhD & John R. Stanley, MD

55 Paraneoplastic Pemphigus 600
Grant J. Anhalt, MD & Daniel Mimouni, MD

56 Bullous Pemphigoid 608
Donna A. Culton, MD, PhD, Zhi Liu, PhD, & Luis A. Diaz, MD

57 Cicatricial Pemphigoid 617
Kim B. Yancey, MD

58 Linear Immunoglobulin A Dermatosis and Chronic Bullous Disease of Childhood 623
Caroline L. Rao, MD & Russell P. Hall III, MD

59 Pemphigoid Gestationis (Herpes Gestationis) . . 630
Jeff K. Shornick, MD, MHA

60 Epidermolysis Bullosa Acquisita. 634
David T. Woodley, MD & Mei Chen, PhD

61 Dermatitis Herpetiformis 642
Arash Ronaghy, MD, PhD, Stephen I. Katz, MD, PhD, & Russell P. Hall III, MD

62 Inherited Epidermolysis Bullosa 649
M. Peter Marinkovich, MD

SECTION 9. DISORDERS OF THE DERMAL CONNECTIVE TISSUE

63 Collagens, Elastic Fibers, and Other Extracellular Matrix Proteins of the Dermis 666
Thomas Krieg, MD, Monique Aumailley, Manuel Koch, PhD, Mon-Li Chu, PhD, & Jouni Uitto, MD, PhD

64 Morphea. 692
Stephanie Saxton-Daniels, MD & Heidi T. Jacobe, MD, MSCS

65 Lichen Sclerosus 702
Ulrich R. Hengge, MD, MBA

66 Dermal Hypertrophies and Benign Fibroblastic/Myofibroblastic Tumors 707
Christine J. Ko, MD

67 Anetoderma and Other Atrophic Disorders of the Skin 718
Catherine Maari, MD & Julie Powell, MD, FRCPC

68 Ainhum and Pseudoainhum 724
Robert T. Brodell, MD & Stephen E. Helms, MD

69 Acquired Perforating Disorders 727
Julia S. Minocha, MD & Bethanee J. Schlosser, MD, PhD

SECTION 10. DISORDERS OF SUBCUTANEOUS TISSUE

70 Panniculitis 732
Iris K. Aronson, MD, Patricia M. Fishman, MD, & Sophie M. Worobec, MD, FAAD

71 Lipodystrophy 755
Abhimanyu Garg, MD

SECTION 11. DISORDERS OF MELANOCYTES

72 Biology of Melanocytes. 765
Hee-Young Park, PhD & Mina Yaar, MD

73 Albinism and Other Genetic Disorders of Pigmentation 781
Thomas J. Hornyak, MD, PhD

74 Vitiligo 792
Stanca A. Birlea, MD, PhD, Richard A. Spritz, MD & David A. Norris, MD

75 Hypomelanoses and Hypermelanoses 804
Hilde Lapeere, MD, PhD, Barbara Boone, MD, PhD, Sofie De Schepper, MD, PhD, Evelien Verhaeghe, MD, Mireille Van Gele, PhD, Katia Ongenae, MD, PhD, Nanja Van Geel, MD, PhD, Jo Lambert, MD, PhD, & Lieve Brochez, MD, PhD

SECTION 12. DISORDERS OF THE ORAL AND GENITAL INTEGUMENT

76 Biology and Pathology of the Oral Cavity 827
Sook-Bin Woo, DMD

77 Diseases and Disorders of the Male Genitalia . . 852
Christopher B. Bunker, MD, FRCP

78 Diseases and Disorders of the Female Genitalia 878
Lynette J. Margesson, MD, FRCPC & F. William Danby, MD, FRCPC, FAAD

PART 3 DISORDERS OF THE SKIN APPENDAGES

SECTION 13. DISORDERS OF THE SEBACEOUS GLANDS

79 Biology of Sebaceous Glands 893
Amanda M. Nelson, PhD & Diane M. Thiboutot, MD

80 Acne Vulgaris and Acneiform Eruptions 897
Andrea L. Zaenglein, MD, Emmy M. Graber, MD, & Diane M. Thiboutot, MD

81 Rosacea 918
Michelle T. Pelle, MD

82 Perioral Dermatitis 925
Leslie P. Lawley, MD & Sareeta R.S. Parker, MD

SECTION 14. DISORDERS OF THE ECCRINE AND APOCRINE GLANDS

83 Biology of Eccrine and Apocrine Glands 929
Theodora M. Mauro, MD

84 Disorders of the Eccrine Sweat Glands and Sweating 936
Robert D. Fealey, MD & Adelaide A. Hebert, MD

85 Disorders of the Apocrine Sweat Glands 947
Christos C. Zouboulis, MD, PhD & Fragkiski Tsatsou, MD, MSc, BSc

SECTION 15. DISORDERS OF THE HAIR AND NAILS

86 Biology of Hair Follicles 960
George Cotsarelis, MD & Vladimir Botchkarev, MD, PhD

87 Keratosis Pilaris and Other Inflammatory Follicular Keratotic Syndromes 973
Paradi Mirmirani, MD & Maureen Rogers, MBBS, FACD

88 Hair Growth Disorders 979
Nina Otberg, MD & Jerry Shapiro, MD, FRCPC, FAAD

89 Biology of Nails and Nail Disorders 1009
Antonella Tosti, MD & Bianca Maria Piraccini, MD, PhD

PART 4 DISORDERS DUE TO THE ENVIRONMENT

SECTION 16. DISORDERS DUE TO ULTRAVIOLET RADIATION

90 Fundamentals of Cutaneous Photobiology and Photoimmunology 1031
Irene E. Kochevar, PhD, Charles R. Taylor, MD, & Jean Krutmann, MD

91 Abnormal Responses to Ultraviolet Radiation: Idiopathic, Probably Immunologic, and Photoexacerbated 1049
Travis W. Vandergriff, MD & Paul R. Bergstresser, MD

92 Abnormal Responses to Ultraviolet Radiation: Photosensitivity Induced by Exogenous Agents 1066
Henry W. Lim, MD

SECTION 17. SKIN CHANGES DUE TO OTHER PHYSICAL AND CHEMICAL FACTORS

93 Thermoregulation 1075
Dean L. Kellogg, Jr., MD, PhD

94 Cold Injuries 1079
Gérald E. Piérard, MD, PhD, Pascale Quatresooz, MD, PhD, & Claudine Piérard-Franchimont, MD, PhD

95 Thermal Injuries 1089
Robert L. Sheridan, MD

96 Skin Problems in Amputees 1095
Calum C. Lyon, MA, FRCP &
Michael H. Beck, FRCP, MBChB

97 Skin Problems in Ostomates 1104
Calum C. Lyon, MA, FRCP &
Michael H. Beck, FRCP, MBChB

98 Corns and Calluses 1111
Thomas M. DeLauro, DPM &
Nicole M. DeLauro, DPM

99 Sports Dermatology 1115
Dirk M. Elston, MD

100 Decubitus (Pressure) Ulcers 1121
Jennifer G. Powers, MD, Lillian Odo, MD, &
Tania J. Phillips, MD, FRCP, FRCPC

101 Body Art 1129
Anne Laumann, MBChB, MRCP(UK), FAAD

PART 5 NEUROCUTANEOUS AND PSYCHOCUTANEOUS ASPECTS OF SKIN DISEASE

SECTION 18. NEUROCUTANEOUS AND PSYCHOCUTANEOUS SKIN DISEASE

102 Neurobiology of the Skin 1137
Martin Steinhoff, MD, PhD &
Thomas A. Luger, MD

103 Pathophysiology and Clinical Aspects of Pruritus 1146
Gil Yosipovitch, MD &
Tejesh S. Patel, MBBS (Lon), BSc (Hons)

104 Psychocutaneous Skin Disease 1158
Evan Rieder, MD & Francisco A. Tausk, MD

105 Cutaneous Manifestations of Drug Abuse 1166
Haley Naik, MD & Richard Allen Johnson, MDCM

106 Skin Signs of Physical Abuse 1177
Howard B. Pride, MD

PART 6 SKIN CHANGES ACROSS THE SPAN OF LIFE

SECTION 19. FROM BIRTH TO OLD AGE

107 Neonatal, Pediatric, and Adolescent Dermatology 1185
Mary Wu Chang, MD

108 Skin Changes and Diseases in Pregnancy 1204
Julie K. Karen, MD &
Miriam Keltz Pomeranz, MD

109 Aging of Skin 1213
Mina Yaar, MD & Barbara A. Gilchrest, MD

PART 7 NEOPLASIA

SECTION 20. CARCINOGENESIS

110 Genome Instability, DNA Repair, and Cancer 1227
Thomas M. Rünger, MD, PhD &
Kenneth H. Kraemer, MD

111 Chemical Carcinogenesis 1239
Adam B. Glick, PhD & Andrzej A. Dlugosz, MD

112 Ultraviolet Radiation Carcinogenesis 1251
Masaoki Kawasumi, MD, PhD &
Paul Nghiem, MD, PhD

SECTION 21. EPIDERMAL AND APPENDAGEAL TUMORS

113 Epithelial Precancerous Lesions 1261
Karynne O. Duncan, MD,
John K. Geisse, MD & David J. Leffell, MD

114 Squamous Cell Carcinoma 1283
Douglas Grossman, MD, PhD & David J. Leffell, MD

115 Basal Cell Carcinoma 1294
John A. Carucci, MD, PhD,
David J. Leffell, MD & Julia S. Pettersen, MD

116 Basal Cell Nevus Syndrome 1304
Anthony E. Oro, MD, PhD &
Jean Y. Tang, MD, PhD

117 Keratoacanthoma 1312
Lorenzo Cerroni, MD & Helmut Kerl, MD

118 Benign Epithelial Tumors, Hamartomas, and Hyperplasias 1319
Valencia D. Thomas, MD, Nicholas R. Snavely, MD,
Ken K. Lee, MD & Neil A. Swanson, MD

119 Appendage Tumors and Hamartomas of the Skin 1337
Divya Srivastava, MD & R. Stan Taylor, MD

120 Merkel Cell Carcinoma 1362
Andrew Tegeder, MS, Olga Afanasiev, BA, &
Paul Nghiem, MD, PhD

121 Mammary and Extramammary Paget's Disease 1371
Sherrif F. Ibrahim, MD, PhD, Roy C. Grekin, MD, &
Isaac M. Neuhaus, MD

SECTION 22. MELANOCYTIC TUMORS

122 Benign Neoplasias and Hyperplasias of Melanocytes 1377
James M. Grichnik, MD, PhD, Arthur R. Rhodes, MD, MPH, & Arthur J. Sober, MD

123 Atypical (Dysplastic) Melanocytic Nevi 1410
James M. Grichnik, MD, PhD & Margaret A. Tucker, MD

124 Cutaneous Melanoma 1416
Evans C. Bailey, MD, PhD, Arthur J. Sober, MD, Hensin Tsao, MD, PhD, Martin C. Mihm Jr, MD, FACP, & Timothy M. Johnson, MD

SECTION 23. TUMORS AND HYPERPLASIAS OF THE DERMIS AND SUBCUTANEOUS FAT

125 Malignant Fibrous, Fibrohistiocytic, and Histiocytic Tumors of the Dermis 1445
Jürgen C. Becker, MD, PhD, Bernadette Liegl-Atzwanger, MD & Selma Ugurel, MD

126 Vascular Tumors 1456
Erin F. Mathes, MD & Ilona J. Frieden, MD

127 Neoplasias and Hyperplasias of Muscular and Neural Origin 1470
Lucile E. White, MD, Ross M. Levy, MD, & Murad Alam, MD, MSci

128 Kaposi's Sarcoma and Angiosarcoma 1481
Erwin Tschachler, MD

129 Neoplasms of Subcutaneous Fat 1489
Thomas Brenn, MD, PhD, FRCPath

Volume Two

PART 8 THE SKIN IN SYSTEMIC DISEASE

SECTION 24. SKIN IN NUTRITIONAL, METABOLIC, AND HERITABLE DISEASE

130 Cutaneous Changes in Nutritional Disease . . . 1499
Melinda Jen, MD & Albert C. Yan, MD

131 Cutaneous Changes in Errors of Amino Acid Metabolism 1525
Peter H. Itin, MD

132 The Porphyrias 1538
David R. Bickers, MD & Jorge Frank, MD, PhD

133 Amyloidosis of the Skin 1574
Helen J. Lachmann, MD, FRCP & Philip N. Hawkins, PhD, FRCP, FRCPath, FMedSci

134 Systemic Autoinflammatory Diseases 1584
Chyi-Chia Richard Lee, MD, PhD & Raphaela Goldbach-Mansky, MD, MHS

135 Xanthomatoses and Lipoprotein Disorders . . . 1600
Ernst J. Schaefer, MD & Raul D. Santos, MD, PhD

136 Fabry Disease 1613
Atul B. Mehta, MD, FRCP, FRCPath & Catherine H. Orteu, MBBS, BSc, MD, FRCP

137 Lipoid Proteinosis and Heritable Disorders of Connective Tissue 1624
Jonathan A. Dyer, MD

138 Cutaneous Mineralization and Ossification . . . 1649
Janet A. Fairley, MD

139 Hereditary Disorders of Genome Instability and DNA Repair 1654
Thomas M. Rünger, MD, PhD, John J. DiGiovanna, MD, & Kenneth H. Kraemer, MD

140 Tuberous Sclerosis Complex 1671
Thomas N. Darling, MD, PhD

141 The Neurofibromatoses 1680
Robert Listernick, MD & Joel Charrow, MD

142 Ectodermal Dysplasias 1691
Alanna F. Bree, MD, Nnenna Agim, MD, & Virginia P. Sybert, MD

143 Genetic Immunodeficiency Diseases 1703
Ramsay L. Fuleihan, MD & Amy S. Paller, MD

SECTION 25. SKIN MANIFESTATIONS OF BONE MARROW OR BLOOD CHEMISTRY DISORDERS

144 Hematologic Diseases 1726
Warren W. Piette, MD

145 Cutaneous Lymphoma 1745
Marc Beyer, MD & Wolfram Sterry, Prof. Dr.

146 Inflammatory Diseases That Simulate Lymphomas: Cutaneous Pseudolymphomas 1767
Gary S. Wood, MD

147 Cutaneous Langerhans Cell Histiocytosis 1782
Carlo Gelmetti, MD

148 Non-Langerhans Cell Histiocytosis 1795
Carlo Gelmetti, MD

149 Mastocytosis 1809
Michael D. Tharp, MD

SECTION 26. SKIN MANIFESTATIONS OF INTERNAL ORGAN DISORDERS

150 The Skin and Disorders of the Alimentary Tract, the Hepatobiliary System, the Kidney, and the Cardiopulmonary System 1819
Graham A. Johnston, MBChB, FRCP & Robin A.C. Graham-Brown, BSc, MB, FRCP, FRCPCH

151 Diabetes Mellitus and Other Endocrine Diseases 1840
Andrea A. Kalus, MD, Andy J. Chien, MD, PhD, & John E. Olerud, MD

152 Sarcoidosis 1869
Richard M. Marchell, MD, Bruce Thiers, MD, & Marc A. Judson, MD

153 Cutaneous Manifestations of Internal Malignant Disease: Cutaneous Paraneoplastic Syndromes 1880
Christine A. DeWitt, MD, Lucinda S. Buescher, MD, & Stephen P. Stone, MD

SECTION 27. THE SKIN IN VASCULAR AND CONNECTIVE TISSUE AND OTHER AUTOIMMUNE DISORDERS

154 Mechanisms of Autoimmune Disease 1901
Insoo Kang, MD & Joseph Craft, MD

155 Lupus Erythematosus 1909
Melissa I. Costner, MD & Richard D. Sontheimer, MD

156 Dermatomyositis 1926
Richard D. Sontheimer, MD, Christopher B. Hansen, MD, & Melissa I. Costner, MD

157 Scleroderma 1942
P. Moinzadeh, MD, Christopher P. Denton, PhD, FRCP, T. Krieg, MD, & Carol M. Black, MD, FRCP, FMedSci

158 Scleredema and Scleromyxedema 1957
Roger H. Weenig, MD, MPH & Mark R. Pittelkow, MD

159 Relapsing Polychondritis 1962
Camille Francès, MD

160 Rheumatoid Arthritis, Rheumatic Fever, and Gout 1965
Warren W. Piette, MD

161 Sjögren's Syndrome 1976
Gabor Illei, MD, PhD, MHS & Stamatina Danielides, MD

SECTION 28. THE SKIN IN INFLAMMATORY AND OTHER VASCULAR DISORDERS

162 Endothelium in Inflammation and Angiogenesis 1986
Peter Petzelbauer, MD, Robert Loewe, MD, & Jordan S. Pober, MD, PhD

163 Cutaneous Necrotizing Venulitis 2003
Nicholas A. Soter, MD

164 Systemic Necrotizing Arteritis 2013
Peter A. Merkel, MD, MPH & Paul A. Monach, MD, PhD

165 Erythema Elevatum Diutinum 2029
Nneka I. Comfere, MD & Lawrence E. Gibson, MD

166 Adamantiades–Behçet Disease 2033
Christos C. Zouboulis, MD, PhD

167 Kawasaki Disease 2042
Anne H. Rowley, MD

168 Pigmented Purpuric Dermatoses 2049
Theresa Schroeder Devere, MD & Anisha B. Patel, MD

169 Cryoglobulinemia and Cryofibrinogenemia 2055
Holger Schmid, MD, MSc PD & Gerald S. Braun, MD

170 Raynaud Phenomenon 2065
John H. Klippel, MD

171 Malignant Atrophic Papulosis (Degos Disease) 2072
Dan Lipsker, MD, PhD

172 Vascular Malformations 2076
Laurence M. Boon, MD, PhD & Miikka Vikkula, MD, PhD

173 Cutaneous Changes in Peripheral Arterial Vascular Disease 2094
Veerendra Chadachan, MD Steven M. Dean, DO, FACP, RPVI, & Robert T. Eberhardt, MD, FACC, FSVM, RPVI

174 Cutaneous Changes in Peripheral Venous and Lymphatic Insufficiency 2110
Craig N. Burkhart, MD, Chris Adigun, MD, & Claude S. Burton, MD

PART 9 DISEASE DUE TO MICROBIAL AGENTS, INFESTATIONS, BITES, AND STINGS

SECTION 29. BACTERIAL DISEASE

175 General Considerations of Bacterial Diseases 2121
Noah Craft, MD, PhD, DTMH

176 Superficial Cutaneous Infections and Pyodermas 2128
Noah Craft, MD, PhD, DTMH

177 Gram-Positive Infections Associated with Toxin Production 2148
Jeffrey B. Travers, MD, PhD & Nico Mousdicas, MBChB, MD

178 Non-Necrotizing Infections of the Dermis and Subcutaneous Fat: Cellulitis and Erysipelas 2160
Adam D. Lipworth, MD, Arturo P. Saavedra, MD, PhD, MBA, Arnold N. Weinberg, MD, & Richard Allen Johnson, MDCM

179 Necrotizing Soft Tissue Infections: Necrotizing Fasciitis, Gangrenous Cellulitis, and Myonecrosis 2169
Adam D. Lipworth, MD, Arturo P. Saavedra, MD, PhD, MBA, Arnold N. Weinberg, MD, & Richard Allen Johnson, MDCM

180 Gram-Negative Coccal and Bacillary Infections 2178
Myron S. Cohen, MD, William A. Rutala, BS, MS, PhD, MPH, & David J. Weber, MD, MPH

181 The Skin in Infective Endocarditis, Sepsis, Septic Shock, and Disseminated Intravascular Coagulation 2194
Laura Korb Ferris, MD, PhD & Joseph C. English, MD

182 Bartonellosis 2201
Timothy G. Berger, MD & Francisco G. Bravo, MD

183 Miscellaneous Bacterial Infections with Cutaneous Manifestations 2210
Scott A. Norton, MD, MPH, MS

184 Tuberculosis and Infections with Atypical *Mycobacteria* 2225
Aisha Sethi, MD

185 Actinomycosis, Nocardiosis, and Actinomycetoma 2241
Francisco G. Bravo, MD, Roberto Arenas, MD, & Daniel Asz Sigall, MD

186 Leprosy 2253
Delphine J. Lee, MD, PhD, FAAD, Thomas H. Rea, & Robert L. Modlin, MD

187 Lyme Borreliosis 2263
Meera Mahalingam, MD, PhD, FRCPath, Jag Bhawan, MD, Daniel B. Eisen, MD, & Linden Hu, MD

SECTION 30. FUNGAL DISEASES

188 Superficial Fungal Infection 2277
Stefan M. Schieke, MD & Amit Garg, MD

189 Yeast Infections: Candidiasis, Tinea (Pityriasis) Versicolor, and *Malassezia* (*Pityrosporum*) Folliculitis 2298
Roopal V. Kundu, MD & Amit Garg, MD

190 Deep Fungal Infections 2312
Roderick J. Hay, DM, FRCP, FRCPath, FMedSci

SECTION 31. VIRAL AND RICKETTSIAL DISEASES

191 General Considerations of Viral Diseases 2329
L. Katie Morrison, MD, Ammar Ahmed, MD, Vandana Madkan, MD, Natalia Mendoza, MD, MS, & Stephen Tyring, MD, PhD

192 Exanthematous Viral Diseases 2337
Leah T. Belazarian, MD, Mayra E. Lorenzo, MD, PhD, Andrea L. Pearson, MD, Susan M. Sweeney, MD, & Karen Wiss, MD

193 Herpes Simplex 2367
Adriana R. Marques, MD & Jeffrey I. Cohen, MD

194 Varicella and Herpes Zoster 2383
Kenneth E. Schmader, MD & Michael N. Oxman, MD

195 Poxvirus Infections 2402
Caroline Piggott, MD, Sheila Fallon Friedlander, MD, & Wynnis Tom, MD

196 Human Papilloma Virus Infections 2421
Elliot J. Androphy, MD & Reinhard Kirnbauer, MD

197 Human T-Lymphotropic Viruses 2434
Erwin Tschachler, MD

198 Cutaneous Manifestations of Human Immunodeficiency Virus Disease 2439
Lily Changchien Uihlein, MD, JD, Arturo P. Saavedra, MD, PhD, MBA, & Richard Allen Johnson, MDCM

199 The Rickettsioses, Ehrlichioses, and Anaplasmoses 2456
Sandra A. Kopp, MD, Analisa V. Halpern, MD, Justin J. Green, MD & Warren R. Heymann, MD

SECTION 32. SEXUALLY TRANSMITTED DISEASES

200 Syphilis. 2471
Kenneth A. Katz, MD, MSc, MSCE

201 Endemic (Nonvenereal) Treponematoses 2493
Nadine Marrouche, MD &
Samer H. Ghosn, MD

202 Chancroid 2501
Stephan Lautenschlager, MD

203 Lymphogranuloma Venereum. 2505
Rim S. Ishak, MD & Samer H. Ghosn, MD

204 Granuloma Inguinale 2510
Abdul-Ghani Kibbi, MD, FAAD, FACP,
Ruba F. Bahhady, MD, & Myrna El-Shareef, MD

205 Gonorrhea, Mycoplasma, and Vaginosis 2514
Ted Rosen, MD

SECTION 33. INFESTATIONS, BITES, AND STINGS

206 Leishmaniasis and Other Protozoan Infections 2527
Joelle M. Malek, MD & Samer H. Ghosn, MD

207 Helminthic Infections 2544
Kathryn N. Suh, MD &
Jay S. Keystone, MD, MSc(CTM), FRCPC

208 Scabies, Other Mites, and Pediculosis 2569
Craig N. Burkhart, MD &
Craig G. Burkhart, MD, MPH

209 Bites and Stings of Terrestrial and Aquatic Life. 2578
Jennifer S. Daly, MD &
Mark Jordan Scharf, MD

210 Arthropod Bites and Stings 2599
Robert A. Schwartz, MD, MPH &
Christopher J. Steen, MD

PART 10 OCCUPATIONAL SKIN DISEASES AND SKIN DISEASES DUE TO BIOLOGIC WARFARE

SECTION 34. OCCUPATIONAL SKIN DISEASES

211 Occupational Skin Diseases Due to Irritants and Allergens 2611
Golara Honari, MD,
James S. Taylor, MD, FAAD, & Apra Sood, MD

212 Occupational Noneczematous Skin Diseases Due to Biologic, Physical, and Chemical Agents: Introduction 2622
Paul X. Benedetto, MD,
James S. Taylor, MD, FAAD, &
Apra Sood, MD

SECTION 35. THE SKIN IN BIOTERRORISM AND BIOLOGIC WARFARE

213 Cutaneous Manifestations of Biologic, Chemical, and Radiologic Attacks 2633
Scott A. Norton, MD, MPH, MSc

PART 11 THERAPEUTICS

SECTION 36. TOPICAL THERAPY

214 Principles of Topical Therapy 2643
Aieska De Souza, MD, MS &
Bruce E. Strober, MD, PhD

215 Pharmacokinetics and Topical Applications of Drugs 2652
Hans Schaefer, PhD, Thomas E. Redelmeier, MD
Gerhard J. Nohynek, PhD, DABT, &
Jürgen Lademann, Prof. Dr. rer. nat. Dr.-Ing. habil.

216 Topical Corticosteroids 2659
Isabel C. Valencia, MD &
Francisco A. Kerdel, MD

217 Topical Retinoids 2665
Anna L. Chien, MD,
John J. Voorhees, MD, FRCP, &
Sewon Kang, MD

218 Topical Antibiotics 2673
Mark W. Bonner, MD & William D. James, MD

219 Topical Antifungal Agents 2677
Whitney A. High, MD, JD, MEng &
James E. Fitzpatrick, MD

220 Topical and Intralesional Cytotoxic Agents 2685
Aieska De Souza, MD, MS,
Megan M. Moore, MD, & Bruce E. Strober, MD, PhD

221 Topical Immunomodulators 2690
Edward M. Esparza, MD, PhD &
Robert Sidbury, MD, MPH

222 Other Topical Medications 2697
Craig N. Burkhart, MD &
Kenneth A. Katz, MD, MSc, MSCE

223 Photoprotection 2707
Henry W. Lim, MD

SECTION 37. SYSTEMIC THERAPY

224 Systemic Glucocorticoids 2714
Victoria P. Werth, MD

225 Dapsone 2721
Joni G. Sago, MD & Russell P. Hall III, MD

226 Aminoquinolines 2726
Susannah E. McClain, MD, Jeffrey R. LaDuca, MD, PhD & Anthony A. Gaspari, MD

227 Cytotoxic and Antimetabolic Agents 2735
Whitney A. High, MD, JD, MEng & James E. Fitzpatrick, MD

228 Retinoids 2759
Anders Vahlquist, MD, PhD & Jean-Hilaire Saurat, MD

229 Antihistamines 2767
Robert A. Wood, MD

230 Antibiotics 2776
Christopher C. Gasbarre, DO, FAAD, Steven K. Schmitt, MD, & Kenneth J. Tomecki, MD

231 Antiviral Drugs 2787
Dirk M. Elston, MD

232 Oral Antifungal Agents 2796
Reza Jacob, MD & Nellie Konnikov, MD

233 Immunosuppressive and Immunomodulatory Drugs 2807
Jeffrey P. Callen, MD

234 Immunobiologicals, Cytokines, and Growth Factors in Dermatology 2814
Stephen K. Richardson, MD & Joel M. Gelfand, MD, MSCE

235 Antiangiogenic Agents 2827
Ricardo L. Berrios, MD, Michael Y. Bonner, BA, Jonathan Hofmekler, BSc, & Jack L. Arbiser, MD, PhD

236 Drug Interactions 2834
Stephen E. Wolverton, MD

SECTION 38. PHYSICAL TREATMENTS

237 Phototherapy 2841
Jennifer A. Cafardi, MD, Brian P. Pollack, MD, PhD, & Craig A. Elmets, MD

238 Photochemotherapy and Photodynamic Therapy 2851
Herbert Hönigsmann, MD, Rolf-Markus Szeimies, MD, PhD, & Robert Knobler, MD

239 Lasers and Flashlamps in Dermatology 2869
Michael Landthaler, MD, Wolfgang Bäumler, PhD, & Ulrich Hohenleutner, MD

240 Radiotherapy 2890
Roy H. Decker, MD, PhD, & Lynn D. Wilson, MD, MPH

SECTION 39. COMPLEMENTARY AND ALTERNATIVE DERMATOLOGY

241 Complementary and Alternative Medicine in Dermatology 2899
Alan Dattner, MD

SECTION 40. SURGERY IN DERMATOLOGY

242 Anatomy and Approach in Dermatologic Surgery 2905
Sumaira Z. Aasi, MD & Brent E. Pennington, MD

243 Excisional Surgery and Repair, Flaps, and Grafts 2921
Jessica M. Sheehan, MD, Melanie Kingsley, MD, & Thomas E. Rohrer, MD

244 Mohs Micrographic Surgery 2950
Joseph Alcalay, MD & Ronen Alkalay, MD, MBA

245 Nail Surgery 2956
Robert Baran, MD

246 Cryosurgery and Electrosurgery 2968
Justin J. Vujevich, MD & Leonard H. Goldberg, MD, FRCP

247 Surgical Complications 2977
Richard G. Bennett, MD

248 Mechanisms of Wound Repair, Wound Healing, and Wound Dressing 2984
Vincent Falanga, MD, FACP & Satori Iwamoto, MD, PhD

249 Treatment for Varicose and Telangiectatic Leg Veins 2997
Robert A. Weiss, MD & Margaret A. Weiss, MD

SECTION 41. COSMETIC DERMATOLOGY

250 Cosmetics and Skin Care in Dermatology 3009
Leslie Baumann, MD

251 Ablative Lasers, Chemical Peels, and Dermabrasion 3021
Elizabeth L. Tanzi, MD &
Tina S. Alster, MD

252 Cosmetic Applications of Nonablative Lasers and Other Light Devices 3032
Elliot T. Weiss, MD,
Anne M. Chapas, MD, &
Roy G. Geronemus, MD

253 Liposuction 3041
William G. Stebbins, MD, Aimee L. Leonard, MD, &
C. William Hanke, MD, MPH, FACP

254 Soft Tissue Augmentation. 3044
Lisa M. Donofrio, MD

255 Botulinum Toxin. 3053
Richard G. Glogau, MD

256 Hair Transplantation and Alopecia Reduction. 3061
Walter P. Unger, MD, Robin H. Unger, MD, &
Mark A. Unger, MD, CCFP

CONTRIBUTORS

Sumaira Z. Aasi, MD
Associate Professor, Department of Dermatology, Yale University, New Haven, CT [242]

Chris Adigun, MD
Physician (PGY-3), Department of Dermatology, UNC-Chapel Hill, Chapel Hill, NC [174]

Olga K. Afanasiev, BA
Department of Dermatology, University of Washington School of Medicine, Seattle, WA [120]

Nnenna Agim, MD
Assistant Professor, Department of Dermatology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX [142]

Ammar Ahmed, MD
Resident Physician, Department of Dermatology, University of Texas Southwestern Medical Center, Dallas, TX [191]

Murad Alam, MD, MSci
Associate Professor, Departments of Dermatology, Otolaryngology, and Surgery, Feinberg School of Medicine, Northwestern University, Chicago, IL [127]

Joseph Alcalay, MD
Director, Mohs Surgery Unit, Assuta Medical Center, Tel Aviv, Israel [244]

Ronen Alkalay, MD, MBA
Mohs Unit, Assuta Medical Hospital, Tel Aviv, Israel [244]

Tina S. Alster, MD
Director, Laser Surgery, Washington Institute of Dermatologic Laser Surgery, Washington, DC [251]

Antoine Amado, MD
Resident in Dermatology, Dermatology and Plastic Surgery Institute, Cleveland Clinic, Cleveland, OH [48]

Elliot J. Androphy, MD
Department chair Dermatology at Indiana University School of Medicine Indianapolis, IN [196]

Grant J. Anhalt, MD
Professor, Department of Dermatology and Pathology, Johns Hopkins University School of Medicine, Baltimore, MD [55]

Jack L. Arbiser, MD, PhD
Professor, Department of Dermatology, Emory University School of Medicine, Atlanta, GA [235]

Roberto Arenas, MD
Professor, Department of Dermatology, University of Mexico, Mexico, DF [185]

Iris K. Aronson, MD
Associate Professor, Department of Dermatology, University of Illinois College of Medicine, Chicago, IL [70]

Daniel Asz-Sigall, MD
Resident, Dermatology, Cutaneous Oncology and Dermatologic Surgery, Department of Dermatology, ABC Hospital, Mexico City, Mexico [185]

Monique Aumailley
Professor, Center for Biochemistry, Cologne, Germany [63]

Wolfgang Bäumler, PhD
Professor, Department of Dermatology, University of Regensburg, Germany [239]

Ruba F. Bahhady, MD
Resident (PGY-4), Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [204]

Evans C. Bailey, MD, PhD
Lecturer, Department of Dermatology, University of Michigan, Ann Arbor, MI [124]

Christine Bangert, MD
Department of Dermatology, Medical University of Vienna, Vienna, Austria [10]

Robert Baran, MD
Honorary Professor, Department of Dermatology, Nail Disease Center, Cannes, France [245]

Leslie Baumann, MD
Chief Executive Officer, Cosmetic Dermatology, Baumann Cosmetic and Research Institute, Miami Beach, FL [250]

Lisa A. Beck, MD
Associate Professor of Dermatology and Medicine, Department of Dermatology and Medicine, University of Rochester School of Medicine, Rochester, NY [31]

Michael H. Beck, FRCP, MBChB
Honorary Clinical Lecturer, Occupational and Environmental Health Group, University of Manchester, Manchester, UK [96, 97]

Jürgen C. Becker, MD, PhD
Professor, Division of General Dermatology, Medical University of Graz, Graz, Austria [125]

Leah T. Belazarian, MD
Assistant Professor of Medicine and Pediatrics, Department of Medicine, Division of Dermatology, University of Massachusetts Medical School, Worcester, MA [192]

Donald V. Belsito, MD
Clinical Professor, Medicine (Dermatology), University of Missouri, Kansas City, MO [17]

Paul X. Benedetto, MD
Resident Physician, Department of Dermatology, Cleveland Clinic Foundation, Cleveland, OH [212]

Richard G. Bennett, MD
Clinical Professor, Dermatology, University of Southern California, Los Angeles, CA [247]

Timothy G. Berger, MD
Professor, Department of Dermatology, University of California, San Francisco, San Francisco, CA [182]

Paul R. Bergstresser, MD
Professor, Department of Dermatology, University of Texas Southwestern Medical Center, Dallas, TX [91]

Jeffrey D. Bernhard, MD, FRCP (Edin)
Professor Emeritus, University of Massachusetts Medical School, Worcester, MA [5]

Ricardo L. Berrios, MD
Post-Doctoral Fellow, Department of Dermatology, School of Medicine, Emory University, Atlanta, GA [235]

Marc Beyer, MD
Department of Dermatology and Allergy, Charité Universitätsmedizin Berlin, Berlin, Germany [145]

Jag Bhawan, MD
Professor, Department of Dermatology and Pathology, Boston University School of Medicine, Boston, MA [187]

David R. Bickers, MD
Carl Truman Nelson Professor, Department of Dermatology, Columbia University Medical Center, New York, NY [132]

Michael Bigby, MD
Associate Professor, Department of Dermatology, Harvard Medical School, Boston, MA [2]

Stanca A. Birlea, MD, PhD
Instructor, Dermatology and Human Medical Genetics Program, School of Medicine, University of Colorado Denver, Aurora, CO [74]

Carol M. Black, MD, FRCP, FMedSci
Professor, Centre for Rheumatology, University College London, London, UK [157]

Andrew Blauvelt, MD
Professor, Department of Dermatology, Oregon Health & Science University, Portland, OR [29, 42]

Mark Boguniewicz, MD
Professor, Department of Pediatrics, Division of Allergy-Immunology, National Jewish Health, Denver, CO [14]

Mark W. Bonner, MD
Georgia Dermatology
Warner Robins, GA [218]

Michael Y. Bonner, BA
Research Associate, Department of Dermatology, School of Medicine, Emory University, Atlanta, GA [235]

Laurence M. Boon, MD, PhD
Center for Vascular Anomalies
Division of Plastic Surgery St Luc University Hospital, Brussels, Belgium [172]

Barbara Boone, MD, PhD
Dermatologist, Ghent University Hospital, Ghent, Belgium [75]

Vladimir Botchkarev, MD, PhD
Professor, Centre for Skin Sciences, University of Bradford and Bradford, UK [86]

Gerald S. Braun, MD
Department of Nephrology and Clinical Immunology, University Hospital, RWTH University of Aachen, Aachen, Germany [169]

Francisco G. Bravo, MD
Associate Professor, Department of Pathology, Universidad Peruana Cayetano Heredia, Lima, Peru [182, 185]

Alanna F. Bree, MD
Pediatric Dermatologist, Dermatology Specialists of Houston, Bellaire, TX [142]

Thomas Brenn, MD, PhD, FRCPath
Consultant Dermatopathologist, Department of Pathology, Western General Hospital, Edinburgh, UK [129]

Lieve Brochez, MD, PhD
Professor, Department of Dermatology, Ghent University Hospital, Ghent, Belgium [75]

Robert T. Brodell, MD
Professor of Internal Medicine and Clinical Professor of Dermatopathology in Pathology, Department of Internal Medicine and Pathology, Northeastern Ohio Universities College of Medicine and Pharmacy, Rootstown, OH [68]

Katherine L. Brown, MD, MPH
Dermatology Resident, Department of Dermatology, Boston University, Boston, MA [9]

Daniela Bruch-Gerharz, MD
Professor, Department of Dermatology, University Hospital of Düsseldorf, Düsseldorf, Germany [24]

Leena Bruckner-Tuderman, MD
Professor, Department of Dermatology, University Medical Center Freiburg, Freiburg, Germany [53]

Lucinda S. Buescher, MD
Associate Professor, Division of Dermatology, Southern Illinois University, Springfield, IL [153]

Christopher B. Bunker, MD, FRCP
Professor, Department of Dermatology, University College London Hospitals, London, UK [77]

Walter H.C. Burgdorf, MD
Lecturer, Department of Dermatology, Ludwig Maximilian University, Munich, Germany [43]

Susan Burge, OBE DM FRCP
Consultant Dermatologist, Oxford University Hospitals, Oxford, UK [51]

Susan Burgin, MD
Assistant Professor, Department of Dermatology, Harvard Medical School, Boston, MA [15]

Craig G. Burkhart, MD, MPH
Clinical Professor, Department of Medicine, College of Medicine, University of Toledo, Toledo, OH [208]

Craig N. Burkhart, MD
Assistant Professor, Department of Dermatology, The University of North Carolina at Chapel Hill, Chapel Hill, NC [174, 208, 222]

Claude S. Burton, MD
Professor, Department of Dermatology, Duke University School of Medicine, Durham, NC [174]

Jennifer A. Cafardi, MD
Assistant Professor, Department of Dermatology, University of Alabama at Birmingham, Birmingham, AL [237]

Jeffrey P. Callen, MD
Professor of Medicine (Dermatology), Department of Medicine, University of Louisville, Louisville, KY [233]

John D. Carter, MD
Associate Professor, Department of Internal Medicine, Division of Rheumatology, University of South Florida College of Medicine, Tampa, FL [20]

John A. Carucci, MD, PhD
Associate Professor, Department of Dermatology, Weill Cornell Medical College, New York, NY [115]

Mari Paz Castanedo-Tardan, MD
Postdoctoral Research Fellow, Section of Dermatology, Dartmouth-Hitchcock Medical Center, Dartmouth Medical School, Lebanon, NH [13]

Lorenzo Cerroni, MD
Associate Professor, Department of Dermatology, Medical University of Graz, Graz, Austria [117]

Veerendra Chadachan, MD
Vascular Medicine Program, Boston University Medical Center, Boston MA, USA Consultant, Department of General Medicine Vascular Medicine and Hypertension Section, Tan Tock Seng Hospital, Singapore [173]

Vinod Chandran, MBBS, MD, DM
Clinical Research Fellow, Department of Medicine, Division of Rheumatology, University of Toronto, Toronto, ON, Canada [19]

Mary Wu Chang, MD
Associate Clinical Professor, Department of Dermatology, Department of Pediatrics, University of Connecticut School of Medicine, Farmington, CT [107]

Anne M. Chapas, MD
Clinical Assistant Professor, Department of Dermatology, New York University School of Medicine, New York, NY [252]

Joel Charrow, MD
Professor, Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL [141]

Mei Chen, PhD
Professor and Director of Research, Department of Dermatology, University of Southern California, Los Angeles, CA [60]

Carol E. Cheng, MD
Department of Dermatology, Massachusetts General Hospital, Boston, MA [16]

Andy J. Chien, MD, PhD
Assistant Professor, Division of Dermatology, University of Washington School of Medicine, Seattle, WA [151]

Anna L. Chien, MD
Assistant Professor, Department of Dermatology, Johns Hopkins School of Medicine, Baltimore, MD [217]

Mary-Margaret Chren, MD
Professor, Department of Dermatology, University of California, San Francisco, San Francisco, CA [1]

David H. Chu, MD, PhD
Division of Dermatology and Cutaneous Surgery, Scripps Clinic Medical Group, La Jolla, CA [7]

Mon-Li Chu, PhD
Professor, Department of Dermatology & Cutaneous Biology, Thomas Jefferson University, Philadelphia, PA [63]

Jeffrey I. Cohen, MD
Chief, Medical Virology Section, Laboratory of Clinical Infectious Diseases, National Institutes of Health, Bethesda, MD [193]

Myron S. Cohen, MD
Associate Vice Chancellor and Professor of Medicine, Microbiology and Immunology, Departments of Medicine and Epidemiology, University of North Carolina, Chapel Hill, NC [180]

Philip R. Cohen, MD
Clinical Associate Professor, Department of Dermatology, MD Anderson Cancer Center, University of Texas, Houston, TX [32]

Chris D. Collins, MD, FAAD
Professor of Clinical Dermatology US Army & Air Force Dermatology Brooke Army Medical Center, Wilford Hall Medical Center San Antonio, TX [22]

Nneka I. Comfere, MD
Assistant Professor, Department of Dermatology, Mayo Clinic College of Medicine, Rochester, MN [165]

Rosamaria Corona, DSc, MD
Attending Physician, Division of Immunodermatology, Istituto Dermopatico dell'Immacolata, Rome, Italy [2]

Melissa I. Costner, MD
Clinical Associate Professor, Department of Dermatology, University of Texas Southwestern Medical Center, Dallas, TX [155, 156]

George Cotsarelis, MD
Professor, Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, PA [86]

Pierre A. Coulombe, PhD
E.V. McCollum Professor and Chair, Department of Biochemistry and Molecular Biology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD [46]

Edward W. Cowen, MD, MHSc
Head, Dermatology Consultation Service, Dermatology Branch, National Cancer Institute, National Institutes of Health, Bethesda, MD [28]

Joseph Craft, MD
Paul B. Beeson Professor of Medicine and Professor of Immunobiology, Department of Internal Medicine, Yale School of Medicine, Yale University, New Haven, CT [154]

Noah Craft, MD, PhD, DTMH
Assistant Professor, Department of Medicine, Divisions of Dermatology and Adult Infectious Disease, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA [175, 176]

Donna A. Culton, MD, PhD
Resident Physician, Department of Dermatology, University of North Carolina at Chapel Hill, Chapel Hill, NC [56]

Jennifer S. Daly, MD
Professor, Department of Medicine, University of Massachusetts Medical School, Worcester, MA [209]

F. William Danby, MD, FRCPC, FAAD
Adjunct Assistant Professor, Department of Surgery (Section of Dermatology), Dartmouth Medical School, Hanover, NH [78]

Stamatina Danielides, MD
Sjögren's Syndrome Clinic Gene Therapy and Therapeutics Branch, National Institute of Dental and Craniofacial Research National Institutes of Health Bethesda, MD [161]

Mazen S. Daoud, MD
Private Practice, Dermatology and Dermatopathology, Advanced Dermatology Specialties, Fort Myers, FL [26, 27]

Thomas N. Darling, MD, PhD
Associate Professor, Department of Dermatology, Uniformed Services University of the Health Sciences, Bethesda, MD [140]

Alan Dattner, MD
Chief Scientific Officer, Founder and CEO, www.holisticdermatology.com, New York, NY [241]

Sofie De Schepper, MD, PhD
Professor, Department of Dermatology, Ghent University Hospital, Ghent, Belgium [75]

Aieska De Souza, MD, MS
Dermatopharmacology Fellow, Department of Dermatology, New York University Langone Medical Center, New York, NY [214, 220]

Steven M. Dean, DO, FACP, RPVI
Associate Professor of Internal Medicine, Department of Cardiovascular Medicine, The Ohio State University College of Medicine, Columbus, OH [173]

Roy H. Decker, MD, PhD
Assistant Professor, Department of Therapeutic Radiology, Yale School of Medicine, Yale University, New Haven, CT [240]

Nicole M. DeLauro, DPM
Associate Physician, Podiatric Medicine and Surgery, Foot and Ankle Center of New Jersey, Plainfield, NJ [98]

Thomas M. DeLauro, DPM
Professor, Departments of Medicine and Surgery, New York College of Podiatric Medicine, New York, NY [98]

Christopher P. Denton, PhD, FRCP
Professor of Experimental Rheumatology, Centre for Rheumatology, University College London, London, UK [157]

Theresa Schroeder Devere, MD
Assistant Professor, Department of Dermatology, Oregon Health & Science University, Portland, OR [168]

Christine A. DeWitt, MD
Assistant Professor, Division of Dermatology, Georgetown University Hospital, Washington, DC [153]

Luis A. Diaz, MD
Professor and Chairman, Department of Dermatology, University of North Carolina, Chapel Hill, NC [56]

John J. DiGiovanna, MD
Staff Clinician, DNA Repair Section, Dermatology Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD [49, 139]

Andrzej A. Dlugosz, MD
Poth Professor of Cutaneous Oncology, Department of Dermatology, University of Michigan Medical School, Ann Arbor, MI [111]

Lisa M. Donofrio, MD
Associate Clinical Professor, Department of Dermatology, Yale School of Medicine, Yale University, New Haven, CT [254]

Daven N. Doshi, MD
Resident, Department of Dermatology, Albert Einstein College of Medicine, Bronx, NY [16]

Karynne O. Duncan, MD
Private Practice, Saint Helena, CA [113]

Jonathan A. Dyer, MD
Assistant Professor, Departments of Dermatology and Child Health, School of Medicine, University of Missouri, Columbia, MO [137]

Robert T. Eberhardt, MD, FACC, FSVM, RPVI
Associate Professor, Department of Medicine, Boston University School of Medicine, Boston, MA [173]

Benjamin D. Ehst, MD, PhD
Assistant Professor, Department of Dermatology, Oregon Health & Science University, Portland, OR [29]

Lawrence F. Eichenfield, MD
Professor, Departments of Pediatrics and Medicine (Dermatology), University of California, San Diego, San Diego, CA [14]

Daniel B. Eisen, MD
Associate Clinical Professor, Dermatology, University of California, Davis, Sacramento, CA [187]

Myrna El Shareef, MD
Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [204]

James T. Elder, MD, PhD
Professor, Department of Dermatology, University of Michigan Medical School, Ann Arbor, MI [18]

Craig A. Elmets, MD
Professor and Chair, Department of Dermatology, University of Alabama at Birmingham, Birmingham, AL [237]

Dirk M. Elston, MD
Director, Department of Dermatology, Geisinger Medical Center, Danville, PA [99, 231]

Joseph C. English, MD
Associate Professor, Department of Dermatology, University of Pittsburgh, Pittsburgh, PA [181]

Edward M. Esparza, MD, PhD
Resident, Division of Dermatology, University of Washington, Seattle, WA [221]

Janet A. Fairley, MD
Professor and Head, Department of Dermatology, University of Iowa, Iowa City, IA [138]

Vincent Falanga, MD, FACP
Professor, Departments of Dermatology and Biochemistry, Boston University School of Medicine, Boston, MA [248]

Robert D. Fealey, MD
Consultant, Department of Neurology, Mayo Clinic College of Medicine, Rochester, MN [84]

Flavia Fedeles, MD, MS
Intern, Internal Medicine, Hospital of St Raphael, New Haven, CT [23]

Laura Korb Ferris, MD, PhD
Assistant Professor, Department of Dermatology, School of Medicine, University of Pittsburgh, Pittsburgh, PA [181]

Patricia M. Fishman, MD
Assistant Professor, Department of Pathology, University of Illinois at Chicago, Chicago, IL [70]

James E. Fitzpatrick, MD
Professor and Vice Chair, Department of Dermatology, University of Colorado, Denver, CO [219, 227]

Philip Fleckman, MD
Professor, Medicine (Dermatology), University of Washington, Seattle, WA [49]

Carsten Flohr, BM, BCh (Hons), MA, Mphil, MRCPCH, MSc, PhD
Senior Lecturer (Associate Professor) and Honorary Consultant Dermatologist, St John's Institute of Dermatology, St Thomas's Hospital and King's College London, London, UK [4]

Camille Francès, MD
Professor, Department of Dermatology-Allergology, Hôpital Tenon, Paris, France [159]

Jorge Frank, MD, PhD
Professor, Department of Dermatology, Maastricht University Medical Center (MUMC), Maastricht, The Netherlands [132]

Ilona J. Frieden, MD
Professor, Department of Dermatology and Pediatrics, School of Medicine, University of California, San Francisco, San Francisco, CA [126]

Sheila Fallon Friedlander, MD
Professor, Departments of Pediatrics and Medicine (Dermatology), School of Medicine, University of California, San Diego, San Diego, CA [195]

Ramsay L. Fuleihan, MD
Associate Professor, Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL [143]

Abhimanyu Garg, MD
Professor, Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX [71]

Amit Garg, MD
Associate Professor, Department of Dermatology, Boston University School of Medicine, Boston, MA [5, 188, 189]

Christopher C. Gasbarre, DO, FAAD
Associate Staff Physician, Department of Dermatology, Cleveland Clinic, Cleveland, OH [230]

Anthony A. Gaspari, MD
Shapiro Professor, Department of Dermatology, University of Maryland School of Medicine, Baltimore, MD [226]

John K. Geisse, MD
Clinical Professor, Department of Dermatology, University of California, San Francisco, San Francisco, CA [113]

Joel M. Gelfand, MD, MSCE
Assistant Professor of Dermatology and Epidemiology, Departments of Dermatology, Epidemiology and Biostatistics, University of Pennsylvania School of Medicine, Philadelphia, PA [234]

Carlo Gelmetti, MD
Full Professor, Department of Anesthesia, Intensive Care and Dermatologic Sciences, Università degli Studi di Milano, Milano, Italy [147, 148]

Roy G. Geronemus, MD
Director, Dermatology, Laser & Skin Surgery Center of New York, New York, NY [252]

Samer H. Ghosn, MD
Assistant Professor, Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [201, 203, 206]

Lawrence E. Gibson, MD
Professor, Department of Dermatology, Mayo Clinic College of Medicine, Rochester, MN [165]

Barbara A. Gilchrest, MD
Chair Emerita and Professor of Dermatology, Department of Dermatology, Boston University School of Medicine, Boston, MA [9, 109]

Dafna D. Gladman, MD, FRCPC
Professor, Department of Medicine, Division of Rheumatology, University of Toronto, Toronto, ON, Canada [19]

Gerald J. Gleich, MD
Professor of Dermatology and Medicine, Department of Dermatology, School of Medicine, University of Utah, Salt Lake City, UT [31]

Adam B. Glick, PhD
Associate Professor, Center for Molecular Toxicology and Carcinogenesis, Department of Veterinary and Biomedical Sciences, Department of Dermatology, Hershey Medical Center, The Pennsylvania State University, University Park, PA [111]

Richard G. Glogau, MD
Clinical Professor, Department of Dermatology, University of California, San Francisco, San Francisco, CA [255]

Raphaela Goldbach-Mansky, MD, MHS
Acting Chief, National Institute of Arthritis and Musculoskeletal and Skin Diseases Intramural Research Program, Translational Autoinflammatory Disease Section, The National Institutes of Health, Bethesda, MD [134]

Leonard H. Goldberg, MD, FRCP
Medical Director, DermSurgery Associates, PA, Houston, TX [246]

Emmy M. Graber, MD
Assistant Professor of Dermatology, Department of Dermatology, Boston University Medical Center, Boston, MA [80]

Robin A.C. Graham-Brown, BSc, MB, FRCP, FRCPCH
Consultant Dermatologist, Department of Dermatology, University Hospitals of Leicester, Leicester, UK [150]

Jane Margaret Grant-Kels, MD
Professor and Chair, Department of Dermatology, University of Connecticut Health Center, Farmington, CT [23]

Justin J. Green, MD
Department of Dermatology, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, Wood Johnson Medical School, Camden, NJ [199]

Roy C. Grekin, MD
Professor, Department of Dermatology, University of California, San Francisco School of Medicine, San Francisco, CA [121]

James M. Grichnik, MD, PhD
Professor, Department of Dermatology, Miller School of Medicine, Miami, FL [122, 123]

Douglas Grossman, MD, PhD
Associate Professor, Department of Dermatology, University of Utah Health Sciences Center, Salt Lake City, UT [114]

Johann E. Gudjonsson, MD, PhD
Assistant Professor, Department of Dermatology, University of Michigan, Ann Arbor, MI [18]

Bridget C. Hackett, MB BCh, BAO, MRCPI
Department of Dermatology, Mater Misericordiae University Hospital, Dublin, Ireland [33]

Russell P. Hall III, MD
J Lamar Callaway Professor and Chair, Department of Dermatology, Duke University Medical Center, Durham, NC [58, 61, 225]

Analisa V. Halpern, MD
Assistant Professor, Department of Medicine, Division of Dermatology, Cooper University Hospital, Rowan University, Camden, NJ [199]

C. William Hanke, MD, MPH, FACP
Visiting Professor of Dermatology, University of Iowa Carver College of Medicine, Iowa City, IA [253]

Christopher B. Hansen, MD
Assistant Professor, Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT [156]

Philip N. Hawkins, PhD, FRCP, FRCPath, FMedSci
Professor of Medicine, Centre for Amyloidosis and Acute Phase Proteins, University College London Medical School, London, UK [133]

Roderick J. Hay, DM, FRCP, FRCPath, FMedSci
Chairman, International Foundation for Dermatology, London, UK [3, 190]

Adelaide A. Hebert, MD
Professor, Department of Dermatology, University of Texas Medical School at Houston, Houston, TX [84]

Stephen E. Helms, MD
Associate Professor, Department of Medicine, Northeastern Ohio Universities College of Medicine, Rootstown, OH [68]

Ulrich R. Hengge, MD, MBA
Professor, Hautzentrum Prof. Hengge, Düesseldorf, NRW, Germany [65]

Warren R. Heymann, MD
Professor of Medicine and Pediatrics, Head, Division of Dermatology, Robert Wood Johnson Medical School at Camden, University of Medicine & Dentistry of New Jersey, Camden, NJ [199]

Whitney A. High, MD, JD, MEng
Associate Professor, Department of Dermatology, University of Colorado Denver Health Sciences Center, Denver, CO [219, 227]

Chad Hivnor, MD
Associate Program Director, San Antonio Uniformed Services Health Education Consortium, San Antonio, TX [22]

Jonathan Hofmekler, BSc
Associate Researcher, Department of Dermatology, School of Medicine, Emory University, Atlanta, GA [235]

Ulrich Hohenleutner, MD
Professor, Klinik und Poliklinik für Dermatologie, Universitätsklinikum Regensburg, Regensburg, Germany [239]

Steven M. Holland, MD
Chief, Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD [30]

Golara Honari, MD
Attending Physician, Dermatology and Plastic Surgery Institute, Cleveland Clinic, Cleveland, OH, [211]

Herbert Hönigsmann, MD
Professor of Dermatology, Emeritus Chairman, Department of Dermatology, Medical University of Vienna, Vienna, Austria [32, 35, 238]

Thomas J. Hornyak, MD, PhD
Investigator, Dermatology Branch, National Cancer Institute, National Institutes of Health, Bethesda, MD [73]

Alain Hovnanian, MD, PhD
Departments of Genetics and Dermatology, University René Descartes, Paris, France [51]

Chung-Hong Hu, MD
Department of Dermatology University of Wisconsin Madison, WI [25]

Linden Hu, MD
Associate Professor, Department of Medicine, School of Medicine, Tufts University, Boston, MA [187]

Sam T. Hwang, MD, PhD
Chair and Professor, Department of Dermatology, Medical College of Wisconsin, Milwaukee, WI [12]

Sherrif F. Ibrahim, MD, PhD
Procedural Dermatology Fellow, Department of Dermatology, University of California, San Francisco, San Francisco, CA [121]

Gabor Illei, MD, PhD, MHS
Head, Sjögren's Syndrome Clinic, Molecular Physiology and Therapeutics Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD [161]

Alan D. Irvine, MD, FRCP, FRCPI
Consultant Dermatologist, Paediatric Dermatology, Our Lady's Children's Hospital, Dublin, Ireland [52]

Rim S. Ishak, MD
Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [203]

Peter H. Itin, MD
Professor, Department of Dermatology, School of Medicine, University of Basel, Basel, Switzerland [131]

Satori Iwamoto, MD, PhD
Assistant Professor, Department of Dermatology and Skin Surgery, Boston University School of Medicine, Boston, MA [248]

Reza Jacob, MD
Resident, Department of Dermatology, Boston University School of Medicine, Boston, MA [232]

Heidi T. Jacobe, MD, MSCS
Assistant Professor, Department of Dermatology, University of Texas Southwestern Medical Center, Dallas, TX [64]

William D. James, MD
Paul R. Gross Professor, Department of Dermatology, School of Medicine, University of Pennsylvania, Philadelphia, PA [218]

Melinda Jen, MD
Pediatric Dermatology Fellow, Division of Pediatric and Adolescent Dermatology, Rady Children's Hospital, University of California, San Diego, San Diego, CA [130]

Jens-Michael Jensen, MD
Department of Dermatology, Venereology and Allergy, University of Kiel, Kiel, Germany [47]

Richard Allen Johnson, MDCM
Assistant Professor, Department of Dermatology, Harvard Medical School, Boston, MA [105, 178, 179, 198]

Timothy M. Johnson, MD
Professor, Department of Dermatology, University of Michigan, Ann Arbor, MI [124]

Graham A. Johnston, MBChB, FRCP
Consultant, Department of Dermatology, Leicester Royal Infirmary, Leicester, Leicestershire, UK [150]

Marc A. Judson, MD
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Medical University of South Carolina, Charleston, SC [152]

Andrea A. Kalus, MD
Assistant Professor, Division of Dermatology, University of Washington School of Medicine, Seattle, WA [151]

Insoo Kang, MD
Associate Professor of Medicine, Department of Internal Medicine, Yale School of Medicine, Yale University, New Haven, CT [154]

Sewon Kang, MD
Noxell Professor and Chairman, Department of Dermatology, Johns Hopkins University School of Medicine, Baltimore, MD [217]

Allen P. Kaplan, MD
Clinical Professor, Department of Medicine, Medical University of South Carolina, Charleston, SC [38]

Julie K. Karen, MD
Clinical Assistant Professor, Department of Dermatology, New York University Langone School of Medicine, New York, NY [108]

Kenneth A. Katz, MD, MSc, MSCE
STD Control Officer and Senior Physician, Health and Human Services Agency, County of San Diego, San Diego, CA [200, 222]

Stephen I. Katz, MD, PhD
Fellow, American Academy of Dermatology, Schaumburg, IL; Past President, Society of Investigative Dermatology, Cleveland, OH; Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD [61]

Masaoki Kawasumi, MD, PhD
Department of Medicine, Division of Dermatology, University of Washington, Seattle, WA [112]

Dean L. Kellogg, Jr., MD, PhD
Professor, Department of Medicine, University of Texas Health Science Center, San Antonio, TX [93]

Francisco A. Kerdel, MD
Director, Dermatology Inpatient Unit, Department of Dermatology, University of Miami Hospital, Miami, FL [216]

Helmut Kerl, MD
Professor of Dermatology, Chairman Emeritus, Department of Dermatology, Medical University of Graz, Graz, Austria [117]

Jay S. Keystone, MD, MSc(CTM), FRCPC
Professor, Department of Medicine, University of Toronto, Toronto, ON, Canada [207]

Abdul-Ghani Kibbi, MD, FAAD, FACP
Professor and Chair, Department of Dermatology, Faculty of Medicine, American University of Beirut, Beirut, Lebanon [6, 204]

Alexa B. Kimball, MD, MPH
Associate Professor, Department of Dermatology, Harvard Medical School, Boston, MA [16]

Reinhard Kirnbauer, MD
Associate Professor, Department of Dermatology, Division of Immunology, Allergy and Infectious Diseases (DIAID), Medical University of Vienna, Vienna, Austria [196]

John H. Klippel, MD
President and Chief Executive Officer, Arthritis Foundation, Atlanta, GA [170]

Robert Knobler, MD
Associate Professor, Department of Dermatology, Medical University of Vienna, Vienna, Austria [238]

Sandra R. Knowles, BScPhm
Lecturer, Faculty of Pharmacy, University of Toronto, Toronto, ON, Canada [41]

Christine J. Ko, MD
Associate Professor, Department of Dermatology, Yale School of Medicine, Yale University, New Haven, CT [66]

Manuel Koch, PhD
Associate Professor, Institute for Oral and Musculoskeletal Biology, Medical Faculty, Center for Dental Medicine, University of Cologne, Cologne, Germany [63]

Irene E. Kochevar, PhD
Professor, Department of Dermatology, Harvard Medical School, Boston, MA [90]

Nellie Konnikov, MD
Professor, Department of Dermatology, Boston University School of Medicine, Boston, MA [232]

Sandra A. Kopp, MD
Resident Physician, Department of Dermatology, Robert Wood Johnson Medical School at Camden, University of Medicine & Dentistry of New Jersey, Camden, NJ [199]

Kenneth H. Kraemer, MD
Chief, DNA Repair Section, Dermatology Branch, National Cancer Institute, Bethesda, MD [110, 139]

T. Krieg, MD
Department of Dermatology, University of Cologne, Cologne, Germany [63, 157]

Jean Krutmann, MD
Univ.- Professor Dr. med., Institut für Umweltmedizinische Forschung (IUF), Düsseldorf, NRW, Germany [90]

Roopal V. Kundu, MD
Assistant Professor, Department of Dermatology, Feinberg School of Medicine, Northwestern University, Chicago, IL [189]

Thomas S. Kupper, MD, FAAD
Thomas B. Fitzpatrick Professor, Department of Dermatology, Harvard Medical School, Boston, MA [11]

Razelle Kurzrock, MD, FACP
Chair and Professor, Investigational Cancer Therapeutics, MD Anderson Cancer Center, University of Texas, Houston, TX [32]

Helen J. Lachmann, MD, FRCP
Senior Lecturer/Honorary Consultant, National Amyloidosis Centre, University College London Medical School, London, UK [133]

Jeffrey N. Lackey, MD
Staff Dermatologist, Kimbrough Ambulatory Care Center, Fort George G. Meade, MD [213]

Jürgen Lademann, Prof. Dr. rer. nat. Dr.-Ing. habil.
Department of Dermatology, Center of Experimental and Applied Cutaneous Physiology (CCP), Charité - Universitätsmedizin Berlin, Berlin, Germany [215]

Jeffrey R. LaDuca, MD, PhD
Reflections Dermatology, Skaneateles, NY [226]

Jo Lambert, MD, PhD
Professor, Department of Dermatology, Ghent University Hospital, Ghent, Belgium [75]

Michael Landthaler, MD
Department of Dermatology, University of Regensburg, Regensburg, Germany [239]

Sinéad M. Langan, MRCP, MSc, PhD
Visiting Scholar, Department of Dermatology, University of Pennsylvania, Philadelphia, PA [4]

Hilde Lapeere, MD, PhD
Department of Dermatology, University Hospital Ghent, Ghent, Belgium [75]

Anne Laumann, MBChB, MRCP(UK), FAAD
Associate Professor of Dermatology, Department of Dermatology, Feinberg School of Medicine, Northwestern University, Chicago, IL [101]

Stephan Lautenschlager, MD
Associate Professor, Outpatient Clinic of Dermatology & Venereology, City Hospital Triemli, Zürich, Switzerland [202]

Leslie P. Lawley, MD
Assistant Professor of Dermatology and Pediatrics, Department of Dermatology, School of Medicine, Emory University, Atlanta, GA [82]

Chyi-Chia Richard Lee, MD, PhD
Staff Clinician, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, MD [134]

Delphine J. Lee, MD, PhD, FAAD
Dirks/Dougherty Laboratory for Cancer Research, Director, Department of Translational Immunology, John Wayne Cancer Institute, Santa Monica, CA [186]

Ken K. Lee, MD
Associate Professor, Department of Dermatology, Director of Dermatologic Surgery, Oregon Health and Science University, Portland, OR [118]

Lela A. Lee, MD
Professor, Departments of Dermatology and Medicine, School of Medicine, University of Colorado Denver, Denver, CO [37]

David J. Leffell, MD
David Paige Smith Professor of Dermatology and Surgery, Chief, Section of Dermatologic Surgery and Cutaneous Oncology Department of Dermatology, Yale School of Medicine, Yale University, New Haven, CT [113, 114, 115]

Kristin M. Leiferman, MD
Professor, Department of Dermatology, University of Utah, Salt Lake City, UT [31, 36]

Yolanda M. Lenzy, MD, MPH
Clinical Dermatologist, Family Dermatology of Massachusetts, Brookline, MA [9]

Aimee L. Leonard, MD
Private Practice, New England Dermatology & Laser Center, Springfield, MA [253]

Donald Y.M. Leung, MD, PhD
Professor, Department of Pediatrics, School of Medicine, University of Colorado Denver, Denver, CO [14]

Nikki A. Levin, MD, PhD
Associate Professor, Department of Medicine, Division of Dermatology, University of Massachusetts Medical School, Worcester, MA [5]

Ross M. Levy, MD
Attending Physician, Division of Dermatology, North Shore University Health System, Skokie, IL [127]

Bernadette Liegl-Atzwanger, MD
Institute of Pathology, Medical University Graz, Graz, Austria [125]

Henry W. Lim, MD
Chairman and C.S. Livingood Chair, Department of Dermatology, Henry Ford Hospital, Detroit, MI [92, 223]

Dan Lipsker, MD, PhD
Professor, Department of Dermatology, Université de Strasbourg, Faculté de Médecine, Strasbourg, France [171]

Adam D. Lipworth, MD
Instructor, Department of Dermatology, Harvard Medical School, Harvard University, Boston, MA [178, 179]

Robert Listernick, MD
Professor, Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL [141]

Rosemarie Liu, MD
Private Practice Skin, Cancer Surgery Center Fairfax, VA [25]

Zhi Liu, PhD
Professor, Department of Dermatology, University of North Carolina School of Medicine, Chapel Hill, NC [56]

Robert Loewe, MD
Associate Professor, Department of Dermatology, Medical University of Vienna, Vienna, Austria [162]

Anke S. Lonsdorf, MD
Department of Dermatology, University Hospital of Heidelberg, Heidelberg, Germany [12]

Mayra E. Lorenzo, MD, PhD
Instructor, Department of Dermatology, Harvard Medical School, Boston, MA [192]

Thomas A. Luger, MD
Professor and Chairman, Department of Dermatology, University of Münster, Münster, Germany [102]

Calum C. Lyon, MA, FRCP
Department of Dermatology, York Hospital, York, North Yorkshire, UK [96, 97]

Catherine Maari, MD
Assistant Professor, Department of dermatology, University of Montreal, Montreal, QC, Canada [67]

Vandana Madkan, MD
Dermatologist, Center for Clinical Studies, Dermatological Association of Texas, Houston, TX [191]

Meera Mahalingam, MD, PhD, FRCPath
Professor of Dermatology and Pathology and Laboratory Medicine, Dermatopathology Section, Department of Dermatology, Boston University School of Medicine, Boston, MA [187]

Joelle M. Malek, MD
Chief Resident, Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [206]

Richard M. Marchell, MD
Assistant Professor, Department of Dermatology, Medical University of South Carolina, Charleston, SC [152]

Lynette J. Margesson, MD, FRCPC
Assistant Professor of Obstetrics and Gynecology and Medicine (Dermatology), Section of Dermatology, Department of Obstetrics and Gynecology, Dartmouth Medical School, Hanover, NH [78]

M. Peter Marinkovich, MD
Associate Professor, Department of Dermatology, Stanford University School of Medicine, Stanford, CA [62]

Adriana R. Marques, MD
National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD [193]

Nadine Marrouche, MD
Department of Dermatology, American University of Beirut Medical Center, Beirut, Lebanon [201]

Erin F. Mathes, MD
Department of Dermatology, University of California, San Francisco, San Francisco, CA [126]

Theodora M. Mauro, MD
Service Chief, Dermatology, San Francisco VA Medical Center, San Francisco, CA [83]

Susannah E. McClain, MD
Resident, Department of Dermatology, University of Maryland Medical System, Baltimore, MD [226]

John A. McGrath, MD, FRCP
Professor, St John's Institute of Dermatology, Guy's Campus, King's College London, London, UK [8]

W. H. Irwin McLean, FRSE, FMedSci
Dermatology and Genetic Medicine University of Dundee, Dundee, UK [8]

Darius R. Mehregan, MD
Associate Professor and Hermann Pinkus Chair, Department of Dermatology, Wayne State University, Detroit, MI [34]

David A. Mehregan, MD
Associate Professor, Department of Dermatology, School of Medicine, Wayne State University, Detroit, MI [34]

Atul B. Mehta, MD, FRCP, FRCPath
Professor, Department of Haematology, Royal Free Hospital, University College London School of Medicine, London, UK [136]

Natalia Mendoza, MD, MS
Assistant Professor, Department of Research and Dermatology, Universidad El Bosque, Bogotá, Colombia [191]

Peter A. Merkel, MD, MPH
Professor of Medicine, Section of Rheumatology, Clinical Epidemiology Unit, Boston University School of Medicine, Boston, MA [164]

Martin C. Mihm, MD, FACP
Director, Melanoma Program in Dermatology, Department of Dermatology, Brigham and Women's Hospital, Boston, MA [6, 124]

Lloyd S. Miller, MD, PhD
Assistant Professor, Division of Dermatology, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA [10]

Stanley J. Miller, MD
Associate Professor, Departments of Dermatology and Otolaryngology-Head and Neck Surgery, Johns Hopkins Hospital, Baltimore, MD [46]

Daniel Mimouni, MD
Senior Lecturer, Department of Dermatology, Beilinson Campus, Rabin Medical Center, Petah-Tikva, Israel [55]

Julia S. Minocha, MD
Clinical Research Fellow, Department of Dermatology, Feinberg School of Medicine, Northwestern University, Chicago, IL [69]

Paradi Mirmirani, MD
Department of Dermatology, The Permanente Medical Group, Vallejo, CA [87]

Robert L. Modlin, MD
Klein Professor of Dermatology, and Professor of Microbiology, Immunology and Molecular Genetics, Department of Medicine, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA [10, 186]

P. Moinzadeh, MD
Department of Dermatology, University of Cologne, Cologne, Germany [157]

Paul A. Monach, MD, PhD
Assistant Professor, Department of Medicine, Section of Rheumatology, Vasculitis Center, Boston University School of Medicine, Boston, MA [164]

Megan M. Moore, MD
Department of Dermatology, The Permanente Medical Group, Walnut Creek, CA [220]

Rebecca J. Morris, PhD
Professor, Laboratory of Stem Cells and Cancer, The Hormel Institute, University of Minnesota, Austin, MN [45]

L. Katie Morrison, MD
Department of Dermatology, University of Texas Health Sciences Center, Houston, TX [191]

Nico Mousdicas, MBChB, MD
Associate Professor, Department of Dermatology, Indiana University, Indianapolis, IN [177]

Ulrich Mrowietz, MD
Associate Professor, Psoriasis Center, Department of Dermatology, Campus Kiel, University Medical Center Schleswig-Holstein, Kiel, Germany [21]

Colin S. Munro, MD, FRCP (Glasg)
Professor, Alan Lyell Centre for Dermatology, Southern General Hospital, Glasgow, UK [50]

George F. Murphy, MD
Professor of Pathology, Harvard Medical School Director, Program in Dermatopathology, Brigham and Women's Hospital, Boston MA [6]

Haley Naik, MD
Department of Dermatology, Massachusetts General Hospital, Boston, MA [105]

Amanda M. Nelson, PhD
Department of Dermatology, College of Medicine, The Pennsylvania State University, Hershey, PA [79]

Isaac M. Neuhaus, MD
Assistant Professor, Department of Dermatology, University of California, San Francisco, San Francisco, CA [121]

Paul Nghiem, MD, PhD
Associate Professor, Departments of Medicine and Dermatology, University of Washington, Seattle, WA [112, 120]

Gerhard J. Nohynek, PhD, DABT
Scientific Director, Worldwide Safety Department, L'Oreal R&D, Asnières, France [215]

David A. Norris, MD
Professor and Chairman, Department of Dermatology, School of Medicine, University of Colorado Denver, Denver, CO [74]

Scott A. Norton, MD, MPH, MSc
Professor of Dermatology, Division of Dermatology, Department of Medicine, Georgetown University Hospital, Washington, DC [183, 213]

Lillian Odo, MD
Associate Professor, Department of Dermatology, University of Santo Amaro, São Paulo, SP, Brazil [100]

John E. Olerud, MD
Professor, Medicine, Division of Dermatology, University of Washington, Seattle, WA [151]

Katia Ongenae, MD, PhD
Professor, Department of Dermatology, University Hospital Ghent, Ghent, Belgium [75]

Grainne M. O'Regan, MRCPI
Department of Paediatric Dermatology, Our Lady's Children's Hospital, Dublin, Ireland [52]

Anthony E. Oro, MD, PhD
Associate Professor, Program in Epithelial Biology, School of Medicine, Stanford University, Stanford, CA [116]

Catherine H. Orteu, MBBS, BSc, MD, FRCP
Consultant Dermatologist, Department of Dermatology, Royal Free Hospital, London, UK [136]

Nina Otberg, MD
Hair Clinic, Skin and Laser Center Berlin, Potsdam, Germany [88]

Michael N. Oxman, MD
Professor of Medicine and Pathology, University Of California, San Diego, San Diego, CA [194]

Amy S. Paller, MD
Walter J. Hamlin Professor and Chair of Dermatology, Professor of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL [143]

Hee-Young Park, PhD
Associate Professor, Department of Dermatology, Boston University School of Medicine, Boston, MA [72]

Sareeta R.S. Parker, MD
Associate Clinical Professor, Department of Dermatology, School of Medicine, Emory University, Atlanta, GA [82]

Anisha B. Patel, MD
Resident, Department of Dermatology, Oregon Health & Science University, Portland, OR [168]

Tejesh S. Patel, MBBS (Lon), BSc (Hons)
Dermatology Resident, Department of Medicine, Division of Dermatology, University of Tennessee Health Science Center, Memphis, TN [103]

Aimee S. Payne, MD, PhD
Assistant Professor, Department of Dermatology, University of Pennsylvania, Philadelphia, PA [53, 54]

Andrea L. Pearson, MD
Resident Physician, Department of Dermatology, University of Massachusetts Medical School, Worcester, MA [192]

Michelle T. Pelle, MD
Attending Physician, Department of Medicine, Scripps Mercy Hospital, San Diego, CA [81]

Brent E. Pennington, MD
Nashville Skin & Cancer, Nashville, TN [242]

Margot S. Peters, MD
Department of Dermatology, Mayo Clinic, Rochester, MN [36]

Julia S. Pettersen, MD
Department of Dermatology, Yale School of Medicine New Haven, CT [115]

Peter Petzelbauer, MD
Professor of Microvascular Research, Department of Dermatology, Medical University of Vienna, Vienna, Austria [162]

Tania J. Phillips, MD, FRCP, FRCPC
Professor of Dermatology, Department of Dermatology, Boston University School of Medicine, Boston, MA [100]

Gérald E. Piérard, MD, PhD
Chief, Dermatopathology Service, Department of Dermatology, University Hospital of Liège, Liège, Belgium [94]

Claudine Piérard-Franchimont, MD, PhD
Professor, Department of Dermatopathology, University Hospital of Liège, Liège, Belgium [94]

Warren W. Piette, MD
Chair, Division of Dermatology, John H. Stroger Jr. Hospital of Cook County, Chicago, IL [144, 160]

Caroline Piggott, MD
Resident, Department of Dermatology, University of California, San Diego, San Diego, CA [195]

Bianca Maria Piraccini, MD, PhD
Researcher, Department of Dermatology, University of Bologna, Bologna, Italy [89]

Mark R. Pittelkow, MD
Professor, Departments of Dermatology and Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Mayo Medical School, Rochester, MN [26, 27, 158]

Jordan S. Pober, MD, PhD
Professor and Vice Chair, Department of Immunobiology, Yale School of Medicine, Yale University, New Haven, CT [162]

Brian P. Pollack, MD, PhD
Assistant Professor of Dermatology and Pathology/Laboratory Medicine, Emory University, Winship Cancer Institute and the Atlanta VA Medical Center, Atlanta, GA [237]

Miriam Keltz Pomeranz, MD
Clinical Assistant Professor, Department of Dermatology, New York University School of Medicine, New York, NY [108]

Frank C. Powell, FRCPI, FAAD
Associate Professor, Department of Dermatology, University College Dublin, Dublin, Ireland [33]

Julie Powell, MD, FRCPC
Associate Clinical Professor, and Director of Pediatric Dermatology, Department of Pediatrics, Division of Dermatology, CHU Sainte-Justine University of Montreal, Montreal, QC, Canada [67]

Jennifer G. Powers, MD
Resident, Department of Dermatology, Boston University School of Medicine, Boston, MA [100]

Julie S. Prendiville, MB, FRCPC
Clinical Professor, Department of Pediatrics, University of British Columbia, Vancouver, British Columbia, Canada [44]

Howard B. Pride, MD
Associate, Departments of Dermatology and Pediatrics, Geisinger Medical Center, Danville, PA [106]

Ehrhardt Proksch, MD, PhD
Professor, Department of Dermatology, University of Kiel, Kiel, Germany [47]

Pascale Quatresooz, MD, PhD
Lecturer Senior Registrar, Department of Dermatopathology, University Hospital of Liège, Liège, Belgium [94]

Caroline L. Rao, MD
Assistant Professor, Department of Dermatology, Duke University, Durham, NC [58]

Thomas H. Rea, MD
Emeritus Professor, Department of Dermatology, Keck School of Medicine, University of Southern California, Los Angeles, CA [186]

Kavitha K. Reddy, MD
Resident, Department of Dermatology, Boston University School of Medicine, Boston, MA [9]

Thomas E. Redelmeier, MD
Dermatology Department Charite Hospital/Humboldt University, Berlin, Berlin, Germany [215]

Arthur R. Rhodes, MD, MPH
Professor, Department of Dermatology, Rush Medical College, Rush University, Chicago, IL [122]

Stephen K. Richardson, MD
Clinical Assistant Professor, Department of Dermatology, Florida State College of Medicine, Tallahassee, FL [234]

Evan Rieder, MD
Department of Psychiatry, New York University School of Medicine, New York, NY [104]

Maureen Rogers, MBBS, FACD
Emeritus Consultant, Department of Dermatology, Royal Alexandra Hospital for Children, Sydney, Australia [87]

Thomas E. Rohrer, MD
Clinical Associate Professor of Dermatology, Brown University, Alpert School of Medicine, Providence, RI [243]

Arash Ronaghy, MD, PhD
Research Associate, Department of Dermatology, Duke University, Durham, NC [61]

Ted Rosen, MD
Professor, Department of Dermatology, Baylor College of Medicine, Houston, TX [205]

IN [243]

PREFACE

New knowledge drives medical progress and improves patient care. The rapid growth of this knowledge in skin diseases and skin biology makes publication of the eighth edition of *Fitzpatrick's Dermatology in General Medicine* (DIGM) particularly timely. Forty years ago, the first edition of "*Fitz*" was a critical textbook devoted to providing a comprehensive knowledge of dermatology. The relevance of dermatology to general medicine and the basic science foundations of the specialty were defining elements of the new text. This edition, more than ever, reinforces those earlier goals and is designed to be easily accessible to those interested in the clinical and basic science of dermatology. This reference text also highlights the relevance of dermatology to general internal medicine and other disciplines of medicine and surgery. It is written for experienced clinicians and skin biologists worldwide as well as for those in training.

The online edition adds further textual and illustrative detail to almost all chapters and provides extensive and robust literature citations, many with online links, which are especially useful for those who seek an in-depth understanding of a particular topic. The accompanying CD-ROM contains the figures from the print edition in an easily downloaded format for slide production.

Because of the explosion of new knowledge relevant to dermatology and cutaneous biology, chapters have been extensively revised and new chapters have been added on global dermatologic health, ethnic, and racial considerations for normal and diseased skin, and stem cell science. Medical and surgical therapeutics sections have been greatly expanded to reflect the increased importance of procedural dermatology.

Twenty percent of the chapters have new authorship, drawing from expertise around the world. These authors provide new perspectives and guarantee that the content of the book remains fresh and vital.

Schematic diagrams of clinical and basic science mechanisms and clinical care algorithms have been revised to allow rapid intuitive guidance while retaining accuracy and critical detail. This edition is enhanced with additional clinical figures and new tables that permit a "quick look" at key points in each chapter. Finally, the Parts of the book are designated with different colors, thus allowing the reader to easily find sections of interest.

Validated, well-synthesized, and critically interpreted information is essential to improve the care of patients, to prevent skin disease, and to advance cutaneous biology. The current editors of DIGM have striven to fulfill these goals of the original text.

ACKNOWLEDGMENTS

We thank and salute the nearly 500 authors who contributed to the creation of this new and vibrant eighth edition of *Fitzpatrick's Dermatology in General Medicine* (DIGM). The eighth edition of this classic text reflects the amazing growth in new knowledge in basic and clinical sciences related to the skin and to its relationship with other organ systems. The authors have worked assiduously to integrate this new information within the context of established knowledge. The authors, all respected experts in their disciplines, wrote some of the most extensively referenced chapters available either in print or online. We are deeply grateful to them and their staff for their commitment to this text. Their expertise has created chapters that continue to define the comprehensiveness of this textbook.

We are deeply grateful to our families, who appreciated the importance and immensity of our task. They recognized and accepted that editing this textbook demanded many hours of time and evenings spent with a computer screen rather than with them. We thank them for their support during this all-consuming effort.

The editors were supported by talented and dedicated staff, Renate Kosma, Jacy Bernal, Jaime Zagami, Nilda Reyes, and Grace Camire, each of whom handled the correspondence with over 50 authors. The debt that we owe to these individuals cannot be calculated. Many readers of previous editions and dermatology residents from several training programs painstakingly reviewed and critiqued the seventh edition and provided extremely useful advice on improving the content and the presentation for this new edition.

The staff at McGraw-Hill Medical made this text their highest priority. They were led by our ever vigilant and talented editor, Anne M. Sydor, and our project manager for manuscript production and completion, Sarah M. Granlund; and a most professional production team led by Robert Pancotti and Sherri Souffrance in New York and by Sandhya Joshi in India.

A major hallmark and the fresh look for this eighth edition are the hundreds of new figures that required meticulous attention by authors and a creative design and art team at Dragonfly Media Group. For their talented and effective partnership we are forever grateful.

PART 1 Introduction

General Considerations

Chapter 1 :: The Epidemiology and Burden of Skin Disease

:: Martin A. Weinstock & Mary-Margaret Chren

Scientists in health-related fields focus on phenomena at different levels. For laboratory scientists, the focus is at the molecular, cellular, or organ system level; for clinical scientists, the focus is on the patient; and for public health practitioners, the focus is on the population. Epidemiology is the basic science of public health.

Epidemiology has many subdivisions and offshoots. Often the *epidemiology of a disease* in a clinical review refers primarily to its frequency and distribution in the population and estimates of its morbidity and mortality. These data are derived by descriptive epidemiology. Case-control, cohort, and cross-sectional studies may seek to identify risk factors and causes of disease and form the core of analytical epidemiology. Evaluations of public health interventions (experimental epidemiology) constitute the third major branch of classic epidemiology. The basic principles of epidemiology have found broad application in many areas, including understanding the public health implications of naturally occurring and synthetic compounds (molecular epidemiology), the complex interactions of genetic and environmental factors in disease (genetic epidemiology), the formulation of better diagnostic and treatment strategies for patients based on available evidence (clinical epidemiology), and the structuring of health care delivery for better outcomes and greater efficiency (health services research). The reader is referred to other sources for a more detailed discussion of various topics in dermatoepidemiology.[1–3]

TYPES OF EPIDEMIOLOGIC STUDIES

Three of the many types of epidemiologic studies are mentioned here because of their prominence in epidemiologic research. The randomized, controlled trial is a particularly rigorous type of study appropriate to the evaluation of public health interventions. In general, the intervention is performed on a random sample of the study population, and the entire study population is then observed for the occurrence of the outcome in question. The random assignment of intervention allows the more rigorous application of many statistical techniques and reduces the potential for bias. Elimination of biases permits these studies to evaluate the efficacy and impact of an intervention more accurately than trials that do not assign the intervention randomly. Standards for reporting have been published[4] (http://www.consort-statement.org, accessed Jul 7, 2010) and adopted by leading dermatology journals to improve assessment of their validity and their use in subsequent systematic reviews[5] (see Chapter 2).

When evaluating risk factors for disease, it is frequently impossible to assign the risk factor randomly. Hence, inference is based on observational studies. In classical cohort studies, a group with exposure to the risk factor and a group without are chosen and observed over time. Occurrences of the study outcome

are counted and compared between groups. Although more vulnerable to bias than randomized trials, cohort studies, in which exposure to the risk factor is known well before the study outcome is knowable, avoid some potentially serious biases. In a cohort study, the incidence of the study outcome can be measured directly in each group, and the relative risk can be measured directly as the ratio of the incidence between the two groups.

Cohort studies often are quite expensive to conduct because they require following a large population over time and may be impossible if the outcome being studied is uncommon. Hence, observational studies often use the case-control approach, in which cases with the outcome being studied and appropriate controls are investigated to determine their past exposure to the risk factor. Relative risks can be estimated by this approach, although incidence of the disorder cannot. Readers are referred to standard texts for more detail regarding epidemiologic study designs.[6] Case-control and cohort study methods in dermatology also have been reviewed.[7–9]

BIAS AND CONFOUNDING

The problem with inference from observational studies is that one may be led to draw erroneous conclusions. In particular, an association that is found between an exposure and a disease may be an artifact due to one or more of the many forms of bias or confounding. Proper inference regarding cause and effect requires understanding these possible artifacts and their potential impacts.[10]

Selection bias occurs when factors that lead to selection of the study population affect the likelihood of the outcomes or exposures evaluated. For example, a case-control study of cutaneous lymphoma may recruit its cases from sources that typically include a high proportion of referred patients. If controls are recruited from a local clinic population, their socioeconomic status and location of residence may be substantially different from those of the cases simply due to the method of recruitment. Under these circumstances, an association of cutaneous lymphoma with occupation may be noted. It then becomes important to note that the observed association may be due not to a carcinogenic chemical in the workplace but rather to the method by which cases and controls were selected. Similarly, if one were conducting a cohort study of the effect of breast-feeding on the risk of atopic dermatitis, it would be important to select breast-fed and bottle-fed infants from similar environments.

Information bias occurs when the assessment of exposure or outcome may differ between the groups being compared. People who were exposed to a publicized environmental toxin may be more likely to seek care for minor symptoms or signs (and hence be more likely to be diagnosed and treated) than those who were not so exposed, even if the exposure had no biologic effect. Similarly, people who are diagnosed with a disease may be more likely to recall past exposures than healthy controls.

Confounding occurs when an observed association (or lack thereof) between exposure and disease is due to the influence of a third factor on both the exposure and the disease. For example, people who use sunscreens may have more intense sun exposure than those who do not, and intense sun exposure is one cause of melanoma. Hence, observational studies may mistakenly conclude that sunscreen use is a cause of melanoma when the observed association is due to sunscreen use serving as an indicator of a lifestyle involving intense sun exposure.

CAUSAL INFERENCE

Key issues in the public health arena often must rely on observational data for inferring cause and effect; in these situations, the validity and generalizability of the individual studies and of the totality of the evidence must be carefully examined. The following criteria generally are applied for causal inference when an association is found. Although they are described for inferring causality between an exposure and a disease, they are more generally applicable to epidemiologic causal inference.

TIME SEQUENCE

The exposure must precede the disease. This concept is simple and obvious in the abstract but sometimes difficult to establish in practice because the onset of disease may precede the diagnosis of disease by years, and the timing of exposure is often not well defined.

CONSISTENCY ON REPLICATION

Replication of the observed association is key and provides the strongest evidence if the replications are many and diverse and with consistent results. The diversity of the replications refers to varied contexts as well as to study designs with different potential weaknesses and strengths.

STRENGTH OF ASSOCIATION

True causal relationships may be strong (i.e., high relative risk) or weak, but artifactual associations are unlikely to have a high relative risk. If the association between factors x and y is due to the association of both with confounding variable z, the magnitude of the association between x and y always will be less than the magnitude of the association of either with z.

GRADED ASSOCIATION

Also described as *biologic gradient*, this criterion refers to an association of the degree of exposure with occurrence of disease, in addition to an overall association of presence of exposure with disease. This dose-response relation may take many forms, as degree of exposure

may, for example, refer to intensity, duration, frequency, or latency of exposure.

COHERENCE

Coherence refers to plausibility based on evidence other than the existence of an association between this exposure and this disease in epidemiologic studies. Coherence with existing epidemiologic knowledge of the disease in question (e.g., other risk factors for the disease and population trends in its occurrence) and other disorders (including but not limited to related disorders) supports inference. Coherence with existing knowledge from other fields, particularly those relevant to pathogenesis, is critically important when those fields are well developed. It may involve direct links, which are preferred, or analogy. Just as observations in the laboratory assume greater significance when their relevance is supported by epidemiologic data, the reverse is equally true.

EXPERIMENT

Experimental support is critical when feasible. As noted in Section "Types of Epidemiologic Studies," the strongest inferences derive from results of randomized trials, although other experimental designs and quasi-experimental designs may contribute useful evidence.

More detailed discussions of these issues are available.[11,12]

INVESTIGATION OF DISEASE OUTBREAKS

Although outbreaks of disease vary tremendously, use of a standard framework for investigation is important to address the public health issues efficiently (see Chapter 4). The Centers for Disease Control and Prevention has outlined this framework as a series of ten steps, which are described in more detail at http://www.cdc.gov.

1. *Preparation*. Before initiating fieldwork, background information on the disease must be gathered, and appropriate interinstitutional and interpersonal contacts should be made.
2. *Confirm the outbreak*. Publicity, population changes, or other circumstances may lead to an inaccurate perception that more cases than expected have occurred. Hence, local or regional data should be sought to confirm the existence of an increased frequency of disease.
3. *Confirm the diagnosis*. Symptoms and signs of persons affected should be determined and laboratory findings confirmed, perhaps with the assistance of reference laboratories.
4. *Establish a case definition, and find cases*. Careful epidemiologic investigation will involve precise and simple case definitions that can be applied in the field. Efforts to find and count additional cases beyond those reported initially are key to defining the scope of the outbreak.
5. *Establish the descriptive epidemiology*. The cases can now be characterized in terms of *time*, including development of an epidemic curve that describes the changes in magnitude of the outbreak; *place*, including mapping the distribution of cases; and *person*, the demographic and potential exposure characteristics of cases.
6. *Develop hypotheses*. On the basis of the data gathered in steps 1 through 5 and the input of other individuals, plausible hypotheses about causality can be developed for further evaluation.
7. *Conduct analytical epidemiologic investigations*. If the data gathered do not yet clearly prove a hypothesis, cohort and case-control investigations can be conducted to verify or disprove the hypotheses.
8. *Revise hypotheses and obtain additional evidence as needed*. Steps 6 and 7 are repeated, each building on prior iterations, to establish the causal chain of events.
9. *Implement control measures*. As soon as the causal chain of events is understood, prevention and control measures are initiated.
10. *Communicate results*. An outbreak investigation is not complete until the results have been appropriately communicated to the relevant communities.

DESCRIPTIONS OF DISEASE IN POPULATIONS: MEASURES OF DISEASE BURDEN

No single number can completely describe the burden of skin disease because that burden has many dimensions and because the term *skin disease* itself is rather ambiguous. Many disorders with substantial morbidity or mortality, such as melanoma or lupus erythematosus, affect multiple organ systems. The degree of skin involvement may vary widely from patient to patient and within the same patient from time to time. Diseases not typically treated by dermatologists, such as thermal burns, often are excluded from estimates of the burden of skin disease even though they primarily involve the skin. In addition, some diseases treated most often by dermatologists may be classified in a different category by funding agencies or others [e.g., melanoma is classified as an oncologic disorder as opposed to a disease of the skin by the National Institutes of Health and by the *International Classification of Diseases*, (http://www.who.int/classifications/apps/icd/icd10online/, accessed Jul 7, 2010) even though it almost always arises in the skin]. Organ systems are interrelated, and the overlap is sufficiently great that any definition of skin disease is necessarily arbitrary, and any global estimate of the public health burden of these diseases is therefore open to challenge. Typical

measures of disease burden are discussed in the following sections.

MORTALITY

Mortality is a critical measure of disease impact. Death certification is universal in the United States, and the *International Classification of Diseases* code of the underlying cause of each death is recorded. For the year 2006, there were 16,163 deaths reported as due to "skin disease" in the United States, of which most were due to melanoma (Table 1-1). Additional major causes included other skin cancers (primarily keratinocyte carcinomas), infections of the skin, and skin ulcers (primarily decubitus ulcers). Bullous disorders represented less than 2% of these deaths. The total number of skin disease deaths, of course, depends critically on the definition of skin disease, as noted in Section "Descriptions of Disease in Populations: Measures of Disease Burden."

In addition to the total number of deaths, mortality typically is expressed as an age-adjusted rate to facilitate comparisons among populations with different age distributions. Statements of age-adjusted rates of mortality (or other results standardized by age) should be accompanied by an indication of the standard used in the adjustment to avoid potentially misleading inferences. For example, when 1998 melanoma mortality rates are estimated using the 2000 US population standard, the result is 50% higher than when the 1940 US standard population is used (1.8 vs. 1.2 per 100,000 per year for women and 4.1 vs. 2.7 per 100,000 per year for men). Similarly, when years of potential life lost are reported, the reader must be wary of different definitions that may be applied. In one analysis, a decline in years lost from melanoma was noted by one definition that was not observed with another.[13]

TABLE 1-1
Skin Disease Deaths, United States, 2006

Disease	Deaths (*n*)
Cancers	12,301
Melanoma	8,441
Genital	1,126
Lymphoma	91[a]
Other cancers	2,643[a] (primarily basal and squamous cell carcinoma)
Ulcers	1,496
Infections	1,793
Bullous disorders	269
Other causes	304
Total	16,163

[a]We estimate that approximately one-half of keratinocyte carcinoma deaths are misclassified squamous cell carcinomas arising from mucosal surfaces in the head and neck[16] and that cutaneous lymphoma deaths are underestimated by a factor of 2 (see text). [Adapted from http://wonder.cdc.gov/ (verified Apr 27, 2010).]

Careful analyses of mortality include assessment of the validity of the data. Melanoma mortality statistics appear to be reasonably accurate.[14,15] However, deaths from keratinocyte carcinomas are overestimated by a factor of 2 (mostly due to the erroneous inclusion of mucosal squamous cell carcinomas of the head and neck region),[16,17] and conventional estimates of deaths from cutaneous lymphoma miss about half of the actual deaths.[18]

INCIDENCE

Incidence refers to the number of new cases of a disorder. Mortality is low for most skin diseases; hence, incidence may be a more useful measure for the assessment of burden of skin disease. However, many features of skin diseases make their incidence difficult to measure. For example, for many skin disorders, there are no diagnostic laboratory tests, and, in fact, some disorders may evade physician diagnosis (e.g., allergic reactions). Incidence for reportable communicable diseases in the United States is published periodically based on reports to health departments, although underreporting of skin diseases due to failure to present for medical care or to misdiagnosis is a concern (Table 1-2). Incidences of melanoma and cutaneous lymphoma have been published based on data from a system of nationwide cancer registries, yet underreporting remains a potential concern with these data.[19,20] Special surveys have been conducted and administrative datasets analyzed to estimate incidence of other disorders, such as keratinocyte carcinomas, although a system of sentinel registries would improve nationwide assessment.[21,22] For some diseases unlikely to evade medical detection due to their severity, such as toxic epidermal necrolysis, efforts to estimate incidence have met with considerable success.[23,24] Specific contexts that permit more accurate incidence estimates include the workplace; for example, where occupational skin disease is a prevalent problem.[25]

COHORT PATTERNS

Cohort patterns of changes in mortality or incidence typically are observed when exposures determined in childhood predict frequency of disease throughout the life span. A classic example is melanoma mortality, for which sun exposure in childhood is an important determinant. A birth cohort is defined as the group of individuals born within a defined (e.g., 10-year) period. Melanoma mortality generally increases as a power function of age within a birth cohort. Until recent decades, each successive birth cohort had higher risk than its predecessor; hence, the curves of mortality versus age were shifted upward. Thus, the cross-sectional relationship of mortality versus age and the increase in mortality risk during most of the twentieth century followed a cohort pattern. For many countries in the past several decades a decline in melanoma mortality has been observed in younger age groups

TABLE 1-2
New Cases of Selected Reportable Diseases in the United States

	1940	1950	1960	1970	1980	1990	2000	2008

despite an increase in older age groups, suggesting a lower baseline in these mortality-versus-age curves for recent cohorts and hence a likely future decline in overall melanoma mortality.

PREVALENCE

Prevalence refers to the proportion of the population affected by a disorder. Because many skin diseases are nonlethal yet chronic, prevalence is a particularly important measure of frequency in dermatology. Population-based data on prevalence of skin disease for the United States were obtained in the first Health and Nutrition Examination Survey, which was conducted in the early 1970s.[26] Despite its limitations, this study was notable because the sample was representative of the general US population, the number surveyed was large (over 20,000), and the entire surveyed population was examined by physicians (primarily dermatology residents), so the resulting estimates were not dependent on patients' ability or inclination to seek medical care. Indeed, one of the findings of the survey was that nearly one-third of those examined had one or more skin conditions judged to be significant enough to merit a visit to a physician. The most common conditions and their age- and gender-specific prevalence are indicated in Table 1-3 and Fig. 1-1. A similar survey in the United Kingdom of over 2,000 Londoners in 1975 noted that almost one-quarter of adults had a skin condition serious enough to warrant medical care.[27] Other efforts have focused on obtaining prevalence estimates of specific conditions with special surveys.[28,29]

LIFETIME RISK

Lifetime risks for certain disorders are quoted commonly, although their validity can be questioned. Lifetime risk can be measured only in retrospect, and even then it reflects competing causes of mortality in addition to incidence. It is commonly quoted for disorders such as cutaneous malignancies that are changing substantially in incidence, yet those changes are frequently ignored in its calculation, and, in any case, projections of future changes are quite speculative and may be misleading.[30]

TABLE 1-3
Prevalence of Skin Conditions—United States, 1971–1974[a]

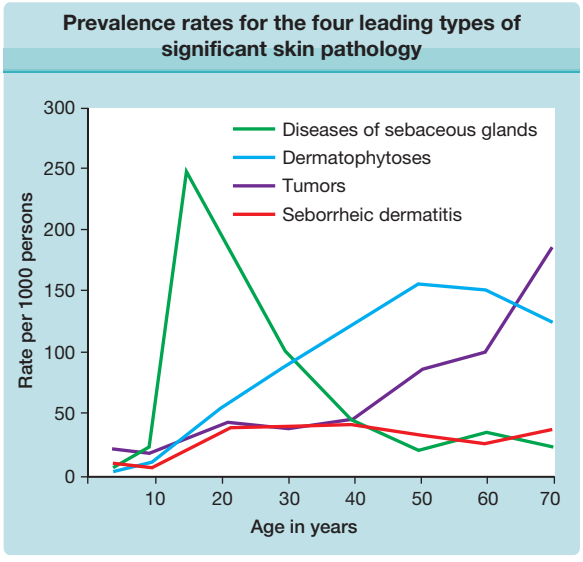

Figure 1-1 Prevalence rates for the four leading types of significant skin pathology among persons 1–74 years, by age, in the United States, 1971–1974.

NUMBER OF PHYSICIAN VISITS

Number of physician visits for a condition is one practical measure of its frequency that may reflect its incidence, prevalence, and severity, as well as access to health care. Table 1-4 lists frequencies of dermatologist and other physician outpatient visits for some of the most common skin conditions. A feature of this measure of disease frequency is its direct relation to expenditures for care of the disease.

OTHER MEASURES OF MORBIDITY: CONCEPTUAL ISSUES

The consequences of skin disease for a population (or the *burden of disease*) are complex; a practical conceptu-

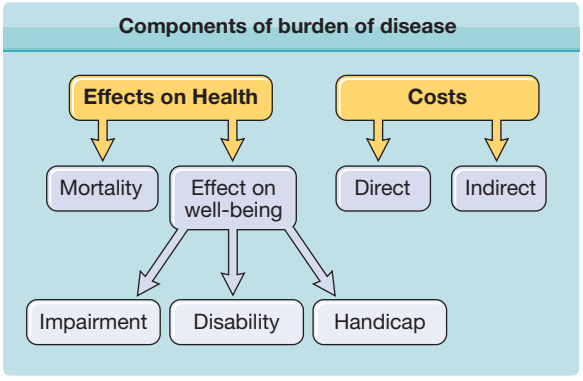

Figure 1-2 Components of burden of disease.

alization is contained in Fig. 1-2. Broadly, components of burden of skin disease are those related to effects on health or costs. Aspects of health include mortality and effects on well-being, including those related to the impairment, disability, or handicap a disease causes. For example, a patient with psoriasis may have thickening and scaling of the palms (a bodily impairment), which may cause disability (e.g., use of the hands), dysfunction (role at work), and effects on quality of life. Costs are either direct (for which funds can be paid) or indirect (for which charges are not routinely assigned, such as lost income because of disease).[31]

The measurement of burden of skin disease is challenging, in part because these conditions typically do not cause mortality and do not result in changes in easily measured laboratory tests. The most important gauges of skin disease status and progression (i.e., the physical examination and patients' reports) can be difficult to measure and compile; in most cases patients' reports of the effects of skin disease on their activities and well-being are crucial for determining the overall consequences of those diseases. The measurement challenges are heightened because people understand and value these aspects of health quite differently due to age, gender, cultural conceptions, or access to health care.

The measurement of nonfatal consequences of disease is the subject of much international scientific and political attention (http://www.who.int/healthinfo/global_burden_disease/en/, accessed Mar 5, 2010, and Chapter 3). An important point for dermatology is that patients' experiences of illness may not be adequately assessed with global measures that focus on single aspects of health, or which were developed without substantial input from patients.[32] For example, skin diseases that are visible and affect appearance may result in social stigma and mood changes, which would not be measured with metrics that are based on dysfunction.

OTHER MEASURES OF MORBIDITY: ISSUES IN QUANTIFICATION

Like all assays, measures of the nonfatal consequences of diseases must be accurate. For example, they must be *reliable* in that the variability in results among subjects who truly differ should be greater than the variability when a stable subject is examined repeatedly. The measures must have evidence of *validity*, which refers to the extent to which an instrument measures what it is supposed to measure and does not measure something else. Health outcome measures also must demonstrate *responsiveness*, the ability to detect clinical change. Furthermore, even when an accurate instrument exists, the clinical significance or *interpretability* of scores or changes in scores often cannot be judged until the tool is used widely and scores are available for many patients with disease of varying severity.[33]

CLINICAL SEVERITY OF DISEASE

A significant challenge for the development of clinimetric measures is developing a consensus among clinicians about the specific features of an individual disease that are important to include in such measures. Substantial progress in the empiric derivation of these features has been made for disease severity measures in certain skin diseases.[34,35] The extent to which a specific skin disease disrupts the skin itself is related both to the percentage of body surface area involved and to physical signs of the eruption, such as the amount of induration and the degree of scale. Given the pleomorphism of skin eruptions, most dermatologic severity-of-disease measures are disease-specific, and for common skin conditions, multiple instruments are often available. Among the most studied instruments to measure clinical severity of disease are the Psoriasis Area and Severity Index (PASI)[36] and the Severity Scoring of Atopic Dermatitis (SCORAD) index.[37] With the PASI, severity of disease is assessed by judgment of the degree of involvement of four body regions with signs of erythema, induration, and desquamation. The SCORAD index combines an assessment of disease area with six clinical signs of disease intensity (scales to measure pruritus and sleep loss also can be included). Standardized reviews of severity measures can be helpful for informing a consensus as well as focusing futures studies; such reviews have recently been published of 20 measures of atopic dermatitis[38] and 53 measures of psoriasis.[39]

PATIENT-REPORTED OUTCOMES

As noted above, patients' reports of their experiences of disease and health care are particularly important for assessing the course of chronic diseases (like most skin diseases). Table 1-5 includes typical aspects of patients' experience that are measured in health care research.

The effects of disease on patients' quality of life can be assessed with generic instruments (which permit comparisons of effects in patients with different diseases), skin-specific instruments (which permit comparisons of patients with different skin diseases), and, more uncommonly, condition-specific instruments (which permit comparisons of patients with the same skin disease). Although more specific instruments may assess aspects of a disease that would be missed with

TABLE 1-5
Typical Instruments Used to Measure Patient Reports

Domain	Typical Instrument(s)	Comment
Overall quality of life	Medical Outcomes Study Short-Form instruments (SF-36)[40] and (SF-12)[41]	36 or 12 items; commonly used in clinical research; interpretable scores
Skin-related quality of life	Dermatology Life-Quality Index[42] Skindex-29[43], Skindex-16[44]	10 items, most commonly used, focuses on functioning 29 or 16 items, focuses on emotional effects, symptoms, and functioning
Disease-specific severity	Patient-Oriented Eczema Measure (POEM)[45], Self-Administered Psoriasis Area and Severity Index (SAPASI)[46]	Correlate well with clinician measures
Symptoms: pruritus	Itch Severity Scale[47], Pruritus-Specific Quality-of-Life Instrument[48]	Demonstrate promising measurement properties
Patient satisfaction	Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey[49]	Correlates with adherence, quality of life, and quality of care
Patient preferences	Utilities[50], Willingness to Pay[51]	Correlations among different measures of preferences can be weak

generic tools, both generic and specific tools contribute unique information to a "snapshot" of a patient's overall health-related quality of life. Substantial progress has been made in the development and testing of patients' reports of the effects of their skin diseases on their activities and quality of life. Although quality of life is the patient-reported outcome most often measured, patients' reports of symptoms, satisfaction with health care, and preferences for health states are other examples. Data continue to be accumulated about the performance of these instruments (including the use of sophisticated psychometric methods and the interpretation of their scores[52]). On a national level, to develop a core set of questions and metrics and to create item banks and repositories of items that perform well using modern analytic techniques, the National Institutes of Health has recently initiated the Patient-Reported Measurement Information System (PROMIS, http://www.nihpromis.org/).

A utility is a numeric measure of the value a patient places on a given health state compared with other health states. In the measurement of utilities, a variety of procedures are used (such as visual analog scales and time tradeoff exercises) to assign a numerical value (or utility) to health states. This value reflects patients' preferences for the health states, in which 1.0 represents perfect health and 0.0 represents death. Utilities are advantageous because they permit the incorporation of patient preferences into medical care decisions. Also, because they describe improvements in morbidity with a single weighted metric, utilities are used for the evaluation of complex tradeoffs such as the calculation of cost-effectiveness, in which the costs of treatments are compared with the values of the health states they make possible. However, utilities are controversial because they can be difficult to measure and can vary among patients in unpredictable ways. An increasing number of studies exist that formally measure utilities of patients with skin diseases.[50]

COSTS

Costs of skin disease depend on the perspective from which they are measured, because the costs to insurers and patients may be quite different from the overall cost to society. Because most skin diseases are chronic and are cared for in the outpatient setting, estimation of both their monetary and intangible costs is difficult. Costs for individual skin conditions have been calculated[53], and therapies have been evaluated in relation to their benefits and effectiveness.[54] In addition, overall direct and indirect cost to payers, patients, and society of 22 skin diseases have been reported.[55]

QUALITY OF CARE IN DERMATOLOGY

Health services research uses many scientific methods from epidemiology, clinical epidemiology, and the quantitative social sciences to study and improve the quality of health care. From the perspective of health services research, access to care, the processes involved in the provision of care, the particular therapeutic interventions, as well as patient and provider characteristics, are all determinants of the quality of care. Studies of both the effectiveness of care (i.e., outcomes of health care as it is usually practiced) and the efficacy of interventions (i.e., the results of interventions implemented in the idealized circumstances of a randomized clinical trial) are important. Many of the examples cited earlier demonstrate a sharpened focus in dermatology on accurate measurement of the clinical encounter. This capacity to measure the progress of chronic diseases and their care will permit rigorous efforts to evaluate and improve the quality of that care.

Chapter 2 :: Evidence-Based Dermatology

:: Michael Bigby, Rosamaria Corona, & Moyses Szklo

EVIDENCE-BASED MEDICINE AT A GLANCE

- Evidence-based medicine (EBM) is the use of the best current evidence in making decisions about the care of individual patients.
- EBM is predicated on asking clinical questions, finding the best evidence to answer the questions, critically appraising the evidence, applying the evidence to the treatment of specific patients, and saving the critically appraised evidence.
- The EBM approach is most appropriate for frequently encountered conditions.
- Results from well-designed clinical studies involving intact patients are at the pinnacle of the hierarchy of evidence used to practice EBM.
- Recommendations about treatment, diagnosis, and avoidance of harm should take into account the validity, magnitude of effect, precision, and applicability of the evidence on which they are based.

WHAT IS "THE BEST EVIDENCE?"

The acceptance of evidence-based medicine (EBM) in the specialty of dermatology has been slow and reluctant. The term and principles are understood by few and misunderstood by many. EBM is perceived as an attempt to cut costs, impose rigid standards of care, and restrict dermatologists' freedom to exercise individual judgment. Practicing EBM in dermatology is hampered by the continued belief among dermatologists that clinical decisions can be guided by an understanding of the pathophysiology of disease, logic, trial and error, and nonsystematic observation.[7,8] It is hampered also by a lack of sufficient data in many areas. As with EBM in general, therapy is often primarily emphasized; however, evidence-based approaches to diagnosis and avoidance or evaluation of harm are also important considerations.

Practicing EBM is predicated on finding and using the best evidence. Potential sources of evidence include knowledge regarding the etiology and pathophysiology of disease, logic, personal experience, the opinions of colleagues or experts, textbooks, articles published in journals, and systematic reviews. An important principle of EBM is that the quality (strength) of evidence is based on a hierarchy. The precise hierarchy of evidence depends on the type of question being asked (Table 2-1).[9] This hierarchy consists of results of well-designed studies (especially if the studies have findings of similar magnitude and direction, and if there is statistical homogeneity among studies), results of case series, expert opinion, and personal experience, in descending order.[6,8] The hierarchy was created to encourage the use of the evidence that is most likely to be accurate and useful in clinical decision-making. The ordering in this hierarchy has been widely discussed, actively debated, and sometimes hotly contested.[10]

A systematic review is an overview that answers a specific clinical question; contains a thorough, unbiased search of the relevant literature; uses explicit criteria for assessing studies; and provides a structured presentation of the results. A systematic review that uses quantitative methods to summarize results is a meta-analysis.[11,12] A meta-analysis provides an objective and quantitative summary of evidence that is

TABLE 2-1
Grades of Evidence[a,b]

Grade	Level of Evidence	Therapy/Harm	Diagnosis
A	1a	Systematic review (with homogeneity[c]) of RCTs	Systematic review (with homogeneity) of level 1 (see column 2) diagnostic studies, or a CPG validated on a test set.
	1b	Individual RCT (with narrow confidence intervals)	Independent blind comparison of an appropriate spectrum of consecutive patients, all of whom have been evaluated by both the diagnostic test and the reference standard.
	1c	All or none[d]	Very high sensitivity or specificity.
B	2a	Systematic review (with homogeneity) of cohort studies	Systematic review (with homogeneity) of level 2 or better (see column 2) diagnostic studies.
	2b	Individual cohort study [including low-quality RCT (e.g., <80% follow-up)]	Independent blind comparison but either in nonconsecutive patients or confined to a narrow spectrum of study individuals (or both), all of whom have been evaluated by both the diagnostic test and the reference standard or a diagnostic CPG not validated in a test set.
	2c	"Outcomes" research[e]	
	3a	Systematic review (with homogeneity) of case-control studies	Systemic review (with homogeneity) of 3b (see column 2) and better studies.
	3b	Individual case-control study	Independent blind comparison of an appropriate spectrum, but the reference standard was not applied to all study patients.
C	4	Case series (and poor-quality cohort and case-control studies)	Reference standard was not applied independently or not applied blindly.
D	5	Expert opinion without explicit critical appraisal, or based on physiology, bench research, or logical deduction.	

CPG = clinical practice guideline, a systematically developed statement designed to help practitioners and patients make decisions about appropriate health care for specific clinical circumstances; RCT = randomized controlled clinical trial.
[a]These levels were generated in a series of iterations among members of the NHS R&D Centre for Evidence-Based Medicine (Chris Ball, Dave Sackett, Bob Phillips, Brian Haynes, and Sharon Straus). For details see Levels of Evidence and Grades of Recommendation, http://www.cebm.net/levels_of_evidence.asp, accessed May 2001.
[b]Recommendations based on this approach apply to "average" patients and may need to be modified in light of an individual patient's unique biology (e.g., risk, responsiveness) and preferences about the care he or she receives.
[c]*Homogeneity* means lacking variation in the direction and magnitude of results of individual studies.
[d]*All or none* means interventions that produced dramatic increases in survival or outcome, such as the use of streptomycin to treat tubercular meningitis.
[e]Outcomes research includes cost-benefit, cost-effectiveness, and cost-utility analyses.

amenable to statistical analysis.[11] Meta-analysis is credited with allowing the recognition of important treatment effects by combining the results of small trials that individually lacked the power to demonstrate differences among treatments. For example, the benefits of intravenous streptokinase in treating acute myocardial infarction were recognized by means of a cumulative meta-analysis of smaller trials at least a decade before this treatment was recommended by experts and before it was demonstrated to be efficacious in large clinical trials.[13,14] Meta-analysis has been criticized because of the discrepancies between the results of meta-analysis and those of large clinical trials.[14–17] For example, results of a meta-analysis of 14 small studies of the use of calcium to treat preeclampsia showed a benefit to treatment, whereas a large trial failed to show a treatment effect.[14] The frequency of such discrepancies ranges from 10% to 23%.[14] Discrepancies can often be explained by differences in treatment protocols, heterogeneity of study populations, or changes that occur over time.[14]

Publication bias is an important concern regarding systematic reviews. It results when factors other than the quality of the study are allowed to influence its acceptability for publication. Several studies have shown that factors such as sample size, direction and statistical significance of findings, and investigators' perceptions of whether the findings are "interesting" are related to the likelihood of publication.[18,19]

For example, in a study by Dickersin et al, the reasons given by investigators that results of completed studies were not published included "negative results" (28%), "lack of interest" (12%), and "sample size problems" (11%).[18] Results of studies with small samples are

less likely to be published, especially if they have negative results.[18,19] This type of publication bias jeopardizes one of the main goals of meta-analysis (i.e., an increase in power through pooling of the results of small studies). Creation of study registers and advance publication of research designs have been proposed as ways to prevent publication bias.[20,21] Publication bias can be detected by using a simple graphic test (funnel plot) or by several other statistical methods.[22,23] In addition, for many diseases, the studies published are dominated by drug company-sponsored trials of new, expensive treatments. The need for studies to answer the clinical questions of most concern to practitioners is not addressed because sources of funding are inadequate.

Not all systematic reviews and meta-analyses are equal. A systematic review can be only as good as the clinical trials that it encompasses. The criteria for critically appraising systematic reviews and meta-analyses are shown in eTable 2-1.1 in online edition. Detailed explanations of each criterion are available.[11,24]

The type of clinical study that constitutes best evidence is determined by the category of question being asked. Questions about therapy and prevention are best addressed by RCT.[11,24–26] Questions about diagnosis are best addressed by cohort studies.[11,24,27,28] Cohort studies, case-control studies, and postmarketing surveillance studies best address questions about harm.[11,24,29] RCT are a good source of evidence about the harmful effects of interventions for adverse events that occur frequently but not for rare adverse events. Case reports are often the first line of evidence regarding rare adverse events, and sometimes they are the only evidence. Methods for assessing the quality of each type of evidence are available.[11,24]

With regard to questions about therapy and prevention, the RCT has become the gold standard for determining treatment efficacy. Thousands of RCT have been conducted. Studies have demonstrated that failure to use randomization or to provide adequate concealment of allocation resulted in larger estimates of treatment effects, caused predominantly by a poorer prognosis in nonrandomly selected control groups than in randomly selected control groups.[30] However, studies comparing randomized and nonrandomized clinical trials of the same interventions have reached disparate and controversial results.[30–32] Some found that observational studies reported stronger treatment effects than RCT.[30] Others found that the results of well-designed observational studies (with either a cohort or a case-control design) do not systematically overestimate the magnitude of the effects of treatment compared with RCT on the same topic.[31,32] Examining the details of the controversy leads to the following limited conclusions. Trials using historical controls do yield larger estimates of treatment effects than do RCT. Large, inclusive, fully blinded RCT are likely to provide the best possible evidence about effectiveness.[10,33,34]

Although personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience have been widely documented.[3,35,36] Nisbett and Ross extensively reviewed people's ability to draw inferences from personal experience and describe several of these pitfalls.[37] These include the following:

- Overemphasis on vivid anecdotal occurrences and underemphasis on significant statistically strong evidence
- Bias in recognizing, remembering, and recalling evidence that supports preexisting knowledge structures (e.g., ideas about disease etiology and pathogenesis) and parallel failure to recognize, remember, and recall evidence that is more valid
- Failure to accurately characterize population data because of ignorance of statistical principles, including sample size, sample selection bias, and regression to the mean
- Inability to detect and distinguish statistical association and causality
- Persistence of beliefs in spite of overwhelming contrary evidence

FINDING THE BEST EVIDENCE

The ability to find the best evidence to answer clinical questions is crucial for the practice of EBM. Finding evidence requires access to electronic search tools, searching skills, and availability of relevant data. Evidence about therapy is the easiest to find. The most useful sources for locating the best evidence about treatment include the following:

- The Cochrane Library
- The MEDLINE (Medical Literature Analysis and Retrieval System OnLine) and EMBASE (*Exerpta-Medica Database*) databases
- Primary journals
- Secondary journals
- Evidence-based dermatology and EBM books
- The National Guideline Clearing-house (http://www.guideline.gov/)
- The National Institute for Health and Clinical Excellence (http://www.nice.org.uk)

The Cochrane Library contains the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effectiveness, the Cochrane Central Register of Controlled Trials, and the Health Technology Assessment Database, among other databases (http://www.thecochranelibrary.com/view/0/index.html). Volunteers write the systematic reviews in the Cochrane Library according to strict guidelines developed by the Cochrane Collaboration. Issue 1, 2010, of the Cochrane Library contained 6,153 completed systematic reviews. The number of reviews of dermatologic topics is steadily increasing.

CRITICALLY APPRAISING THE EVIDENCE

After evidence is found, the next step in practicing EBM is critically appraising the quality of the evidence and determining the magnitude of effects and

the precision of the evidence. The criteria for critically appraising papers about treatment, diagnostic tests, and harmful effects of exposures are shown in eTables 2-1.2, 2-1.3, and 2-1.4 in online edition, respectively.[11,24] Papers that meet these criteria are more likely to provide information that is accurate and useful in the care of patients.[11,24] Critically appraising evidence consists in determining whether the results are:

- valid (i.e., they are as unbiased as possible);
- clinically important; and
- applicable to the specific patient being seen.

Determining the validity of evidence centers on ascertaining whether the evidence was produced in a manner most likely to eliminate and avoid bias. The critical questions to ask to determine the validity of papers about therapy, diagnostic tests, and harmful effects are shown at the tops of eTables 2-1.2, 2-1.3, and 2-1.4 in online edition, respectively.

EVIDENCE ABOUT THERAPY AND PREVENTION

Studies of therapy should randomly assign patients to treatment groups (using a table of random numbers or pseudorandom numbers generated by computer) and ensure concealed allocation (e.g., by using opaque envelopes) so that the treating physician cannot know or anticipate to which treatment group the patient has been assigned. In addition, there should be nearly complete follow-up of all patients entered into the study; intention-to-treat analysis of results; masking of investigators, patients, and statisticians where possible; equal treatment of groups; and similarity between treatment groups with regard to the distributions of prognostic variables. These criteria represent only a small subset of the features of a well-designed and well-reported clinical trial.[35] A more complete set of criteria has been published and recently updated, and adherence to these criteria is required by many of the leading medical journals.[47,48]

Important terms and concepts that must be understood to determine whether the results of a paper about therapy are clinically important include the following:

- The magnitude of the treatment effect
- The precision of this value
- The difference in response rates
- Its reciprocal, the number needed to treat (NNT)
- The confidence interval

In evaluating a clinical trial, the physician should look for clinical outcome measures that are clear-cut and clinically meaningful to the physician and his or her patients.[35] For example, in a study of a systemic treatment for warts, complete disappearance of warts is a meaningful outcome, whereas a decrease in the volume of warts is not. Historically, two principal methods have been used to determine patient outcomes in dermatologic clinical trials. The first involves examining the patient before, during, and at the conclusion of treatment and reporting how the patient appears at the various time points. The second involves determining the degree of improvement during treatment.[49] A third method, determining the impact of therapy on the quality of the patient's life, is being increasingly used in dermatologic trials.[35]

An example of the first method is commonly encountered in therapeutic trials of psoriasis. A common practice is to assign numerical values to (1) the amount of erythema, (2) the amount of scaling, (3) the degree of infiltration, and (4) the body surface area involved, and to formulate an "index" by calculating a derivative of some product of these four numbers.[50,51] The overall condition of the patient can then be represented by this index. A common index is the psoriasis area and severity index, which ranges from 0 to 72.[50] The major problem with indices is that they confound area of involvement with severity of disease.[49] For instance, a patient with thick plaque-type psoriasis of the knees, elbows, and scalp may have the same index as a patient with diffuse but minimal psoriasis of the trunk and arms. Whereas the former condition is notoriously difficult to treat, the latter will generally respond rapidly and easily to many forms of therapy.[49] The second problem with indices is that they lend an air of precision to the analysis and presentation of data that is not warranted.[49] For instance, Tiling-Grosse and Rees demonstrated that physicians and medical students were poor at estimating the area of involvement of skin disease, and therefore some of the components that make up indices may be inaccurate.[52] Finally, calculations of the means, differences in means, and percentages of change in indices in response to treatment often do not convey an accurate clinical picture of the changes that have occurred.[49]

The second method of assessment groups patients according to their degree of improvement. Treatments are then compared in terms of their ability to move patients into categories representing higher degrees of improvement. There are two major problems with this form of assessment. The first is that the categories of improvement are often not well defined. The second problem is that the categories are not additive.[49] That is, 60% to 80% improvement is often assumed to be twice as good as 20% to 40% improvement, but no such numerical relationship exists between these subjectively defined categories.

To be most useful, the outcome variables to be measured must be clearly defined, must be as objective as possible, and must have clinical and biologic significance.[35,49] The best indices and scales are the ones that accurately reflect the state of the disease and the ones whose validity and reliability have been verified by previous work.[35,49,53] The development of scales and indices for assessing cutaneous diseases and the testing of their validity, reproducibility, and responsiveness have been inadequate.[35,49,54] Therefore, a lack of clearly defined and useful outcome variables remains a major problem in interpreting dermatologic clinical trials.

Until better scales are developed, trials with the simplest and most objective outcome variables are

the best. They lead to the least amount of confusion and support the strongest conclusions. Thus, trials in which a comparison is made between death and survival, recurrence of disease and no recurrence, or cure and lack of cure are studies whose outcome variables are easily understood and verified. For trials in which the outcomes are less clear-cut and more subjective, a simple ordinal scale is probably the best choice.[49] The best ordinal scales involve a minimum of human judgment, have a precision that is much smaller than the differences being sought, and are sufficiently standardized so that they can be used by others and produce similar results.[36]

In addition to being clearly defined, outcome variables should have clinical and biologic significance.[25,26] For example, in a therapeutic trial of patients with severe acne, treatment was associated with a decrease in lesion count from a mean of 40 to a mean of 35. This numerical difference may be of statistical significance, but it does not convey the biologic significance of the change in lesion number.[49] This result may mean that some patients with severe acne experienced complete clearance, whereas in others the acne remained the same or got worse. It could also mean that in most patients the acne got slightly better. Furthermore, does an individual patient look better when the lesion number has been reduced from 40 to 35? Is there less scarring and fewer complications?

To strengthen clinical trials and help validate their conclusions, investigators should select only a few outcome variables and should choose them before initiation of the study. Measurement of many outcome variables increases the likelihood that spurious, chance differences will be detected. An ineffective treatment may be found efficacious when tested using poorly designed outcome assessment tools. Conversely, an effective therapy may be found ineffective when an insensitive scale is used.

Special precautions are recommended to recognize and remain skeptical of substitute or surrogate endpoints, especially when no differences are detected in clinically important outcomes.[26,55] Examples of such endpoints include CD4/CD8 ratios instead of survival rates in studies of treatments for acquired immunodeficiency syndrome, antinuclear antibody levels or sedimentation rates instead of clinical measures of disease activity in lupus erythematosus, and volume of warts instead of proportion of patients cleared of warts. The use of carefully chosen and validated surrogate endpoints often allows studies to provide answers to questions that would typically require much larger or longer trials if the targeted clinical endpoint were used. For example, a well-designed short clinical trial may be sufficient to demonstrate that a new drug effectively lowers serum cholesterol level or that a given drug is effective in controlling hypertension. In both cases, much longer and larger studies would be required to demonstrate that the cholesterol-lowering drug and the antihypertensive drug reduced morbidity and mortality from atherosclerotic and hypertensive cardiovascular diseases, respectively. However, surrogate endpoints must correlate with clinical outcomes and their validity must have been demonstrated in prior studies.

Once sound, clinically relevant outcome measures are chosen, the magnitude of the difference between the treatment groups in achieving these meaningful outcomes should be determined. The precision of the estimate of the differences among treatments should be assessed. Useful measures of the magnitude of the treatment effect are the difference in response rate and its reciprocal, the NNT.[11,24,41] The NNT represents the number of patients one would need to treat to achieve one additional cure or clinically relevant improvement.

The confidence interval provides a useful measure of the precision of the treatment effect.[11,24,41,56,57] The calculation and interpretation of confidence intervals have been extensively described.[58] In simple terms, the reported result (known as the *point estimate*) provides the best estimate of the treatment effect. Values become less and less likely as they move away from the reported result within the confidence interval.[11,24,41] The confidence interval provides a range of values in which the "population" or true response to treatment is likely to lie.

Examples of the application of the concepts of NNT and confidence interval are given in a paper identified through a search of the Cochrane Library that reported the results of a RCT the use of a placebo, acyclovir, prednisone, and acyclovir plus prednisone in the treatment of herpes zoster.[59] At day 30 of the trial, 48 of 52 patients treated with acyclovir experienced total healing compared with 22 of 52 patients who received a placebo. The response rates for acyclovir and placebo were 0.92 and 0.42, respectively, and the difference in response rates was 0.5. The NNT was 2 (1/0.5). This result means that for every two patients treated with acyclovir instead of placebo, one additional patient would show total healing by day 30. The 95% confidence interval for the difference in response rates is 0.35 to 0.65, and the 95% confidence interval for the NNT is 2 to 3.

What does it actually mean that the confidence interval for the difference in response rates in the foregoing example is 0.35 to 0.65? If the investigators in this study had the opportunity to repeat the study many times using the same design and procedures, sampling variability would prevent obtaining the same results in each study. Repeated trials were simulated using resampling (resampling is a computer-intensive method that uses the reported results of a trial to simulate the results that would be obtained if the trial were repeated a number of times).[41,60] The results when the trial was repeated 10 and 1,000 times are shown in eFigs. 2-0.1A and 2-0.1B in online edition, respectively. A 95% confidence interval of 0.35 to 0.65 means that if the trial is repeated many times and a confidence interval is calculated for each trial, the true result or response to treatment will be included in 95% of the confidence intervals so produced. Alternatively, if the trial were repeated multiple times, the results would lie within that interval (0.35 to 0.65) 95% of the time.

The population or true response to treatment will most likely lie near the middle of the confidence

interval and will rarely be found at or near the ends of the interval. The population or true response to treatment has only a 1 in 20 chance of being outside of the 95% confidence interval. Unless a given patient is very different from the patients included in the study, his or her response will most likely lie near the middle of the confidence interval. If the 95% confidence interval of the difference in response rates excludes zero difference, one can reject the null hypothesis that the two treatments are the same.[24,41,56,57]

Misinterpreting trials that fail to show statistically significant differences among treatments is a common error in dermatologic clinical trials. It is important to remember that "not statistically significant" means that a difference has a reasonably high probability of having been due to chance; it does not mean that there is no difference or that treatment is necessarily ineffective.[35] Significant differences in treatment effects in comparison trials may be missed if the number of subjects tested is small. For example, in a 1978 survey of 71 published trials with negative results, Freiman et al found that a 25% or 50% improvement in outcome might have been missed in 57 (80%) and 34 (48%) of the studies, respectively.[61] A follow-up study conducted by Moher, Dulberg, Wells in 1994 indicated that a 25% or 50% improvement in outcome might have been missed in 84% and 64%, respectively, of 102 studies with negative results.[62] The sample sizes of many dermatologic trials are often inadequate to detect clinically important differences.

The acceptance of a significance level of .05 as the cutoff for rejecting the null hypothesis is a tradition based on quality control standards and is not an absolute truth. At times (e.g., when treatments have substantial side effects) more stringent standards are required, and paradoxically, results that do not meet the $p = 0.05$ standard sometimes may be clinically significant. For example, consider a hypothetical trial of a new chemotherapeutic agent involving 30 patients with metastatic melanoma randomly assigned to treatment groups that produced a 5-year survival rate of 7 of 15 among patients treated with the new agent and 3 of 15 among control patients treated with conventional surgery, chemotherapy, and radiation. Whereas the result does not achieve statistical significance when analyzed by χ^2 testing (Yates corrected $\chi^2 = 1.35$; $p = 0.25$), the result is nonetheless potentially significant. If the therapy is beneficial and the estimated difference in response rates is the true difference in response rates, it may result in the saving of 2,880 lives annually (based on 8,650 deaths from melanoma annually and the improvement in survival in this hypothetical example). Because of the biologic and clinical importance of the results suggested by the trial, the treatment should be investigated in a study that uses a larger patient group and has more power to detect a significant difference if one exists.[35]

The potential benefit of the treatment may be further revealed by the use of confidence intervals. To determine whether a treatment effect may have been missed in a study reporting negative (not statistically significant) results, one should look at the upper boundary of the 95% confidence interval. If this value would be clinically important if it were the true response, then an important treatment effect may have been missed in the study. Consider our hypothetical new treatment for metastatic melanoma. The cure rates for the new treatment and the conventional treatment were 47% and 20%, respectively, and the difference between them was thus 27%. The 95% confidence interval for the difference in cure rates was –10% to 51%. The upper boundary of the difference in cure rates was 51%. This difference would clearly have a significant impact on the treatment of patients with metastatic melanoma (the NNT is 2!), and therefore a significant treatment advance may have been missed in this study. Also note that the 95% confidence interval of the difference in cure rates includes zero difference; therefore, we cannot conclude with a high degree of confidence that the response rates of the two treatments are different. However, when zero is included as one of the values in the confidence interval, the inference that the therapy is not efficacious fails to consider the fact that the best estimate of effect is the point estimate (e.g., the observed difference in cure rates of 27% in our hypothetical example).[63] In other words, the values contained in the confidence interval are not equally likely and become less and less likely as they move away from the point estimate. Thus, in the example, a difference of 25% (close to the observed 27%) is much more likely than a difference of –5% (far from the observed 27%).[35]

APPLYING EVIDENCE TO SPECIFIC PATIENTS

Applying the evidence to treatment of specific patients involves determining whether the evidence from studies is applicable to a given patient. This decision is based on the patient's condition and values. It involves asking a series of questions that are specific to the type of evidence being considered (see eTables 2-1.2–2-1.4 in online edition). When faced with the task of determining whether the results of a particular study are applicable to specific patients, physicians should determine whether there are any compelling reasons that the result should not be applied.[35] Applying evidence to specific patients always involves physician's judgment.

Chapter 3 :: Global Health in Dermatology

:: Roderick J. Hay

The word "global" describing something that is worldwide is not a concept that is difficult to understand, whereas the term "health" is frequently misused on the assumption that it simply means freedom from disease. However, *health* and *disease* are not merely examples of the converse, a point that is captured by the mission statement of the World Health Organization (WHO), whose objective is to promote health. The WHO definition of health, which is widely used as the definitive descriptor of health, says that *health* is a state of complete physical, mental, and social well-being and not merely the absence of *disease* or infirmity. Therefore, global health implies a worldwide mission to promote complete well-being.

HEALTH AND GLOBAL INTERDEPENDENCE

The rational basis for this idea is simple as no nation or region is a complete island in terms of health; what affects one country may well, in time, affect another. The most obvious examples of this concept from past history involve the spread of infections. At present, there is a concerted effort to follow the international spread of HIV or avian influenza. Both present global risks to health, which is the reason why their current distributions are tracked regularly and with accuracy.[1] Spread of these diseases has occurred and will continue to occur through a combination of both social and economic factors and the movement of populations and individuals. Yet historically, infectious diseases that have spread rapidly to cause maximum chaos have often resulted from a relatively minor, and often unrecognized, episode rather than a large movement of individuals. For instance, the impact that a localized outbreak of bubonic plague had on medieval Europe when the besieged Genoese garrison in Caffa, in the Crimea, fled by ship bringing the rat host with them was not foreseen.[2] The subsequent epidemic, caused by *Yersinia pestis*, known as the Black Death, reduced the population of Europe by a third over the following 2 years. In addition to the mortality and distress, it resulted in profound social and economic changes that long outlived the epidemic itself. Predicting and tracking the international course of infections is now a key element of global surveillance.

However, global health problems and disease are not limited to infections, although the propensity to spread is more demonstrable in this group; chronic noninfectious conditions are also global. The relentless increase in the prevalence of diabetes mellitus type 2 in aging populations is such an example. Global health is affected by other factors that include the impact of social, economic, and environmental change on populations. This reflects the fact that human populations are no more isolated socially than they are geographically, but manifest a measure of interdependence where what happens in Kazakhstan may be reflected, in time, in New York City. In the case of diabetes, the causes of changes in health status are different; the international dissemination and adoption of Western dietary behaviors are, at least partly, responsible for this. Health-determining trends such as diet, lifestyles, or global warming are all examples of noninfective risk factors that may affect global health. The international spread of risks to health may follow different routes, often simultaneously.

In many parts of Europe and the United States, the decline of tuberculosis was a marker of economic progress in the twentieth century,[3] the main reduction in disease incidence, and subsequently mortality, preceding by many years the development of new specific treatments such as streptomycin or the introduction of BCG immunization. This health improvement reflected the huge social changes made during this era, such as the provision of sustainable and affordable water supplies and drainage, heating schemes, better housing, and nutrition. While the increasing prosperity and subsequent social reforms that affected the industrialized Western nations in the late nineteenth and early twentieth centuries had a huge impact, mainly for the good, in promoting better health, in international terms the benefits were relatively restricted and not global in their reach; large areas of the world did not benefit from this change. In the recent report by Michael Marmot,[4] the continuing influence of social and economic conditions on both national and global health are

clearly demonstrated and poor social and economic status linked closely to poor health indicators such as high maternal and infant mortality. He cites Sweden as an example of a country that has adopted a policy where the creation of appropriate social conditions would ensure the health of the nation. Much of this health initiative concentrates on social initiatives such as improvement of participation, economic security, and healthy working. This type of policy has been supported in both rich and poor countries. For instance, the Mexican initiative, Programa de Educacion, Salud y Alimentacion (Progresa), which provides financial incentives for families to adopt measures that will ensure social improvements leading to better health, is a good example.[5] While this may seem oversimplistic, poor health is often an indicator of social ills and vice versa; the two are interdependent. Health can make a significant impact on both micro- and macroeconomics; conversely economic performance has a direct impact on health. The WHO report on macroeconomics and health[6] asserted the view that the investment of both time and money on health improvement had multiple benefits through reduction of mortality and increase in the healthy employed, measures that would lead to improvement in both family and national economics. By ensuring good health of their populations nations would improve economic performance and social conditions, which, in turn, would improve health status of their peoples. So good health is an important facet of social and economic development, just as poor health is an indicator of poor performance in both domains. Therefore, global health becomes an important social aspiration in a world where international collaboration and interdependence as well as increasing global industry are slowly replacing, or at any rate adding another dimension to, the nation state.[7]

GLOBAL BURDEN OF DISEASE PROJECT

In order to determine the impact of global health, a consortium of international bodies such as the World Bank in 1990 commissioned a report on the global burden of disease (GBD); a project that has now gone through several iterations involving other organizations, including WHO and an international group of universities.[8] In doing this work, there were two key objectives, namely: (1) to provide up-to-date information on the incidence of disease states in all the regions of the globe and (2) to assess their impact on mortality and disability. In carrying out this work, the interdependence of health and social and economic well-being was clearly recognized. These large surveys of global disease have had to draw on the availability of studies that can provide the necessary information. A subsequent development from GBD, aimed at health in developing countries, was the Disease Control Priorities Project (DCPP), an international report focusing on sustainable measures of disease elimination or control.[9] The latest GBD round of studies is incomplete at the time of writing.[8] However, it differs from other studies in that much of the work of collecting data is the task of specialist groups, including one for dermatology. The target is to provide data covering diseases and risk factors (such as consumption of alcohol or atmospheric pollution) in the WHO designated regions and, where this is missing, to provide robust means of adducing the data using defined mathematical models. The study aims to target disease incidence at two time points—(1) 1990 and (2) 2005. It will also provide measures of mortality as well as disability. The methods used to assess the latter is more refined than previously in that lay panels (i.e., patients) will be asked to assign the weighting that determines the disability that accompanies disease states.

GLOBAL HEALTH AND THE SKIN

Within this international perspective, there is a similar connection between global health, dermatology, and the spread of skin disease. Dermatology is subject to the same factors that regulate the spread of other diseases and determine its control; infection, social, and economic factors are all important in determining the prevalence and impact of skin disease.[10] Skin infections are very common in all societies; tinea pedis (athlete's foot), onychomycosis, scabies and childhood pyoderma, viral warts, and recurrent human herpes virus (HHV1) are all examples of everyday skin infections that affect many people. There are also examples to show that this spread is mediated by human contact and, where there is facility for this to occur, for instance, in a swimming pool in the case of human papilloma virus infections of the feet and tinea pedis, there is a higher incidence of disease.[11] Likewise, movements of numbers of individuals through travel, migration, or war increase the chance of global spread of these infections. For instance, the world diffusion of infection due to *Trichophyton rubrum* is said to have followed the displacements of populations and the movement of soldiers in the 1914–1918 and 1939–1945 wars.[12] More recently, the spread of *Staphylococcus aureus* bearing the *Panton–Valentin leukocidin* (PVL) virulence gene causing furunculosis has been tracked, in some cases, to international travel.[13] Despite this, in some parts of the world there are still unique and geographically localized skin infections, largely because these occur in remote areas. The lower limb infection of children and young adults seen in remote regions of the developing world where there is a high rainfall, tropical ulcer (Fig. 3-1), is an example of a condition that has remained relatively isolated[14]; the fungal infection of the skin, tinea imbricata, is a further example.[15] However, even where there is relative isolation, changes over time such as migration can lead to epidemic spread of previously endemic disease. Tinea capitis has undergone a remarkable transformation in the Western hemisphere in the past 50 years. It has seen the introduction of an effective treatment regimen with griseofulvin initially and subsequent decline in infection rates followed by the relentless spread of one dermatophyte fungus, *Trichophyton tonsurans*, initially from a zone of endemic disease in

Figure 3-1 Tropical ulcer. (From CDC/K. Mae Lennon, Tulane Medical School; Clement Benjamin.)

Mexico, where it still remains as a stable infection of moderate incidence, to reach epidemic proportions in children in inner cities, initially in the United States, but subsequently in Canada, Europe, the West Indies, and Latin America.[16] The spread appears to follow an increased susceptibility to infection of children with African Caribbean hair type; in recent years it has begun to spread in Africa as well.

In a similar way, noninfectious skin disease, as with other illnesses, is also affected by those social and economic changes that are international in dimension. The complex history of the medical reaction to the fashion for sun exposure was formed initially by the recognition of the health promoting, and then health limiting, effects of sun and ultraviolet (UV) light.[17] The current concern over excessive exposure to both natural sun or UV exposure, for instance, in sunbed parlors, or as part of UV therapies, is an important stage in an exercise that started as genuine attempt at health promotion. The ancient Greeks, for instance, promoted sun exposure or heliotherapy as beneficial for a number of medical problems.[3] While largely ignored for the best part of two millennia the revolution in medical ideas in the nineteenth century led to sun exposure being adopted as a health-giving practice with the discovery of Vitamin D and the award of the Nobel Prize to Finsen for light therapy. Health-giving sun exposure was adopted widely and became a fashion that was the rage of the health conscious, delivered in spa environments such as William Kellogg's Battle Creek clinic.[18] However, the habit, perhaps fueled by the recognition that exposure to natural light was in some ways health giving, led inevitably to one of the consequences, the sun tan. It is not certain if the recognition of the suntanned skin as fashionable can all be laid at the door of Coco Chanel, who is said to have been overexposed to the sun during a holiday in Cap Antibes in France. The resulting effect on her skin color was soon to be adopted by the fashionable and white wherever they lived.[19] Soon it became a global trend in fashion. The recognition that sun exposure also led to a rising incidence of skin cancer followed more slowly, but perhaps with greater speed than that concerned with the connection between smoking and lung cancer. Protection against sun exposure has become a major global focus of preventive measures of public health medicine, from public education to the risks involved to early detection of melanoma and nonmelanoma skin cancers. Dermatological organizations have reacted with admirable speed to the recognition of the risk of UV exposure. This has been accomplished through seminars, magazine articles, public health campaigns, and training camps. The introduction of educational programs in schools has been a welcome addition.

The trend to the opposite, skin lightening, in women of color has been an equally global trend where the use of skin bleaching products has been adopted by different cultures throughout the world. The common agents in use include hydroquinone- or steroid-containing creams—with a resulting risk of the development of skin disease such as ochronosis and more general medical problems, including low birth weight infants in pregnant women using topical corticosteroids to achieve lightening.[20] As with infections, there are also examples of skin diseases that are caused by social customs or economic conditions that remain geographically localized. *Erythema ab igne* of the forearms is almost unknown in most parts of the world but is associated with the cooking of tortillas (enfermedad de las tortilleras)—so it is only seen where the tortilla is a staple of diet; oral submucous fibrosis occurs where the Betel nut is chewed is another example. However, some noninfective skin conditions occur in isolated communities for a different reason, genetic susceptibility, such as actinic dermatitis seen in native American communities in North and South America (Fig. 3-2). These are not the only examples of the relation between noninfectious skin disease as an international concern and social and economic factors. One of the earliest public health campaigns that crossed national boundaries stemmed from the recognition that industrial workers exposed to oil during the operation of large-scale spinning were

Figure 3-2 Actinic cheilitis. Mexico, Guerrero State.

susceptible to skin cancer and the ingestion of arsenic at work or as a medication was also potentially harmful through the development of skin cancer.[21] Recently, much international interest has focused on the changing face of atopic dermatitis and although the evidence suggests that this is a condition associated with societies enjoying improved socioeconomic status,[22] the quest for modifiable risks whose resolution may, in turn, provide benefit to children with this condition is now the subject of a global initiative (the ISAAC study).

So skin disease is subject to different, but nonetheless global influences, compared with other illnesses and in the pursuit of skin health there is a great need to promote international cooperation. This objective is identified, not just in order to share learning experiences, but also because the burden of skin disease is spread unequally around the world and many of the poorest nations face the greatest problems.[9] Here, the social and economic factors plus uncontrolled or poorly controlled infection play key roles in determining the pattern of disease.

SKIN DISEASE IN RESOURCE POOR ENVIRONMENTS

In the poorest countries skin disease usually ranks as one of the first three common disorders encountered in frontline medical facilities, i.e., the first point of call for a patient seeking treatment. Whereas in the developed countries many of the problems facing dermatologists and primary care practitioners are noninfectious skin diseases, the opposite is true in developing countries where infections dominate the pattern of presentation.[23] Where infections occur in the industrialized countries, the general public have widespread access to treatment through pharmacies or primary care doctors as well as specialists. Access to treatment is limited by a number of factors that range from poor training of health care workers to the need to journey considerable distances in order to obtain help.[24] Likewise in the poorest communities ready access to cash is more limited, with a large part of household economics depending on self-sufficiency in growing food or creating housing from local materials. Cash is necessary for some things such as clothing and for additional food. Treatment of even the simplest of conditions such as scabies or pyoderma presents a competing call on the available household cash income (Fig. 3-3); poor or ineffective treatment is a drain on resources that would otherwise be spent on food. The exact sums are small but their impact is large.[25]

The burden of skin disease is often unrecognized at national or international level as it is perceived to come low in the global league table of illnesses and, compared with diseases that carry a significant mortality such as HIV, community acquired pneumonias and tuberculosis, skin disease-related mortality is low. However, as skin problems are generally found to be amongst the most common presentations of diseases seen in a primary care setting in tropical[9] and nontropical[10] areas, in some regions, where transmissible diseases such as tinea imbricata or onchocerciasis are endemic, they are the commonest reason for an individual to present themselves for treatment. The GBD estimates for 2001 indicated that skin disease was associated with mortality rates of 20,000 in Sub-Saharan Africa.[8] This was comparable to mortality rates attributed to meningitis and hepatitis B, obstructed labor, and rheumatic heart disease in the same region. The disability rate calculated as disability adjusted life years (DALYs) in the same report showed an estimated total of 896,000 DALYs recorded for the region in the same year; this was comparable to that attributed to gout, endocrine disease, panic disorders, and war-related injury. While, as described before, these figures are currently being reassessed, it suggests that the burden of disease due to skin-related illness is high. Many of the international studies that have focused on the impact of illness on individuals utilize disability scores. Those interested in skin disease frequently use patient-focused measures Quality of Life (QOL) scales.[26] While these may be less objective they do, by concentrating on the impact of disease on personal values and performances, provide, according to many interested in the impact of disease, a more realistic measure of how patients are likely to use health services. Assessing the impact of skin

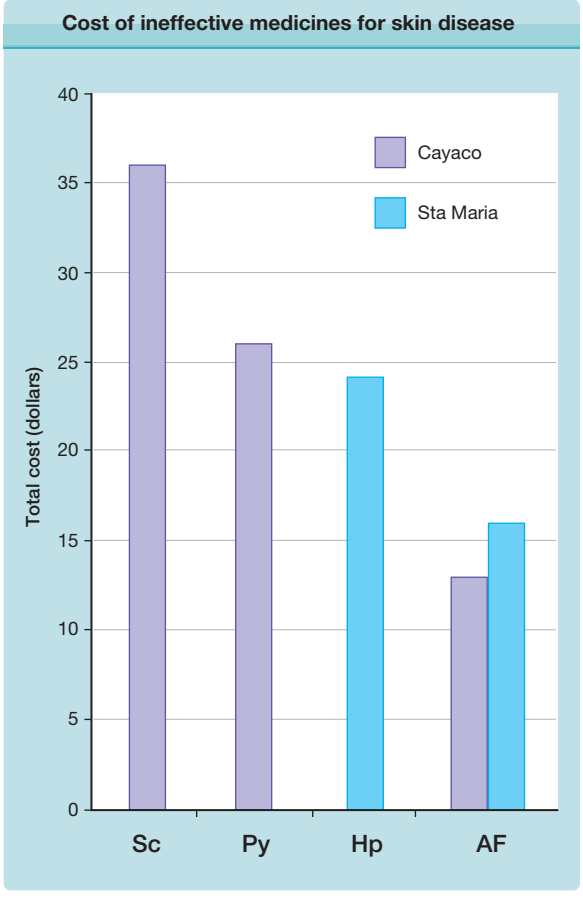

Figure 3-3 Cost of ineffective medicines for skin disease in two rural communities, Mexico. Sc = scabies; Py = pyoderma; Hp = hypopigmentation; AF = expected cost of additional food during the same period.

disease on quality of life in comparison with other chronic nondermatological diseases is difficult. However, the decline in QOL for patients with the common skin disease, acne, is similar to that experienced by patients with chronic disorders such as asthma, diabetes, and arthritis; all showed comparable deficits in objective measurements of life quality.[26] Skin disease related to HIV, which constitutes an important skin disease burden, particularly in Sub-Saharan Africa, leads to a similar diminution of QOL compared with non-HIV related skin problems, although the use of antiretroviral therapy produces a significant improvement.[27]

PRACTICAL PROBLEMS IN SKIN CARE

Despite the unequal comparison of mortality rates with other diseases, there are a number of important and relevant reasons why the needs of the populace for effective remedies or control policies for skin conditions should be in place. Firstly, the diseases are very common and patients present in very large numbers in primary care settings. In some cases more than 60% of the population has at least one skin disease.[23] Even though significant numbers never seek treatment for a variety of reasons, including lack of awareness that treatments are available, the workload generated by patients presenting with skin problems at primary care level can be huge. This is a problem in all countries but particularly in those with the lowest gross domestic product.[28] Children and the elderly, in particular, are affected, adding to the burden of disease in already vulnerable groups. Secondly, the morbidity can cause significant disability through disfigurement or restriction of movement. For instance, the effects of elephantiasis secondary to lymphatic filariasis last for years after the elimination of the filarial parasites. As stated previously, the relative economic cost of treating even trivial skin complaints in families in poor regions reduces the capacity of families to contribute to their local economies as their disposable cash is exchanged for poor medicine rather than other goods.[25] The skin is often the site where changes of a number of other neglected tropical diseases are present. Leprosy, onchocerciasis, guinea worm, HIV/AIDS, tuberculosis, yaws, and Buruli ulcer are all examples.[29] A shortage of elementary skills in the recognition and management of disease that present with skin abnormalities reduces the capacity for surveillance of these important diseases. In truth, skin disease in the tropics is a neglected problem that should be added to the list of neglected tropical diseases.

Globally, one of the current problems highlighted in a number of studies has been the management of skin disease in primary care settings. In the developing world high treatment failure rates of over 70% are common in frontline health posts.[30] The same may be true in settings in industrialized nations where lack of recognition of some skin problems at primary care level is a factor limiting effective treatment. This situation is compounded by changes to the undergraduate medical curriculum where, in many countries, the factual and academic content, such as knowledge of skin or eye disease, has been reduced to allow students to assimilate greater patient-oriented skills such as communication; the gap in learning for those not intending to follow a career in subjects, such as dermatology, yet who have some responsibility for managing skin problems, has not yet been plugged satisfactorily. One way forward in streamlining the capacity to cope with common diseases, such as skin disease, has been to prioritize treatment options. For instance, in the developing world a small number of common skin diseases, mainly infections, account for the vast majority of the disease burden. Therefore, implementation of effective treatment targeted on these conditions confers significant gains to both personal and public health. Two prime examples are scabies[31,32] and pyoderma.[33] In the industrialized nations concerted efforts to prevent or diagnose skin cancer at an early stage have formed key elements of public health strategy.[34]

IDENTIFYING RISK

In Western societies there have been few studies aimed at estimating disease prevalence or risk, a necessary prelude to health intervention. However, a study in Lambeth, South London in 1976 using a questionnaire-based population-centered approach, backed by random examination, revealed an overall 52% prevalence of skin disease of which just over half the cases were judged by the investigators to require treatment.[35] The NHANES study in the United States[36] produced very similar figures. More recent studies of skin disease burden in the United States and the United Kingdom confirm these earlier investigations. Studies from developing countries have generally been conducted through systematic community-based surveys backed by clinical examination. Published figures for skin disease prevalence in developing countries range from 20% to 80%.[9] From these studies it became clear that different populations have different levels of awareness of illness. For instance, in a study in Ethiopia between 47% and 53% of members of two rural communities claimed to have skin disease.[30] However, when they were examined 67% of those who denied having a skin problem were found to have a treatable skin condition; the majority of these were infections. Tinea capitis, which is equally common in the same population may be ignored because it is common knowledge that this follows a benign and asymptomatic course in many patients, although in those communities where the clinical form of tinea capitis, favus, occurs, the local populations recognize that this type of infection is associated with permanent scalp scarring and so present for treatment.

The main risk factors associated with skin disease in developing countries are largely socioeconomic; the most important of these appears to be household overcrowding estimated by person per room in living accommodation. For instance, in Tanzania, Gibbs found that 27% of patients had treatable skin disease in surveying two village communities; once again infections were the most common diseases found.[37] Overcrowding was a major risk factor in this latter survey. What also

seems to influence the overall prevalence and pattern of skin conditions is the existence of a number of common contagious diseases, notably scabies and pyoderma, in certain areas. Hot and humid climatic conditions may also predispose to certain skin infections such as pyoderma, thereby affecting the distribution of disease.

SKIN DISEASE—THE PATTERN AT COMMUNITY LEVEL AND INTERNATIONAL INITIATIVES

Using the World Bank figures (World Development Indicators 2002) for low-income populations in 2000, the estimated numbers of individuals infected with pyoderma and scabies based on the highest prevalence figures from community surveys in the developing world are 400 and 600 million, those based on the lowest prevalence figures are 40 and 50 million. For tinea capitis the estimated number of cases based on the highest estimates of prevalence for Sub-Saharan Africa alone is 78 million.[9]

Overall these data suggest that significant improvements could be made in reducing the burden of skin disease by focusing on the small group of conditions, particularly infections, which comprise the majority of the community caseload. This may be accomplished by community control programs (see Chapter 4). The examples of scabies and skin cancer have already been cited. There are now a number of different bodies that understand the need to prioritize and have started, at first individually but increasingly in collaboration, to try to improve this situation.

The main focus of these efforts has been the identification of the health needs for skin disease in poor countries, the simplest methods of dealing with the majority and the development of programs to cope with these. In most cases, the key elements necessary to deliver an effective program are as follows:

a. Data on skin disease and current resources that could be mobilized to deal with the problem.
b. Education of those charged with improving skin health.
c. Evidence of the efficacy of each project.

DATA ON SKIN DISEASE

Data on the global epidemiology of skin disease are inadequate, not just because current estimates of global health are subject to enormous variations. In skin disease a major and recurrent problem has been the very small number of studies that document the prevalence or incidence of disease at population level. The reasons are not difficult to identify. Firstly, because skin disease is not associated with significant mortality, the first international indicators of disease activity, death rates, have not triggered a demand at governmental or even regional levels for comprehensive epidemiological surveys. Secondly, and allied to the first point, the disability associated with skin disease is often thought to be minor—another reason why there has been few central calls for further investigation. There are also practical reasons why studies of this nature have been few until recently. Because the diagnosis of changes in the skin depends on a visual assessment, whose accuracy is largely based on experience, it becomes very difficult to teach those without the relevant experience to assign diagnostic labels. It is only comparatively recently that attempts have been made to simplify and validate diagnostic criteria for use in large population studies and those originating from the international studies of allergy now provide a global picture of the prevalence of atopic dermatitis.[38] However, this is but one example and there have been a few similar initiatives in other areas of dermatology, for example, classification of skin changes in lymphatic filariasis.[39] The upshot has been that skin disease has remained a subject where epidemiological studies have relied on the diagnosis of a trained observer, usually a dermatologist. The large studies of global disease have had to draw on the availability of a few surveys that can provide the necessary information. Most of these are the fruits of a comparatively small number of dermatologists who have taken on the task of investigating the impact of skin disease and developing measures for assessing disease prevalence and quality of life. Yet there are examples where disease presenting in the skin has attracted more global attention. Yaws, for instance, was one of the first examples of an infectious disease that was targeted by WHO for elimination through mass penicillin therapy.[40] In the first few years, the campaign made extraordinary advances with massive reductions in the numbers of new cases. As with other diseases lack of resources and major disruption, such as human conflict, have ensured that there are still pockets of yaws that have yet to be brought under control. The recognition of the risk of skin cancer has stimulated regional and national initiates in areas such as Australia[34]; but there are still few cancer registries that collect data on nonmelanoma skin cancer.

EDUCATION AND TRAINING

More effort has gone into education to improve knowledge of skin disease and its management and the examples of initiatives established by departments and national and international dermatology societies are important to recognize. These range from the national programs of skin cancer prevention to Web sites that promote public awareness. These often also include training for other health professionals, such as pharmacists, who may encounter skin disease. In the developing world the International Foundation for Dermatology has established a number of such programs.[41,42] The first of these, the Regional Dermatology Training Centre (RDTC) in Moshi, Tanzania was set up as collaboration between the International Foundation for Dermatology; The Ministry of Health and the Good Samaritan Foundation is an example of a training initiative that affects many countries. The Centre trains clinical officers with regional responsibility for skin disease, sexually transmitted infection, and leprosy, and more recently it has established an international dermatology residency-

training program for Sub-Saharan Africa. Other programs of training or assistance established in Mexico,[43] Mali,[44] Ethiopia,[45] Haiti,[46] Fiji,[47] and Cambodia amongst others are all examples of international collaboration to improve skin health in poorer countries.

HOW EFFECTIVE ARE THESE INITIATIVES?

These initiatives have been less successful in the provision of evidence that the campaigns have worked. There are some data from the sun protection programs that the incidence of advanced melanoma is improved by early screening measures.[48] However, measuring the impact of education on disease incidence is difficult, but it is clearly needed in order to justify the outlay of time and expense.

SUMMARY

In summary, the global incidence of disease affecting the skin is very large; the disability related to it is less, but is nonetheless significant. Managing this burden remains the responsibility of those specially trained in the field. Increasingly, dermatologists and dermatological nurses have turned their attention to adopting measures that benefit a wider group of individuals than the patient sitting on the other side of the consulting desk. To do so means setting up partnerships and alliances both nationally and internationally. Whether developing or assisting local or global public health schemes to control, eliminate, or improve skin problems through education or community initiatives is realistic is a matter for debate. What is certain, though, is that intervention to improve the health of those with skin problems within communities improves both the health of the people as well as the image of the profession.

Chapter 4 :: Public Health in Dermatology

:: Hywel C. Williams, Sinéad M. Langan, & Carsten Flohr

PUBLIC HEALTH IN DERMATOLOGY AT A GLANCE

- Public health dermatology promotes skin health.
- Modern public health dermatology is still relatively underdeveloped.
- Doctors help individual patients but have little influence on the health of entire populations.
- Conversely, the impact of large population interventions is rarely appreciated by individuals.
- Prevention is often more logical than only treating sick individuals.
- A "low-risk" approach of reducing risk in the whole population for diseases such as melanoma may achieve more than a "high-risk" approach of targeting just those who have skin cancer or who are at higher risk of developing skin cancer.
- When entire populations are considered, a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people.
- Modern public health dermatology has had some success in the reduction of skin cancer incidence and control of infectious diseases.
- Low-technology educational interventions directed at entire communities can result in more benefit than high-technology drugs targeted at a few ill individuals.

WHAT IS PUBLIC HEALTH MEDICINE ALL ABOUT?

DEFINITION

The World Health Organization defines health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity."[1] The key message of this definition is that health is a holistic measure that is influenced by socioeconomic factors and inequality. Public health is a discipline in which the level of focus is on the health of *populations* as opposed to that of *individuals*, as is the case in clinical medicine. A useful definition of public health is as follows:

> *Public health is the science and the art of preventing disease, prolonging life, and promoting physical health and mental health and efficiency through organized community efforts toward a sanitary environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing service for the early diagnosis and treatment of disease and the development of the social machinery to ensure to every individual in the community a standard of living adequate for the maintenance of health.*[2]

This definition articulates some of the roles of public health practitioners in relation to society and health. It also highlights the four key areas of public health action: (1) preventing disease and promoting health, (2) improving medical care, (3) promoting health-enhancing behavior, and (4) modifying the environment.[3]

HISTORICAL PERSPECTIVES

As early as in the fifth century BC, Hippocrates suggested a clear link between environmental factors and disease states. In more recent centuries, the physician John Snow helped to establish the field of public health during the 1854 London cholera epidemic.[4] By carefully counting the number of deaths from cholera according to population denominators in specific London districts, he was able to establish that household water supply might be the key common factor leading to cholera deaths. Snow hypothesized that cholera was a water-borne disease, and he was able to trace the origin of the epidemic to a contaminated water pump in Broad Street, Soho. Consequently, he ordered removal of the pump handle, which was followed by a dramatic reduction in cholera deaths. Thus, Snow first made detailed planned observations, then analyzed the data, formulated a hypothesis, tested this hypothesis through experiment, and finally mounted a campaign to prevent further disease. This led to a widespread political campaigning for clean water from which millions have benefited worldwide ever since. What is intriguing about Snow's work on the causal relationship between water and cholera is that it preceded the discovery of the *Vibrio cholerae* organism by Koch a third of a century later.

Public health has played a key role in the prevention and treatment of dermatologic diseases. One of the first historical examples is scurvy. In 1746, James Lind discovered through observation, analysis, and performance of a controlled trial that scurvy in sailors was a dietary disease that could be cured by administration of oranges and lemons[5] (see eFigs. 4-0.1 and 4-0.2 in online edition). Lind's treatise preceded the discovery of vitamin C by more than a century. In 1775, Percivall Pott was the first to describe an occupationally induced cancer by noting that the mortality from scrotal cancer was 200 times higher in chimney sweeps than in other workers.[6] He attributed the excess mortality to tar and soot exposure in combination with poor personal hygiene. The first carcinogenic polycyclic aromatic hydrocarbon was not discovered until 1933. In the early twentieth century, pellagra was a major public health problem (see eFig. 4-0.3 in online edition). There were 100,000 deaths from the disease in a 40-year period and over 3 million sufferers in the United States at that time. In 1914, Dr. Joseph Goldberger noticed that inmates at the Georgia State Sanatorium developed high rates of pellagra whereas the nurses and attendants did not, and concluded that the origin of pellagra was probably a disease caused by a dietary deficiency. He confirmed his hypothesis with controlled clinical trials.[7] The deficient dietary factor, niacin, was discovered in 1937.

Collectively, these examples illustrate the importance and potential power of public health in the prevention of disease. These examples also highlight the fact that knowledge of disease pathophysiology (i.e., mechanisms) is not always a prerequisite to determining the cause or risk factors for a disease and the potential for effective public health interventions.

HIGH-RISK AND LOW-RISK APPROACHES TO PUBLIC HEALTH

Traditionally, dermatology, like other branches of specialist medicine, has concentrated on the treatment of those who have fallen ill, those who believe they are ill, or people at high risk of developing disease. For instance, we prescribe topical corticosteroids for those with atopic dermatitis, and we may give advice on sun protection to patients who previously had a malignant melanoma. We may see such melanoma patients on a regular basis in skin cancer follow-up clinics to monitor treatment success and to be able to detect recurrences or new early second melanomas. Doctors and patients alike tend to be highly motivated when such an approach is used. The potential benefits seem obvious, and although there may be adverse effects associated with the prescribed treatment, such as skin thinning with prolonged use of topical corticosteroids, or a scar from excision of a melanoma, many patients will accept such risks, because appropriate treatment leads to a tangible and significant improvement of symptoms and improved quality of life or survival. Such an

approach to tackling disease has often been referred to in the literature as the *high-risk* approach, because it focuses on the treatment and detection of those at high risk of developing disease and those who have already fallen ill.[8]

In contrast to the high-risk approach, the ultimate aim of public health medicine and public health dermatology is to prevent the development of disease in the first place whenever possible, not only by forestalling it in those identified as being at high risk (e.g., because of a strong family history), but by shifting the entire distribution of a certain exposure in a healthier direction for the whole population (population strategy). Such a low-risk approach can be implemented through large-scale public health education campaigns aimed at fundamentally changing the entire population's behavior and lifestyle. For example, based on the data of the Framingham study one can extrapolate that a reduction of everybody's blood pressure by 10 mm Hg would result in an overall reduction in mortality from heart disease of around 30%.[8] In dermatology, a good example of a such a population strategy is attempts to change the general population's sun exposure behavior to reduce exposure to ultraviolet light and ultimately skin cancer incidence and mortality through public health education campaigns that are national (e.g., Australia) or international (e.g., the World Health Organization's INTERSUN program, http://www.who.int/uv/intersunprogramme/en/) in scope (Fig. 4-1). This makes sense particularly in a country like Australia, because a strong association between ultraviolet radiation and melanocytic and nonmelanocytic skin cancer is well established, and such risk is distributed widely through the predominantly fair-skinned population. Skin cancer is an important cause of death in economically active younger people, and treatments for all forms of skin cancer pose an important burden on many countries' health care resources. Simple measures, such as avoiding sun exposure during peak hours of radiation and wearing suitable clothing, can provide adequate protection. The state of Victoria, Australia, has the most comprehensive population-based primary prevention campaign against skin cancer in the world (SunSmart campaign, http://www.sunsmart.com.au/), and it has been reported that this program's public investment was worthwhile. Not only has it resulted in a significant reduction in skin cancer incidence and mortality, but the returns from savings on skin cancer treatments have also exceeded the overall costs of the SunSmart campaign.[9]

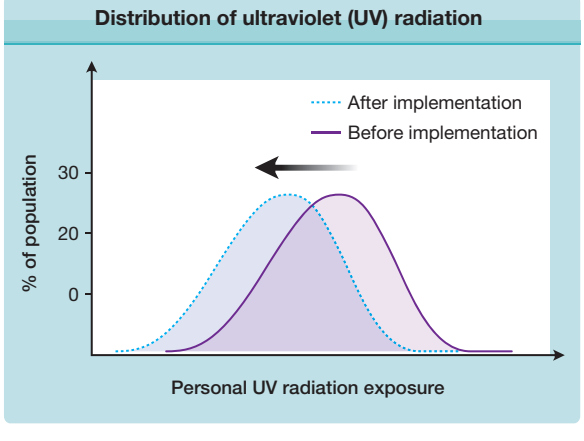

Figure 4-1 Distribution of ultraviolet (UV) radiation exposure before (*solid line*) and after (*dashed line*) implementation of a population strategy to reduce personal UV radiation exposure.

In view of the above, it seems obvious that upstream prevention is more desirable than treating sick individuals who come for treatment downstream after a long chain of pathologic events, some of which may be irreversible. However, it is generally more difficult to persuade healthy individuals to protect themselves against prolonged sun exposure than to persuade those who have already had a malignant melanoma excised. Partly because of this, funding for population prevention strategies is often difficult to obtain, yet the whole population will potentially benefit, as long as such interventions are evidence based and sustainable. It is also worth pointing out that although a public health intervention such as vaccination against measles has dramatically reduced the incidence of disease at a population level, it is impossible to say which individuals have been helped by such a population intervention—a phenomenon known as the *prevention paradox*.

A population strategy is not suitable for trying to control all skin diseases at present, because such a strategy depends on the knowledge of modifiable risk factors. In the many cases for which exposures that predispose to a particular skin condition are unknown, prevention through avoidance is not possible, and the only option available is treatment of disease rather than primary disease prevention.

BALANCING BENEFIT AND HARM

Making the conceptual jump from thinking about individual patients to thinking about entire populations can be challenging for practicing dermatologists, especially because such jumps can come up with some surprising results. For example, a dermatologist with an interest in contact dermatitis might see a case of severe hand dermatitis in a printer caused by allergic contact dermatitis from a chemical and then publicize such a case in a respected journal.[10] Another dermatologist reading such a case report might come to the conclusion that allergic contact dermatitis is an important cause of hand dermatitis in printers. Yet when this dermatologist visits the workplace to conduct a survey of all cases of hand eczema in printers, it becomes apparent that true allergic contact dermatitis is probably quite rare, and by far the most common cause of hand eczema is constant low-grade exposure to soap and water from repeated washing and friction from paper and dirt.[11] Thus, it is possible that a little bit of harm affecting a lot of individuals can add up to much more in absolute terms (the realm of the public health/occupational health physician) than a lot of harm affecting one or two workers (the realm of the dermatologist).

Another well-known example of such a phenomenon is the effects of smoking on reduction in cardiovascular disease. Even though the association between tobacco smoking and lung cancer (relative risk of 14.0) is much stronger than that between smoking and cardiovascular disease (relative risk of 1.6), strategies for smoking cessation save around twice as many lives from cardiovascular disease than from lung cancer simply because heart disease is much more common than lung cancer.[12] Therefore, from a public health perspective the population-attributable risk (the proportion of the disease that may be attributable to a particular risk factor) is more important than other traditional measures of risk, such as the relative risk (whose magnitude may tell us something about the strength of a particular association). In a study of risk factors for psoriasis in Italy, Naldi et al found that smoking accounted for up to 26% of all cases.[13] In individuals with psoriasis who smoked and who also had a family history of psoriasis, an increased body mass index might accounted for up to 48% of disease.[13] The fact that smoking and obesity are modifiable risk factors suggests that psoriasis is preventable, at least to some degree, in this population.

PUBLIC HEALTH APPROACHES IN DERMATOLOGY

So far, we have illustrated the public health approach in dermatology using mainly historical examples. Yet although current dermatologic research is still relatively dominated by the pursuit of studies in which the unit of analysis is at a cellular or subcellular level, there are some good examples of public health dermatology "in action."

One of the classic studies illustrating the public health approach "in action" for infectious skin disease was that conducted by Taplin and colleagues concerning scabies among Kuna Indians on the San Blas Archipelago.[14] These islands off the coast of Panama were plagued by very high rates of scabies in children in the 1980s, which led to misery and secondary bacterial infections. Despite the use of the best treatments available to combat the problem, the population burden of scabies remained largely unchanged. Only after the adoption of a public health approach in which everyone in defined areas was treated did the prevalence of scabies fall dramatically from approximately 33% to approximately 1%. Similar dramatic decreases in scabies prevalence (from 25% to 1%) and in associated pyoderma and possibly poststreptococcal nephritis have been observed through the use of population-based treatment with ivermectin in the Solomon Islands.[15] Another example is the Global Alliance to Eliminate Lymphatic Filariasis (GAELF; http://www.filariasis.org/), an alliance between the World Health Organization, ministries of health, and the private sector aimed at the worldwide eradication of this devastating disease by 2020. GAELF is probably the biggest public health program ever and involves mass treatment of around 750 million people in 48 countries with antifilarial drugs and also includes public health education and advice on skin care of lymphedematous legs to prevent further morbidity. Public health interventions are not restricted to administration of pharmaceutical drugs but can also include educational interventions such as the public education campaigns for reducing skin cancer through reduction in ultraviolet light exposure. One such successful program has been the introduction of basic dermatologic care in Mali through the development of a training program for general health care workers on the management of common skin diseases.[16] The proportion of patients with skin disease with a clear diagnosis increased from 42% before the training to 81% after it. Although such dramatic effects might be overestimated in a simple before-and-after study, the effects were sustained for up to 18 months after training. Paradoxically, these improvements in care were associated with a 25% reduction in prescription costs, which suggests that inappropriate empirical prescribing was a source of unnecessary expenditure before the training. Other researchers have also documented how scarce family income can be wasted on inappropriate treatment for skin diseases such as pyoderma and scabies in Mexico.[17] Ryan has described the role of educational clinics in the prevention of skin cancers as well as the management of early lesions in the albino population of 170,000 in Tanzania.[18] The principles of community dermatology in the face of mobile populations are also discussed elsewhere.[19]

Three further points in relation to public health dermatology are worth noting. The first is that although dermatologists are best placed to provide an accurate diagnosis of skin diseases, such provision may not be realistic for interventions on a public health scale in poorer countries, where there is a strong argument for embedding dermatological skills into primary health care services as has been done successfully in training health care workers in the diagnosis of leprosy in Mali.[20] The second is that public health interventions, like drug treatments, are not without their potential drawbacks. For example, limiting sun exposure in order to reduce the incidence of skin cancer may be associated with drawbacks including depression and less skin synthesis of vitamin D, deficiency of which may be associated with a range of diseases such as cancer, bone disease, and heart disease.[21] Yet recent studies of seasonal variations in vitamin D levels suggest that the commonly held view that 10 to 20 minutes sun exposure during the summer is enough to boost overall 25 hydroxy Vitamin D levels is wrong, and that sufficient sun exposure for a worthwhile benefit would be countered by an unacceptable burden of skin cancer.[22] Therefore, fortifying foods with Vitamin D seems a safer public health option than increasing sun exposure for maintaining adequate vitamin D levels.[23] Balancing benefits and harms requires special consideration in public health simply because they affect so many people. Whilst some public health interventions, such as immunization or advice on reduction of sun exposure, allow some degree of choice for individuals to heed or ignore as they choose, others, such as fluoridation of water or addition of iodine to salt, are less amenable to personal modification. Third is that although many public health interventions may not sound as "high

tech" as drugs targeted at specific biologic receptors, they may be more effective and appropriate for sick populations. The concept that a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people was developed earlier, but a similar maxim also holds true: sometimes a low-technology beneficial intervention that can be applied to a large population can add up to far greater benefit in population terms than a high-technology solution that will benefit only a few.

FUTURE OF PUBLIC HEALTH IN DERMATOLOGY

Some dermatologists, rather than just viewing the world of skin disease from within the narrow confines of a private practice or hospital-based practice, have already conducted population-based needs assessments for dermatologic care, followed by organization of the appropriate services at a population level. A health care needs assessment conducted in the United Kingdom found that skin diseases are one of the commonest reasons why people consult their family doctor where training was paradoxically the least.[24] New data from the World Health Organization project on the Global Burden of Diseases will include important information on the comparative burden of skin diseases compared with other skin diseases (http://www.who.int/healthinfo/global_burden_disease/en/). New methods of communication such as social networking Internet sites have become an increasingly important source of public health information.[25]

There are increasing international collaborations to try to prevent and reduce the burden of skin diseases at a global level through health care planning and focused interventions. These are carried out through organizations such as the International Foundation for Dermatology (http://www.ifd.org/) in conjunction with the International League of Dermatological Societies (http://web.ilds.org/). The International League of Dermatological Societies is working to improve community dermatologic programs in developing countries, focusing on better diagnosis and clear evidence-based guidance for the management of common dermatoses. Training courses have been established, such as those at the Regional Dermatology Training Centre in Moshi, Tanzania (http://www.global-campus.org/rdtc) and short courses in Guerrero, Mexico, and Mali. One of the key aims of these programs is to educate at the primary care level, with the idea that the trainees will then multiply such knowledge by training others in their own countries. As Weinstock points out in Chapter 1, the burden of skin diseases is high. Many skin diseases such as infections, cancer, and atopic eczema can already benefit from a public health approach. What is needed to redress the relative paucity of public health dermatology is to understand the concept that populations are as important as individuals and to build on the sort of collaboration championed by the International Foundation for Dermatology.

SECTION 2

Approach to Dermatologic Diagnosis

Chapter 5 :: Structure of Skin Lesions and Fundamentals of Clinical Diagnosis

:: Amit Garg, Nikki A. Levin, & Jeffrey D. Bernhard

"You see, but you do not observe"

—Holmes to Watson in "*Scandal in Bohemia*," by Arthur Conan Doyle, 1892

SKIN LESIONS AND DIAGNOSIS AT A GLANCE

- A patient and thorough approach to the evaluation decreases the risk of making an incorrect diagnosis or overlooking another diagnosis.
- Knowledge and appropriate use of dermatological terminology are fundamental.
- Recognition of disease patterns requires repeated patient encounters.
- The history is indispensable in elucidating complex diagnoses.
- The entire mucocutaneous surface, as well as the hair and nails, should be examined whenever reasonable.
- Morphologic characteristics derived from cell type in skin must be carefully scrutinized.
- Diseases have characteristic morphology and distribution.
- Common pitfalls in dermatologic diagnosis exist and can be avoided.

THE ART AND SCIENCE OF DERMATOLOGIC DIAGNOSIS

The diagnosis and treatment of diseases that affect the skin rest on the physician's ability to use the language of dermatology, to recognize the primary and sequential lesions of the skin, and to recognize the various patterns in which they occur. In this chapter, we discuss a fundamental approach to the patient presenting with a skin problem. We introduce the technical vocabulary of dermatologic description, the "dermatology lexicon." It is important to know and use this standard terminology, as it is the first step in generating a differential diagnosis. Once a lesion has been described as a pearly, flesh-colored, telangiectatic, ulcerated nodule, the experienced physician puts basal cell carcinoma at the top of the differential diagnosis. It is also important to use standard dermatologic terminology for consistency in clinical documentation, in research, and in communication with other physicians.

The process of examining and describing skin lesions may be likened to that of viewing a painting. First, one stands back and takes in the whole "canvas," viewing the patient from a few feet away, at which distance an overall assessment of the patient's general and cutaneous health may be made. One may note such findings as skin color and turgor, presence of pallor or jaundice, degree of sun damage, and the overall number and location of lesions. Next, one looks more closely at the "trees" or "mountains" that make up the landscape, describing and categorizing the specific lesions on the patient. Finally, one may closely examine the details of the canvas, taking in the texture and brush-strokes, using magnification to see the borders of a nevus or compressing a lesion to see if it blanches. Just as a knowledgeable viewer of art may recognize a work of Georges Seurat by its tiny, dot-like brush strokes, an experienced observer of the skin can recognize a melanoma by its asymmetry, irregular borders, and multiple colors.

APPROACH TO THE PATIENT

HISTORY

Dermatology is a visual specialty and some skin lesions may be diagnosed at a glance. Nonetheless, the history is important and in complex cases, such as the

patient with rash and fever or the patient with generalized pruritus, history may be crucial. Dermatologists vary in whether they prefer to take a history prior to, during, or after performing a physical examination. In practice, many take a brief history, perform a physical examination, then undertake more detailed questioning based on the differential diagnosis that the examination suggests.

For the following reasons, it is often useful to at least briefly examine the patient before taking a lengthy history:

- Certain skin conditions, such as classic plaque-type psoriasis or molluscum contagiosum, for example, present with such distinctive morphologies that the diagnosis may be immediately obvious, rendering extensive history taking unnecessary.
- A patient's history may contain "red herrings," which lead the physician away from, rather than toward, the correct diagnosis. Examination of the patient before taking a history may yield a more complete and unbiased differential diagnosis.
- In certain situations, such as the evaluation of alopecia, initial examination of the patient to determine what type of hair loss is present allows the physician to pursue a line of questions pertinent to that type of alopecia.

In taking a history from a patient presenting with a new skin complaint, the physician's primary goal is to establish a diagnosis, with a secondary goal of evaluating the patient as a candidate for therapy. In patients whose diagnosis is already established, the physician's goals are to reevaluate the original diagnosis, monitor disease progress and complications, and modify treatment accordingly.

Box 5-1 presents a suggested approach to obtaining the history in a patient presenting with a skin problem. Clearly, not all of the questions are necessary for every patient. The physician will need to tailor the history depending on whether the chief complaint is a growth or an eruption, a nail or hair disorder, or another condition, and whether it is a new problem or a follow-up visit for an ongoing condition.

EXAMINATION OF THE DERMATOLOGIC PATIENT

SCOPE OF THE COMPLETE CUTANEOUS EXAMINATION.

The complete cutaneous examination includes inspection of the entire skin surface, including often-overlooked areas such as the scalp, eyelids, ears, genitals, buttocks, perineal area, and interdigital spaces; the hair; the nails; and the mucus membranes of the mouth, eyes, anus, and genitals. In routine clinical practice, not all of these areas are examined unless there is a specific reason to do so, such as a history of melanoma or a particular localizing complaint. A guide to performing the physical examination of the patient presenting with a skin problem is presented in Box 5-2.

ADVANTAGES TO PERFORMING A COMPLETE CUTANEOUS EXAMINATION.

Although it is not always essential or practical to perform a complete skin examination, there are many advantages to doing so, especially for new patients and challenging cases:

- Identification of potentially harmful lesions (e.g., skin cancers) of which the patient is unaware; any patient with a history of skin cancer or a chief complaint of a "new growth" deserves a full skin examination.
- Identification of benign lesions (e.g., seborrheic keratoses, angiokeratomas) that the patient was concerned about but reluctant to mention, thereby enabling the physician to provide reassurance.
- Finding hidden clues to diagnosis (e.g., scabies lesions on the penis, psoriatic plaques on the buttocks, Wickham striae of lichen planus on the buccal mucosa, nail pitting in alopecia areata).
- Opportunity for patient education (e.g., lentigines are a sign of sun damage and suggest the need for improved sun protection).
- Opportunity to convey the physician's concern about the patient's skin health as a whole. Patients appreciate this and also regard the physician as thorough.

BARRIERS TO PERFORMING A COMPLETE SKIN EXAMINATION.

Despite the advantages of performing a full cutaneous examination, numerous barriers exist that may prevent the dermatologist from performing such an evaluation for every patient. Understandably, patients may decline a full examination when their chief complaint is relatively minor or localized, such as a wart or acne. In other cases, patients may express resistance to disrobing for a full examination due to embarrassment, especially when the physician is of the opposite gender. Sometimes the physician is uncomfortable performing a complete skin examination with the concern that a patient may misinterpret the examination as improper. In many instances, time constraints and lack of personnel to serve as chaperones limit the ability to perform full skin examination.

IDEAL CONDITIONS FOR THE COMPLETE SKIN EXAMINATION.

A complete skin examination is most effective when performed under ideal conditions. It is most important to have excellent lighting, preferably bright, even light that simulates the solar spectrum. Without good lighting, subtle but important details may be missed. The patient should be fully undressed, wearing only a gown that is easily moved aside, with a sheet over the legs, if desired. Underwear, socks, and shoes should be removed, as should any makeup or eyeglasses. The examining table should be at a comfortable height, with a head that reclines, an extendable footrest, and gynecologic stirrups. The examining room should be at a comfortable temperature for the lightly dressed patient. It should contain a sink for hand washing and disinfecting hand foam, as patients are reassured by seeing their physician wash hands before the examination. If the patient and physician are of opposite genders, having a chaperone in

BOX 5-1 HISTORY TAKING IN DERMATOLOGIC DIAGNOSIS

CHIEF COMPLAINT AND HISTORY OF THE PRESENT ILLNESS

- ***Duration:*** When the condition was first noted and dates of any recurrences or remissions
- ***Periodicity:*** For example, constant, waxing and waning, worst at night, worst in winter
- ***Evolution:*** How the condition has spread or developed over time; often useful to ask patient whether lesion "always looked this way," or if not, how it looked when it first started
- ***Location:*** Where lesions were first noted and how they have spread, if applicable
- ***Symptoms:*** For example, pruritus, pain, bleeding, nonhealing, change of preexisting moles
- ***Severity:*** Especially for painful or pruritic conditions, it can be useful to ask patient to rate severity on a ten-point scale in order to follow severity over time
- ***Ameliorating and Exacerbating Factors:*** Relation to sun exposure, heat, cold, wind, trauma, and exposure to chemicals, topical products, plants, perfumes or metals, relation to menses or pregnancy
- Preceding illness, new medications, new topical products, or exposures
- Therapies tried, including over-the-counter or home remedies, and response to therapy
- Prior similar problems, prior diagnosis, results of biopsies or other studies performed

PAST MEDICAL HISTORY

- A history of all chronic illnesses, particularly those that may manifest in the skin, (diabetes, renal and hepatic disease, infection with HIV or hepatitis viruses, polycystic ovarian syndrome, lupus, thyroid disease) and those that are associated with skin disease (asthma, allergies)
- History of surgical procedures, including organ transplantation and bariatric surgery
- ***Immunosuppression:*** Either iatrogenic, infectious, genetic
- Pregnancies
- Psychiatric disease
- History of blistering sunburns, exposure to arsenic or ionizing radiation
- ***Medication History:*** A detailed history with particular attention to those medications started recently
- Prescription
- Over-the-counter medications
- Vitamins and dietary supplements
- Herbal remedies
- ***Allergies:*** To medications, foods, environmental antigens, and contactants
- ***Social History:*** Occupation, hobbies and leisure activities, alcohol and tobacco use, illicit drug use, sexual history (including high-risk activities for sexually transmitted diseases), dietary history, bathing habits, pets, living conditions (e.g., alone, with family, homeless, in an institution), history of travel or residence in endemic areas for infectious diseases, ethnicity, religious practices
- ***Family History:*** Of skin disease, atopy (atopic dermatitis, asthma, hay fever) or skin cancer
- ***Review of Systems:*** Constitutional symptoms (fatigue, weight loss, fever, chills, night sweats), acute illness symptoms (headache, photophobia, stiff neck, nausea, vomiting, cough, rhinorrhea, sneezing, myalgias, arthralgias), symptoms of conditions such as hypothyroidism (cold intolerance, weight gain, constipation) or psoriatic arthritis (joint pain, swelling and stiffness), which may accompany a dermatologic condition

the room can make the examination more comfortable for both.

RECOMMENDED TOOLS FOR THE COMPLETE SKIN EXAMINATION. Although the physician's eyes and hands are the only essential tools for examination of the skin, the following are often useful and highly recommended:

- A magnifying tool such as a loupe, magnifying glass, and/or dermatoscope.
- A bright focused light such as a flashlight or penlight to sidelight lesions.
- Glass slides or a hand magnifier for diascopy.
- Alcohol pads to remove scale or surface oil.
- Gauze pads or tissues with water for removing makeup.
- Gloves to be used for examination when scabies or another highly infectious condition (secondary syphilis) is suspected, when examining mucus membranes, and vulvar and genital areas, and when performing any procedure.
- A ruler for measuring lesions.
- Number 15 and number 11 scalpel blades for scraping and incising lesions, respectively.
- A camera for photographic documentation.
- A Wood's lamp (365 nm) for highlighting subtle pigmentary changes.

BOX 5-2 PHYSICAL EXAMINATION IN DERMATOLOGIC DIAGNOSIS

GENERAL IMPRESSION OF THE PATIENT

- Well or ill
- Obese, cachectic, or normal weight
- ***Skin Color:*** Degree of pigmentation, pallor (anemia), carotenemia, jaundice
- ***Skin Temperature:*** For example, warm, cool, and clammy
- ***Skin Surface Characteristics:*** Xerosis (dryness), seborrhea (excessive oil), turgor, hyper- or hypohidrosis (excessive or decreased sweating), and texture
- ***Degree of Photoaging:*** Lentigines, actinic purpura, rhytides

Describe the Distribution of Lesions: Localized (isolated), grouped, regional, generalized, universal, symmetrical, sun-exposed, flexural, extensor extremities, acral, intertriginous, dermatomal, follicular

PRIMARY LESIONS

- Define their type (e.g., papule, plaque, bulla)
- Describe their shape (e.g., arcuate, annular, linear)
- Describe any secondary changes (e.g., crusting, excoriations)

PALPATION

- Superficial (e.g., scaly, rough, smooth)
- Deep (e.g., firm, rubbery, mobile)

ASPECTS OF GENERAL PHYSICAL EXAMINATION THAT MAY BE HELPFUL

- Vital signs
- Abdominal examination for hepatosplenomegaly
- Pulses
- Lymph node examination (especially in cases of suspected infection and malignancy)

TECHNIQUE OF THE DERMATOLOGIC PHYSICAL EXAMINATION. Just as there is no one correct way to perform a general physical examination, each physician approaches the complete skin examination with his or her own style. A common thread to effective styles of skin examination is consistency in the order of examining different body areas to ensure that no areas are overlooked. One approach to the complete skin examination is presented here. First, observe the patient at a distance for general impressions (e.g., asymmetry due to a stroke, obesity, pallor, fatigue, jaundice). Next, examine the patient in a systematic way, usually from head to toe, uncovering one area at a time to preserve patient modesty. Move the patient (e.g., from sitting to lying) and the illumination as needed for the best view of each body area. Palpate growths to determine whether they are soft, fleshy, firm, tender, or fluid-filled. Use of the hands to stretch the skin is especially useful in diagnosis of basal cell carcinoma, in which stretching skin reveals a "pearly" quality often not seen on routine inspection. A magnifier worn on the head leaves both hands free for palpation of lesions. Certain lesions, such as porokeratosis, are best examined with side lighting that reveals depth and the details of borders. During the examination, patients often find it reassuring for the physician to name and demystify benign lesions as they are encountered.

Special examination techniques for hair disorders are discussed in Chapter 88; these include having the patient sit in a chair so that the entire scalp is easily examined, parting the patient's hair at the front and occiput, and gently tugging on hairs to determine the fraction of loose (telogen) hairs. Examination of the nails is discussed in Chapter 89.

After completing the examination, it is important to document the skin findings, including the type of lesions and their locations, either descriptively or on a body map. Careful documentation is particularly important for suspicious lesions that are to be biopsied, so that the exact location may be found and definitively treated at a later date. Instant or digital photography is a useful adjunct for documentation.

INTRODUCTION TO MORPHOLOGY

Siemens (1891–1969) wrote, "he who studies skin diseases and fails to study the lesion first will never learn dermatology." His statement reinforces the notion that the primary skin lesion, or the evolution thereof, is the essential element on which clinical diagnosis rests. Joseph Jakob von Plenck's (1738–1807) and Robert Willan's (1757–1812) work in defining basic morphologic terminology have laid the foundation for the description and comparison of fundamental lesions, thereby facilitating characterization and recognition of skin disease as, Wolff and Johnson state, to read words, one must recognize letters; to read the skin, one must

recognize the basic lesions. To understand a paragraph, one must know how words are put together; to arrive at a differential diagnosis, one must know what the basic lesions represent, how they evolve, and how they are arranged and distributed.

Variation and ambiguity in the morphologic terms generally accepted by the international dermatology community have engendered barriers to communication among physicians of all disciplines, including dermatologists. In dermatologic textbooks, the papule, for example, has been described as no greater than 1 cm in size, less than 0.5 cm, or ranging from the size of a pinhead to that of a split pea. Thus, in forming a mental image of a lesion or eruption after hearing its morphologic description, physicians sometimes remain irresolute. The mission of the Dermatology Lexicon Project has been to create a universally accepted and comprehensive glossary of descriptive terms to support research, medical informatics, and patient care. Morphologic definitions in this chapter parallel and amplify those of the Dermatology Lexicon Project. Table 5-1 contains a summary of the lesions discussed.

Figure 5-1 Papule. Multiple, well-defined papules of varying sizes are seen. Flat tops and glistening surface are characteristic of lichen planus.

RAISED LESIONS

PAPULE. A papule is a solid, elevated lesion less than 0.5 cm in size in which a significant portion projects above the plane of the surrounding skin. Papules surmounted with scale are referred to as papulosquamous lesions. Sessile, pedunculated, dome-shaped, flat-topped, rough, smooth, filiform, mammillated, acuminate, and umbilicated constitute some common shapes and surfaces of papules. A clinical example is lichen planus (Fig. 5-1; see Chapter 26).

PLAQUE. A plaque is a solid plateau-like elevation that occupies a relatively large surface area in comparison with its height above the normal skin level and has a diameter larger than 0.5 cm. Plaques are further characterized by their size, shape, color, and surface change. A clinical example is psoriasis (Fig. 5-2; see Chapter 18).

NODULE. A nodule is a solid, round or ellipsoidal, palpable lesion that has a diameter larger than 0.5 cm. However, size is not the major consideration in the definition of nodule. Depth of involvement and/or substantive palpability, rather than diameter, differentiates a nodule from a large papule or plaque. Depending on the anatomic component(s) primarily involved, nodules are of five main types: (1) epidermal, (2) epidermal–dermal, (3) dermal, (4) dermal–subdermal, and (5) subcutaneous. Some additional features of a nodule that may help reveal a diagnosis include whether it is warm, hard, soft, fluctuant, movable, fixed, or painful. Similarly, different surfaces of nodules, such as smooth, keratotic, ulcerated, or fungating, also help direct diagnostic considerations. A clinical example of a nodule is nodular basal cell carcinoma (Fig. 5-3; see Chapter 115).

Tumor, also sometimes included under the heading of nodule, is a general term for any mass, benign or malignant. A *gumma* is, specifically, the granulomatous nodular lesion of tertiary syphilis.

CYST. A cyst is an encapsulated cavity or sac lined with a true epithelium that contains fluid or semi-

TABLE 5-1
The Lesions of the Skin

Raised	Depressed	Flat	Surface Change	Fluid Filled	Vascular
Papule	Erosion	Macule	Scale	Vesicle	Purpura
Plaque	Ulcer	Patch	Crust	Bulla	Telangiectasia
Nodule	Atrophy	Erythema	Excoriation	Pustule	Infarct
Cyst	Poikiloderma	Erythroderma	Fissure	Furuncle	
Wheal	Sinus		Lichenification	Abscess	
Scar	Striae		Keratoderma		
Comedo	Burrow		Eschar		
Horn	Sclerosis				
Calcinosis					

Figure 5-2 Plaque. Well-demarcated pink plaques with a silvery scale representing psoriasis vulgaris.

solid material (cells and cell products such as keratin). Its spherical or oval shape results from the tendency of the contents to spread equally in all directions. Depending on the nature of the contents, cysts may be hard, doughy, or fluctuant. A clinical example is a cystic hidradenoma (Fig. 5-4; see Chapter 119).

WHEAL. A wheal is a swelling of the skin that is characteristically evanescent, disappearing within hours. These lesions, also known as *hives* or *urticaria*, are the result of edema produced by the escape of plasma through vessel walls in the upper portion of the dermis. Wheals may be tiny papules or giant plaques, and they may take the form of various shapes (round, oval, serpiginous, or annular), often in the same patient. Borders of a wheal, although sharp, are not stable and in fact move from involved to adjacent uninvolved areas over a period of hours. The flare, or ring of pink erythema, of a wheal may be intense if superficial vessels are dilated. If the amount of edema is sufficient to compress superficial vessels, wheals may in fact be white in the center or around the periphery, producing a zone of pallor. With associated inflammatory disruption of the vessels walls, wheals may have a deeper red color, may be purpuric, and are more persistent.

Figure 5-3 Nodule. A nodular basal cell carcinoma with well-defined, firm nodule with a glistening surface through which telangiectasia can be seen.

Figure 5-4 Cyst. A bluish colored resilient cyst filled with a mucous-like material on the cheek is cystic hidradenoma.

A clinical example is dermatographism (Fig. 5-5; see Chapter 38).

Angioedema is a deeper, edematous reaction that occurs in areas with very loose dermis and subcutaneous tissue such as the lip, eyelid, or scrotum. It may occur on the hands and feet as well, and result in grotesque deformity.

SCAR. A scar arises from proliferation of fibrous tissue that replaces previously normal collagen after a wound or ulceration breaches the reticular dermis. Scars have a deeper pink to red color early on before becoming hypo- or hyperpigmented. In most scars, the epidermis is thinned and imparts a wrinkled appearance at the surface. Adnexal structures, such as hair

Figure 5-5 Wheal. A sharply demarcated wheal with a surrounding erythematous flare occurring within seconds of the skin being stroked.

Figure 5-6 Comedo. Open and closed comedones on the face of this patient with acne.

follicles, normally present in the dermis are absent. Hypertrophic scars typically take the form of firm papules, plaques, or nodules. Keloid scars are also elevated. Unlike hypertrophic scars (see eFig. 5-5.1 in online edition; see Chapter 66), keloids exceed, with web-like extensions, the area of initial wounding. Atrophic scars are thin depressed plaques.

COMEDO. A comedo is a hair follicle infundibulum that is dilated and plugged by keratin and lipids. When the pilosebaceous unit is open to the surface of the skin with a visible keratinaceous plug, the lesion is referred to as an *open comedo*. The black color of the comedo is due to the oxidized sebaceous content of the infundibulum ("blackhead"). A closed infundibulum in which the follicular opening is unapparent accumulates whitish keratin and is called a *closed comedo*. A clinical example is comedonal acne (Fig. 5-6; see Chapter 80).

HORN. A horn is a hyperkeratotic conical mass of cornified cells arising over an abnormally differentiating epidermis. A clinical example is verruca vulgaris (see eFig. 5-6.1 in online edition; see Chapter 196).

CALCINOSIS. Deposits of calcium in the dermis or subcutaneous tissue may be appreciated as hard, whitish nodules or plaques, with or without visible alteration of the skin's surface. A clinical example is cutaneous calcinosis in dermatomyositis (see eFig. 5-6.2 in online edition; see Chapter 156).

DEPRESSED LESIONS

EROSION. An *erosion* is a moist, circumscribed, depressed lesion that results from loss of a portion or all of the viable epidermal or mucosal epithelium. The defect extending to the most superficial part of the dermis may result in pinpoint bleeding in a sievelike fashion. Erosions may result from trauma, detachment of epidermal layers with maceration, rupture of vesicles or bullae, or epidermal necrosis, for example. Unless they become secondarily infected, erosions do not scar. A clinical example is toxic epidermal necrolysis (Fig. 5-7; see Chapter 40).

ULCERS. An ulcer is a defect in which the epidermis and at least the upper (papillary) dermis have been destroyed. Breach of the dermis and destruction of adnexal structures impede reepithelialization, and the defect heals with scarring. Borders of the ulcer may be rolled, undermined, punched out, jagged, or angular. The base may be clean, ragged, or necrotic. Discharge may be purulent, granular, or malodorous. Surrounding skin may be red, purple, pigmented, reticulated, indurated, sclerotic, or infarcted. A clinical example is pyoderma gangrenosum (Fig. 5-8; see Chapter 33).

ATROPHY. *Atrophy* refers to a diminution in the size of a cell, tissue, organ, or part of the body. An atrophic epidermis is glossy, almost transparent, paper thin and wrinkled, and may not retain normal skin lines. Atrophy of the papillary or reticular dermal connective tissue manifests as a depression of the skin. Atrophy of the panniculus results in a more substantial depression of the skin. eFig. 5-8.1 in online edition shows aged skin of the arm in an elderly woman (see Chapter 109).

Figure 5-7 Erosion. Sloughing of the skin in this patient with toxic epidermal necrolysis leaves behind a large erosion.

Figure 5-8 Ulcer. A large ulcer with a ragged base and heaped-up pink erythematous border on the leg representing progressing pyoderma gangrenosum.

POIKILODERMA. As a morphologic term, *poikiloderma* refers to the combination of atrophy, telangiectasia, and varied pigmentary changes (hyper- and hypo-) over an area of skin. This combination of features may give rise to a dappled appearance to the skin. A clinical example is chronic radiodermatitis (see eFig. 5-8.2 in online edition).

SINUS. A sinus is a tract connecting deep suppurative cavities to each other or to the surface of the skin. A clinical example is hidradenitis suppurativa (see eFig. 5-8.3 in online edition; see Chapter 85).

STRIAE. Striae are linear depressions of the skin that usually measure several centimeters in length and result from changes to the reticular collagen that occur with rapid stretching of the skin. A clinical example is striae distensae (see eFig. 5-8.4 in online edition; see Chapter 108).

BURROW. A burrow is a wavy, threadlike tunnel through the outer portion of the epidermis excavated by a parasite. A clinical example is scabetic burrow (see eFig. 5-8.5 in online edition; see Chapter 208).

SCLEROSIS. *Sclerosis* refers to a circumscribed or diffuse hardening or induration of the skin that results from dermal fibrosis. It is detected more easily by palpation, on which the skin may feel board-like, immobile, and difficult to pick up. A clinical example is morphea (see eFig. 5-8.6 in online edition; see Chapter 64).

FLAT AND MACULAR LESIONS

MACULE. A macule is flat, even with the surface level of surrounding skin, and perceptible only as an area of color different from the surrounding skin or mucous membrane. Maculosquamous is a neologism invented to describe macules with fine nonpalpable scaling, which may become apparent only after light scraping and scratching.

Perhaps the most important additional feature of a lesion other than primary morphology is color. Lesional color, which is often the first visual assessment made, is reliably reproducible with particular types of pathologies, such as destruction of melanocytes, dilatation of dermal blood vessels, or inflammation of vessel walls with extravasation of red blood cells. As such, color provides meaningful insight into pathologic processes of the skin and facilitates clinical diagnosis. Pigmentary changes represent an important and common type of macular color change and may be described as hyperpigmented (as in postinflammatory hyperpigmentation), hypopigmented (as in tinea versicolor), or depigmented (as in vitiligo).

Table 5-2 describes characteristic colors that may be noted with inspection of altered skin. A clinical example is lentigo (Fig. 5-9; see Chapter 122).

PATCH. A patch is similar to a macule; it is a flat area of skin or mucous membranes with a different color from its surrounding. However, a patch is larger than

Figure 5-9 Macule. Uniform-colored brown macule with slightly irregular, sharply defined borders representing a lentigo on the lip.

0.5 cm, and it may have a fine, very thin scale. Clinical examples include vitiligo, where the term "patch" may be used to describe larger macules or a "patchy" configuration (Fig. 5-10; see Chapter 74), and also cutaneous T-cell lymphoma, where early lesions may be thin slightly scaly patches.

ERYTHEMA. Erythema represents the blanchable pink to red color of skin or mucous membrane that is due to dilatation of arteries and veins in the papillary and reticular dermis. It exists in different colors, and to dub a primary lesion as *erythematous* alone is incomplete. Describing erythema with the color it most closely resembles provides a meaningful clue to diagnosis. For example, violaceous erythema brings to mind a differential distinct from salmon pink-colored erythema, even if both types of erythema involve papules. A clinical example is dusky erythema, as may be seen in a fixed drug eruption (see eFig. 5-10.1 in online edition; see Chapter 41).

ERYTHRODERMA. Erythroderma is a generalized deep redness of the skin involving more than 90% of the body surface within days to weeks. Type of scaling

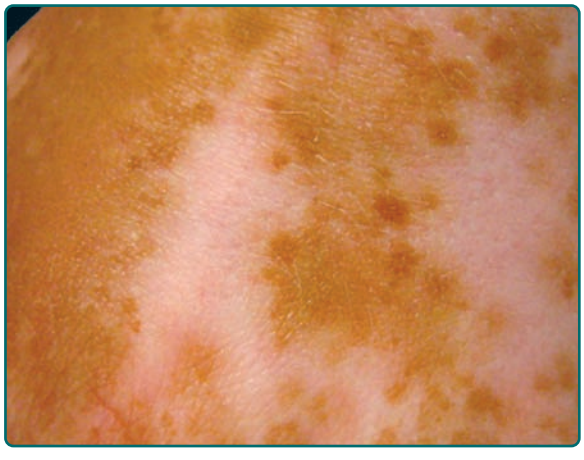

Figure 5-10 Patch. Depigmented patches within areas of normal skin tone representing vitiligo.

TABLE 5-2
Implications of Color Changes in Altered Skin

Color	Pathology	Diagnostic Consideration
Apple jelly	Granulomatous inflammation	Tuberculosis, sarcoidosis, leishmaniasis
Black	Melanin, necrosis	Melanoma, purpura fulminans, calciphylaxis
Blue	Deep dermal pigment, reduced hemoglobin, tattoo, medication	Blue nevus, amiodarone
Brown	Melanin, hemosiderin, chronic inflammation, postinflammatory, dried serum	Nevus, melasma
Copper	Inflammation with plasma cells	Secondary syphilis
Green	Deep hemosiderin, pyocyanin pigment, tissue eosinophilia	*Pseudomonas* infection, tattoo, Wells syndrome
Gray	Deep melanin or other pigment deposition	Chloroquine toxicity, Mongolian spot, erythema dyschromicum perstans
Lilac	Inflammation, dilatation of deep dermal blood vessels	Borders of evolving morphea, dermatomyositis
Orange	Granulomatous inflammation with histiocytes having abundant cytoplasm	Juvenile xanthogranuloma
Pearly	Epidermal proliferation without surface keratin	Basal cell carcinoma
Pink	Acute inflammation, dilatation of superficial dermal blood vessels, hemorrhage	Eczema
Red	Hemorrhage, acute inflammation, dilatation of blood vessels	Psoriasis, drug eruptions
Salmon pink	Inflammation with involvement of epidermis, dilatation of blood vessels' inflammation with edema	Pityriasis rubra pilaris, psoriasis, urticaria
Violet	Hemorrhage, deep hemosiderin, lichenoid inflammation	Lichen planus, Kaposi sarcoma
White	Reduced or absent melanin synthesis, postinflammatory	Tinea versicolor, albinism, vitiligo
Yellow	Superficial *Staphylococcus* or *Streptococcus* infection mixed with keratinized cells, carotenoids, hemosiderin, bile pigment, accumulated lipid	Impetigo, xanthomas, sebaceous hyperplasia, necrobiosis lipoidica diabeticorum, jaundice

or desquamation, which follows establishment of the generalized erythema, noted is suggestive of the primary process (Table 5-3). A clinical example is Sézary syndrome (see eFig. 5-10.2 in online edition; see Chapters 23 and 145).

SURFACE CHANGE

SCALE, DESQUAMATION (SCALING). A scale is flat plate or flake arising from the outermost layer of the stratum corneum. Groups of coherent cornified cells packed with filamentous proteins desquamate in scales imperceptibly from the skin's surface under normal circumstances on a regular basis as the epidermis is replaced completely every 27 days. When epidermal differentiation is disordered, accumulation and casting of stratum corneum become apparent as scale that ranges in size from fine dust-like particles to extensive parchment-like sheets. In some cases, scale is observed only after scratching the lesion, a phenomenon known as *latent desquamation*. Scaly lesions are often described as "hyperkeratotic," a term that is used both clinically and histopathologically.

Not all scales are similar, and the expert dermatologist with a well-trained eye can obtain diagnostically useful information from close examinations of the type of scale present. Table 5-3 describes the types of scale one may encounter. A clinical example is psoriasis vulgaris (Fig. 5-11; see Chapter 18).

HYPERKERATOSIS. Leider and Rosenblum define hyperkeratosis as "excessive cornification." Siemens states that "the stratum corneum may be thinned or thickened." In the latter, thickening may consist of normal keratin (hyperkeratosis) or of an abnormal keratin in which the cellular nuclei are retained and are stainable (parakeratosis). Different types of hyperkeratosis can be discerned histopathologically, but in clinical parlance "hyperkeratosis" refers to an excessive or thickened stratum corneum, often but not always scaly.

TABLE 5-3
Types of Scale

Type of Scale	Description	Prototype Diagnosis
Crack-like/craquelé	Desquamation giving the appearance of dried, cracked skin.	Eczema craquelé
Exfoliative	Scales split of from the epidermis in finer scales or in sheets.	Drug reaction
Follicular	Scales appear as keratotic plugs, spines, or filaments.	Keratosis pilaris
Gritty	Densely adherent scale with a sandpaper texture.	Actinic keratosis
Ichthyosiform	Scales are regular polygonal plates arranged in parallel rows or diamond patterns (fish-like, tesselated).	Ichthyosis vulgaris
Keratotic/hyperkeratotic	Scales appear as heaped-up column of scale.	Cutaneous horn
Lamellar	Scales are thin large plates or shields attached in the middle and looser around the edges.	Lamellar ichthyosis
Pityriasiform	Scale is small and branny.	Pityriasis rosea
Psoriasiform (micaceous and ostraceous)	Scale is silvery and brittle and forms thin platelets in several loose sheets, like mica (micaceous scale). Large scales may accumulate in heaps, giving the appearance of an oyster shell (ostraceous scale).	Psoriasis vulgaris
Seborrheic	Scales are thick, waxy or greasy, yellow-to-brown, flakes.	Seborrheic dermatitis
Wickham striae	Scale appears as a lacy white pattern overlying violaceous flat-topped papules.	Lichen planus

CRUSTS (ENCRUSTED EXUDATES). Crusts are hardened deposits that result when serum, blood, or purulent exudate dries on the surface of the skin. The color of crust is a yellow-brown when formed from dried serous secretion; turbid yellowish-green when formed from purulent secretion; and reddish-black when formed from hemorrhagic secretion. Removal of the crust may reveal an underlying erosion or ulcer. A clinical example is impetigo (Fig. 5-12; see Chapter 176).

Figure 5-11 Scale. Brittle silvery scales forming thin platelets in several loose sheets, like mica, on this plaque of psoriasis.

EXCORIATIONS. Excoriations (see eFig. 5-12.1 in online edition) are surface excavations of epidermis that result from scratching.

FISSURE. A fissure is a linear loss of continuity of the skin's surface or mucosa that results from excessive tension or decreased elasticity of the involved tissue. Fissures frequently occur on the palms and soles where the thick stratum corneum is least expandable. A clinical example is fissure on the palm associated with contact dermatitis (see eFig. 5-12.2 in online edition; see Chapter 13).

LICHENIFICATION. Repeated rubbing of the skin may induce a reactive thickening of the epidermis, with changes in the collagen of the underlying superficial dermis. These changes produce a thickened skin

Figure 5-12 Crust. Glistening, honey-colored, delicate crusts under the nose representing impetigo.

Figure 5-13 Lichenification. An area of thickened skin with accentuated skin markings induced by repeated rubbing, representing lichenification noted in lichen simplex chronicus.

with accentuated markings, which may resemble tree bark. A clinical example is lichen simplex chronicus (Fig. 5-13; see Chapter 15).

KERATODERMA. Keratoderma is an excessive accumulation of scale (hyperkeratosis) that results in a yellowish thickening of the skin, usually on the palms or soles, that may be inherited (abnormal keratin formation) or acquired (mechanical stimulation). A clinical example is plantar keratoderma in psoriasis (see eFig. 5-13.1 in online edition; see Chapter 18).

ESCHAR. The presence of an eschar implies tissue necrosis, infarction, deep burns, gangrene, or other ulcerating process. It is a circumscribed, adherent, hard, black crust on the surface of the skin that is moist initially, protein rich, and avascular. A clinical example is thermal burn (see eFig. 5-13.2 in online edition; see Chapter 95).

FLUID-FILLED LESIONS

VESICLE AND BULLA. A vesicle is a fluid-filled cavity or elevation smaller than or equal to 0.5 cm, whereas a bulla (blister) measures larger than 0.5 cm. The fluid in the cavity exerts equal pressure in all directions to give rise to a spherical shape. Because of their size, bullae are easily identifiable as tense or flaccid weepy blisters. Clear, serous, hemorrhagic, or pus-filled contents may be visualized when the cavity wall is thin and translucent enough. Vesicles and bullae arise from cleavage at various levels of the epidermis (intraepidermal) or of the dermal–epidermal interface (subepidermal). The amount of pressure required to collapse the lesion may help predict whether the bulla is intraepidermal or subepidermal. However, reliable differentiation requires histopathologic examination of the blister cavity edge.

A clinical example of vesicle is the blistering aspect of impetigo caused by toxin-producing staphylococci (Fig. 5-14A; see Chapter 177). A clinical example of bulla is a bullous pemphigoid (Fig. 5-14B; see Chapter 56).

PUSTULE. A pustule is a circumscribed, raised cavity in the epidermis or infundibulum containing pus. The purulent exudate, composed of leukocytes with

Figure 5-14 Vesicle (**A**) and bulla (**B**). Fragile subcorneal translucent vesicles representing impetigo caused by a toxin-producing *Staphylococcus* (**A**) and large tense subepidermal bullae filled with serous or hemorrhagic fluid in this patient with bullous pemphigoid (**B**).

Figure 5-15 Pustule. Two pustules representing superficial pyoderma.

or without cellular debris, may contain bacteria or may be sterile. Depending on its sterility, the exudate may be white, yellow, or greenish-yellow in color. Pustules may vary in size and, in certain situations, may coalesce to form "lakes" of pus. When associated with hair follicles, pustules may appear conical and contain a hair in the center. A clinical example is superficial pyoderma (Fig. 5-15; see Chapter 176).

FURUNCLE. A furuncle (see eFig. 5-15.1 in online edition; see Chapter 176) is a deep necrotizing folliculitis with suppuration. It presents as an inflamed follicle-centered nodule usually greater than 1 cm with a central necrotic plug and an overlying pustule. Several furuncles may coalesce to form a carbuncle.

ABSCESS. An abscess (see eFig. 5-15.2 in online edition; see Chapter 176) is a localized accumulation of purulent material so deep in the dermis or subcutaneous tissue that the pus is usually not visible on the surface of the skin. An abscess is a pink erythematous, warm, tender, fluctuant nodule.

PURPURA/VASCULAR LESIONS

PURPURA. Extravasation of red blood from cutaneous vessels into skin or mucous membranes results in reddish-purple lesions included under the term *purpura*. The application of pressure with two glass slides or an unbreakable clear lens (diascopy) on a reddish-purple lesion is a simple and reliable method for differentiating redness due to vascular dilatation (erythema) from redness due to extravasated erythrocytes or erythrocyte products (purpura). If the redness is nonblanching under the pressure of the slide, the lesion is purpuric. As extravasated red blood cells decompose over time, the color of purpuric lesions change from bluish-red to yellowish-brown or green.

Figure 5-16 Purpura. Nonblanching red erythematous papules and plaques (palpable purpura) on the legs, representing leukocytoclastic vasculitis.

Petechiae are small, pinpoint purpuric macules. Ecchymoses are larger, bruise-like purpuric patches. These lesions correspond to a noninflammatory extravasation of blood. If a lesion is purpuric and palpable ("palpable purpura"), the suggestion of an inflammatory insult to the vessel wall as a cause of extravasation of blood and inflammatory cells exists. A clinical example is leukocytoclastic vasculitis (Fig. 5-16; see Chapter 163).

TELANGIECTASIA. Telangiectasia (see eFig. 5-16.1 in online edition; see Chapter 174) are persistent dilatations of small capillaries in the superficial dermis that are visible as fine, bright, nonpulsatile red lines or net-like patterns on the skin.

INFARCT. An infarct is an area of cutaneous necrosis resulting from a bland or inflammatory occlusion of blood vessels in the skin. A cutaneous infarct presents as a tender, irregularly shaped dusky reddish-gray macule or firm plaque that is sometimes depressed slightly below the plane of the skin. A clinical example is cholesterol emboli (Fig. 5-17; see Chapter 173).

SHAPE, ARRANGEMENT, AND DISTRIBUTION OF LESIONS

Once the type or types of lesions have been identified, one needs to describe their shape, arrangement, and pattern of distribution, all useful characteristics in morphologic diagnosis. For example, a single scaly plaque on a patient's trunk may have a broad differential diagnosis, but the same plaques symmetrically

Figure 5-17 Infarct. Dusky purple discoloration representing an area of infarction that eventuates in tissue necrosis. This patient had cholesterol emboli lodged in the distal end arteries of the toes.

Figure 5-19 Nummular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

distributed on the elbows, knees, and umbilicus would be highly suggestive of psoriasis. The following descriptions of shapes and arrangements of skin lesions may be applied to single or multiple lesions. For example, a single lesion may be linear or multiple lesions may assume a linear pattern.

SHAPE OR CONFIGURATION OF SKIN LESIONS

- *Annular (Fig. 5-18):* Ring-shaped; implies that the edge of the lesion differs from the center, either by being raised, scaly, or differing in color (e.g., granuloma annulare, tinea corporis, erythema annulare centrifugum).
- *Round/nummular/discoid (Fig. 5-19):* Coin-shaped; usually a round to oval lesion with uniform morphology from the edges to the center (e.g., nummular eczema, plaque-type psoriasis, discoid lupus).
- *Polycyclic (see eFig. 5-19.1 in online edition):* Formed from coalescing circles, rings, or incomplete rings (e.g., urticaria, subacute cutaneous lupus erythematosus).
- *Arcuate (see eFig. 5-19.2 in online edition):* Arc-shaped; often a result of incomplete formation of an annular lesion (e.g., urticaria, subacute cutaneous lupus erythematosus).
- *Linear (see eFig. 5-19.3 in online edition):* Resembling a straight line; often implies an external contactant or Koebner phenomenon has occurred in response to scratching; may apply to a single lesion (e.g., a scabies burrow, poison ivy dermatitis, or bleomycin pigmentation) or to the arrangement of multiple lesions (e.g., lichen nitidus or lichen planus).
- *Reticular (Fig. 5-20):* Net-like or lacy in appearance, with somewhat regularly spaced rings or partial rings and sparing of intervening skin (e.g., livedo reticularis, cutis marmorata).
- *Serpiginous (Fig. 5-21):* Serpentine or snake-like (e.g., cutaneous larva migrans, in which the larva migrates this way and that through the skin in a wandering pattern).

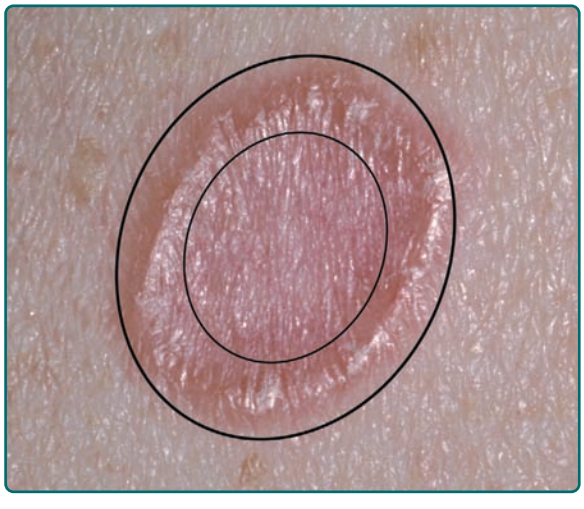

Figure 5-18 Annular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

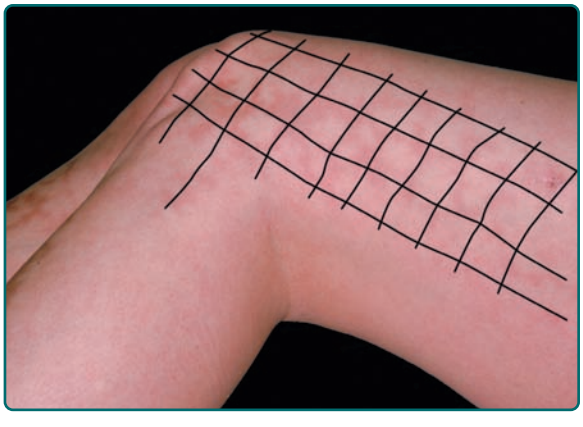

Figure 5-20 Reticular lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

Figure 5-21 Serpiginous lesion. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

- *Targetoid (see eFig. 5-21.1 in online edition):* Target-like, with at least three distinct zones (e.g., erythema multiforme).
- *Whorled (Fig. 5-22):* Like marble cake, with two distinct colors interspersed in a wavy pattern; usually seen in mosaic disorders in which cells of differing genotypes are interspersed (e.g., incontinentia pigmenti, hypomelanosis of Ito, linear and whorled nevoid hypermelanosis).

ARRANGEMENT OF MULTIPLE LESIONS

- *Grouped/herpetiform (Fig. 5-23):* Lesions clustered together (e.g., classic example is herpes simplex virus 1 reactivation noted as grouped vesicles on an erythematous base; also seen with certain arthropod bites).
- *Scattered (see eFig. 5-23.1 in online edition):* Irregularly distributed.

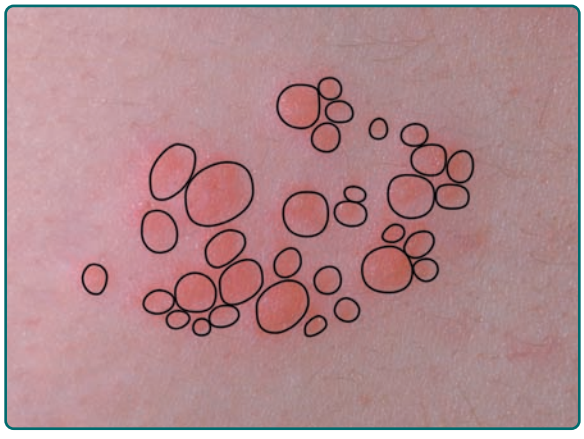

Figure 5-23 Grouped: clustered. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

DISTRIBUTIONS OF MULTIPLE LESIONS

- *Dermatomal/zosteriform:* Unilateral and lying in the distribution of a single spinal afferent nerve root; the classic example is herpes zoster (see Chapter 194).
- *Blaschkoid (Fig. 5-24):* Following lines of skin cell migration during embryogenesis; generally longitudinally oriented on the limbs and circumferential on the trunk, but not perfectly linear (see also

Figure 5-22 Whorled: marbled appearance. (Illustration by Glen Hintz, MS. Dermatology Lexicon Project.)

TABLE 5-4
Selection of Cutaneous Signs[a]

Cutaneous Sign	Description	Significance
Apple-jelly sign	A yellowish hue is produced from pressure on the lesion with a glass slide.	Noted in granulomatous processes.
Asboe–Hansen sign	Lateral extension of a blister with downward pressure.	Noted in blistering disorders in which the pathology is above the basement membrane zone.
Auspitz sign	Pinpoint bleeding at the tops of ruptured capillaries with forcible removal of outer scales from a psoriatic plaque.	Not entirely sensitive or specific for psoriasis.
Butterfly sign	Butterfly-shaped sparing from excoriations of the nonreachable interscapular region.	Noted in disorders associated with pruritus and implies that the physical findings are a consequence of rubbing and scratching.
Buttonhole sign	A flesh-colored, soft papule feels as though it can be pushed through a "buttonhole" into the skin.	Noted in a neurofibroma.
Carpet tack sign	Horny plugs at the undersurface of scale removed from a lesion.	Noted in lesions of chronic cutaneous lupus.
Crowe sign	Axillary freckling.	Noted in neurofibromatosis type I; may be seen as part of lentiginosis profuse.
Darier sign	Urticarial wheal produced in a lesion after it is rubbed with the rounded end of a pen. The wheal, which is strictly confined to the borders of the lesion, may not appear for several minutes.	Noted in urticaria pigmentosa and rarely with cutaneous lymphoma or histiocytosis.
Dermatographism	Firmly stroking unaffected skin produces a wheal along the shape of the stroke within seconds to minutes.	Symptomatic dermatographism represents a physical urticaria.
Pseudo-Darier sign	Transient induration of a lesion or piloerection after rubbing.	Noted in congenital smooth muscle hamartoma.
Fitzpatrick (dimple) sign	Dimpling of the skin with lateral compression of the lesion with the thumb and index finger produces dimpling due to tethering of the epidermis to the dermal lesion.	Characteristic of dermatofibroma.
Gottron sign	Raised or flat pink to violaceous erythema and/or papules of metacarpal or interphalangeal joints, olecranon, patellae, or malleoli.	Classically used in reference to dermatomyositis.
Hair collar	Ring of dark long scalp hair encircling a congenital lesion.	Associated with aplasia cutis, encephalocele, meningocele, or heterotopic brain tissue.
Heliotrope sign	Violaceous erythema over eyelids.	Noted in dermatomyositis.
Hertoghe sign	Thinning or loss of the outer third of the eyebrow.	May be associated with atopic dermatitis, hypothyroidism, systemic sclerosis.
Hutchinson nail sign	Periungual extension of pigment to the proximal and lateral nail folds.	Noted in subungual melanoma.
Hutchinson nose sign	Vesicles on the tip of the nose in a patient with herpes zoster of the face.	Due to the involvement of the nasociliary branch of ophthalmic nerve (V1) and indicates a higher likelihood of ocular disease.
Leser–Trélat sign	Sudden eruption of inflammatory seborrheic keratoses-like lesions.	Associated with systemic malignancy. Also reported with benign neoplasms, eczema, pregnancy, and leprosy.
Nikolsky sign	Lateral pressure on unblistered skin with resulting shearing of the epidermis.	Noted in blistering disorders in which the pathology is above the basement membrane zone. Relevant entities include pemphigus vulgaris and toxic epidermal necrolysis.
Oil drop sign	Area of yellowish discoloration resembling an oil drop involving the nail bed distally (but not involving the free edge).	Indicates onycholysis noted in psoriatic nail disease.
Russell sign	Abrasions, lacerations, callosities of metacarpal and proximal interphalangeal joints.	Due to trauma from incisor teeth during self-induced vomiting in bulimia.
Shawl sign	Erythema over upper back and shoulders.	Classically used in reference to dermatomyositis.
Trousseau sign	Recurrent migratory superficial thrombophlebitis of small and large cutaneous veins.	Associated with internal malignancy (usually pancreatic), Behçet disease, rickettsial infections.
Ugly duckling sign	A pigmented lesion, among numerous atypical but clinically benign nevi, that stands out from the rest and may be a melanoma.	Helpful in screening numerous pigmented lesions in a low-risk individual. Once the lesion is distinguished from the others, it may be evaluated further for abnormal clinical features.

[a]Others are discussed in the chapters on diseases in which the signs occur.

TABLE 5-5
Ten Pointers and Pitfalls in Dermatologic Diagnosis

- Approach each and every evaluation with patience and thoroughness.
- Beware of "snap," "curbside," or "doorway" diagnoses.
- Examine the entire mucocutaneous surface, as well as the hair and nails.
- A new or changing mole should be carefully evaluated.
- Do not remove tissue without sending a portion for histologic examination.
- If the dermatopathologic findings are not consistent with the clinical impression, obtain another biopsy.
- If forced to choose between incongruent clinical and pathologic impression, follow clinical lead (cautiously).
- Generalized pruritus of more than 1 month's duration mandates a complete systemic workup.
- Seemingly nonspecific rashes may just be camouflaged specific disorders.
- Drug-induced eruptions can mimic most skin conditions.
- Be wary of the "atypical" diagnosis. Atypical "this" may be "typical" that to someone who has seen it before.
- Consider all other reasonable possibilities before making a diagnosis of factitial disorder.

Section "Shape or Configuration of Skin Lesions"); described by Alfred Blaschko and implies a mosaic disorder (e.g., incontinentia pigmenti, inflammatory linear verrucous epidermal nevus).

- *Lymphangitic:* Lying along the distribution of a lymph vessel; implies an infectious agent that is spreading centrally from an acral site, usually a red streak along a limb due to a staphylococcal or streptococcal cellulitis.
- *Sun exposed:* Occurring in areas usually not covered by clothing, namely the face, dorsal hands, and a triangular area corresponding to the opening of a V-neck shirt on the upper chest (e.g., photodermatitis, subacute cutaneous lupus erythematosus, polymorphous light eruption, squamous cell carcinoma).
- *Sun protected:* Occurring in areas usually covered by one or more layers of clothing; usually a dermatosis that is improved by sun exposure (e.g., parapsoriasis, mycosis fungoides).
- *Acral:* Occurring in distal locations, such as on the hands, feet, wrists, and ankles (e.g., palmoplantar pustulosis, chilblains).
- *Truncal:* Occurring on the trunk or central body.
- *Extensor:* Occurring over the dorsal extremities, overlying the extensor muscles, knees, or elbows (e.g., psoriasis).
- *Flexor:* Overlying the flexor muscles of the extremities, the antecubital and popliteal fossae (e.g., atopic dermatitis).
- *Intertriginous:* Occurring in the skin folds, where two skin surfaces are in contact, namely the axillae, inguinal folds, inner thighs, inframammary skin, and under an abdominal pannus; often related to moisture and heat generated in these areas (e.g., candidiasis).
- *Localized:* Confined to a single body location (e.g., cellulitis).
- *Generalized:* Widespread. A generalized eruption consisting of inflammatory (red) lesions is called an *exanthema* (rash). A macular exanthema consists of macules, a papular exanthema of papules, a vesicular exanthema of vesicles, etc. (e.g., viral exanthems, drug eruption).
- *Bilateral symmetric:* Occurring with mirror-image symmetry on both sides of the body (e.g., vitiligo, plaque-type psoriasis).
- *Universal:* Involving the entire cutaneous surface (e.g., erythroderma, alopecia universalis).

Table 5-4 describes some clinically relevant maneuvers and morphologic signs that point to particular integumentary or systemic diseases.

As the late Thomas B. Fitzpatrick often said, "dermatologists are physicians who can diagnose a rash!" They may also be internists, surgeons, biochemists, or immunologists; but without competency in dermatologic diagnosis they cannot qualify as dermatologists. However, this skill is not specific to dermatologists. Any physician who makes the effort to study the skin and learn the dermatologic lexicon can develop a functional appreciation of the fundamentals of diagnosis. The advanced diagnostic eye can only be acquired by endlessly repeated encounters in which the physician is forced not only to look at, but also to observe, the rash while an experienced mentor points the way. The most common error in dermatologic diagnosis is to regard the lesions as nonspecific "rashes" rather than as aggregates of specific individual lesions. As in surveying a blood smear, a "general impression" is not enough: The morphologic aspects of each individual cell must be carefully scrutinized and judged to be normal or abnormal. Too often, physicians adopt a speedy, superficial approach to the skin that they would not apply to any other organ that they examine (Table 5-5).

Lewis Thomas has said that "Medicine is no longer the laying on of hands, it is more like the reading of signals from machines." In dermatology, there can be no replacement for the laying on of hands, and the physician is repeatedly gratified by reading signals not from machines, but from people.

Chapter 6 :: Basic Pathologic Reactions of the Skin

:: Martin C. Mihm Jr., Abdul-Ghani Kibbi, George F. Murphy, & Klaus Wolff

BASIC PATHOLOGIC REACTIONS AT A GLANCE

- Different tissue compartments interconnect anatomically and interact functionally. These are the reactive units of skin.
- The superficial reactive unit comprises the epidermis, the junction zone, and the papillary body with its vascular system.
- The reticular dermis with the deeper dermal vascular plexus is the second reactive unit.
- The third reactive unit is the subcutaneous tissue with its septal and lobular compartments.
- Hair follicles and glands are a fourth reactive unit embedded into these three units.
- Pathologic processes may involve these reactive units alone or several of them in a concerted fashion.
- The heterogeneity and interaction of these individual cutaneous compartments explain why a few basic pathologic reactions lead to a multiplicity of clinical and pathologic reaction patterns.

The skin is composed of different tissue compartments that interconnect anatomically and interact functionally. It is difficult to envisage epidermal function without signals from the dermis or passenger leukocytes traveling to and from the skin. On the other hand, epidermis, dermis, and subcutaneous tissue are heterogeneous in nature and an analysis of pathologic processes involving the skin should therefore consider both this heterogeneity and the interactions of the individual cutaneous compartments; only then will it be understood why a few basic reactions lead to a multiplicity of reaction patterns within this tissue.

Pathophysiologically, the skin can be subdivided into three reactive units that extend beyond anatomic boundaries (Fig. 6-1); they overlap and can be divided into different subunits that respond to pathologic stimuli according to their inherent reaction capacities in a coordinated pattern.

The superficial reactive unit comprises the subunits epidermis, the junction zone, the subjacent loose, delicate connective tissue of the papillary body and its capillary network, and the superficial vascular plexus (see Fig. 6-1, SRU). The reticular layer of the dermis represents a second reactive unit and is composed of coarse connective tissue and the deeper dermal vascular plexus (see Fig. 6-1, DRU). The third reactive unit, the subcutaneous tissue, is also anatomically and functionally heterogeneous; septal and lobular compartments may be involved either alone or together (see Fig. 6-1, S). Hair follicles and glands are a separate (fourth) reactive unit embedded in these three basic units.

SUPERFICIAL REACTIVE UNIT

EPIDERMIS

(See Fig. 6-1, E)

Keratinocytes, which have the capacity to synthesize keratin protein, represent the bulk of the epidermis. The epidermis, an ectodermal epithelium, also harbors a number of other cell populations such as melanocytes, Langerhans cells, Merkel cells, and

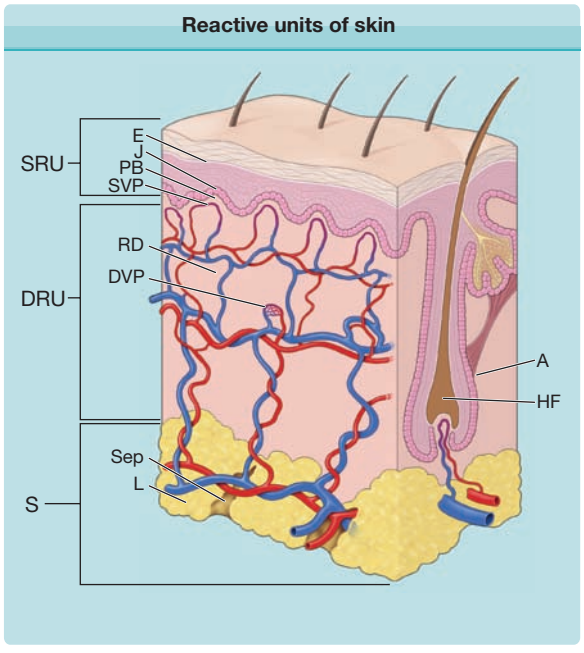

Figure 6-1 Reactive units of skin. The superficial reactive unit (SRU) comprises the epidermis (E), the junction zone (J), and the papillary body (PB) with the superficial microvascular plexus. The dermal reactive unit (DRU) consists of the reticular dermis (RD) and the deep dermal microvascular plexus (DVP). The subcutaneous reactive unit (S) consists of lobules (L) and septae (Sep). A fourth unit is the appendages (A; hair and sebaceous glands are the only appendages shown). HF = hair follicle.

cellular migrants (see Chapter 7). The basal cells of the epidermis undergo proliferation cycles that provide for the renewal of the epidermis and, as they move toward the surface of the skin, undergo a differentiation process that results in surface keratinization. Thus, the epidermis is a dynamic tissue in which cells are constantly in nonsynchronized replication and differentiation; this precisely coordinated physiological balance between progressive keratinization as cells approach the epidermal surface to eventually undergo programed cell death and be sloughed, and their continuous replenishment by dividing basal cells is in contrast to the relatively static minority populations of Langerhans cells, melanocytes, and Merkel cells. However, at the same time, these dynamic keratinocytes are interconnected through cohesive molecular interactions that guarantee the continuity, stability, and integrity of the epithelium. Stability for this directional cellular flow is provided by the basal membrane complex (see Chapter 53), which anchors the epidermis to the dermis, and the stratum corneum, which encases the epidermis on the outside. It is here that individual cell differentiation ceases as the keratinizing cells are firmly interconnected by an intercellular cement-like substance forming a permeability barrier (see Chapter 47). These forces of cohesion are finally lost at the surface of the epidermis where the individual cornified cells are sloughed (desquamated). Therefore, pathologic changes within the epidermis may relate to the replicative kinetics of epidermal cells, their differentiation, alterations in cohesive forces, or a combination of these factors (see Chapter 46). These primary factors may also influence the stability and migratory characteristics of Langerhans cell, melanocytes, and migrant lymphocytes, accounting for the complexity of certain reaction patterns that arise from primary pathological defects in the epidermal layer. For example, unless a Langerhans cell expresses the chemokine receptor CCR6, it cannot migrate from the dermis to the epidermis, and without expression of the CCR7 receptor, migration to the lymph node is not possible. Because cytokines that regulate the expression of such receptors are synthesized and secreted by keratinocytes within the immediate microenvironment of Langerhans cells, impairment of keratinocyte homeostasis may have far-reaching functional implications that are reflected in the complexity of the resultant reaction patterns.

DISTURBANCES OF EPIDERMAL CELL KINETICS. The mitotic rate of germinative basal cells, the desquamation rate of corneocytes, and the generation time of epidermal cells determine the homeostasis of the epidermis (see Chapter 46). Under physiologic conditions, there is a balance among proliferation, differentiation, and desquamation. Enhanced cell proliferation accompanied by an enlargement of the germinative cell pool and increased mitotic rates lead to an increase of the epidermal cell population and thus to a thickening of the epidermis (*acanthosis*) (Fig. 6-2A). A shift in the ratio of resting to proliferating cell as is the case in psoriasis (see Chapter 18) will lead to both an increase in the turnover of the entire epidermis and to a considerable increase of the volume of germinative cells that have to be accommodated at the dermal–epidermal junction. This, in turn, results in a widening and elongation of the rete ridges, which is accompanied by a compensatory elongation of the connective tissue papillae, resulting in an expansion of the dermal–epidermal interface and, consequently, in an increased surface area for dermal–epidermal interactions (see Fig. 6-2).

In contrast to acanthosis is epidermal *atrophy*. Although there are many causes, one primary etiology is a decrease in epidermal proliferative capacity, as may be seen with physiological aging or after the prolonged use of potent topical or systemic steroids. With atrophy, the epidermal rete ridges are initially lost, followed by progressive thinning of the epidermal layer. Depending on the underlying causes and how they affect the keratinocyte differentiation program, there may also be hyperkeratosis or parakeratosis (thickening of the stratum corneum or retention of nuclei into the stratum corneum, respectively). It is likely that many forms of acanthosis and atrophy have primary effects of the homeostasis and function of keratinocyte stem cells, critically important slow-cycling minority populations of epidermal cells that are normally sequestered in the bulge areas of hair follicles and at tips of epidermal rete ridges.

DISTURBANCES OF EPIDERMAL CELL DIFFERENTIATION. A simple example of disturbed epidermal differentiation is parakeratosis, in which

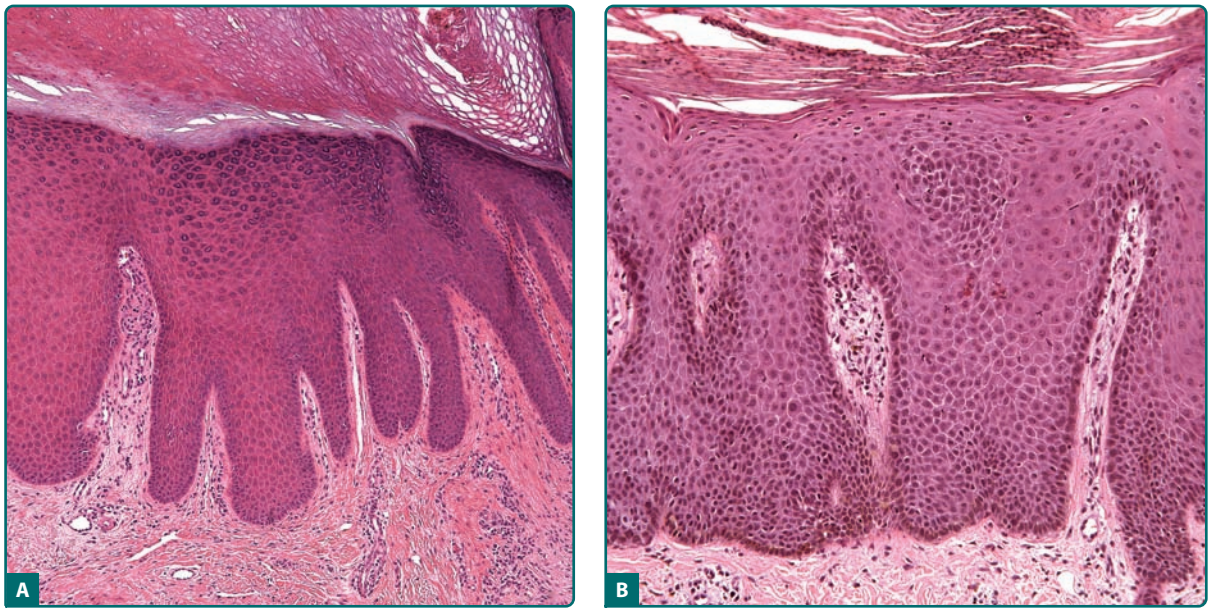

Figure 6-2 **A**. Acanthosis. This sign of increased epidermal kinetics is illustrated in a photomicrograph of psoriasis. **B**. Parakeratosis, the retention of nuclei in the horny layer, is evident.

faulty and accelerated cornification leads to a retention of pyknotic nuclei of epidermal cells at the epidermal surface that is normally formed by anucleate cell remnants that form a "basket-weave" architectural pattern (see Fig. 6-2B). A parakeratotic stratum corneum is not a continuous sheet of cornified cells but a loose structure with gaps between cells; these gaps lead to a loss of the barrier function of the epidermis.

Parakeratosis can be the result of incomplete differentiation in postmitotic germinative cells due to factors that influence the timing and complex integrity of the differentiation program whereby keratin pairs of relatively low molecular weight are progressively assembled as cells approach the epidermal surface. Alternatively, parakeratosis can also be the result of reduced transit time, which does not permit epidermal cells to complete the entire differentiation process, as for example in psoriasis. However, "parakeratosis" of cellophane-stripped epidermis becomes microscopically visible as early as 1 hour after trauma; here, parakeratosis does not represent disturbed differentiation; rather, it results from direct cellular injury to a viable epidermis deprived of its protective horny layer. Therefore, the morphologic term *parakeratosis* may signify a programed disturbance of differentiation and maturation, alterations in cell replication kinetics, or direct cellular injury.

Dyskeratosis represents altered, often premature or abnormal, keratinization, of individual keratinocytes but it also refers to the morphologic presentation of apoptosis of keratinocytes. Dyskeratotic cells have an eosinophilic cytoplasm and a pyknotic nucleus and are packed with keratin filaments arranged in perinuclear aggregates. Such a cell will tend to round up and lose its attachments to the surrounding cells. Therefore, dyskeratosis is often associated with acantholysis (see Section "Disturbances of Epidermal Cohesion") but not vice versa (Fig. 6-3).

In some diseases, dyskeratosis is the expression of a genetically programed disturbance of keratinization as is the case in Darier disease (see Chapter 51). Dyskeratosis may occur in actinic keratosis and squamous cell carcinoma. Dyskeratosis may also be caused by direct physical and chemical injuries. In the sunburn reaction, eosinophilic, apoptotic cells—so-called sunburn cells—are found within the epidermis within the first 24 hours after irradiation with ultraviolet B (UVB) (see Chapter 90), and similar cells may occur after

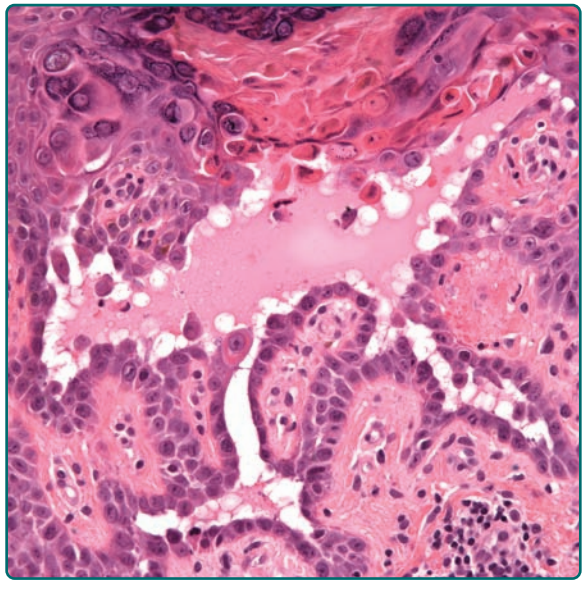

Figure 6-3 The association of dyskeratosis and acantholysis is seen in this high-power view of Darier disease, which also demonstrates the intraepidermal cleft formation resulting from these phenomena.

TABLE 6-1

Classification of Intraepidermal Blisters by Anatomic Level with Clinical Examples

Granular layer
Friction blister
Pemphigus foliaceus
Subcorneal pustular dermatosis
Staphylococcal scalded-skin syndrome/bullous impetigo
Spinous layer
Eczematous dermatitis
Herpes virus infection
Familial benign pemphigus
Suprabasal
Pemphigus vulgaris
Darier disease
Basal layer
Erythema multiforme
Lupus erythematosus
Lichen planus
Epidermolysis bullosa

high-dose systemic cytotoxic treatment. Individual cell death within the epidermis is a regular phenomenon in graft versus host reactions of the skin (see Chapter 28) and in erythema multiforme (see Chapter 39). It is important to remember that although both premature or abnormal keratinization and apoptosis may produce an end product referred to as "dyskeratosis," the early events and mechanisms responsible are different. Whereas cells early in the process of abnormal keratinization often have increased eosinophilic keratin aggregates within their cytoplasm with viable-appearing nuclei, apoptotic cells during early evolutionary stages have shrunken, pyknotic, and sometimes fragmented nuclei in the setting of normal-appearing cytoplasm.

DISTURBANCES OF EPIDERMAL COHESION. Epidermal cohesion is the result of a dynamic equilibrium of forming and dissociating intercellular contacts. Specific intercellular attachment devices (desmosomes) and the related intercellular molecular interactions are responsible for intercellular cohesion. However, epidermal cohesion must permit epidermal cell motion. Desmosomes dissociate and reform at new sites of intercellular contact as cells migrate through the epidermis and keratinocytes mature toward the epidermal surface. Intercellular cohesive forces are strong enough to guarantee the continuity of the epidermis as an uninterrupted epithelium but, on the other hand, are adaptable enough to permit locomotion, permeability of the intercellular space, and intercellular interactions.

The most common result of disturbed epidermal cohesion is the intraepidermal vesicle, a small cavity filled with fluid. A classification of intraepidermal blistering by anatomic level is shown in Table 6-1.

Three basic morphologic patterns of intraepidermal vesicle formation are classically recognized. *Spongiosis* is an example of the *secondary* loss of cohesion between epidermal cells due to the influx of tissue fluid into the epidermis. Serous exudate may extend from the dermis into the intercellular compartment of the epidermis; as it expands, epidermal cells remain in contact with each other only at the sites of desmosomes, acquiring a stellate appearance and giving the epidermis a sponge-like morphology (spongiosis). As the intercellular edema increases, individual cells rupture and lyse, and microcavities (spongiotic vesicles) result (Fig. 6-4). Confluence of such microcavities leads to larger blisters. Epidermal cells may also be separated by leukocytes that disturb intraepidermal coherence; thus, the migration of leukocytes into the epidermis and spongiotic edema are often a combined phenomenon, best illustrated by acute allergic contact

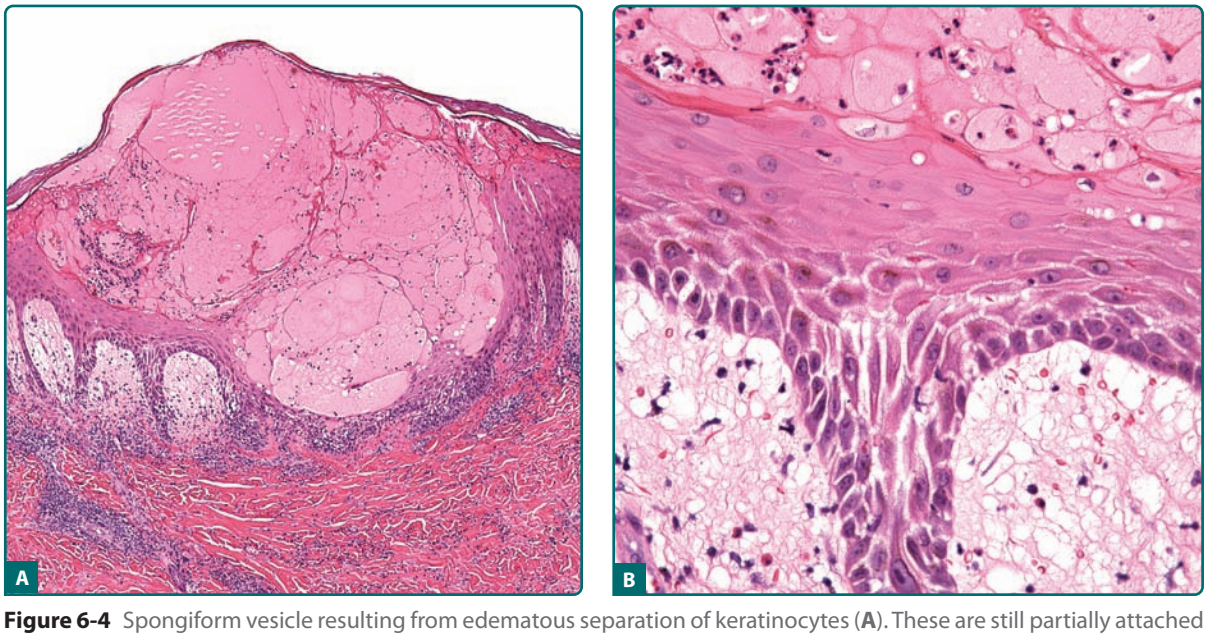

Figure 6-4 Spongiform vesicle resulting from edematous separation of keratinocytes (**A**). These are still partially attached to each other by desmosomes and have thus acquired a stellate appearance as is evident at higher magnification (**B**).

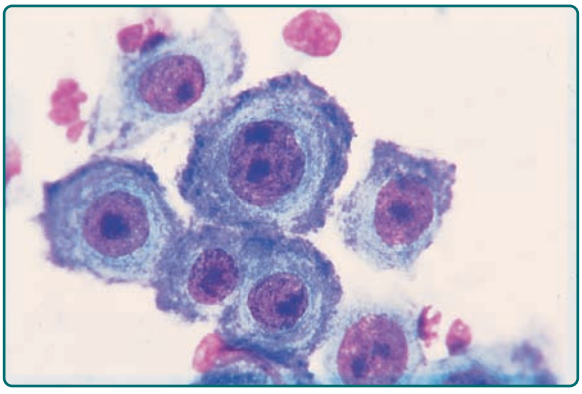

Figure 6-5 Acantholysis. Single as well as clusters of acantholytic cells are seen. The round shapes result from the loss of intercellular connections. Cytologic smear preparation of pemphigus vulgaris.

dermatitis. The accumulation of polymorphonuclear leukocytes within the epidermis, the resulting separation of epidermal cells, and their subsequent destruction by neutrophil-derived enzymes, eventually lead to the formation of a spongiform pustule, one of the histopathologic hallmarks of psoriasis (see Chapter 18).

Acantholysis is a *primary* loss of cohesion of epidermal cells. This is initially characterized by a widening and separation of the interdesmosomal regions of the cell membranes of keratinocytes, followed by splitting and a disappearance of desmosomes (see Chapter 53). The cells are intact but are no longer attached; they revert to their smallest possible surface and round up (Figs. 6-3 and 6-5). Intercellular gaps and slits result, and the influx of fluid from the dermis leads to a cavity, which may form in a suprabasal (Fig. 6-6), midepidermal, or even subcorneal location. Acantholytic cells can easily be demonstrated in cytologic smears (see Fig. 6-5) and in some conditions have diagnostic significance.

Acantholysis occurs in a number of different pathologic processes that do not have a common etiology and pathogenesis. Acantholysis may be a primary event leading to intraepidermal cavitation (primary acantholysis) or a secondary phenomenon in which epidermal cells are shed from the walls of established intraepidermal blisters (secondary acantholysis). Primary acantholysis is a pathogenetically relevant event in diseases of the pemphigus group (see Chapter 54), in which it results from the interaction of autoantibodies and antigenic determinants on the keratinocyte membranes and related desmosomal adhesive proteins, and in the staphylococcal scalded-skin syndrome, where it is caused by a staphylococcal exotoxin (epidermolysin) (see Chapter 177). In familial benign pemphigus, it results from the combination of a genetically determined defect of the keratinocyte cell membrane and exogenous factors (see Chapter 51). A similar phenomenon, albeit more confined to the suprabasal epidermis, occurs in Darier disease, where it is combined with dyskeratosis in the upper epidermal layers (see Fig. 6-3) and a compensatory proliferation of basal cells into the papillary body (see Chapter 51). When acantholysis results from viral infection, it is usually combined with other cellular phenomena such as ballooning, giant cells, and cytolysis (Fig. 6-7; see Chapters 193 and 194).

Indeed, a loss of epidermal cohesion can also result from a primary dissolution of cells (i.e., cytolysis). In the epidermolytic forms of epidermolysis bullosa, genetically defective and thus structurally compromised basal cells rupture as a result of trauma so that the cleft forms through the basal cell layer independently from preexisting anatomic boundaries (see Chapter 62). Cytolytic phenomena in the stratum granulosum are characteristic for epidermolytic hyperkeratosis, bullous congenital ichthyosiform erythroderma, ichthyosis hystrix, and some forms of hereditary palmoplantar keratoderma (see Chapters 49 and 50).

Figure 6-6 Pemphigus vulgaris. An intraepidermal suprabasal cleft is visible that has resulted from suprabasal acantholysis. It contains acantholytic and inflammatory cells.

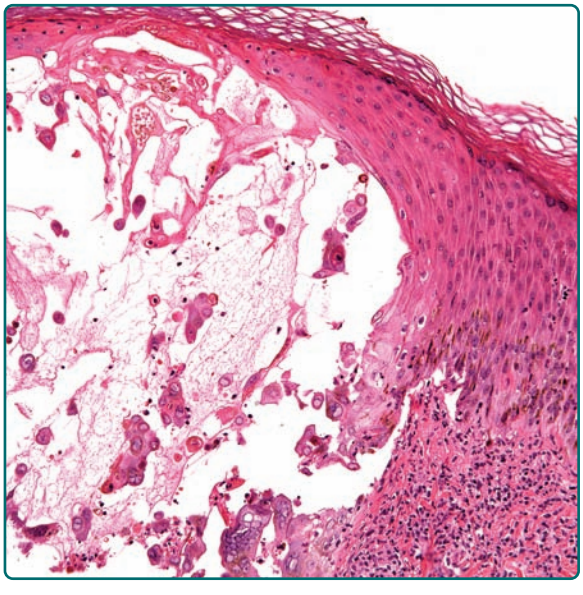

Figure 6-7 Herpes simplex infection. The epidermis shows marked ballooning degeneration, cytolysis, and intraepidermal vesiculation. Acantholytic and multinucleated epidermal giant cells are a clue to herpetic infection.

DERMAL–EPIDERMAL JUNCTION

(See Fig. 6-1, J)

Epidermis and dermis are structurally interlocked by means of the epidermal rete ridges and the corresponding dermal papillae, and foot-like submicroscopic cytoplasmic microprocesses of basal cells that extend into corresponding indentations of the dermis. Dermal–epidermal attachment is enforced by hemidesmosomes that anchor basal cells onto the basal lamina; this, in turn, is attached to the dermis by means of anchoring filaments and microfibrils (see Chapter 53). These structural relationships correlate with complex molecular interactions that serve to bind the epidermis, basement membrane, and superficial dermis in a manner that promotes resistance to potentially life-threatening epidermal detachment. The basal lamina is not a rigid or impermeable structure because leukocytes, Langerhans cells, or other migratory cells pass through it without causing a permanent breach in the junction. After being destroyed by pathologic processes, the basal lamina is reconstituted; this represents an important phenomenon in wound healing and other reparative processes. Functionally, the basal lamina is part of a unit that, by light microscopy, appears as the periodic acid-Schiff–positive "basement membrane" and, in fact, represents the entire junction zone. This consists of the lamina lucida, spanned by microfilaments, and subjacent anchoring fibrils, small collagen fibers, and extracellular matrix (see Chapter 53). The junction zone is a functional complex that is primarily affected in a number of pathologic processes.

DISTURBANCES OF DERMAL–EPIDERMAL COHESION. The destruction of the junction zone or its components usually manifests as disturbance of dermal–epidermal cohesion and leads to blister formation. These blisters appear to be subepidermal by light microscopy (Fig. 6-8), but in reality may be localized at different levels and result from pathogenetically heterogeneous processes. A classification of blisters at the junction by anatomic level is given in Table 6-2. Subepidermal blister formation occurs in forms of epidermolysis bullosa (see Chapter 62) or can be the result of a complex inflammatory process that involves the entire junction zone, as is the case in lupus erythematosus, erythema multiforme, or lichen planus; therefore, it may be a phenomenon occurring in a group of etiologically and pathogenetically heterogeneous conditions. In bullous pemphigoid (see Fig. 6-8), cleft formation runs through the lamina lucida of the basal membrane and is caused by autoantibodies directed against specific antigens on the cytomembrane of basal cells (*junctional blistering*) (see Fig. 6-8A; see Chapter 56). The presence of eosinophil granules that contain major basic protein that is toxic to keratinocytes also causes keratinocyte injury and may present as eosinophilic apongiosis (Fig. 6-8B). Junctional blistering also occurs in the junctional forms of epidermolysis bullosa, but here it is due to the hereditary impairment or absence of molecules important for dermal–epidermal cohesion (see Chapter 62; see Table 6-2).

TABLE 6-2

Classification of Blisters at the Dermal–Epidermal Junction by Anatomic Level with Clinical Examples

Junctional (at the lamina lucida)
Junctional epidermolysis bullosa
Bullous pemphigoid
Dermolytic (below basal lamina)
Epidermolysis bullosa dystrophicans
Epidermolysis bullosa acquisita
Porphyria cutanea tarda
Dermatitis herpetiformis

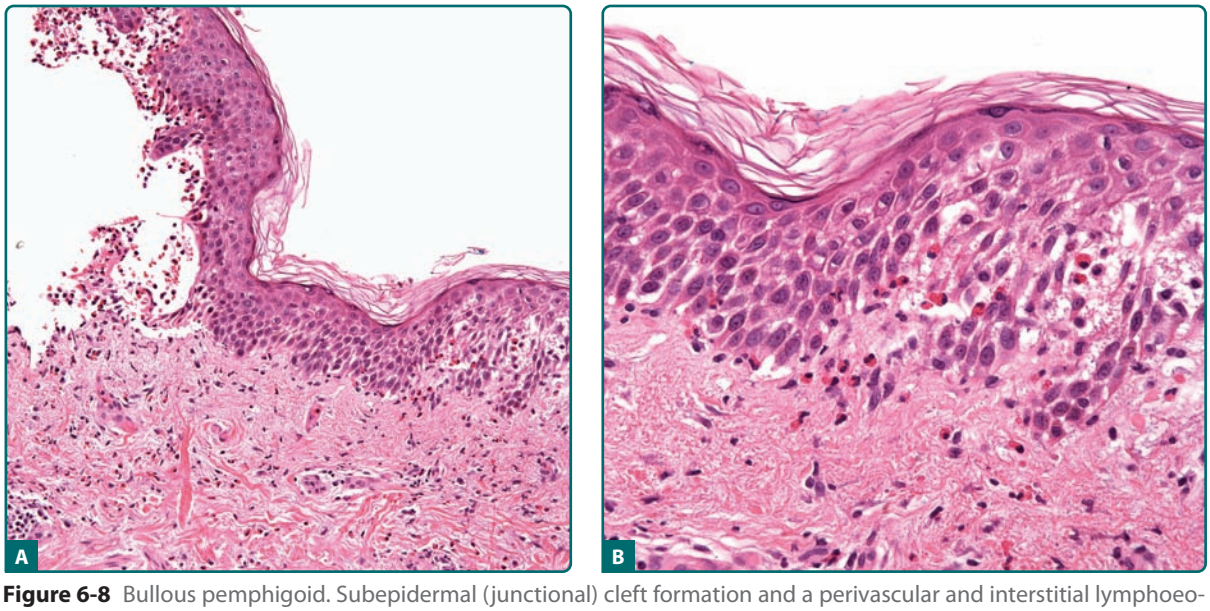

Figure 6-8 Bullous pemphigoid. Subepidermal (junctional) cleft formation and a perivascular and interstitial lymphoeosinophilic infiltrate are characteristic (**A**). Eosinophilic spongiosis can also occur (**B**).

In subepidermal blistering, the target of the pathologic process is below the basal lamina (dermolytic blistering) (see Table 6-2). Reduced anchoring filaments and increased collagenase production result in dermolytic dermal–epidermal separation in recessive epidermolysis bullosa (see Chapter 62); circulating autoantibodies directed against type VII collagen in anchoring fibrils are the cause of dermolytic blistering in acquired epidermolysis bullosa (see Chapter 60). Other immunologically mediated inflammatory mechanisms result in dermolytic blistering in dermatitis herpetiformis (see Chapter 61), and physical and chemical changes in the junction zone and papillary body are the cause for a dermolytic cleft formation after trauma in porphyria cutanea tarda (see Chapter 132).

MOLECULAR AND CELLULAR MECHANISMS FOR REACTION PATTERNS AFFECTING THE SUPERFICIAL REACTIVE UNIT

Although Virchow envisioned what is today known as the superficial reactive unit as a simple layer of cells involved in producing environmentally protective surface keratin, we now realize that this layer is a potent producer of regulatory and stimulatory molecules that, when perturbed, choreograph architectural and cytologic changes that produce the reaction patterns that we equate with specific clinical disorders. Upon immunological stimulation via cytokines with attendant activation of signal transduction pathways, for example, the keratinocyte often acquires an "activated" phenotype whereby the nucleus enlarges, the nucleolus becomes more prominent, and the cell may actually appear atypical. Hyperproliferation frequently accompanies keratinocyte activation, and biosynthetic alterations also may develop, resulting in production of additional factors, such as keratinocyte-derived cytokines, that further fuel the activated phenotype. In such instances, epidermal thickening and increased mitotic activity is evidenced by conventional histology, and Ki-67 staining will disclose evidence of suprabasal cell cycling. It is likely that such activated and hyperproliferative states involve stimulation at the level of the epidermal and follicular stem cell compartments, as is also seen in wound healing responses. In such circumstances, normally quiescent stem cells that are normally sequestered at the tips of epidermal rete ridges and in the bulge regions of hair follicles begin to proliferate and differentiate, further driving the acanthotic epidermal thickening. Alterations in epidermal kinetics are frequently also evidenced by faulty differentiation. Premature differentiation may trigger defective cell adhesion, and hence cells may seem abnormally keratinized (dyskeratotic) as well as separated (acantholytic). Other factors that may perturb adhesion may provide exquisite correlation between the molecular composition of the superficial reactive unit and the morphology of the reaction patterns themselves, as is the case in various forms of pemphigus, where the level of keratinocyte dyshesion and acantholytic blister formation follows precisely the concentration gradients of the targeted adhesive proteins (desmogleins 1 and 3) that assist in binding keratinocytes at the level of the desmosome.

The patterns of cellular inflammation that affect the superficial reactive unit also are dictated at a molecular level. Circulating leukocytes, often T cells, bind the endothelium of postcapillary venules of the superficial vascular plexus upon cytokine-induced endothelial activation (see also dermal reaction patterns in Section "Molecular and Cellular Mechanisms for Reaction Patterns Affecting the Dermis"). This results in expression of endothelial–leukocyte adhesion molecules at the endothelial surface that slows circulating leukocytes to a roll, followed by more secure directed binding and transvascular diapedesis. Cells so extravasated may remain in the perivascular space or migrate upward toward the nearby epidermal layer as a consequence of chemokinetic and chemotactic gradients. Depending on their immunologic mission, the responding leukocytes may either produce cytotoxic injury at the dermal–epidermal interface, or migrate through the basement membrane into the epidermis in the company of transudate that contributes to the intercellular edema that forms the pattern of spongiosis. Thus, depending on the nature of the provocative stimulus as well as the complex downstream molecular events that are set into motion, specific reaction patterns result that, upon recognition, provide key diagnostic information.

PATHOLOGIC REACTIONS OF THE ENTIRE SUPERFICIAL REACTIVE UNIT

(See Fig. 6-1, SRU)

Most pathologic reactions of the superficial skin involve the subunits of the superficial reactive unit jointly and thus include the papillary body of the dermis with the superficial microvascular plexus. This is a highly reactive tissue compartment consisting of capillaries, pre- and postcapillary vessels (see Chapter 162), mast cells, fibroblasts, macrophages, dendritic cells, and peripatetic lymphocytes all embedded in a loose connective tissue and extracellular matrix (Fig. 6-9). The prominence of involvement of one of the components over the others may lead to the development of different clinical pictures. A few examples of such interactions are detailed below.

ALLERGIC CONTACT DERMATITIS. (See Chapter 13.) In allergic contact dermatitis, there is an inflammatory reaction of the papillary body and superficial microvascular plexus and spongiosis of the epidermis (see Fig. 6-4) with signs of cellular injury and parakeratosis. Lymphocytes infiltrate the epidermis early in the process and aggregate around Langerhans cells, and this is followed by spongiotic vesiculation (Fig. 6-10). Parakeratosis develops as a consequence of epidermal injury and proliferative responses, and the inflammation in the papillary body and around the superficial venular plexus stimulates mitotic processes within the epidermis, which, in turn, result in acanthosis and epidermal hyperplasia in chronic lesions.

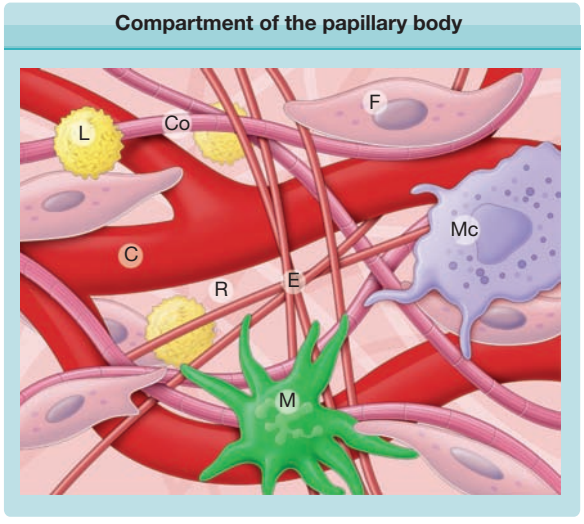

Figure 6-9 The compartment of the papillary body consists of capillaries (C), fibroblasts (F), macrophages and dendritic cells (M), peripatetic lymphocytes (L) and mast cells (Mc), all embedded in a loose connective tissue of extracellular matrix, thin collagen fibers (Co), elastic fibers (E) that are mostly oriented perpendicularly to the skin surface, and branched reticulin fibers (R).

The reaction pattern that involves the superficial vascular plexus of vessels is one of a superficial perivascular lymphocytic infiltrate, often with admixed eosinophils and histiocytes. As noted above, many of these lymphocytes also migrate into the epidermal layer to produce a pattern referred to as *exocytosis*. The superficial perivascular pattern of inflammation is one of a number of inflammatory patterns that may be of assistance at low magnification in generating an initial differential diagnostic algorithm for various types of dermatitis. Pathophysiologically, very early forms of allergic contact dermatitis (e.g., within 24 hours) will exclusively involve perivascular lymphocytes, their influx preceded by mast cell degranulation that releases factors promoting adhesive interactions with superficial dermal endothelium. The epidermal changes follow soon thereafter.

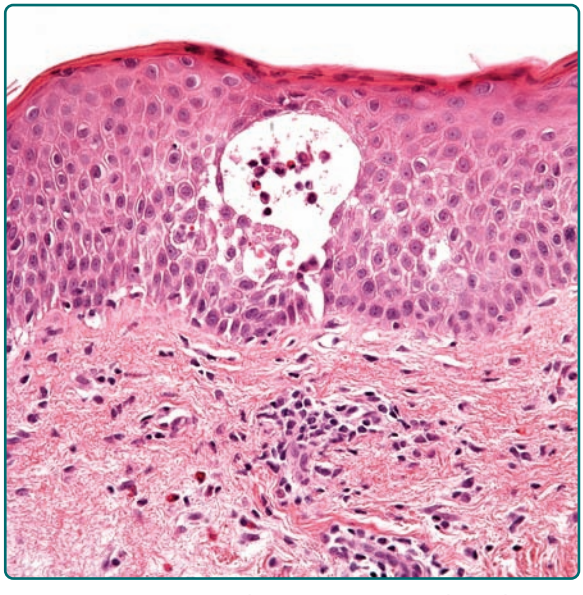

Figure 6-10 Contact dermatitis. Intraepidermal spongiotic vesicles and pronounced intercellular edema are present in the epidermis. The dermis contains perivascular aggregates of lymphocytes and histiocytes admixed with occasional eosinophils.

PSORIASIS. (See Chapter 18.) The initial lesion of psoriatic lesions appears to be the perivascular accumulation of lymphocytes and monocytoid elements within the papillary body and superficial venules and focal migration of leukocytes (often neutrophils, although T cells are integral to pathogenesis as well) into the epidermis. Acanthosis caused by increased epidermal proliferation, elongation of rete ridges sometimes accompanied by an undulant epidermal surface (papillomatosis), and edema of the elongated dermal papillae together with vasodilatation of the capillary loops and a progressive perivascular inflammatory infiltrate develop almost simultaneously (see Fig. 6-2); the disturbed differentiation of the epidermal cells results in parakeratosis, and small aggregates of neutrophils infiltrating the epithelium from tortuous capillaries (squirting capillaries) result in spongiform pustules and, in the parakeratotic stratum corneum, to Munro microabscesses. The stimulus for increased epidermal proliferation follows signals released from T cells that are attracted to the epidermis by the expression of adhesion molecules at the keratinocyte surface and are maintained by cytokines released by keratinocytes (see Chapter 18). Therefore, the composite picture characteristic of psoriasis results from a combined pathology of the papillary body with participation of superficial venules, the epidermis, and circulating cells.

Psoriasis is an instructive example of the limited specificity of histopathologic reaction patterns within the skin because psoriasiform histologic features occur in a number of diseases unrelated to psoriasis.

INTERFACE DERMATITIS. Inflammation along the dermal–epidermal junction associated with vacuolation or destruction of the epidermal basal cell layer characterizes interface dermatitis. This common type of reaction may lead to papules or plaques in some skin diseases and bullae in others.

ERYTHEMA MULTIFORME. (See Chapter 39.) Two types of reactions occur. In both there is interface dermatitis characterized by lymphocytes scattered along a vacuolated dermal–epidermal junction.

LUPUS ERYTHEMATOSUS. (See Chapter 155.) Inflammation, edema, and a lymphocytic infiltrate in the papillary body and superficial venular plexus, as well as in the deeper layers of the dermis, are hallmarks of lupus erythematosus. The main target is the dermal–epidermal junction, where scattered lymphocytes appear and immune complex deposition leads to broadening of the PAS-positive basement membrane zone, accompanied by hydropic degeneration and

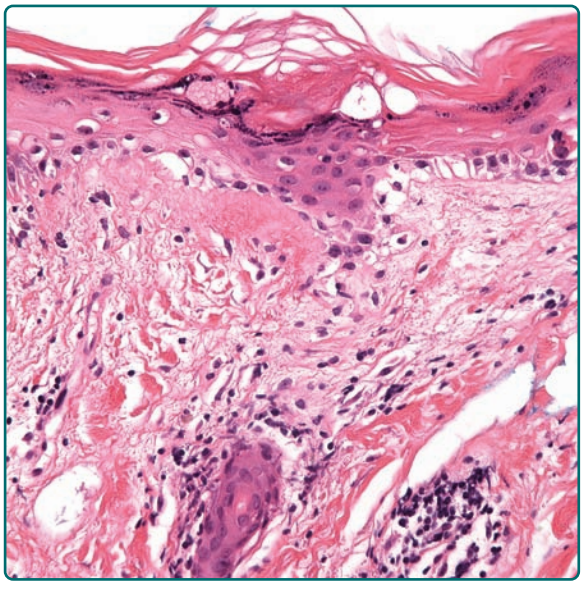

Figure 6-11 Lupus erythematosus. Hyperkeratosis, thinned epidermis devoid of rete ridges, and vacuolization of the basement membrane zone are present.

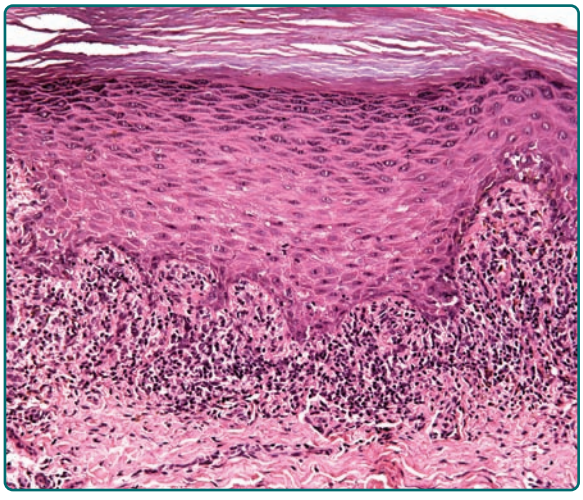

Figure 6-12 Lichen planus. There is hyperkeratosis, wedge-shaped hypergranulosis, basal cell vacuolization, and a lymphocytic infiltrate at the dermal–epidermal junction. This infiltrate "hugs" the basal cell layer and is associated with many cytoid bodies.

destruction of basal cells and progressive atrophy (Fig. 6-11). Cytoid bodies in the form of anucleate keratin aggregates that may undergo amyloid transformation result from apoptosis of individual epidermal cells that are infiltrated and coated by immunoglobulins. The changes in the junctional zone reflect on epidermal differentiation resulting in thickening of stratum corneum (orthokeratosis) and parakeratosis. Lupus erythematosus readily illustrates the heterogeneity, as well as the lack of specificity, of cutaneous reaction patterns: histologically, it is possible to distinguish between acute and chronic lesions but not between cutaneous and systemic lupus erythematosus. In certain chronic, persisting lesions, the changes in the junctional zone initially associated with atrophy secondarily result in hyperplasia, hyperkeratosis, and an increased interdigitation between epidermis and connective tissue, whereas in acute cases, the destruction of the basal cell layer may lead to subepidermal blistering.

LICHEN PLANUS. (See Chapter 26.) This disease also exhibits a primarily junctional reaction pattern with accumulation of a dense lymphocytic infiltrate in the subepidermal tissue and cytoid bodies at the junction (Fig. 6-12). Lymphocytes encroach on the epidermis, destroying the basal cells, but they do not infiltrate the suprabasal layers and blister formation only rarely ensues. These alterations are accompanied by changes of epidermal differentiation—there is a widening of the stratum granulosum (*hypergranulosis*) and hyperkeratosis. Identical changes can be seen in the epidermal type of graft-versus-host disease (see Chapter 28). Current thinking imputes a delayed hypersensitivity reaction to a keratinocyte antigen, the nature of which is unclear. The association of $CD8^+$ lymphocytes in apposition to and even surrounding apoptotic keratinocytes (so-called *satellitosis*) supports this view. The expression of Fas/FasL is also in favor of a role for apoptosis in the pathogenesis of these lesions.

DERMATITIS HERPETIFORMIS. (See Chapter 61.) This condition is usually included among the classic bullous dermatoses; however, it illustrates that the preponderance of one or several pathologic reaction patterns may obscure the true pathogenesis of the condition. The deposition of immunoglobulin A and complement on fibrillar and nonfibrillar sites within the tips of the dermal papillae, and the activation of the alternative pathway of the complement cascade, lead to an influx of leukocytes (primarily neutrophils), which form small abscesses at the tips of the dermal papillae, as well as inflammation and edema (Fig. 6-13). This explains why

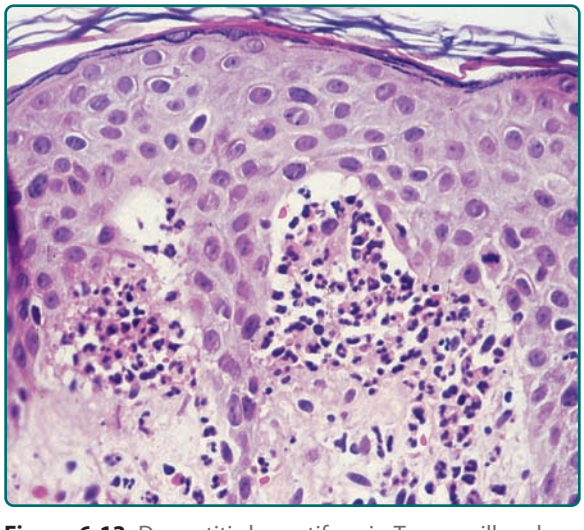

Figure 6-13 Dermatitis herpetiformis. Two papillae show microabscesses composed of neutrophils. Vacuolization and early cleft formation are evident in both papillae.

the primary clinical lesion in dermatitis herpetiformis is urticarial or papular in nature, because only in the case of massive neutrophil infiltration will there be tissue destruction and cleft formation below the lamina densa that results in clinically visible vesiculation.

RETICULAR DERMIS

(See Fig. 6-1, DRU)

The dermis represents a strong fibroelastic tissue with a network of collagen and elastic fibers embedded in an extracellular matrix with a high water-binding capacity (see Chapter 63). In contrast to the tightly interwoven fibrous components of this reticular layer of the dermis (Fig. 6-14), the previously described fibrous texture of the papillary body and the perifollicular and perivascular compartments is loose (see Fig. 6-9), and the orientation of the collagen bundles here follows the structures they surround.

The dermis contains a superficial and deep vascular network. In the upper dermis, the superficial plexus supplies individual vascular districts consisting of several dermal papillae. Superficial and deep networks are connected so intimately that the entire dermal vascular system represents a single three-dimensional unit (see Chapter 162). On the other hand, there are profound functional differences between superficial and deep dermal vascular networks, which explain the differences of homing patterns of inflammatory cells to these sites.

As for the superficial microvascular system, two reaction patterns occur: (1) acute inflammatory processes in which the epidermis and junctional zone are often involved together with the vascular system, and (2) more chronic processes that often remain confined to the perivascular compartment. In this context, it should be noted that the cytologic composition ("acute vs. chronic inflammation") of an inflammatory infiltrate within the skin does not always mirror the temporal characteristics of an inflammatory process. Thus, polymorphonuclear leukocytic infiltrates are not always synonymous with an acute process; conversely, chronic processes are not always represented by a lymphohistiocytic infiltrate.

Inflammation confined to the superficial connective tissue–vascular unit is characterized by endothelial activation, vascular dilatation, increased permeability, edema, a reduction of intravascular blood flow, an accumulation of red blood cells in the capillary loops, and cellular infiltration of the perivascular tissue. Depending on the degree of inflammation, the macroscopic corollary of the histologic changes represents erythematous, urticarial, and infiltrative (papular) lesions. The release of mediators from immunoglobulin E-laden mast cells in type I immune reactions, such as immune forms of urticaria, is histologically manifested primarily as vasodilatation, edema of the papillary body, and a rather sparse infiltrate of leukocytes (neutrophils) and histiocytic elements around the superficial venules (Fig. 6-15). These lesions usually resolve relatively rapidly without any residual pathology. However, more massive reactions lead to a dense perivascular infiltrate (Fig. 6-16A), and this may represent a transition to those processes where edema is less pronounced and where dense lymphocytic infiltrates surround the vessels in a sleeve-like fashion, as is the case in cutaneous drug eruptions (see Figs. 6-16A and 6-16B). More dramatic alterations occur when the vascular system itself is the target of the inflammatory process, resulting in a destruction of at least some of the

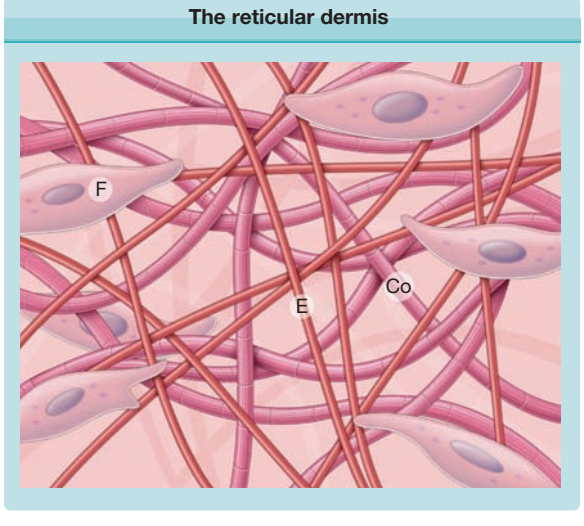

Figure 6-14 The reticular dermis is tightly woven fibroelastic tissue with a network of thick, banded collagen fibers (Co) and elastic (E) fibers embedded in an extracellular matrix. All are produced by fibroblasts (F). This tissue is much denser, relatively acellular, and has fewer capillary vessels than the papillary body (compare with Fig. 6-9).

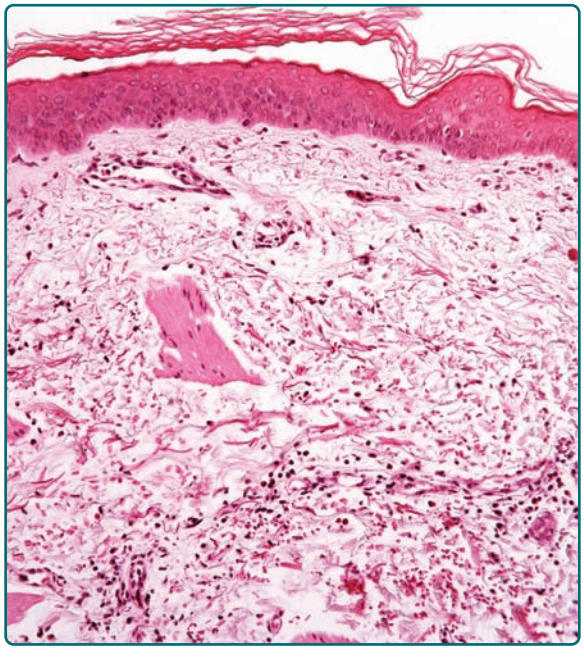

Figure 6-15 Urticaria. Characteristic of this reaction is a sparse, perivascular lymphocytic infiltrate with few eosinophils. Note the slight edema in the dermis and around the postcapillary venules.

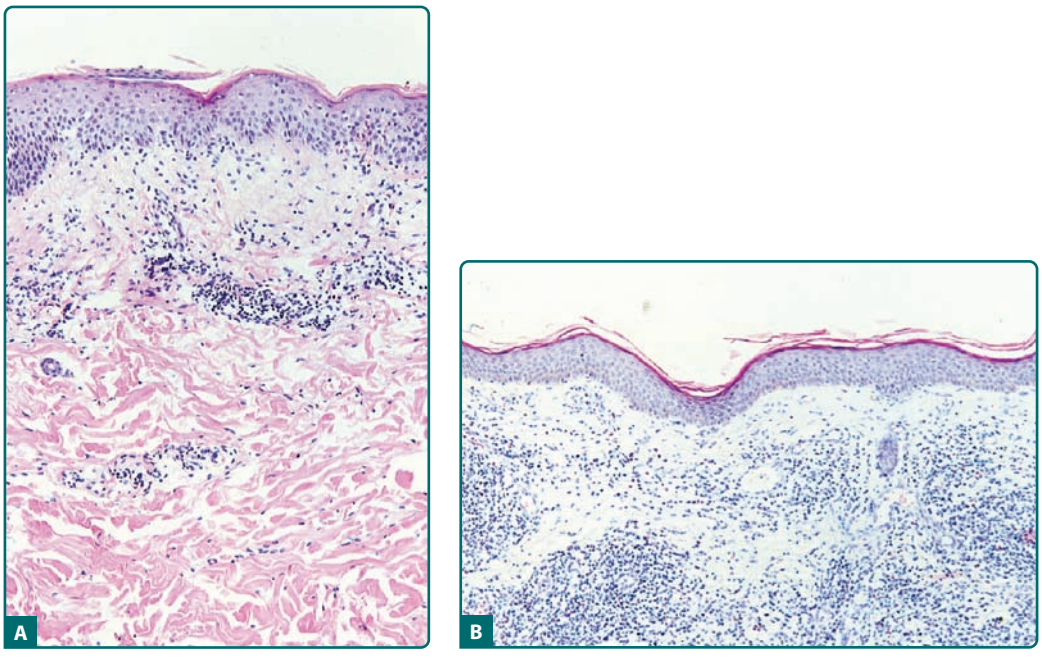

Figure 6-16 Drug eruption. **A.** Throughout the dermis, perivascular sleeves of mononuclear cells, mainly lymphocytes, are present about superficial and deep venules. There is slight edema in the papillary body and minimal interface dermatitis in this reaction to nifedipine. **B.** More pronounced, even nodular, mononuclear cell infiltrates around vessels in a drug reaction to a β blocker.

vessel components, as is the case in necrotizing vasculitis. These exudative changes result in clinical palpable purpura (Fig. 6-17; see Chapter 163).

Chronic inflammatory reactions of the superficial microvascular plexus usually reveal lymphocytic infiltrates in close association with the vascular walls and are clinically manifested as erythema. In purpura simplex (see Chapter 168), damage to the vessel wall is much less evident than in necrotizing vasculitis, but the integrity of the vessels is also impaired, as is evidenced by hemorrhage into the tissue. Lymphocytes and, as a secondary reaction, histiocytic elements partly laden with phagocytosed material including iron, constitute the inflammatory infiltrate.

The reaction patterns described for the vascular system of the papillary body and the superficial venular

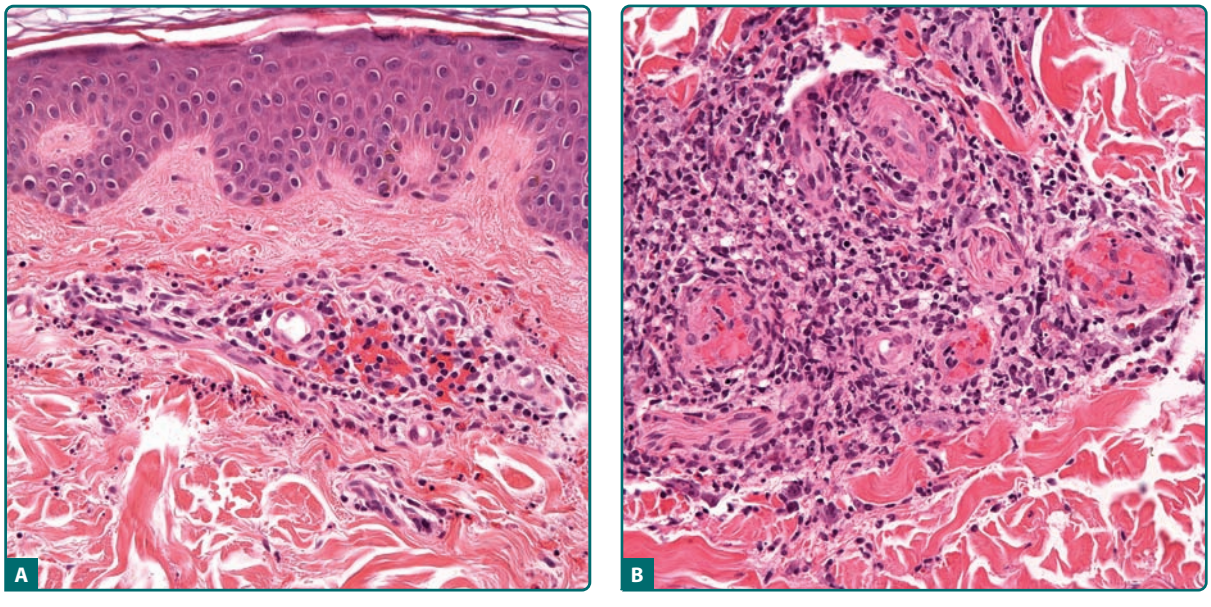

Figure 6-17 Necrotizing vasculitis. An inflammatory infiltrate composed mostly of neutrophils and nuclear dust is present both around and in the wall of a venule where fibrin is also deposited (**A**). More severe reaction with destruction of vessels (**B**).

plexus also occur in the deep dermis, but there are morphologic and functional differences because here larger vessels are involved. Lymphocytic infiltrates surrounding the vessels in a sleeve-like fashion lead to clinical signs only when they are substantial, and then they represent the histopathologic substrate for papular or nodular lesions. This is the case with drug eruptions (see Chapter 41; see Fig. 6-16B) and it is also true for deep-seated infiltrates in lupus erythematosus. In the case of necrotizing vasculitis of the medium-sized and larger vessels, there is usually a much more pronounced inflammatory infiltrate, clinically appearing as papular and nodular lesions, and secondary changes due to the interruption of the vascular flow are more pronounced: necrosis, blistering, and ulceration result as is the case in cutaneous panarteritis nodosa of the macroscopic type (see Chapter 164). In contrast to the macroscopic variant, microscopic polyarteritis nodosa affects vessels of varying sizes including venules and arterioles, involves lungs and kidneys, and is positive for perinuclear neutrophil antibodies. Granulomatous vasculitis also leads to nodular lesions, whereas the hyalinizing vascular changes and vascular occlusion in livedoid vasculitis result in ischemic necrosis (see Chapter 163).

LYMPHOCYTIC INFILTRATES

Although lymphocytic infiltrates occur in the majority of inflammatory dermatoses, there are a number of pathologic processes in which such infiltrates are the most prominent features and thus determine the histologic picture. Lymphocytic infiltrates are formed in inflammatory or proliferative conditions and in the latter may represent a benign or malignant process. They may differ in their cytologic appearance and distribution, may be confined to the periadventitial compartments of the vascular system (superficial and deep perivascular dermatitis), or may occur diffusely throughout the collagenous tissue (diffuse dermatitis). They may be confined almost exclusively to the papillary dermis (interface dermatitis) and spare the subepidermal compartment or may exhibit pronounced epidermotropism. They may be independent of vessels, sparse (interstitial dermatitis) or nodular (nodular dermatitis). Because lymphocytes are a heterogeneous population of cells, the analysis of such infiltrates should take into account not only the cytomorphology and distribution pattern but histochemical properties and immunologic markers as well. The analysis of round cell infiltrates by monoclonal antibodies (immunophenotyping) and determination of their clonality are important aspects of dermatopathology (see Chapter 146).

Among the many possible reaction patterns characterized by lymphocytic infiltrates, several typical patterns can be distinguished.

- Superficial perivascular infiltrates are often accompanied by secondary reactions of the epidermis. Lymphoid cells surround the vascular channels in a sleeve-like fashion but often extend diffusely to the epidermis, which may reveal focal parakeratosis in these areas. Clinically, these changes are often characterized as palpable figurate erythemas such as erythema annulare centrifugum, but polymorphic light eruption, drug eruptions (see Fig. 6-16A), or insect bites can produce a similar histopathologic picture.
- Lymphocytic cuffing of venules without involvement of the papillary body and the epidermis may occur in figurate erythemas and in drug eruptions (see Fig. 6-16B). The infiltrates of chronic lymphocytic leukemia show a similar distribution pattern but are usually more pronounced.
- Perivascular lymphocytic infiltrates with a mucinous infiltration of the nonperivascular connective tissue may be found in lymphocytic infiltration of Jessner–Kanof, reticular erythematous mucinosis or in lupus erythematosus (Fig. 6-18) and dermatomyositis (see Chapters 155 and 156).
- Nodular lymphocytic infiltrates, which extend throughout the dermis exhibiting focal accumulations of histiocytic cells and thus acquiring the appearance of lymphoid follicles, are typical of lymphocytoma cutis (see Chapter 146). Phagocytosed polychrome bodies in histiocytic cells (tingible body macrophages), mitoses in the center of the lymphoid follicles, and an admixture of eosinophils are characteristic features, as is the fact that the papillary body is usually spared so that a conspicuous grenz zone is found between the infiltrate and the epidermis.
- Nonfollicular lymphocytic infiltrates sparing the superficial reactive unit may also occur in benign lymphoid hyperplasias, but in these cases, the differentiation from malignant lymphoma is very difficult. Polymorphic infiltrates showing histiocytes,

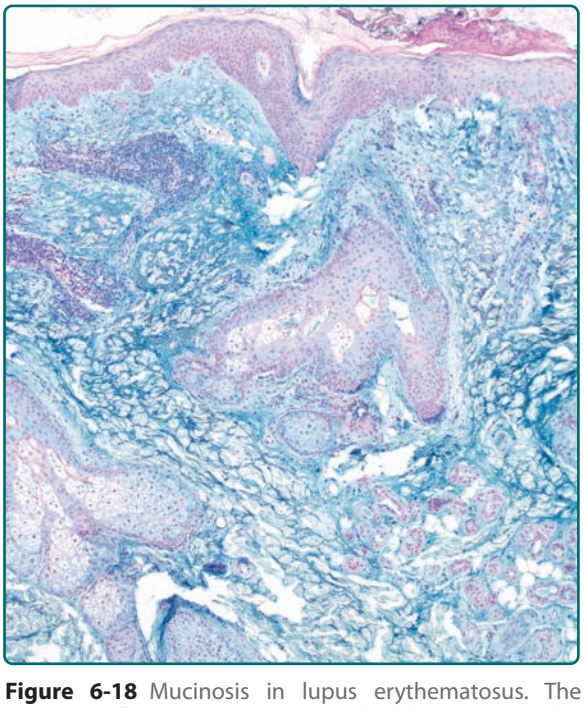

Figure 6-18 Mucinosis in lupus erythematosus. The prominent feature shown here is abundant mucin in the superficial dermis and middermis.

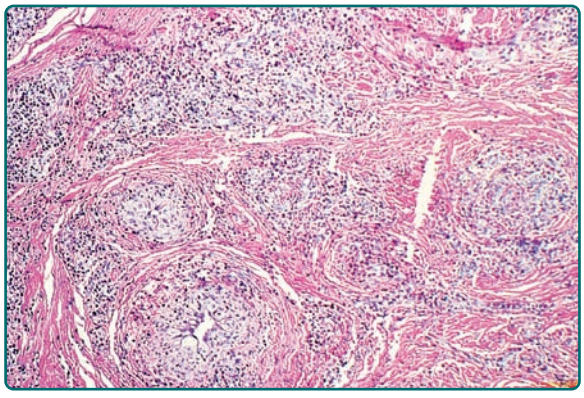

Figure 6-19 Angiolymphoid hyperplasia. Numerous vascular channels are surrounded by aggregates of inflammatory cells made up of lymphocytes and eosinophils. Note the protrusion of endothelial cells into the lamina of these vessels.

plasma cells, and occasional eosinophils are usually benign, whereas most malignant non-Hodgkin lymphomas exhibit a more monomorphous cytologic picture.

- Nodular accumulations of lymphocytes with an admixture of plasma cells and eosinophils accompanied by vascular hyperplasia are characteristic of angiolymphoid hyperplasia (Fig. 6-19), in which blood vessel walls are thickened and the endothelial cells proliferate and become swollen, and enlarged.
- Atypical lymphocytic infiltrates involving both the superficial and deeper dermis, and cytologically characterized by pronounced pleomorphism of the cellular infiltrate, are characteristic of lymphomatoid papulosis, one of the spectrum of $CD30^+$ lymphoproliferative disorders (see Chapter 145). This condition exemplifies the problems that arise when the histopathology of a lesion is used alone to determine whether a process is benign or malignant. Without knowledge of the clinical features and the course of disease, a definite diagnosis is extremely difficult.

POLYMORPHONUCLEAR LEUKOCYTIC INFILTRATES

Although neutrophils are the classic inflammatory cells of acute bacterial infections, there are diseases in which neutrophils dominate the histopathology, even in the absence of a bacterial cause. In pyoderma gangrenosum, massive neutrophilic infiltration of the dermis leads to sterile abscesses, breakdown of the tissue, and ulceration (see Chapter 33). In dermatitis herpetiformis, neutrophils accumulate in the tips of dermal papillae and form papillary abscesses (see Fig. 6-13) that precede the dermolytic blister formation described in Section "Disturbances of Dermal–Epidermal Cohesion" (see also Chapter 61). In erythema elevatum diutinum, neutrophils are the predominant cells centering around superficial and middermal vessels, which exhibit fibrinoid homogenization of their walls (toxic hyalin) and signs of vasculitis (see Chapter 163). The neutrophil is also the predominant cell in the early stages of the more common necrotizing vasculitis (see Fig. 6-17). Neutrophils also represent the majority of the often massive inflammatory infiltrate in acute febrile neutrophilic dermatosis, which is accompanied by pronounced subepidermal edema (see Chapter 32).

GRANULOMATOUS REACTIONS

Skin is an ideal tissue for granuloma formation in which histiocytes play a key role. Although these cells are involved at one time or another in practically all inflammatory processes, it is only the proliferation and focal aggregation of histiocytic cells that may be termed a *granuloma*. When such cells are closely clustered they resemble epithelial tissue, hence the designation *epithelioid cells*. Development of giant cells, storage of phagocytosed material, and the admixture of inflammatory cells, such as lymphocytes, plasma cells, and eosinophils, may render the histologic picture of a granulomatous reaction more complex. To these have to be added vascular changes and alterations in the fibrous structure of the connective tissue. Granulomas almost always lead to destruction of preexisting tissue, particularly elastic fibers, and in such instances result in atrophy, fibrosis, or scarring. Tissue damage or destruction manifests either as necrobiosis or fibrinoid or caseous necrosis, or it may result from liquefaction and abscess formation or from replacement of preexisting tissue by fibrohistiocytic infiltrate and fibrosis.

Sarcoidal granulomas (see Chapter 152) are typically characterized by naked nodules consisting of epithelioid cells, occasional Langerhans giant cells, and only a small number of lymphocytes (Fig. 6-20). Silica, zirconium, and beryllium granulomas and a number of foreign-body granulomas may have such histopathologic features.

Granulomatous reactions of the skin comprise a large spectrum of histopathologic features. Palisading granulomas surround necrobiotic areas of the

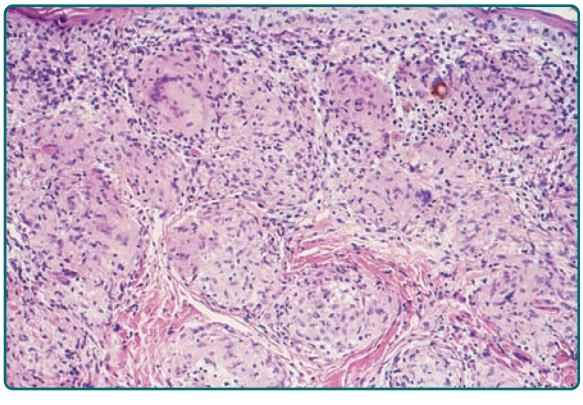

Figure 6-20 Sarcoidal granuloma. In the dermis, numerous "naked" tubercles consisting of epithelioid cells and scant lymphocytes are seen. The overlying epidermis is atrophic.

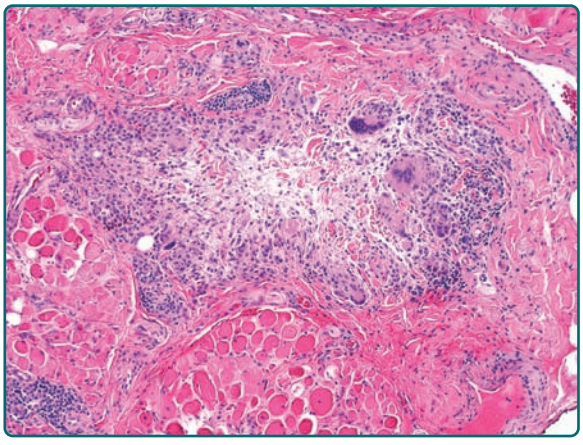

Figure 6-21 Granuloma annulare. A well-circumscribed palisading granuloma is seen in the dermis. Necrobiotic collagen is surrounded by histiocytes, lymphocytes, and a few scattered multinucleated giant cells.

connective tissue with histiocytes in radial alignment (Fig. 6-21). Granuloma annulare, necrobiosis lipoidica, rheumatoid nodules, and the juxtaarticular nodules of syphilis belong to this group. These reactions may have significance as signs of systemic disease. For example, when there are prominent neutrophils in the necrobiotic area of granuloma annulare or necrobiosis, one may suspect an associated inflammatory bowel disease. Endocrinopathies can also be associated with these disorders, diabetes mellitus is a classic example associated with necrobiosis lipoidica. Of course, rheumatoid nodules can be associated with rheumatoid arthritis but can also occur as a result of trauma in some cutaneous locations. Drugs may also cause these reactions.

Infectious granulomas with a sarcoidal appearance may occur in tuberculosis, syphilis, leishmaniasis, leprosy, or fungal infections. Necrosis can also develop within the granuloma proper, as is the case for fibrinoid necrosis in sarcoidosis, caseation in tuberculosis, or the necrosis developing in mycotic granulomas. Many of the infectious granulomas are associated with epidermal hyperplasia, often exhibiting intraepidermal abscesses in which the causative organism can be found, often in a multinucleate giant cell. In the dermis there is a mixture of cells, including histiocytes, epithelioid cells, eosinophils, neutrophils, and lymphocytes.

It is often difficult to classify granulomatous reactions within the skin by histopathology alone, for even completely different etiologic conditions such as immunopathies and some forms of vasculitis are associated with the development of granulomas.

A specific form of granulomatous reaction results when the cellular infiltrate consists almost exclusively of the key granuloma cell, the *histiocyte*. One property of this cell is its capacity to store phagocytosed material. In xanthomatous reaction patterns, histiocytes take up and store fat and are thus transformed into foam cells. They are distributed either diffusely, as is the case in diffuse normolipemic xanthomatosis, or as an aggregate infiltrate mimicking a tumor, as in the xanthomas occurring in the hyperlipoproteinemias and xanthelasma (see Chapter 135).

FIBROUS DERMIS AND EXTRACELLULAR MATRIX

(See Fig. 6-1, DRU)

Sclerosing processes of the skin involve mainly the connective tissue of the dermis (see Figs. 6-1, DRU, and 6-14) but usually reflect dynamic changes of structure and function that involve practically all compartments of this organ. The hallmark of scleroderma (see Chapter 157) is the homogenization, thickening, and dense packing of the collagen bundles, a narrowing of the interfascicular clefts within the reticular dermis, and the disappearance of the boundary between this portion of the dermis and the papillary body. There is also a diminution of the small papillary and subpapillary vessels, which appear narrowed, and, in the early stages, a perivascular lymphocytic infiltrate and edema. The impressive thickening of the dermis not only results from an increase of its fibrous components, but is also caused by the fibrosis of the superficial layers of the subcutaneous fat that follows lymphocytic infiltration and a histiocytic reaction.

Sclerodermoid changes may be found in the toxic oil syndrome and l-tryptophan disease, eosinophilic fasciitis (see Chapter 36), and mixed connective tissue disease; they also occur in pachydermoperiostosis, where an increase of fibroblasts and ground substance accompany the sclerotic changes, and in porphyria cutanea tarda, which shows typical hyalinization of the papillary vessels. In lichen sclerosus, there is a massive edema of the papillary body and a dense lymphocytic infiltrate that initially hugs the epidermis and later separates the edematous papillary body from the reticular dermis (see Chapter 65). As sclerosis sets in, there is also a disappearance of elastic tissue from the papillary body; the concomitant involvement of the epidermis includes hydropic degeneration of basal cells, atrophy, and, at the same time, hyperkeratosis. Changes in the junctional zone in this condition may occasionally lead to a separation of the epidermis from the dermis and thus to blister formation.

Faulty synthesis or cross-linking of collagen results in a number of well-defined diseases or syndromes but leads to relatively few characteristic histopathologic changes. In the different types of the Ehlers–Danlos syndrome (see Chapter 137), the faulty collagen cannot be recognized histopathologically, and only the relative increase of elastic tissue may indicate that something abnormal has occurred in the dermis. In generalized elastolysis, a fragmentation of elastic fibers is the histopathologic substrate of the clinical appearance of cutis laxa, and the fragmentation and curled and clumped appearance of elastic fibers are similarly diagnostic in pseudoxanthoma elasticum (see Chapter 137). On the other hand, in actinic elastosis, the histologic correlate of dermatoheliosis, all components of the superficial connective tissue are involved (see Chapter 109). Except for a narrow grenz zone below the epidermis, the papillary body, and the superficial layers of the

reticular dermis are filled with clumped and curled fibers that progressively become homogenized and basophilic. They are stained by dyes that have an affinity for elastic tissue and thus histochemically behave similar to elastic fibers.

Such profound changes of dermal architecture become clinically apparent: the taut and firm connective tissue in scleroderma reflects the sclerotic texture and homogenization of the collagen bundles seen histologically; the loose folds of cutis laxa are a result of the fragmentation of elastic fibers; the cobblestone-like papules in pseudoxanthoma elasticum correspond to the focal aggregation of the pathologically altered elastic material; and the coarseness of skin lines and surface profile in dermatoheliosis are the clinical manifestations of the focal aggregation of elastotic material.

MOLECULAR AND CELLULAR MECHANISMS FOR REACTION PATTERNS AFFECTING THE DERMIS

The reaction patterns that affect the dermis take the forms of cellular infiltrations as well as acellular patterns that primarily are based in the extracellular matrix. However, these two general categories are difficult to separate, as there is constant interplay between the cellular and acellular components of the dermis. As discussed above, the vascular plexuses in the dermis are the primary conduits for influx of cellular elements, and leukocyte–endothelial adhesion molecule expression play a critical role in regulating leukocyte entry and the reaction patterns that result. The adhesive molecules themselves assist in regulating the relative strength and kinetics of the influx of various cell types, and hence some stimuli may provoke an adhesion cascade that favors entry of neutrophils or eosinophils, whereas others may result in infiltration of primarily mononuclear cells. Moreover, once inflammatory cells have extravasated into the dermal interstitium, their migratory fate and secondary morphological alterations are also in large part determined by molecular cues in their new microenvironment. Hence, an encounter with insect bite venom may provoke interstitial accumulation of histiocytes and eosinophils, and perhaps poorly formed granulomas, whereas an immune response in the setting of Lyme disease may provoke intensely perivascular localization of lymphocytes conjuring up the appearance of a "coat-sleeve." Mediators released by cellular infiltrates may have a profound effect on the extracellular matrix as well, resulting in additional dermal reaction patterns. For example, fibrogenic mediators such as TGFβ, may have a variety of effects on dermal homeostasis, including fibroblast transformation in the direction of myofibroblasts, with attendant collagen synthesis as might be seen as a normal response to wounding, but in this setting resulting in the diffuse dermal thickening that correlates with the reaction pattern typical of morphea scleroderma.

SUBCUTANEOUS FAT

(See Fig. 6-1, S)

Inflammatory processes in the subcutaneous adipose tissue take a slightly different course than in the connective tissue of the dermis because of the specific anatomy of the subcutis (see Chapters 7 and 70). Inflammation of subcutaneous fat reflects either an inflammatory process of the adipose tissue proper or the fat lobules (see Fig. 6-1, L) or a process arising in the septa (see Fig. 6-1, Sep); it can involve small venules and capillaries or arise from the larger muscular vessels. The histopathologic manifestations may vary accordingly. Small-vessel pathology is usually manifested locally, involving the neighboring fat lobules, whereas the destruction or occlusion of a larger vessel influences the entire tissue segment. Destruction of fat, be it of a traumatic or inflammatory nature, leads to the release of fatty acids that by themselves are strong inflammatory stimuli, attracting neutrophils and scavenger histiocytes and macrophages; phagocytosis of destroyed fat usually results in lipogranuloma formation.

Septal processes that follow inflammatory changes of the trabecular vessels are usually accompanied by edema, infiltration of inflammatory cells, and a histiocytic reaction. This is the classic appearance in erythema nodosum (Fig. 6-22; see Chapter 70). Recurring septal inflammation may lead to a broadening of the interlobular septa, fibrosis, the accumulation of histiocytes and giant cells, and may result in vascular proliferation. By contrast, in nodular vasculitis (Fig. 6-23), large-vessel vasculitis in the septal area is accompanied by necrosis of the fat, followed by histiocytic reactions, epithelioid cell granulomas within the fat lobules, and a fibrotic reaction sclerosing the entire subcutaneous fat. On the other hand, lobular panniculitis results from the necrosis of fat lobules as the primary event, as is the case in idiopathic nodular panniculitis (see Chapter 70), followed by an accumulation of neutrophils and leukocytoclasia. The lipid material

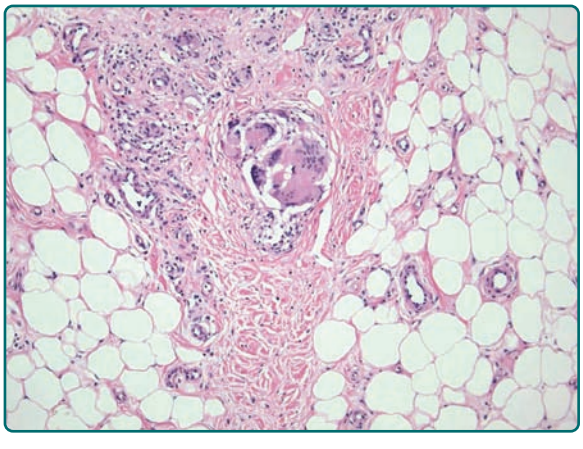

Figure 6-22 Erythema nodosum. A chronic granulomatous inflammatory infiltrate with giant cells extends along the thickened septum into the adjacent fat lobule.

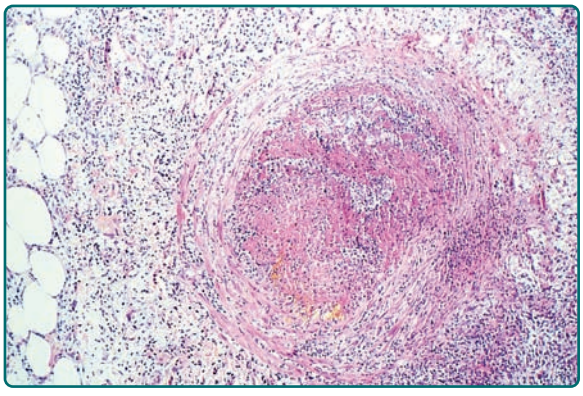

Figure 6-23 Nodular vasculitis. The characteristic features illustrated are severe vasculitis with necrosis of the large vessel wall and occlusion of the lumen. Necrosis of the fat lobules is present, as well as an acute and chronic inflammatory cell infiltrate.

derived from necrotic adipocytes contains free and esterified cholesterol, neutral fats, soaps, and free fatty acids, which, in turn, exert an inflammatory stimulus. Histiocytic cells migrate into the inflamed fat, and phagocytosis leads to foam cell formation. Epithelioid granulomas with giant cells may also result, and all types of fibrosis may develop. Therefore, fat necrosis is the primary, and inflammation the secondary, event in this type of panniculitis.

The inherent capacity of the adipose tissue to respond to pathologic stimuli also holds true for disease conditions that affect the subcutaneous tissue only secondarily or result from exogenous factors. Traumatic panniculitis leads to necrosis of fat lobules and a reactive inflammatory and granulomatous tissue response. After the injection of oils or silicone, large cystic cavities may be formed, whereas after the injection of pentazocine, for instance, fibrosis and sclerosis dominate the histopathologic picture. Oily substances may remain within the adipose tissue for long periods without causing a significant tissue reaction; oil cysts evolve that are surrounded by multiple layers of residual connective tissue, so that the tissue acquires a "Swiss cheese" appearance. Animal or vegetable oils often lead to tuberculoid or lipophagic granulomas with massive histiocytic reactions, foam cells, and secondary fibrosis.

Panniculitis also occurs as a result of infectious agents (cocci, mycobacteria, and other bacterial and fungal organisms) or a specific disease process. In sarcoidosis, fat is gradually replaced by epithelioid cell nodules and, in lymphoma, by specific lymphomatous infiltrates. In lupus panniculitis, a dense lymphocytic infiltrate of the septal and lobular tissue determines the histopathologic picture, as does involvement of vessels manifesting as vasculitis. However, destruction of fat, liquefaction, and lipogranuloma may be so pronounced that the vascular component can hardly be recognized, and the histopathologic picture may resemble idiopathic nodular panniculitis.

MOLECULAR AND CELLULAR MECHANISMS FOR REACTION PATTERNS AFFECTING THE SUBCUTIS

We are in the infancy of understanding the molecular underpinnings of various reaction patterns in the subcutis. This is in part because our understanding of the normal physiology of subcutaneous fat has only recently moved past the historical notion of energy storage. We now know that the subcutis is a potent source of stem cells that have remarkable differentiation plasticity and thus implications for use in regenerative medicine. The fat lobule itself is much more that an energy storage site; it also generates a variety of proinflammatory and thrombogenic cytokines that, as is the case with epidermally derived cytokines, are likely to play a key role in regulating the various reaction patterns to which fat is heir. Moreover, given its location deep to the dermal–epidermal environmental interface, the subcutaneous fat has the spatial attributes to serve as a barometer for systemic molecular cues that may herald generalized disease. Finally, perturbation in the fat producing specific reaction patterns in association with aberrant cytokine production may themselves contribute to systemic health and disease, as is currently speculated with regard to proinflammatory mediators produced in the subcutis that may contribute to the evolution of some forms of cardiovascular disease.

SECTION 3

Overview of Biology, Development, and Structure of Skin

Chapter 7 :: Development and Structure of Skin

:: David H. Chu

STRUCTURE AND FUNCTION OF SKIN AT A GLANCE

- Three major layers—epidermis, dermis, hypodermis:
  - Epidermis: major permeability barrier, innate immune function, adhesion, and ultraviolet protection.
  - Dermis: major structural element, three types of components—cellular, fibrous matrix, and diffuse and filamentous matrix. Also site of vascular, lymphatic, and nerve networks.
  - Hypodermis (subcutis): insulation, mechanical integrity, containing the larger source vessels and nerves.

SKIN: AN OVERVIEW

Skin is a complex organ that protects its host from its environment, at the same time allowing interaction with its environment. It is much more than a static, impenetrable shield against external insults. Rather, skin is a dynamic, complex, integrated arrangement of cells, tissues, and matrix elements that mediates a diverse array of functions: skin provides a physical permeability barrier, protection from infectious agents, thermoregulation, sensation, ultraviolet (UV) protection, wound repair and regeneration, and outward physical appearance (Table 7-1). These various functions of skin are mediated by one or more of its major regions—the epidermis, dermis, and hypodermis (Fig. 7-1; see also Fig. 6-1, Chapter 6). These divisions are interdependent, functional units; each region of skin relies upon, and is connected with, its surrounding tissue for regulation and modulation of normal structure and function at molecular, cellular, and tissue levels of organization (see Chapter 6).

Whereas the epidermis and its outer stratum corneum provide a large part of the physical barrier provided by skin, the structural integrity of skin as a whole is provided primarily by the dermis and hypodermis. Antimicrobial activities are provided by the innate immune system and antigen-presenting dendritic cells of the epidermis, circulating immune cells that migrate from the dermis, and antigen-presenting cells of the dermis (see Chapter 10). Protection from UV irradiation is provided in great measure by the most superficial cells of the epidermis. Inflammation begins with the keratinocytes of the epidermis or immune cells of the dermis, and sensory apparatus emanates from nerves that initially traverse the hypodermis to the dermis and epidermis, ending in specialized receptive organs or free nerve endings. The largest blood vessels of the skin are found in the hypodermis, which serve to transport nutrients and immigrant cells (see Fig. 6-1, Chapter 6). The cutaneous lymphatics course through the dermis and hypodermis, serving to filter debris and regulate tissue hydration. Epidermal appendages provide special protective or sensory functions. Skin also determines a person's physical appearance, influenced by pigmentation provided by melanocytes, with body contours, appearance of age, and actinic damage influenced by the epidermis, dermis, and hypodermis. The skin begins to be organized during embryogenesis, where intercellular and intracellular signals, as well as reciprocal cross talk between different tissue layers, are instrumental in regulating the eventual maturation of the different components of skin.

What follows is an integrated description of the major structural features of the skin and how these structures allow the skin to achieve its major functions, followed by a review of their embryologic origins. Also highlighted are illustrative cutaneous diseases that manifest when these functions are defective. Understanding the genetic and molecular bases of skin disease has confirmed, and in some cases revealed, the many factors and regulatory elements that play critical roles in skin function.

EPIDERMIS

One of the most fundamental and visible features of skin is the stratified, cornified epidermis (Fig. 7-2). The epidermis is a continually renewing structure that gives rise to derivative structures called append-

TABLE 7-1
Functions of Skin

Function	Tissue Layer	Some Associated Diseases

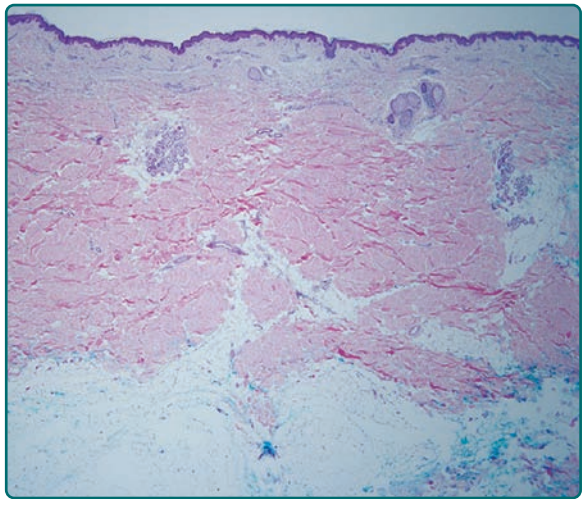

Figure 7-1 The major regions of skin. Skin is composed of three layers: (1) epidermis, (2) dermis, and (3) hypodermis. The outermost epidermis is separated from the dermis by a basement membrane zone, the dermal–epidermal junction. Below the dermis lies the subcutaneous fat (hypodermis). Epidermal appendages, such as hair follicles and eccrine and apocrine sweat glands, begin in the epidermis but course through the dermis and/or the epidermis. Blood vessels, lymphatics, and nerves course through the subcutaneous fat and emerge into the dermis.

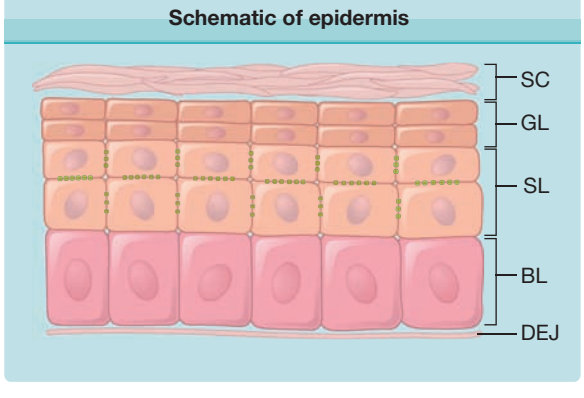

Figure 7-2 Schematic of epidermis. The epidermis is a stratified, cornified epithelium. The deepest layer consists of basal cells (BL) that rest upon the basement membrane of the dermal–epidermal junction (DEJ). These cells differentiate into the cells of the spinous layer (SL), characterized by abundant desmosomal spines. Spinous cells eventually become granular layer cells (GL), producing many of the components of the cornified envelope. Ultimately, the terminally differentiated keratinocytes shed their nuclei and become the stratum corneum (SC), a cross-linked network of protein and glycolipids.

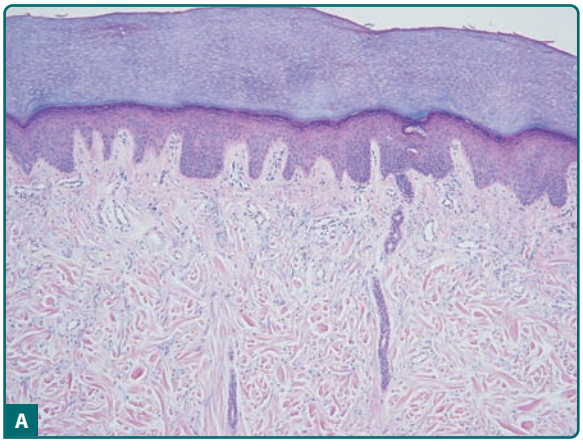
ages (pilosebaceous units, nails, and sweat glands). The epidermis ranges in thickness from 0.4 to 1.5 mm, as compared with the 1.5- to 4.0-mm full-thickness skin. The majority of cells in the epidermis are keratinocytes that are organized into four layers, named for either their position or a structural property of the cells. These cells progressively differentiate from proliferative basal cells, attached to the epidermal basement membrane, to the terminally differentiated, keratinized stratum corneum, the outermost layer and barrier of skin (see Chapter 46). Intercalated among the keratinocytes at various levels are the immigrant resident cells—melanocytes, Langerhans cells, and Merkel cells. Other cells, such as lymphocytes, are transient inhabitants of the epidermis and are extremely sparse in normal skin. There are many regional differences in the epidermis and its appendages. Some of these differences are apparent grossly, such as thickness (e.g., palmoplantar skin vs. truncal skin, Fig. 7-3); other differences are microscopic.

Pathologic changes in the epidermis can occur as a result of a number of different stimuli: repetitive mechanical trauma (as in lichen simplex chronicus), inflammation (as in atopic dermatitis and lichen planus), infection (as in verruca vulgaris), immune system activity and cytokine abnormalities (as in psoriasis, Fig. 7-4), autoantibodies (as in pemphigus vulgaris and bullous pemphigoid), or genetic defects that influence differentiation or structural proteins [as in epidermolysis bullosa (EB) simplex, epidermolytic ichthyosis and other ichthyoses, and Darier disease].



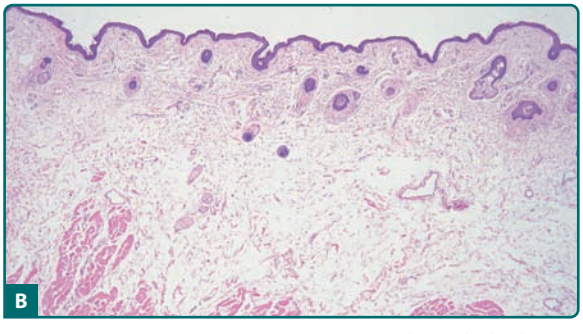


Figure 7-3 Anatomic variation in epidermal thickness. **A.** Acral skin. **B.** Eyelid skin. Note that the epidermis is considerably thicker in (**A**) than (**B**), including the compact layers of the stratum corneum, as well as the deeper epidermal layers.

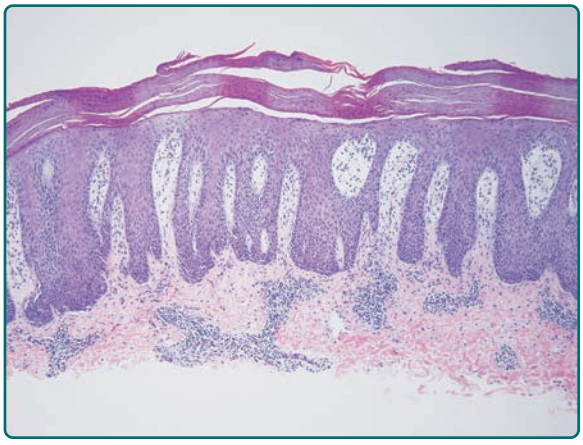

Figure 7-4 Epidermal hyperplasia. Hyperproliferation of the epidermis can occur due to a number of causes, as manifested in diseases such as psoriasis (pictured), as well as lichen simplex chronicus, atopic dermatitis, lichen planus, and verruca vulgaris.

LAYERS OF THE EPIDERMIS

BASAL LAYER. The keratinocyte is an ectodermally derived cell and is the primary cell type in the epidermis, accounting for at least 80% of the total cells. The ultimate fate of these cells is to contribute the components for the epidermal barrier as the stratum corneum. Thus, much of the function of the epidermis can be gleaned from the study of the structure and development of the keratinocyte.

Keratinocyte differentiation (keratinization) is a genetically programed, carefully regulated, complex series of morphologic changes and metabolic events whose endpoint is a terminally differentiated, dead keratinocyte (corneocyte) that contains keratin filaments, matrix protein, and a protein-reinforced plasma membrane with surface-associated lipids (see Chapter 46).

Keratins are a family of intermediate filaments and are the hallmark of all epithelial cells, including keratinocytes.[1,2] They serve a predominantly structural role in the cells. Fifty-four different functional keratin genes have been identified in humans—34 epithelial keratins and 17 hair keratins.[3] The coexpression of specific keratin pairs is dependent on cell type, tissue type, developmental stage, differentiation stage, and disease condition (Table 7-2). Furthermore, the critical role of these molecules is underscored by the numerous manifestations of disease that arise because of mutations in these genes (see Table 7-2). Thus, knowledge of keratin expression, regulation, and structure provides insight into epidermal differentiation and structure.

The basal layer (stratum germinativum) contains mitotically active, columnar-shaped keratinocytes that attach via keratin filaments (K5 and K14) to the basement membrane zone at hemidesmosomes (see Chapter 53), attach to other surrounding cells through

TABLE 7-2
Expression Patterns of Keratin Genes and Keratin-Associated Diseases

Basic	Acidic	Tissue Expression	Disease Association
1	10	Suprabasal keratinocytes	Epidermolytic ichthyosis; diffuse nonepidermolytic PPK (keratin 1)
1	9	Suprabasal keratinocytes (palmoplantar skin)	Epidermolytic PPK (epidermolytic hyperkeratosis)

8	18	Simple epithelium	Cryptogenic cirrhosis

PPK = palmoplantar keratoderma.

desmosomes, and that give rise to cells of the more superficial, differentiated epidermal layers. Membrane-bound vacuoles that contain pigmented melanosomes are transferred from melanocytes by phagocytosis.[4] The pigment within melanosomes contributes to the overall skin pigmentation perceived macroscopically.[5] The basal layer is the primary location of mitotically active cells of the epidermis. Cell kinetic studies suggest that the basal layer cells exhibit different proliferative potentials (stem cells, transit amplifying cells, and postmitotic cells), and in vivo and in vitro studies suggest that there exist long-lived epidermal stem cells (see Chapter 45).[6,7] Because basal cells can be expanded in tissue culture and used to reconstitute sufficient epidermis to cover the entire skin surface of burn patients,[8,9] such a starting population is presumed to contain long-lived stem cells with extensive proliferative potential, located within the basal epidermal layer (at the base of *epidermal proliferating units*) and the hair follicle bulge.[10–13]

The second type of cell, the transit amplifying cells of the basal layer, arises as a subset of daughter cells produced by the infrequent division of stem cells, either by symmetric or asymmetric cell division.[14] These cells provide the bulk of the cell divisions needed for stable self-renewal and are the most common cells in the basal compartment. These cells subsequently give rise to the third class of epidermal basal cells, the postmitotic cells that undergo terminal differentiation. In humans, the normal transit time for a basal cell, from the time it loses contact with the basal layer to the time it enters the stratum corneum, is at least 14 days. Transit through the stratum corneum and subsequent desquamation require another 14 days. These periods of time can be altered in hyperproliferative or growth-arrested states.

SPINOUS LAYER. The shape, structure, and subcellular properties of spinous cells correlate with their position within the midepidermis. They are named for the spine-like appearance of the cell margins in histologic sections. Suprabasal spinous cells are polyhedral in shape with a rounded nucleus. As these cells differentiate and move upward through the epidermis, they become progressively flatter and develop organelles known as *lamellar granules* (see Section "Granular Layer"). Spinous cells also contain large bundles of keratin filaments, organized around the nucleus and inserted into desmosomes peripherally.

Spinous cells retain the stable K5/K14 keratins that are produced in the basal layer and only synthesize new messenger RNA (mRNA) for these proteins in hyperproliferative disorders. Instead, new synthesis of the K1/K10 keratin pair occurs in this epidermal layer. These keratins are characteristic of an epidermal pattern of differentiation and thus are referred to as the *differentiation-specific* or *keratinization-specific keratins*. However, in hyperproliferative conditions such as psoriasis, actinic keratoses, and wound healing, synthesis of K1 and K10 mRNA and protein is downregulated, and the synthesis and translation of messages for K6 and K16 are favored. Correlated with this change in keratin expression is a disruption of normal differentiation in the subsequent granular and cornified epidermal layers (see Sections "Granular Layer" and "Stratum Corneum"). mRNA for K6 and K16 are present throughout the epidermis normally, but the message is only translated on stimulation of proliferation.

The "spines" of spinous cells are abundant desmosomes, calcium-dependent cell surface modifications that promote adhesion of epidermal cells and resistance to mechanical stress (see Chapters 46 and 53).[15] Although desmosomes are related to adherens junctions, the latter associate with actin microfilaments at cell–cell interfaces, via a distinct set of cadherins (e.g., E-cadherin) and intracellular catenin adapter

TABLE 7-3
Diseases Resulting from Disruption of Desmosomal Proteins

Protein	Diseases
Desmoglein 1	Pemphigus foliaceus Striate palmoplantar keratoderma Staphylococcal scalded-skin syndrome Bullous impetigo
Desmoglein 3	Pemphigus vulgaris
Desmoglein 4	Autosomal recessive hypotrichosis
Plakoglobin	Palmoplantar keratoderma with wooly hair and arrhythmogenic right ventricular cardiomyopathy (Naxos disease)
Plakophilin 1	Ectodermal dysplasia/skin fragility syndrome (skin erosions, dystrophic nails, sparse hair, and painful palmoplantar keratoderma)
Plakophilin 2	Arrhythmogenic right ventricular cardiomyopathy
Desmoplakin	Lethal acantholytic epidermolysis bullosa Striate palmoplantar keratoderma, type I Palmoplantar keratoderma with left ventricular cardiomyopathy and wooly hair Autosomal dominant arrhythmogenic right ventricular cardiomyopathy

molecules. That the desmosomes are integral mediators of intercellular adhesion is clearly demonstrated in diseases in which these structures are disrupted, by genetic disorders, autoantibodies, or bacterial proteases (Table 7-3).[16,17]

The importance of calcium as a mediator of adhesion is well illustrated in the cases of two conditions that exhibit characteristic epidermal dyscohesion: (1) Darier disease (keratosis follicularis) and (2) Hailey–Hailey disease (benign chronic pemphigus) (see Chapter 51).[18] Both of these diseases are caused by mutations in genes that regulate calcium transport, *SERCA2* in Darier disease and *ATP2C1* in Hailey–Hailey disease.

Lamellar granules are also formed in this layer of epidermal cells (Fig. 7-5). These secretory organelles deliver precursors of stratum corneum lipids into the intercellular space (see Chapter 47). Genetic diseases demonstrate the importance of steroid and lipid metabolism for sloughing of cornified cells—in recessive X-linked ichthyosis, for example, mutation of steroid sulfatase results in a retention hyperkeratosis (see Chapter 49).[19]

GRANULAR LAYER. Named for the basophilic keratohyalin granules that are prominent within cells at this level of the epidermis, the granular layer is the site of generation of a number of the structural components that will form the epidermal barrier, as well as a number of proteins that process these components (see Fig. 7-2).[20,21] Keratohyalin granules (see Fig. 7-5) are composed primarily of profilaggrin, keratin filaments, and loricrin. It is in this layer that the cornified cell envelope begins to form, with the conversion of profilaggrin to filaggrin. After aggregation with keratin to form macrofilaments, filaggrin is degraded into molecules such as urocanic acid and pyrrolidone carboxylic acid, which contribute to hydration of the stratum corneum and help filter UV radiation. Loricrin is a cysteine-rich protein that forms the major protein component of the cornified envelope. Upon its release from keratohyalin granules, loricrin binds to desmosomal structures and is subsequently cross-linked to the plasma membrane by tissue transglutaminases (TGMs, primarily TGMs 3 and 1) to form the cornified cell envelope.

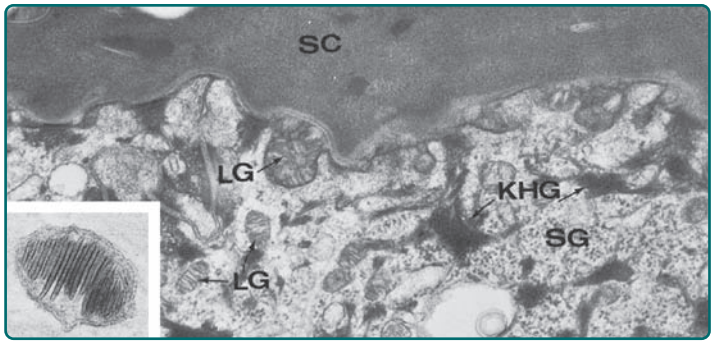

Figure 7-5 Junction of the stratum granulosum (SG) and stratum corneum (SC). Lamellar granules (LG) are in the intercellular space and cytoplasm of the granular cell. Keratohyalin granules (KHG) are also evident. *Inset:* Lamellar granule, ×28,750. (From Holbrook K: Structure and development of the skin. In: *Pathophysiology of Dermatologic Disease*, 2nd edition, edited by Soter NA, Baden HP. New York, McGraw-Hill, 1991, p. 7, with permission. Inset used with permission from EC Wolff-Schreiner, MD.)

Mutations in the *TGM1* gene have been shown to be the basis of some cases of lamellar ichthyosis.[22,23] Another form of ichthyosis, ichthyosis vulgaris, is caused by mutations in the gene encoding filaggrin.[24,25] Loricrin abnormalities result in a form of Vohwinkel syndrome with ichthyosis and pseudoainhum, as well as the disease progressive symmetric keratoderma.[26–28] These findings emphasize the importance of proper formation of the cornified envelope in normal epidermal keratinization.

The final stage of granular cell differentiation into a corneocyte involves the cell's own programed destruction, during which process almost all cellular contents are destroyed, with the exception of the keratin filaments and filaggrin matrix.[20]

STRATUM CORNEUM (SEE CHAPTER 47).

Complete differentiation of granular cells results in stacked layers of anucleate, flattened cornified cells that form the stratum corneum. It is this layer that provides mechanical protection to the skin and a barrier to water loss and permeation of soluble substances from the environment.[21,29] The stratum corneum barrier is formed by a two-compartment system of lipid-depleted, protein-enriched corneocytes surrounded by a continuous extracellular lipid matrix. These two compartments provide somewhat segregated but complementary functions that together account for the "barrier activity" of the epidermis. Regulation of permeability, desquamation, antimicrobial peptide activity, toxin exclusion, and selective chemical absorption are all primarily functions of the extracellular lipid matrix. On the other hand, mechanical reinforcement, hydration, cytokine-mediated initiation of inflammation, and protection from UV damage are all provided by the corneocytes.

NONKERATINOCYTES OF THE EPIDERMIS

Melanocytes are neural crest-derived, pigment-synthesizing dendritic cells that reside primarily in the basal layer (see Chapter 72).[30] The function of melanocytes has been highlighted by disorders in melanocyte number or function. The classic dermatologic disease, vitiligo, is caused by the autoimmune depletion of melanocytes.[31] Causes of other disorders of pigmentation are found in various defects in melanogenesis, including melanin synthesis, melanosome production, and melanosome transport and transfer to keratinocytes (see Chapters 72 and 75). Regulation of melanocyte proliferation and homeostasis is under intensive study as well as a means to understanding melanoma (see Chapter 124).[32] Keratinocyte–melanocyte interactions are critical for melanocyte homeostasis and differentiation, influencing proliferation, dentricity, and melanization.

Merkel cells are slow-adapting type I mechanoreceptors located in sites of high-tactile sensitivity (see Chapter 120).[33] They are present among basal keratinocytes in hairy skin and in the glabrous skin of the digits, lips, regions of the oral cavity, and the outer root sheath of the hair follicle. Keratin 20 is restricted to Merkel cells in the skin and thus may be the most reliable molecular marker. Ultrastructurally, Merkel cells are easily identified by the membrane-bounded, dense-core granules that collect opposite the Golgi and proximal to an unmyelinated neurite (Fig. 7-6). These granules contain neurotransmitter-like substances and markers of neuroendocrine cells, including Met-enkephalin, vasoactive intestinal peptide, neuron-specific enolase, and synaptophysin. Although increasingly more is being learned about the normal function of Merkel cells, they are of particular clinical note because Merkel cell-derived neoplasms are particularly aggressive and difficult to treat (see Chapter 120).

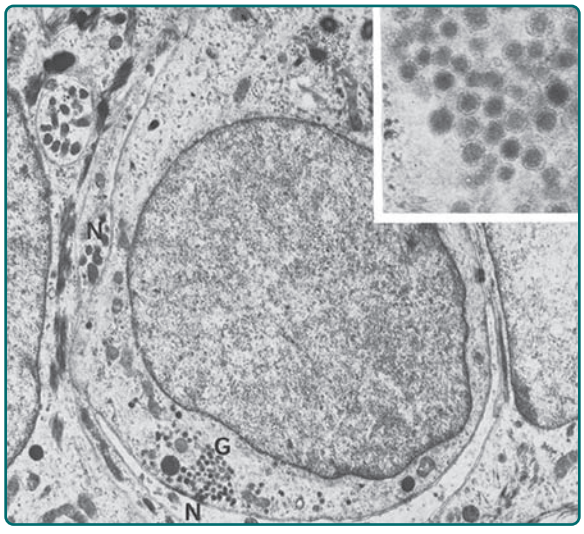

Figure 7-6 Merkel cells from the finger of a 130-mm CR (crown-rump) 21-week human fetus. Note nerve (N) in direct contact with the lateral and basal surfaces of the cell and dense core cytoplasmic granules (G). ×13,925. *Inset:* Merkel cell granules, ×61,450.

Langerhans cells are dendritic antigen-processing and antigen-presenting cells in the epidermis (see Chapter 10).[34] Although they are not unique to the epidermis, they form 2% to 8% of the total epidermal cell population, mostly found in a suprabasal position. The cytoplasm of the Langerhans cells contains characteristic small rod- or racket-shaped structures called *Langerhans cell granules* or *Birbeck granules* (Fig. 7-7). Langerhans cells principally function to sample and present antigens to T cells of the epidermis. Because of these functions, they are implicated in the pathologic mechanisms underlying allergic contact dermatitis, cutaneous leishmaniasis, and human immunodeficiency virus infection. Langerhans cells are reduced in the epidermis of patients with certain conditions, such as psoriasis, sarcoidosis, and contact dermatitis; they are functionally impaired by UV radiation, especially UVB.

Because of their effectiveness in antigen presentation and lymphocyte stimulation, dendritic cells and Langerhans cells have become prospective vehicles for tumor therapy and tumor vaccines. These cells are loaded with tumor-specific antigens, which will

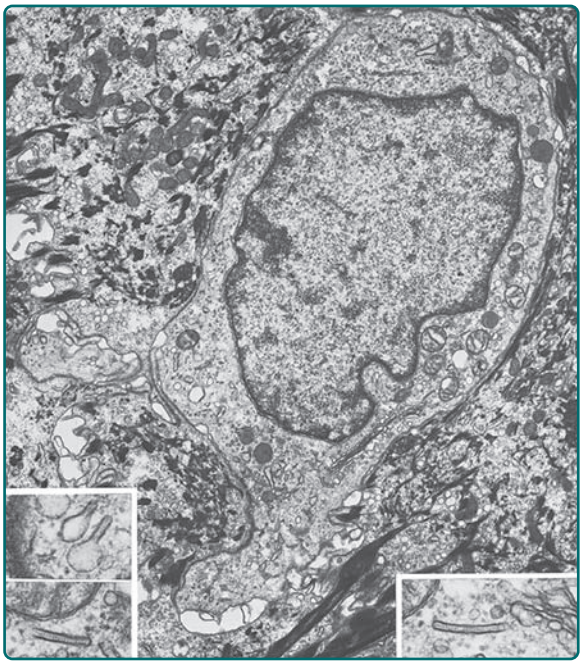

Figure 7-7 Langerhans cell. Note indented nucleus, lysosomes, as well as rod- and racket-shaped cytoplasmic granules (Birbeck granules), and the absence of keratin filaments. ×13,200. *Inset:* Birbeck granules ×88,000. (Used with permission from N. Romani, MD.)

then stimulate the host immune response to mount an antigen-specific, and therefore tumor-specific, response.

DERMAL–EPIDERMAL JUNCTION

The dermal–epidermal junction (DEJ) is a basement membrane zone that forms the interface between the epidermis and dermis (see Chapter 53).[35,36] The major functions of the DEJ are to attach the epidermis and dermis to each other and to provide resistance against external shearing forces. It serves as a support for the epidermis, determines the polarity of growth, directs the organization of the cytoskeleton in basal cells, provides developmental signals, and serves as a semipermeable barrier.

The DEJ can be subdivided into three supramolecular networks: (1) the hemidesmosome-anchoring filament complex, (2) the basement membrane itself, and (3) the anchoring fibrils. The critical role of this region in maintaining skin structural integrity is revealed by the large number of mutations in DEJ components that cause blistering diseases of varying severity, covered in detail in Chapter 62. These bullous diseases are grouped according to the level of the cleavage within the DEJ—the most superficial, EB simplex, involves basal keratinocyte cleavage. Junctional EB occurs within the lamina lucida and lamina densa regions. Dystrophic EB is the deepest level of blistering, within the sublamina densa/anchoring filaments. Chapter 53 provides a detailed discussion of the DEJ networks.

DERMIS

The dermis is an integrated system of fibrous, filamentous, diffuse, and cellular connective tissue elements that accommodates nerve and vascular networks, epidermally derived appendages, and contains many resident cell types, including fibroblasts, macrophages, mast cells, and transient circulating cells of the immune system (see Figs. 6-9 and 6-14). The dermis makes up the majority of skin and provides its pliability, elasticity, and tensile strength. It protects the body from mechanical injury, binds water, aids in thermal regulation, and includes receptors of sensory stimuli. The dermis interacts with the epidermis in maintaining the properties of both tissues, collaborates during development in the morphogenesis of the DEJ and epidermal appendages (see Section "Development of Skin Appendages"), and interacts in repairing and remodeling skin after wounding.

The dermis is arranged into two major regions: (1) the upper papillary dermis and (2) the deeper reticular dermis. These two regions are readily identifiable on histologic section, and they differ in their connective tissue organization, cell density, and nerve and vascular patterns. The papillary dermis abuts the epidermis, molds to its contours, and is usually no more than twice its thickness (see Fig. 6-9). The reticular dermis forms the bulk of the dermal tissue. It is composed primarily of large-diameter collagen fibrils, organized into large, interwoven fiber bundles, with branching elastic fibers surrounding the bundles (see Fig. 6-14). In normal individuals, the elastic fibers and collagen bundles increase in size progressively toward the hypodermis. The subpapillary plexus, a horizontal plane of vessels, marks the boundary between the papillary and reticular dermis. The lowest boundary of the reticular dermis is defined by the transition of fibrous connective tissue to adipose connective tissue of the hypodermis.

FIBROUS MATRIX OF THE DERMIS

The connective tissue matrix of the dermis is comprised primarily of collagenous and elastic fibrous tissue.[37,38] These are combined with other, nonfibrous connective tissue molecules, including finely filamentous glycoproteins, proteoglycans (PGs), and glycosaminoglycans (GAGs) of the "ground substance."[39]

Collagen forms the bulk of the acellular portion of the dermis, accounting for approximately 75% of the dry weight of skin, and providing both tensile strength and elasticity. (For details regarding the polypeptide structure and distribution of collagens, see Chapter 63.) The periodically banded, interstitial collagens account for the greatest proportion of collagen in adult dermis (type I, 80% to 90%; type III, 8% to 12%; and type V, <5%). Type VI collagen is associated with fibril and in the interfibrillar spaces. Type IV collagen is confined to the basal lamina of the DEJ, vessels, and epidermal appendages. Type VII collagen forms anchoring fibrils at the DEJ.

Elastic connective tissue (see Chapter 63) is a complex molecular mesh, extending from the lamina densa of the DEJ throughout the dermis and into the connective tissue of the hypodermis.[38] Elastic fibers return the

skin to its normal configuration after being stretched or deformed. They are also present in the walls of cutaneous blood vessels and lymphatics and in the sheaths of hair follicles. Mutations in elastin, the elastic fiber matrix component, cause the disease cutis laxa. Elastic fibers are normally located between bundles of collagen fibers, although in certain pathologic conditions, such as Buschke–Ollendorff syndrome, both elastic and collagen fibers become assembled within the same bundle. The importance of the elastic fiber network is clearly seen in the number of multisystem diseases that arise because of mutations in components of this network. The defect underlying pseudoxanthoma elasticum (PXE) is a mutation in *ABCC6*, a member of the large adenosine triphosphate-dependent transmembrane transporter family. Thus, this disease that is characterized by loss of skin elasticity and calcified elastic fibers is unlikely a primary defect in elastic tissue, but rather a metabolic disorder with secondary involvement of elastic fibers.[40–42] In addition to genetic mutations, solar radiation and aging also contribute to elastic fiber damage.[43]

FILAMENTOUS AND DIFFUSE MATRIX COMPONENTS OF THE DERMIS (SEE CHAPTER 63)

The fibrous and cellular matrix elements are embedded within more amorphous matrix components, which also are found in basement membranes.[44–46] PGs are large molecules consisting of a core protein that determines which GAGs will be incorporated into the molecule. The PG/GAG complex can bind water up to 1,000 times its own volume and have roles in regulation of water binding and compressibility of the dermis, as well as increasing local concentrations of growth factors through binding (e.g., basic fibroblast growth factor). They also link cells with the fibrillar and filamentous matrix, influencing proliferation, differentiation, tissue repair, and morphogenesis.

The major PGs in the adult dermis are chondroitin sulfates/dermatan sulfate, including biglycan, decorin, and versican; heparan/heparan sulfate PGs, including perlecan and syndecan; and chondroitin-6 sulfate PGs, which are components of the DEJ (see Chapter 63). Glycoproteins interact with other matrix components via integrin receptors. They facilitate cell migration, adhesion, morphogenesis, and differentiation. Fibronectin is synthesized by both epithelial and mesenchymal cells, and it covers collagen bundles and the elastic network. Vitronectin is present on all elastic fibers except for oxytalan. Tenascin is found around the smooth muscle of blood vessels, arrector pili muscles, and appendages such as sweat glands.

CELLULAR COMPONENTS OF THE DERMIS

Fibroblasts, macrophages, and mast cells are the regular residents of the dermis, mostly found around the papillary region and surrounding vessels of the subpapillary plexus (see Fig. 6-20), as well as in the reticular dermis between collagen fiber bundles. The fibroblast is a mesenchymally derived cell that migrates through the tissue and is responsible for the synthesis and degradation of fibrous and nonfibrous connective tissue matrix proteins and a number of soluble factors. Fibroblasts provide a structural extracellular matrix framework as well as promote interaction between epidermis and dermis by synthesis of soluble mediators. Studies of human fibroblasts indicate that even within a single tissue, phenotypically distinct populations exist, some of which relate to regional anatomical differences.[47,48] These cells are also instrumental in wound healing and scarring, increasing their proliferative and synthetic activity during these processes.

The monocytes, macrophages, and dermal dendrocytes constitute the mononuclear phagocytic system of cells in the skin. Macrophages are derived from precursors in the bone marrow, differentiate into circulating monocytes, and then migrate into the dermis to differentiate. These cells are phagocytic; process and present antigen to immunocompetent lymphoid cells; are microbicidal, tumoricidal, secretory, and hematopoietic (see Chapter 10); and are involved in coagulation, atherogenesis, wound healing, and tissue remodeling.

Mast cells (see Chapter 149) are specialized secretory cells that, in skin, are present in greatest density in the papillary dermis, near the DEJ, in sheaths of epidermal appendages, and around blood vessels and nerves of the subpapillary plexus. The surface of dermal mast cells is coated with fibronectin, which probably assists in securing cells within the connective tissue matrix. Mast cells are secretory cells that are responsible for immediate-type hypersensitivity reaction in skin and are involved in the production of subacute and chronic inflammatory disease. They synthesize secretory granules composed of histamine, heparin, tryptase, chymase, carboxypeptidase, neutrophil chemotactic factor, and eosinophilic chemotactic factor of anaphylaxis, which are mediators in these processes. Mast cells can become hyperplastic and hyperproliferative in mastocytosis (see Chapter 149).

The dermal dendrocyte is a dendritic, highly phagocytic fixed connective tissue cell in the dermis of normal skin. Similar to many other bone marrow-derived cells, dermal dendrocytes express factor XIIIa and CD45, and they lack typical markers of fibroblasts. These cells are particularly abundant in the papillary dermis and upper reticular dermis, frequently in the proximity of vessels of the subpapillary plexus. Dermal dendrocytes function in the afferent limb of an immune response as antigen presenting cells (see Chapter 10). They are also likely the cells of origin of a number of benign fibrotic proliferative conditions in the skin, such as dermatofibromas and fibroxanthomas (see Chapter 66).

CUTANEOUS VASCULATURE

BLOOD VESSELS (SEE CHAPTER 162)

The blood vessels of skin provide nutrition for the tissue and are involved in temperature and blood pressure regulation, wound repair, and numerous immunologic

events.[49] The microcirculatory beds in skin progress from arterioles to precapillary sphincters. Extending from the sphincters are arterial and venous capillaries, which become postcapillary venules, and finally, collecting venules. When compared with vasculature of other organs, the vessels of skin are adapted to shearing forces, as they have thick walls supported by connective tissue and smooth muscle cells. Special cells, known as *veil cells*, surround the cutaneous microcirculation, defining a domain for the vessels within the dermis while remaining separate from the vessel walls.

The rich vascular network of the skin is located at boundaries within the dermis and supplies the epidermal appendages (see Fig. 163-2). The vessels that supply the dermis branch from musculocutaneous arteries that penetrate the subcutaneous fat and enter the deep reticular dermis. At this point, they are organized into a horizontal arteriolar plexus. From this plexus, ascending arterioles extend toward the epidermis. These arterioles contain two layers of smooth muscle cells, as well as pericytes, a second type of contractile cell of the vessel wall. At the junction between the papillary and reticular dermis, terminal arterioles form the subpapillary plexus. Capillary loops then extend from the terminal arterioles of the plexus into the papillary dermis. At the apex of each capillary loop is the thinnest portion, allowing for transport of material out of the capillary. The descending limbs of capillary loops are venous capillaries that drain into venous channels of the subpapillary plexus. The postcapillary venules of the subpapillary plexus are responsive to histamine and are therefore often the sites of inflammatory cells during these responses.

Certain regions of skin, such as the palms and soles, contain direct connections between arterial and venous circulation as potential shunts around congested capillary beds. These sites consist of an ascending arteriole (a glomus body), which is modified by three to six layers of smooth muscle cells and has associated sympathetic nerve fibers.

In the adult, the cutaneous vasculature normally remains quiescent, in part due to inhibition of angiogenesis by factors such as thrombospondin. Pathogenic stimuli sometimes result in secondary angiogenesis, from tumors or during wounding. One of the key mediators of such angiogenesis is vascular endothelial growth factor (VEGF), often secreted by tumors or by keratinocytes (see Chapter 162).[50,51]

Numerous disorders can manifest themselves within the cutaneous vasculature. Leukocytoclastic vasculitis (cutaneous necrotizing venulitis) occurs within the venules in response to a number of potential pathogenic mechanisms (see Chapter 163). Stasis dermatitis, urticaria, polyarteritis nodosa, thrombosis, and thrombophlebitis all affect vessels in the skin, of different sizes, some by occlusion of vessels (vasculopathy) and others by inflammation of the vessels (vasculitis).

LYMPHATICS

The lymph channels of the skin regulate pressure of the interstitial fluid by resorption of fluid released from vessels and in clearing the tissues of cells, proteins, lipids, bacteria, and degraded substances.[52,53] The vessels begin in blind-ending initial lymphatics in the papillary dermis. They drain into a horizontal plexus of larger lymph vessels located deep to the subpapillary venous plexus. A vertical system of lymphatics then carries fluid and debris through the reticular dermis to another deeper collecting plexus at the reticular dermis–hypodermis border. Lymph flow within the skin depends on movements of the tissue caused by arterial pulsations and larger scale muscle contractions and movement of the body, with backflow prevented by bicuspid-like valves within the vessels.

Lymphatic vessels are often collapsed in skin and therefore are only seen with difficulty on histologic section. They are composed of a large lumen and a thinner wall than blood vessels. Molecular characterization of these vessels has identified Prox1, VEGFR-3, and LYVE-1 as specific markers of lymphatic character.[53]

Certain pathologic conditions involve or highlight the function of lymphatic vessels, such as lymphedema, lymphangioma circumscriptum, and stasis dermatitis. The importance of lymphatics in the progression and spread of cancer is also becoming more clear, as melanoma cells destroy endothelial cells of the initial lymphatics to gain entry to the lymph circulation, and recent studies have shown that tumors themselves can promote lymphangiogenesis as part of their early program on the way to metastasis.[51,54] The discovery of the molecular defects in hereditary lymphedemas has implicated the VEGFR-3 and FoxC2 in lymphatic development. One of the most heavily studied lymphangiogenic molecules is VEGF-C (Chapter 162).

CUTANEOUS NERVES AND RECEPTORS (SEE CHAPTERS 102 AND 103)

The nerve networks of the skin contain somatic sensory and sympathetic autonomic fibers.[55] The sensory fibers alone (free nerve endings) or in conjunction with specialized structures (corpuscular receptors) function as receptors of touch, pain, temperature, itch, and mechanical stimuli. The density and types of receptors are regionally variable, accounting for the variation in acuity at different sites of the body. Receptors are particularly dense in hairless areas such as the areola, labia, and glans penis. Sympathetic motor fibers are codistributed with the sensory nerves in the dermis until they branch to innervate the sweat glands, vascular smooth muscle, the arrector pili muscle of hair follicles, and sebaceous glands.

The nerves of skin branch from musculocutaneous nerves that arise segmentally from spinal nerves. The pattern of nerve fibers in skin is similar to the vascular patterns—nerve fibers form a deep plexus, then ascend to a superficial, subpapillary plexus.

Free nerve endings include the penicillate and papillary nerve fibers and are the most widespread sensory receptors in skin. In humans, they are ensheathed by Schwann cells and a basal lamina. Free nerve endings are particularly common in the papillary dermis.

The penicillate fibers are the primary nerve fibers found subepidermally in haired skin. These are rapidly adapting receptors that function in the perception of touch, temperature, pain, and itch. Because of overlapping innervation, discrimination tends to be generalized in these regions. On the other hand, free nerve endings present in nonhaired, ridged skin, such as the palms and soles, project individually without overlapping distribution and so are thought to function in fine discrimination.

Papillary nerve endings are found at the orifice of a follicle and are thought to be particularly receptive to cold sensation. Hair follicles also contain other receptors, slow-adapting receptors that respond to the bending or movement of hairs. Cholinergic sympathetic fibers en route to the eccrine sweat gland and adrenergic and cholinergic fibers en route to the arrector pili muscle are carried along with the sensory fibers in the hair basket.

Free nerve endings are also associated with individual Merkel cells. In haired skin, touch domes are associated with hair follicles. In palmoplantar skin, these complexes are found at the site where the eccrine sweat duct penetrates a glandular epidermal papilla.

Corpuscular receptors, both Meissner's and Pacinian, contain a capsule and inner core and are composed of both neural and nonneural components. The capsule is a continuation of the perineurium, and the core includes the nerve fiber surrounded by lamellated wrappings of Schwann cells. Meissner's corpuscles are elongated or ovoid mechanoreceptors located in the dermal papillae of digital skin and oriented vertically toward the epidermal surface (Fig. 7-8).

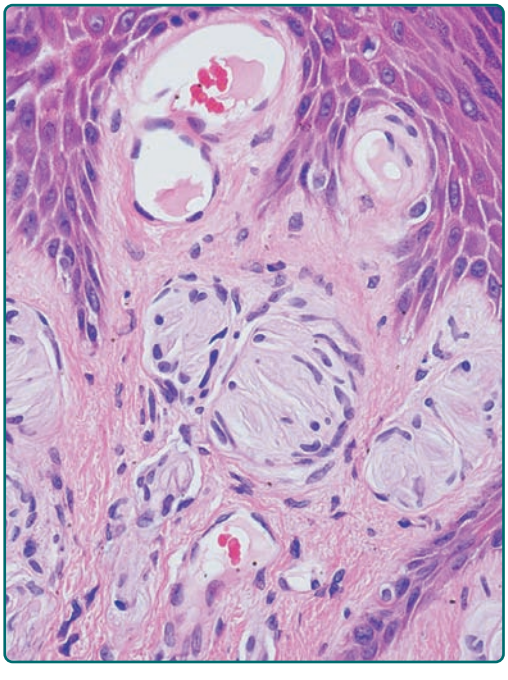

Figure 7-8 Meissner's corpuscle. Note the capsule and inner core located in the dermal papillae. These collections of cells serve as mechanoreceptors.

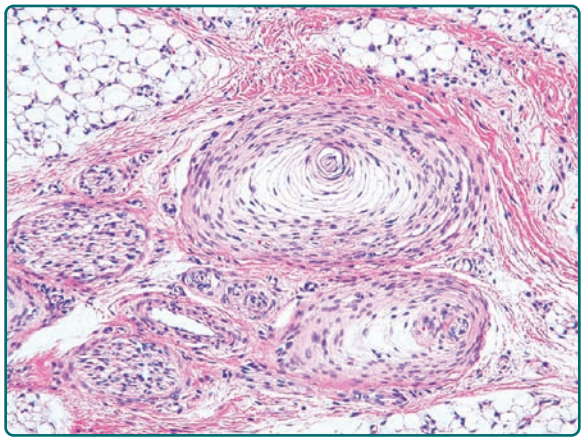

Figure 7-9 Pacinian corpuscle. Note the characteristic perineural capsule, likened to the appearance of an "onion-skin." Pacinian corpuscles serve as rapidly adapting mechanoreceptors that respond to vibrational stimuli.

The Pacinian corpuscle lies in the deep dermis and subcutaneous tissue of skin that covers weight-bearing surfaces of the body. It has a characteristic capsule and lamellar wrappings (Fig. 7-9). Pacinian corpuscles serve as rapidly adapting mechanoreceptors that respond to vibrational stimuli.

HYPODERMIS (SUBCUTIS)

The tissue of the hypodermis insulates the body, serves as a reserve energy supply, cushions and protects the skin, and allows for its mobility over underlying structures. It has a cosmetic effect in molding body contours. The boundary between the deep reticular dermis and the hypodermis is an abrupt transition from a predominantly fibrous dermal connective tissue to a primarily adipose subcutaneous one (see Fig. 6-1, Chapter 6). Despite this clear distinction anatomically, the two regions are still structurally and functionally integrated through networks of nerves and vessels and through the continuity of epidermal appendages. Actively growing hair follicles span the dermis and extend into the subcutaneous fat, and the apocrine and eccrine sweat glands are normally confined to this depth of the skin.

Adipocytes form the bulk of the cells in the hypodermis.[56,57] They are organized into lobules defined by septa of fibrous connective tissue. Nerves, vessels, and lymphatics are located within the septa and supply the region. The synthesis and storage of fat continues throughout life by enhanced accumulation of lipid within fat cells, proliferation of existing adipocytes, or by recruitment of new cells from undifferentiated mesenchyme. The hormone leptin, secreted by adipocytes, provides a long-term feedback signal regulating fat mass. Leptin levels are higher in subcutaneous than omental adipose, suggesting a role for leptin in control of adipose distribution as well.

The importance of the subcutaneous tissue is apparent in patients with Werner syndrome (see Chapter 139),

in which subcutaneous fat is absent in lesion areas over bone, or with scleroderma (see Chapter 157), where the subcutaneous fat is replaced with dense fibrous connective tissue. Such regions in Werner patients ulcerate and heal poorly. The skin of patients with scleroderma is taut and painful. In the hereditary and acquired lipodystrophies, loss of subcutaneous fat disrupts glucose, triglyceride, and cholesterol regulation, and causes significant cosmetic alteration, increasing the interest in possible hormonal therapy for these disorders (see Chapter 71).[58] The subcutaneous tissue is involved in different inflammatory conditions (Chapter 70).

DEVELOPMENT OF SKIN

Significant advances in the understanding of the molecular processes responsible for the development of skin have been made over the last several years. Such advances increase the understanding of clinicopathologic correlation among some inherited disorders of skin and allow for the early diagnosis of such diseases. The developmental progression of various components of the skin is well documented, and a time line indicating the events that occur during embryonic and fetal development is provided (Table 7-4).[59,60] Of note, the estimated gestational age (EGA) is used throughout this chapter; this system refers to the age of the fetus, with fertilization occurring on day 1. To avoid confusion, it should be pointed out that obstetricians and most clinicians define day 1 as the first day of the last menstrual period (menstrual age), in which fertilization occurs on approximately day 14. Thus, the two dating systems differ by approximately 2 weeks, such that a woman who is 14 weeks pregnant (menstrual age) is carrying a 12-week-old fetus (EGA).

Conceptually, fetal skin development can be divided into three distinct but temporally overlapping stages, those of (1) specification, (2) morphogenesis, and (3) differentiation. These stages roughly correspond to the embryonic period (0–60 days), the early fetal period (2–5 months), and the late fetal period (5–9 months) of development, respectively. The earliest stage, specification, refers to the process by which the ectoderm lateral to the neural plate is committed to become epidermis, and subsets of mesenchymal and neural crest cells are committed to form the dermis. It is at this time that patterning of the future layers and specialized structures of the skin occurs, often via a combination of gradients of proteins and cell–cell signals. The second stage, morphogenesis, is the process by which these committed tissues begin to form their specialized structures, including epidermal stratification, epidermal appendage formation, subdivision between the dermis and subcutis, and vascular formation. The last stage, differentiation, denotes the process by which these newly specialized tissues further develop and assume their mature forms. Table 7-5 integrates specification, morphogenesis, and differentiation with skin morphology and genetic diseases.

For simplification and greater clarity, the stages of development of the epidermis—dermis and hypodermis, dermal–epidermal junction, and epidermal appendages—are presented sequentially.

EPIDERMIS

EMBRYONIC DEVELOPMENT. During the third week after fertilization, the human embryo undergoes gastrulation, a complex process of involution and cell redistribution that results in the formation of the three primary embryonic germ layers: (1) ectoderm, (2) mesoderm, and (3) endoderm. Shortly after gastrulation, ectoderm further subdivides into neuroectoderm and presumptive epidermis. The specification of the presumptive epidermis is believed to be mediated by the bone morphogenetic proteins (BMPs). Later during this period, BMPs again appear to play a critical role, along with Engrailed-1 (En1), in specifying the volar versus interfollicular skin.[61–63] By 6 weeks EGA, the ectoderm that covers the body consists of basal cells and superficial periderm cells.

The basal cells of the embryonic epidermis differ from those of later developmental stages. Embryonic basal cells are more columnar than fetal basal cells, and they have not yet formed hemidesmosomes. Although certain integrins (e.g., α6β4) are expressed in these cells, they are not yet localized to the basal pole of the cells. Before the formation of hemidesmosomes and desmosomes, intercellular attachment between individual basal cells appears to be mediated by adhesion molecules such as E- and P-cadherin, which have been detected on basal cells as early as 6 weeks EGA. Keratins K5 and K14, proteins restricted to definitive stratified epithelia, are expressed even at these early stages of epidermal formation.

At this stage, periderm cells form a "pavement epithelium." These cells are embryonic epidermal cells that are larger and flatter than the underlying basal cells. Apical surfaces contact the amniotic fluid and are studded with microvilli. Connections between periderm cells are sealed with tight junctions rather than desmosomes. By the end of the second trimester, these cells are sloughed and eventually form part of the vernix caseosa. Like stratified epithelial cells, periderm cells express K5 and K14, but they also express simple epithelial keratins K8, K18, and K19.

Aplasia cutis (see Chapter 107) may reflect focal defects in either epidermal specification or development caused by somatic mosaicism, or mutations that occur postzygotically. However, the molecular defect for this disorder is not known. The fact that few genetic diseases have been described in which either epidermal specification or morphogenesis is defective likely reflects the fact that such defects would be incompatible with survival.

EARLY FETAL DEVELOPMENT (MORPHOGENESIS). By the end of 8 weeks of gestation, hematopoiesis has switched from the extraembryonic yolk sac to the bone marrow, the classical division between embryonic and fetal development. By this time, the epidermis begins its stratification and formation of an intermediate layer between the two preexisting cell layers. The cells in this new layer are similar to the cells of the spinous layer in mature epidermis. Like spinous cells, they express keratins K1/K10 and the desmosomal

protein desmoglein-3. The cells are still highly proliferative and, during this period of development, they evolve into a multilayer structure that will eventually replace the degenerating periderm.

Expression of the *p63* gene plays a critical role in the proliferation and maintenance of the basal layer cells. Epidermal stratification does not occur in mice deficient for *p63*. In humans, although no null mutations have been isolated, partial loss of *p63* function mutations have been identified in ankyloblepharon, ectodermal dysplasia, and cleft lip/palate syndrome (Hay–Wells syndrome) as well as ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome (see Chapter 142).[64–66] The preexisting basal cell layer also undergoes morphologic changes at this time, becoming more cuboidal and expressing new keratin genes, *K6*, *K8*, *K19*, and *K6/K16*, that are usually expressed in hyperproliferative tissues. The basal layer also begins to elaborate proteins that will ultimately anchor them to the developing basal lamina (see Section "Dermal–Epidermal Junction"), including hemidesmosomal proteins BPAG1, BPAG2, and collagens V and VII (see Chapters 53, 56, and 62).

Embryonic lines of ectodermal formation are revealed in mosaic disorders that follow the lines of Blaschko, including congenital, nevoid, and acquired conditions.[67–69] Molecular demonstration of genetic mosaicism has been reported for a number of X-linked disorders, as well as epidermal nevi in epidermolytic hyperkeratosis.[70]

LATE FETAL DEVELOPMENT (DIFFERENTIATION).

Late fetal development reveals the further specialization and differentiation of keratinocytes in the epidermis. It is at this time that the granular and stratum corneal layers are formed, and the rudimentary periderm is sloughed. Keratinization of the surface epidermis is a process of keratinocyte terminal differentiation, which begins at 15 weeks EGA. The granular layer becomes prominent, and important structural proteins are elaborated in the basal layer cells. The hemidesmosomal proteins plectin and α6β4 integrin are expressed and correctly localized at this time. Mutations in these genes result in various bullous genodermatoses (reviewed in Chapter 62). The more superficial cells undergo further terminal differentiation, and the keratin-aggregating protein filaggrin is expressed at this time.

The formation of the cornified envelope is a late feature of differentiating keratinocytes, and it relies on a number of different modifications to create an impermeable barrier. Enzymes such as transglutaminase, LEKTI (encoded by the gene *SPINK-5*), phytanoyl coenzyme A reductase, fatty aldehyde dehydrogenase, and steroid sulfatase are all important in the elaboration of the cornified envelope and mature lipid barrier, and defects in these enzymes can lead to abnormal epidermal barrier formation (see Chapter 49).

SPECIALIZED CELLS WITHIN THE EPIDERMIS.

The three major nonepidermal cell types—(1) melanocytes, (2) Langerhans cells, and (3) Merkel cells—can be detected within the epidermis by the end of the embryonic period. Melanocytes are derived from the neural crest, a subset of neuroectoderm cells. Pigment mosaicism (formerly called *hypomelanosis of*

AEC = ankyloblepharon-ectodermal dysplasia-clefting; BMPs = bone morphogenetic proteins; BPAG = bullous pemphigoid antigen; EB = epidermolysis bullosa; EEC = ectrodactyly-ectodermal dysplasia-clefting; EI = epidermolytic ichthyosis; GABEB = generalized atrophic benign epidermolysis bullosa form of non-Herlitz junctional EB; HHT = hereditary hemorrhagic telangiectasia; K = keratin; KID = keratitis-ichthyosis-deafness; MD = multiple dystrophy; NCIE = nonbullous congenital ichthyosiform erythroderma; NGFR = nerve growth factor receptor; PA = pyloric atresia; PXE = pseudoxanthoma elasticum.
Protein names are indicated in **boldface**. Associated diseases/genodermatoses are listed in parentheses. Multiple names for the same protein or syndrome are separated by /. Genes and associated diseases can be found in Online Mendelian Inheritance in Man (OMIM) at http://www.ncbi.nlm.nih.gov/omim.

Ito and *linear and whorled hypermelanosis*) (see Chapter 75) following the lines of Blaschko may reflect the migratory paths of melanoblasts, or alternatively, mosaic defects in pigment transfer from melanocytes to keratinocytes. The founders of each melanoblast clone originate at distinct points along the dorsal midline, traversing ventrally and distally to take up residence in the epidermis.

Melanocytes are first seen within the epidermis at 50 days EGA. Melanocytes express integrin receptors in vivo and in vitro and may use these to migrate to the epidermis during embryonic development. Migration, colonization, proliferation, and survival of melanocytes in developing skin depend on the cell surface tyrosine kinase receptor, *c-kit*, and its ligand, stem cell factor.[71,72] Melanin becomes detectable between 3 and 4 months EGA, and by 5 months, melanosomes begin to transfer pigment to keratinocytes. Many genetic disorders of pigmentation have been characterized and are presented in detail in Chapters 73, 75, and 143. In the adult, a pool of melanocyte precursor cells resides in the upper permanent portion of the hair follicle, capable of producing mature melanocytes.[71,73,74]

Langerhans cells, another immigrant population, are detectable by 40 days EGA. They begin to express CD1 on their surface and to produce their characteristic Birbeck granules by the embryonic–fetal transition. By the third trimester, most of the adult numbers of Langerhans cells will have been produced.[75]

Merkel cells, as described earlier in the chapter (see Section "Nonkeratinocytes of the Epidermis"), reside in the epidermis. They are first detectable in the volar epidermis of the 11- to 12-week EGA human fetus. The embryonic derivation of this population of cells is controversial, as there is experimental evidence supporting both in situ differentiation of Merkel cells from epidermal ectoderm as well as migration from the neural crest.[33,76]

DERMAL AND SUBCUTANEOUS DEVELOPMENT

The origin of the dermis and subcutaneous tissue is more diverse than that of the epidermis, which is exclusively ectodermally derived. The embryonic tissue that forms the dermis depends on the specific body site.[77,78] Dermal mesenchyme of the face and anterior scalp is derived from neural crest ectoderm. The limb and ventral body wall mesenchyme is derived from the lateral plate mesoderm. The dorsal body wall mesenchyme derives from the dermomyotomes of the embryonic somite. LIM homeobox transcription factor 1β (Lmx1B) and Wnt7a are important in the specification of the dorsal limb.[79–81] En1 and BMPs, on the other hand, specify the volar (ventral) limb mesenchyme (see Table 7-5).[66,80]

The embryonic dermis, in contrast to the mature dermis, is cellular and amorphous, with few organized fibers. The mature dermis contains a complex mesh of collagen and elastic fibers embedded in a matrix of PGs, whereas the embryonic mesenchyme contains a large variety of pluripotent cells in a hydrated gel that is rich in hyaluronic acid. These mesenchymal cells are thought to be the progenitors of cartilage-producing cells, adipose tissue, dermal fibroblasts, and intramembranous bone. Dermal fibers exist as fine filaments but not thick fibers. The protein components of the future elastin and collagen fibers are synthesized during this period but not assembled. At this point, there is no obvious separation between cells that will become musculoskeletal elements and those that will give rise to the skin dermis.

Proteus syndrome, exhibits focal defects in multiple tissues, probably and is the result of genetic mosaicism affecting genes important in this process caused by *AKT1* associated activating mutations.[81a] Rarely is the mutation found in peripheral blood cells demonstrating the importance of studying affected tissues. (see Chapter 118). Mutations causing a global defect in this process would likely be incompatible with life.

The superficial mesenchyme becomes distinct from the underlying tissue by the embryonic–fetal transition (about 60 days EGA). By 12–15 weeks, the reticular dermis begins to take on its characteristic fibrillar appearance in contrast to the papillary dermis, which is more finely woven. Large collagen fibers continue to accumulate in the reticular dermis, as well as elastin fibers, beginning around midgestation and continuing until birth. By the end of the second trimester, the dermis has changed from a nonscarring tissue to one that is capable of forming scars. As the dermis matures, it also becomes thicker and well organized, such that at birth, it resembles the dermis of the adult, although it is still more cellular.

Many well-known clinical syndromes and molecules have been discovered that affect this final stage of dermal differentiation. These diseases include dystrophic EB (see Chapter 62), Marfan syndrome, Ehlers–Danlos syndrome, cutis laxa, PXE, hereditary hemorrhagic telangiectasia, and osteogenesis imperfecta (see Chapter 137).

SPECIALIZED COMPONENTS OF THE DERMIS

BLOOD VESSELS AND NERVES. Cutaneous nerves and vessels begin to form early during gestation, but they do not evolve into those of the adult until a few months after birth. The process of vasculogenesis requires the in situ differentiation of the endothelial cells at the endoderm–mesoderm interface. Originally, horizontal plexuses are formed within the subpapillary and deep reticular dermis, which are interconnected by groups of vertical vessels. This lattice of vessels is in place by 45–50 days EGA.

At 9 weeks EGA, blood vessels are seen at the dermal–hypodermal junction. By 3 months, the distinct networks of horizontal and vertical vessels have formed. By the fifth month, further changes in the vasculature derive from budding and migration of endothelium from preexisting vessels, the process of angiogenesis. Depending on the body region, gestational age, and presence of hair follicles and glands, this pattern can vary with blood supply requirements.

Defects in vascular development have been described (see Chapter 172). In the Klippel–Trénaunay syndrome, unilateral cutaneous vascular malformations develop, with associated venous varicosities, edema, and hypertrophy of associated soft tissue and bone. In Sturge–Weber syndrome, many cutaneous capillary malformations are seen in the lips, tongue, nasal, and buccal mucosae. Some familial defects in vascular formation result from mutations in the gene encoding Tie-2 receptor tyrosine kinase. Capillary malformations seen in hereditary hemorrhagic telangiectasia have been linked to mutations in transforming growth factor-β-binding proteins—endoglin, and activin receptor-like kinase 1.

LYMPHATICS. Accumulating evidence suggests that lymphatics originate from endothelial cells that bud off from veins. The pattern of embryonic lymphatic vessel development parallels that of blood vessels. Recent studies have identified new genes that appear to be specific for some of the earliest lymphatic precursors. *LYVE-1* and *Prox-1* are genes considered to be critical for earliest lymphatic specification, whereas *VEGF-R3* and *SLC* may be important in later lymphatic differentiation.[53]

NERVES. The development of cutaneous nerves parallels that of the vascular system in terms of patterning, maturation, and organization. Nerves of the skin consist of somatic sensory and sympathetic autonomic fibers, which are predominantly small and unmyelinated. As these nerves develop, they become myelinated, with associated decrease in the number of axons. This process may continue as long as puberty.

SUBCUTIS

As mentioned in Section "Specialized Components of the Dermis," by 50–60 days EGA, the hypodermis is separated from the overlying dermis by a plane of thin-walled vessels. Toward the end of the first trimester, the matrix of the hypodermis can be distinguished from the more fibrous matrix of the dermis. By the second trimester, adipocyte precursors begin to differentiate and accumulate lipids. By the third trimester, fat lobules and fibrous septae are found to separate the mature adipocytes. The molecular pathways that define this process are currently an area of intense investigation. Although few regulators important in embryonic adipose specification and development have been identified, several factors critical for preadipocyte differentiation have been demonstrated, including leptin, a hormone important in fat regulation, and the peroxisome proliferator-activated receptor family of transcription factors.[57]

DERMAL–EPIDERMAL JUNCTION

The dermal–epidermal junction is an interface where many inductive interactions occur that result in the specification or differentiation of the characteristics of the dermis and epidermis. This zone includes specialized basement membrane, basal cell extracellular matrix, the basal-most portion of the basal cells, and the superficial-most fibrillar structures of the papillary dermis. Both the epidermis and dermis contribute to this region.

As early as 8 weeks EGA, a simple basement membrane separates the dermis from the epidermis and contains many of the major protein elements common to all basement membranes, including laminin 1, collagen IV, heparin sulfate, and PGs. Components specific to the cutaneous basement membrane zone, such as proteins of the hemidesmosome and anchoring filaments, are first detected at the embryonic–fetal transition. By the end of the first trimester, or around the time of late embryonic development, all basement membrane proteins are in place. The α6 and β4 integrin subunits are expressed earlier than most of the other basement membrane components. However, they are not localized to the basal surface until 9.5 weeks EGA, coincident with the time that the hemidesmosomal proteins are expressed and hemidesmosomes are first observed. At the same time, anchoring filaments (laminin-332) and anchoring fibrils (collagen VII) begin to be assembled. The actual synthesis of collagen VII can be detected slightly earlier, at 8 weeks EGA.

Many congenital blistering disorders have been demonstrated to be a result of defects in proteins of the DEJ (for details, see Chapters 53 and 62). The severity of the disease, plane of tissue separation, and involvement of noncutaneous tissues depend on the proteins involved and the specific mutations. These genes are important candidates for prenatal testing.

DEVELOPMENT OF SKIN APPENDAGES

Skin appendages, which include hair, nails, and sweat and mammary glands, are composed of two distinct components: (1) an epidermal portion, which produces the differentiated product, and (2) the dermal component, which regulates differentiation of the appendage. During embryonic development, dermal–epidermal interactions are critical for the induction and differentiation of these structures (Fig. 7-10). Disruption of these signals often has profound influences on development of skin appendages. Hair differentiation serves as a paradigm for appendageal development, because it is the appendage that has been studied most intensely.[82,83]

HAIR (SEE CHAPTER 86)

Dermal signals are initially responsible for instructing the basal cells of the epidermis to begin to crowd at regularly spaced intervals, starting between days 75 and 80 on the scalp. This initial grouping is known as the *follicular placode* or *anlage*. From the scalp, follicular placode formation spreads ventrally and caudally, eventually covering the skin. The placodes then signal back to the underlying dermis to form a "dermal condensate," which occurs at 12–14 weeks EGA. This process is thought to be a balance of placode

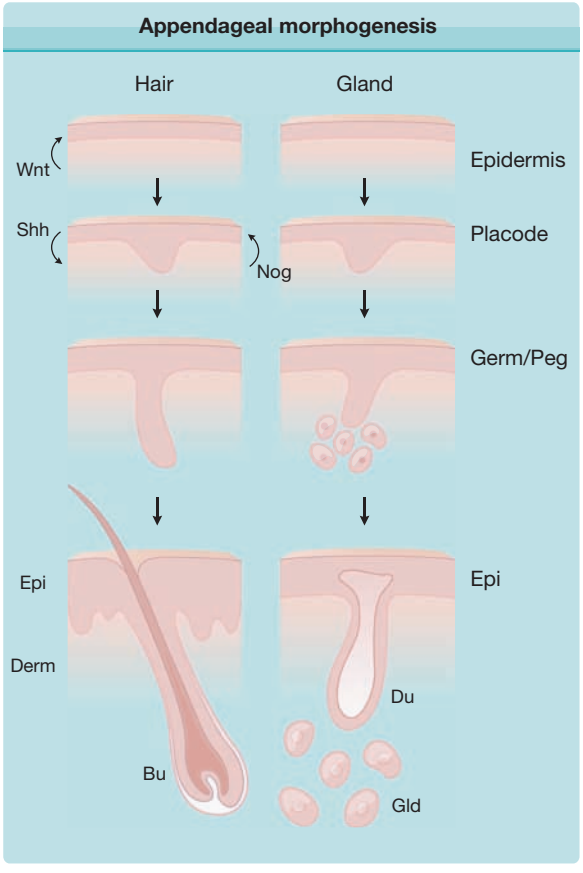

Figure 7-10 Appendageal morphogenesis. Through a series of reciprocal epithelial (epidermal)–mesenchymal (dermal) signals, including Wnt, sonic hedgehog (Shh), and Noggin (Nog), appendages such as the hair follicle and eccrine gland begin as epidermal invaginations (placodes), which signal the organization of specialized dermis (dermal condensate). This dermal condensate subsequently signals the differentiation of the epidermal downgrowth into the germ, peg, and mature appendageal structure. Bu = bulge; Derm = dermis; Du = duct; Epi = epidermis; Gld = gland.

promoters and placode inhibitors.[83] Wnt family signaling molecules are proposed to promote placode formation, whereas BMP family molecules are postulated to inhibit follicle formation. Subsequent reciprocal signaling between the epidermal and dermal components of the appendage result in its ultimate development and maturation.

In addition to the widened bulge at the base, two other bulges form along the length of the developing follicle, termed the *bulbous hair peg*. The uppermost bulge is the presumptive sebaceous gland, whereas the middle bulge serves as the site for insertion of the arrector pili muscle. This middle bulge is also the location of the multipotent hair stem cells, which are capable of differentiating into any of the cells of the hair follicle, and also have the potential to replenish the entire epidermis, as has been seen in cases of extensive surface wounds or burns.

By 19–21 weeks EGA, the hair canal is completely formed and the hairs on the scalp are visible above the surface of the fetal epidermis. They continue to lengthen until 24–28 weeks, at which time they complete the first hair cycle (see Chapter 86). With subsequent hair cycles, hairs increase in diameter and coarseness. During adolescence, vellus hairs of androgen-sensitive areas mature to terminal-type hair follicles.

SEBACEOUS GLANDS (SEE CHAPTER 79)

Sebaceous glands mature during the course of follicular differentiation. This process begins between 13 and 16 weeks EGA, at which point the presumptive sebaceous gland is first visible as the most superficial bulge of the maturing hair follicle. The outer proliferative cells of the gland give rise to the differentiated cells that accumulate lipid and sebum. After they terminally differentiate, these cells disintegrate and release their products into the upper portion of the hair canal. Sebum production is accelerated in the second and third trimesters, during which time maternal steroids cause stimulation of the sebaceous glands. Hormonal activity is once again thought to influence the production of increased sebum during adolescence, resulting in the increased incidence in acne at this age.

NAIL DEVELOPMENT (SEE CHAPTER 89)

Presumptive nail structures begin to appear on the dorsal digit tip at 8–10 weeks EGA, slightly earlier than the initiation of hair follicle development. The first sign is the delineation of the flat surface of the future nail bed. A portion of ectoderm buds inward at the proximal boundary of the early nail field, and gives rise to the proximal nail fold. The presumptive nail matrix cells, which differentiate to become the nail plate, are present on the ventral side of the proximal invagination. At 11 weeks, the dorsal nail bed surface begins to keratinize. By the fourth month of gestation, the nail plate grows out from the proximal nail fold, completely covering the nail bed by the fifth month. Mutations in *p63* affect nail development in syndromes such as ankyloblepharon, ectodermal dysplasia, and cleft lip/palate syndrome, as well as ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome. Functional *p63* is required for the formation and maintenance of the apical ectodermal ridge, an embryonic signaling center essential for limb outgrowth and hand plate formation. Wnt7a is thought to be important for dorsal limb patterning, and thus nail formation. In contrast to follicular development, Shh is not required for nail plate formation. Also similar to follicular differentiation, *LMX1b* and *MSX1* are important for nail specification; *LMX1b* and *MSX1* are mutated in nail–patella syndrome and Witkop syndrome, respectively.[84–86] *Hoxc13* appears to be an important homeodomain-containing gene for both follicular and nail appendages, at least in murine models.[87]

ECCRINE AND APOCRINE SWEAT GLAND DEVELOPMENT (SEE CHAPTER 83)

Eccrine glands begin to develop on the volar surfaces of the hands and feet, beginning as mesenchymal pads between 55 and 65 days EGA. By 12–14 weeks EGA, parallel ectodermal ridges are induced, which overlay these pads. The eccrine glands arise from the ectodermal ridge. By 16 weeks EGA, the secretory portion of the gland becomes detectable. The dermal duct begins around week 16, but the epidermal portion of the duct and opening are not complete until 2 weeks EGA.

Interfollicular eccrine and apocrine glands, in contrast, do not begin to bud until the fifth month of gestation. Apocrine sweat glands usually bud from the upper portion of the hair follicle. By 7 months EGA, the cells of the apocrine glands become distinguishable.

Although not much is known with regard to the molecular signals responsible for the differentiation of these structures, the *EDA*, *EDAR*, *En1*, and *Wnt10b* genes have been implicated. Hypohidrotic ectodermal dysplasia results from mutations in *EDA* or the *EDAR* (see Chapter 142).

Chapter 8 :: Genetics in Relation to the Skin

:: John A. McGrath & W. H. Irwin McLean

THE HUMAN GENOME IN DERMATOLOGY

In the 30 years since the first human gene, placental lactogen, was cloned in 1977, huge investments in time, money, and effort have gone into disclosing the innermost workings of the human genome. The Human Genome Project, which began in 1990, has led to sequence information on more than 3 billion base pairs (bp) of DNA, with identification of most of the estimated 25,000 genes in the entire human genome.[1] Although a few relatively small gaps remain, the near completion of the entire sequence of the human genome is having a huge impact on both the clinical practice of genetics and the strategies used to identify disease-associated genes. Laborious positional cloning approaches and traditional functional studies are gradually being transformed by the emergence of new genomic and proteomic databases.[2] Some of the exciting challenges that clinicians and geneticists now face are determining the function of these genes, defining disease associations and, relevant to patients, correlating genotype with phenotype. Nevertheless, many discoveries are already influencing how clinical genetics is practiced throughout the world, particularly for patients and families with rare, monogenic inherited disorders. The key benefits of dissection of the genome thus far have been the documentation of new information about disease causation, improving the accuracy of diagnosis and genetic counseling, and making DNA-based prenatal testing feasible.[3] Indeed, the genetic basis of more than 2,000 inherited single gene disorders has now been determined, of which about 25% have a skin phenotype. Therefore, these discoveries have direct relevance to dermatologists and their patients. Recently, studies in rare inherited skin disorders have also led to new insight into the pathophysiology of more common complex trait skin disorders.[4] This new information is expected to have significant implications for the development of new therapies and management strategies for patients. Therefore, for the dermatologist understanding the basic language and principles of clinical and molecular genetics has become a vital part of day-to-day practice. The aim of this chapter is to provide an overview of key terminology in genetics that is clinically relevant to the dermatologist.

THE HUMAN GENOME

Normal human beings have a large complex genome packaged in the form of 46 chromosomes. These consist of 22 pairs of autosomes, numbered in descending order of size from the largest (chromosome 1) to the smallest (chromosome 22), in addition to two sex chromosomes, X

and Y. Females possess two copies of the X chromosome, whereas males carry one X and one Y chromosome. The haploid genome consists of about 3.3 billion bp of DNA. Of this, only about 1.5% corresponds to protein-encoding exons of genes. Apart from genes and regulatory sequences, perhaps as much as 97% of the genome is of unknown function, often referred to as "junk" DNA. However, caution should be exercised in labeling the noncoding genome as "junk," because other unknown functions may reside in these regions. Much of the noncoding DNA is in the form of repetitive sequences, pseudogenes ("dead" copies of genes lost in recent evolution), and transposable elements of uncertain relevance. Although initial estimates for the number of human genes was in the order of 100,000, current predictions, based on the essentially complete genome sequence, are in the range of 20,000 to 25,000.[1] Surprisingly, therefore, the human genome is comparable in size and complexity to primitive organisms such as the fruit fly. However, it is thought that the generation of multiple protein isoforms from a single gene via alternate splicing of exons, each with a discrete function, is what contributes to increased complexity in higher organisms, including humans. In addition to protein-encoding genes, there are also many genes encoding untranslated RNA molecules, including transfer RNA, ribosomal RNA, and, as recently described, microRNA genes. MicroRNA is thought to be involved in the control of a large number of other genes through the RNA inhibition pathway. Very recently, it has emerged that tracts of the genome are transcribed at low levels in the form of exotic new RNA species, including natural antisense RNA and long interspersed noncoding RNA. These transcripts are emerging as key regulatory molecules. Thus, a much greater proportion of the genome is actively transcribed than was previously recognized and this trend is likely to continue in the current "postgenome" era of human genetics.

The draft sequence of the human genome was completed in 2003. Subsequently, small gaps have been filled, and the sequence has now been extensively annotated in terms of genes, repetitive elements, regulatory sequences, polymorphisms, and many other features recognizable by in silico data mining methods informed, wherever possible, by functional analysis. This annotation process will continue for some time as more features are uncovered. The human genome data, and that for an increasing number of other species, is freely available on Web sites (Table 8-1). Some regions of the genome, particularly near the centromeres, consist of long stretches of highly repetitive sequences that are difficult or impossible to clone and/or sequence. These heterochromatic regions of the genome are unlikely to be sequenced and are thought to be structural in nature, mediating the chromosomal architecture required for cell division, rather than contributing to heritable characteristics.

GENETIC AND GENOMIC DATABASES

Given the size and complexity of the human genome and other genomes now available, analysis of these enormous datasets in any kind of meaningful way is heavily reliant on computers. Even storage and retrieval of the sequence data associated with mammalian genome require considerable computer power and memory, and even the assembly of the raw sequence of any mammalian genome would have been unfeasible without computers. Many Web browsers for accessing genome data are available and the most useful of these are listed in Table 8-1. Each of these interfaces, which are the ones which the authors find most useful and user-friendly, contains a wide variety of tools for analysis and searching of sequences according to keyword, gene name, protein name, and homology to DNA or protein sequence data.

Online Mendelian Inheritance in Man	http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim

The main source of historical, clinical, molecular, and biochemical data relating to human genetic diseases is the Online Mendelian Inheritance in Man (OMIM) (see Table 8-1). All recognized genetic diseases and nonpathogenic heritable traits, including common diseases with a genetic component, as well as all known genes and proteins, are listed and reviewed by OMIM number with links to PubMed.

CHROMOSOME AND GENE STRUCTURE

Human chromosomes share common structural features (Fig. 8-1). All consist of two chromosomal arms, designated as "p" and "q." If the arms are of unequal length, the short arm is always designated as the "p" arm. Chromosomal maps to seek abnormalities are based on the stained, banded appearance of condensed chromosomes during metaphase of mitosis. During interphase, the uncondensed chromosomes are not discernible by normal microscopy techniques. Genes can now be located with absolute precision in terms of the range of bp that they span within the DNA sequence for a given chromosome. The bands are numbered from the centromere outwards using a system that has evolved as increasingly discriminating chromosome stains, as well as higher resolution light microscopes, became available. A typical cytogenetic chromosome band is 17q21.2, within which the type I keratin genes reside (see Fig. 8-1).

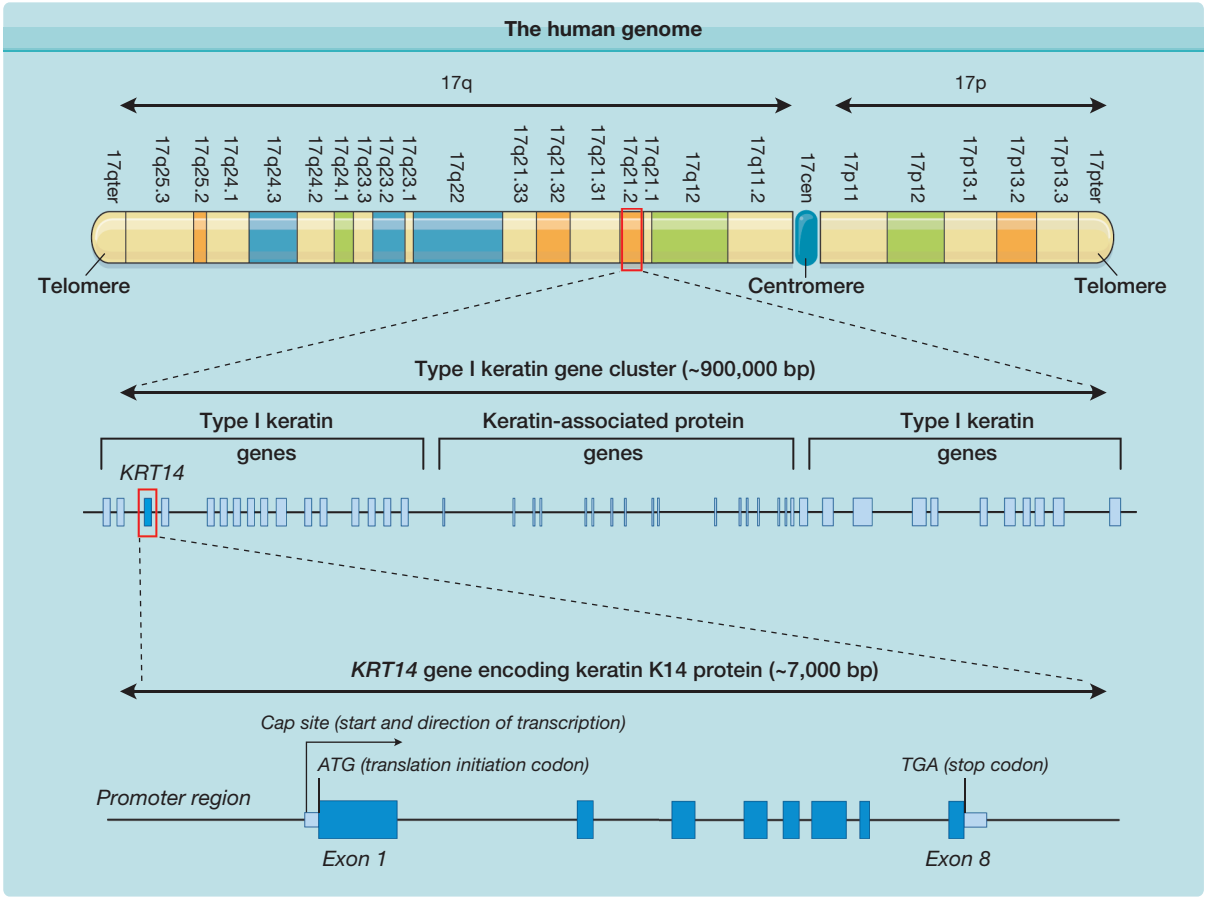

Figure 8-1 Illustration of the complexity of the human genome. At the top, the short (p) and long (q) arms of human chromosome 17 are depicted with their cytogenetic chromosome bands. One of these band regions, 17q21.2, is then highlighted to show that it is made up of approximately 900,000 base pairs (bp) and contains several genes, including 27 functional type I keratin genes. Part of this region is then further amplified to show one keratin gene, *KRT14*, encoding keratin 14, which is composed of eight exons.

The ends of the chromosomal arms are known as *telomeres*, and these consist of multiple tandem repeats of short DNA sequences. In germ cells and certain other cellular contexts, additional repeats are added to telomeres by a protein–RNA enzyme complex known as *telomerase*. During each round of cell division in somatic cells, one of the telomere repeats is trimmed off as a consequence of the DNA replication mechanism. By measuring the length of telomeres, the "age" of somatic cells, in terms of the number of times they have divided during the lifetime of the organism, can be determined. Once the telomere length falls below a certain threshold, the cell undergoes senescence. Thus, telomeres contribute to an important biological clock function that removes somatic cells that have gone through too many rounds of replication and are at a high risk of accumulating mutations that could lead to tumorigenesis or other functional aberration.[5]

The chromosome arms are separated by the centromere, which is a large stretch of highly repetitious DNA sequence. The centromere has important functions in terms of the movement and interactions of chromosomes. The centromeres of sister chromatids are where the double chromosomes align and attach during the prophase and anaphase stages of mitosis (and meiosis). The centromeres of sister chromatids are also the site of kinetochore formation. The latter is a multiprotein complex to which microtubules attach, allowing mitotic spindle formation, which ultimately results in pulling apart of the chromatids during anaphase of the cell division cycle.

The majority of chromosomal DNA contains genes interspersed with noncoding stretches of DNA of varying sizes. The density of genes varies widely across the chromosomes so that there are gene-dense regions or, alternately, large areas almost devoid of functional genes. An example of a comparatively gene-rich region of particular relevance to inherited skin diseases is the type I keratin gene cluster on chromosome band 17q21.2 (see Fig. 8-1). This diagram also gives an idea of the sizes in bp of DNA of a typical chromosome and a typical gene located within it. This gene cluster spans about 900,000 bp of DNA and contains 27 functional type I keratin genes, several genes encoding keratin-associated proteins, and a number of pseudogenes (not shown). Because chromosome 17 is one of the smaller chromosomes, Fig. 8-1 starts to give some idea of the overall complexity and organization of the genome.

Protein-encoding genes normally consist of several exons, which collectively code for the amino acid sequence of the protein (or open reading frame). These are separated by noncoding introns. In human genes, few exons are much greater than 1,000 bp in size, and introns vary from less than 100 bp to more than 1 million bp. A typical exon might be 100 to 300 bp in size. The *KRT14* gene encoding keratin 14 (K14) protein is one of the genes in which mutations lead to epidermolysis bullosa (EB) simplex (see Chapter 62) and is illustrated in Fig. 8-1. *KRT14* is contained within about 7,000 bp of DNA and consists of eight modestly sized exons interspersed by seven small introns. Although all genes are present in all human cells that contain a nucleus, not every gene is expressed in all cells of tissues. For example, the *KRT14* gene is only active in basal keratinocytes of the epidermis and other stratified epithelial tissues and is essentially silent in all other tissues. When a protein-encoding gene is expressed, the RNA polymerase II enzyme transcribes the coding strand of the gene, starting from the cap site and continuing to the end of the final exon, where various signals lead to termination of transcription. The initial RNA transcript, known as *heteronuclear RNA*, contains intronic as well as exonic sequences. This primary transcript undergoes splicing to remove the introns, resulting in the messenger RNA (mRNA) molecule.[6] In addition, the bases at the 5′ end (start) of the mRNA are chemically modified (capping) and a large number of adenosine bases are added at the 3′ end, known as the *poly-A tail*. These posttranscriptional modifications stabilize the mRNA and facilitate its transport within the cell. The mature mRNA undergoes a test round of translation which, if successful, leads to the transport of the mRNA to the cytoplasm, where it undergoes multiple rounds of translation by the ribosomes, leading to accumulation of the encoded protein. If the mRNA contains a nonsense mutation, otherwise known as a *premature termination codon mutation*, the test round of translation fails, and the cell degrades this mRNA via the nonsense-mediated mRNA pathway.[7] This is a mechanism that the cell has evolved to remove aberrant transcripts, and it may also contribute to gene regulation, particularly when very low levels of a particular protein are required within a given cell.

Splicing out of introns is a complex process. The genes of prokaryotes, such as bacteria, do not contain introns, and so mRNA splicing is a process that is specific to higher organisms. In some more primitive eukaryotes, RNA molecules contain catalytic sequences known as *ribozymes*, which mediate the self-splicing out of introns without any requirement for additional factors. In mammals, splicing involves a large number of protein and RNA factors encoded by several genes. This allows another level of control over gene expression and also facilitates alternative splicing of exons, so that a single gene can encode several functionally distinct variants of a protein. These isoforms are often differentially expressed in different tissues. In terms of the gene sequences important for splicing, a few bp at the beginning and at the end of an intron, known as the 5′ splice site (or splice donor site) and the 3′ splice site (or splice acceptor site) are crucial. A few other bp within the intron, such as the branch point site located 18–100 bp away from the 3′ end, are also critical. Mutations affecting any of the invariant residues of these splice sites lead to aberrant splicing and either complete loss of protein expression or generation of a highly abnormal protein.

The mRNA also contains two untranslated regions (UTR): (1) the 5′UTR upstream of the initiating ATG codon and (2) the 3′UTR downstream of the terminator (or stop codon, which can be TGA, TAA, or TAG). The 5′ UTR can and often does possess introns, whereas the 3′UTR of more than 99% of mammalian genes does not contain introns. The nonsense-mediated mRNA decay pathway identifies mutant transcripts by means of assessing where the termination codon occurs in relation to introns. The natural stop codon is always followed immediately by the 3′UTR, which, in turn, does not normally possess any introns. If a stop codon occurs in an mRNA upstream of a site where an intron has been excised, this message is targeted for nonsense-mediated decay. The only genes that contain introns within their 3′UTR sequences are expressed at extremely low levels. This is one of the ways in which the cell can determine how much protein is made from a particular gene.

Gene complexity is widely variable and not necessarily related to the size of the protein encoded. Some genes consist of only a single small exon, such as those encoding the connexin family of gap junction proteins. Such single exon genes are rapid and inexpensive to analyze routinely. In contrast, the type VII collagen gene, *COL7A1*, in which mutations lead to the dystrophic forms of EB (see Chapter 62), has 118 exons, meaning that 118 different parts of the gene need to be isolated and analyzed for molecular diagnosis of each dystrophic EB patient. The filaggrin gene (*FLG*) on chromosome 1, recently shown to be the causative gene for ichthyosis vulgaris (see Chapter 49) and a susceptibility gene for atopic dermatitis (see Chapter 14), has only three exons. However, the third exon of *FLG* is made up of repeats of a 1,000-bp sequence and varies in size from 12,000 to 14,000 bp among different individuals in the population. This unusual gene structure makes routine sequencing of genes such as *COL7A1* or *FLG* difficult, time consuming, and expensive.

GENE EXPRESSION

Each specific gene is generally only actively transcribed in a subset of cells or tissues within the body. Gene expression is largely determined by the promoter elements of the gene. In general, the most important region of the promoter is the stretch of sequence immediately upstream of the cap site. This proximal promoter region contains consensus binding sites for a variety of transcription factors, some of which are general in nature and required for all gene expression, others are specific to particular tissue or cell lineage, and some are absolutely specific for a given cell type and/or stage of development or differentiation. The size of the promoter can vary widely according to gene family or between the individual genes themselves. For

example, the keratin genes are tightly spaced within two gene clusters on chromosomes 12q and 17q, but these are exquisitely tissue specific in two different ways. First, these genes are only expressed in epithelial cells, and therefore their promoters must possess regulatory sequences that determine epithelial expression. Therefore, these regulatory elements are specific for cells of ectodermal origin. Second, these genes are expressed in very specific subsets of epithelial cells, and so there must be a second level of control that specifies which epithelial cell layers express specific keratin genes. This is best illustrated in the hair follicle, where there are many different epithelial cell layers, each with a specific pattern of keratin gene expression (see Chapter 86).[8]

Transcription factors are proteins that either bind to DNA directly or indirectly by associating with other DNA-binding proteins. Binding of these factors to the promoter region of a gene leads to activation of the transcription machinery and transcription of the gene by RNA polymerase II. The transcription factor proteins are encoded by genes that are in turn controlled by promoters that are regulated by other transcription factors encoded by other genes. Thus, there are several tiers of control over gene expression in a given cell type, and the intricacies of this can be difficult to fully unravel experimentally. Nevertheless, by isolation of promoter sequences from genes of interest and placing these in front of reporter genes that can be assayed biochemically, such as firefly luciferase that can be assayed by light emission, the activity of promoters can be reproduced in cultured cells that normally express the gene. Combining such a reporter gene system with site-directed mutagenesis to make deletions or alter small numbers of bp within the promoter can help define the extent of the promoter and the important sequences within it that are required for gene expression. A variety of biochemical techniques, such as DNA footprinting, ribonuclease protection, electrophoretic mobility shift assays, or chromatin immunoprecipitation, can be used to determine which transcription factors bind to a particular promoter and help delineate the specific promoter sequences bound. Expression of reporter genes under the control of a cloned promoter in transgenic mice also helps shed light on the important sequences that are required to recapitulate the endogenous expression of the gene under study. Keratin promoters are unusual in that, generally, a small fragment of only 2,000 to 3,000 bp upstream of the gene can confer most of the tissue specificity. For this reason, keratin promoters are widely used to drive exogenous transgene expression in the various specific cellular compartments of the epidermis and its appendages for experiments to determine gene, cell, or tissue function.[9]

Some promoter or enhancer sequences act over very long distances. In some cases, sequences located millions of bp distant, with several other genes in the intervening region, somehow influence expression of a target gene. In some genetic diseases, mutations affecting such long-range promoter elements are now emerging. These types of mutations appear to be rare, but since they occur so far away from the target gene and are therefore very difficult to find, this class of mutation may, in fact, be more common than is immediately obvious. In general, relatively few disease-causing mutations have been shown to involve promoters, but this class of defect is probably greatly underrepresented because the sequences that are important for promoter activity are poorly characterized. Prediction of transcription factor binding sites by computer analysis is an area for further study. Although these undoubtedly exist, there are relatively few examples so far of pathogenic defects in microRNA or other noncoding regulatory RNA species.

FINDING DISEASE GENES

In establishing the molecular basis of an inherited skin disease, there are two key steps. First, the gene linked to a particular disorder must be identified, and second, pathogenic mutations within that gene should be determined. Diseases can be matched to genes either by genetic linkage analysis or by a candidate gene approach.[10] Genetic linkage involves studying pedigrees of affected and unaffected individuals and isolating which bits of the genome are specifically associated with the disease phenotype. The goal is to identify a region of the genome that all the affected individuals and none of the unaffected individuals have in common; this region is likely to harbor the gene for the disorder, as well as perhaps other nonpathogenic neighboring genes that have been inherited by linkage disequilibrium. Traditionally, genome-wide linkage strategies make use of variably sized microsatellite markers scattered throughout the genome, although for recessive diseases involving consanguineous pedigrees, a more rapid approach may be to carry out homozygosity mapping using single nucleotide polymorphism (SNP) chip arrays. By contrast, the candidate gene approach involves first looking for a clue to the likely gene by finding a specific disease abnormality, perhaps in the expression (or lack thereof) of a particular protein or RNA, or from an ultrastructural or biochemical difference between the diseased and control tissues. Nevertheless, the genetic linkage and candidate gene approaches are not mutually exclusive and are often used in combination. For example, to identify the gene responsible for the autosomal recessive disorder, lipoid proteinosis (see Chapter 137), genetic linkage using microsatellites was first used to establish a region of linkage on 1q21 that contained 68 genes.[11] The putative gene for this disorder, *ECM1* encoding extracellular matrix protein 1, was then identified by a candidate gene approach that searched for reduced gene expression (lack of fibroblast complementary DNA) in all these genes. A reduction in *ECM1* gene expression in lipoid proteinosis compared with control provided the clue to the candidate gene because there were no differences in any of the other patterns of gene expression. Ultrastructural and immunohistochemical analyses can also provide clues to underlying gene pathology. For example, loss of hemidesmosomal inner plaques noted on transmission electron microscopy and a complete absence of skin immunostaining

for the 230-kDA bullous pemphigoid antigen (BP230) at the dermal–epidermal junction, led to the discovery of loss-of-function mutations in the dystonin (*DST*) gene, which codes for BP230, in a new form of autosomal recessive epidermolysis bullosa simplex.[12]

Having identified a putative gene for an inherited disorder, the next stage is to find the pathogenic mutation(s). This can be done by sequencing the entire gene, a feat which is becoming easier as technologic advances make automated nucleotide sequencing faster, cheaper, and more accessible. However, the large size of some genes may make comprehensive sequencing impractical, and therefore initial screening approaches to identify the region of a gene that contains the mutation may be a necessary first step. There are many mutation detection techniques available to scan for sequence changes in cellular RNA or genomic DNA, and these include denaturing gradient gel electrophoresis, chemical cleavage of mismatch, single stranded conformation polymorphism, heteroduplex analysis, conformation sensitive gel electrophoresis, denaturing high-performance liquid chromatography and the protein truncation test.[13]

The most critical factor that determines the success of any gene screening protocol is the sensitivity of the detection technique. In addition, when choosing a mutation screening strategy using genomic DNA, the size of the gene and its number of exons must be taken into account. The sensitivities of these methods vary greatly, depending on the size of template screened. For example, single-stranded conformation polymorphism has a sensitivity of >95% for fragments of 155 bp, but this is reduced to only 3% for 600 bp. Once optimized, denaturing gradient gel electrophoresis has a sensitivity of about 99% for fragments of up to 500 bp, and conformation sensitive gel electrophoresis is expected to have a sensitivity of 80% to 90% for fragments of up to 600 bp. Chemical cleavage of mismatch, on the other hand, has a sensitivity of 95% to 100% for fragments >1.5 kilobases (kb) in size and is ideal for screening compact genes where more than one exon can be amplified together using genomic DNA as the template. All these techniques detect sequence changes such as truncating and missense mutations as well as polymorphisms; however, the protein truncation test screens only for truncating mutations and is predicted to have a sensitivity of >95% and can be used for RNA or DNA fragments in excess of 3 kb.

Whichever approach is taken, having identified a difference in the patient's DNA compared with the control sample, the next stage is to determine how this segregates within a particular family and also whether it is pathogenic or not. Very recently, great advances have been made in DNA sequencing technology, with the emergence of "next generation sequencing" (NGS) technology. Currently, it is quite feasible to carry out whole exome sequencing in an individual using NGS, i.e., sequencing of all the protein-encoding exons in the genome, in a matter of days and for only a few thousand dollars. It is expected that whole genome sequencing, at a cost of $1,000 or less will be a commonplace in 2–3 years. This incredible new technology is set to revolutionize human genetics once more, and in particular, will facilitate identification of mutated genes in small kindreds that are not tractable by genetic linkage methods. These advances will also impact on diagnosis—in the near future it may be faster and cheaper to sequence a patient's whole genome rather than to do targeted sequencing of specific genes or regions.

GENE MUTATIONS AND POLYMORPHISMS

Within the human genome, the genetic code of two healthy individuals may show a number of sequence dissimilarities that have no relevance to disease or phenotypic traits. Such changes within the normal population are referred to as *polymorphisms* (Fig. 8-2). Indeed, even within the coding region of the genome, clinically irrelevant substitutions of one bp, known as *SNPs*, are common and occur approximately once every 250 bp.[14] Oftentimes, these SNPs do not change the amino acid composition; for example, a C-to-T transition in the third position of a proline codon (CCC to CCT) still encodes for proline, and is referred to as a *silent mutation*. However, some SNPs do change the nature of the amino acid; for example, a C-to-G transversion at the second position of the same proline codon (CCC to CGC) changes the residue to arginine. It then becomes necessary to determine whether a missense change such as this represents a nonpathogenic polymorphism or a pathogenic mutation. Factors favoring the latter include the sequence segregating only with the disease phenotype in a particular family, the amino acid change occurring within an evolutionarily conserved residue, the substitution affecting the function of the encoded protein (size, charge, conformation, etc.), and the nucleotide switch not being detectable in at least 100 ethnically matched control chromosomes. Nonpathogenic polymorphisms do not always involve single nucleotide substitutions; occasionally, deletions and insertions may also be nonpathogenic.

A mutation can be defined as a change in the chemical composition of a gene. A missense mutation changes one amino acid to another. Mutations may also be insertions or deletions of bases, the consequences of which will depend on whether this disrupts the normal reading frame of a gene or not, as well as nonsense mutations, which lead to premature termination of translation (see Fig. 8-2). For example, a single nucleotide deletion within an exon causes a shift in the reading frame, which usually leads to a downstream stop codon, thus giving a truncated protein, or often an unstable mRNA that is readily degraded by the cell. However, a deletion of three nucleotides (or multiples thereof) will not significantly perturb the overall reading frame, and the consequences will depend on the nature of what has been deleted. Nonsense mutations typically, but not exclusively, occur at CpG dinucleotides, where methylation of a cytosine nucleotide often occurs. Inherent chemical instability of this modified cytosine leads to a high rate of mutation to thymine. Where this alters the codon (e.g., from CGA to TGA), it will change an arginine residue to a stop codon. Nonsense mutations

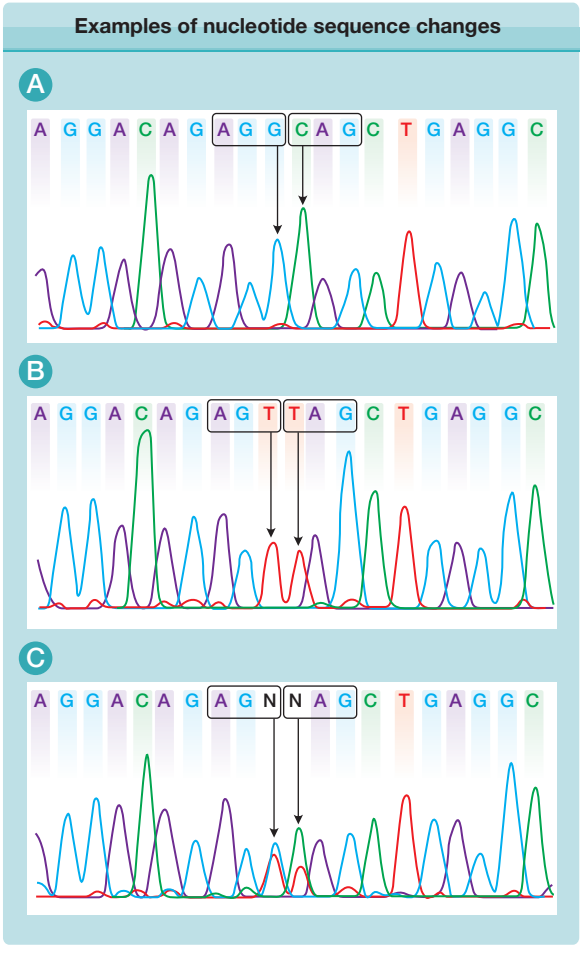

Figure 8-2 Examples of nucleotide sequence changes resulting in a polymorphism and a nonsense mutation. **A.** Two adjacent codons are highlighted. The AGG codon encodes arginine and the CAG codon encodes glutamine. **B.** The sequence shows two homozygous nucleotide substitutions. The AGG codon now reads AGT (i.e., coding for serine rather than arginine). This is a common sequence variant in the normal population and is referred to as a *nonpathogenic missense polymorphism*. In contrast, the glutamine codon CAG now reads TAG, which is a stop codon. This is an example of a homozygous nonsense mutation. **C.** This sequence is from one of the parents of the subject sequenced in **B** and shows heterozygosity for both the missense polymorphism AGG > AGT and the nonsense mutation CAG > TAG, indicating that this individual is a carrier of both sequence changes.

usually lead to a reduced or absent expression of the mutant allele at the mRNA and protein levels. In the heterozygous state, this may have no clinical effect [e.g., parents of individuals with Herlitz junctional EB are typically carriers of nonsense mutations in one of the laminin 332 (laminin 5) genes but have no skin fragility themselves; see Chapter 62], but a heterozygous nonsense mutation in the desmoplakin gene, for example, can result in the autosomal dominant skin disorder, striate palmoplantar keratoderma (see Chapter 50). This phenomenon is referred to as *haploinsufficiency* (i.e., half the normal amount of protein is insufficient for function).

Apart from changes in the coding region that result in frameshift, missense, or nonsense mutations, approximately 15% of all mutations involve alterations in the gene sequence close to the boundaries between the introns and exons, referred to as *splice site mutations*. This type of mutation may abolish the usual acceptor and donor splice sites that normally splice out the introns during gene transcription. The consequences of splice site mutations are complex; sometimes they lead to skipping of the adjacent exon, and other times they result in the generation of new mRNA transcripts through utilization of cryptic splice sites within the neighboring exon or intron.

Mutations within one gene do not always lead to a single inherited disorder. For example, mutations in the *ERCC2* gene may lead to xeroderma pigmentosum (type D), trichothiodystrophy, or cerebrofacioskeletal syndrome, depending on the position and type of mutation. Other transacting factors may further modulate phenotypic expression. This situation is known as *allelic heterogeneity*. Conversely, some inherited diseases can be caused by mutations in more than one gene (e.g., non-Herlitz junctional EB; see Chapter 62) and can result from mutations in either the *COL17A1*, *LAMA3*, *LAMB3*, or *LAMC2* genes. This is known as *genetic heterogeneity*. In addition, the same mutation in one particular gene may lead to a range of clinical severity in different individuals. This variability in phenotype produced by a given genotype is referred to as the *expressivity*. If an individual with such a genotype has no phenotypic manifestations, the disorder is said to be *nonpenetrant*. Variability in expression reflects the complex interplay between the mutation, modifying genes, epigenetic factors, and the environment and demonstrates that interpreting what a specific gene mutation does to an individual involves more than just detecting one bit of mutated DNA in a single gene.

MENDELIAN DISORDERS

There are approximately 5,000 human single-gene disorders and, although the molecular basis of less than one-half of these has been established, understanding the pattern of inheritance is essential for counseling prospective parents about the risk of having affected children. The four main patterns of inheritance are (1) autosomal dominant, (2) autosomal recessive, (3) X-linked dominant, and (4) X-linked recessive.

For individuals with an autosomal dominant disorder, one parent is affected, unless there has been a de novo mutation in a parental gamete. Males and females are affected in approximately equal numbers, and the disorder can be transmitted from generation to generation; on average, half the offspring will have the condition (Fig. 8-3). It is important to counsel affected individuals that the risk of transmitting the disorder is 50% for each of their children, and that this is not influenced by the number of previously affected or unaffected offspring. Any offspring that are affected will have a 50% risk of transmitting the mutated gene to the next generation, whereas for any unaffected offspring, the risk of the next generation being affected

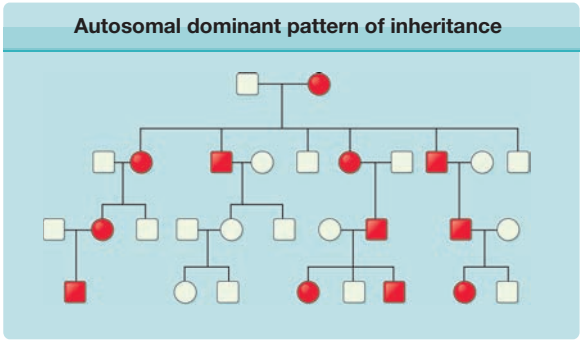

Figure 8-3 Pedigree illustration of an autosomal dominant pattern of inheritance. Key observations include: the disorder affects both males and females; on average, 50% of the offspring of an affected individual will be affected; affected individuals have one normal copy and one mutated copy of the gene; affected individuals usually have one affected parent, unless the disorder has arisen de novo. Importantly, examples of male-to-male transmission, seen here, distinguish this from X-linked dominant and are therefore the best hallmark of autosomal dominant inheritance. Filled circles indicate affected females; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

is negligible, providing that the partner does not have the autosomal dominant condition. Some dominant alleles can behave in a partially dominant fashion. The term *semidominant* is applied when the phenotype in heterozygous individuals is less than that observed for homozygous subjects. For example, ichthyosis vulgaris is a *semidominant* disorder in which the presence of one or two mutant profilaggrin gene (*FLG*) alleles can strongly influence the clinical severity of the ichthyosis.

In autosomal recessive disorders, both parents are carriers of one normal and one mutated allele for the same gene and, typically, they are phenotypically unaffected (Fig. 8-4). If both of the mutated alleles are transmitted to the offspring, this will give rise to an autosomal recessive disorder, the risk of which is 25%. If one mutated and one wild-type allele is inherited by the offspring, the child will be an unaffected carrier, similar to the parents. If both wild-type alleles are transmitted, the child will be genotypically and phenotypically normal with respect to an affected individual. If the mutations from both parents are the same, the individual is referred to as a *homozygote*, but if different parental mutations within a gene have been inherited, the individual is termed a *compound heterozygote*. For someone who has an autosomal recessive condition, be it a homozygote or compound heterozygote, all offspring will be carriers of one of the mutated alleles but will be unaffected because of inheritance of a wild-type allele from the other, clinically and genetically unaffected, parent. This assumes that the unaffected parent is not a carrier. Although this is usually the case in nonconsanguineous relationships, it may not hold true in first-cousin marriages or other circumstances where there is a familial interrelationship. For example, if the partner of an individual with an autosomal recessive disorder is also a carrier of the same mutation, albeit clinically unaffected, then there is a 50% chance of the offspring inheriting two mutant alleles and therefore also inheriting the same autosomal recessive disorder. This pattern of inheritance is referred to as *pseudodominant*.

In X-linked dominant inheritance, both males and females are affected, and the pedigree pattern may resemble that of autosomal dominant inheritance (Fig. 8-5). However, there is one important difference. An affected male transmits the disorder to all his daughters and to none of his sons. X-linked dominant inheritance has been postulated as a mechanism in incontinentia pigmenti (see Chapter 75), Conradi–Hünermann syndrome, and focal dermal hypoplasia (Goltz syndrome), conditions that are almost always limited to females. In most X-linked dominant

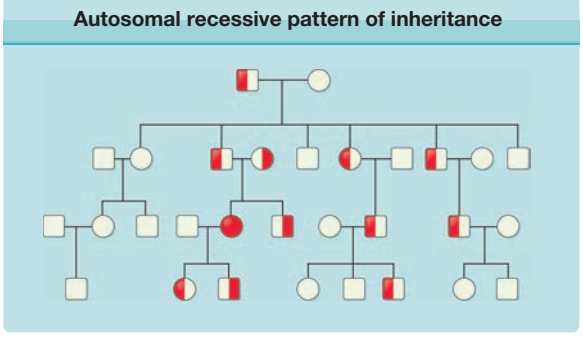

Figure 8-4 Pedigree illustration of an autosomal recessive pattern of inheritance. Key observations include: the disorder affects both males and females; there are mutations on both inherited copies of the gene; the parents of an affected individual are both heterozygous carriers and are usually clinically unaffected; autosomal recessive disorders are more common in consanguineous families. Filled circle indicates affected female; half-filled circles/squares represent clinically unaffected heterozygous carriers of the mutation; unfilled circles/squares represent unaffected individuals.

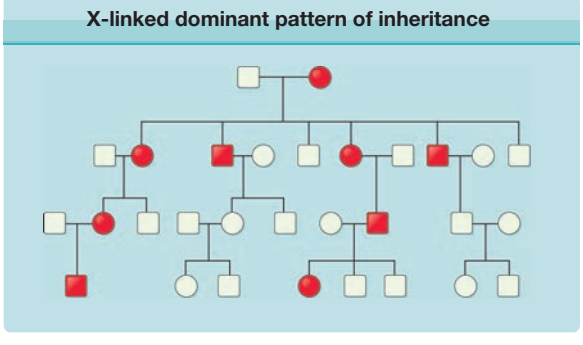

Figure 8-5 Pedigree illustration of an X-linked dominant pattern of inheritance. Key observations include: affected individuals are either hemizygous males or heterozygous females; affected males will transmit the disorder to their daughters but not to their sons (no male-to-male transmission); affected females will transmit the disorder to half their daughters and half their sons; some disorders of this type are lethal in hemizygous males and only heterozygous females survive. Filled circles indicate affected females; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

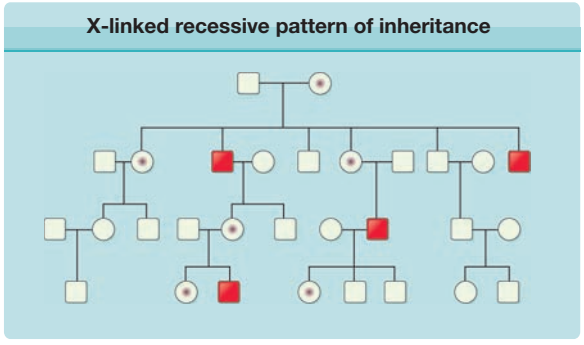

Figure 8-6 Pedigree illustration of an X-linked recessive pattern of inheritance. Key observations include: usually affects only males but females can show some features because of lyonization (X-chromosome inactivation); transmitted through female carriers, with no male-to-male transmission; for affected males, all daughters will be heterozygous carriers; female carrier will transmit the disorder to half her sons, and half her daughters will be heterozygous carriers. Dots within circles indicate heterozygous carrier females who may or may not display some phenotypic abnormalities; filled squares indicate affected males; unfilled circles/squares represent unaffected individuals.

disorders with cutaneous manifestations, affected males may be aborted spontaneously or die before implantation (leading to the appearance of female-to-female transmission). Most viable male patients with incontinentia pigmenti have a postzygotic mutation in NEMO and no affected mother; occasionally, males with an X-linked dominant disorder have Klinefelter syndrome with an XXY genotype.

X-linked recessive conditions occur almost exclusively in males, but the gene is transmitted by carrier females, who have the mutated gene only on one X chromosome (heterozygous state). The sons of an affected male will all be normal (because their single X chromosome comes from their clinically unaffected mother) (Fig. 8-6). However, the daughters of an affected male will all be carriers (because all had to have received the single X chromosome from their father that carries the mutant copy of the gene). Some females show clinical abnormalities as evidence of the carrier state (such as in hypohidrotic ectodermal dysplasia; see Chapter 142); the variable extent of phenotypic expression can be explained by lyonization, the normally random process that inactivates either the wild-type or mutated X chromosome in each cell during the first weeks of gestation and all progeny cells.[15] Other carriers may not show manifestations because the affected region on the X chromosome escapes lyonization (as in recessive X-linked ichthyosis) or the selective survival disadvantage of cells in which the mutated X chromosome is activated (as in the lymphocytes and platelets of carriers of Wiskott–Aldrich syndrome; see Section "Mosaicism").

CHROMOSOMAL DISORDERS

Aberrations in chromosomes are common. They occur in about 6% of all conceptions, although most of these lead to miscarriage, and the frequency of chromosomal abnormalities in live births is about 0.6%. Approximately two-thirds of these involve abnormalities in either the number of sex chromosomes or the number of autosomes; the remainder is chromosomal rearrangements. The number and arrangement of the chromosomes is referred to as the *karyotype*. The most common numerical abnormality is trisomy, the presence of an extra chromosome. This occurs because of nondisjunction, when pairs of homologous chromosomes fail to separate during meiosis, leading to gametes with an additional chromosome. Loss of a complete chromosome, monosomy, can affect the X chromosome but is rarely seen in autosomes because of nonviability. A number of chromosomal disorders are also associated with skin abnormalities, as detailed in Table 8-2.

Structural aberrations (fragility breaks) in chromosomes may be random, although some chromosomal regions appear more vulnerable. Loss of part of a chromosome is referred to as a *deletion*. If the deletion leads to loss of neighboring genes this may result in a contiguous gene disorder, such as a deletion on the X chromosome giving rise to X-linked ichthyosis (see Chapter 49) and Kallman syndrome. If two chromosomes break, the detached fragments may be exchanged, known as *reciprocal translocation*. If this process involves no loss of DNA it is referred to as a *balanced translocation*. Other structural aberrations include duplication of sections of chromosomes, two breaks within one chromosome leading to inversion, and fusion of the ends of two broken chromosomal arms, leading to joining of the ends and formation of a ring chromosome. Chromosomal anomalies may be detected using standard metaphase cytogenetics but newer approaches, such as SNP arrays and comparative genomic hybridization arrays, can also be used for karyotyping. Array-based cytogenetic tools do not rely on cell division and are very sensitive in detecting unbalanced lesions as well as copy number-neutral loss of heterozygosity. These new methods have become commonplace in diagnostic genetics laboratories. A further possible chromosomal abnormality is the inheritance of both copies of a chromosome pair from just one parent (paternal or maternal), known as *uniparental disomy*.[16] *Uniparental heterodisomy* refers to the presence of a pair of chromosome homologs, whereas *uniparental isodisomy* describes two identical copies of a single homolog, and *meroisodisomy* is a mixture of the two. Uniparental disomy with homozygosity of recessive alleles is being increasingly recognized as the molecular basis for several autosomal recessive disorders, and there have been more than 35 reported cases of recessive diseases, including junctional and dystrophic EB (see Chapter 62), resulting from this type of chromosomal abnormality. For certain chromosomes, uniparental disomy can also result in distinct phenotypes depending on the parental origin of the chromosomes, a phenomenon known as *genomic imprinting*.[17,18] This parent-of-origin, specific gene expression is determined by epigenetic modification of a specific gene or, more often, a group of genes, such that gene transcription is altered, and only one inherited copy of the relevant imprinted gene(s) is expressed in the embryo. This means that,

TABLE 8-2
Chromosomal Disorders with a Skin Phenotype

Chromosomal Abnormality	Synonym	General Features	Skin Manifestations
Trisomy 21	Down syndrome	Small head with flat face Nose short and squat Ears small and misshapen Slanting palpebral fissures Thickened eyelids Eyelashes short and sparse Shortened limbs, lax joints Fingers short, sometimes webbed Hypoplastic iris, lighter outer zone (Brushfield's spots)	1–10 year: dry skin, xerosis, lichenification 10+ year: increased frequency of atopic dermatitis, alopecia areata, single crease in palm and fifth finger Other associations: skin infections, angular cheilitis, geographic tongue, blepharitis, red cheeks, folliculitis, seborrheic dermatitis, boils, onychomycosis, fine hypopigmented hair, vitiligo, delayed dentition and hypoplastic teeth, acrocyanosis, livedo reticularis, cutis marmorata, calcinosis cutis, palmoplantar keratoderma, pityriasis rubra pilaris, syringomas, elastosis perforans serpiginosa, anetoderma, hyperkeratotic form of psoriasis, collagenoma, eruptive dermatofibromas, urticaria pigmentosa, leukemia cutis, keratosis follicularis spinulosa decalvans
Trisomy 18	Edwards syndrome	Severe mental deficiency Abnormal skull shape Small chin, prominent occiput Low-set, malformed ears "Rocker bottom" feet Short sternum Malformations of internal organs Only 10% survive beyond first year	Cutis laxa (neck), hypertrichosis of forehead and back, superficial hemangiomas, abnormal dermatoglyphics, single palmar crease, hyperpigmentation, ankyloblepharon filiforme adnatum
Trisomy 13	Patau syndrome	Mental retardation Sloping forehead due to forebrain maldevelopment (holoprosencephaly) Microphthalmia or anophthalmia Cleft palate/cleft lip Low-set ears "Rocker bottom" feet Malformations of internal organs Survival beyond 6 months is rare	Vascular anomalies (especially on forehead) Hyperconvex nails Localized scalp defects Cutis laxa (neck) Abnormal palm print (distal palmar axial triradius)
Chromosome 4, short arm deletion		Microcephaly Mental retardation Hypospadias Cleft lip/palate Low-set ears, preauricular pits	Scalp defects
Chromosome 5, short arm deletion		Mental retardation Microcephaly Cat-like cry Low-set ears, preauricular skin tag	Premature graying of hair
Chromosome 18, long arm deletion		Hypoplasia of midface Sunken eyes Prominent ear antihelix Multiple skeletal and ocular abnormalities	Eczema in 25% of cases
45 XO	Turner syndrome	Early embryonic loss; prenatal ultrasound findings of cystic hygroma, chylothorax, ascites and hydrops Short stature, amenorrhea Broad chest, widely spaced nipples Wide carrying angle of arms Low misshapen ears, high arched palate Short fourth/fifth fingers and toes Skeletal abnormalities, coarctation of aorta	Redundant neck skin and peripheral edema Webbed neck, low posterior hairline Cutis laxa (neck, buttocks) Hypoplastic, soft upturned nails Increased incidence of keloids Increased number of melanocytic nevi and halo nevi Failure to develop full secondary sexual characteristics Lymphatic hypoplasia/lymphedema
47 XXY	Klinefelter syndrome	No manifestations before puberty Small testes, poorly developed secondary sexual characteristics Infertility Tall, obese, osteoporosis	May develop gynecomastia Sparse body and facial hair Increased risk of leg ulcers Increased incidence of systemic lupus erythematosus
48 XXYY		Similar to Klinefelter syndrome	Multiple cutaneous angiomas Acrocyanosis, peripheral vascular disease
47 XYY		Phenotypic males (tall) Mental retardation Aggressive behavior	Severe acne
49 XXXXY		Low birth weight Slow mental and physical development Large, low-set, malformed ears Small genitalia	Hypotrichosis (variable)
Fragile X syndrome		Mental retardation Mild dysmorphism Hyperextensible joints, flat feet	—

during development, the parental genomes function unequally in the offspring. The most common examples of genomic imprinting are Prader–Willi (OMIM #176270) and Angelman (OMIM #105830) syndromes, which can result from maternal or paternal uniparental disomy for chromosome 15, respectively. Three phenotype abnormalities commonly associated with uniparental disomy for chromosomes with imprinting are (1) intrauterine growth retardation, (2) developmental delay, and (3) reduced stature.[19]

MITOCHONDRIAL DISORDERS

In addition to the 3.3 billion bp nuclear genome, each cell contains hundreds or thousands of copies of a further 16.5-kb mitochondrial genome, which is inherited solely from an individual's mother. This closed, circular genome contains 37 genes, 13 of which encode proteins of the respiratory chain complexes, whereas the other 24 genes generate 22 transfer RNAs and two ribosomal RNAs used in mitochondrial protein synthesis.[20] Mutations in mitochondrial DNA were first reported in 1988, and more than 250 pathogenic point mutations and genomic rearrangements have been shown to underlie a number of myopathic disorders and neurodegenerative diseases, some of which show skin manifestations, including lipomas, abnormal pigmentation or erythema, and hypo- or hypertrichosis.[21] Mitochondrial DNA mutations are very common in somatic mammalian cells, more than two orders of magnitude higher than the mutation frequency in nuclear DNA.[22] Mitochondrial DNA has the capacity to form a mixture of both wild-type and mutant DNA within a cell, leading to cellular dysfunction only when the ratio of mutated to wild-type DNA reaches a certain threshold. The phenomenon of having mixed mitochondrial DNA species within a cell is known as *heteroplasmy*. Mitochondrial mutations can induce, or be induced by, reactive oxygen species, and may be found in, or contribute to, both chronologic aging and photoaging.[23] Somatic mutations in mitochondrial DNA have also been reported in several premalignant and malignant tumors, including malignant melanoma, although it is not yet known whether these mutations are causally linked to cancer development or simply a secondary bystander effect as a consequence of nuclear DNA instability. Indeed, currently there is little understanding of the interplay between the nuclear and mitochondrial genomes in both health and disease. Nevertheless, it is evident that the genes encoded by the mitochondrial genome have multiple biologic functions linked to energy production, cell proliferation, and apoptosis.[24]

COMPLEX TRAIT GENETICS

For Mendelian disorders, identifying genes that harbor pathogenic mutations has become relatively straightforward, with hundreds of disease-associated genes being discovered through a combination of linkage, positional cloning, and candidate gene analyses. By contrast, for complex traits, such as psoriasis and atopic dermatitis, these traditional approaches have been largely unsuccessful in mapping genes influencing the disease risk or phenotype because of low statistical power and other factors.[25,26] Complex traits do not display simple Mendelian patterns of inheritance, although genes do have an influence, and close relatives of affected individuals may have an increased risk. To dissect out genes that contribute and influence susceptibility to complex traits, several stages may be necessary, including establishing a genetic basis for the disease in one or more populations; measuring the distribution of gene effects; studying statistical power using models; and carrying out marker-based mapping studies using linkage or association. It is possible to establish quantitative genetic models to estimate the heritability of a complex trait, as well as to predict the distribution of gene effects and to test whether one or more quantitative trait loci exist. These models can predict the power of different mapping approaches, but often only provide approximate predictions. Moreover, low power often limits other strategies such as transmission analyses, association studies, and family-based association tests. Another potential pitfall of association studies is that they can generate spurious associations due to population admixture. To counter this, alternative strategies for association mapping include the use of recent founder populations or unique isolated populations that are genetically homogeneous, and the use of unlinked markers (so-called *genomic controls*) to assign different regions of the genome of an admixed individual to particular source populations. In addition, and relevant to several studies on psoriasis, linkage disequilibrium observed in a sample of unrelated affected and normal individuals can also be used to fine-map a disease susceptibility locus in a candidate region.

In recent years, advances in the identification of many millions of SNPs across the entire genome, as well as major advances in gene chip technology that allows up to 2 million SNPs to be typed in a given individual for a few hundred dollars, coupled with high powered computation, have led to the current era of genome-wide association studies (GWAS).[27] This has become the predominant technology for tacking complex traits, with GWAS having already been performed for psoriasis, atopic eczema, vitiligo, and alopecia areata. GWAS for other dermatological complex traits are underway. A typical GWAS design involves collecting DNA from a well-phenotyped case series of the condition of choice, preferably from an ethnically homogenous population. Normally, 2,000 or more cases are required versus 3,000 ethnically matched random population controls. Correct clinical ascertainment of the cases is paramount and so GWAS represents a great opportunity for close cooperation between physicians and scientists. These 5,000 or more individuals are genotyped for 500,000 to 2 million SNPs, generating billions of data points. For each SNP across the genome, a statistical test is performed and a *P* value derived. If an SNP is closely linked to a disease susceptibility gene, then a particular genotype will be greatly enriched in the case series compared to the general unselected

population. The *P* values are plotted along each chromosome ("Manhattan plot") and where disease susceptibility loci exist, there are clusters of strong association. Typically, *P* values of 10^{-10} or lower are indicative of a true locus, although this generally has to be replicated in a number of other case-control sets for confirmation. Although SNP-based GWAS is currently the weapon of choice in complex trait genetics, it has limitations. If a causative lesion in a susceptibility locus is very heterogeneous, i.e., if there are multiple mutations or other changes that cause the susceptibility, then the locus is poorly identified by GWAS. Furthermore, across the entire field of complex trait genetics, relatively few causative genes have emerged (the role of the filaggrin gene in atopic dermatitis, below, being a notable exception). In the majority of cases, there is currently little clue about what defect the associated SNPs are linked to that actually causes the disease susceptibility.

However, recently, a conventional genetics approach has revealed fascinating new insight into the pathophysiology of one particular complex trait, namely atopic dermatitis (eczema). This finding emanated from the discovery that the disorder ichthyosis vulgaris was due to loss-of-function mutations in the gene encoding the skin barrier protein filaggrin (see Chapters 14 and 49).[28] To dermatologists, the clinical association between this condition and atopic dermatitis is well known, and the same loss-of-function mutations in filaggrin have subsequently been shown to be a major susceptibility risk factor for atopic dermatitis, as well as asthma associated with atopic dermatitis, but not asthma alone.[4] This suggests that asthma in individuals with atopic dermatitis may be secondary to allergic sensitization, which develops because of the defective epidermal barrier that allows allergens to penetrate the skin to make contact with antigen-presenting cells. Indeed, transmission–disequilibrium tests have demonstrated an association between filaggrin gene mutations and extrinsic atopic dermatitis associated with high total serum immunoglobulin E levels and concomitant allergic sensitizations.[29] These recent data on the genetics of atopic dermatitis demonstrate how the study of a "simple" genetic disorder can also provide novel insight into a complex trait. Therefore, Mendelian disorders may be useful in the molecular dissection of more complex traits.[30]

MOSAICISM

The presence of a mixed population of cells bearing different genetic or chromosomal characteristics leading to phenotypic diversity is referred to as *mosaicism*. There are several different types of mosaicism, including single gene, chromosomal, functional, and revertant mosaicism.[31] Multiple expression patterns are recognized.[32]

Mosaicism for a single gene, referred to as *somatic mosaicism*, indicates a mutational event occurring after fertilization. The earlier this occurs, the more likely it is that there will be clinical expression of a disease phenotype as well as involvement of gonadal tissue (gonosomal mosaicism); for example, when individuals with segmental neurofibromatosis subsequently have offspring with full-blown neurofibromatosis (see Chapter 141). However, in general, if the mutation occurs after generation of cells committed to gonad formation, then the mosaicism will not involve the germ line, and the reproductive risk of transmission is negligible. *Gonosomal mosaicism* refers to involvement of both gonads and somatic tissue, but mosaicism can occur exclusively in gonadal tissue, referred to as *gonadal mosaicism*. Clinically, this may explain recurrences among siblings of autosomal dominant disorders such as tuberous sclerosis or neurofibromatosis, when none of the parents has any clinical manifestations and gene screening using genomic DNA from peripheral blood samples yields no mutation. Segmental mosaicism for autosomal dominant disorders is thought to occur in one of two ways: either there is a postzygotic mutation with the skin outside the segment and genomic DNA being normal (type 1), or there is a heterozygous genomic mutation in all cells that is then exacerbated by loss of heterozygosity within a segment or along the lines of Blaschko (type 2). This pattern has been described in several autosomal dominant disorders, including Darier disease, Hailey–Hailey disease (see Chapter 51), superficial actinic porokeratosis (see Chapter 52), and tuberous sclerosis (see Chapter 140).

The lines of Blaschko were delineated over 100 years ago; the pattern is attributed to the lines of migration and proliferation of epidermal cells during embryogenesis (i.e., the bands of abnormal skin represent clones of cells carrying a mutation in a gene expressed in the skin).[33] Apart from somatic mutations [either in dominant disorders, such as epidermolytic ichthyosis (formerly called bullous congenital ichthyosiform erythroderma) leading to linear epidermolytic ichthyosis (epidermal nevus of the epidermolytic hyperkeratosis type) (see Chapter 49), or in conditions involving mutations in lethal dominant genes such as in McCune–Albright syndrome], mosaicism following Blaschko's lines is also seen in chromosomal mosaicism and functional mosaicism (random X-chromosome inactivation through lyonization). Monoallelic expression on autosomes (with random inactivation of either the maternal or paternal allele) is also feasible, and probably underdocumented.[34] Chromosomal mosaicism results from nondisjunction events that occur after fertilization. Clinically, this is found in the linear mosaic pigmentary disorders (hypomelanosis of Ito (see Chapter 75) and linear and whorled hyperpigmentation). It is important to point out that hypomelanosis of Ito is not a specific diagnosis but may occur as a consequence of several different chromosomal abnormalities that perturb various genes relevant to skin pigmentation, which has led to the term "pigmentary mosaicism" to describe this group of disorders.

Functional mosaicism relates to genes on the X chromosome, because during embryonic development in females, one of the X chromosomes, either the maternal or the paternal, is inactivated. For X-linked dominant disorders, such as focal dermal hypoplasia (Goltz syndrome) or incontinentia pigmenti (see Chapter 75), females survive because of the presence of some cells in which the X chromosome without the mutation is

active and able to function. For males, these X-linked dominant disorders are typically lethal, unless associated with an abnormal karyotype (e.g., Klinefelter syndrome; 47, XXY) or if the mutation occurs during embryonic development. For X-linked recessive conditions, such as X-linked recessive hypohidrotic ectodermal dysplasia (see Chapter 142), the clinical features are evident in hemizygous males (who have only one X chromosome), but females may show subtle abnormalities due to mosaicism caused by X-inactivation, such as decreased sweating or reduced hair in areas of the skin in which the normal X is selectively inactivated. There are 1,317 known genes on the X chromosome, and most undergo random inactivation but a small percentage (approximately 27 genes on Xp, including the steroid sulfatase gene, and 26 genes on Xq) escape inactivation.

Revertant mosaicism, also known as *natural gene therapy*, refers to genetic correction of an abnormality by various different phenomena including back mutations, intragenic crossovers, mitotic gene conversion, and second site mutations.[35,36] Indeed, multiple different correcting events can occur in the same patient. Such changes have been described in a few genes expressed in the skin, including the keratin 14, laminin 332, collagen XVII, collagen VII, and kindlin-1 (fermitin family homolog 1) genes in different forms of EB (Fig. 8-7; see Chapter 62). The clinical relevance of the conversion process depends on several factors, including the number of cells involved, how much reversal actually occurs, and at what stage in life the reversion takes place. Attempts have been made to culture reverted keratinocytes and graft them to unreverted sites,[37] a pioneering approach that may have therapeutic potential for some patients.

Apart from mutations in nuclear DNA, mosaicism can also be influenced by environmental factors, such as viral DNA sequences (retrotransposons) that can be incorporated into nuclear DNA, replicate, and activate or silence genes through methylation or demethylation. This phenomenon is known as *epigenetic mosaicism*; such events may be implicated in tumorigenesis but have not been associated with any genetic skin disorder.

Figure 8-7 Revertant mosaicism in an individual with non-Herlitz junctional epidermolysis bullosa. The subject has loss-of-function mutations on both alleles of the type XVII collagen gene, *COL17A1*, but spontaneous genetic correction of the mutation in some areas has led to patches of normal-appearing skin (areas within black marker outline) that do not blister. (From Jonkman MF et al: Revertant mosaicism in epidermolysis bullosa caused by mitotic gene conversion. *Cell* **88**:543, 1997, with permission.)

EPIGENETICS

Disease phenotypes reflect the result of the interaction between a particular genotype and the environment, but it is evident that some variation, for example, in monozygotic twins, is attributable to neither. Additional influences at the biochemical, cellular, tissue, and organism levels occur, and these are referred to as *epigenetic phenomena*.[38] Single genes are not solely responsible for each separate function of a cell. Genes may collaborate in circuits, be mobile, exist in plasmids and cytoplasmic organelles, and can be imported by nonsexual means from other organisms or as synthetic products. Even prion proteins can simulate some gene properties. Epigenetic effects reflect chemical modifications to DNA that do not alter DNA sequence but do alter the probability of gene transcription. Mammalian DNA methylation machinery is made up of two components: (1) DNA methyltransferases, which establish and maintain genome-wide DNA methylation patterns, and (2) the methyl-CpG-binding proteins, which are involved in scanning and interpreting the methylation patterns. Analysis of any changes in these processes is known as *epigenomics*.[39] Examples of modifications include direct covalent modification of DNA by methylation of cytosines and alterations in proteins that bind to DNA. Such changes may affect DNA accessibility to local transcriptional complexes as well as influencing chromatin structure at regional and genome-wide levels, thus providing a link between genome structure and regulation of transcription. Indeed, epigenome analysis is now being carried out in parallel with gene expression to identify genome-wide methylation patterns and profiles of all human genes. For example, there is considerable interindividual variation in cytosine methylation of CpG dinucleotides within the major histocompatibility complex (MHC) region genes, although whether this has any bearing on the expression of skin disorders such as psoriasis remains to be seen. New sensitive and quantitative methylation-specific polymerase chain reaction-based assays can identify epigenetic anomalies in cancers such as melanoma.[40] DNA hypermethylation contributes to gene silencing by preventing the binding of activating transcription factors and by attracting repressor complexes that induce the formation of inactive chromatin structures. With regard to melanoma, such changes may impact on several biologic processes, including cell cycle control, apoptosis, cell signaling, tumor cell invasion, metastasis, angiogenesis, and immune recognition. A further but as yet unresolved issue is whether there is heritability of epigenetic characteristics. Likewise, it is unclear whether environmentally induced changes in epigenetic status, and hence gene transcription and phenotype, can be transmitted through more than one generation. Such a phenomenon might account for the cancer susceptibility of grandchildren

of individuals who have been exposed to diethylstilbestrol, but this has not been proved. However, germ line epimutations have been identified in other human diseases, such as colorectal cancers characterized by microsatellite instability and hypermethylation of the *MLH1* DNA mismatch repair gene, although the risk of transgenerational epigenetic inheritance of cancer from such a mutation is not well established and probably small. Over the course of an individual's lifespan, epigenetic mutations (affecting DNA methylation and histone modifications) may occur more frequently than DNA mutations, and it is expected that, over the next decade, the role of epigenetic phenomena in influencing phenotypic variation will gradually become better understood.[41]

HISTOCOMPATABILITY ANTIGEN DISEASE ASSOCIATION

Human leukocyte antigen (HLA) molecules are glycoproteins that are expressed on almost all nucleated cells. The HLA region is located on the short arm of chromosome 6, at 6p21, referred to as the *MHC*. There are three classic loci at HLA class I: (1) HLA-A, (2) HLA-B, and (3) HLA-Cw, and five loci at class II: (1) HLA-DR, (2) HLA-DQ, (3) HLA-DP, (4) HLA-DM, and (5) HLA-DO. The HLA molecules are highly polymorphic, there being many alleles at each individual locus. Thus, allelic variation contributes to defining a unique "fingerprint" for each person's cells, which allows an individual's immune system to define what is foreign and what is self. The clinical significance of the HLA system is highlighted in human tissue transplantation, especially in kidney and bone marrow transplantation, where efforts are made to match at the HLA-A, -B, and -DR loci. MHC class I molecules, complexed to certain peptides, act as substrates for $CD8^+$ T-cell activation, whereas MHC class II molecules on the surface of antigen-presenting cells display a range of peptides for recognition by the T-cell receptors of $CD4^+$ T helper cells (see Chapter 10). Therefore, MHC molecules are central to effective adaptive immune responses. Conversely, however, genetic and epidemiologic data have implicated these molecules in the pathogenesis of various autoimmune and chronic inflammatory diseases. Several skin diseases, such as psoriasis (see Chapter 18), psoriatic arthropathy (central and peripheral), dermatitis herpetiformis, pemphigus, reactive arthritis syndrome (see Chapter 20), and Behçet disease (see Chapter 166), all show an association with inheritance of certain HLA haplotypes (i.e., there is a higher incidence of these conditions in individuals and families with particular HLA alleles). However, the molecular mechanisms by which polymorphisms in HLA molecules confer susceptibility to certain disorders are still unclear. This situation is further complicated by the fact that, for most diseases, it is unknown which autoantigens (presented by the disease-associated MHC molecules) are primarily involved. For many diseases, the MHC class association is the main genetic association. Nevertheless, for most of the MHC-associated diseases, it has been difficult to unequivocally determine the primary disease-risk gene(s), owing to the extended linkage disequilibrium in the MHC region. However, recent genetic and functional studies support the long-held assumption that common MHC class I and II alleles themselves are responsible for many disease associations, such as the HLA cw6 allele in psoriasis. Of practical clinical importance is the strong genetic association between certain HLA alleles and the risk of adverse drug reactions. For example, in Han Chinese and some other Asian populations, HLA-B*1502 confers a greatly increased risk of carbamazepine-induced Stevens–Johnson syndrome and toxic epidermal necrolysis. Therefore, screening for HLA-B*1502 before starting carbamazepine in patients from high-risk populations is recommended or required by regulatory agencies.[42]

GENETIC COUNSELING

The National Society of Genetic Counselors (http://www.nsgc.org) has defined genetic counseling as "the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease." Genetic counseling should include: (1) interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; (2) education about inheritance, testing, management, prevention, resources, and research; and (3) counseling to promote informed choice and adaptation to the risk or condition.[43]

Once the diagnosis of an inherited skin disease is established and the mode of inheritance is known, every dermatologist should be able to advise patients correctly and appropriately, although additional support from specialists in medical genetics is often necessary. Genetic counseling must be based on an understanding of genetic principles and on a familiarity with the usual behavior of hereditary and congenital abnormalities. It is also important to be familiar with the range of clinical severity of a particular disease, the social consequences of the disorder, the availability of therapy (if any), and the options for mutation detection and prenatal testing in subsequent pregnancies at risk for recurrence (one useful site is http://www.genetests.com).

A key component of genetic counseling is to help parents, patients, and families know about the risks of recurrence or transmission for a particular condition. This information is not only practical but often relieves guilt and can allay rather than increase anxiety. For example, it may not be clear to the person that he or she cannot transmit the given disorder. The unaffected brother of a patient with an X-linked recessive disorder such as Fabry disease (see Chapter 136), X-linked ichthyosis (see Chapter 49), Wiskott–Aldrich syndrome (see Chapter 143), or Menkes syndrome (see Chapter 88) need not worry about his children being affected or even carrying the abnormal allele, but he may not know this.

Prognosis and counseling for conditions such as psoriasis in which the genetic basis is complex or still

unclear is more difficult (see Chapter 18). Persons can be advised, for example, that if both parents have psoriasis, the probability is 60% to 75% that a child will have psoriasis; if one parent and a child of that union have psoriasis, then the chance is 30% that another child will have psoriasis; and if two normal parents have produced a child with psoriasis, the probability is 15% to 20% for another child with psoriasis.[44] Ongoing discoveries in other diseases, such as melanoma genetics, can also impact on genetic counseling. The identification of family-specific mutations in the *CDKN2A* and *CDK4* genes, as well as risk alleles in the *MC1R* and *OCA2* genes and other genetic variants, allow for more accurate and informative patient and family consultations.[45]

PRENATAL DIAGNOSIS

In recent years, there has been considerable progress in developing prenatal testing for severe inherited skin disorders (Fig. 8-8). Initially, ultrastructural examination of fetal skin biopsies was established in a limited number of conditions. In the late 1970s, the first diagnostic examination of fetal skin was reported for epidermolytic hyperkeratosis and Herlitz junctional EB (see Chapter 62).[46,47] These initial biopsies were performed with the aid of a fetoscope to visualize the fetus. However, with improvements in sonographic imaging, biopsies of fetal skin are now taken under ultrasound guidance. The fetal skin biopsy samples obtained during the early 1980s could be examined only by light microscopy and transmission electron microscopy. However, the introduction of a number of monoclonal and polyclonal antibodies to various basement membrane components during the mid-1980s led to the development of immunohistochemical tests to help complement ultrastructural analysis in establishing an accurate diagnosis, especially in cases of EB.[48] Fetal skin biopsies are taken during the midtrimester. For disorders such as EB, testing at 16 weeks' gestation is appropriate. However, for some forms of ichthyosis, the disease-defining structural pathology may not be evident at this time, and fetal skin sampling may need to be deferred until 20 to 22 weeks of development.

Nevertheless, since the early 1990s, as the molecular basis of an increasing number of genodermatoses has been elucidated, fetal skin biopsies have gradually been superseded by DNA-based diagnostic screening using fetal DNA from amniotic fluid cells or samples of chorionic villi; the latter are usually taken at 10 to 12 weeks' gestation (i.e., at the end of the first trimester).[49,50] In addition, advances with in vitro fertilization and embryo micromanipulation have led to the feasibility of even earlier DNA-based assessment through preimplantation genetic diagnosis, an approach first

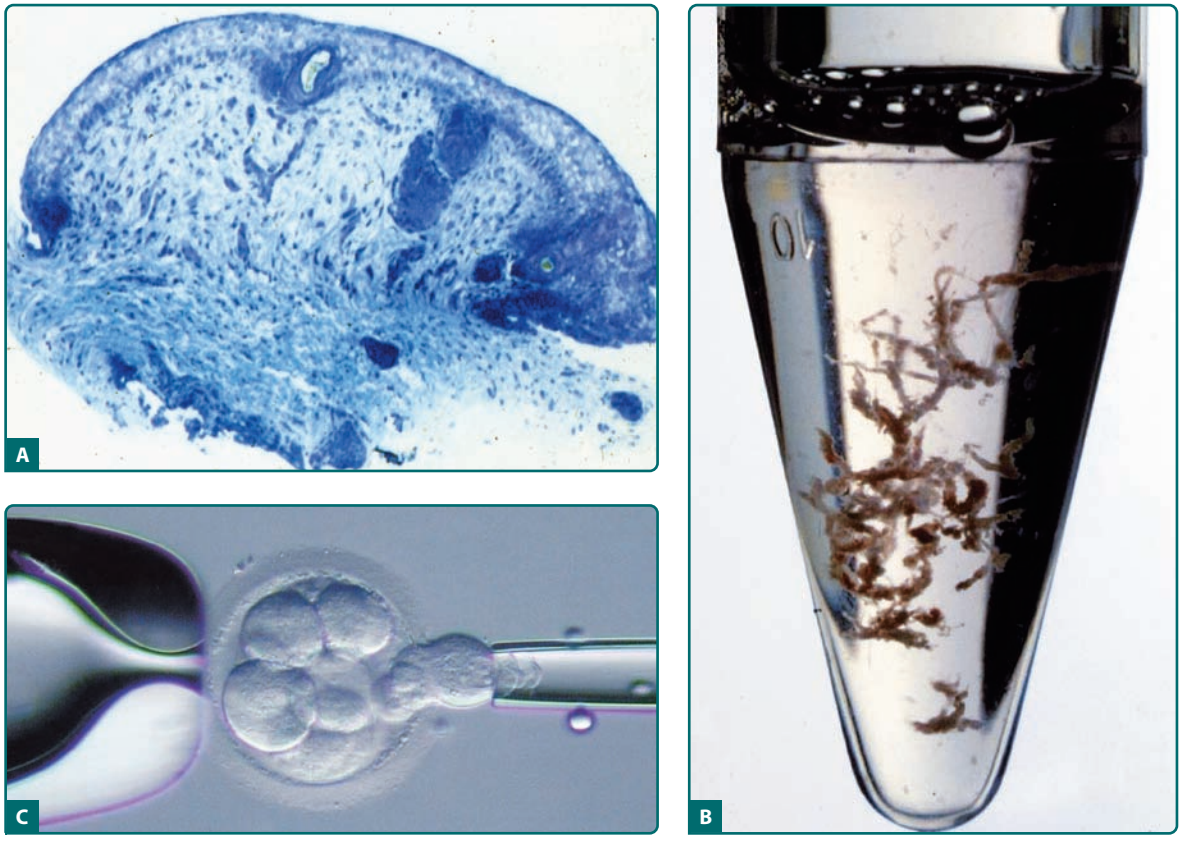

Figure 8-8 Options for prenatal testing of inherited skin diseases. **A.** Fetal skin biopsy, here shown at 18 weeks' gestation. **B.** Chorionic villi sampled at 11 weeks' gestation. **C.** Preimplantation genetic diagnosis. A single cell is being extracted from a 12-cell embryo using a suction pipette.

successfully applied in 1990, for risk of recurrence of cystic fibrosis.[51] Successful preimplantation testing has also been reported for severe inherited skin disorders.[52] This is likely to become a more popular, though still technically challenging, option for some couples, in view of recent advances in amplifying the whole genome in single cells and the application of multiple linkage markers in an approach termed *preimplantation genetic haplotyping*.[53] This approach has been developed and applied successfully for Herlitz junctional epidermolysis bullosa.[54] For some disorders, alternative less invasive methods of testing are now also being developed, including analysis of fetal DNA or RNA from within the maternal circulation and the use of three-dimensional ultrasonography.

In the current absence of effective treatment for many hereditary skin diseases, prenatal diagnosis can provide much appreciated information to couples at risk of having affected children, although detailed and supportive genetic counseling is also a vital element of all prenatal testing procedures.

GENE THERAPY

The field of gene therapy can be subdivided in different ways.[55] First, there are approaches aimed at treatment of recessive genetic diseases where homozygous or compound heterozygous loss-of-function mutations lead to complete absence or complete functional ablation of a vital protein. These types of diseases are amenable to gene replacement therapy, and it is this form of gene therapy that has tended to predominate because it is generally technically more feasible than treatment of dominant genetic conditions.[56] In dermatology, these include diseases such as lamellar ichthyosis (see Chapter 49), where in most cases, there is hereditary absence of transglutaminase-1 activity in the outer epidermis, or the severe Hallopeau–Siemens form of recessive dystrophic EB, where there is complete absence of type VII collagen expression due to recessive mutations.[57]

The second form of gene therapy, in broad terms, is aimed at treatment of dominant-negative genetic disorders and is known as *gene inhibition therapy*. Here, there is a completely different type of problem to be tackled because these patients already carry one normal copy of the gene and one mutated copy. The disease results because an abnormal protein product produced by the mutant allele, dominant-negative mutant protein, binds to and inhibits the function of the normal protein produced by the wild-type allele. In many cases, it can be shown from the study of rare recessive variants of dominant diseases that one allele is sufficient for normal skin function, and so if a means could be found of specifically inhibiting the expression of the mutant allele, this should be therapeutically beneficial. However, finding a gene therapy agent that is capable of discriminating the wild-type and mutant alleles, which can differ by as little as one bp of DNA, is challenging and, until recently has resulted in little success. A typical dominant-negative genetic skin disease is EB simplex (see Chapter 62), caused by mutations in either of the genes encoding keratins 5 or 14. The vast majority of cases are caused by dominant-negative missense mutations, changing only a single amino acid, carried in a heterozygous manner on one allele.[58]

Gene therapy approaches can also be broadly subdivided according to whether they involve in vivo or ex vivo strategies.[55] Using an in vivo approach, the gene therapy agent would be applied directly to the patient's skin or another tissue. A disadvantage of the skin as a target organ for gene therapy is that it is a barrier tissue that is fundamentally designed to prevent entry of foreign nucleic acid in the form of viruses or other pathogenic agents. This is an impediment to in vivo gene therapy development but is not insurmountable due to developments in liposome technology and other methods for cutaneous macromolecule delivery.[59] In an ex vivo approach, a skin biopsy would be taken, keratinocytes or fibroblasts would be grown and expanded in culture, treated with the gene therapy agent, and then grafted onto or injected back into the patient. The skin is a good organ system for both these approaches because it is very accessible for in vivo applications. In addition, the skin can be readily biopsied, and cell culture and regrafting of keratinocytes can be adapted for ex vivo gene therapy.

Gene replacement therapy systems have been developed for lamellar ichthyosis (see Chapter 49) and the recessive forms of EB (see Chapter 62), among other diseases. These mostly consist of expressing the normal complementary DNA encoding the gene of interest from some form of gene therapy vector adapted from viruses that can integrate their genomes stably into the human genome. Therefore, such viral vectors can lead to long-term stable expression of the replacement gene.[60] Early studies tended to use retroviral vectors or adeno-associated viral vectors, but these have a number of limitations. For example, retroviruses only transduce dividing cells and therefore fail to target stem cells; consequently, gene expression is quickly lost due to turnover of the epidermis through keratinocyte differentiation. Furthermore, there have been some safety issues in small-scale human trials for both retroviral and adeno-associated viral vectors. Lentiviral vectors, derived from short integrating sequences found in a number of immunodeficiency viruses, have the advantage of being able to stably transduce dividing and nondividing cells, with close to 100% efficiency and at low copy number. These may be the current vectors of choice, but they also have potential problems because their preferred integration sites in the human genome are currently ill defined and may lead to concerns about safety. However, with a wide variety of vectors under development and testing, it should become clear in future years which vectors are effective and safe for human use. Ultimately, like all novel therapeutics, animal testing can only act as a guide because the human genome is quite different and may react differently to foreign DNA integration, so that phase I, II, and III human trials or adaptations thereof will ultimately have to be performed to determine efficacy and safety. Currently, small-scale clinical trials are ongoing for junctional EB and are planned for a number of other genodermatoses, mainly concentrating on the more severe recessive conditions.

Treatment of dominant-negative disorders has recently started to receive a great deal of attention with the discovery of the RNA inhibition pathway in humans and the finding that small synthetic double-stranded RNA molecules of 19 to 21 bp, known as *short inhibitory RNA* (siRNA), can efficiently inhibit expression of human genes in a sequence-specific, user-defined manner.[58,61] There is currently a great deal of attention being focused on development of siRNA inhibitors to selectively silence mutant alleles in dominant-negative genetic diseases, such as the keratin disorders—EB simplex and pachyonychia congenita (PC). Currently, the big challenge in this rapidly evolving new field is finding an effective, noninvasive method to get siRNA through the stratum corneum and into keratinocytes or other target cells. A number of groups are working on means of delivering siRNA to skin and other organ systems, and there is currently much optimism about these developing into clinically applicable agents in the near future.

In particular, a great deal of rapid progress has been made in PC in recent years. Following development of reporter gene methodology to rapidly screen many different siRNA species, two siRNAs were identified that could specifically and potently silence mutant keratin K6a mRNA differing from the wild-type mRNA by only a single nucleotide, i.e., these siRNAs represent allele-specific gene silencing agents. Following a battery of preclinical studies in cells and animal models to show efficacy, the K6a mutation-specific siRNA was manufactured to Good Manufacturing Practice standards and was shown to have an excellent toxicity profile in rodents, as per a small molecule drug. This facilitated FDA approval for a double blind split body Phase 1b clinical trial in a single volunteer with PC. The trial was successful, with a number of objective measures showing statistically significant clinical improvement. This study, funded by the patient advocacy organization PC Project (www.pachyonychia.org), was the first in human siRNA trial using a mutation-specific gene silencing approach and only the fifth siRNA trial in humans. This personalized medicine strategy gives hope for patients with incurably dominant genodermatoses and future trials in EB simplex are currently in the planning stages.

Chapter 9 :: Racial Considerations: Skin of Color

:: Kavitha K. Reddy, Yolanda M. Lenzy, Katherine L. Brown, & Barbara A. Gilchrest

SKIN OF COLOR AT A GLANCE

- Race and ethnicity are closely related but distinct factors that may influence skin disease prevalence or presentation.
- The Fitzpatrick skin phototype classification was developed to convey risk of photodamage in white skin and is often less useful in describing skin of color.
- The complex polygenic basis for variation in human skin, hair, and eye color has been partially elucidated.
- The structure and function of skin of color is similar or identical to that of white (Caucasian) skin, other than differences related to pigmentation.
- Differences in the character of hair among whites, Asians, and Africans relate to shape of the hair follicle and thickness of the cuticle layer.
- African hair displays low tensile strength and easy breakage. This fragility may be compounded by chemical or heat application, apparently predisposing to several types of alopecia.
- Postinflammatory hyper- or hypopigmentation is often prominent and long lasting in skin of color; preventive and therapeutic measures should be considered in the plan of care.

RACIAL AND ETHNIC INFLUENCES ON SKIN DISEASE AND THERAPY

In the United States and worldwide, myriad cutaneous phenotypes characterize mankind. Most striking is the range of skin and hair color (Fig. 9-1). The Census Bureau estimates that half of the US population will be of non-European descent by the year 2050.[1] There are currently more than 95 million persons in the United State[2] and billions of individuals worldwide categorized as having "skin of color." There has been increasing awareness of racial and ethnic influences (see Table 9-1) on skin biology and on diagnosis and treatment of skin disease.

The literature regarding "skin of color" primarily focuses on promoting awareness of normal and abnormal skin conditions in a patient regardless of skin phenotype. It seeks to identify risks and benefits of treatments in diverse skin types, to develop effective treatments for common dermatoses in skin of color, recognizing the importance of individualized therapy, and to avoid stereotyping and generalization.

DEFINING SKIN OF COLOR

In defining skin of color, it is important to consider the reasons for doing so. Many have questioned the common propensity of medical practitioners to state a patient's race among the first few words, as a primary identifier. The skin type, color, or ethnic background of most patients may be better suited to the physical examination or to relevant points in the history. The International Committee of Medical Journal Editors' *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* recommends that authors using variables such as race or ethnicity should "define how they measured the variables and justify their relevance."[6] The *Journal of the American Academy of Dermatology* similarly suggests that authors inclined to submit racial, ethnic, or skin color descriptors in manuscripts ask themselves a series of questions regarding whether such identification is important to the understanding or pedagogical value of the manuscript, whether the patient would self-identify in the same way and how this is known, whether the descriptor used could be open to racist interpretation, and what the evidence is that the descriptor plays a role in the entities described.[7]

Most would argue that "nonwhite" skin is "skin of color." However, there is a diverse array of phenotypes within the nonwhite and white spectra, and two categories are inadequate to describe them. The most commonly used classification system in dermatologic practice is the Fitzpatrick phototype,[8,9] designed to provide an estimate of skin cancer and photoaging risk, in which individuals are assigned a number

TABLE 9-1
Race Versus Ethnicity

Term	Derivation	Current Usage or Implication
Race	<Latin, root	A population distinguished as a more or less distinct group by genetically transmitted physical characteristics; originally geographically segregated Groups increasingly blurred by interracial offspring Determined at conception, immutable May influence disease predilection/susceptibility
Ethnicity	<Greek, race or distinct population with its own customs	A social construct in which a group of individuals shares a language, cultural practices, or customs Self-assigned and somewhat mutable Often but not always associated with race May influence treatment choices and exposure to disease-promoting or disease-preventing factors

Stein J, Urdang L, eds.: *Derivations from the Random House Dictionary of the English Language*. New York, Random House, 1967. Usage or implication is the authors' distillation of a large and contradictory literature.[3–5]

based on their ability to burn and tan after a single, rather modest sun exposure. The original Fitzpatrick system consisted of types I–IV; types V and VI were soon added with the goal of representing individuals of Asian/Indian and African/Aboriginal origin, respectively. Skin of color is now commonly regarded as encompassing types IV through VI,[10] but many patients and physicians would argue that the spectrum is broader. For example, Japanese women not infrequently describe themselves as having type II skin. In any case, for the purpose of studying nonwhite skin, the Fitzpatrick system has several limitations. Although intended to utilize patient-reported characteristics, in practice a patient is commonly "assigned" to a type without benefit of a history. Also, the Fitzpatrick type has been shown in studies not to correspond well to constitutive skin color and to correlate poorly with minimal erythema dose (MED) values.[11] Interestingly, the physician-assigned skin phototype has been shown to correlate moderately with race, and race assignment does not correlate well with objective measures of pigmentation or self-reported skin phototype, suggesting that assignment of Fitzpatrick types is often based on perceived race rather than either objective skin color or response to ultraviolet (UV) light.[12]

Other scales have been developed with a goal of more accurately defining skin pigmentation and corresponding to defined clinical features. It has been suggested that for skin of color a scale based on propensity to postinflammatory hyperpigmentation, for example, might be more useful than one based on burning and tanning responses to UV exposure.[10] A variety of visual scales seek to convey skin color more accurately and precisely and to measure changes over time. These include the physician's global assessment, melasma area and severity index (MASI), visual hyperpigmentation scale,[13] and skin tone color scale.[14] Skin photometers employing UV light, polarized light, reflectance spectroscopy, tristimulus colorimetry, and spectrophotometry are also available and can provide an objective skin color score.[13] However, it is possible that, parallel to the Fitzpatrick phototype classification for white skin, a classification system based on patient perceptions of desirable or adverse responses to environmental challenges would be most useful in managing dermatologic patients with skin of color. For example, asking the patient about the frequency, severity, and duration of postinflammatory hyperpigmentation in the past may provide critical guidance when considering a skin care or treatment regimen.

STRUCTURE AND FUNCTION IN SKIN OF COLOR

The perceived skin color is the result of the spectrum of incident light and its absorption and reflection by chromophores in the skin. It is largely determined by melanin amount, type (ratio of black/brown eumelanin to red/yellow pheomelanin), and intracellular distribution and location within the layers of the skin. The number of melanocytes in a given area of skin is similar among all individuals. Vascular pigments

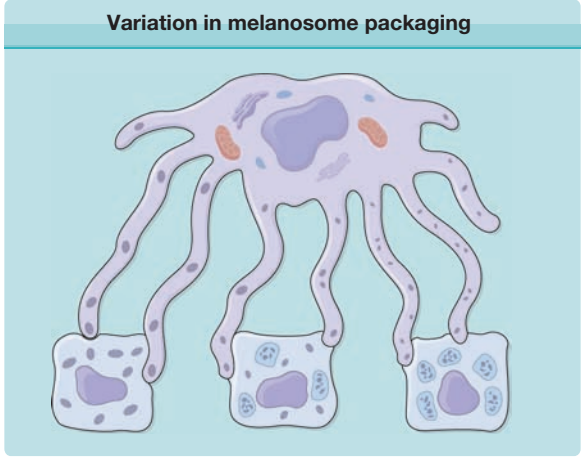

Figure 9-2 Variation in melanosome packaging within the keratinocyte of skin of differing colors. White skin (*right*) typically shows spherical melanosomes clustered within a membrane, black skin has larger elliptical melanosomes dispersed singly, and Asian or golden brown skin typically has a combination of the two (*middle*). (Used with permission from Jag Bhawan, MD.)

oxyhemoglobin and deoxyhemoglobin also play a role in observed color along with capillary blood flow, dietary pigments carotene and lycopene, collagen, the spectrum of ambient light, reflection, refraction, and absorption of light by the skin, and transparency of the stratum corneum and epidermis.[15] Endocrine, inflammatory, neural, and pharmacologic factors also influence skin color.

Melanosome size and distribution vary in skin of differing colors (Fig. 9-2). In individuals of African descent, the melanosomes are typically large and dispersed singly in the keratinocytes. In white individuals, melanosomes are smaller and grouped within a membrane. In Asian skin, a combination of individual and clustered melanosomes is found.[16] Melanin may also be degraded more slowly in skin of color.[17] Increasing melanin provides higher natural photoprotection, due to a greater absorption of UV photons, but also typically increases risk of pigmentary disorders including hypopigmentation or hyperpigmentation as a result of physiologic responses to trauma or inflammation.[18] For further discussion, see Chapter 72.

Structural or functional differences in white versus nonwhite human skin beyond those related to photoprotection[19] and pigmentary alterations are not known. Conflicting data have been presented on variations in lipid content, sebum content, and the number of stratum corneum layers and compaction.[20] Histologic sections of normal skin generally appear identical aside from the difference in melanin. Whether there are genetically determined functional differences of the skin associated with skin color is the subject of study and debate.[15]

GENETICS OF PIGMENTATION

There is a polygenic basis for human pigmentation. Genes already implicated in pigmentary variation

TABLE 9-2
Genes with Polymorphisms that Influence Human Pigmentary Variation

Gene	Gene Product	Recognized Function	Pigmentary Variation Effect
TYR	Tyrosinase	Rate-limiting enzyme in melanin biosynthesis	Europeans and South Asians: lighter/darker skin within group; little variation among races
TYRP1 (*TRP1*)	5,6-Dihydroxyindole-2-carboxylic acid oxidase or tyrosinase related protein 1	Enzyme in melanin biosynthesis	Europeans: lighter/darker skin and eye color
OCA2 (*HERC2*)	P protein	L-Tyrosine transmembrane transporter	Blond/brown hair, blue/nonblue eyes; East Asians, Africans: lighter/darker skin Loss of function causes oculocutaneous albinism type 2
SLC45A2 (*MATP*)	Membrane-associated transporter protein	Transmembrane transport	Black/nonblack hair; dark/light skin; dark/light eyes
SLC 24A4	Sodium/potassium/calcium exchanger 4	Transmembrane potassium-dependent sodium/calcium exchanger	Blond/brown hair; blue/green eyes
SLC24A5	Sodium/potassium/calcium exchanger 5	Transmembrane potassium-dependent sodium/calcium exchanger	Africans and Asians: ancestral form (111Ala), darker skin; Europeans: variant (111Thr), lighter skin
MC1R	Melanocortin 1 receptor	Receptor for melanocyte-stimulating hormone (MSH) and ASIP	Red hair–fair skin: *R151C*, *R160W*, *D294H* mutations; loss of function increases pheomelanin
ASIP	Agouti-signaling protein	Ligand for *MC1R*; antagonist for MSH that increases pheomelanin	Inactivating mutations associated with dark hair/eyes
KITLG	*KIT* ligand (steel factor, stem cell factor, mast cell growth factor)	Ligand of *KIT* tyrosine–kinase receptor (cell-migration effects)	Blond/brown hair; lighter/darker skin
IRF4	Interferon regulatory factor 4	Regulator of RNA polymerase II transcription factor activity	Light/dark hair
TPCN2	Two-pore calcium channel 2	Lysosomal membrane calcium channel	Blond/brown hair

of human skin, hair, and iris include *TYR*, *TYRP1*, *OCA2/HERC2*, *SLC45A2 (OCA4/MATP)*, *SLC24A5*, *SLC24A4*, *MC1R*, *ASIP*, *KITLG*, *IRF4*, and *TPCN2*[21,22] (Table 9-2).

Examination of mitochondrial DNA and Y chromosome analysis suggests that all humans descended from three African females and three African males.[22,23] It is believed that some of these descendants stayed in Africa, while others migrated to Europe and Asia and from Asia across the polar land bridge to the Americas. West Africans with the ancestral variant of the *SLC24A5* gene expressing alanine at amino acid 111 have dark brown skin. East Asians also have this form of *SLC24A5*.[24] A variant of the *SLC24A5* gene with threonine at amino acid 111 is nearly constant in those of European ancestry, determining lighter skin types, and is believed to have resulted from natural selection.[24] *SLC24A5* encodes a potassium-dependent sodium/calcium exchanger that is hypothesized to play a role in melanosome morphogenesis and melanogenesis through changes in intraorganellar calcium concentration and pH. The *SLC24A5* variation is believed to explain 25–38% of the melanin difference between Africans and Europeans.[24] Polymorphisms of *SLC45A2*, *OCA2*, and *KITLG* have also been shown to contribute to pigmentation differences between European and African populations.[25]

Within European-derived populations, *TYR*, *OCA2*, *MC1R*, *ASIP*, and *IRF4* polymorphisms account for much of the observed pigmentary variation.[25] The best studied concerns the highly polymorphic *MC1R*, a melanocyte surface receptor that when activated by its ligand αMSH increases intracellular cAMP levels, induces the microphthalmia transcription factor MiTF and ultimately increases black/brown eumelanin synthesis. A number of loss-of-function variant alleles of *MC1R* have been identified and shown to result in a fair-skinned red-hair phenotype.[26] Other *MC1R* variant alleles result in blond or light brown hair and fair skin.[26] Conversely, dark brown or black hair and dark skin are observed in individuals expressing the wild type *MC1R*. Risk of skin cancer, including melanoma,

is also affected by the inherited *MC1R* alleles and is generally correlated with fair skin color.[26] However, some variant alleles appear to confer an increased risk independent of their effect on pigmentation.[26]

No genetic basis for the different pigmentary phenotypes of Africans compared with Asians has yet been identified. Both have the ancestral form of *SLC24A5* and *MC1R*, suggesting that evolution to lighter skin colors may have occurred independently in Europe and in Asia. The genes regulating pigmentation differences among Asians are not adequately characterized, although *OCA2* variant alleles have been associated recently with some East Asian skin pigmentation variations. South Asian skin pigmentation shows considerable variation; variants of *SLC24A5*, *SLC45A2*, and *TYR* have been associated with these pigmentary differences.[27]

The "Hispanic" skin color group is least well defined. It is genotypically and phenotypically variable, representing mixtures of European (largely Spanish), African, and Central and South American Native origins. The Hispanic phenotype often differs on average in different geographic areas. Perhaps because of these challenges, genetic determinants of Hispanic skin color remain virtually unstudied.

VARIATION IN HAIR CHARACTERISTICS

Human hair is typically categorized into three major distinct groups: (1) Asian, (2) Caucasian, and (3) African.[28] However, the world's population encompasses people of multiple and mixed backgrounds, resulting in the existence of multiple hair types.[29] All hair exhibits common characteristics of morphology, chemical makeup, and molecular structure. There are nevertheless differences in hair morphology and physical properties that contribute to the unique features of the hair fiber, response to hair treatments, and development of disease processes in different groups.[30] Understanding the biology and the differences in physical properties of various hair types can assist clinicians in managing hair and scalp problems. A variety of terms are used in the dermatologic literature to describe different hair types based upon an author's personal preference, country of origin, or current trends. To date, most studies have focused on African hair, which presents the greatest array of clinical disorders.

BIOCHEMICAL COMPOSITION

African or black hair is known to be more affected by breakage, with easily observed fragility in vivo.[31] There are no known chemical differences in black versus Caucasian or Asian hair to explain this observed fragility. The biochemical composition of hair in people from different geographic regions and racial groups has been shown to be virtually identical in terms of keratin and amino acid content,[32,33] despite significant differences in tensile strength, combability, and moisture content. In contrast, numerous studies have described the physical differences in hair from people of different races.[34–37] As well, African-Americans have a significantly lower hair density (number of follicles per unit area) than whites (22.4 vs. 35.5 follicles); and a study examining Asian scalp biopsies found lower hair density than in Caucasians.[38] Such differences must be taken into account in the interpretation of scalp biopsy specimens.[39]

HAIR SHAPE

Initially, the cross-sectional shape of the hair shaft was thought to determine the macroscopic appearance of hair and to distinguish people of different genetic backgrounds.[40] The round cross-section of Asian hair was thought to result in straight hair, the elliptical or flattened cross-section of African hair to result in curly hair and an intermediate to round and elliptical cross-section results in wavy to straight European hair (Table 9-3). However, three-dimensional computer-aided reconstructions of scalp biopsy cross-sections suggest that the shape of the hair follicles (helical or curved in Africans vs. straight and perpendicular to the skin surface in Asians) also play an important role. The finding that Caucasians can have hair follicles that are elliptical in cross-section and yet have straight hair shafts further implies that the three-dimensional

TABLE 9-3
Comparison of Physical Properties of Hair

Racial Group	African	Caucasian	Asian
Cross-sectional shape	Elliptical	Ovoid	Round
Hair follicle shape	Curved	Variable	Straight
Tensile strength	Low	High	High
Work of combing	High	Low	Low
Moisture content	Low	High	High
Average number of cuticle layers	Highly variable (6–8 along the major axis, 1–2 along the minor axis)	Constant (4–5)	Constant (6–7)

structure of the hair follicle is responsible for the shape of the hair shaft. In vitro experiments comparing the growth of curly and straight hair found that follicles producing curled hairs, when dissected out of the scalp and placed in culture, continue to grow curled hair shafts.[41] This suggests that the shape of the hair may be genetically programed by the bulb, with or without the usual dermal environment.[42]

HAIR STRUCTURE

Recent studies have identified Asian-specific alleles of the *EDAR* and *FGFR2* genes that are associated with thick, straight hair.[43,44] Likewise, a recent genome-wide association scan for hair morphology (straight, wavy, curly) in Australians of European descent suggested that polymorphisms of the trichohyalin gene (*TCHH*), which is expressed in the developing inner root sheath of the hair follicle, contributes to the variance in hair morphology.[45] A quantitative study examining hair formation in seven populations demonstrated African hair to have the highest amount of curvature and kinking and a periodic widening and narrowing of the cuticle layer. The cuticle layer of curly hair averages 6–8 layers thick at the end of the major axis but only 1–2 layers at the ends of the minor axis, a weak point susceptible to hair damage from mechanical and chemical forces.[46] A study of cuticle differences between Asian (Koreans specifically) and Caucasian hair revealed a 40% larger mean hair diameter, an increased number of cuticle layers, and a thicker cuticle layer in Asian compared to Caucasian hair (Table 9-3).[47] Cuticle thickness may play a role in determining the different characteristics of hair, such as chemical reactivity to hair coloring or perms, resistance to UV radiation, and mechanical resilience.

Differences have also been observed in the rate of hair growth. Although hair from individuals of European descent has been observed to grow an average of 1 cm a month,[48] African hair grows an average of 0.77 cm a month.[49–51] In a comparative light and scanning electron-microscopic study of African, European, and Asian hair, African subjects who did not have a hair cut for over 1 year had hair lengths significantly shorter than would be expected at a growth rate of 1 cm per month. Possible contributors to the differences in hair length, other than a slower growth rate, could include a significantly shorter anagen phase of the hair cycle or perhaps repeated breakage of African hair. In the same comparative study of African, European, and Asian hair, the African hair appeared as a tightly coiled spring-like structure. Compared with shafts from other ethnic groups, many shafts contained trichonodosis or knots (10–16% vs. 0.15%) and other shafts appeared broken (eFig. 9-2.1 in online edition). The study found a lower incidence (<40%) of hairs with attached roots in the African hair samples compared with more than 75% and approximately 90%, respectively, for the Caucasian and Asian samples; and a greater incidence of tips with frayed or serrated appearance when compared to Asian and Caucasian hair that had cut tips. These data suggest that most of the African hair collected from combing in this study was broken and not shed.[51] This raises the question of whether African hair is breaking off during grooming because of increased fragility.

TENSILE STRENGTH

Hair fragility is measured using tests of tensile strength, and it has been suggested that the force needed to break African hair fibers is less than that for other population groups. In a review of tensile strength tests obtained from four different private laboratories, two showed no difference between African hair and that of Caucasian and Asian hair and the other two found African hair to be weaker. Others found a lower tensile strength of both wet and dry curly African hair compared to wet and dry Caucasian hair.

The strength of hair has been shown to be dependent upon the integrity of its sulfur-rich proteins and disulfide bonds. In a study of trichothiodystrophy (TTD), a condition characterized by reduced sulfur-rich proteins and increased hair fragility, control hairs from African, Asian, and Caucasian subjects had statistically comparable sulfur staining using transmission electron microscopy and specific sulfur stains, while hair of patients with TTD was distinct.[52] Examination of cultured curly hairs in vitro showed a variable thickness of the outer root sheath, which was thicker on the concave side of the follicle, indicating some alteration in the differentiation process of hair compartments. It is unclear whether the lack of symmetry of the African hair bulb increases the tendency to mechanical damage, but it is likely that the shape of African hair makes it susceptible to physical damage as a result of certain grooming practices. In addition, intraracial variation in the degree of curl may influence mechanical properties. In a comparative study of African-American hair with different degrees of curl, from a loose to a tight curl pattern, mechanical fragility of hair increased with a tighter curl pattern.[53] Certain ethnic hair care practices, such as repeatedly subjecting hair to extremely high temperatures or processing with chemical straighteners, may further damage African hair.

COMBING PROPERTIES

In a study examining the amount of work required (measured in joules) to pass a comb through locks of hair, it was found that the work of combing wet African-American hair is almost five times that of combing wet straight hair. For dry hair, the work is 50 times greater. The teeth of a comb and method of combing can influence the extent of resulting damage. Broken hairs from combing are more numerous and of shorter length in curly African-American hair compared to straight Caucasian and Asian hair. Knots or trichonodes that are commonly seen in tightly curled hair are sites especially susceptible to damage by comb teeth.

MOISTURE CONTENT AND STATIC ELECTRICITY

African-American hair demonstrated a slightly lower water content than Caucasian hair.[37] The spiraling of the hair shaft may be another reason for increased hair dryness in African-American hair, as sebum from sebaceous glands cannot effectively navigate the twist and turns of the hair shaft, leading to a drier, more brittle hair. The relative "dryness" of African-American hair is worsened by the cumulative effect of environmental forces. Features of such weathering include a damaged cuticle, longitudinal fissures known as "split ends," and transverse fissures resembling the nodes of trichorrhexis nodosa.

When combing untreated curly hair, a highly negative electrostatic charge develops, in contrast to the low positive electrostatic charge for untreated straight hair. The highly negative charge on African-American hair may be the result of decreased moisture content and increased pulling force from combing. Also, the higher electrostatic charges in African-American hair can produce "flyaway" hair and can lead to difficulty in styling.

HAIR DISORDERS MORE COMMON IN SKIN OF COLOR

The differences in physical properties and hair care practices may explain certain dermatologic disorders in patients with skin of color. These include central centrifugal cicatricial alopecia (CCCA) (Fig. 9-3), traction alopecia (TA), pseudofolliculitis barbae (PFB), and acne keloidalis nuchae (AKN) (Table 9-4). The curved African hair follicle has been proposed to contribute to the pathogenesis of PFB and AKN,[54,55] though this has been debated.[56,57]

DIAGNOSIS AND TREATMENT OF SKIN DISEASE

No clear difference has been found between the structure and function of skin of varying colors aside from the visible pigmentary changes and associated variation in photoprotection.[15] Skin often responds to trauma or inflammation with hyperpigmentation; and this is often more prominent and long lasting in darker skin (Fig. 9-4). Hypopigmentation may similarly be more common and more apparent in skin of darker color. Treatment of skin disorders may also affect pigmentation, either positively or negatively (Fig. 9-5). Finally, epidermal melanin may alter disease presentation by masking erythema. Hypertrophic scarring and keloids are more frequent in black and Asian skin than white skin, a major problem for which the pathogenesis remains unknown. There are also some variations in the prevalence and presentation of certain skin diseases in patients with skin of color (Table 9-5). Not all of these can be attributed to pigmentation differences, but other contributing factors are as yet unidentified.

Figure 9-3 Central centrifugal cicatrizing alopecia (CCCA) early (**A**) and late (**B**) in the disease course. (Photographs used with permission from Lynne Goldberg, MD.)

TABLE 9-4
Hair Disorders that Commonly Affect Persons of African Descent

Disorder	Alternative Names	Presumed Pathophysiology	Clinical Features	Preventive Measures	Treatment[a]
Central centrifugal cicatricial alopecia (CCCA)[58]	■ Hot comb alopecia ■ Follicular[59] Degeneration syndrome[60]	■ Genetic predisposition ■ Heat injury ■ Chemical relaxers ■ Traction with rollers,[61] tight sewn-in and glued-in hair weaves, braids with extension hair[62]	■ Progressive: begins on the scalp vertex and advances centrifugally (Figs. 9-3A and 9-3B); noninflamed late stage; smooth patch of alopecia with loss of follicular orifices	■ Minimize use of heat, braids, weaves ■ Discontinue or decrease chemical relaxer frequency	■ Aimed at symptoms and halting progression ■ Intralesional triamcinolone, topical steroids (in vehicle of patient's choice) ■ Antiseborrheic shampoos ■ Oral tetracyclines or hydroxychloroquine[63,64] ■ Minoxidil for miniaturized or regrowing hairs[65] ■ Hair transplantation (for stable disease)[66,67]
Traction alopecia (TA)	■ Traumatic alopecia ■ Associated with traction folliculitis[68,69]	■ Hairstyles that place chronic traction on the hair follicle: ponytails,[70] tight braids and cornrows,[71,72] nylon hairbrushes,[73] elastic hair bands,[74] rollers,[75,76] and tight knotting (Sikh men[77,78]) ■ Highest risk of TA seen in women who attach extensions to relaxed hair[79]	■ Distribution of hair loss reflects that of maximal traction, but is most commonly seen at the scalp margins (eFig 9-5.1 in online edition)	■ Avoid the chronic use of styles that place traction on the follicles ■ Rotate hairstyles more frequently	■ Remove offending source ■ Trial of intralesional triamcinolone (if caught early) ■ Minoxidil for miniaturized or regrowing hairs[54] ■ Hair transplantation (for individuals no longer placing traction on the hair)[55,66]
Pseudofolliculitis barbae (PFB) and acne keloidalis (nuchae) (AKN)[56,57]	■ Razor bumps	■ Curved nature of the hair shaft resulting in ingrown hairs[80,81] ■ Primary scarring alopecia, AKN.[82,83]	■ Presents as multiple keloidal papules or plaques most commonly in the beard area in PFB and occipital scalp/neck in AKN (eFigs. 9-5.2 and 9-5.3 in online edition)	■ Avoid shaving	■ Depilation ■ Laser hair removal ■ Intralesional triamcinolone for keloids

[a]There have been no clinical trials for the treatment of patients with CCCA or TA or, so little evidence-based data exist regarding treatment regimens.

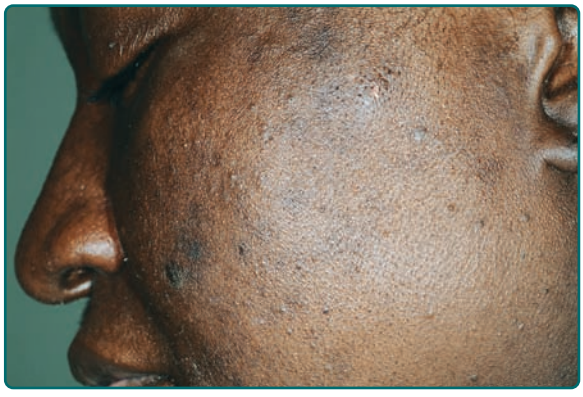

Figure 9-4 Acne with postinflammatory hyperpigmentation on the cheek of an African-American woman.

Treatment choices often affect pigmentation (Table 9-6). For example, topical corticosteroids may produce unwanted hypopigmentation in treated skin but may also speed resolution of postinflammatory hyperpigmentation. Cryotherapy, which preferentially damages melanocytes, may produce striking and/or irreversible pigment loss. Conversely, the irritation associated with many topical therapies and dermatologic procedures may produce unwanted hyperpigmentation. Awareness of these possibilities, careful choice of therapies and detailed patient education can avoid these iatrogenic problems.

SKIN CANCER

Cutaneous melanoma merits particular attention in skin of color because of the trend toward poorer prognosis. Lesions are more often of the acral or subungual subtype than the more common superficial spreading type seen in whites and present at more advanced stages. Some estimate that 20% of the world's melanoma cases occur in skin of color.[119] The incidence rates have remained relatively stable in Asians and blacks, while a large increase in melanoma incidence in the past century, attributed to increased UV exposure, has occurred in white populations.[120] Not surprisingly, lightly pigmented Hispanic skin has a risk similar to that of whites, while darkly pigmented Hispanic skin has a risk similar to Asians and blacks.[121]

Figure 9-5 Perioral hyperpigmentation secondary to retinoid dermatitis in an African-American man treated for acne. (Used with permission from RM Halder, MD and reproduced with permission from Halder RM: *Dermatology and Dermatologic Therapy of Pigmented Skins*. Boca Raton, CRC Press, 2006.)

Acral and subungual melanomas are associated with higher mortality than nonacral melanoma.[122] While the absolute incidence of acral melanomas is nearly identical for black and white Americans (1.7 vs. 2.0 per 100,000, respectively),[123] acral melanomas in darker populations tend to present later with large surface areas (>3 cm) and more advanced disease. According to SEER data (1986–1991), US blacks were 3-fold more likely to have distant metastases compared to US whites (12% vs. 4%, respectively).[120] Similarly, a study of subungual melanomas showed blacks had a 3.5-fold higher mortality rate than whites, even after controlling for Clark's level and stage.[124] However, existing data are inadequate to determine whether race is an independent risk factor for biologic aggressiveness in melanoma or whether the differences are instead a function of delayed diagnosis due to darker background pigmentation, the higher prevalence of benign palmar and plantar lentigines and pigmented bands on nails with which melanomas may be confused, or socioeconomic factors that affect the care received.

Public education and melanoma screening campaigns typically target Caucasians and often do not provide relevant information or convey the risk to those with skin of color, and in fact may even provide false reassurance. Development of education campaigns directed toward skin of color may aid in improving detection and prognosis, but until then individualized patient counseling and education remain important.

Nonmelanoma skin cancers (NMSC) also occur in skin of color, though far less commonly than in whites. Basal and squamous cell carcinomas (BCC and SCC) tend not to occur in sun-exposed areas, but rather at sites of nonhealing ulcers or other chronic proliferative stimulation. The incidence rate of SCC in blacks is reported as 3.4 per 100,000 and 1.8–3.2 in Asians. One series showed a rate of 5.8–6.4 BCC per 100,000 in Asians.[125] Gorlin's syndrome (basal cell nevus syndrome) occurs in all populations and may demonstrate few BCCs in skin of color, so careful observation of other findings including palmar pits, frontal bossing, and odontogenic cysts are important in screening for the disease, which has increased risk of internal malignancy and should prompt referral for genetic counseling. Immunosuppressed patients with skin of color, like whites, are at increased risk for NMSC and should be screened for malignancy. Cutaneous T-cell lymphoma has a 1.2–2-fold increased incidence and a higher mortality rate in blacks than in whites.[126–128]

COSMETIC AND PROCEDURAL DERMATOLOGY

It is important for providers to be cognizant of the options, effectiveness, and potential adverse effects

TABLE 9-5
Dermatologic Diseases with Special Considerations in Skin of Color

Dermatologic Disease	Considerations
Normal Findings and Nevi	
■ Pigmentary demarcation lines	Six types recognized[84] Most prominent on the arms
■ Melanonychia striata	Common, increases with age A single nail affected with >6 mm width lesion and variegation in color should prompt consideration of malignancy in appropriate setting
■ Palmoplantar melanosis	Common, increases with age Consider acral lentiginous melanoma in large, changing, or raised lesions
■ Circumscribed dermal melanocytosis	Blue-gray macules and patches present at birth Occur in all skin colors, more common in darker skin Typically resolve in childhood Term "Mongolian Spot" not preferred
■ Nevus of Ito/Ota	Nevoid form of dermal melanocytosis More frequent in Asian populations
Scars	
■ Hypertrophic scars and keloids	Blacks affected 5–16 times more often than Caucasians[85] Coiffure keloid can result from tightly braided hair styles[86]
Inflammatory Disease	
■ Confluent and reticulate papillomatosis	More prevalent in darker-skinned individuals and young women
■ Lichen planus	Certain subtypes such as lichen planus pigmentosus and lichen planus actinicus have a predilection for darker-skinned individuals.[87,88]
■ Lichen nitidus	May be hypo- or hyperpigmented in darker skin[89]
■ Lichen striatus	Can present as hypopigmented (rather than erythematous) papules lesions followed by hypopigmented macules.[90]
■ Pseudofolliculitis barbae	Curled shaved hairs penetrate inwards inciting inflammatory response Commonly leads to scarring and postinflammatory hyperpigmentation Laser hair removal, chemical delapitories, increased beard length with less frequent shaving, single-blade razors, and gentle lifting of ingrown hair loops out of skin provide improvement
■ Acne keloidalis nuchae	Mostly in males with skin of color Etiology poorly understood Avoid close cutting or shaving and friction Treatment includes medical anti-inflammatory therapies and surgical options
■ Scarring alopecias	More common in skin of color (See Table 9-4)
Acquired Pigmentary Disorders	
■ Idiopathic guttate hypomelanosis	Affects ~50% of African-Americans over 50 years of age No effective treatment available
■ Melasma	Women with darker skin types have a higher incidence[91,92]; Hispanics seem particularly at risk
■ Periorbital hypermelanosis	Can be more striking in darker-skinned individuals
■ Pityriasis alba	While estimated to affect 1–5% of all children, some reports indicate up to 25% of African-American children and 35% of Hispanic children
■ Postinflammatory hyper- and hypopigmentation	Often more apparent and more persistent in darker-skinned individuals Preventive and therapeutic measures warranted
■ Tinea versicolor	More common in tropical climates Higher incidence rates reported in black individuals[93,94]
■ Vitiligo	Often more striking in darker-skinned individuals Trichrome lesions more common in darker skin types[95] Vogt–Koyanagi–Harada syndrome tends to be more severe in Asians Evidence shows linkage to chromosome 4q13-q21 in Chinese families[96]

(continued)

TABLE 9-5
Dermatologic Diseases with Special Considerations in Skin of Color (Continued)

Dermatologic Disease	Considerations
Congenital Pigmentary Disorders	
■ Piebaldism	Often more striking in darker-skinned individuals
■ Oculocutaneous albinism (OCA)	Although OCA affects all racial groups (1:17,000 persons worldwide),[97] regional incidence depends on gene pools, social customs, and other environmental factors. Particularly high rates of OCA have been noted in Cuna Moonchild Indians in Panama (1:160)[98], Native Americans of the Hopi and Zuni tribes (1:227 and 1:240, respectively), Mayans in Guatemala (1:6500), South Africa (OCA2, 1:3900; OCA3, 1:8500), Nigeria (1:1100), Tanzania (OCA2, 1:1429), Zimbabwe (OCA2, 1:2833)[97,99,100] Hermansky–Pudlak syndrome is a rare form of tyrosinase-positive OCA found almost exclusively in Puerto Ricans (1:1800 Puerto Ricans)[101] In Japan, 24% of albino patients have OCA type 4[102]
Neoplastic Disease	
■ Mycosis fungoides	Can present as hypopigmented macules or patches in a central, rather than acral, distribution.[103]
■ Melanoma	Differences in anatomic distribution and type More often at advanced stage at presentation Poorer overall prognosis even for same risk factors
■ Nonmelanoma skin cancer	Occurs uncommonly but not rarely in skin of color, usually in the context of chronic proliferation, as at the site of a nonhealing wound
Other	
■ Sarcoidosis	Ten times more likely in blacks than in whites[104] Hypopigmented lesions more common in persons of color[105,106] Morbidity and mortality higher in African-Americans than in Caucasians[107]
■ Lichen amyloidosis	Increased prevalence in Asians, Middle Easterners, and South Americans[108–111]
■ Dermatosis papulosa nigra	Incidence as high as 70% in African-Americans[112]
■ Ashy dermatosis	Scattering of incident light by an irregular "dry" stratum corneum; management as for xerosis with emollients and gentle skin care

of cosmetic treatments for conditions affecting darker skin types. The cosmetic procedure literature has focused primarily on white skin, and often does not discuss outcomes in dark-skinned patients. However, this is changing as greater numbers of patients with skin of color seek cosmetic and procedural treatments.

PREVENTIVE MEASURES

Photoaging has been a prevalent issue for Caucasians, but nonwhites also demonstrate changes associated with photoaging, particularly facial lentigines and other forms of dyspigmentation that often appear up to two decades earlier in women with skin of color, after controlling for latitude of residence. Hence, sun protection is recommended for optimal prevention of age-associated changes, regardless of skin color. However, dyschromia (irregular pigmentation) unrelated to photoaging is perhaps the most frequent complaint for patients with skin of color. Prevention and minimization of postinflammatory pigmentary changes due to trauma and irritation, whenever possible, are paramount. Avoidance of melanogenic stimulation by direct sun exposure is also critical in this context, although care must be taken to assure adequate vitamin D levels through oral supplementation if vitamin D photosynthesis is minimized (see Chapter 90).

TOPICAL THERAPIES FOR HYPERPIGMENTATION

In treating hyperpigmentation, it is important to consider the location of deposited pigment. Dermal pigmentation retained in melanophages is not affected by topical therapies and is highly resistant to all treatment modalities. However, increased epidermal melanin can often be improved with topical therapy that reduces melanogenetic stimulation, tyrosinase activity, or melanin transfer to keratinocytes (Table 9-6). Topical therapies generally produce slow and subtle improvements, and treatment expectations should be discussed with patients.

COSMETIC CAMOUFLAGE

Camouflage makeups that hide dyschromic areas continue to represent a significant aid for some patients,

TABLE 9-6
Topical Therapies for Hyperpigmentation

Therapeutic Agent(s), by Category	Special Considerations
UV Protection	
■ Sunscreens	Prevent UV-induced tanning and may hasten resolution of postinflammatory hyperpigmentation; recommended for most patients with hyperpigmentation concerns, can be used concomitantly with other therapies
Tyrosinase Inhibitors[a]	
■ Azelaic acid	Dicarboxylic acid derived from *Plasmodium ovale* cultures
■ Hydroquinone	Higher concentrations may lead to irritation; low risk of permanent depigmentation and ochronosis (typically seen at concentrations >6%); shows increased efficacy in combination therapy with 0.01% fluocinonide cream and 0.05% tretinoin
■ Arbutin	Hydroquinone derivative; inhibits tyrosinase and DHICA[113]
■ Licorice extract	Active ingredient glabridin decreases tyrosinase activity and has anti-inflammatory effects[114]
■ Paper Mulberry	Potent tyrosinase inhibition[115]
■ Vitamin C	Product should be stable for efficacy Also provides anti-inflammatory effect
■ Tretinoin	Inhibits tyrosinase transcription and glycosylation; normalizes epidermal melanin distribution
■ Kojic acid	Fungal derivative; inhibits tyrosinase
■ *N*-Acetylglucosamine	Inhibits conversion of protyrosinase to tyrosinase[116]
■ Pycnogenol	Flavanoid compounds with antioxidant activity; oral treatment (25 mg TID) may improve melasma[117]
Melanosome Transfer Inhibition[a]	
■ Niacinamide	Amide of niacin (B3), inhibits melanosome transfer to keratinocytes[118]
■ Soy	Soybean trypsin inhibitor (STI) and Bowman-Birk inhibitor (BBI) inhibit cleavage of PAR-2, reducing melanosome transfer
Increased Cellular Turnover	
■ α-Hydroxy and β-hydroxy acids	Reduce corneocyte adhesion

[a]Reported mechanism of action, based on data of varying strength.

and can be less expensive than other options. Branded products include Veil Cover Cream, Keromask, Dermacolor, and Dermablend. These and the many other marketed formulations must be judged by the user on the basis of esthetics, cost, and other factors of importance to the individual. Referral to a professional makeup artist or camouflage makeup therapist for application demonstration and education regarding proper use can provide significant benefit.

PROCEDURAL DERMATOLOGY IN SKIN OF COLOR. Superficial and medium depth chemical peels, when appropriately selected and performed, are appropriate for Fitzpatrick skin types IV–VI. Specific choices regarding chemical agent depend on the efficacy, safety, desired depth of peel, and the physician's preference and experience. Microdermabrasion is appropriate for all skin types, is often used for acne and other types of facial scarring, and is a good option for those unable to tolerate peels or extensive recovery times.

Laser treatment in patients with skin of color should be selected with the knowledge that epidermal melanin can act as a competitive chromophore. Inadvertent absorption of laser energy by epidermal melanin can lead to scarring and dyspigmentation.

PATIENT INDIVIDUALIZATION

The spectrum of human phenotypes results from a combination of genetic and environmental influences. Complexities of racial and ethnic contributors to disease susceptibility, clinical presentation, and therapeutic response are still poorly understood. Because there is on average greater genetic diversity between any two individuals (85–90%) than between races (10–15%),[129] and because genes determining pigmentation make up an exceedingly small proportion of the genome, it is desirable that race not be overemphasized in determining a dermatologic plan of care. The welcome movement toward considering skin types as a continuous spectrum rather than dichotomously as white and nonwhite may one day render obsolete the term "skin of color."

Disorders Presenting in Skin and Mucous Membranes

PART 2

Inflammatory Disorders Based on T-Cell Reactivity and Dysregulation

Chapter 10 :: Innate and Adaptive Immunity in the Skin

:: Robert L. Modlin, Lloyd S. Miller, Christine Bangert, & Georg Stingl

INNATE AND ADAPTIVE IMMUNITY AT A GLANCE

- Innate immune responses
  - are used by the host to immediately defend itself;
  - determine the quality and quantity of many adaptive immune responses;
  - are short lived;
  - have no memory;
  - include physical barriers (skin and mucosal epithelia);
  - include soluble factors such as complement, antimicrobial peptides, chemokines, and cytokines;
  - include cells such as monocytes/macrophages, dendritic cells, natural killer cells, and polymorphonuclear leukocytes.
- Adaptive immune responses
  - have memory;
  - have specificity;
  - are long lasting;
  - in skin, are initiated by dendritic antigen-presenting cells in the epidermis (Langerhans cells) and by dermal dendritic cells;
  - are executed by T lymphocytes and antibodies produced by B lymphocytes/plasma cells.

The human immune system is comprised of two distinct functional parts: (1) innate and (2) adaptive. These two components have different types of recognition receptors and differ in the speed in which they respond to a potential threat to the host (Fig. 10-1). Cells of the innate immune system, including macrophages and dendritic cells (DCs), use pattern recognition receptors encoded directly by the germ line DNA, respond to biochemical structures commonly shared by a variety of different pathogens, and elicit a rapid

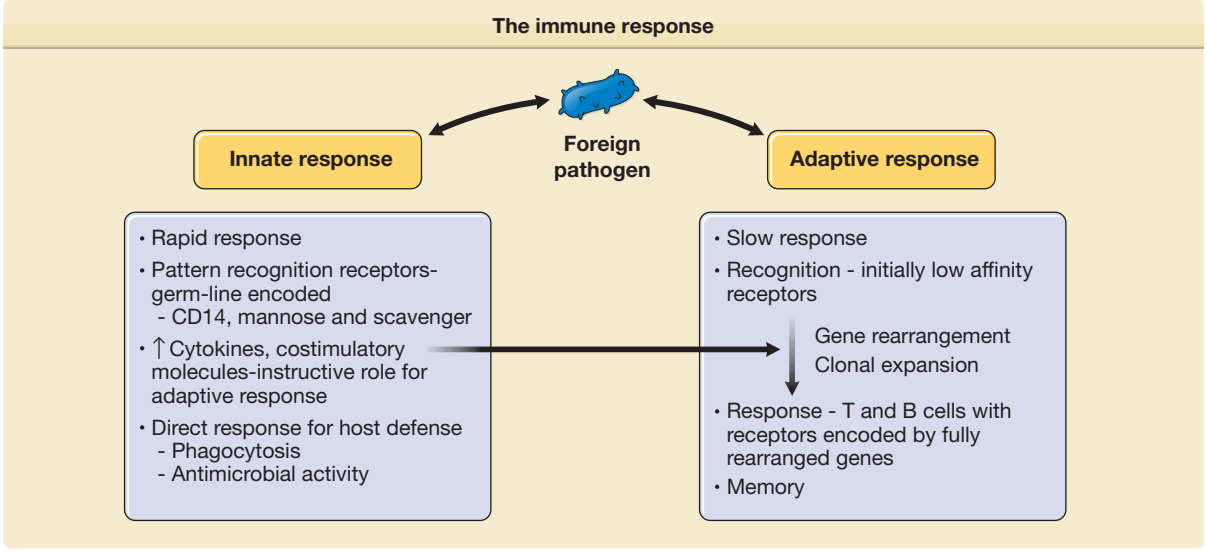

Figure 10-1 The immune system of higher vertebrates uses both innate and adaptive immune responses. These immune responses differ in the way they recognize foreign antigens and the speed with which they respond; yet, they complement each other in eradicating foreign pathogens.

response against these pathogens, although no lasting immunity is generated. In contrast, cells of the adaptive immune system, T and B lymphocytes, bear specific antigen receptors encoded by rearranged genes, and in comparison to the innate response, adaptive immunity develops more slowly. A unique feature of the adaptive immune response is its ability to generate and retain memory; thus, it has the capability of providing a more rapid response in the event of subsequent immunologic challenge. Although the innate and adaptive immune responses are distinct, they interact and can each influence the magnitude and type of their counterpart. Together, the innate and adaptive immune systems act in synergy to defend the host against infection and cancer. This chapter describes the roles of the innate and adaptive immune response in generating host defense mechanisms in skin.

INNATE IMMUNE RESPONSE

Immune mechanisms that are used by the host to immediately defend itself are referred to as *innate immunity*. These include physical barriers such as the skin and mucosal epithelium; soluble factors such as complement, antimicrobial peptides, chemokines, and cytokines; and cells, including monocytes/macrophages, DCs, natural killer cells (NK cells), and polymorphonuclear leukocytes (PMNs) (Fig. 10-2).

Our present understanding of innate immunity is based on the studies of Elie Metchnikoff who, in 1884, published studies on the water flea *Daphnia* and its interaction with a yeast-like fungus.[1] He demonstrated that cells of the water flea, which he termed "phagocytes," were attracted to and engulfed the foreign spores, which were subsequently "killed and destroyed." Thus, Metchnikoff described the key direct functions of cells of the innate immune system: (1) rapid detection of microbes, (2) phagocytosis, and (3) antimicrobial activity. In addition to this direct role in host defense, the innate immune system has an indirect role in instructing and determining the type of adaptive T and B cell responses. Finally, by inducing inflammation, the innate immune response can also induce tissue injury.

PHYSICAL AND CHEMICAL BARRIERS[2]

Physical structures prevent most pathogens and environmental toxins from harming the host. The skin and the epithelial lining of the respiratory, gastrointestinal, and the genitourinary tracts provide physical barriers between the host and the external world. Skin, once thought to be an inert structure, plays a vital role in protecting the individual from the external environment. The epidermis impedes penetration of microbial organisms, chemical irritants, and toxins; absorbs and blocks solar and ionized radiation; and inhibits water loss (see Chapter 47).

MOLECULES OF THE INNATE IMMUNE SYSTEM

COMPLEMENT.[3] (See eFig. 10-2.1 in online edition; see also Chapter 37). One of the first innate defense mechanisms that awaits pathogens that overcome the epithelial barrier is the alternative pathway of complement. Unlike the classical complement pathway that requires antibody triggering, the lectin-dependent pathway as well as the alternative pathway of complement activation can be spontaneously activated by microbial surfaces in the absence of specific antibodies (see eFig. 10-2.1 in online edition). In this way, the host defense mechanism is activated immediately

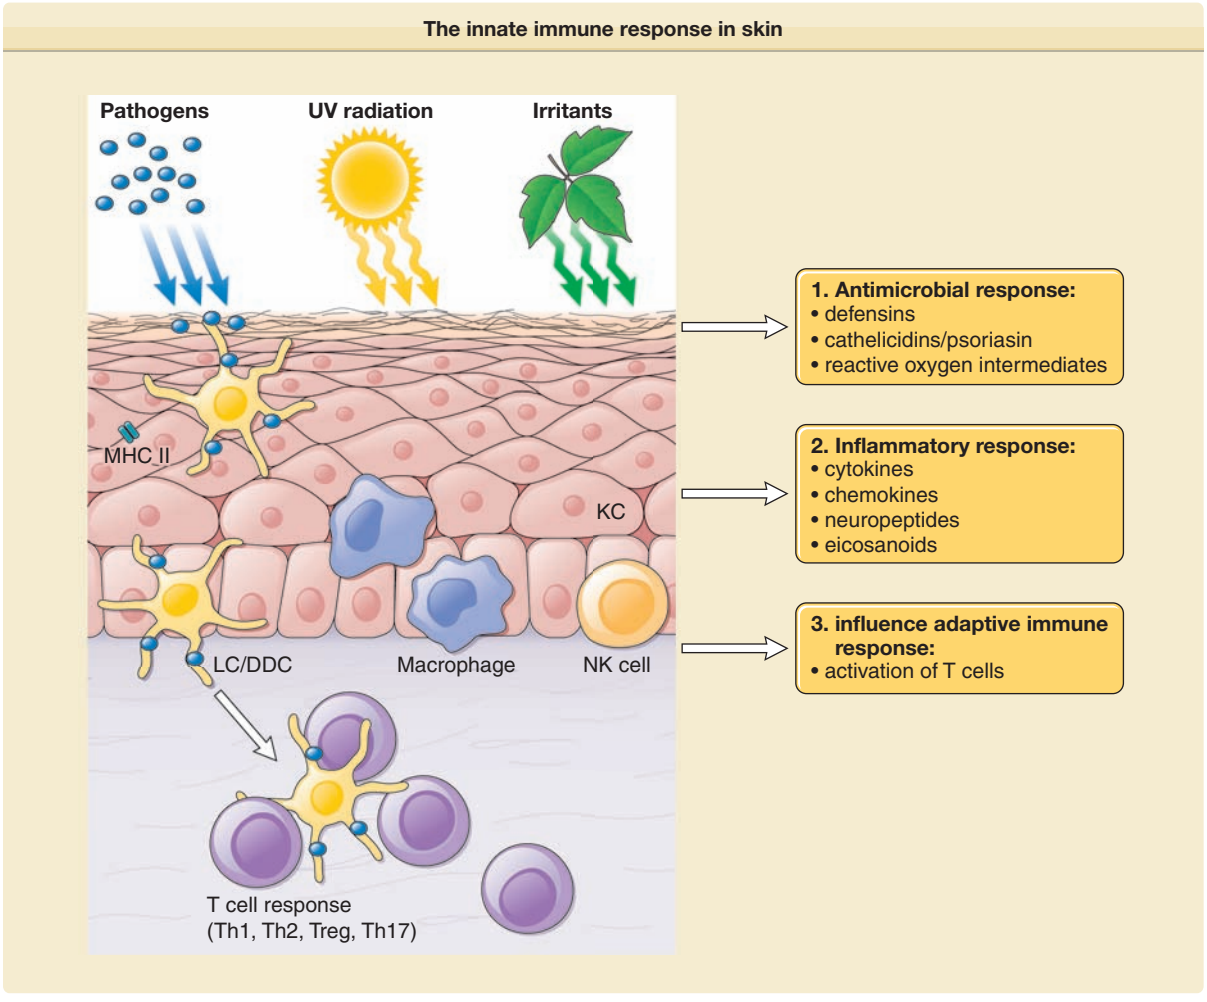

Figure 10-2 The innate immune response in skin. In response to exogenous factors, such as foreign pathogens, ultraviolet (UV) radiation, and chemical irritants, innate immune cells [granulocytes, mononuclear phagocytes, natural killer (NK) cells, keratinocytes] mount different types of responses including (1) release of antimicrobial agents; (2) induction of inflammatory mediators, such as cytokines, chemokines, neuropeptides, and eicosanoids; and (3) initiation and modulation of the adaptive immune response. DDC = dermal dendritic cell; KC = keratinocyte; LC = Langerhans cell; MHC II = major histocompatibility complex class II; Th1 = type I T cells; Th2 = type II T cells; Th17 = type 17 T cells; T reg = regulatory T cells.

after encountering the pathogen without the 5–7 days required for antibody production.

ANTIMICROBIAL PEPTIDES.[4]

Antimicrobial peptides serve as an important evolutionarily conserved innate host defense mechanism in many organisms. They typically are positively charged and are amphipathic, possessing both hydrophobic and hydrophilic surfaces. The antimicrobial activity of these peptides is thought to relate to their ability to bind membranes of microbes (through their hydrophobic surface) and form pores in the membrane, leading to microbial killing. There are numerous antimicrobial peptides identified in various human tissues and secretions. This section will focus on antimicrobial peptides identified in resident skin cells, including human β-defensins (HBD-1, HBD-2, HBD-3), cathelicidin (LL-37), psoriasin, and RNase 7, which have all been demonstrated to be produced by keratinocytes, and dermcidin, which is secreted in human sweat. In addition, there are numerous other antimicrobial peptides that are produced by cells that infiltrate the skin and may participate in cutaneous innate immune responses.[5]

β-Defensins are cysteine-rich cationic low-molecular-weight antimicrobial peptides. The first human β-defensin, HBD-1, is constitutively expressed in the epidermis and is not transcriptionally regulated by inflammatory agents. HBD-1 has antimicrobial activity against Gram-negative bacteria and appears to play a role in keratinocyte differentiation. A second human β-defensin, HBD-2, was discovered in extracts of lesions from psoriasis patients.[6] Unlike HBD-1 expression, HBD-2 expression is inducible by components of microbes, including *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida albicans*.[6] Not only can components of microbes stimulate expression of HBD-2, but proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin 1 (IL-1) can also induce HBD-2 transcription in keratinocytes.[6] When tested for antimicrobial activity, HBD-2 was effective

against Gram-negative bacteria such as *Escherichia coli* and *P. aeruginosa* and has a weak bacteriostatic effect against Gram-positive bacteria such as *S. aureus*.[6] HBD-3 is another β-defensin that was first isolated from extracts of lesions from psoriasis patients.[7] Contact with TNF-α and with bacteria was found to induce HBD-3 messenger RNA expression in keratinocytes. In addition, HBD-3 demonstrated potent bactericidal activity against *S. aureus* and vancomycin-resistant *Enterococcus faecium*. Therefore, HBD-3 is among the first human β-defensins in skin to demonstrate effective antimicrobial activity against Gram-positive bacteria. The localization of human β-defensins to the outer layer of the skin and the fact the β-defensins have antimicrobial activity against a variety of microbes suggest that human β-defensins are an essential part of cutaneous innate immunity. Furthermore, evidence indicating that human β-defensins attract DCs and memory T cells via CC chemokine receptor 6 (CCR6)[8] provides a link between the innate and the adaptive immunity in skin.

Cathelicidins are cationic peptides with a structurally variable antimicrobial domain at the *C*-terminus. Whereas in mammals like pigs or cattle a variety of cathelicidin genes exists, men (and mice) possess only one gene. The human precursor protein hCAP18 (human cathelicidin antimicrobial protein 18) is produced by skin cells, including keratinocytes, mast cells, neutrophils, and ductal cells of eccrine glands. Neutrophil proteases (i.e., proteinase 3) process hCAP18 into the effector molecule LL-37 (named LL-37 for the 37-amino acid active antimicrobial peptide liberated from the *C*-terminus of the protein), which plays an important role in cutaneous host defense because of its pronounced antibacterial,[9,10] antifungal,[11] and antiviral[12,13] activities. LL-37 further contributes to innate immunity by attracting mast cells and neutrophils via formyl peptide receptor-like 1 and by inducing mediator release from the latter cells via a G protein-dependent, immunoglobulin (Ig) E-independent mechanism.[14] It has now been shown that LL-37 is secreted into human sweat, where it is cleaved by a serine protease-dependent mechanism into its peptides RK-31 or KS-30. Interestingly, these components display an even more potent antimicrobial activity than intact LL-37.[15] One of the most important inducers of LL-37 expression is vitamin D, which can be triggered by Toll-like receptor (TLR) activation of the vitamin D receptor and vitamin D-1-hydroxylase genes, leading to enhanced antimicrobial killing.[16,17]

In atopic dermatitis (see Chapter 14), LL-37 is downregulated, probably due to the effect of the T2 cytokines IL-4 and IL-13, which renders atopic skin more susceptible to skin infections with, for example, *S. aureus*, vaccinia virus (eczema vaccinatum), or herpes simplex virus (HSV) (eczema herpeticum).[10,12,13] Furthermore, patients with rosacea have been found to possess high levels of aberrantly processed forms of cathelicidin peptides (due to posttranslational processing by stratum corneum tryptic enzyme), which contributes to the increased inflammation in the skin.[18] Cathelicidin can also form complexes with self-DNA, which promotes activation of TLR9 on plasmacytoid dendritic cells in the dermis, resulting in enhanced cutaneous inflammation that contributes to psoriasis pathogenesis.[19]

Another important human antimicrobial peptide has now been identified, psoriasin (S100A7),[20] which elicits its antimicrobial effect by permeabilization of bacterial membranes.[21] It is secreted predominantly by keratinocytes and plays a major role in killing the common gut bacterium *E. coli*. In fact, in vivo treatment of human skin with antipsoriasin antibodies results in the massive growth of *E. coli*.[20] Furthermore, expression of psoriasin by keratinocytes has been shown to occur via TLR5 stimulation by *E. coli* flagellin.[22] In addition to antimicrobial activity, psoriasin also functions as a chemoattractant for CD4 cells and neutrophils.[23]

RNase 7 was originally isolated from the stratum corneum from healthy human skin.[24] RNase 7 has potent ribonuclease activity but also broad-spectrum antimicrobial activity against *S. aureus*, *P. acnes*, *P. aeruginosa*, *E. coli*, and *C. albicans.* RNase 7 production can be induced in cultured human keratinocytes by IL-1β, IFN-γ, and bacterial challenge. Interestingly, high expression of RNase 7 in human skin confers protection against *S. aureus* cutaneous infection.[25]

Dermcidin is an antimicrobial peptide that is expressed by human sweat glands.[26] Dermcidin goes through postsecretory proteolytic processing in sweat that gives rise to anionic and cationic dermcidin peptides that are secreted onto the skin surface. These dermcidin peptides have broad antimicrobial activity against *S. aureus*, *E. coli*, *E. faecalis*, and *C. albicans.* Although the mechanism of action of dermcidin activity is unknown, it does not involve pore formation like other antimicrobial peptides.[27]

PATTERN RECOGNITION RECEPTORS. How do the cells of the innate immune system recognize foreign pathogens? One way that pathogens can be recognized and destroyed by the innate immune system is via receptors on phagocytic cells. Unlike adaptive immunity, the innate immune response relies on a relatively small set of germ line-encoded receptors that recognize conserved molecular patterns that are shared by a large group of pathogens. These are usually molecular structures required for survival of the microbes and therefore are not subject to selective pressure. In addition, pathogen-associated molecular patterns are specific to microbes and are not expressed in the host system. Therefore, the innate immune system has mastered a clever way to distinguish between self and nonself and relays this message to the adaptive immune system.

Of key importance was the discovery of the Toll-like receptors (TLRs), named after the *Drosophila* Toll gene whose protein product, Toll, participates in innate immunity and in dorsoventral development in the fruit fly.[30,31] The importance of Toll signaling in mammalian cells was confirmed by the demonstration that the transmembrane leucine-rich protein TLR4 is involved in lipopolysaccharide (LPS) recognition.[32]

In addition to TLRs, there exist a variety of other molecules that sense the presence of pathogens. These include the NOD proteins (see below), triggering

receptors expressed on myeloid cell (TREM) proteins,[33] the family of Siglec molecules,[34] and a group of *C*-type lectin receptors.[35] The latter are prominently expressed on antigen-presenting cells (APCs) as, for instance, dectin-1 and DC-SIGN [DC-specific intercellular adhesion molecule 3 (ICAM-3) grabbing nonintegrin], which is actually expressed on tissue macrophages.[36] They are able to mediate efficient binding of microorganisms; facilitate phagocytosis; and induce activation of signaling pathways that result in antimicrobial activity.

Members of the TREM protein family function as amplifiers of innate responses. Extreme examples of the consequences of microbe activation of TREM proteins are life-threatening septicemia and the deadly hemorrhagic fevers caused by Marburg and Ebola virus infection.[37]

TOLL-LIKE RECEPTORS.[38]

There is now substantial evidence to support a role for mammalian TLRs in innate immunity (Fig. 10-3). First, TLRs recognize pathogen-associated molecular patterns present in a variety of bacteria, fungi, and viruses. Second, TLRs are expressed at sites that are exposed to microbial threats. Third, the activation of TLRs induces signaling pathways that, on the one hand, stimulate the production of antimicrobial effector molecules, and, on the other, promote the expression of costimulatory molecules and the release of cytokines and, as a result, the augmentation of the adaptive response. Fourth, TLRs directly activate host defense mechanisms that then combat the foreign invader.

Experiments performed in the Modlin laboratory[39] and others[40] led to the exciting finding that microbial lipoproteins trigger host responses via TLR2, requiring the acyl functions for activity. Subsequently, triacylated lipoproteins were found to activate TLR2/1 heterodimers,[41] whereas diacylated lipoproteins were found to activate TLR2/6 heterodimers.[42] For recognition of bacteria, the TLR system is redundant: TLR9 is activated by unmethylated DNA sequences (CpG dinucleotides) found in bacterial DNA[43] and TLR5 activated by bacterial flagellin.[44] Specific TLRs are involved in viral recognition: TLR3 is activated by viral derived double-stranded RNA[45] and TLR7 and TLR8 by virus-derived single-stranded RNA.[46] The finding that different TLRs have distinct patterns of expression, particularly on monocytes, macrophages, dendritic cells, B cells, endothelia, and epithelia, suggests that each TLR could trigger a specific host response. Furthermore, TLRs are expressed in specific

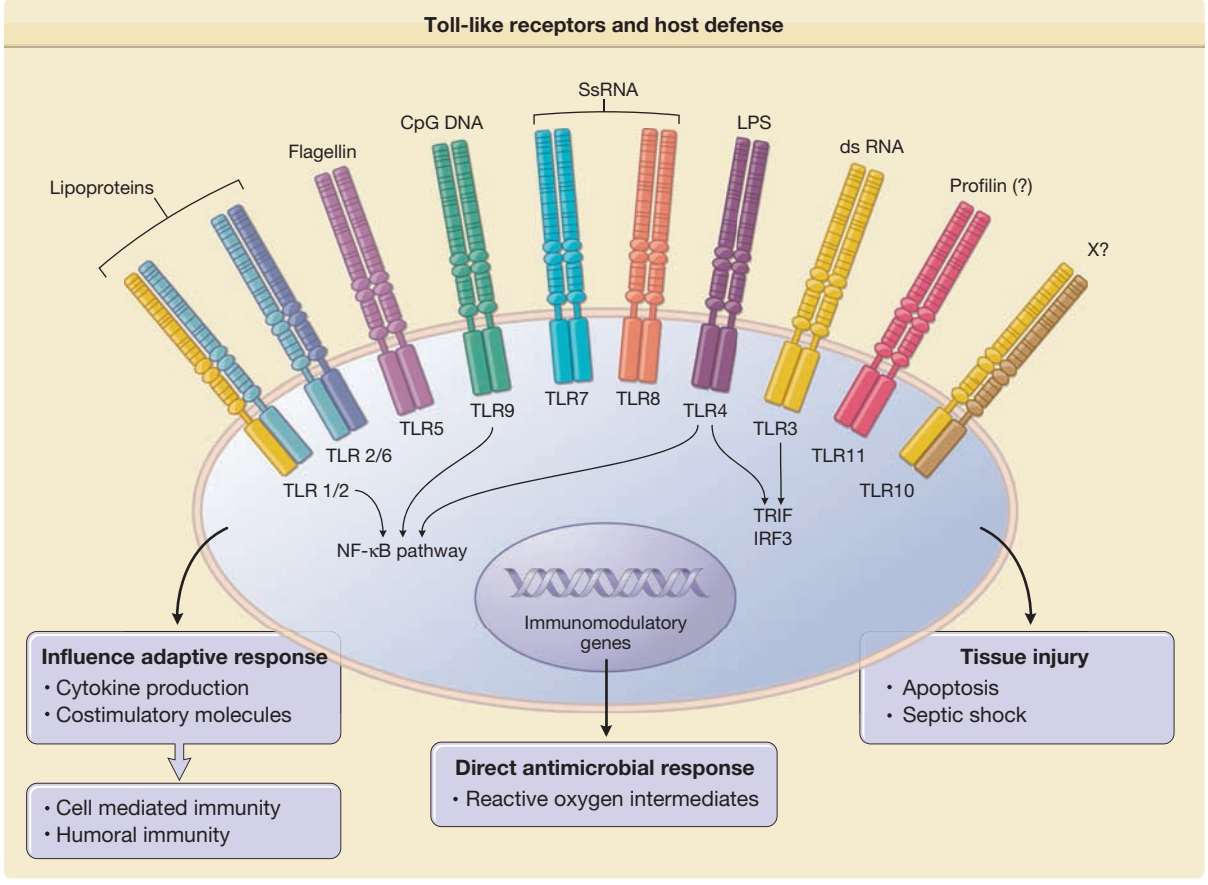

Figure 10-3 Toll-like receptors (TLRs) mediate innate immune response in host defense. Activation of TLRs by specific ligands induces (1) cytokine release and costimulatory molecules that instruct the type of adaptive immune response; (2) direct antimicrobial response; and (3) tissue injury. CpG DNA = immunostimulatory cytosine- and guanine-rich sequences of DNA; dsRNA = double-stranded RNA; LPS = lipopolysaccharide; NF-κB = nuclear factor κB; ssRNA = single-stranded RNA; X = ligand unknown.

subcellular compartments: TLR7, 8, and 9 are located in endosomes, where they encounter microbial pathogens in the endocytic pathway. The other TLRs are expressed on the cell surface and detect microbial ligands in the extracellular environment.

The expression of TLRs on cells of the monocyte/macrophage lineage is consistent with the role of TLRs in modulating inflammatory responses via cytokine release. Because these cells migrate into sites that interface with the environment—lung, skin, and gut—the location of TLR-expressing cells would situate them to defend against invading microbes. TLR expression by adipocytes, intestinal epithelial cells, and dermal endothelial cells supports the notion that TLRs serve a sentinel role with regard to invading microorganisms. The regulation of TLR expression is critical to their role in host defense, yet few factors have been identified that modulate this process. IL-4 acts to downregulate TLR expression,[47] which suggests that T helper 2 (T2) adaptive immune responses might inhibit TLR activation.

DETAILED STUDIES OF TLR

TLR-Induced Cytokine Release. TLR activation of a variety of cell types has been shown to trigger release of both proinflammatory and immunomodulatory cytokines.[48–52] TLR activation of monocytes and DC induces IL-12 and IL-18, required for generation of a Th1 response, and IL-1β, IL-6, IL-23, involved in the generation of a Th17 response, as well as the anti-inflammatory IL-10.[53–56] The relative induction of specific cytokine patterns determines the type of adaptive T-cell response (see Chapter 11).

MΦ and DC Differentiation. TLRs can regulate phagocytosis either through enhancing endosomal fusion with the lysosomal compartment[57] or through induction of a phagocytic gene program including multiple scavenger receptors.[58] Activation of TLRs on monocytes leads to the induction of IL-15 and IL-15R, triggering differentiation into $CD209^+$ MΦ[36] with microbicidal activity.[59] Activation of TLRs on monocytes also induces GM-CSF and GM-CSFR, triggering differentiation into immature DC with the capacity to release cytokines and efficiently present antigen to T cells.[36] In addition, activation of TLRs on immature DC leads to further maturation with enhanced T-cell stimulatory capacity.[60]

TLR-Induced Antimicrobial Activity. In *Drosophila*, Toll is critical for host defense. The susceptibility of mice with spontaneous mutations in TLRs to bacterial infection indicates that mammalian TLRs play a similar role. Activation of TLR2 by microbial lipoproteins induces activation of the inducible nitric oxide (NO) synthase (NOS-II or iNOS) promoter,[39] which leads to the production of NO, a known antimicrobial agent. There is strong evidence that TLR2 activation leads to killing of intracellular *Mycobacterium tuberculosis* in both mouse and human macrophages.[54] In mouse macrophages, bacterial lipoprotein activation of TLR2 leads to a NO-dependent killing of intracellular tubercle bacilli. In human monocytes and alveolar macrophages, bacterial lipoproteins similarly activate TLR2 to kill intracellular *M. tuberculosis*; however, this occurs by an antimicrobial pathway that is NO-independent. Instead, a key antimicrobial mechanism for TLR-activated human monocytes involves induction of the 25-hydroxyvitamin D3-1α-hydroxylase (CYP27b1), which converts the 25D into the active 1,25D form, upregulation and activation of the vitamin D receptor (VDR), and downstream induction of the antimicrobial peptide cathelicidin.[16,59,61–63] The ability of TLR2/1 activation to upregulate expression of CYP27b1 and the VDR is IL-15 dependent.[36] Simultaneous triggering of IL-1β activity and activation of the VDR induces HBD-2, also required for antimicrobial activity.

Activation of TLRs 3, 4, 7, 8, and 9 leads to induction of antiviral activity, dependent on type I IFN secretion and involving specific signaling pathways.[64] Two TLR-mediated pathways have been identified: type I IFN production occurs through a MyD88-independent pathway in response to TLR3 and TLR4 activation,[65] and, following stimulation with agonists of TLRs 7, 8, and 9, through a MyD88-dependent pathway.[66]

The activation of TLRs can also be detrimental, leading to tissue injury. The administration of LPS to mice can result in manifestations of septic shock, which is dependent on TLR4.[32] Evidence suggests that TLR2 activation by *Propionibacterium acnes* induces inflammatory responses in acne vulgaris, which lead to tissue injury.[67] Aliprantis et al demonstrated that microbial lipoproteins induce features of apoptosis via TLR2.[40] Thus, microbial lipoproteins have the ability to elicit both TLR-dependent activation of host defense and tissue pathology. This dual signaling pathway is similar to TNF receptor and CD40 signaling, which leads to both nuclear factor-κB activation and apoptosis.[68,69] In this manner, it is possible for the immune system to use the same molecules to activate host defense mechanisms and then, by apoptosis, to downregulate the response from causing tissue injury. Activation of TLR can lead to the inhibition of the major histocompatibility complex (MHC) class II antigen presentation pathway, which can downregulate immune responses leading to tissue injury but may also contribute to immunosuppression.[70] Finally, Toll activation has been implicated in bone destruction.[52]

The critical biologic role of TLRs in human host defense can be deduced from the finding that TLR4 mutations are associated with LPS hyporesponsiveness in humans.[71] By inference, one can anticipate that humans with genetic alterations in TLR may have increased susceptibility to certain microbial infections. Furthermore, it should be possible to exploit the pathway of TLR activation as a means to endorse immune responses in vaccines and treatments for infectious diseases as well as to abrogate responses detrimental to the host.

CELLS OF THE INNATE IMMUNE SYSTEM

PHAGOCYTES. Two key cells of the innate immune system are characterized by their phagocytic function:

macrophages and PMNs. These cells have the capacity to take up pathogens, recognize them, and destroy them. Some of the functions of these cells are regulated via TLRs and complement receptors as outlined earlier.

PMNs are normally not present in skin; however, during inflammatory processes, these cells migrate to the site of infection and inflammation, where they are the earliest phagocytic cells to be recruited. These cells have receptors that recognize pathogens directly (see Pattern Recognition Receptors), and due to their expression of FcγRIII/CD16 and C3bR/CD35, can phagocytose microbes coated with antibody and with the complement component C3b. As a consequence, granules (containing myeloperoxidase, elastase, lactoferrin, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated (see Chapter 30).

Effector Functions of Phagocytes. Activation of phagocytes by pathogens induces several important effector mechanisms, for example, triggering of cytokine production. A number of important cytokines are secreted by macrophages in response to microbes, including IL-1, IL-6, TNF-α, IL-8, IL-12, and IL-10 (see also Chapter 11).

Another important defense mechanism triggered in phagocytes in response to pathogens is the induction of direct antimicrobial responses. Phagocytic cells such as PMNs and macrophages recognize pathogens, engulf them, and induce antimicrobial effector mechanisms to kill the pathogens. The induction and/or release of toxic oxygen radicals, lysosomal enzymes, and antimicrobial peptides leads to direct killing of microbial organisms.[4] Similarly, activation of TLRs on macrophages induces these various antimicrobial pathways as already discussed above.

Macrophage Subsets and Functional Programs. Cytokines of the adaptive T-cell response influence macrophage differentiation: IFN-γ treatment results in "classically activated" macrophages, with antimicrobial activity, whereas in contrast IL-4 or IL-13 triggers differentiation into "alternatively activated" macrophages, which contribute to humoral and antiparasite immunity.[82,83] Cytokines produced by the innate immune response also induce distinct macrophage differentiation programs.[84] IL-10 induces the phagocytic program in macrophages, leading to the uptake of lipids and bacteria. In contrast, IL-15 induces a macrophage antimicrobial program. These data establish that the innate immune response, by selectively inducing IL-10 versus IL-15, differentially programs macrophages for phagocytosis versus antimicrobial responses that largely determines the outcome of infection.

Phagocytic cells of the innate immune system can also be activated by cells of the adaptive immune system. CD40 is a 50-κDa glycoprotein present on the surface of B cells, monocytes, DCs, and endothelial cells. The ligand for CD40 is CD40L, a type II membrane protein of 33 kDa, preferentially expressed on activated $CD4^+$ T cells and mast cells. CD40–CD40 ligand interaction plays a crucial role in the development of effector functions. $CD4^+$ T cells activate macrophages and monocytes to produce TNF-α, IL-1, IL-12, interferon-γ (IFN-γ), and NO via CD40–CD40L interaction. CD40L has also been shown to rescue circulating monocytes from apoptotic death, thus prolonging their survival at the site of inflammation. In addition, CD40–CD40L interaction during T-cell activation by APCs results in IL-12 production. Therefore, it can be concluded that CD40–CD40L interactions between T cells and macrophages play a role in maintenance of T1-type cellular responses and mediation of inflammatory responses. Other studies have established a role for CD40–CD40L interactions in B-cell activation, differentiation, and Ig class switching.[85] In addition, CD40–CD40L interaction leads to upregulation of B7.1 (CD80) and B7.2 (CD86) on B cells. This costimulatory activity induced on B cells then acts to amplify the response of T cells. These mechanisms underscore the importance of the interplay between the innate and the adaptive immune system in generating an effective host response.

NATURAL KILLER CELLS.[86] NK cells appear as large granular lymphocytes. In humans, the vast majority of these cells exhibit the $CD3^-$, $CD56^+$, $CD16^+$, $CD94^+$, and $CD161^+$ phenotype. Their function is to survey the body looking for altered cells, be they transformed or infected with viruses (e.g., cytomegalovirus), bacteria (e.g., *Listeria monocytogenes*), or parasites (e.g., *Toxoplasma gondii*). These pathogens are then killed directly via perforin/granzyme- or Fas/Fas ligand (FasL)-dependent mechanisms or indirectly via the secretion of cytokines (e.g., IFN-γ).

How Do NK Cells Discriminate Between Normal and Transformed or Pathogen-Infected Tissue? All nucleated cells express the MHC class I molecules. NK cells have receptors, termed *killer inhibitory receptors*, which recognize the self-MHC class I molecules. This recognition results in the delivery of a negative signal to the NK cell that paralyzes it. If a nucleated cell loses expression of its MHC class I molecules, however, as often happens after malignant transformation or virus infection, the NK cell, on encountering it, will become activated and kill it.

In addition, NK cells have activating receptors that bind MHC-like ligands on target cells. One such receptor is NKGD2, which binds to the human nonclassic MHC class I chain-related A and B molecules, MICA and MICB.[87] MICA and MICB are not expressed in substantial amounts on normal tissues, but are overexpressed on carcinomas.[88] NK cells are able to kill MICA/MICB-bearing tumors, which suggests a role for NKGD2 in immune surveillance.

Another cell type that, at least in mice, could serve a similar function is the IFN-producing killer DC, which shares several features with DCs and NK cells.[89,90] Their human equivalent has yet to be identified.

KERATINOCYTES. Once thought to only play a role in maintaining the physical barrier of the skin, keratinocytes, the predominant cells in the epidermis, can participate in innate immunity by mounting

an immune and/or inflammatory response through secretion of cytokines and chemokines, arachidonic acid metabolites, complement components, and antimicrobial peptides.

Keratinocytes of unperturbed skin produce only a few of these mediators, such as the cytokines IL-1, IL-7, and transforming growth factor-β (TGF-β), constitutively. Resident keratinocytes contain large quantities of preformed and biologically active IL-1α as well as immature IL-1β in their cytoplasm.[91] The likely in vivo role of this stored intracellular IL-1 is that of an immediate initiator of inflammatory and repair processes after epidermal injury. IL-7 is an important lymphocyte growth factor that may have a role in the survival and proliferation of the T lymphocytes of human skin. Some evidence exists for the IL-7-driven propagation of lymphoma cells in Sézary syndrome.

TGF-β, in addition to its growth-regulating effects on keratinocytes and fibroblasts, modulates the inflammatory as well as the immune response[92] and is important for LC development (see in Langerhans Cells).[93] On delivery of certain noxious, or at least potentially hazardous, stimuli (e.g., hypoxia, trauma, nonionizing radiation, haptens, or other rapidly reactive chemicals like poison ivy catechols, silica, LPS, and microbial toxins), the production and/or release of many cytokines is often dramatically enhanced. The biologic consequences of this event are manifold and include the initiation of inflammation (IL-1, TNF-α, IL-6, members of the chemokine family), the modulation of LC phenotype and function (IL-1, GM-CSF, TNF-α, IL-10, IL-15), T-cell activation (IL-15, IL-18),[94,95] T-cell inhibition (IL-10, TGF-β),[96] and skewing of the lymphocytic response in either the type 1 (IL-12, IL-18),[97] type 2 (thymic stromal lymphopoietin),[98] or Th17 (IL-23) direction.[99] In some cases, keratinocytes may also play a role in amplifying inflammatory signals in the epidermis originating from numerically minor epidermal cell subsets. One prominent example is the induction of proinflammatory cytokines such as TNF-α in keratinocytes by LC-derived IL-1β in the initiation phase of allergic contact dermatitis.[100] In the presence of a robust stimulus, keratinocyte-derived cytokines may be released into the circulation in quantities that cause systemic effects. During a severe sunburn reaction, for example, serum levels of IL-1, IL-6, and TNF-α are clearly elevated and probably responsible for the systemic manifestations of this reaction, such as fever, leukocytosis, and the production of acute-phase proteins.[101] There is also evidence that the ultraviolet (UV) radiation-inducible cytokines IL-6 and IL-10 can induce the production of autoantibodies and thus be involved in the exacerbation of autoimmune diseases such as lupus erythematosus. The fact that secreted products of keratinocytes can reach the circulation could conceivably also be used for therapeutic purposes. The demonstration by Fenjves et al[102] that grafting of apolipoprotein E gene-transfected human keratinocytes onto mice results in the detection of apolipoprotein E in the circulation of the mouse supports the feasibility of such an approach.

Some of the innate functions of keratinocytes can be elicited by TLR activation, since keratinocytes express TLRs 1–6 and 9. Thus, by sensing microbial pathogens via TLRs, keratinocytes may act as first-responders in cutaneous innate immunity. Activation of TLRs leads to keratinocyte production of proinflammatory cytokines (including TNF-α and IL-8), antimicrobial peptides (HBD-2 and HBD-3), and reactive oxygen mediators (iNOS).[103–105] Activation of TLR3 and TLR9 on keratinocytes induces production of type I interferon (IFN-α/β), which may be important in promoting antiviral immune responses.[105] Lastly, these TLR-mediated responses can be enhanced via danger signals such as toxins, irritants, UV light, purines generated during an infection (P2×7 receptor activation), and activation of other pattern-recognition receptors (NOD1 and NOD2), which all promote inflammasome-mediated activation of caspase-1 that results in cleavage of pro-IL-1β into its active form.[106]

Another important function of keratinocytes is the production/secretion of factors governing the influx and efflux of leukocytes into and out of the skin. Two good examples are the chemokines thymus and activation-regulated chemokine (TARC; CC chemokine ligand 17, or CCL17) and cutaneous T cell-attracting chemokine (CTACK)/CCL27 and their corresponding receptors CCR4 and CCR10, selectively expressed on skin-homing T lymphocytes. Blocking of both chemokines drastically inhibits the migration of T cells to the skin in a murine model of contact hypersensitivity (CHS).[107] KC-derived macrophage inflammatory protein 3α (MIP-3α)/CCL20 also plays an important role in leukocyte recruitment to the epidermis. Its secretion is triggered or enhanced by IL-17 and its counterreceptor CCR6 is present on LC precursors and certain T cells.[108–110] The T17 cytokines, IL-17, IL-21, and IL-22 also modulate other keratinocyte innate immune functions. For example, IL-17 and IL-22 promote keratinocyte production of antimicrobial peptides, including HBD-2, cathelicidin, and psoriasin.[111,112] In addition, IL-21 and IL-22 induce keratinocyte proliferation, leading to epidermal hyperplasia and acanthosis as seen in psoriasis.[113,114]

The demonstration of cytokine receptors on and cytokine responsiveness of keratinocytes established that the functional properties of these cells can be subject to regulation by cells of the immune system. As a consequence, keratinocytes express, or are induced to express, immunologically relevant surface moieties that can be targeted by leukocytes for stimulatory or inhibitory signal transduction.

In addition to cytokines, keratinocytes secrete other factors such as neuropeptides, eicosanoids, and reactive oxygen species. These mediators have potent inflammatory and immunomodulatory properties and play an important role in the pathogenesis of cutaneous inflammatory and infectious diseases as well as in aging.

Keratinocytes synthesize complement and related receptors including the C3b receptor [complement receptor 1 (CR1), CD35], the Epstein-Barr virus receptor CR2 (C3d receptor, CD21), the C5a receptor (CD88), the membrane cofactor protein (CD46), the decay-accelerating factor (CD55), and complement protectin (CD59). CD59 may protect keratinocytes from attack by complement. Its engagement by CD2 stimulates the

secretion of proinflammatory cytokines from keratinocytes. Membrane cofactor (CD46) is reported to be a receptor for M protein of group A *Streptococci* and for measles virus.[115] Its ligation induces proinflammatory cytokines in keratinocytes such as IL-1α, IL-6, and GM-CSF.

ADAPTIVE IMMUNE RESPONSE

The strength and the type of the innate response determines both the quantity and quality of an adaptive response initiated by dendritic APCs in the epidermis (LCs) and dermis (dermal DCs or DDCs) and executed by T lymphocytes and antibodies.

LYMPHOCYTES

Three subsets of lymphocytes exist in the human immune system: B cells, T cells, and NK cells (see Section "Cells of the Innate Immune System"). The adaptive immune response is mediated by T and B lymphocytes. The unique role of these cells is the ability to recognize antigenic specificities in all their diversity. All lymphocytes derive from a common bone marrow stem cell. This finding has been exploited in various clinical settings, with attempts to restore the entire lymphocyte pool by bone marrow or stem cell transplantation.

B CELLS. B cells mature in the fetal liver and adult bone marrow. They produce antibody-protein complexes that bind specifically to particular molecules defined as antigens. As a consequence of recombinatorial events in different Ig gene segments (V or variable; D or diversity; J or joining), each B cell produces a different antibody molecule (eFig. 10-3.1 in online edition). Some of this antibody is present on the surface of the B cell, conferring the unique ability of that B cell to recognize a specific antigen. B cells then differentiate into plasma cells, the actual antibody-producing and -secreting cells. Plasma-cell secreted Ig comprise the dimer IgA, the monomers IgD, IgE, and IgG as well as the pentamer IgM that mediate humoral immune responses. In general, antibodies bind to microbial agents and neutralize them or facilitate uptake of the pathogen by phagocytes that destroy them. Briefly, IgA can be found in mucosal tissues, saliva, tears, or breast milk and prevents colonization by various pathogens. IgD functions mainly as an antigen receptor on B cells and, as recently discovered, activates mast cells and basophils to produce antimicrobial factors.[116] IgE binds to allergens on mast cells and basophils and can thereby trigger histamine release and allergic reactions including anaphylaxis and urticaria. In addition, some evidence exists that it can protect against parasitic and helminthic infections. IgG provides the majority of antibody responses that contribute to the immune defense against extracellular pathogens. It is the only antibody that is capable of crossing the placenta in order to protect the fetus. Finally, IgM is available either surface-bound on B cells or as secreted form and eliminates microbes in the early stages of humoral immunity before there is sufficient IgG production. Antibodies are also responsible for mediating certain pathologic conditions in skin. In particular, antibodies against self-antigens (mostly IgG, but also IgA) lead to autoimmune disease, typified in the pathogenesis of pemphigus and bullous pemphigoid (see Chapter 37 for more details about B cells and antibody production).

T CELLS. T cells mature in the thymus, where they are selected to live or to die. Those T cells that will have the capacity to recognize foreign antigens are positively selected and can enter the circulation. Those T cells that react to self are negatively selected and destroyed. T cells have the unique ability to direct other cells of the immune system. They do this, in part, by releasing cytokines. For example, T cells contribute to cell-mediated immunity (CMI), required to eliminate intracellular pathogens, by releasing cytokines that activate macrophages and other T cells. T cells release cytokines that activate NK cells and permit the growth, differentiation, and activation of B cells.

T cells can be classified and subdivided in different ways: (1) on the basis of the T cell receptor; (2) on the basis of the accessory molecules CD4 and CD8; (3) on the basis of their virginity, i.e., their activation status (naive, memory, effector T cells); and (4) on the basis of their functional role in the immune response, which is often linked to the cytokine secretion property of the respective cell population. We have used the abbreviations Th1 and Th2 to distinguish $CD4^+$ helper T cell subtypes but, as discussed below, many of the functional attributes, including cytokine production, of Th cells are not as clearly defined as previously thought and some cytokine profiles are also attributable to $CD8^+$ cytotoxic T cells (Tc) (see Section "Functionality").

T-Cell Antigen Receptor (TCR). The T-cell antigen receptor (TCR) is a complex of molecules consisting of an antigen-binding heterodimer (α/β or γ/δ chains) that is noncovalently linked with five CD3 subunits [(1) γ, (2) δ, (3) ε, (4) ζ, or (5) η). The TCR chains have amino acid sequence homology with structural similarities to Ig heavy and light chains. The genes encoding TCR molecules are encoded as clusters of gene segments (V, J, D, C, or constant) that rearrange during T-cell maturation (eFig. 10-3.1 in online edition). Together with the addition of nucleotides at the junction of rearranged gene segments, this recombinatorial process, which involves the enzymes recombinase activating gene 1 and 2, results in a heterogeneity and diversity of the antigen recognition unit that is broad enough to allow for a successful host defense. TCR α/β or TCR γ/δ molecules must be paired with CD3 molecules to be inserted into the T-cell surface membrane[117] (see Fig. 10-4). The TCR chains form the actual antigen-binding unit, whereas the CD3 complex mediates signal transduction, which results in either productive activation or nonproductive silencing of the T lymphocyte. Most T cells express α/β TCRs, which typically bind antigenic peptides presented by MHC molecules. Immunity provided by α/β T cells includes Th1, Th2, Th17 and T reg responses (see Section "Functionality").

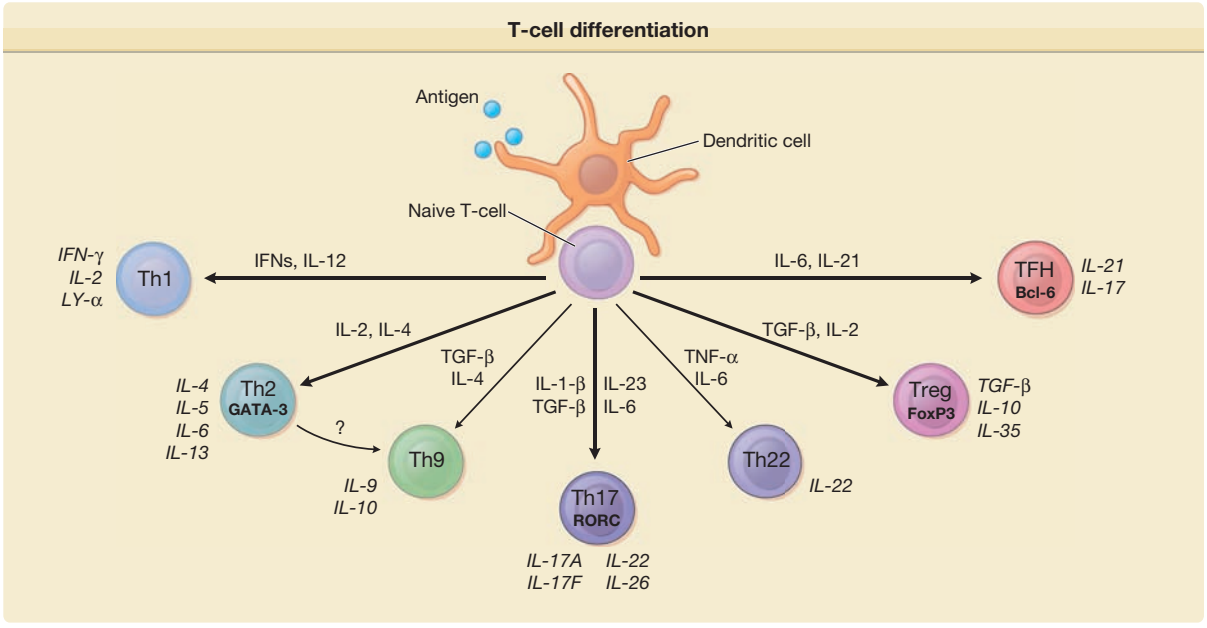

Figure 10-4 Schematic view of events governing and occurring in T-cell differentiation. Depending on the type and activation status of the antigen-presenting dendritic cells (DCs) and on the type and amounts of cytokines secreted by these and/or other cells, naive T cells will expand and differentiate into various directions, i.e., Th1 cells, Th2 cells, Th9 cells, Th17 cells, Th22 cells, T reg cells, and Tfh cells. They exhibit different types of transcription factors (e.g., T-bet, GATA-3, RORC, FoxP3, Bcl-6) and secrete different types of cytokines.

In contrast, only a small subset of T cells express γ/δ TCRs. These T cells have the capacity to directly bind pathogen-derived glycoproteins or nonclassical MHC molecules. It has been shown that γ/δ T cells in men and mice predominantly display a tissue-associated TCR repertoire as well as a memory phenotype, both probably due to chronical stimulation by nonpeptide antigens within the tissue. Importantly, they act early during immune response and are therefore termed "innate-like effectors." Previous studies conducted in mice infected with *Listeria monocytogenes* or *Nippostrongylus brasiliensis* revealed that $\tilde{\gamma}/\delta$ T cells discriminate early between these pathogens and react by IFN-γ versus IL-4 production, skewing $\tilde{\alpha}/\beta$ T-cell responses in a Th1 or Th2 direction, respectively.[118] Meanwhile, growing evidence exists that human and murine $\tilde{\gamma}/\delta$ T cells also have the capacity to produce IL-17 during bacterial or viral infections and thereby significantly contribute to the early innate immune defense.[119–121]

CD4⁺ Helper T Cells. The original observation that CD4⁺ T cells are critical for helping B cells to produce antibodies by triggering their differentiation into plasma cells in the humoral response coined the term "T helper cells" (Th cells). During the past years these lymphocytes have been characterized extensively. To our current knowledge, CD4⁺ T cells represent a heterogeneous cell population with diverse function depending on environmental requirements that play a central role in humoral and cell-mediated immunity. Effector CD4⁺ T cells protect against pathogens mainly by their production of Th1, Th2, or Th17 cytokines (i.e., IFN-γ, IL-4, IL-17) and influence immune responses through both "helper" and "effector" functions. In contrast, regulatory CD4⁺ T cells have the capacity to downregulate disproportionate effector responses to (self-) antigen (see Section "Functionality").

CD8⁺ Cytotoxic T Cells. In responding to an intracellular pathogen (e.g., a virus) the T cell must lyse the infected cell. To do so, it must be able to recognize and respond to antigenic peptides encoded by this pathogen and displayed on the cell surface. For this to occur, antigens arising in the cytosol are cleaved into small peptides by a complex of proteases, called the *proteasome*. The peptide fragments are then transported from the cytosol into the lumen of the endoplasmic reticulum, where they associate with MHC class I molecules. These peptide–class I complexes are exported to the Golgi apparatus and then to the cell surface (see Section "General Principles of Antigen Presentation"). The maturation of a CD8⁺ T cell to a killer T cell requires not only the display of the antigenic signal but also the delivery of helper signals from CD4⁺ T cells, for which the functional interaction between CD40 on the APC and CD40L on the CD8⁺ T cell can substitute.

VIRGINITY

Naive T Cells. After positive selection in the thymus, mature T cells with low affinity for self-peptide/MHC molecules are released into the blood stream and form the long-lived pool of naive T cells. In order to survive, naive T cells require IL-7 signaling and a low level of self-reactivity entertained by constant TCR engagement with self-p/MHC molecules.[145]

Functionality. With regard to the functional capacities of various T-cell subsets, it was originally assumed that $CD4^+$ cells predominantly subserve helper functions and that $CD8^+$ cells act as killer cells. Many exceptions to this rule are now known to exist; for example, both $CD4^+$ and $CD8^+$ regulatory cells are found, but $CD4^+$ cells are still commonly referred to as helper T cells (Th cells) and $CD8^+$ cells as cytotoxic T cells (Tc cells).

During an immune response, naive Th/Tc cells can differentiate into several functional classes of cells: (1) Th1 cells (type 1 T cells); (2) Th2 cells (type 2 T cells); (3) Th17 cells; (4) natural killer T cells (NKT); (5) regulatory T cells (T reg); and (6) T follicular helper (Tfh) cells (Fig. 10-4). Originally, all these T-cell subsets have mainly been defined as $CD4^+$ Th cells. In the meantime we have learned that both $CD4^+$ Th and $CD8^+$ Tc cells can produce cytokines allowing their classification into these distinct T-cell subsets. The functional commitment of effector T-cell populations is controlled by the expression of lineage-specific transcription factors, but individual T cells can also express cytokines that are not lineage-specific. It therefore remains to be determined whether T cells display heterogeneity within a lineage or whether each distinct cytokine-expression pattern already reflects a separate lineage. It seems that T cells, although already polarized, still possess a high degree of functional plasticity that allows further differentiation depending on various factors such as the strength of antigenic signaling, cytokines, or interactions with other cells encountered in their microenvironment.[155]

T HELPER 1/T HELPER 2 PARADIGM. T cells that produce IL-2, IFN-γ, and TNF are termed *Th1 cells*. They are the main carriers of cell-mediated immunity (CMI). Other T cells produce IL-4, IL-5, IL-6, IL-13, and IL-15. These are termed *Th2 cells* and are primarily responsible for extracellular immunity (see below).[160,161] Many factors influence whether an uncommitted T cell develops into a mature Th1 or Th2 cell. The cytokines IL-12 and IL-4, acting through signal transducer and activator of transcription (STAT) 4 and 6, respectively, are key determinants of the outcome, as are antigen dose, level of costimulation, and genetic modifiers. Certain transcription factors have causal roles in the gene-expression programs of Th1 and Th2 cells. For example, the T-box transcription factor T-bet is centrally involved in Th1 development, inducing both transcriptional competence of the IFN-γ locus and selective responsiveness to the growth factor IL-12.[162] By contrast, the zinc-finger transcription factor GATA-3 seems to be crucial for inducing certain key attributes of Th2 cells, such as the transcriptional competence of the Th2 cytokine cluster, which includes the genes encoding IL-4, IL-5, and IL-13.[163,164]

In murine models of intracellular infection, resistant versus susceptible immune responses appear to be regulated by these two T-cell subpopulations.[165–167] Th1 cells, primarily by the release of IFN-γ, activate macrophages to kill or inhibit the growth of the pathogen and trigger cytotoxic T-cell responses, which results in mild or self-curing disease. In contrast, Th2 cells facilitate humoral responses and inhibit some cell-mediated immune responses, which results in progressive infection. These cytokine patterns are cross-regulatory. The Th1 cytokine IFN-γ downregulates Th2 responses. The Th2 cytokines IL-4 and IL-10 downregulate both Th1 responses and macrophage function. The result is that the host responds in an efficient manner to a given pathogen by making either a Th1 or Th2 response. Sometimes, the host chooses an inappropriate cytokine pattern, which results in clinical disease.

Of particular interest to immunologists is the delineation of factors that influence the T-cell cytokine pattern. The innate immune response is one important factor involved in determining the type of T-cell cytokine response.

The ability of the innate immune response to induce the development of a Th1 response is mediated by release of IL-12, a 70-kDa heterodimeric protein.[168] For example, in response to various pathogens, APCs including DCs and macrophages release IL-12, which acts on NK cells to release IFN-γ. The presence of IL-12, IL-2, and IFN-γ, with the relative lack of IL-4, facilitates Th1 responses. In contrast, in response to allergens or extracellular pathogens, mast cells or basophils release IL-4, which in the absence of IFN-γ leads to differentiation of T cells along the Th2 pathway. It is intriguing to speculate that keratinocytes may also influence the nature of the T-cell cytokine response. Keratinocytes can produce IL-10, particularly after exposure to UVB radiation.[96] The released IL-10 can specifically downregulate T1 responses, thus facilitating the development of Th2 responses.

Th17 CELLS.[169] Not every T-cell-mediated immune response and/or disease can be easily explained by the T1/T2 paradigm. Certain T-cell subpopulations are characterized by the secretion of IL-17. These cells are therefore termed *Th17 cells*. It was originally assumed that Th1 and Th17 cells arise from a common T1 precursor, but it now appears that Th17 cells are a completely separate and early lineage of effector $CD4^+$ T cells produced directly from naive $CD4^+$ T cells. This was proven by the identification of the Th17-specific transcription factor ROR (RAR-related orphan nuclear receptor) that regulates the expression of IL-17, IL-23R, and CCR6 in Th17 cells.[170] The expression of CCR6 is unique for Th17 cells amongst T cells and regulates their migration into epithelial sites depending on its ligand CCL20.[171] Recently, it has been demonstrated that Th17 cells may originate from a small subset of $CD4^+$ T cells bearing the NK-cell-associated *C*-type lectin NKP-1A (CD161), which are present in cord blood and newborn thymus.[172] Differentiation of human Th17 cells strongly depends on IL-23, a member of the IL-12 family, as well as on IL-1β, IL-6, and low doses of TGF-β[173,174]; murine Th17-lineage commitment is mainly induced by IL-6 and TGF-β. Importantly, the induction of Th17 cells from naive precursors may be inhibited by IFN-γ and IL-4, using a cross-regulatory mechanism between Th1, Th2, and Th17 cells. One of the main physiological roles of Th17 cells is to promote protection against fungi, protozoa, viruses, and various extracellular bacteria, but Th17 cells have also been

linked to a growing list of autoimmune and inflammatory diseases such as neuroinflammatory disorders, asthma, lupus erythematosus, rheumatoid arthritis, Crohn's disease and, most notably, psoriasis.[99,175] Very recent evidence exists that Th17 cells might also play a role in antitumor immunity.[176] Importantly, IL-17 expression is not restricted to $CD4^+$ cells only, but has also been detected in $CD8^+$ T cells.[177] Th17 cells exert their function by producing effector cytokines including IL-17A, IL-17F, IL-22, and IL-26. Whereas IL-17 is believed to contribute to the pathogenesis of these diseases by acting as potent proinflammatory mediator, IL-22 has been described as a multifunctional cytokine with inflammatory as well as protective properties. In vitro stimulation of normal keratinocytes with IL-22, for example, results in inhibition of keratinocyte differentiation followed by epidermal hyperplasia and upregulated expression of proinflammatory genes in these cells.[178]

REGULATORY T CELLS. An important type of immunomodulatory T cells that controls immune responses are the so-called *regulatory T cells (T reg cells)*, formerly known as *T suppressor cells*.[181] T reg cells are induced by immature APCs/DCs and play key roles in maintaining tolerance to self-antigens in the periphery. Loss of T reg cells is the cause of organ-specific autoimmunity in mice that results in thyroiditis, adrenalitis, oophoritis/orchitis, etc. T reg cells are also critical for controlling the magnitude and duration of immune responses to microbes. Under normal circumstances, the initial antimicrobial immune response results in the elimination of the pathogenic microorganism and is then followed by an activation of T reg cells to suppress the antimicrobial response and prevent host injury. Some microorganisms (e.g., *Leishmania* parasites, mycobacteria) have developed the capacity to induce an immune reaction in which the T reg component dominates the effector response. This situation prevents elimination of the microbe and results in chronic infection.

The best-characterized T reg subset is the $CD4^+$/$CD25^+$/CTLA-4^+/$GITR^+$ (glucocorticoid-induced TNF receptor family-related gene)/$FoxP3^+$ lymphocytes.[182] The transcription factor FoxP3 is specifically linked to the suppressor function, as evidenced by the findings that mutations in the *FoxP3* gene cause the fatal autoimmune and inflammatory disorder of scurfy in mice and IPEX (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) in humans. The cytokines TGF-β and IL-10 are thought to be the main mediators of suppression.

During the past years the situation has become even more complicated, because, at least under certain conditions, subsets with different phenotypes have been associated with regulatory functions such as $CD4^+$, $CD8^+$, and NKT cells. Accordingly, the existence of T reg cells coexpressing IL-17 and FoxP3 has been described.[183] $CD8^+$ cells can also be activated to become suppressor cells by antigenic peptides that are presented in the context of an MHC class Ib molecule [Qa1 in mice; human leukocyte antigen E (HLA-E) in humans]. $CD8^+$ T reg cells suppress T cells that have intermediate affinity for self or foreign antigens and are primarily involved in self–nonself discrimination. In addition, recent data provides evidence for a suppressive function of human FoxP3-, TGf-β-producing γ/δ T cells.[184]

T FOLLICULAR HELPER (Tfh) CELLS. Tfh cells represent a distinct subset of $CD4^+$ T cells found in limited numbers, especially in B-cell areas of lymph nodes and spleen.

Homing and long-term residency in B-cell follicles of these newly described T cells is secured by their surface expression of CXCR5. They have a crucial role in orchestrating T-cell-dependent effector and memory B-cell responses, produce IL-21 and express inducible T-cell costimulator (ICOS) and programed cell death 1 (PD-1) as costimulatory and coinhibitory molecules, respectively. Specific differentiation of Tfh cells was associated to the transcription factor Bcl6 as well as to the cytokines IL-6 and IL-21.[185–187]

LYMPHOCYTES IN NORMAL AND DISEASED SKIN. As opposed to normal mouse skin, in which a resident population of dendritic epidermal T cells uniformly equipped with a nonpolymorphic, canonical $\tilde{\gamma}\delta$ TCR exists, the lymphocytes of normal human skin are mainly located in the dermis and predominantly express the $\tilde{\alpha}\beta$ TCR rather than the γ/δ TCR. While the majority of epidermal T cells exhibit the $CD8^+$/$CD4^-$ phenotype, dermal T cells are mainly $CD4^+$/$CD8^-$, belong to the CD45RO memory population, express the addressins CLA (cutaneous lymphocyte antigen) and CCR4 which they use for skin-homing purposes,[188] and are largely devoid of CCR7 and L-selectin, i.e., addressins promoting the homing of lymphocytes to the lymphoid organs.[152,189] This situation is true also for homeostatic conditions which means that a cutaneous pool of effector memory cells is already in place when danger is imminent. Some of these effector memory T cells have a rather long life span and have been found in different skin conditions, for example, at sites of HSV infection of mice [190,191] and men[192] as well as in clinically resolved, hyperpigmented fixed drug eruptions.[193]

Normal human skin contains approximately 1 million T cells per cm^2, 2%–3% of which reside within the epidermis,[194] primarily in the basal and suprabasal layers. The T cells of the dermis are preferentially clustered around postcapillary venules of the superficial plexus high in the papillary dermis and are often situated just beneath the dermal–epidermal junction and within, or in close proximity to, adnexal appendages such as hair follicles and eccrine sweat ducts.

The process of T-cell trafficking to the skin is guided by a series of receptor–ligand interactions between cells. It is of note that DCs are capable of imprinting homing receptor expression on T cells,[195] which means that T cells programed by skin and/or skin-derived DCs will preferentially return to the skin. One such moiety is the glycoprotein cutaneous lymphocyte antigen (CLA) that defines a subset of memory T cells that home to skin. It is a glycosylated form of P-selectin–glycoprotein ligand 1 that is expressed constitutively

on all human peripheral blood T cells. The level of CLA on cells is regulated by an enzyme, α (1,3)-fucosyltransferase VII, which modifies P-selectin glycoprotein ligand 1. In this manner, CLA+ cells bind to both E-selectin and P-selectin, whereas CLA^- cells bind P-selectin, but not E-selectin.[196,197] The chemokine–chemokine receptor system is the other major regulator and coordinator of leukocyte migration to the skin (see Chapter 12).

SKIN HOMING OF MEMORY T CELLS. Of particular importance for skin homing of memory T cells, independent of their polarization, is the interaction of CCL17 and CCL22 with CCR4 and of CCL27 with its counterreceptor CCR10 on CLA+ T cells. CCL17 is synthesized by activated keratinocytes, DCs and endothelial cells of the skin, while CCL22 is mainly of macrophage and DC origin. The CCR10 ligand, CCR27, appears to be exclusively produced by epidermal keratinocytes.[198] Although it was originally assumed that functionally different T-cell subsets can be distinguished from each other by their chemokine receptor expression pattern and their responsiveness to the respective chemokines, the situation is less clear now. Reportedly, T1 cells selectively bear CXCR3 and CCR5, T2 cells preferentially exhibit CCR8 and CCR3, and T17 as well as T reg express CCR6, allowing them to respond to the keratinocyte- and endothelial cell-derived chemokine CCL20.[199,200]

From all that has been said so far, one can surmise that the accumulation of T cells in skin is not stochastic. This is indeed the case as exemplified by the dominance of $CD8^+$ T cells in skin lesions, but not in the peripheral blood of patients with lepromatous leprosy[201] as well as by the clonality of the T-cell population in cutaneous T-cell lymphoma, in which a single V gene usage is found to predominate in different skin lesions from the same individual.[202,203] A limited TCR V gene usage has also been reported to be present in skin lesions of leprosy,[204] psoriasis,[205] basal cell carcinoma, and countless other reactions in which T cells are present.

The most direct indication of relevant T-cell populations in skin is determination of the number of antigen-specific T cells. It has been documented that 1 in 1,000 to 1 in 10,000 T cells in the peripheral blood, but only 1 in 50 to 1 in 100 T cells recognize the antigen causing the disease at sites of inflammation.[206,207] Thus, there is as much as a 100-fold enrichment of antigen-reactive T cells at the site of cutaneous inflammation.

With regard to survival and/or expansion of T cells of human skin/epidermis, it appears that IL-2, IL-7, and IL-15 play important roles.[208] Notably, the latter two T-cell growth factors can be produced by human epidermal cells, and all of them are frequently overexpressed in T cell-rich skin lesions, for example, in patients with tuberculoid leprosy. For a long period of time, the Th1/Th2 paradigm was used to explain the pathogenesis and, more often, the course of infectious, inflammatory and, even, neoplastic skin diseases. Leprosy and leishmaniasis are outstanding examples of diseases in which the clinical manifestations are decisively determined by the dominance of either Th1 or Th2 cells. With the identification of new function-based T-cell subpopulations (e.g., T0 cells, Th17 cells, Th22 cells), this classification is too rigid and no longer tenable. In fact, we come to realize that the T-cell pathogenesis of certain diseases that we had originally considered to belong into either the Th1 (e.g., psoriasis, allergic contact dermatitis) or the Th2 world (atopic dermatitis) is very complex and sometimes even stage-specific. Th17 and/or Th22 cells are apparently major players in psoriasis[158] and allergic contact dermatitis.[177] In atopic dermatitis, the acute lesions harbor not only Th2, but also Th17 and Th22 cells; in the chronic stage, however, Th1 cells seem to predominate. In syphilis, perhaps not only Th1 cells, but also $CD8^+$IFN-γ-producing Th17 cells do confer immunologic resistance to T. pallidum.[209,210] Th17 cells may also be important in the pathogenesis of *Borrelia burgdorferi*-induced Lyme arthritis, which was long attributed to be a solely Th1 cell-mediated response.[211,212] In patients with cutaneous T cell lymphoma (CTCL), Th2 responses dominate the inflammatory infiltrate of the skin, especially at late stages.[213] In early lesions, however, infiltrating $CD3^+CD45RO^+CLA^+CCR4^+$ T cells also express IFN-γ and IL-17 (see Chapter 145). In basal cell carcinomas the presence of a Th2-dominated environment with an increased expression of IL-4 and IL-10 as well as tumor-surrounding T reg cells may be responsible for tumor growth[214] (see Chapter 115). In alopecia areata, recent data suggest a role for Th1 cells.[215]

ANTIGEN PRESENTING CELLS

While lymphocytes are the only cells capable of recognizing antigenic moieties, the recognition process per se, at least as far as T cells are concerned, is dependent on the presence of antigen-presenting cells (APC). Unlike B cells, T cells cannot recognize soluble protein antigen per se; their antigen receptor (TCR) is designed to recognize antigen-derived peptides bound to MHC locus-encoded molecules expressed by APCs. Most $CD8^+$ T cells, destined to become cytotoxic T cells, recognize the endogenous antigen in association with MHC class I molecules.[216] Because most nucleated cells transcribe and express MHC class I genes and gene products, it is evident that many cell types can serve as APCs for MHC class I-restricted antigen presentation and/or as targets for MHC class I-dependent attack by T cells. For the antigen-specific activation of $CD4^+$ T cells, exogenous antigen-derived peptides are usually presented in the context of MHC class II molecules.[216] In this situation, peptides are generated in the endocytic, endosomal/lysosomal pathway and are bound to MHC class II molecules. The resulting MHC-peptide complex is expressed at the APC surface for encounter by the TCR of $CD4^+$ T cells. In the MHC class II-dependent antigen presentation pathway, dendritic cells (DCs), including Langerhans cells (LCs) and dermal dendritic cells (DDCs), B cells, and activated monocytes/macrophages are the major APC populations. Among these, DCs act as professional APC, i.e., are capable of migration and stimulating antigen-specific responses in naive, resting T cells.

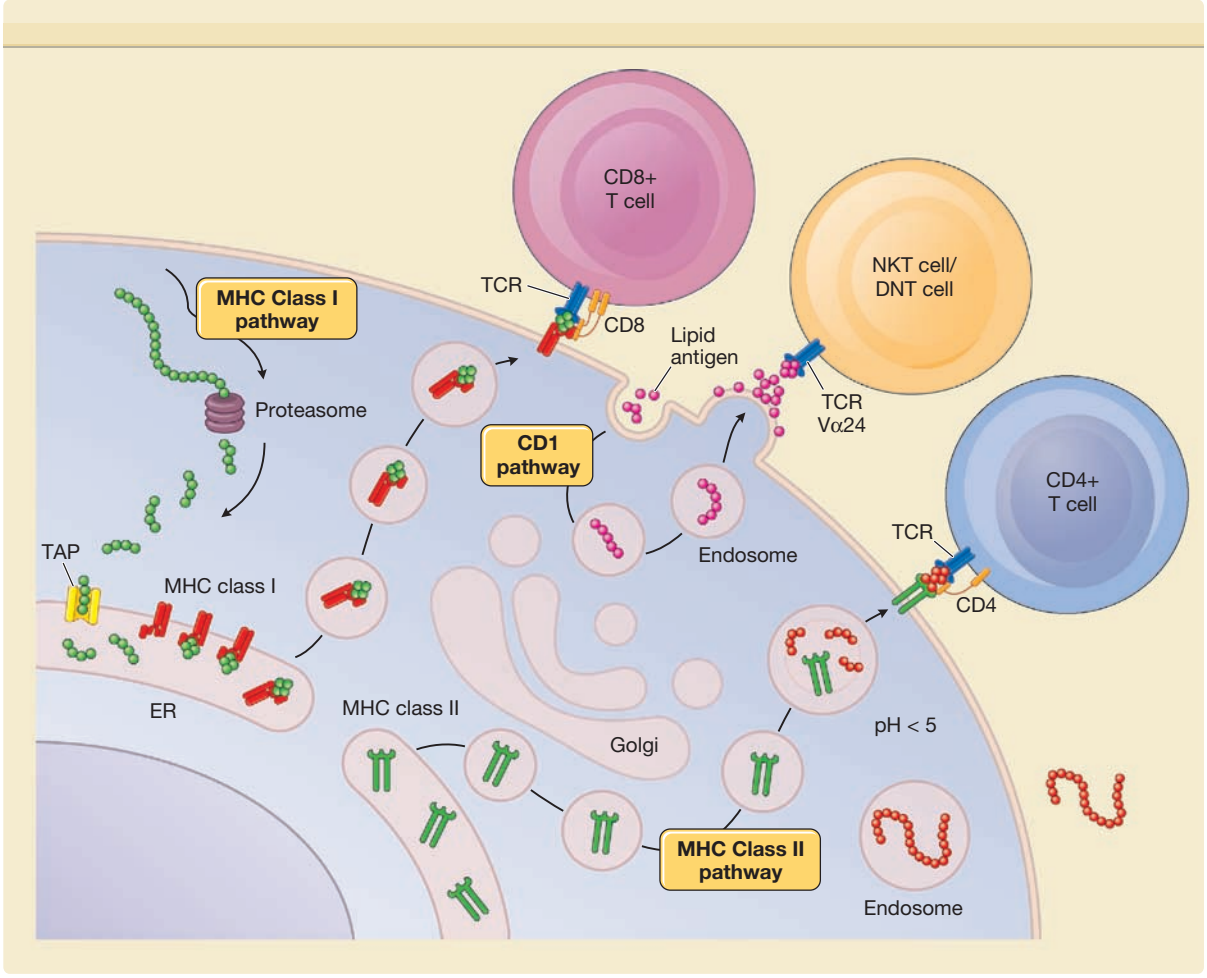

Figure 10-5 Antigen-processing pathways. The intracellular antigen-processing pathways for major histocompatibility complex (MHC) class I, MHC class II, and CD1 presentation are shown. The MHC class I pathway involves the processing of cytoplasmic proteins, whereas the MHC class II pathway involves the processing of exogenous proteins. The CD1 pathway regulates the processing and presentation of self-glycosphingolipids and bacterial lipoglycans. DN T cell = double-negative ($CD4^-/CD8^-$) T cell; ER = endoplasmic reticulum; MIIC = MHC class II lysosomal peptide-loading compartment; NKT cell = natural killer T cell; TAP = transporter associated with antigen processing; TCR = T-cell receptor.

GENERAL PRINCIPLES OF ANTIGEN PRESENTATION. (Fig. 10-5)

Major Histocompatibility Complex Class I-Restricted Antigen Presentation: Classic Pathway.[217,218] Immediately after their biosynthesis, MHC class I heavy and light (β_2-microglobulin) chains are inserted into the membranes of the endoplasmic reticulum. The third subunit of the functional MHC class I complex is the peptide itself. The major sources of peptides for MHC class I loading are cytosolic proteins, which can be targeted for their rapid destruction through the catalytic attachment of ubiquitin. These cytosolic proteins can be self-proteins, viral particles, or neoantigens (altered self-proteins). Cytosolic proteinaceous material undergoes enzymatic digestion by the proteasome to yield short peptide chains of 8–12 amino acids, an appropriate length for MHC class I binding. In its basic conformation, the proteasome is a constitutively active "factory" for self-peptides. IFN-γ, by replacing or adding certain proteasomal subunits, induces "immunoproteasomes," presumably to fine-tune the degradation activity and specificity to the demands of the immune response. The processed peptides are translocated to the endoplasmic reticulum by the transporter associated with antigen processing (TAP), an MHC-encoded dimeric peptide transporter. With the aid of chaperons (calnexin, calreticulin, tapasin), MHC class I molecules are loaded with peptides, released from the endoplasmic reticulum, and transported to the cell surface. Several infectious agents with relevance to skin biology have adopted strategies to subvert MHC class I presentation, and thus the surveillance of cell integrity, by interfering with defined molecular targets. Important examples of such interference are the inhibition of proteasomal function by the Epstein–Barr virus-encoded EBNA-1 protein, the competition for peptide–TAP interactions by a herpes

simplex virus protein, and the retention or destruction of MHC class I molecules by adenovirus- and human cytomegalovirus-encoded products.

Alternative Pathway (Cross-Presentation). Under certain conditions, exogenous antigen can reach the MHC class I presentation pathway. Significant evidence for this cross-presentation first came from in vivo experiments in mice demonstrating that viral, tumor, and MHC antigens can be transferred from MHC-mismatched donor cells to host bone marrow-derived APCs to elicit antigen-specific cytotoxic T-cell responses that are restricted to self-MHC molecules.[219] In vitro studies have defined that exosomes (i.e., small secretory vesicles of approximately 100 nm in diameter secreted by various cell types, including tumor cells), heat shock proteins, immune complexes, and apoptotic cells (taken up via CD36 and αvβ3 or αvβ5 integrins) can all serve as vehicles for the delivery of antigen to DCs in a manner that permits the cross-presentation of antigen. In all in vitro systems in which a direct comparison has been made, DCs, including LCs, but not monocytes/macrophages, were capable of cross-presentation.[220,221] Three distinct pathways are currently exploited by which antigen can access MHC class I molecules of DCs: (1) a recycling pathway for MHC class I in which antigen is loaded in the endosome; (2) a pathway by which retrograde transport of the antigen from the endosome to the endoplasmic reticulum facilitates entry into the classic MHC class I antigen presentation pathway; and (3) an endosome to the cytosol transport pathway, which again allows antigen processing via the classic MHC class I antigen presentation pathway.

Major Histocompatibility Complex Class II-Restricted Antigen Presentation.[216] MHC class II molecules predominantly bind peptides within endosomal/lysosomal compartments. Sampling peptides in these subcellular organelles allow class II molecules to associate with a broad array of peptides derived from proteins targeted for degradation after internalization by fluid phase or receptor-mediated endocytosis, macropinocytosis, or phagocytosis. One of the striking structural differences between MHC class I and class II molecules is the conformation of their peptide-binding grooves. Whereas MHC class I molecules have binding pockets to accommodate the charged termini of peptides and thus selectively associate with short peptides, the binding sites of MHC class II molecules are open at both ends. Thus, MHC class II molecules bind peptides with preferred lengths of 15–22 amino acids but can also associate with longer moieties. An important chaperone for MHC II molecules and responsible for the correct folding and the functional stability of MHC II molecules is the type II transmembrane glycoprotein invariant chain (Ii; CD74). Ii also prevents class II molecules from premature loading by peptides intended for binding to MHC class I molecules in the endoplasmic reticulum and participates in the sorting of MHC II toward the endocytic pathway.[222] Depending on the cell type and the activation status of a cell, the half-life of class II–peptide complexes varies from a few hours to days. It is particularly long (more than 100 hours) on DCs that have matured into potent immunostimulatory cells of lymphoid organs on encounter with an inflammatory stimulus in nonlymphoid tissues. The very long retention of class II–peptide complexes on mature DCs ensures that only the peptides generated at sites of inflammation will be displayed in lymphoid organs for T cell priming. Cytokines have long been known to regulate antigen presentation by DCs. In fact, proinflammatory (TNF-α, IL-1, IFN-γ) and anti-inflammatory (IL-10, TGF-β1) cytokines regulate presentation in MHC class II molecules in an antagonistic fashion. Mechanistically, regulatory effects include the synthesis of MHC components and proteases, and the regulation of endolysosomal acidification.[223,224]

CD1-Dependent Antigen Presentation.[225,226] Besides peptides, self-glycosphingolipids and bacterial lipoglycans may also act as T-cell-stimulatory ligands. Molecules that bind and present these moieties belong to the family of nonpolymorphic, MHC class I- and II-related CD1 proteins. CD1 molecules are structurally close to MHC class I molecules, but functionally related to MHC class II molecules. In the skin, members of the CD1 family are expressed mainly by LCs and DDCs. The CD1 isoforms CD1a, CD1b, CD1c, and CD1d sample both recycling endosomes of the early endocytic system and late endosomes and lysosomes to which lipid antigens are delivered. Unlike in the MHC class II pathway, antigen loading in the CD1 pathway occurs in a vacuolar acidification-independent fashion. T cells expressing a Vα24-containing canonic TCR, NKT cells, and $CD4^-$/$CD8^-$ T cells include the most prominent subsets of CD1-restricted T cells. CD1-restricted T cells play important roles in host defense against microbial infections. Accordingly, human subjects infected with *M. tuberculosis* showed stronger responses to CD1c-mediated presentation of a microbial lipid antigen than control subjects, and activation of CD1d-restricted NKT cells with a synthetic glycolipid antigen resulted in improved immune responses to several infectious pathogens. Thus, the CD1 pathway of antigen presentation and glycolipid-specific T cells may provide protection during bacterial and parasite infection, probably by the secretion of proinflammatory cytokines, the direct killing of infected target cells, and B cell help for Ig production.

DENDRITIC CELLS. DCs are the only APC capable of interacting with naive T cells. Depending on the DC activation status (i.e., mature versus immature), this cellular contact will result in either productive or nonproductive T-cell responses. Originally, DCs were identified in peripheral lymphoid organs in mice (lymphoid DC).[227] A few years later the presence of DC in nonlymphoid tissue (nlDC) was first demonstrated as evidenced by the expression of Fc and C3 receptors as well as MHCII antigens on epidermal LC.[228–230] This finding anchored LC as cells of the immune system.

DCs populate nearly every mammalian tissue under homeostatic (indigenous DC) and inflammatory (inflammatory DC) conditions (Fig. 10-6). Both indigenous and inflammatory DCs ultimately derive from

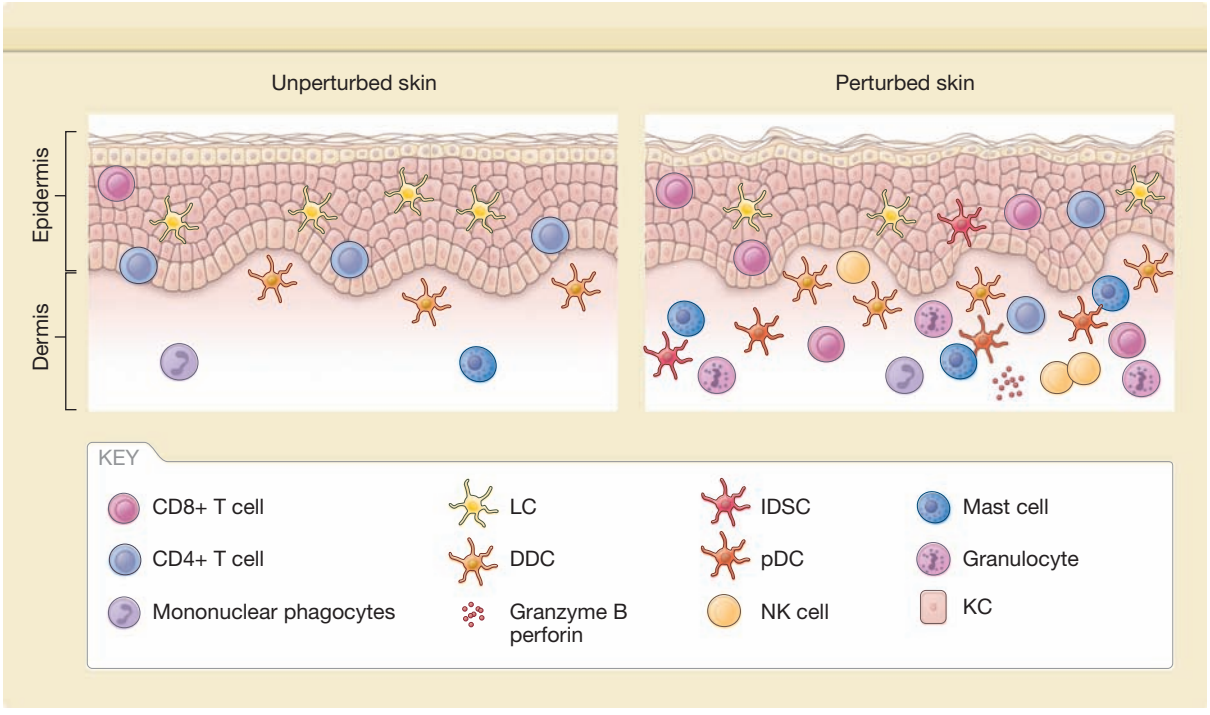

Figure 10-6 Resident and passenger leukocytes of the skin. Unperturbed skin: under homeostatic, steady-state conditions, the skin harbors only limited numbers of leukocytes. They consist mainly of dendritic cells (Langerhans cells in the epidermis and dermal dendritic cells in the dermis) and, to a lesser extent, of T cells in the epidermis (largely $CD8^+$) and dermis (largely $CD4^+$) and a few mononuclear phagocytes and mast cells. Granulocytes, NK cells, B cells, and inflammatory dendritic cells are essentially absent. Perturbed skin: upon delivery of exogenous (e.g., microorganisms, chemical irritants, ultraviolet radiation) and perhaps endogenous danger signals, resident skin cells such as keratinocytes become activated and, as a consequence, initiate an inflammatory tissue response arising mainly from circulating, but probably also resident leukocytes. KC = keratinocyte; LC = Langerhans cells; DDC = dermal dendritic cells; pDC = plasmacytoid dendritic cells; IDSC = inflammatory dendritic skin cells; NK cell = natural killer cells.

hematopoietic stem and progenitor cells (HSPC) in the bone marrow. HSPCs give rise to progenitor cells that can further differentiate into one or more DC subsets.[231,232] DC precursors can be found in multiple locations throughout the body such as the bone marrow, the thymus as well as the peripheral lymphoid organs including the blood.[233–235] These blood-derived DC precursors populate nonlymphoid tissues and organs using specific chemokine receptor–ligand pathways (e.g., CCR2-CCL2, CCR5-CCL5, CCR6-CCL20).[236–239] Upon arrival in the periphery, they either undergo a process of differentiation or maintain their density by self-renewal.[234] Inflammatory DCs are mainly mobilized into the tissues from peripheral blood precursors upon receipt of danger signals. They probably do not constitute a DC subpopulation per se, but rather represent an activated state of a given DC.

Within the periphery, differentiated DCs accumulate in extravascular areas and survey their surroundings for microbial invasion, always prepared for antigen capture. Under homeostatic conditions, the overwhelming majority of DCs are in an immature state that allows them to efficiently take up antigen (e.g., serum proteins, extracellular matrix components, dead cells) with the help of specific receptor sites (e.g., Langerin, macrophage mannose receptor, C-type lectin receptor DEC-205, low-affinity IgG receptor CD32/FcγRII, high-affinity IgE receptor FcεRI, the thrombospondin receptor CD36, DC-SIGN), but does not endow them with immunostimulatory properties for naive resting T cells. DCs apparently increase their efficacy in antigen-uptake by repetitively extending and retracting their dendrites through intercellular spaces (dSEARCH: dendrite surveillance extension and retracting cycling habitude).[240] Antigen-engulfment triggers DC maturation, which is followed by DC detachment from neighboring cells and trafficking to draining lymph nodes dependent on CCR7 signaling.[241–243]

DC trafficking from nonlymphoid to lymphoid tissues occurs, in a limited fashion, also under homeostatic conditions,[244,245] but is much more enhanced upon the delivery of danger signals. During this journey, DCs have to overcome several obstacles such as vessel walls, connective tissue, basement membranes, or other anatomical barriers. To be capable of traveling, DCs are equipped with distinct proteolytic enzymes such as matrix metalloproteinase 2 (MMP-2) and MMP-9 that lead to the degradation of extracellular matrix proteins.[246–248] Interstitial DC migration is partly controlled by tissue inhibitors of metalloproteinases (TIMPs), which inhibit MMP activity under nondanger conditions. However, upon maturation of DCs, TIMP expression is downregulated and MMPs exert their function.[249] In the LN, DCs rapidly extend their dendrites in a "probing" way thereby

establishing physical contacts with adjacent T cells, as in vivo two-photon intravital microscopy of inguinal lymph nodes of mice has revealed.[250,251] The display of MHC-peptide complexes on the DC surface delivers the "first signal" to T cells thereby starting communication, i.e., the triggering of the TCR by the APC-bound peptide-MHC complex. Upon activation, DCs display an upregulated and prolonged surface expression of MHCII as compared with nonactivated APC. Although this event may be sufficient to induce the proliferation of primed T cells, it is insufficient for the productive activation of naive T cells. The occurrence of the latter requires the receipt of "second signals," which are also delivered by professional APCs. In fact, antigen-specific T cells that encounter MHC-expressing cells that cannot deliver second signals (e.g., MHC class II-induced keratinocytes, endothelial cells, fibroblasts) enter a state of anergy.[252] Second signals, which include secreted cytokines and membrane-bound costimulatory molecules, determine the magnitude and quality of primary and secondary T-cell responses. Upon contact with the DC-derived cytokine IL-12, for example, T cells turn into type 1 IFN-γ-producing cells, whereas DC-derived IL-23 may skew T-cell responses in the type 17 direction (see Section "Functionality"). Upon danger stimuli, DCs produce a variety of additional cytokines such as IL-1β, TNF-α, TGF-β, or IL-6 that all have the potential to polarize distinct T-cell responses. Costimulatory molecules on DCs are upregulated during the process of maturation induced by surface receptors triggered by ligands secreted or presented by other somatic cells or, alternatively, by microbial products (danger signals).[253] The best-defined costimulatory molecules are the two members of the B7 family, B7.1/CD80 and B7.2/CD86. LCs/DCs in situ do not express or express only minute amounts of these costimulatory molecules, but greatly upregulate these moieties during maturation. Other costimulatory molecules include the ICAM-1 that binds to LFA-1 and LFA-3, the ligand of T cell-expressed CD2. Other important ligand–receptor pairs that positively affect T-cell activation by DCs include heat-stable antigen CD24/CD24L, CD40/CD40L, CD70/CD27L, OX40 (CD134)/OX40L, and receptor activator of nuclear factor κB (RANK)/RANKL. Another costimulatory molecule of great importance is the membrane-bound glycoprotein CD83. It is significantly upregulated during DC maturation and enhances $CD8^+$ T cell proliferation upon binding to an as yet unknown CD83 ligand on T cells whose expression is strictly dependent on CD28-mediated costimulation.[254,255]

Recent evidence suggests that DCs/LCs themselves can actively induce immune tolerance. The main mechanism to maintain immune tolerance is deletion of T cells with high affinity to self-peptide/MHC complexes in the thymus by inducing apoptosis (negative selection). Another variation of tolerance is T cell-anergy induced by contact with APC that do not provide second signals. Finally, DCs, at least in their immature state, preferentially activate T reg cells.[256] When antigen is targeted to these nonactivated DCs in vivo, antigen-specific hyporesponsiveness occurs.[257–261] This finding has therapeutic implications for the treatment of autoimmune diseases.[262]

Mechanisms responsible for the tolerance-inducing property of nonactivated DCs, although not entirely understood, include (1) a reduced expression of MHC-antigen complexes[263] and costimulatory molecules[264] on the cell surface; (2) expression of the coinhibitory receptor ligands programed cell death-ligand 1 (PD-L1/B7-H1) and, to a lesser extent, PD-L2 (B7-DC)[265–267]; (3) the secretion of immunosuppressive cytokines such as IL-10,[268] which fits well to the finding of T reg induction by UV-irradiated, IL-10-producing T reg cells[269]; (4) the expression of immunoinhibitory enzymes such as indoleamine 2,3-dioxygenase[270]; and (5) the receipt of signals interfering with the maturation and migration of DCs, for example, neuropeptides such as CGRP[271] and vasoactive intestinal peptide,[272] or the engagement of the CD47/SHPS-1 signal transduction cascade.[273,274] It appears that these different factors are not equally operative in all situations. LCs, for example, can activate self-antigen-specific CD8 T cells in the steady state, which leads to chronic skin disease,[275] and, at the same time, LCs are dispensable for[276] or can even downregulate[277] the induction of CHS.

Dendritic Cells of Normal and Diseased Skin. In essentially unperturbed normal human skin we find several APC including epidermal *Langerhans cells* (LC) and *dermal dendritic cells*[278] (DDC). LCs and DDCs are lineage-negative (Lin^-), bone marrow-derived leukocytes, which phenotypically and functionally resemble other DCs present in most, if not all, lymphoid and nonlymphoid tissues.[279] As gatekeepers of the immune system, they control the response to events perturbing tissue/skin homeostasis. In other species such as mice an additional DC subset has been described recently, namely $CD103^+CD207^+$ cells, which in humans have yet to be identified.[280–282] Healthy skin also harbors other cells which at least theoretically could subserve APC function, such as basophils and mast cells. While these cells have been shown to play a role in the modulation of cutaneous immune responses, their functions as APC remain to be defined.

Under inflammatory conditions, DC types that are not residents of the normal cutaneous environment appear in the skin. These include DCs from the plasmacytoid lineage, so-called *plasmacytoid DC* (pDCs) and *inflammatory dendritic skin cells* (IDSC), which originate from myeloid precursors and phenotypically resemble myeloid DCs (mDC) of the peripheral blood.

LANGERHANS CELLS.[283] In 1868, the medical student Paul Langerhans, driven by his interest in the anatomy of skin nerves, identified a population of dendritically shaped cells in the suprabasal regions of the epidermis after impregnating human skin with gold salts.[284] These cells, which later were found in virtually all stratified squamous epithelia of mammals, are now eponymously referred to as *Langerhans cells* (Fig. 10-7).

The expression of the Ca^{2+}-dependent lectin Langerin (CD207) is currently the single best feature discriminating LCs from other cells. Langerin is a transmembrane molecule associated with and sufficient to form Birbeck granules, the prototypic, and cell type-defining organelles of LCs (see Fig. 10-7). Birbeck granules are

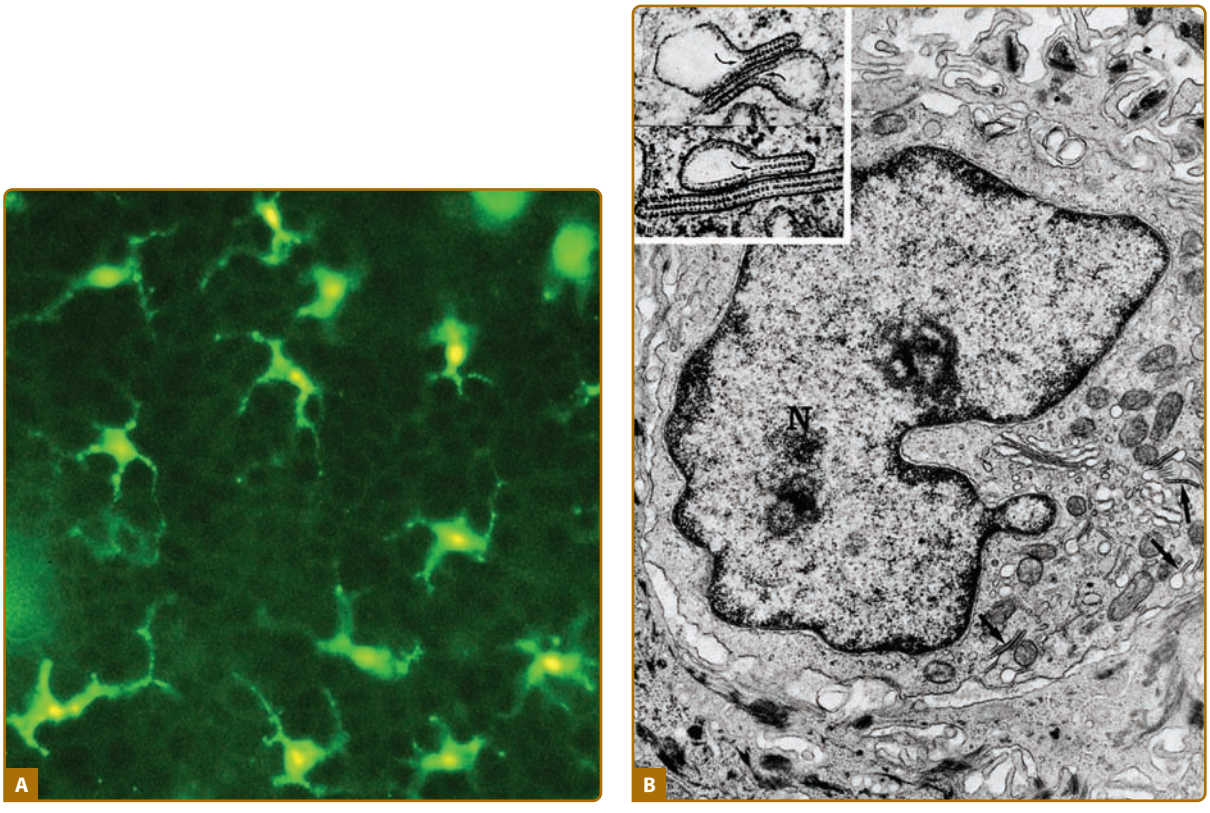

Figure 10-7 A. Langerhans cells in a sheet preparation of murine epidermis as revealed by antimajor histocompatibility complex class II (fluorescein isothiocyanate) immunostaining. **B.** Electron micrograph of a Langerhans cell in human epidermis. *Arrows* denote Birbeck granules. N = nucleus. (From Stingl G: New aspects of Langerhans cell functions. *Int J Dermatol* **19**:189, 1980, with permission.) *Inset:* High-power electron micrograph of Birbeck granules. The *curved arrows* indicate the zipper-like fusion of the fuzzy coats of the vesicular portion of the granule. The delimiting membrane envelops two sheets of particles attached to it and a central lamella composed of two linear arrays of particles. (From Wolff K: The fine structure of the Langerhans cell granule. *J Cell Biol* **35**:466, 1967, with permission.)

pentilaminar cytoplasmic structures frequently displaying a tennis racket shape at the ultrastructural level. The additional presence of Langerin on the cell surface coupled with its binding specificity for mannose suggests that Langerin is involved in the uptake of mannose-containing pathogens by LCs. However, the disruption of the Langerin gene in experimental animals does not result in a marked loss in LC functionality.[285] Additional molecules besides Langerin allow the identification of LCs within normal unperturbed epidermis. These include CD1a; the MHC class II antigens HLA-DR, HLA-DQ, and HLA-DP; and CD39, a membrane-bound, formalin-resistant, sulfhydryl-dependent adenosine triphosphatase (ATPase).

The tissue distribution of LC varies regionally in human skin. On head, face, neck, trunk, and limb skin, the LC density ranges between 600 and 1,000/mm^2. Comparatively low densities (approximately 200/mm^2) are encountered in palms, soles, anogenital and sacrococcygeal skin, and the buccal mucosa. The density of human LCs decreases with age, and LC counts in skin with chronic actinic damage are significantly lower than those in skin not exposed to UV light (Fig. 23-7). HLADR$^+$/ATPase$^+$ DCs can be identified in the human epidermis by 6–7 weeks of estimated gestational age. These cells must originate from hemopoietic progenitor cells in the yolk sac or fetal liver, the primary sites of hemopoiesis during the embryonic period. Until week 14 of estimated gestational age (EGA), these cells acquire the full phenotypic profile of LC in a stepwise fashion.[286] The relative numeric stability of LC counts during later life must be achieved by a delicate balance of LC generation and immigration into the epidermis and LC death and emigration from the epidermis. Within the epidermis, LCs are anchored to surrounding keratinocytes by E-cadherin-mediated homotypic adhesion.[287] This anchoring and the display of TGF-β1 also prevent terminal differentiation and migration, thus securing intraepidermal residence for the cells under homeostatic conditions. Two nonmutually exclusive pathways of LC repopulation of the epidermis may exist: (1) LC division within the epidermis, and (2) the differentiation of LCs from skin-resident or blood-borne precursors. Evidence for the first possibility is the demonstration of cycling/mitotic LCs in the epidermis,[288] although it remains to be established whether this cell division alone suffices for maintaining the epidermal LC population.

The observation that the half-life of LCs within unperturbed murine epidermis is around 2–3 months[289] suggests a significant turnover of the epidermal LC population even under noninflammatory conditions. In seeming contradiction stands the observation that the LC

population of human skin grafted onto a nude mouse remains rather constant for the life of the graft, despite epidermal proliferation and the absence of circulating precursors for human LCs. Moreover, epidermal LCs in mice whose bone marrow was lethally irradiated and subsequently transplanted are only partially replaced by LCs of donor origin,[290] whereas DCs in other organs are efficiently exchanged for donor DCs.[238] Together, these observations suggest that a precursor cell population resides in the dermis that is engaged constantly in the self-renewal of the epidermal LC population under noninflammatory conditions. The prime candidate LC precursors are dermal $CD14^+/CD11c^+$ cells that have the potential to differentiate in vitro into LCs in a TGF-β1-dependent fashion.[291]

Under inflammatory conditions (e.g., UV radiation exposure, graft-versus-host disease), an additional pathway of epidermal LC recruitment becomes operative. In this situation, LC precursors enter the tissue, and their progeny populate the epidermis in a fashion dependent on chemoattraction mediated by LC-expressed chemokine receptors CCR2 and CCR6,[239] the ligands of which are secreted by endothelial cells and keratinocytes. Thus, CCR6 and its ligand MIP-3α/CCL20 may be essential for epidermal LC localization in vivo, as postulated previously in studies of LCs differentiated from human progenitor cells in vitro.[108] The action of MIP-3α/CCL20 may be assisted or replaced under noninflammatory situations by the chemokine BRAK/CXCL14, which is constitutively produced by keratinocytes.[292] The differentiation stage of the biologically relevant circulating LC precursors entering inflamed skin in vivo remains to be resolved. However, evidence exists that common myeloid progenitors, granulocyte–macrophage progenitors, monocytes, and even common lymphoid progenitors can give rise to the emergence of an epidermal LC population in experimental animals.[293,294]

Compelling evidence exists from in vitro and in vivo studies that LCs play a pivotal role in the induction of adaptive immune responses against antigens introduced into and/or generated in the skin (immunosurveillance). This is best illustrated by the early observation that LC-containing, but not LC-depleted, epidermal cell suspensions pulse-exposed to either soluble protein antigens or haptens elicit a genetically restricted, antigen-specific, proliferative T cell response.[295] Inaba et al[296] found that freshly isolated LCs ("immature" LCs) can present soluble antigen to primed MHC class II-restricted T cells but are only weak stimulators of naive, allogeneic T cells. In contrast, LCs purified from epidermal cell suspensions after a culture period of 72 hours or LCs purified from freshly isolated murine epidermal cells and cultured for 72 hours in the presence of GM-CSF and IL-1 ("mature" LC) are extremely potent stimulators of primary T cell-proliferative responses to alloantigens,[296] soluble protein antigens,[297] and haptens.[297] Immature LCs, however, far excel cytokine-activated LCs in their capacity to take up and process native protein antigens.[298] Accordingly, immature rather than mature LCs express antigen uptake receptors. Mature LCs, although fully capable of presenting preprocessed peptides, have lost their capacity to process and present native protein antigens.[298]

Upon perturbance of skin homeostasis (e.g., TLR ligation, contact with chemical haptens, hypoxia), LCs gain access to antigen/allergen encountering the epidermis by distending their dendrites through epidermal tight junctions, thereby demonstrating strikingly remarkable cooperation between keratinocytes and LC.[299] After a few hours, LCs begin to enlarge, to display increased amounts of surface-bound MHC class II molecules, and to migrate downward in the dermis, where they enter afferent lymphatics and, finally, reach the T-cell zones of draining lymph nodes.[300] During this process, LCs undergo phenotypic changes similar to those that occur in single epidermal cell cultures,[301] i.e., downregulation of molecules or structures responsible for antigen uptake and processing as well as for LC attachment to keratinocytes (e.g., Fc receptors, E-cadherin) and upregulation of moieties required for active migration and stimulation of robust responses of naive T cells (e.g., CD40, CD80, CD83, CD86). The mechanisms governing LC migration are becoming increasingly clear. TNF-α and IL-1β (in a caspase 1-dependent fashion) are critical promoters of this process, whereas IL-10 inhibits its occurrence. Increased cutaneous production and/or release of the proinflammatory cytokines are probably one of the mechanisms by which certain immunostimulatory compounds applied to or injected into the skin [e.g., imiquimod, unmethylated cytosine–phosphate–guanosine (CpG) oligonucleotides] accelerate LC migration. Another example is the topical application of contact sensitizers (e.g., dinitrofluorobenzene), which leads to the activation of certain protein tyrosine kinases, the modification of cellular content and structure of intracytoplasmic organelles (increase in coated pits and vesicles, endosomes and lysosomes, Birbeck granules), and increased in situ motility of these cells.[302] Interestingly, Cumberbatch et al[303] reported that, in psoriasis, LCs are impaired in their migratory capacity. This was somewhat unexpected in view of the remarkable overexpression of TNF-α in psoriatic skin. These investigators also found that the failure of TNF-α and/or IL-1β to induce LC migration from uninvolved skin was not attributable to an altered expression of receptors for these cytokines. An important hurdle for emigrating LCs is the basement membrane. During their downward journey, LCs probably attach to it via α_6-containing integrin receptors and produce proteolytic enzymes such as type IV collagenase (MMP-9) to penetrate it and to pave their way through the dense dermal network into the lymphatic system. IL-16 also induces LC mobilization. This process could perhaps be operative in atopic dermatitis. In this disease, DCs of lesional skin exhibit surface IgE bound to high-affinity Fc receptors (FcεRI), and allergen-mediated receptor cross-linking results in enhanced IL-16 production. Evidence is accumulating that DC migration occurs in an active, directed fashion. Osteopontin is a chemotactic protein that is essential in this regard. It initiates LC emigration from the epidermis and attracts LCs to draining nodes by interacting with an *N*-terminal epitope of the CD44 molecule.[304] The entry into and active transport of cutaneous DCs

within lymphatic vessels appears to be mediated by MCPs binding to CCR2 and by secondary lymphoid-organ chemokine/CCL21 produced by lymphatic endothelial cells of the dermis and binding to CCR7 on maturing LCs and DDCs.[242,305] Interestingly, CCL21 expression is upregulated in irritant and allergic contact dermatitis, which implicates its regulated impact on DC emigration from the skin.[306]

DERMAL DENDRITIC CELLS. Like resident LCs in the epidermis, dermal dendritic cells (DDCs) constitute another resident DC subpopulation in normal and inflamed skin that is capable of activating the immune system upon receipt of danger signals. Located primarily in the vicinity of the superficial vascular plexus, DDCs have been identified by their surface expression of CD1b, CD1c (BDCA-1), CD11c, CD36, CD205, MHCII, as well as the subunit A of the clotting proenzyme factor XIII (FXIIIa).[307] They can be distinguished from LCs by the absence of Langerin expression and lack of Birbeck granules. Based on the positive reactivity for FXIIIa, DDCs from dermal single-cell suspensions were originally classified into at least three different subsets: (1) $CD1a^-/CD14^-$ cells, (2) $CD1a^-/CD14^-$ cells, and (3) $CD1a^-/CD14^+$ cells. Many assays conducted with DDCs during the past years revealed that they possess functional features of both macrophages and DCs, i.e., the capacity of efficient phagocytosis on the one hand as well as antigen-presenting, migratory and T-cell-stimulating capacities on the other hand.[308,309]

LC Versus DDC in Skin Immunity. (Fig. 10-8). What is the function of LCs/DDCs in normal skin? Is there a natural flux of LCs/DDCs to the regional lymph nodes? If so, what are the consequences of such an occurrence? Evidence exists that melanin granules captured in the skin accumulate in the regional lymph nodes but not in other tissues. The further observation of only very few melanin granule-containing cells in TGF-$\beta1^{-/-}$ mice suggests that, under steady-state conditions, epidermal and/or dermal antigens are carried to the regional lymph nodes by TGF-β1-dependent cells (most likely LCs/DDCs) only. It appears that T lymphocytes encountering such APCs in vivo are rendered unresponsive in an antigen-specific manner.[259] It is therefore conceivable that immature resident skin DC, i.e., LCs and DDCs, are endowed with tolerogenic skills inhibiting inflammatory T-cell responses in the steady state and, consequently, that absence of pathogenic T-cell autoimmunity and/or lack of reactivity against seemingly innocuous environmental compounds (e.g., aeroallergens) in the periphery is primarily the consequence of an active immune response rather than the result of its nonoccurrence.

In the past few years, there has been a heavy debate about the relative sensitizing capacity of LCs versus DDCs in skin-derived immune responses. This discussion was initiated by seemingly controversial results obtained with different types of LC-depleted mice undergoing contact sensitization.

INFLAMMATORY DENDRITIC CELLS.[309] DCs appearing in inflamed skin can be subdivided into two major subpopulations, i.e., (1) inflammatory dendritic epidermal/dermal cells (IDECs/IDDCs) and (2) plasmacytoid dendritic cells (pDCs). The former ones will be referred to as inflammatory dendritic skin cells (IDSCs).

Inflammatory Dendritic Skin Cells (IDSC). It is still unclear whether IDSCs represent a subpopulation of myeloid DCs which, upon danger stimuli, are recruited to the sites of inflammation from the blood, or whether indigenous DDCs are converted into specialized IDSCs that have the capacity to adapt their function according to the kind of danger signal delivered. Supporting the idea of circulating DC precursors infiltrating the skin upon danger signals, potential precursor cells including pre-DCs[320,321] or hematopoietic precursor cells[234] have been identified.

Much work on the identification and characterization of epidermal and/or dermal inflammatory DC populations in various skin diseases has lately been provided by different groups.[322–325] In the dermis of psoriatic lesions, the number of $CD11c^+$ DCs is 30-fold increased as compared to normal skin.[325,326] In contrast to steady-state DDC, these dermal $CD11c^+$ DCs are $CD1c^-$, but produce a number of proinflammatory cytokines (e.g., TNF-α) and inducible oxide synthetase (iNOS) and were therefore termed TIP-DCs (TNF-α and iNOS-producing DCs). Initially identified in 2003 in a murine model of *Listeria monocytogenes* infection,[327] they have been located in the lamina propria of human gut[328] as well as in imiquimod-treated human basal cell carcinoma.[324] Imiquimod and the other imidazoquinolines as ligands of TLR7/8 induce strong inflammation and, ultimately, regression of viral acanthomas and other superficial skin neoplasms.[329] Upon treatment, TIP-DCs are abundantly present around regressing tumor cell islands[330] and, interestingly, can express molecules of the lytic machinery such as perforin, granzyme B, and TRAIL, suggesting their cytotoxic potential. In psoriasis, TIP-DC have the capacity to prime T cells to become Th1, Th17, and a mixture of Th1/Th17 cells, which simultaneously produce IFN-γ and IL-17[325] and may contribute to the pathogenesis of the disease. In addition, their pathogenic role is indicated by downregulation of TNF-α, iNOS, and other cytokines they produce, namely, IL-20 and IL-23, upon effective psoriasis treatment.[331] Recent work also identified TRAIL on $CD11c^+$ $CD1c^-$ TIP-DCs in psoriasis, proposing a proinflammatory, cell-damaging interaction with keratinocytes that express activating TRAIL receptors (death receptor 4 and decoy receptor 2).[332]

In the epidermis of atopic dermatitis (AD) skin, the emergence of inflammatory dendritic epidermal cells (IDECs) has been well documented.[333] They are characterized by the expression of CD1a, CD1b, CD1c, CD11c, FcεRI, CD23, HLA-DR, CD11b, CD206 (MMR/macrophage mannose receptor), and CD36.[333,334] In situ staining of costimulatory molecules on epidermal $CD1a^+$ DC in AD skin showed that mainly cells with the phenotype of IDEC display CD80 and CD86, whereas $Langerin^+$ $CD1a^+$ epidermal LC are almost devoid of these molecules.[335] CD86 signaling is critical for the stimulatory capacity of IDEC. Evidence exists that, upon engagement of FcεRI on IDEC, an immune

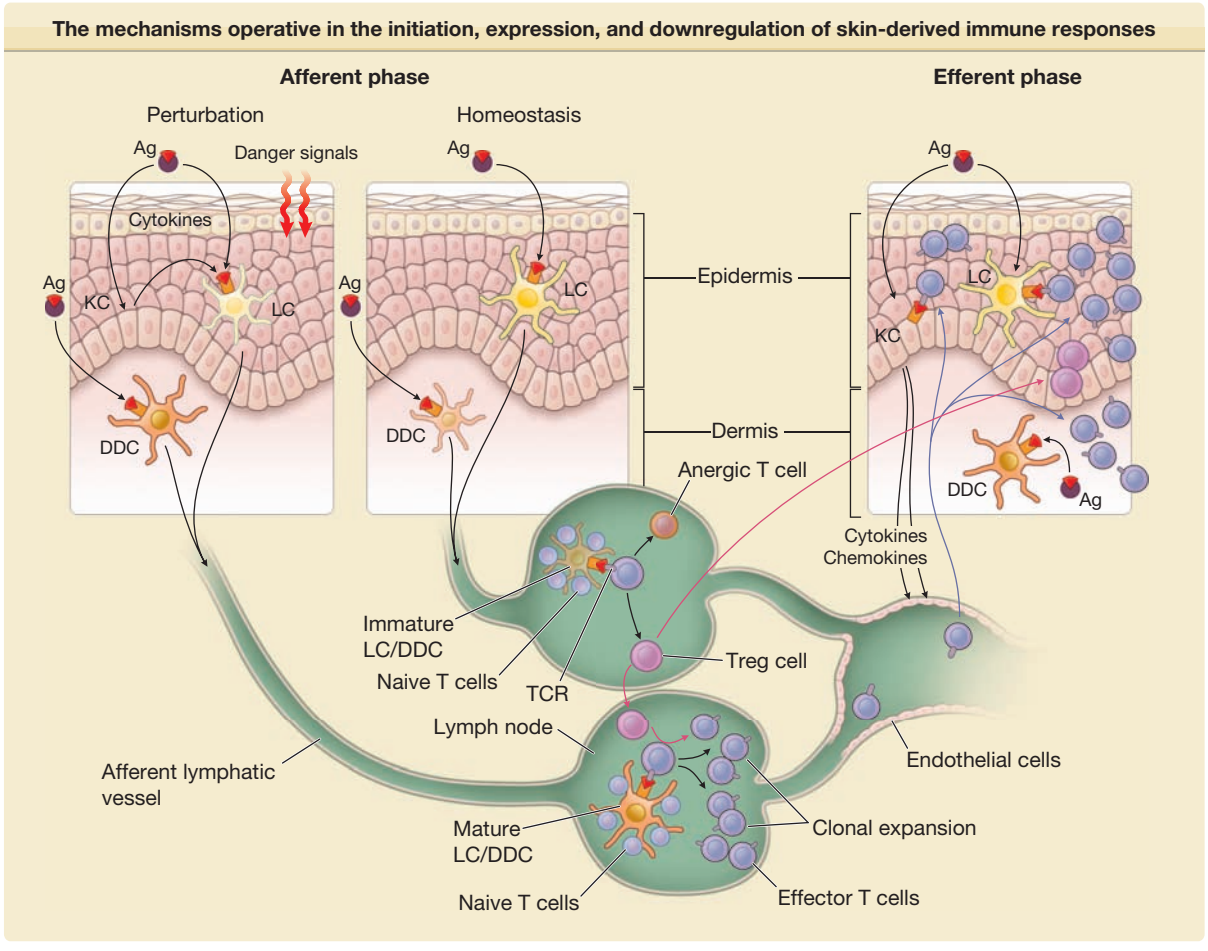

Figure 10-8 The mechanisms operative in the initiation, expression, and downregulation of skin-derived immune responses. Induction of T cell immunity via the skin: Antigens administered to or occurring in the skin (microbial products, haptens, etc.) will be picked up, engulfed, processed and presented by dendritic antigen-presenting cells in the epidermis (LC = Langerhans cells) and/or the dermis (DDC = dermal dendritic cells). When danger signals, particularly those reaching beyond the dermal–epidermal junction, are present at the time of antigenic exposure, these DC will undergo a process of maturation as evidenced by an enhanced expression of MHC antigens, costimulatory molecules (CD80, CD86, CD40, CD83, etc.), and immunostimulatory cytokines (IL-1β, IL-6, IL-12, IL-23) as well as their enhanced emigration from the skin to the paracortical areas of the draining lymph nodes. At this site, the skin-derived DCs provide activation stimuli to the naive resting T cells surrounding them. This occurs in an antigen-specific fashion and thus results in the expansion of the respective clone(s). T cells thus primed begin to express skin-homing receptors (e.g., CLA) as well as receptors for various chemoattractants that promote their attachment to dermal microvascular endothelial cells of inflamed skin and, ultimately, their entry into this tissue. Elicitation of T-cell-mediated tissue inflammation and pathogen clearance: on receipt of a renewed antigenic stimulus by activated skin DCs or other APCs, the skin-homed T cells expand locally and display the effector functions needed for the elimination of the pathogen. Downregulation and prevention of cutaneous T cell immunity: In the absence of danger signals (tissue homeostasis), antigen-loaded skin DCs leave their habitat and migrate toward the draining lymph node. These cells or, alternatively, resident lymph node DCs that had picked up antigenic moieties from afferent lymphatics present this antigen in a nonproductive fashion, i.e., they induce antigen-specific T-cell unresponsiveness or allow the responding T cell(s) to differentiate into immunosuppressive T regulatory cells. The latter may limit antigen-driven clonal T-cell expansion during primary immune reactions in lymph nodes and during secondary immune reactions at the level of the peripheral tissue. Such events can result in the downregulation of both desired (antitumor, antimicrobial) and undesired (hapten-specific, autoreactive) immune responses. Ag = antigen; T = T naive cell; T* = anergic T cell; TCR = T-cell receptor; T reg = regulatory T cells; EM T cells = effector memory T cells.

response triggered by these cells is skewed into the Th1 direction.[336] Recent work also located a substantial number of $CD1a^+$ $CD11c^+$ Langerin-DC within the dermis of AD lesions. Interestingly, these cells showed an upregulation of the chemokines CCL17 and CCL18 and can thereby provide a Th2 polarizing environment.[323] Importantly, this subset of IDSC does not produce iNOS or TNF-α, thus confirming the presence of different inflammatory DC subsets in different cutaneous pathologies.

Plasmacytoid Dendritic Cells.[337] pDCs are DCs that are characterized by a highly developed endoplasmic reticulum, which results in their plasma

cell-like appearance.[338] Functionally, pDCs display a unique ability to produce up to 1,000 times more natural IFNs than any other blood mononuclear cell in response to TLR ligands and thus were also named *principal type 1 IFN-producing cells*.[339]

Chapter 11 :: Cytokines

:: Ifor R. Williams & Thomas S. Kupper

CYTOKINES AT A GLANCE

- Cytokines are polypeptide mediators that function in communication between hematopoietic cells and other cell types.
- Cytokines often have multiple biologic activities (pleiotropism) and overlapping biologic effects (redundancy).
- Primary cytokines, such as interleukin 1 and tumor necrosis factor-α, are sufficient on their own to trigger leukocyte influx into tissue.
- Most cytokines signal through either the nuclear factor-κB or the Jak/STAT signaling pathways.
- Cytokine-based therapeutics now in use include recombinant cytokines, inhibitory monoclonal antibodies, fusion proteins composed of cytokine receptors and immunoglobulin chains, topical immunomodulators such as imiquimod, and cytokine fusion toxins.

THE CONCEPT OF CYTOKINES

When cells and tissues in complex organisms need to communicate over distances greater than one cell diameter, soluble factors must be employed. A subset of these factors is most important when produced or released transiently under emergent conditions. When faced with an infection- or injury-related challenge, the host must orchestrate a complex and carefully choreographed series of steps. It must mobilize certain circulating white blood cells precisely to the relevant injured area (but not elsewhere) and guide other leukocytes involved in host defense, particularly T and B cells, to specialized lymphatic tissue remote from the infectious lesion but sufficiently close to contain antigens from the relevant pathogen. After a limited period of time in this setting (i.e., lymph node), antibodies produced by B cells and effector-memory T cells, can be released into the circulation and will localize at the site of infection. Soluble factors produced by resident tissue cells at the site of injury, by leukocytes and platelets that are recruited to the site of injury, and by memory T cells ultimately recruited to the area, all conspire to generate an evolving and effective response to a challenge to host defense. Most important, the level of this response must be appropriate to the challenge and the duration

of the response must be transient; that is, long enough to decisively eliminate the pathogen, but short enough to minimize damage to healthy host tissues. Much of the cell-to-cell communication involved in the coordination of this response is accomplished by cytokines.

Cytokines (which include the large family of chemokines, discussed in Chapter 12) are soluble polypeptide mediators that play pivotal roles in communication between cells of the hematopoietic system and other cells in the body.[1] Cytokines influence many aspects of leukocyte function including differentiation, growth, activation, and migration. While many cytokines are substantially upregulated in response to injury to allow a rapid and potent host response, cytokines also play important roles in the development of the immune system and in homeostatic control of the immune system under basal conditions. The growth and differentiation effects of cytokines are not limited to leukocytes, although we will not discuss soluble factors that principally mediate cell growth and differentiation of cells other than leukocytes in this chapter. The participation of cytokines in many parts of immune and inflammatory responses has prompted the examination of a variety of cytokines or cytokine antagonists (primarily antibodies and fusion proteins) as agents for pharmacologic manipulation of immune-mediated diseases. Only a few classes of effective cytokine drugs have emerged from the lengthy pathway of clinical trials to achieve FDA approval and widespread therapeutic use, but some of these drugs are now valuable therapeutics in dermatology. This chapter discusses these approved drugs and other promising biological agents still in clinical trials.

General features of cytokines are their pleiotropism and redundancy. Before the advent of a systematic nomenclature for cytokines, most newly identified cytokines were named according to the biologic assay that was being used to isolate and characterize the active molecule (e.g., T-cell growth factor for the molecule that was later renamed *interleukin 2*, or IL-2). Very often, independent groups studying quite disparate bioactivities isolated the same molecule that revealed the pleiotropic effects of these cytokines. For example, before being termed *interleukin 1* (IL-1), this cytokine had been variously known as *endogenous pyrogen*, *lymphocyte-activating factor*, and *leukocytic endogenous mediator*. Many cytokines have a wide range of activities, causing multiple effects in responsive cells and a different set of effects in each type of cell capable of responding. The redundancy of cytokines typically means that in any single bioassay (such as induction of T-cell proliferation), multiple cytokines will display activity. In addition, the absence of a single cytokine (such as in mice with targeted mutations in cytokine genes) can often be largely or even completely compensated for by other cytokines with overlapping biologic effects.

CLASSIFICATIONS OF CYTOKINES

The first cytokines described had distinct and easily recognizable biological activities, exemplified by IL-1, IL-2, and the interferons (IFNs). The term cytokine was first coined by Cohen in 1975, to describe several such activities released into the supernatant of an epithelial cell line.[2] Prior to this, such activities had been thought to be the exclusive domain of lymphocytes (lymphokines) and monocytes (monokines) and were considered a function of the immune system. Keratinocyte cytokines were first discovered in 1981,[3] and the list of cytokines produced by this epithelial cell rivals nearly any other cell type in the body.[4,5] The number of molecules that can be legitimately termed cytokines continues to expand and has brought under the cytokine rubric molecules with a broad range of distinct biological activities. The progress in genomic approaches has led to identification of novel cytokine genes based on homologies to known cytokine genes. Making sense of this plethora of mediators is more of a challenge than ever, and strategies to simplify the analysis of the cytokine universe are sorely needed.

PRIMARY AND SECONDARY CYTOKINES

A simple concept that continues to be extremely useful for discussion of cytokine function is the concept of "primary" and "secondary" cytokines.[6] Primary cytokines are those cytokines that can, by themselves, initiate all the events required to bring about leukocyte infiltration in tissues. IL-1 (both α and β forms) and tumor necrosis factor (TNF; includes both TNF-α and TNF-β) function as primary cytokines, as do certain other cytokines that signal through receptors that trigger the nuclear factor κB (NF-κB) pathway. IL-1 and TNF are able to induce cell adhesion molecule expression on endothelial cells [selectins as well as immunoglobulin superfamily members such as intercellular adhesion molecule 1 (ICAM-1) and vascular cellular adhesion molecule 1 (VCAM-1)], to stimulate a variety of cells to produce a host of additional cytokines, and to induce expression of chemokines that provide a chemotactic gradient allowing the directed migration of specific leukocyte subsets into a site of inflammation (see Chapter 12). Primary cytokines can be viewed as part of the innate immune system (see Chapter 10), and in fact share signaling pathways with the so-called *Toll-like receptors (TLRs)*, a family of receptors that recognize molecular patterns characteristically associated with microbial products.[7] Although other cytokines sometimes have potent inflammatory activity, they do not duplicate this full repertoire of activities. Many qualify as secondary cytokines whose production is induced after stimulation by IL-1 and/or TNF family molecules. The term *secondary* does not imply that they are less important or less active than primary cytokines; rather, it indicates that their spectrum of activity is more restricted.

T-CELL SUBSETS DISTINGUISHED BY PATTERN OF CYTOKINE PRODUCTION

Another valuable concept that has withstood the test of time is the assignment of many T-cell-derived cytokines into groups based on the specific helper T-cell

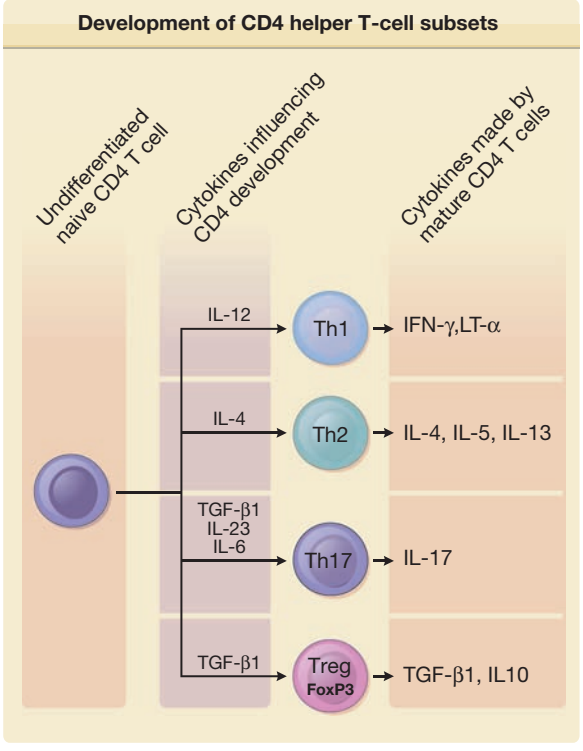

Figure 11-1 Cytokines control the development of specific CD4 helper T-cell subsets. The cytokine milieu at the time of activation of naive undifferentiated CD4 T cells has a profound influence on the ultimate pattern of cytokine secretion adopted by fully differentiated T cells. Subsets of effector CD4 T cells with defined patterns of cytokine secretion include T helper 1 (Th1), Th2, and Th17 cells. Regulatory CD4 T cells (Treg cells) express the FoxP3 transcription factor, and their effects are mediated in part by their production of transforming growth factor-β1 (TGF-β1) and/or interleukin 10 (IL-10). IFN = interferon; LT = lymphotoxin. (Adapted from Tato CM, O'Shea JJ: What does it mean to be just 17? *Nature* **441**:166, 2006.)

subsets that produce them (Fig. 11-1). The original two helper T-cell subsets were termed *Th1* and *Th2*.[8] Commitment to one of these two patterns of cytokine secretion also occurs with CD8 cytotoxic T cells and γ/δ T cells. Dominance of type 1 or type 2 cytokines in a T-cell immune response has profound consequences for the outcome of immune responses to certain pathogens and extrinsic proteins capable of serving as allergens. Over two decades after the original description of the Th1 and Th2 subsets, strong evidence has emerged that there are other functionally significant patterns of cytokine secretion by T cells. Most prominent among these newer T-cell lineages are *Th17* cells and *regulatory T cells* (or *Treg cells* for short). The Th17 subset is distinguished by production of a high level of IL-17, but many Th17 cells also secrete IL-21 and IL-22. Th17 cells promote inflammation, and there is consistent evidence from human autoimmune diseases and mouse models of these diseases that IL-17-producing cells are critical effectors in autoimmune disease.[9] A subset of T cells known as Treg cells has emerged as a crucial subset involved in the maintenance of peripheral self-tolerance.[10] Two of the most distinctive features of Treg cells are their expression of the FoxP3 transcription factor and production of transforming growth factor-β (TGF-β), a cytokine that appears to be required for Treg cells to limit the excess activity of the proinflammatory T-cell subsets.[11] IL-10 is also a significant contributor to the suppressive activity of Treg cells, particularly at some mucosal interfaces.[12] Additional proposed helper T-cell subsets are follicular helper T cells (Tfh) that specialize in providing B cell help in germinal centers, Th9 cells distinguished by high levels of IL-9 production that function in antiparasite immunity along with Th2 cells, and Th22 cells associated with skin inflammation that produce Th22, but not other Th17-associated cytokines. Not only does each of these T-cell subsets exhibit distinctive patterns of cytokine production, cytokines are key factors in influencing the differentiation of naive T cells into these subsets. IL-12 is the key Th1-promoting factor, IL-4 is required for Th2 differentiation, and IL-6, IL-23, and TGF-β are involved in promoting Th17 development.

STRUCTURAL CLASSIFICATION OF CYTOKINES

Not all useful classifications of cytokines are based solely on analysis of cytokine function. Structural biologists, aided by improved methods of generating homogenous preparations of proteins and establishment of new analytical methods (e.g., solution magnetic resonance spectroscopy) that complement the classical X-ray crystallography technique, have determined the three-dimensional structure of many cytokines. These efforts have led to the identification of groups of cytokines that fold to generate similar three-dimensional structures and bind to groups of cytokine receptors that also share similar structural features. For example, most of the cytokine ligands that bind to receptors of the hematopoietin cytokine receptor family are members of the four-helix bundle group of proteins. Four-helix bundle proteins have a shared tertiary architecture consisting of four antiparallel α-helical stretches separated by short connecting loops. The normal existence of some cytokines as oligomers rather than monomers was discovered in part as the result of structural investigations. For example, interferon-γ (IFN-γ) is a four-helix bundle cytokine that exists naturally as a noncovalent dimer. The bivalency of the dimer enables this ligand to bind and oligomerize two IFN-γ receptor complexes, thereby facilitating signal transduction. TNF-α and TNF-β are both trimers that are composed almost exclusively of β-sheets folded into a "jelly roll" structural motif. Ligand-induced trimerization of receptors in the TNF receptor family is involved in the initiation of signaling.

SIGNAL TRANSDUCTION PATHWAYS SHARED BY CYTOKINES

To accomplish their effects, cytokines must first bind with specificity and high affinity to receptors on the cell surfaces of responding cells. Many aspects of the

TABLE 11-1
Major Families of Cytokine Receptors

Receptor Family	Example	Major Signal Transduction Pathway(s) Leading to Biologic Effects
IL-1 receptor family	IL-1R, type I	NF-κB activation via TRAF6
TNF receptor family	TNFR1	NF-κB activation involving TRAF2 and TRAF5 Apoptosis induction via "death domain" proteins
Hematopoietin receptor family (class I receptors)	IL-2R	Activation of Jak/STAT pathway
IFN/IL-10 receptor family (class II receptors)	IFN-γR	Activation of Jak/STAT pathway
Immunoglobulin superfamily	M-CSF R	Activation of intrinsic tyrosine kinase
TGF-β receptor family	TGF-βR, types I and II	Activation of intrinsic serine/threonine kinase coupled to Smad proteins
Chemokine receptor family	CCR5	Seven transmembrane receptors coupled to G proteins

CCR = CC chemokine receptor; IFN = interferon; IL = interleukin; Jak = Janus kinase; M-CSF = macrophage colony-stimulating factor; NF-κB = nuclear factor κB; STAT = signal transducer and activator of transcription; TGF = transforming growth factor; TNF = tumor necrosis factor; TRAF = tumor necrosis factor receptor-associated factor.

pleiotropism and redundancy manifested by cytokines can be understood through an appreciation of shared mechanisms of signal transduction mediated by cell surface receptors for cytokines. In the early years of the cytokine biology era, the emphasis of most investigative work was the purification and eventual cloning of new cytokines and a description of their functional capabilities, both in vitro and in vivo. Most of the cytokine receptors have now been cloned, and many of the signaling cascades initiated by cytokines have been described in great detail. The vast majority of cytokine receptors can be classified into a relatively small number of families and superfamilies (Table 11-1), the members of which function in an approximately similar fashion. Table 11-2 lists the cytokines of particular relevance for cutaneous biology, including the major sources, responsive cells, features of interest, and clinical relevance of each cytokine. Most cytokines send signals to cells through pathways that are very similar to those used by other cytokines binding to the same class of receptors. Individual cytokines often employ several downstream pathways of signal transduction, which accounts in part for the pleiotropic effects of these molecules. Nevertheless, we propose here that a few major signaling pathways account for most effects attributable to cytokines. Of particularly central importance are the NF-κB pathway and the Jak/STAT pathway, described in the following sections.

NUCLEAR FACTOR κB, INHIBITOR OF κB, AND PRIMARY CYTOKINES

A major mechanism contributing to the extensive overlap between the biologic activities of the primary cytokines IL-1 and TNF is the shared use of the NF-κB signal transduction pathway. IL-1 and TNF use completely distinct cell surface receptor and proximal signaling pathways, but these pathways converge at the activation of the NF-κB transcription factor. NF-κB is of central importance in immune and inflammatory processes because a large number of genes that elicit or propagate inflammation have NF-κB recognition sites in their promoters.[13] NF-κB-regulated genes include cytokines, chemokines, adhesion molecules, nitric oxide synthase, cyclooxygenase, and phospholipase A2.

In unstimulated cells, NF-κB heterodimers formed from p65 and p50 subunits are inactive because they are sequestered in the cytoplasm as a result of tight binding to inhibitor proteins in the IκB family (Fig. 11-2). Signal transduction pathways that activate the NF-κB system do so through the activation of an IκB kinase (IKK) complex consisting of two kinase subunits (IKKα and IKKβ) and a regulatory subunit (IKKγ). The IKK complex phosphorylates IκBα and IκBβ on specific serine residues, yielding a target for recognition by an E3 ubiquitin ligase complex. The resulting polyubiquitination marks this IκB for rapid degradation by the 26S proteasome complex in the cytoplasm. Once IκB has been degraded, the free NF-κB (which contains a nuclear localization signal) is able to pass into the nucleus and induce expression of NF-κB-sensitive genes. The presence of κB recognition sites in cytokine promoters is very common. Among the genes regulated by NF-κB are *IL-1β* and *TNF-α*. This endows *IL-1β* and *TNF-α* with the capacity to establish a positive regulatory loop that favors persistent inflammation. Cytokines besides IL-1 and TNF that activate the NF-κB pathway as part of their signal transduction mechanisms include IL-17 and IL-18.

Proinflammatory cytokines are not the only stimuli that can activate the NF-κB pathway. Bacterial products

TABLE 11-2
Cytokines of Particular Relevance for Cutaneous Biology

Cytokine	Major Sources	Responsive Cells	Features of Interest	Clinical Relevance
IL-1α	Epithelial cells	Infiltrating leukocytes	Active form stored in keratinocytes	IL-1Ra used to treat rheumatoid arthritis
IL-1β	Myeloid cells	Infiltrating leukocytes	Caspase 1 cleavage required for activation	IL-1Ra used to treat rheumatoid arthritis
IL-2	Activated T cells	Activated T cells, Treg cells	Autocrine factor for activated T cells	IL-2 fusion toxin targets CTCL
IL-4	Activated Th2 cells, NKT cells	Lymphocytes, endothelial cells, keratinocytes	Causes B-cell class switching and Th2 differentiation	—
IL-5	Activated Th2 cells, mast cells	B cells, eosinophils	Regulates eosinophil response to parasites	Anti-IL-5 depletes eosinophils
IL-6	Activated myeloid cells, fibroblasts, endothelial cells	B cells, myeloid cells, hepatocytes	Triggers acute-phase response, promotes immunoglobulin synthesis	Anti-IL-6R used to treat rheumatoid arthritis
IL-10	T cells, NK cells	Myeloid and lymphoid cells	Inhibits innate and acquired immune responses	—
IL-12	Activated APCs	Th1 cells	Promotes Th1 differentiation, shares p40 subunit with IL-23	Anti-p40 inhibits Crohn's disease and psoriasis
IL-13	Activated Th2 cells, nuocytes	Monocytes, keratinocytes, endothelial cells	Mediates tissue responses to parasites	—
IL-17	Activated Th17 cells	Multiple cell types	Mediates autoimmune diseases	Potential drug target in autoimmune disease
IL-22	Activated Th17 cells and Th22 cells	Keratinocytes	Induces cytokines and antimicrobial peptides	Contributes to psoriasis
IL-23	Activated dendritic cells	Memory T cells, Th17 cells	Directs Th17 differentiation, mediates autoimmune disease	Anti-p40 inhibits Crohn's disease and psoriasis
IL-25	Activated Th2 cells, mast cells	Th17 cells	Promotes Th2 differentiation, inhibits Th17 cells	—
IL-27	Activated APCs	Th1 cells	Promotes Th1 differentiation	—
IL-35	Treg cells	Th17 cells and Treg cells	Inhibits Th17 cells and expands Treg cells	—
TNF-α	Activated myeloid, lymphoid, and epithelial cells	Infiltrating leukocytes	Mediates inflammation	Anti-TNF-α effective in psoriasis
IFN-α and IFN-β	Plasmacytoid dendritic cells	Most cell types	Major part of innate antiviral response	Elicited by topical imiquimod application
IFN-γ	Activated Th1 cells, CD8 T cells, NK cells, dendritic cells	Macrophages, dendritic cells, naive T cells	Macrophage activation, specific isotype switching	IFN-γ used to treat chronic granulomatous disease
TSLP	Epithelial cells including keratinocytes	Dendritic cells, B cells, Th2 cells	Promotes Th2 differentiation	Involved in atopic diseases

APC = antigen-presenting cell; CTCL = cutaneous T-cell lymphoma; IFN = interferon; IL = interleukin; NK = natural killer; NKT = natural killer T cell; Th = T helper; TNF = tumor necrosis factor; Treg = T regulatory; TSLP = thymic stromal lymphopoietin.

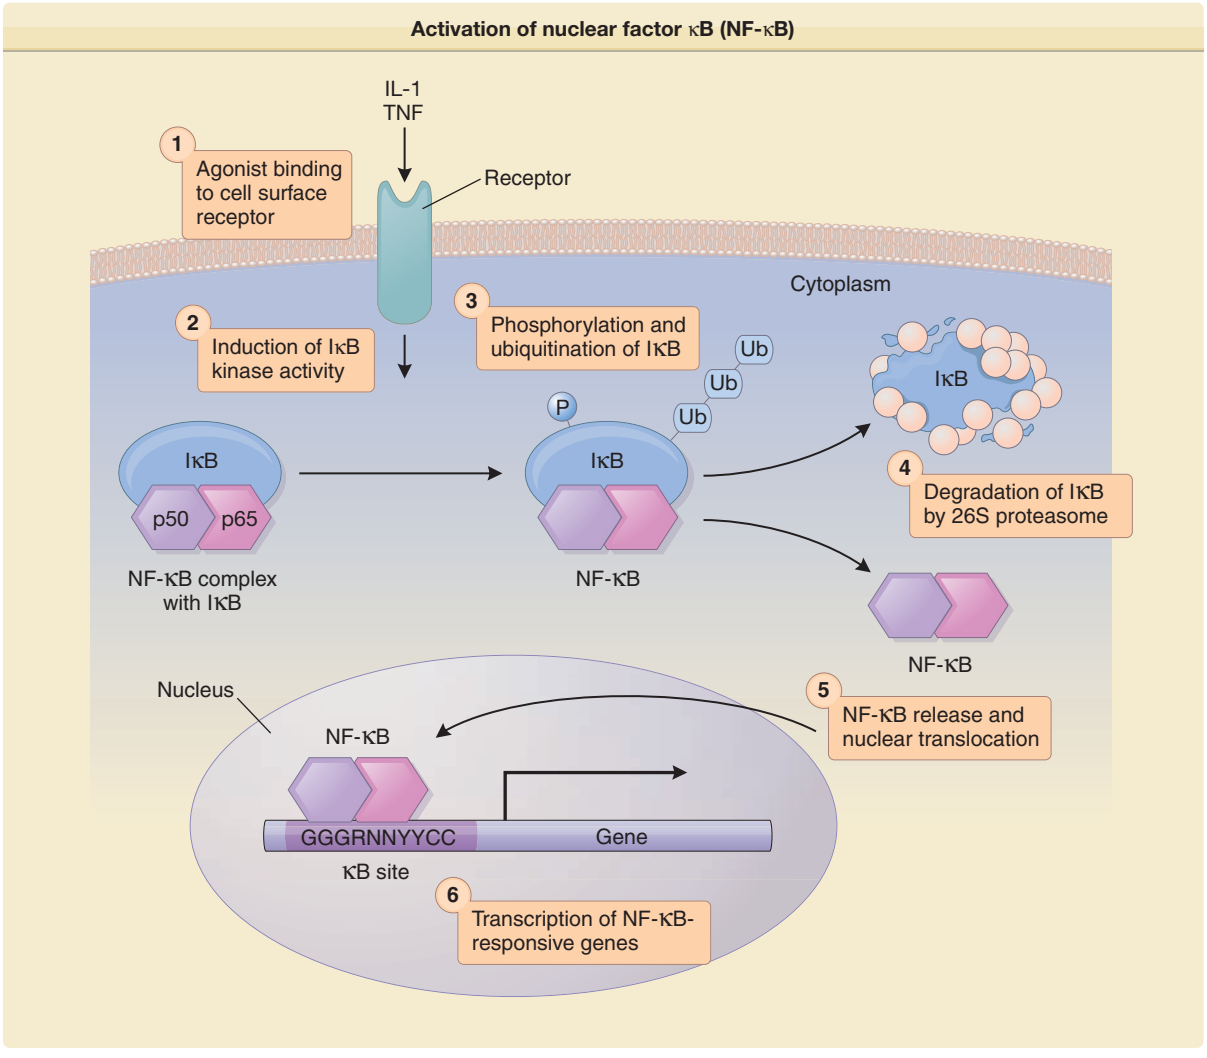

Figure 11-2 Activation of nuclear factor κB (NF-κB)-regulated genes after signaling by receptors for primary cytokines or by Toll-like receptors (TLRs) engaged by microbial products. Under resting conditions, NF-κB (a heterodimer of p50 and p65 subunits) is tightly bound to an inhibitor called Iκ*B* that sequesters NF-κB in the cytoplasm. Engagement of one of the TLRs or the signal transducing receptors for interleukin 1 (IL-1) or tumor necrosis factor (TNF) family members leads to induction of IκB kinase activity that phosphorylates IκB on critical serine residues. Phosphorylated IκB becomes a substrate for ubiquitination, which triggers degradation of IκB by the 26S proteasome. Loss of IκB results in release of NF-κB, which permits it to move to the nucleus and activate transcription of genes whose promoters contain κB recognition sites. Ub = ubiquitin.

(e.g., lipopolysaccharide, or LPS), oxidants, activators of protein kinase C (e.g., phorbol esters), viruses, and ultraviolet (UV) radiation are other stimuli that can stimulate NF-κB activity. TLR4 is a cell surface receptor for the complex of LPS, LPS-binding protein, and CD14. The cytoplasmic domain of TLR4 is similar to that of the IL-1 receptor type 1 (IL-1R1) and other IL-1R family members and is known as the *TIR* domain (for Toll/IL-1 receptor).[14] When ligand is bound to a TIR domain-containing receptor, one or more adapter proteins that also contain TIR domains are recruited to the complex. MyD88 was the first of these adapters to be identified; the other known adapters are TIRAP (TIR domain-containing adapter protein), TRIF (TIR domain-containing adapter inducing IFN-β), and TRAM (TRIF-related adapter molecule). Engagement of the adapter, in turn, activates one or more of the IL-1R-associated kinases (IRAK1 to IRAK4) that then signal through TRAF6, a member of the TRAF (TNF receptor-associated factor) family, and TAK1 (TGF-β-activated kinase) to activate the IKK complex.[15]

JAK/STAT PATHWAY

A major breakthrough in the analysis of cytokine-mediated signal transduction was the identification of a common cell surface to nucleus pathway used by the majority of cytokines. This Jak/STAT pathway was first elucidated through careful analysis of signaling initiated by IFN receptors (Fig. 11-3), but was subsequently shown to play a role in signaling by all

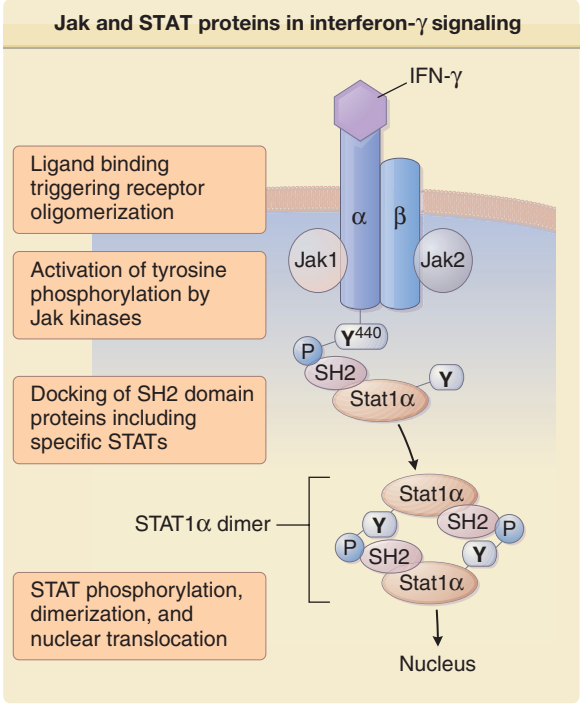

Figure 11-3 Participation of Jak (Janus kinase) and STAT (signal transducer and activator of transcription) proteins in interferon-γ (IFN-γ) signaling. Binding of human IFN-γ (a dimer) to its receptor brings about oligomerization of receptor complexes composed of α and β chains. The nonreceptor protein tyrosine kinases Jak1 and Jak2 are activated and phosphorylate critical tyrosine residues in the receptor such as the tyrosine at position 440 of the α chain (Y^{440}). STAT1α molecules are recruited to the IFN-γ receptor based on the affinity of their Src homology 2 (SH2) domains for the phosphopeptide sequence around Y^{440}. Receptor-associated STAT1α molecules then dimerize through reciprocal SH2-phosphotyrosine interactions. The resulting STAT1α dimers translocate to the nucleus and stimulate transcription of IFN-γ-regulated genes.

cytokines that bind to members of the hematopoietin receptor family.[16] The Jak/STAT pathway operates through the sequential action of a family of four nonreceptor tyrosine kinases (the Jaks or *Ja*nus family *k*inases) and a series of latent cytosolic transcription factors known as *STATs* (*s*ignal *t*ransducers and *a*ctivators of *t*ranscription). The cytoplasmic portions of many cytokine receptor chains are noncovalently associated with one of the four Jaks [Jak1, Jak2, Jak3, and tyrosine kinase 2 (Tyk2)].

The activity of the Jak kinases is upregulated after stimulation of the cytokine receptor. Ligand binding to the cytokine receptors leads to the association of two or more distinct cytokine receptor subunits and brings the associated Jak kinases into close proximity with each other. This promotes cross-phosphorylation or autophosphorylation reactions that in turn fully activate the kinases. Tyrosines in the cytoplasmic tail of the cytokine receptor as well as tyrosines on other associated and newly recruited proteins are also phosphorylated. A subset of the newly phosphorylated tyrosines can then serve as docking points for attachment of additional signaling proteins bearing Src homology 2 (SH2) domains. Cytoplasmic STATs possess SH2 domains and are recruited to the phosphorylated cytokine receptors via this interaction. Homodimeric or heterodimeric STAT proteins are phosphorylated by the Jak kinases and subsequently translocate to the nucleus. In the nucleus they bind recognition sequences in DNA and stimulate transcription of specific genes, often in cooperation with other transcription factors. The same STAT molecules can be involved in signaling by multiple different cytokines. The specificity of the response in these instances may depend on the formation of complexes involving STATs and other transcription factors that then selectively act on a specific set of genes.

INTERLEUKIN 1 FAMILY OF CYTOKINES (INTERLEUKINS 1α, 1β, 18, 33)

IL-1 is the prototype of a cytokine that has been discovered many times in many different biologic assays. Distinct genes encode the α and β forms of human IL-1, with only 26% homology at the amino acid level. Both IL-1s are translated as 31-kDa molecules that lack a signal peptide, and both reside in the cytoplasm. This form of IL-1α is biologically active, but 31-kDa *IL-1β* must be cleaved by caspase 1 (initially termed *interleukin-1β-converting enzyme*) in a multiprotein cytoplasmic complex called the *inflammasome* to generate an active molecule.[17]

In general, IL-1β appears to be the dominant form of IL-1 produced by monocytes, macrophages, Langerhans cells, and dendritic cells, whereas IL-1α predominates in epithelial cells, including keratinocytes. This is likely to relate to the fact that epithelial IL-1α is stored in the cytoplasm of cells that comprise an interface with the external environment. Such cells, when injured, release biologically active 31-kDa IL-1α and, by doing so, can initiate inflammation.[6] However, if uninjured, these cells will differentiate and ultimately release their IL-1 contents into the environment. Leukocytes, including dendritic and Langerhans cells, carry their cargo of IL-1 inside the body, where its unregulated release could cause significant tissue damage. Thus, biologically active IL-1β release from cells is controlled at several levels: *IL-1β* gene transcription, *caspase 1* gene transcription, and availability of the adapter proteins that interact with caspase 1 in the inflammasome to allow the generation of mature IL-1β. IL-1β stimulates the egress of Langerhans cells from the epidermis during the initiation of contact hypersensitivity, a pivotal event that leads to accumulation of Langerhans cells in skin-draining lymph nodes. Studies of mice deficient in *IL-1α* and *IL-1β* genes suggest that both molecules are important in contact hypersensitivity, but that IL-1α is more critical.

Active forms of IL-1 bind to the IL-1R1 or type 1 IL-1 receptor.[14] This is the sole signal-transducing receptor for IL-1, and its cytoplasmic domain has

little homology with other cytokine receptors, showing greatest homology with the *Toll* gene product identified in *Drosophila*. A second cell surface protein, the IL-1R accessory protein, or IL-1RAcP, must associate with IL-1R1 for signaling to occur. When IL-1 engages the IL-1R1/IL-1RAcP complex, recruitment of the MyD88 adapter occurs, followed by interactions with one or more of the IRAKs. These kinases in turn associate with TRAF6. Stepwise activation and recruitment of additional signaling molecules culminate in the induction of IKK activity. The net result is the activation of a series of NF-κB-regulated genes.

A molecule known as the *IL-1 receptor antagonist*, or IL-1ra, can bind to IL-1R1 but does not induce signaling through the receptor. This IL-1ra exists in three alternatively spliced forms, and an isoform produced in monocytes is the only ligand for the IL-1R1 that both contains a signal peptide and is secreted from cells. Two other isoforms of IL-1ra, both lacking signal peptides, are contained within epithelial cells. The function of IL-1ra seems to be as a pure antagonist of IL-1 ligand binding to IL-1R1, and binding of IL-1ra to IL-1R1 does not induce the mobilization of IL-1RAcP. Consequently, although both IL-1α/β and IL-1ra bind with equivalent affinities to IL-1R1, the association of IL-1R1 with IL-1RAcP increases the affinity for IL-1α/β manyfold while not affecting the affinity for IL-1ra. This is consistent with the observation that a vast molar excess of IL-1ra is required to fully antagonize the effects of IL-1. The biologic role of IL-1ra is likely to be in the quenching of IL-1-mediated inflammatory responses, and mice deficient in IL-1ra show exaggerated and persistent inflammatory responses.

A second means of antagonizing IL-1 activity occurs via expression of a second receptor for IL-1, IL-1R2. This receptor has a short cytoplasmic domain and serves to bind IL-1α/β efficiently, but not IL-1ra. This 68-kDa receptor can be cleaved from the cell surface by an unknown protease and released as a stable, soluble 45-kDa molecule that retains avid IL-1-binding function. By binding the functional ligands for IL-1R1, IL-1R2 serves to inhibit IL-1-mediated responses. It is likely that IL-1R2 also inhibits IL-1 activity by associating with IL-1RAcP at the cell surface and removing and sequestering it from the pool available to associate with IL-1R1. Thus, soluble IL-1R2 binds to free IL-1, whereas cell surface IL-1R2 sequesters IL-1RAcP. Expression of IL-1R2 can be upregulated by a number of stimuli, including corticosteroids and IL-4. However, IL-1R2 can also be induced by inflammatory cytokines, including IFN-γ and IL-1, probably as a compensatory signal designed to limit the scale and duration of the inflammatory response. Production of IL-1R2 serves to make the producing cell and surrounding cells resistant to IL-1-mediated activation. Interestingly, some of the most efficient IL-1-producing cells are also the best producers of the IL-1R2.

IL-18 was first identified based on its capacity to induce IFN-γ. One name initially proposed for this cytokine was IL-1γ, because of its homology with IL-1α and IL-1β. Like IL-1β, it is translated as an inactive precursor molecule of 23 kDa and is cleaved to an active 18-kDa species by caspase 1. It is produced by multiple cell types in skin, including keratinocytes, Langerhans cells, and monocytes. IL-18 induces proliferation, cytotoxicity, and cytokine production by Th1 and natural killer (NK) cells, mostly synergistically with IL-12. The IL-18 receptor bears striking similarity to the IL-1 receptor.[14] The binding chain (IL-18R) is an IL-1R1 homolog, originally cloned as IL-1Rrp1. IL-18R alone is a low-affinity receptor that must recruit IL-18RAcP (a homolog of IL-1RAcP). As for IL-1, both chains of the IL-18 receptor are required for signal transduction. Although there is no IL-18 homolog of IL-1ra, a molecule known as *IL-18-binding protein* binds to soluble mature IL-18 and prevents it from binding to the IL-18R complex.

More recently, it has become clear that there is a family of receptors homologous to the IL-1R1 and IL-18R molecules,[14] having in common a TIR motif (Fig. 11-4). All of these share analogous signaling pathways initiated by the MyD88 adapter molecule. One of these receptors, originally known as *ST2*, was initially characterized as a gene expressed by Th2 cells, but not by Th1 cells. The description of a natural ligand for ST2 designated IL-33 has added a new member to the IL-1 family that shares characteristic features of other cytokines in the family, such as a requirement for

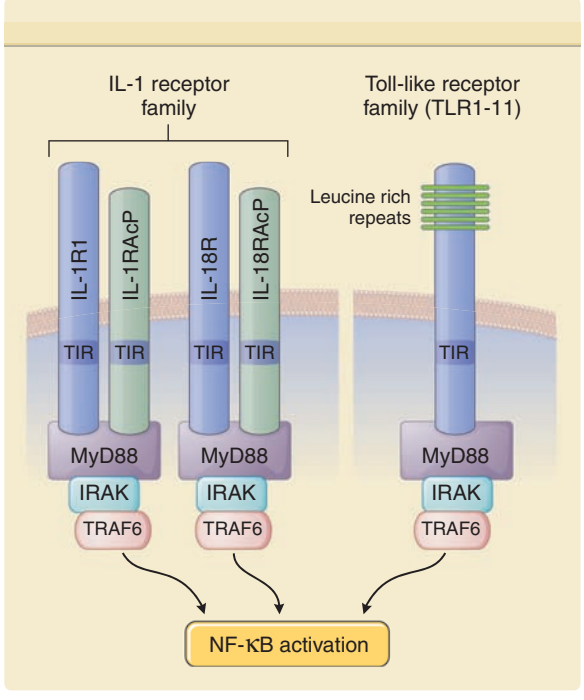

Figure 11-4 The interleukin 1 receptor (IL-1R) family and Toll-like receptors (TLRs) use a common intracellular signaling pathway. Receptors for cytokines in the IL-1 family (typified by the IL-1 and IL-18 receptors) share a common signaling domain with the TLRs (TLR1 to TLR11) called the *Toll/IL-1 receptor (TIR)* domain. The TIR domain receptors interact with TIR domain-containing adapter proteins such as MyD88 that couple ligand binding to activation of IL-1R-associated kinase (IRAK) and ultimately activation of nuclear factor κB (NF-κB). IL-1RAcP = IL-1R accessory protein; TRAF = tumor necrosis factor receptor-associated factor.

processing by caspase 1 to release a mature form of the ligand.[18] IL-33 stimulation of Th2 cells promotes their production of the characteristic Th2 cytokines IL-4, IL-5, and IL-10.[19] IL-1R1, IL-18R, IL-33R (ST2), the TLRs, and their ligands are all best viewed as elements of the innate immune system that signal the presence of danger or injury to the host.

When IL-1 produced by epidermis was originally identified, it was noted that both intact epidermis and stratum corneum contained significant IL-1 activity, which led to the concept that epidermis was a shield of sequestered IL-1 surrounding the host, waiting to be released on injury. More recently, it was observed that high levels of the IL-1ra coexist within keratinocytes; however, repeated experiments show that in virtually all cases, the amount of IL-1 present is sufficient to overcome any potential for inhibition mediated by IL-1ra. Studies have now shown that mechanical stress to keratinocytes permits the release of large amounts of IL-1 in the absence of cell death. Release of IL-1 induces expression of endothelial adhesion molecules, including E-selectin, ICAM-1, and VCAM-1, as well as chemotactic and activating chemokines. This attracts not only monocytes and granulocytes but a specific subpopulation of memory T cells that bear cutaneous lymphocyte antigen on their cell surface. Memory T cells positive for cutaneous lymphocyte antigen are abundant in inflamed skin, comprising the majority of T cells present. Therefore, any injury to the skin, no matter how trivial, releases IL-1 and attracts this population of memory T cells. If they encounter their antigen in this microenvironment, their activation and subsequent cytokine production will amplify the inflammatory response. This has been proposed as the basis of the clinical observation of inflammation in response to trauma, known as the *Koebner reaction*.

Several biologics that act by inhibiting IL-1 function have been developed for clinical use including recombinant IL-1Ra (anakinra), antibody to IL-1β (canakinumab), and an IgG Fc fusion protein that includes the ligand binding domains of the type I IL-1R and IL-1RAcP (rilonacept, also known as IL-1 Trap). All of these agents are efficacious in countering the IL-1-induced inflammation associated with a group of rare autoinflammatory diseases called the cryopyrin-associated periodic syndromes (CAPS). Anakinra was initially US Food and Drug Administration (FDA) approved as a therapy for adult rheumatoid arthritis. IL-1 inhibition is also being tested as a therapy for gout, an inflammatory arthritis triggered by uric acid-mediated activation of inflammasomes that generate IL-1β.

TUMOR NECROSIS FACTOR: THE OTHER PRIMARY CYTOKINE

TNF-α is the prototype for a family of related signaling molecules that mediate their biologic effects through a family of related receptor molecules. TNF-α was initially cloned on the basis of its ability to mediate two interesting biologic effects: (1) hemorrhagic necrosis of malignant tumors, and (2) inflammation-associated cachexia. Although TNF-α exerts many of its biologically important effects as a soluble mediator, newly synthesized TNF-α exists as a transmembrane protein on the cell surface. A specific metalloproteinase known as *TNF-α-converting enzyme (TACE)* is responsible for most TNF-α release by T cells and myeloid cells. The closest cousin of TNF-α is TNF-β, also known as *lymphotoxin α (LT-α)*. Other related molecules in the TNF family include lymphotoxin β (LT-β) that combines with LT-α to form the LT-α1β2 heterotrimer; Fas ligand (FasL); TNF-related apoptosis-inducing ligand (TRAIL); receptor activator of NF-κB ligand (RANKL); and CD40 ligand (CD154). Although some of these other TNF family members have not been traditionally regarded as cytokines, their structure (all are type II membrane proteins with an intracellular *N*-terminus and an extracellular *C*-terminus) and signaling mechanisms are closely related to those of TNF. The soluble forms of TNF-α, LT-α, and FasL are homotrimers, and the predominant form of LT-β is the membrane-bound LT-α1β2 heterotrimer. Trimerization of TNF receptor family members by their trimeric ligands appears to be required for initiation of signaling and expression of biologic activity.

The initial characterization of TNF receptors led to the discovery of two receptor proteins capable of binding TNF-α with high affinity. The p55 receptor for TNF (TNFR1) is responsible for most biologic activities of TNF, but the p75 TNF receptor (TNFR2) is also capable of transducing signals (unlike IL-1R2, which acts solely as a biologic sink for IL-1). TNFR1 and TNFR2 have substantial stretches of close homology and are both present on most types of cells. Nevertheless, there are some notable differences between the two TNFRs.

Unlike cytokine receptors from several of the other large families, TNF signaling does not involve the Jak/STAT pathway. TNF-α evokes two types of responses in cells: (1) proinflammatory effects, and (2) induction of apoptotic cell death (Fig. 11-5). The proinflammatory effects of TNF-α that include upregulation of adhesion molecule expression and induction of secondary cytokines and chemokines, stem in large part from activation of NF-κB and can be transduced through both TNFR1 and TNFR2. Induction of apoptosis by signaling through TNFR1 depends on a region known as a *death domain* that is absent in TNFR2, as well as interactions with additional proteins with death domains within the TNFR1 signaling complex. Signaling initiated by ligand binding to TNFR1, Fas, or other death domain-containing receptors in the TNF family eventually leads to activation of caspase 8 or 10 and the nuclear changes and DNA fragmentation characteristic of apoptosis.

At least two TNFR family members (TNFR1 and the LT-β receptor) also contribute to the normal anatomic development of the lymphoid system. Mice deficient in TNF-α lack germinal centers and follicular dendritic cells. TNFR1 mutant mice show the same abnormalities plus an absence of Peyer's patches. Mice with null mutations in LT-α or LT-β have further abnormalities in lymphoid organogenesis and fail to develop peripheral lymph nodes.

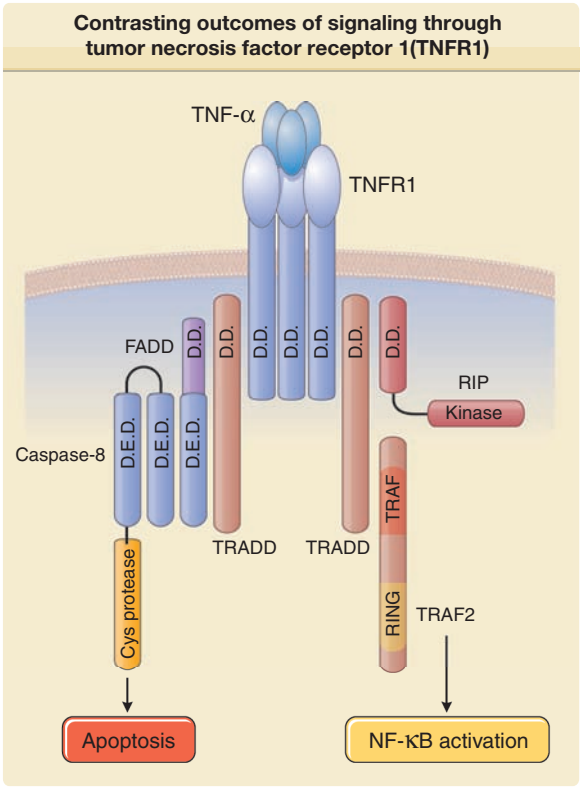

Figure 11-5 Two contrasting outcomes of signaling through tumor necrosis factor receptor 1 (TNFR1). Engagement of TNFR1 by trimeric tumor necrosis factor-α (TNF-α) can trigger apoptosis and/or nuclear factor κB (NF-κB) activation. Both processes involve the adapter protein TNFR-associated death domain (TRADD), which associates with TNFR1 via interactions between "death domains" (D.D.) on both proteins. For NF-κB activation, TNFR-associated factor 2 (TRAF2) and receptor-interacting protein (RIP) are required. Induction of apoptosis occurs when the death domain-containing protein Fas-associated death domain protein (FADD) associates with TRADD. FADD also contains a "death effector domain" (D.E.D.) that interacts with caspase 8 to initiate the apoptotic process. Cys = cysteine. (Adapted from Yuan J: Transducing signals of life and death. *Curr Opin Cell Biol* **9**:247, 1997; and Nagata S: Apoptosis by death factor. *Cell* **88**:355, 1997.)

TNF-α is an important mediator of cutaneous inflammation, and its expression is induced in the course of almost all inflammatory responses in skin. Normal human keratinocytes and keratinocyte cell lines produce substantial amounts of TNF-α after stimulation with LPS or UV light. Cutaneous inflammation stimulated by irritants and contact sensitizers is associated with strong induction of TNF-α production by keratinocytes. Exposure to TNF-α promotes Langerhans cell migration to draining lymph nodes, allowing for sensitization of naive T cells. One molecular mechanism that may contribute to TNF-α-induced migration of Langerhans cells toward lymph nodes is reduced expression of the E-cadherin adhesion molecule after exposure to TNF-α. Induction of CC chemokine receptor 7 on both epidermal and dermal antigen-presenting cells correlates with movement into the draining lymphatics. The predominant TNFR expressed by keratinocytes is TNFR1. Autocrine signaling loops involving keratinocyte-derived TNF-α and TNFR1 lead to keratinocyte production of a variety of TNF-inducible secondary cytokines.

The central role of TNF-α in inflammatory diseases, including rheumatoid arthritis and psoriasis, has become evident from clinical studies. Clinical drugs that target the TNF pathway include the humanized anti-TNF-α antibody infliximab, the fully human anti-TNF-α antibody adalumimab, and the soluble TNF receptor etanercept. Drugs in this class are FDA approved for the treatment of several autoimmune and inflammatory diseases, including Crohn's disease and rheumatoid arthritis. These three anti-TNF drugs are also FDA approved for the treatment of psoriasis and psoriatic arthritis (see Chapter 234). This class of drugs also has the potential to be valuable in the treatment of other inflammatory dermatoses. Paradoxically, they are not effective against all autoimmune diseases—multiple sclerosis appears to worsen slightly after treatment with these agents. The TNF antagonists are powerful immunomodulating drugs, and appropriate caution is required in their use. Cases of cutaneous T-cell lymphoma initially thought to represent psoriasis have rapidly progressed to fulminant disease after treatment with TNF antagonists. TNF antagonists can also allow the escape of latent mycobacterial infections from immune control, with a potentially lethal outcome for the patient.

IL-17 FAMILY OF CYTOKINES

IL-17 (also known as IL-17A) was the first described member of a family of related cytokines that now includes IL-17B through F. IL-17A and IL-17F have similar proinflammatory activities, bind to the same heterodimeric receptor composed of the IL-17RA and IL-17RC receptor chains, and act to promote recruitment of neutrophils and induce production of antimicrobial peptides. These IL-17 species normally function in immune defense against pathogenic species of extracellular bacteria and fungi. Signaling by IL-17A and IL-17F depends on STAT3; mutations in STAT3 associated with the hyper-IgE syndrome block IL-17 signaling and lead to recurrent skin infections with *Staphylococcus aureus* and *Candida albicans*. Less is currently known about the actions of IL-17B, C, and D. IL-17E, also known as IL-25, is a product of Th2 cells and mast cells that signals through IL-17RB. A total of five receptor chains for IL-17 family cytokines have been identified, but how each of these individual receptor chains associates to form receptors for all the members of the IL-17 family remains to be worked out. These IL-17 receptor chains are homologous to each other, but display very limited regions of homology to the other major families of cytokine receptors. Recent expansion of interest in Th17 cells and the entire IL-17 family is closely linked to observations that the immunopathology of autoimmune disease in human patients and mouse models is often associated with an inappropriate expansion of Th17 cells. Thus, the cytokines produced by Th17 cells and the receptors that

transduce these signals may turn out to be useful targets for therapies designed to dampen autoimmunity.

LIGANDS OF THE CLASS I (HEMATOPOIETIN RECEPTOR) FAMILY OF CYTOKINE RECEPTORS

The hematopoietin receptor family (also known as the *class I cytokine receptor family*) is the largest of the cytokine receptor families and comprises a number of structurally related type I membrane-bound glycoproteins. The cytoplasmic domains of these receptors associate with nonreceptor tyrosine kinase molecules, including the Jak kinases and src family kinases. After ligand binding and receptor oligomerization, these associated nonreceptor tyrosine kinases phosphorylate intracellular substrates, which leads to signal transduction. Most of the multiple-chain receptors in the hematopoietin receptor family consist of a cytokine-specific α chain subunit paired with one or more shared receptor subunits. Five shared receptor subunits have been described to date: (1) the common γ chain (γ_c), (2) the common β chain shared between the IL-2 and IL-15 receptors; (3) a distinct common β chain shared between the granulocyte-macrophage colony stimulating factor (GM-CSF), IL-3, and IL-5 receptors; (4) the IL-12Rβ2 chain shared by the IL-12 and IL-23 receptors; and (5) finally the glycoprotein 130 (gp130) molecule, which participates in signaling by IL-6 and related cytokines.

CYTOKINES WITH RECEPTORS THAT INCLUDE THE γ_c CHAIN

The receptor complexes using the γ_c chain are the IL-2, IL-4, IL-7, IL-9, IL-13, IL-15, and IL-21 receptors. Two of these receptors, IL-2R and IL-15R, also use the IL-2Rβ_c chain. The γ_c chain is physically associated with Jak3, and activation of Jak3 is critical to most signaling initiated through this subset of cytokine receptors.[20]

INTERLEUKIN 2 AND INTERLEUKIN 15. IL-2 and IL-15 can each activate NK cells and stimulate proliferation of activated T cells. IL-2 is a product of activated T cells, and IL-2R is largely restricted to lymphoid cells. The *IL-15* gene is expressed by nonlymphoid tissues, and its transcription is induced by UVB radiation in keratinocytes and fibroblasts and by LPS in monocytes and dendritic cells. Multiple isoforms of IL-15Rα are found in various hematopoietic and nonhematopoietic cells. The IL-2R and IL-15R complexes of lymphocytes incorporate up to three receptor chains, whereas most other cytokine receptor complexes have two. The affinities of IL-2R and IL-15R for their respective ligands can be regulated, and to some extent, IL-2 and IL-15 compete with each other. The highest affinity receptor complexes for each ligand (approximately 10^{-11} M) consist of the IL-2Rβ_c and γ_c chains, as well as their respective α chains (IL-2Rα, also known as CD25, and IL-15Rα). γ_c and IL-2Rβ_c without the α chains form a functional lower affinity receptor for either ligand (10^{-8} to 10^{-10} M). Although both ligands transmit signals through the γ_c chain, those signals elicit overlapping but distinct responses in various cells. Activation of naive CD4 T cells by T-cell receptor and costimulatory molecules induces expression of IL-2, IL-2Rα, and IL-2Rβ_c, which leads to vigorous proliferation. Prolonged stimulation of T-cell receptor and IL-2R leads to expression of FasL and activation-induced cell death. Although IL-2 signaling facilitates the death of CD4 T cells in response to sustained exposure to antigen, IL-15 inhibits IL-2-mediated activation-induced cell death as it stimulates growth. Similarly, IL-15 promotes proliferation of memory CD8 T cells, whereas IL-2 inhibits it. IL-15 is also involved in the homeostatic survival of memory CD8 T cells, NK cells, and NK T cells. These contrasting biologic roles are illustrated by mice deficient in IL-2 or IL-2Rα that develop autoimmune disorders, and mice deficient in IL-15 or IL-15Rα, which have lymphopenia and immune deficiencies. Thus, IL-15 appears to have an important role in promoting effector functions of antigen-specific T cells, whereas IL-2 is involved in reining in autoreactive T cells.[21]

INTERLEUKIN 4 AND INTERLEUKIN 13. IL-4 and IL-13 are products of activated Th2 cells that share limited structural homology (approximately 30%) and overlapping but distinct biologic activities. A specific receptor for IL-4, which does not bind IL-13, is found on T cells and NK cells. It consists of IL-4Rα (CD124) and γ_c and transmits signals via Jak1 and Jak3. A second receptor complex that can bind either IL-4 or IL-13 is found on keratinocytes, endothelial cells, and other nonhematopoietic cells. It consists of IL-13Rα1 and IL-4Rα and transmits signals via Jak1 and Jak2. These receptors are expressed at low levels in resting cells, and their expression is increased by various activating signals. Curiously, exposure of monocytes to IL-4 or IL-13 suppresses expression of IL-4Rα and IL-13Rα1, whereas the opposite effect is observed in keratinocytes. Both signal transduction pathways appear to converge with the activation of STAT6, which is both necessary and sufficient to drive Th2 differentiation. IL-13Rα2 is a cell surface receptor homologous to IL-13Rα1 that specifically binds to IL-13 but is not known to transmit any signals.[20]

The biologic effects of engagement of the IL-4 receptor vary depending on the specific cell type, but most pertain to its principal role as a growth and differentiation factor for Th2 cells. Exposure of naive T cells to IL-4 stimulates them to proliferate and differentiate into Th2 cells, which produce more IL-4, which in turn leads to autocrine stimulation that prolongs Th2 responses. Thus the expression of IL-4 early in the immune response can initiate a cascade of Th2 cell development that results in a predominately Th2 response. The genes encoding IL-4 and IL-13 are located in a cluster with IL-5 that undergoes structural changes during Th2 differentiation that are associated with increased expression. Although naive T cells can make low levels of IL-4 when activated, IL-4

is also produced by activated NK T cells. Mast cells and basophils also release preformed IL-4 from secretory granules in response to FcεRI-mediated signals. A prominent activity of IL-4 is the stimulation of class switching of the immunoglobulin genes of B cells. Nuocytes and natural helper cells are recently identified populations of innate immune effector cells that provide an early source of IL-13 during helminth infection. As critical factors in Th2 differentiation and effector function, IL-4 and IL-13 are mediators of atopic immunity. In addition to controlling the behavior of effector cells they also act directly on resident tissue cells, such as in inflammatory airway reactions.[22]

INTERLEUKIN 9 AND INTERLEUKIN 21. IL-9 is a product of activated Th2 cells exposed to TGF-β that acts as an autocrine growth factor as well as a mediator of inflammation.[23] It is also produced by mast cells in response to IL-10 or stem cell factor. It stimulates proliferation of T and B cells and promotes expression of immunoglobulin E by B cells. It also exerts proinflammatory effects on mast cells and eosinophils. IL-9-deficient mice exhibit deficits in mast cell and goblet cell differentiation. IL-9 can be grouped with IL-4 and IL-13 as cytokines that function as effectors of allergic inflammatory processes and may play an important role in asthma and allergic disorders. IL-21 is also a product made by the Th2, Th17, and Tfh lineages that signals through a receptor composed of a specific α chain (IL-21R) homologous to the IL-4R α chain and γ_c.[24] Absence of an intact IL-21 receptor is associated with impaired Th2 responses.[25]

INTERLEUKIN 7 AND THYMIC STROMAL LYMPHOPOIETIN. Mutations abrogating the function of IL-7, IL-7Rα (CD127), γ_c, or Jak3 in mice or humans cause profound immunodeficiency as a result of T- and NK-cell depletion.[20] This is principally due to the indispensable role of IL-7 in promoting the expansion of lymphocytes and regulating the rearrangement of their antigen receptor genes. IL-7 is a potent mitogen and survival factor for immature lymphocytes in the bone marrow and thymus. The second function of IL-7 is as a modifier of effector cell functions in the reactive phase of certain immune responses. IL-7 transmits activating signals to mature T cells and certain activated B cells. Like IL-2, IL-7 has been shown to stimulate proliferation of cytolytic T cells and lymphokine-activated killer cells in vitro and to enhance their activities in vivo. IL-7 is a particularly significant cytokine for lymphocytes in the skin and other epithelial tissues. It is expressed by keratinocytes in a regulated fashion, and this expression is thought to be part of a reciprocal signaling dialog between dendritic epidermal T cells and keratinocytes in murine skin. Keratinocytes release IL-7 in response to IFN-γ, and dendritic epidermal T cells secrete IFN-γ in response to IL-7.

An IL-7-related cytokine using one chain of the IL-7 receptor as part of its receptor is thymic stromal lymphopoietin (TSLP). TSLP was originally identified as a novel cytokine produced by a thymic stromal cell line that could act as a growth factor for B- and T-lineage cells. The TSLP receptor consists of the IL-7Rα and a second receptor chain (TSLPR) homologous to but distinct from the γ_c chain. TSLP has attracted interest because of its ability to prime dendritic cells to become stronger stimulators of Th2 cells. This activity may permit TSLP to foster the development of some types of allergic diseases.[26,27]

CYTOKINES WITH RECEPTORS USING THE INTERLEUKIN 3 RECEPTOR β CHAIN

The receptors for IL-3, IL-5, and GM-CSF consist of unique cytokine-specific α chains paired with a common β chain known as *IL-3R*β or β_c (CD131). Each of these factors acts on subsets of early hematopoietic cells.[28] IL-3, which was previously known as *multilineage colony-stimulating factor*, is principally a product of CD4+ T cells and causes proliferation, differentiation, and colony formation of various myeloid cells from bone marrow. IL-5 is a product of Th2 CD4+ cells and activated mast cells that conveys signals to B cells and eosinophils. IL-5 has a costimulatory effect on B cells in that it enhances their proliferation and immunoglobulin expression when they encounter their cognate antigen. In conjunction with an eosinophil-attracting chemokine known as *CC chemokine ligand 11* or *eotaxin*, IL-5 plays a central role in the accumulation of eosinophils that accompanies parasitic infections and some cutaneous inflammatory processes. IL-5 appears to be required to generate a pool of eosinophil precursors in bone marrow that can be rapidly mobilized to the blood, whereas eotaxin's role is focused on recruitment of these eosinophils from blood into specific tissue sites. GM-CSF is a growth factor for myeloid progenitors produced by activated T cells, phagocytes, keratinocytes, fibroblasts, and vascular endothelial cells. In addition to its role in early hematopoiesis, GM-CSF has potent effects on macrophages and dendritic cells. In vitro culture of fresh Langerhans cells in the presence of GM-CSF promotes their transformation into mature dendritic cells with maximal immunostimulatory potential for naive T cells. The effects of GM-CSF on dendritic cells probably account for the dramatic ability of GM-CSF to evoke therapeutic antitumor immunity when tumor cells are engineered to express it.[29,30]

INTERLEUKIN 6 AND OTHER CYTOKINES WITH RECEPTORS USING GLYCOPROTEIN 130

Receptors for a group of cytokines including IL-6, IL-11, IL-27, leukemia inhibitory factor, oncostatin M, ciliary neurotrophic factor, and cardiotrophin-1 interact with a hematopoietin receptor family member, gp130, which does not appear to interact with any ligand by itself. The gp130 molecule is recruited into signaling complexes with other receptor chains when they engage their cognate ligands.

IL-6 is the most thoroughly characterized of the cytokines that use gp130 for signaling and serves as a paradigm for discussion of the biologic effects of this family of cytokines. IL-6 is yet another example of a highly pleiotropic cytokine with multiple effects. A series of different names (including *IFN-β_2*, *B-cell stimulatory factor 2*, *plasmacytoma growth factor*, *cytotoxic T cell differentiation factor*, and *hepatocyte-stimulating factor*) were used for IL-6 before it was recognized that a single molecular species accounts for all of these activities. IL-6 acts on a wide variety of cells of hematopoietic origin. IL-6 stimulates immunoglobulin secretion by B cells and has mitogenic effects on B lineage cells and plasmacytomas. IL-6 also promotes maturation of megakaryocytes and differentiation of myeloid cells. Not only does it participate in hematopoietic development and reactive immune responses, but IL-6 is also a central mediator of the systemic acute-phase response. Increases in circulating IL-6 levels stimulate hepatocytes to synthesize and release acute-phase proteins.

There are two distinct signal transduction pathways triggered by IL-6. The first of these is mediated by the gp130 molecule when it dimerizes on engagement by the complex of IL-6 and IL-6Rα. Homodimerization of gp130 and its associated Jak kinases (Jak1, Jak2, Tyk2) leads to activation of STAT3. A second pathway of gp130 signal transduction involves Ras and the mitogen-activated protein kinase cascade and results in phosphorylation and activation of a transcription factor originally designated *nuclear factor of IL-6*.

IL-6 is an important cytokine for skin and is subject to dysregulation in several human diseases, including some with skin manifestations. IL-6 is produced in a regulated fashion by keratinocytes, fibroblasts, and vascular endothelial cells as well as by leukocytes infiltrating the skin. IL-6 can stimulate the proliferation of human keratinocytes under some conditions. Psoriasis is one of several inflammatory skin diseases in which elevated expression of IL-6 has been described. Human herpesvirus 8 produces a viral homolog of IL-6 that may be involved in the pathogenesis of human herpes virus-8-associated diseases, including Kaposi sarcoma and body cavity-based lymphomas.

The other cytokines using gp130 as a signal transducer have diverse bioactivities. IL-11 inhibits production of inflammatory cytokines and has shown some therapeutic activity in patients with psoriasis. Exogenous IL-11 also stimulates platelet production and has been used to treat thrombocytopenia occurring after chemotherapy. IL-27 is discussed in the next section with the IL-12 family of cytokines.

INTERLEUKIN 12, INTERLEUKIN 23, INTERLEUKIN 27, AND INTERLEUKIN 35: PIVOTAL CYTOKINES REGULATING T HELPER 1 AND T HELPER 17 RESPONSES

IL-12 is different from most other cytokines in that its active form is a heterodimer of two proteins, p35 and p40. IL-12 is principally a product of antigen-presenting cells such as dendritic cells, monocytes, macrophages, and certain B cells in response to bacterial components, GM-CSF, and IFN-γ. Activated keratinocytes are an additional source of IL-12 in skin. Human keratinocytes constitutively make the p35 subunit, whereas expression of the p40 subunit can be induced by stimuli including contact allergens, phorbol esters, and UV radiation.

IL-12 is a critical immunoregulatory cytokine that is central to the initiation and maintenance of Th1 responses. Th1 responses that are dependent on IL-12 provide protective immunity to intracellular bacterial pathogens. IL-12 also has stimulatory effects on NK cells, promoting their proliferation, cytotoxic function, and the production of cytokines, including IFN-γ. IL-12 has been shown to be active in stimulating protective antitumor immunity in a number of animal models.[31]

Two chains that are part of the cell surface receptor for IL-12 have been cloned. Both are homologous to other β chains in the hematopoietin receptor family and are designated β1 and β2. The β1 chain is associated with Tyk2 and the β2 chain interacts directly with Jak2. The signaling component of the IL-12R is the β2 chain. The β2 chain is expressed in Th1 but not Th2 cells and appears to be critical for commitment of T cells to production of type 1 cytokines. IL-12 signaling induces the phosphorylation of STAT1, STAT3, and STAT4, but it is STAT4 that is essential for induction of a Th1 response.

IL-23 is a heterodimeric cytokine in the IL-12 family that consists of the p40 chain of IL-12 in association with a distinct p19 chain. IL-23 has overlapping activities with IL-12, but also induces proliferation of memory T cells. Interest in IL-23 has been sparked by the observation that IL-23 promotes the differentiation of T cells producing IL-17 (Th17 subset). The IL-23 receptor consists of two chains: (1) the IL-12Rβ1 chain that forms part of the IL-12 receptor and (2) a specific IL-23 receptor.[32]

The third member of the IL-12 family to be discovered was IL-27. IL-27 is also a heterodimer and consists of a subunit called *p28* that is homologous to IL-12 p35 and a second subunit known as *EBI3* that is homologous to IL-12 p40. IL-27 plays a role in the early induction of the Th1 response. The IL-27 receptor consists of a receptor called *WSX-1* that associates with the shared signal-transducing molecule gp130.[32,33]

The newest member of the IL-12 family is IL-35. The IL-35 heterodimer is composed of the p35 chain of IL-12 associated with the IL-27β chain EBI3. In contrast to the other IL-12 family cytokines, IL-35 is selectively made by Treg cells, promotes the growth of Treg cells, and suppresses the activity of Th17 cells.[34]

The IL-12 family of cytokines has emerged as a promising new target for anticytokine pharmacotherapy. The approach that has been developed the furthest to date is targeting both IL-12 and IL-23 with monoclonal antibodies directed against the p40 subunit that is part of both cytokines. Ustekinumab is an antihuman p40 monoclonal antibody that has shown therapeutic activity against psoriasis comparable to that of TNF inhibitors and has received FDA approval for the treatment of psoriasis.[35] The development of

anti-p40 therapies is several years behind anti-TNF-α drugs, but development of additional anti-p40 biologics for clinical use is anticipated.

LIGANDS OF THE CLASS II FAMILY OF CYTOKINE RECEPTORS

A second major class of cytokine receptors with common features includes two types of receptors for IFNs, IL-10R, and the receptors for additional IL-10- related cytokines including IL-19, IL-20, IL-22, IL-24, and IL-26.

INTERFERONS: PROTOTYPES OF CYTOKINES SIGNALING THROUGH A JAK/STAT PATHWAY

IFNs were one of the first families of cytokines to be characterized in detail. The IFNs were initially subdivided into three classes: (1) IFN-α (the leukocyte IFNs), (2) IFN-β (fibroblast IFN), and (3) IFN-γ (immune IFN). The α and β IFNs are collectively called *type I IFNs*, and all of these molecules signal through the same two-chain receptor (the IFN-αβ receptor).[36] The second IFN receptor is a distinct two-chain receptor specific for IFN-γ. Both of these IFN receptors are present on many cell types within skin as well as in other tissues. Each of the chains comprising the two IFN receptors is associated with one of the Jak kinases (Tyk2 and Jak1 for the IFN-αβR, and Jak1 and Jak2 for the IFN-γR). Only in the presence of both chains and two functional Jak kinases will effective signal transduction occur after IFN binding. A new class of IFNs known as *IFN-γ* or *type III IFNs* has now been identified that has a low degree of homology with both type I IFNs and IL-10.[37] The current members of this class are IL-28A, IL-28B, and IL-29. Although the effects of these cytokines are similar to those of the type I IFNs, they are less potent. These type III IFNs use a shared receptor that consists of the β chain of the IL-10 receptor associated with an IL-28 receptor α chain.

Viruses, double-stranded RNA, and bacterial products are among the stimuli that elicit release of the type I IFNs from cells. Plasmacytoid dendritic cells have emerged as a particularly potent cellular source of type I IFNs. Many of the effects of the type I IFNs directly or indirectly increase host resistance to the spread of viral infection. Additional effects mediated through IFN-αβR are increased expression of major histocompatibility complex (MHC) class I molecules and stimulation of NK cell activity. Not only does it have well-known antiviral effects, but IFN-α also can modulate T-cell responses by favoring the development of a Th1 type of T-cell response. Finally, the type I IFNs also inhibit the proliferation of a variety of cell types, which provides a rationale for their use in the treatment of some types of cancer. Forms of IFN-α enjoy considerable use clinically for indications ranging from hairy cell leukemia, various cutaneous malignancies, and papillomavirus infections (see Chapter 196). Some of the same conditions that respond to therapy with type I IFNs also respond to topical immunomodulatory agents like imiquimod. This synthetic imidazoquinoline drug is an agonist for the TLR7 receptor, whose natural ligand is single-stranded RNA. Imiquimod stimulation of cells expressing TLR7 elicits local release of large amounts of type I IFNs from plasmacytoid dendritic cells, which can trigger clinically useful antiviral and tumor inhibitory effects against genital warts, superficial basal cell carcinoma, and actinic keratoses. Resiquimod is a related synthetic compound that activates both TLR7 and TLR8, eliciting a slightly different spectrum of cytokines.[38]

Production of IFN-γ is restricted to NK cells, CD8 T cells, and Th1 CD4 T cells. Th1 cells produce IFN-γ after engagement of the T-cell receptor, and IL-12 can provide a strong costimulatory signal for T-cell IFN-γ production. NK cells produce IFN-γ in response to cytokines released by macrophages, including TNF-γ, IL-12, and IL-18. IFN-γ has antiviral activity, but it is a less potent mediator than the type I IFNs for induction of these effects. The major physiologic role of IFN-γ is its capacity to modulate immune responses. IFN-γ induces synthesis of multiple proteins that play essential roles in antigen presentation to T cells, including MHC class I and class II glycoproteins, invariant chain, the Lmp2 and Lmp7 components of the proteasome, and the TAP1 and TAP2 intracellular peptide transporters. These changes increase the efficiency of antigen presentation to CD4 and CD8 T cells. IFN-γ is also required for activation of macrophages to their full antimicrobial potential, enabling them to eliminate microorganisms capable of intracellular growth. Like type I IFNs, IFN-γ also has strong antiproliferative effects on some cell types. Finally, IFN-γ is also an inducer of selected chemokines (CXC chemokine ligands 9 to 11) and an inducer of endothelial cell adhesion molecules (e.g., ICAM-1 and VCAM-1). Because of the breadth of IFN-γ's activities, it comes the closest of the T-cell cytokines to behaving as a primary cytokine.

INTERLEUKIN 10: AN "ANTI-INFLAMMATORY" CYTOKINE

IL-10 is one of several cytokines that primarily exert regulatory rather than stimulatory effects on immune responses. IL-10 was first identified as a cytokine produced by Th2 T cells that inhibited cytokine production after activation of T cells by antigen and antigen-presenting cells. IL-10 exerts its action through a cell surface receptor found on macrophages, dendritic cells, neutrophils, B cells, T cells, and NK cells. The ligand-binding chain of the receptor is homologous to the receptors for IFN-α/β and IFN-γ, and signaling events mediated through the IL-10 receptor use a Jak/STAT pathway. IL-10 binding to its receptor activates the Jak1 and Tyk2 kinases and leads to the activation of STAT1 and STAT3. The effects of IL-10 on antigen-presenting cells such as monocytes, macrophages, and dendritic cells include inhibition of expression of class II MHC and costimulatory molecules (e.g., B7–1, B7–2) and decreased production of T cell-stimulating cytokines (e.g., IL-1, IL-6, and IL-12). At least four viral

genomes harbor viral homologs of IL-10 that transmit similar signals by binding to the IL-10R.[39]

A major source of IL-10 within skin is epidermal keratinocytes. Keratinocyte IL-10 production is upregulated after activation; one of the best-characterized activating stimuli for keratinocytes is UV irradiation. UV radiation-induced keratinocyte IL-10 production leads to local and systemic effects on immunity. Some of the well-documented immunosuppressive effects that occur after UV light exposure are the result of the liberation of keratinocyte-derived IL-10 into the systemic circulation. IL-10 also plays a dampening role in other types of cutaneous immune and inflammatory responses, because the absence of IL-10 predisposes mice to exaggerated irritant and contact sensitivity responses.

NOVEL INTERLEUKIN 10-RELATED CYTOKINES: INTERLEUKINS 19, 20, 22, 24, AND 26

A series of cytokines related to IL-10 have been identified and shown to engage a number of receptor complexes with shared chains.[40] IL-19, IL-20, and IL-24 transmit signals via a complex consisting of IL-20Rα and IL-20Rβ. IL-22 signals through a receptor consisting of IL-22R and IL-10Rβ. The receptors for these IL-20 family cytokines are preferentially expressed on epithelial cells including keratinocytes. Increased expression of these cytokines and their receptors is associated with psoriasis. The IL-20 family cytokines have profound effects on the proliferation and differentiation of human keratinocytes in culture.[41] Transgenic mice overexpressing IL-20, IL-22, or IL-24 develop epidermal hyperplasia and abnormal keratinocyte differentiation.[42] All of these findings point to a significant role for these cytokines in the epidermal changes associated with cutaneous inflammation. T cells producing IL-22 that elaborate a distinct set of cytokines from Th1, Th2 and Th17 cells have been isolated from the epidermis of patients with psoriasis and other inflammatory skin disorders. The IL-22 produced by these T cells promotes keratinocyte proliferation and epidermal acanthosis.[43,44]

TRANSFORMING GROWTH FACTOR-β FAMILY AND ITS RECEPTORS

TGF-β1 was first isolated as a secreted product of virally transformed tumor cells capable of inducing normal cells in vitro to show phenotypic characteristics associated with transformation. Over 30 additional members of the TGF-β family have now been identified. They can be grouped into several families: the prototypic TGF-βs (TGF-β1 to TGF-β3), the bone morphogenetic proteins, the growth/differentiation factors, and the activins. The TGF name for this family of molecules is somewhat of a misnomer, because TGF-β has antiproliferative rather than proliferative effects on most cell types. Many of the TGF-β family members play an important role in development, influencing the differentiation of uncommitted cells into specific lineages. TGF-β family members are made as precursor proteins that are biologically inactive until a large prodomain is cleaved. Monomers of the mature domain of TGF-β family members are disulfide linked to form dimers that strongly resist denaturation.

Participation of at least two cell surface receptors (type I and type II) with serine/threonine kinase activity is required for biologic effects of TGF-β.[45] Ligand binding by the type II receptor (the true ligand-binding receptor) is associated with the formation of complexes of type I and type II receptors. This allows the type II receptor to phosphorylate and activate the type I receptor, a "transducer" molecule that is responsible for downstream signal transduction. Downstream signal transmission from the membrane-bound receptors in the TGF-β receptor family to the nucleus is primarily mediated by a family of cytoplasmic Smad proteins that translocate to the nucleus and regulate transcription of target genes.

TGF-β has a profound influence on several types of immune and inflammatory processes. An immunoregulatory role for TGF-β1 was identified in part through analysis of TGF-β1 knockout mice that develop a wasting disease at 20 days of age associated with a mixed inflammatory cell infiltrate involving many internal organs. This phenotype is now appreciated to be a result in part of the compromised development of regulatory T cells when TGF-β1 is not available. Development of cells in the dendritic cell lineage is also perturbed in the TGF-β1-deficient mice, as evidenced by an absence of epidermal Langerhans cells and specific subpopulations of lymph node dendritic cells. TGF-β-treated fibroblasts display enhanced production of collagen and other extracellular matrix molecules. In addition, TGF-β inhibits the production of metalloproteinases by fibroblasts and stimulates the production of inhibitors of the same metalloproteinases (tissue inhibitors of metalloproteinase, or TIMPs). TGF-β may contribute to the immunopathology of scleroderma through its profibrogenic effects.[46]

CHEMOKINES: SECONDARY CYTOKINES CENTRAL TO LEUKOCYTE MOBILIZATION

Chemokines are a large superfamily of small cytokines that have two major functions. First, they guide leukocytes via chemotactic gradients in tissue. Typically, this is to bring an effector cell to where its activities are required. Second, a subset of chemokines has the capacity to increase the binding of leukocytes via their integrins to ligands at the endothelial cell surface, which facilitates firm adhesion and extravasation of leukocytes in tissue. The activities of this important class of cytokines are sufficiently complex that they are the subject of a separate chapter (Chapter 12).

CYTOKINE NETWORK—THERAPEUTIC IMPLICATIONS AND APPLICATIONS

This chapter has attempted to bring some degree of order and logic to the analysis of a field of human biology that continues to grow at a rapid rate. Although many things may change in the world of cytokines, certain key concepts have stood the test of time. Principal among them is the idea that cytokines are emergency molecules, designed to be released locally and transiently in tissue microenvironments. When cytokines are released persistently, the result is typically chronic disease. One potential way to treat such diseases is with cytokine antagonists or other drugs that target cytokines or cytokine-mediated pathways.

Cytokines and cytokine antagonists are being used therapeutically by clinicians, and development of additional agents continues. With certain notable exceptions, systemic cytokine therapy has been disappointing and is often accompanied by substantial morbidity. In contrast, local and transient administration of cytokines may yield more promising results. An example of this approach is the transduction of tumor cells to express GM-CSF to create the therapeutic cancer vaccines that are capable of boosting antitumor immune responses.[30] Conversely, multiple biologics that specifically block cytokine activity have been developed and approved for clinical use. Antibodies and TNF receptor–Fc fusion proteins are FDA-approved antagonists of TNF-α activity that are highly effective at inducing durable remissions in psoriasis (see Chapters 18 and 234). Antibodies against the p40 subunit shared by IL-12 and IL-23 are also active in treating psoriasis. An IL-1 receptor-Fc fusion protein, an antibody to IL-1β, and recombinant IL-1Ra are all effective therapy for patients with the cryopyrin-associated periodic syndromes. IL-1Ra is FDA-approved for treatment of adult rheumatoid arthritis. A class of pharmacologic agents that inhibits the production of multiple T cell-derived cytokines is the calcineurin inhibitors. Tacrolimus and pimecrolimus both bind to the immunophilin FK-506 binding protein-12 (FKBP-12), producing complexes that bind to calcineurin, a calcium-dependent phosphatase that acts on proteins in the nuclear factor of activated T-cells (NFAT) family to promote their nuclear translocation and activation of cytokine genes (including IL-2, IL-4, and IFN-γ)[47] (see Chapters 221 and 233). Finally, fusion toxins linked to cytokines, such as the IL-2 fusion protein denileukin diftitox, exploit the cellular specificity of certain cytokine–receptor interactions to kill target cells (see Chapter 234). Denileukin diftitox is FDA approved for the treatment of cutaneous T-cell lymphoma and has also shown therapeutic activity in other types of lymphoid malignancies.[48] Each of the aforementioned approaches is still relatively new and open to considerable future development. An understanding of cytokines by clinicians of the future is likely to be central to effective patient care.

Chapter 12 :: Chemokines

:: Anke S. Lonsdorf & Sam T. Hwang

CHEMOKINES AT A GLANCE

- Chemokines and their receptors are vital mediators of cellular trafficking.
- Most chemokines are small proteins with molecular weights in the 8- to 10-kDa range.
- Chemokines are synthesized constitutively in some cells and can be induced in many cell types.
- Chemokines play roles in inflammation, angiogenesis, neural development, cancer metastasis, hematopoiesis, and infectious disease.
- In skin, chemokines play important roles in atopic dermatitis, psoriasis, melanoma, melanoma metastasis, and some viral (including retroviral) infections.
- Promising therapeutic applications of chemokines include the prevention of T-cell arrest on activated endothelium or blocking infection of T cells by human immunodeficiency virus 1 using CC chemokine receptor 5 analogs.

INTRODUCTION

The skin is an organ in which the migration, influx, and egress of leukocytes occur in both homeostatic and inflammatory processes. Chemokines and their receptors are accepted as vital mediators of cellular trafficking. Since the discovery of the first *chemo*attractant cyto*kine* or chemokine in 1977, 50 additional new chemokines and 17 chemokine receptors have been discovered. Most chemokines are small proteins with molecular weights in the 8–10 kDa range and are synthesized constitutively in some cells and can be induced in many cell types by cytokines. Initially associated only with recruitment of leukocyte subsets to inflammatory sites,[1] it has become clear that chemokines play roles in angiogenesis, neural development, cancer metastasis, hematopoiesis, and infectious diseases. This chapter will focus primarily on the function of chemokines in inflammatory conditions, but will also touch upon the role of these molecules in other settings as well.

An overview of the structure of chemokines and chemokine receptors will be provided that will detail the molecular signaling pathways initiated by the binding of a chemokine to its cognate receptor. Expression patterns of chemokine receptors will be detailed because of the many types of immune cells that potentially can be recruited to skin under inflammatory conditions. Individual chemokine receptors will be highlighted in regard to biologic function, including facilitation of migration of effector T cells into the skin and the egress of antigen-presenting cells out of the skin. Finally, the roles of chemokines and their receptors in several cutaneous diseases—atopic dermatitis, psoriasis, cancer, and infectious disease—provide a better idea of the diversity of chemokine function in skin.

STRUCTURE OF CHEMOKINES

Chemokines are grouped into four subfamilies based on the spacing of amino acids between the first two cysteines. The CXC chemokines (also called α-chemokines) show a C–X–C motif with one nonconserved amino acid between the two cysteines. The other major subfamily of chemokines lacks the additional amino acid and is termed the CC subfamily (or β-chemokines). The two remaining subfamilies contain only one member each: the C subfamily is represented by lymphotactin, and fractalkine is the only member of the CXXXC (or CX3C) subfamily. Chemokines can also be assigned to one of two broad and, perhaps, overlapping functional groups. One group (e.g., RANTES, MIP-1α/β LARC, etc.) mediates the attraction and recruitment of immune cells to sites of active inflammation while other (e.g., SLC and SDF-1) appear to play a role in constitutive or homeostatic migration pathways.[2]

The complexity and redundancy in the nomenclature of chemokines has led to the proposal for a systematic nomenclature for chemokines based on the type of chemokine (C, CXC, CX3C, or CC) and a number based on the order of discovery as proposed by Zlotnik and Yoshie.[2] For example, stromal-derived factor-1 (SDF-1), a CXC chemokine, has the systematic name CXCL12. Because both nomenclatures are still in wide use, the original names (abbreviated in most cases) as well as systematic names will be used interchangeably throughout the chapter. Table 12-1 provides a list of chemokine receptors of interest in skin that are discussed in this chapter as well as the major chemokine ligands that bind to them.

Chemokines are highly conserved and have similar secondary and tertiary structure. Based on crystallography studies, a disordered amino terminus followed by three conserved antiparallel β-pleated sheets is a common structural feature of chemokines. Fractalkine is unique in that the chemokine domain sits atop a mucin-like stalk tethered to the plasma membrane via a transmembrane domain and short cytoplasmic tail.[30] Although CXC and CC chemokines form multimeric structures under conditions required for structural studies, these associations may be relevant only when

TABLE 12-1
Chemokine Receptors in Skin Biology

Chemokine Receptor	Chemokine Ligand	Expression Pattern	Comments	References
CCR1	MIP-1α (CCL3), RANTES (CCL5), MCP-3 (CCL7)	T, Mo, DC, NK, B	Migration of DC and monocytes; strongly upregulated in T cells by IL-2	12
CCR2	MCP-1 (CCL2),-3,-4 (CCL13)	T, Mo	Migration of T cells to inflamed sites; replenish LC precursors in epidermis; involved in skin fibrosis via MCP-1	3–5
CCR3	Eotaxin (CCL11) >RANTES, MCP-2 (CCL8),3,4	Eo, Ba, Th2, K	Migration of Th2 T cells and "allergic" immune cells	6,7
CCR4	TARC (CCL17), MDC (CCL22)	T (benign and malignant)	Expression in Th2 > Th1 cells; highly expressed on CLA^+ memory T cells; TARC expression by keratinocytes may be important in atopic dermatitis; may guide trafficking of malignant as well as benign inflammatory T cells	8–12
CCR5	RANTES, MIP-1α,β (CCL3,4)	T, Mo, DC	Marker for Th1 cells; migration to acutely inflamed sites; may be involved in transmigration of T cells through endothelium; major HIV-1 fusion coreceptor	3,13
CCR6	LARC (CCL20)	T, DC, B	Expressed by memory, not naive, T cells; possibly involved in arrest of memory T cells to activated endothelium and recruitment of T cells to epidermis in psoriasis	76,77,82
CCR7	SLC (CCL21), ELC (CCL19)	T, DC, B, melanoma cells	Critical for migration of naive T cells and "central memory" T cells to secondary lymphoid organs; required for mature DC to enter lymphatics and localize to lymph nodes; facilitates nodal metastasis	14–18
CCR9	Thymus-expressed chemokine (CCL25)	T, melanoma cells	Associated with melanoma small bowel metastases	19
CCR10	CTACK (CCL27)	T (benign and malignant), melanoma cells	Preferential response of CLA+ T cells to CTACK in vitro; may be involved in T cell (benign as well as malignant) homing to epidermis, where CTACK is expressed; survival of melanoma is skin	20–23
CXCR1,2	IL-8 (CXCL8), MGSA/ GRO α (CXCL1), ENA-78 (CXCL5)	N, NK, En, melanoma cells	Recruitment of neutrophils (e.g., epidermis in psoriasis); may be involved in angiogenesis; melanoma growth factor	24–26
CXCR3	IP-10 (CXCL10), Mig (CXCL9), I-TAC (CXCL11)	T	Marker for Th1 Cells and may be involved in T cell recruitment to epidermis in CTCL; induces arrest of activated T cells on stimulated endothelium	27,28
CXCR4	SDF-1α,β (CXCL12)	T, DC, En, melanoma cells	Major HIV-1 fusion coreceptor; involved in vascular formation; involved in melanoma metastasis to lungs	3,29
CX3CR1	Fractalkine (CX3CL1)	T, Mo, MC, NK	May be involved in adhesion on activated T cells, Mo, NK cells to activated endothelium	30,31

GRO = growth regulated oncogene; MGSA = melanoma growth stimulatory activity; Mig = monokine-induced by IFN-γ; I-TaC = interferon-inducible T-cell alpha chemoattractant; SDF = stromal-derived factor; MCP = monocyte chemattractant protein; MIP = macrophage inflammatory protein; RANTES = regulated upon activation, normal T cell expressed and secreted; IL-8 = interleukin-8; TARC = thymus and activation-regulated chemokine; LARC = liver and activation-regulated chemokine (also known as MIP-3α); SLC = secondary lymphoid-tissue chemokine; MDC = macrophage-derived chemokine; CTACK = cutaneous T cell attracting chemokine; T = T cells; Mo = monocytes; DC = dendritic cells; Eo = eosinophils; Ba = basophils; B = B cells; En = endothelial cells; Th1,2 = T helper 1,2 cell; N = neutrophils; MC = mast cells; NK = natural killer cells; CLA = cutaneous lymphocyte-associated antigen; HIV = human immunodeficiency virus.

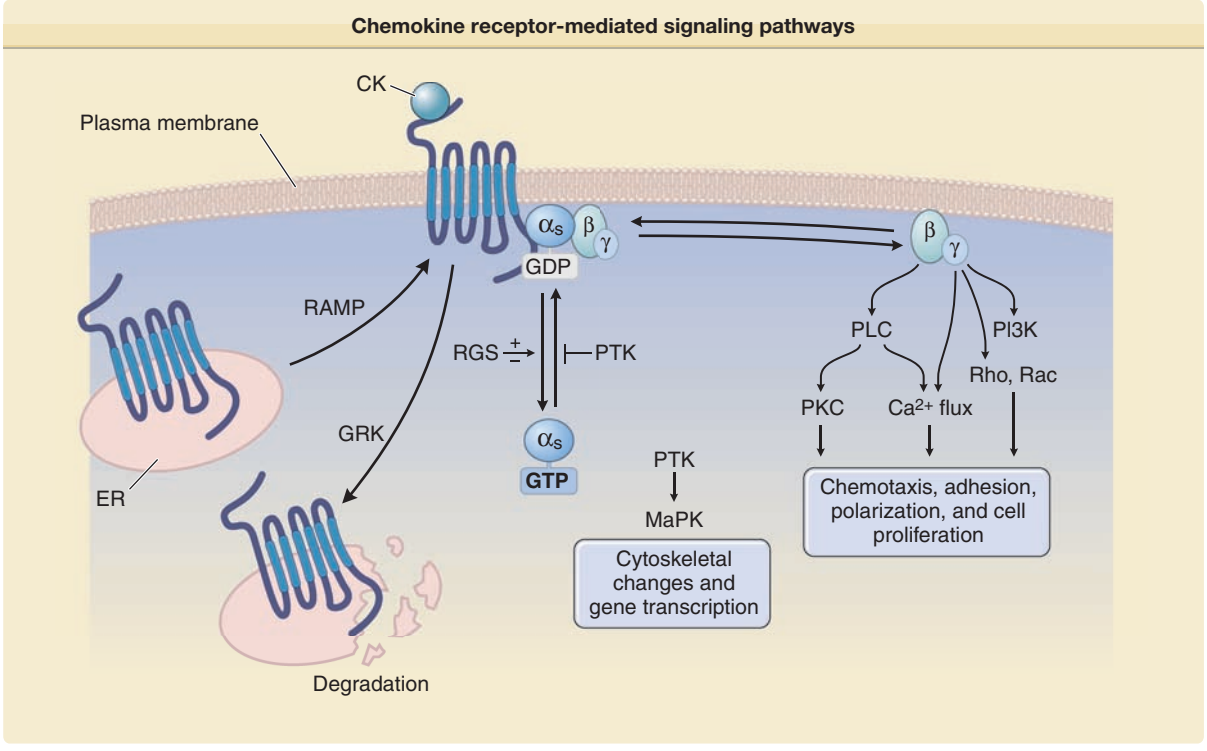

Figure 12-1 Chemokine receptor-mediated signaling pathways. RAMP = receptor-activity-modifying protein; RGS = regulator of G-protein signaling; GRK = G-protein coupled receptor kinase; DG = 1,2-diacylglycerol; PLC = phospholipase C; PIP2 = phosphatidylinositol-4,5-bisphosphate; IP3 = inositol-1,4,5-triphosphate; PKC = protein kinase C; CK = chemokine; PTX = pertussis toxin; ER = endoplasmic reticulum; PTK = protein tyrosine kinase(s); MAPK = Mitogen activated protein kinase.

chemokines associate with cell-surface components such as glycosaminoglycans (GAGs) or proteoglycans. Since most chemokines have a net positive charge, these proteins tend to bind to negatively charged carbohydrates present on GAGs. Indeed the ability of positively charged chemokines to bind to GAGs is thought to enable chemokines to preferentially associate with the lumenal surface of blood vessels despite the presence of shear forces from the blood that would otherwise wash the chemokines away.

CHEMOKINE RECEPTORS AND SIGNAL TRANSDUCTION

Chemokine receptors are seven transmembrane spanning membrane proteins that couple to intracellular heterotrimeric G-proteins containing α, β, and γ subunits.[2] They represent a part of a large family of G-protein coupled receptors (GPCR), including rhodopsin, that have critical biologic functions. Leukocytes express several Gα protein subtypes: s, i, and q, while the β and γ subunits each have 5 and 11 known subtypes, respectively. This complexity in the formation of the heterotrimeric G-protein may account for specificity in the action of certain chemokine receptors. Normally G-proteins are inactive when GDP is bound, but they are activated when the GDP is exchanged for GTP (Fig. 12-1). After binding to a ligand, chemokine receptors rapidly associate with G-proteins, which in turn increases the exchange of GTP for GDP. Pertussis toxin is a commonly used inhibitor of GPCR that irreversibly ADP-ribosylates Gα subunits of the α_i class and subsequently prevents most chemokine receptor-mediated signaling.

Activation of G-proteins leads to the dissociation of the G_α and $G_{\beta\gamma}$ subunits (Fig. 12-1). The G_α subunit has been observed to activate protein tyrosine kinases and mitogen-activated protein kinase, leading to cytoskeletal changes and gene transcription. The G_α subunit retains GTP, which is slowly hydrolyzed by the GTPase activity of this subunit. This GTPase activity is both positively and negatively regulated by GTPase-activating proteins [also known as regulator of G-protein signaling (RGS) proteins]. The $G_{\beta\gamma}$ dimer initiates critical signaling events in regard to chemotaxis and cell adhesion. It activates phospholipase C (PLC)[32] leading to formation of diacylglycerol (DAG) and inositol triphosphate [Ins(1,4,5)P_3]. Ins(1,4,5)P_3 stimulates Ca^{2+} entry into the cytosol, which along with DAG, activates protein kinase C isoforms. While the $G_{\beta\gamma}$ subunits have been shown to be critical for chemotaxis, the $G_{\alpha\alpha}$ subunit has no known role in chemotactic migration. There is also evidence that binding of chemokine receptors results in the activation of other intracellular effectors including Ras and Rho, phosphatidylinositol-3-kinase [PI(3)K].[33]

RhoA and protein kinase C appear to play a role in integrin affinity changes, while PI(3)K may be critical for changes in the avidity state of LFA-1. Other proteins have been found that regulate the synthesis, expression, or degradation of G-protein coupled receptors. For example, receptor-activity-modifying proteins (RAMPS) act as chaperones of seven transmembrane spanning receptors and regulate surface expression as well as the ligand specificity of chemokine receptors (Fig. 12-1). Importantly, after chemokine receptors are exposed to appropriate ligands, they are frequently internalized, leading to an inability of the chemokine receptor to mediate further signaling. This downregulation of chemokine function, which has been termed "desensitization," occurs because of phosphorylation of Ser/Thr residues in the *C*-terminal tail by proteins termed GPCR kinases (GRK) and subsequent internalization of the receptor (Fig. 12-1). Desensitization may be an important mechanism for regulating the function of chemokine receptors by inhibiting cell migration as leukocytes arrive at the primary site of inflammation.

CHEMOKINES AND CUTANEOUS LEUKOCYTE TRAFFICKING

Generally speaking, chemokines are thought to play at least three different roles in the recruitment of host defense cells, predominantly leukocytes, to sites of inflammation.[34] First, they provide the signal or signals required to cause leukocytes to come to a complete stop (i.e., arrest) in blood vessels at inflamed sites such as skin. Second, chemokines have been shown to have a role in the transmigration of leukocytes from the lumenal side of the blood vessel to the ablumenal side. Third, chemokines attract leukocytes to sites of inflammation in the dermis or epidermis following transmigration. Keratinocytes and endothelial cells are a rich source of chemokines when stimulated by appropriate cytokines. In addition, chemokines and their receptors are known to play critical roles in the emigration of resident skin dendritic cells (i.e., Langerhans cells and dermal dendritic cells) from the skin to draining lymph nodes (LN) via afferent lymphatic vessels, a process that is essential for the development of acquired immune responses.

This section will be divided into three subsections. The first will introduce basic concepts of how all leukocytes arrest in inflamed blood vessels prior to transmigration by introducing the multistep model of leukocyte recruitment. The second will detail mechanisms of T cell migration, while the final subsection will focus on the mechanisms by which chemokines mediate the physiological migration of DC from the skin to regional LN.

THE MULTISTEP MODEL OF LEUKOCYTE RECRUITMENT

In order for leukocytes to adhere and migrate to peripheral tissues, they must overcome the pushing force of the vascular blood stream as they bind to activated endothelial cells at local sites of inflammation. According to the multistep or cascade model of leukocyte recruitment (Fig. 12-2), one set of homologous adhesion molecules termed *selectins* mediates the transient attachment of leukocytes to endothelial cells while another set of adhesion molecules termed *integrins* and their receptors (*immunoglobulin superfamily members*) mediates stronger binding (i.e., arrest) and transmigration.[35] The selectins (E-, L-, and P-selectins) are members of a larger family of carbohydrate-binding proteins termed lectins. The selectins bind their respective carbohydrate ligands located on protein scaffolds and thus mediate the transient binding or "rolling" of leukocytes on endothelial cells.

The skin-associated vascular selectin known as E-selectin is upregulated on endothelial cells by inflammatory cytokines such as tumor necrosis factor (TNF)-α and binds to sialyl Lewis x-based carbohydrates. E-selectin ligands form distinct epitopes known as the cutaneous lymphocyte-associated antigen (CLA). CLA is expressed by 10%–40% of memory T cells and has been suggested as a marker for skin-homing T cells.[36] At least two chemokine receptors (CCR10 and CCR4) show preferential expression in CLA^+ memory T cells.[8,20] While E-selectin is likely to be an important component of skin-selective homing, there is also evidence to suggest that L-selectin is involved in T cell migration to skin.[37,38]

In the second phase of this model, leukocyte integrins such as those of the β_2 family must be "turned on" or activated from their resting state in order to bind to their counter receptors such as intercellular adhesion molecule-1 (ICAM-1) that are expressed by endothelial cells. A vast array of data suggest that the binding of chemokines to leukocyte chemokine receptors plays a critical role in activating both β1 and β2 integrins.[33,39] Activation of chemokine receptors leads to a complex signaling cascade (Fig. 12-1) that causes a conformational change in individual integrins that leads to increases in the affinity and avidity of individual leukocyte integrins for their ligands. Furthermore, later steps of migration (i.e., transmigration or diapedesis) have been shown to be dependent on chemokines as well in selective cases.[13] In the case of neutrophils, their ability to roll on inflamed blood vessels likely depends on their expression of L-selectin and E-selectin ligands while their arrest on activated endothelia likely depends on their expression of CXCR1 and CXCR2 as described below for wound healing. Integrin activation via chemokine-mediated signals appears to be more complex in T cells, which appear to use multiple chemokine receptors, and is described in more detail below.

CHEMOKINE-MEDIATED MIGRATION OF T CELLS

Antigen-inexperienced T cells are termed naive and can be identified by expressing three cell surface proteins: CD45RA (an isoform of the pan-leukocyte marker), L-selectin, and the chemokine receptor CCR7. These T cells migrate efficiently to secondary LN,

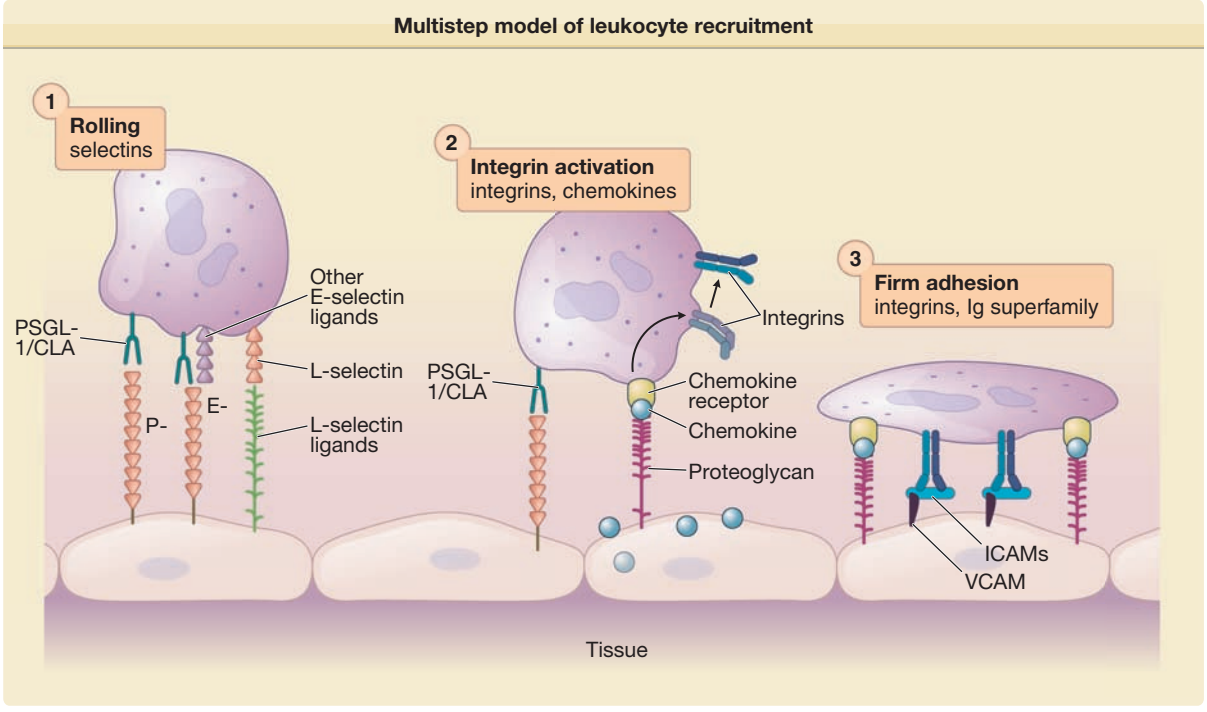

Figure 12-2 Multistep model of leukocyte recruitment. Leukocytes, pushed by the blood stream, first transiently bind or "roll" on the surface of activated endothelial cells via rapid interactions with P-, E-, or L-selectin. Chemokines are secreted by endothelial cells and bind to proteoglycans that present the chemokine molecules to chemokine receptors on the surface of the leukocyte. After chemokine receptor ligation, intracellular signaling events lead to a change in the conformation of integrins and changes in their distribution on the plasma membrane resulting in "Integrin Activation." These changes result in high affinity/avidity binding of integrins to endothelial cell intercellular adhesion molecules (ICAMs) and vascular cell adhesion molecule-(VCAM)-1 in a step termed "Firm Adhesion," which is then followed by transmigration of the leukocyte between endothelial cells and into tissue.

where they may make contact with antigen-bearing dendritic cells from the periphery. Once activated by dendritic cells presenting antigen, T cells then express CD45RO, are termed "memory" T cells, and appear to express a variety of adhesion molecules and chemokine receptors, which facilitate their extravasation from blood vessels to inflamed peripheral tissue. A specific subset of $CCR7^{-}$, L-selectin memory T cells has been proposed to represent an effector memory T cell subset that is ready for rapid deployment at peripheral sites in terms of their cytotoxic activity and ability to mobilize cytokines.[14]

Although chemokines are both secreted and soluble, the net positive charge on most chemokines allows them to bind to negatively charged proteoglycans such as heparin sulfate that are present on the lumenal surface of endothelial cells, thus allowing them to be presented to T cells as they roll along the lumenal surface (Fig. 12-2). After ligand binding, chemokine receptors send intracellular signals that lead to increases in the affinity and avidity of T-cell integrins such as LFA-1 and VLA-4 for their endothelial receptors ICAM-1 and VCAM-1, respectively.[40] Only a few chemokine receptors (CXCR4, CCR7, CCR4, and CCR6) are expressed at sufficient levels on resting peripheral blood T cells to mediate this transition. With activation and IL-2 stimulation, increased numbers of chemokine receptors (e.g., CXCR3) are expressed on activated T cells, making them more likely to respond to other chemokines. In several different systems, inhibition of specific chemokines produced by endothelial cells or chemokine receptors found on T cells dramatically influences T cell arrest in vivo and in vitro.[41]

CXCR3 serves as a receptor for chemokine ligands Mig, IP-10, and I-Tac. All three of these chemokines are distinguished from other chemokines by being highly upregulated by interferon-γ. Resting T cells do not express functional levels of CXCR3, but upregulate this receptor with activation and cytokines such as IL-2. Once expressed on T cells, CXCR3 is capable of mediating arrest of memory T cells on activated endothelial cells.[27] The expression of its chemokine ligands is strongly influenced by the cytokine interferon-γ, which synergistically works with pro-inflammatory cytokines such as TNF-α to increase expression of these ligands by activated endothelial cells[27] and epithelial cells.

In general, activation of T cells by cytokines such as IL-2 is associated with the enhanced expression of CCR1, CCR2, CCR5, and CXCR3. Just as Th1 and Th2 (T cell) subsets have different functional roles, it might have been predicted that these two subsets of T cells would express different chemokine receptors. Indeed, CCR4[9,42,43] and CCR3[6] are associated with Th2 cells in vitro while Th1 cells are associated with CCR5 and CXCR3.[44]

In some instances, chemokine receptors may be regarded as functional markers that characterize distinct T helper cell subsets while also promoting their recruitment to inflammatory sites characterized by "allergic" or "cell-mediated" immune responses, respectively. When T cells are activated in vitro in the presence of Th1-promoting cytokines, CXCR3 and CCR5 appear to be highly expressed, while in the presence of Th2-promoting cytokines, CCR4, CCR8, and CCR3 expression predominates. In rheumatoid arthritis, a Th1-predominant disease, many infiltrating T cells express CCR5 and CXCR3[45] whereas, in atopic disease, CCR4 expressing T cells may be more frequent.[9] CCR6 has recently been described as a marker for a newly characterized T-helper subset, expressing the hallmark effector cytokines IL-17 and IL-22.[46] These so-called Th17 cells play a central role in the pathogenesis of psoriasis and other chronic inflammatory autoimmune diseases.[47] However, in normal skin, the majority of skin resident T cells also coexpress CCR6, suggesting that CCR6 and CCL20 interactions regulate T cell infiltration in the skin under inflammatory as well as homeostatic conditions.[48]

While certain chemokine receptors characterize distinct T-cell subsets, flexible regulation of their expression may increase the migratory potential of circulating T cells to diverse tissues. For example, under some conditions, both Th1 and Th2 type T cells can express CCR4.[43] Similarly, T regulatory cells (Treg) and Th17 cells share chemokines receptors with other T cell lineages but may alter their chemokine receptor expression profiles, depending on the microenvironment in which they are activated.[49]

The epidermis is a particularly rich source of chemokines, including RANTES, MIP-3α (CCL20), MCP-1, IP-10, IL-8, LARC, and TARC, which likely contribute to epidermal T cell migration. Keratinocytes from patients with distinctive skin diseases appear to express unique chemokine expression profiles. For instance, keratinocytes derived from patients with atopic dermatitis synthesized mRNA for RANTES at considerably earlier time points in response to IL-4 and TNF-α in comparison to healthy individuals and psoriatic patients.[50] Keratinocytes derived from psoriatic patients synthesized higher levels of IP-10 with cytokine stimulation as well as higher constitutive levels of IL-8,[50] a chemokine known to recruit neutrophils. IL-8 may contribute to the large numbers of neutrophils that localize to the suprabasal and cornified layers of the epidermis in psoriasis. IP-10 may serve to recruit activated T cells of the Th1 helper phenotype to the epidermis and has been postulated to have a role in the recruitment of malignant T cells to the skin in cutaneous T cell lymphomas.[28]

CTACK/CCL27 is selectively and constitutively expressed in the epidermis, and its expression is only marginally increased under inflammatory conditions.[21] Interestingly, CTACK has been reported to preferentially attract CLA^+ memory T cells in vitro[21] and has been demonstrated to play a role in the recruitment and function of skin-homing T cells in inflammatory disease models.[51,52]

CHEMOKINES IN THE TRAFFICKING OF DENDRITIC CELLS FROM SKIN TO REGIONAL LYMPH NODES

Antigen-presenting cells, including dendritic cells (DC) of the skin, are critical initiators of immune responses and their trafficking patterns are thought to influence immunological outcomes. Their mission includes taking up antigen at sites of infection or injury and bringing these antigens to regional LN where they both present antigen and regulate the responses of T and B cells. Skin-resident DCs are initially derived from hematopoietic bone marrow progenitors[53] and migrate to skin during the late prenatal and newborn periods of life. Under resting (steady state) conditions, homeostatic production by keratinocytes of CXCL14 (receptor unknown) may be involved in attracting $CD14^+$ DC precursors to the basal layer of the epidermis.[54] Similarly, Langerhans cells (LC) as well as CD1c+ LC precursors are strongly chemoattracted to keratinocyte-derived CCL20.[55] Under inflammatory conditions, when skin-resident DC and LC leave the skin in large numbers, keratinocytes release a variety of chemokines, including CCL2 and CCL7 (via CCR2)[4] and CCL20 (via CCR6),[56] which may attract monocyte-like DC precursors to the epidermis in order to replenish the LC population.

When activated by inflammatory cytokines (e.g., TNF-α and IL-1β), lipopolysaccharide, or injury, skin DC, including LC, leave the epidermis, enter afferent lymphatic vessels, and migrate to draining regional LN where they encounter both naive and memory T cells. Chemokines guide the DC on this journey. Activated DC specifically upregulate expression of CCR7, which binds to secondary lymphoid tissue chemokine (SLC/CCL21), a chemokine expressed constitutively by lymphatic endothelial cells[15,57] (eFig. 12-2.1 in online edition). SLC guides DC into dermal lymphatic vessels and helps retain them in SLC-rich regional draining LN (Fig. 12-3).[58]

Interestingly, naive T cells also strongly express CCR7 and use this receptor to arrest on high endothelial venules.[59] The importance of the CCR7 pathway is demonstrated by LC from CCR7 knockout mouse that demonstrate poor migration from the skin to regional LN[16] and by the observation that antibodies to SLC block migration of DC from the periphery to LN.[15] Thus, CCR7 and its ligands facilitate the recruitment of at least two different kinds of cells—naive T cells and DC—to the LN through two different routes under both inflammatory[16] and resting conditions.[58]

After DC reach the LN, they must interact with T cells to form a so-called "immunological synapse" that is critical for T cell activation. Activated DC secrete a number of chemokines, including macrophage-derived chemokine (MDC),[60] which attracts T cells to the vicinity of DC and promotes adhesion between the two cell types.[61,62] CCR5 (via CCL3/4) has also been identified as mediating recruitment of naive CD8+ T

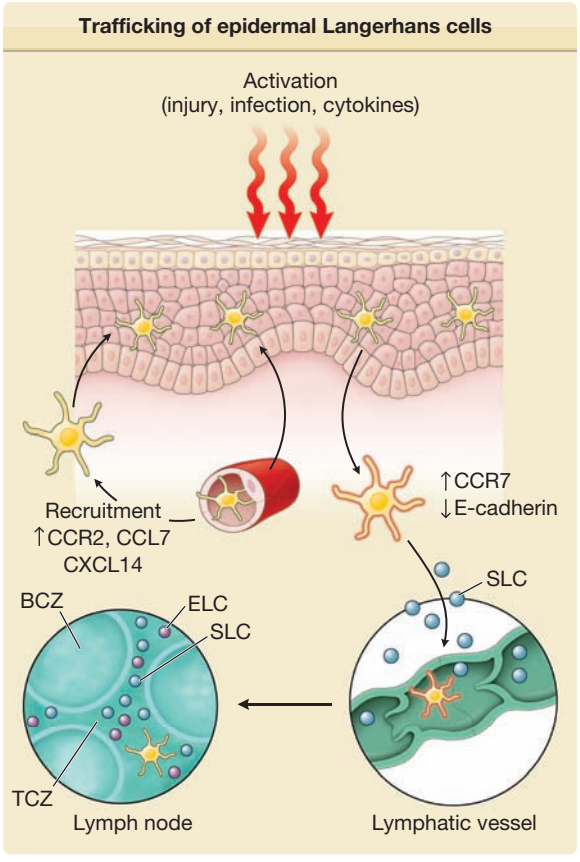

Figure 12-3 Trafficking of epidermal Langerhans cells to regional lymph nodes. Langerhans cells are activated by a variety of stimuli including injury, infectious agents, and cytokines such as IL-1α and TNF-α. Having sampled antigens, the activated LC downregulate E-cadherin and strongly upregulate CCR7. Sensing the CCR7-ligand, SLC (●), produced by lymphatic endothelial cells, the LC migrate into lymphatic vessels, passively flow to the lymph nodes, and stop in the T-cell zones (TCZ) that are rich in two CCR7 ligands, SLC and ELC. Note that chemokines also contribute to the recruitment of LC under both resting and inflammatory conditions. BCZ, B-cell zones.

cells to aggregates of antigen-specific $CD4^+$ T cells and DC.[63] Therefore, chemokines orchestrate a complex series of migration patterns bringing both DC and T cells to the confines of the LN, where expression of chemokines by DC themselves appears to be a direct signal for binding of the T cell (Fig. 12-3).

CHEMOKINES IN DISEASE

ATOPIC DERMATITIS

Atopic dermatitis is a prototypical Th2-mediated, allergic skin disease with multifactorial genetic and environmental factors involved in its pathogenesis. Although multiple chemokines have been associated with the atopic phenotype, the roles of CCR4 and CCR10 in AD have been particularly well documented.[64] Clinical data from humans as well as experimental data in the NC/Nga mouse model of atopic dermatitis suggest that the Th2-associated chemokine receptor, CCR4, in conjunction with its ligand, TARC/CCL17, may play a role in recruiting T cells to atopic skin. In patients with atopic dermatitis, $CLA^+CCR4^+CCR10^+$ lymphocytes were found to be increased in the peripheral blood and in lesional skin compared to controls.[9] Moreover, serum levels of TARC/CCL17 and CTACK/CCL27 in atopic dermatitis patients were significantly higher than concentrations found in healthy or psoriatic controls and correlated with disease severity.[10]

CCL18, whose receptor is currently unknown, has been reported to be expressed at higher levels in the skin of patients with atopic disease compared to psoriasis.[65] CCL18 is produced by antigen-presenting cells and attracts CLA^+ memory T cells to the skin.[66] Elevated levels of CCL18 can be found in the skin and sera of patients with AD but show a significant decrease after therapy.[67] Of note, CCL18 and another chemokine, CCL1 (produced by mast cells and endothelial cells), are elicited in volunteer skin after topical challenge with dust mite allergen and *Staphylococcal superantigen*.[65,68]

The recruitment of eosinophils to skin is a frequently observed finding in allergic skin diseases, including atopic dermatitis and cutaneous drug reactions, and likely is mediated by chemokines. Eotaxin/CCL11 was initially isolated from the bronchoalveolar fluid of guinea pigs after experimental allergic inflammation and binds primarily to CCR3, a receptor expressed by eosinophils,[69] basophils, and Th2 cells.[6] Injection of eotaxin into the skin promotes the recruitment of eosinophils while anti-eotaxin antibodies delay the dermal recruitment of eosinophils in the late-phase allergic reaction in mouse skin.[70] Immunoreactivity and mRNA expression of eotaxin and CCR3 are both increased in lesional skin and serum of patients with atopic dermatitis, but not in nonatopic controls.[71,72] Eotaxin has also been shown to increase proliferation of CCR3-expressing keratinocytes in vitro.[73] Finally, expression of eotaxin (and RANTES) by dermal endothelial cells has been correlated with the appearance of eosinophils in the dermis in patients with onchocerciasis that experience allergic reactions following treatment with ivermectin.[74] The observations above suggest that production of eotaxin and CCR3 may contribute to the recruitment of eosinophils and Th2 lymphocytes in addition to stimulating keratinocyte proliferation.

PSORIASIS

Psoriasis is characterized by hyperplasia of the epidermis (acanthosis) and a prominent dermal and epidermal inflammatory infiltrate, typically resulting in thickened, hyperkeratotic plaques. The inflammatory infiltrate of psoriatic skin is predominantly composed of Th1- and Th17-polarized memory T cells, as well as neutrophils, macrophages, and increased numbers of dendritic cells.[75] As shown in eFig. 12-3.1 in online edition and reviewed by others,[64] there is a growing body of evidence supporting a central role for chemokines in regulating the complex events leading to psoriatic

skin inflammation. Chemokines, including CCL20[76] and CCL17[8] mediate the arrest of effector memory T cells on endothelial cells that synthesize these chemokines.[77] In addition, both CCL17 and CCL20 can be synthesized by keratinocytes, possibly contributing to T cell migration to the epidermis.

While psoriasis has traditionally been considered a classical Th1-associated disease, accumulating evidence points to an important pathogenetic contribution of Th17 cells, which strongly express CCR6.[79] Th17 cells, their signature effector cytokines IL-17 and IL-22, as well as high levels of IL-23, a major growth and differentiation factor for Th17 cells, are abundant in psoriatic skin lesions.[80] Recent research suggests that CCR6 and its ligand, CCL20, are important mediators of psoriasis since both CCL20 as well as CLA^+CCR6^+ skin-homing Th17 cells are found in abundance in lesional psoriatic skin.[80,81] Moreover, CCR6-deficient mice failed to develop psoriasis-like inflammation[82] in response to intradermal IL-23 injections, a murine model for human psoriasis[83] (eFig. 12-3.2 in online edition). Interestingly, CCR6 was required for both T cell dependent as well as T cell independent skin inflammation in this model.[82]

Neutrophils found in the epidermis of psoriatic skin are probably attracted there by high levels of IL-8, which would act via CXCR1 and CXCR2. In addition to attracting neutrophils, IL-8 is an ELR^+ CXC chemokine that is known to be angiogenic, and it may also attract endothelial cells. This may lead to the formation of the long tortuous capillary blood vessels in the papillary dermis that are characteristic of psoriasis. Moreover, keratinocytes also express CXCR2 and thus may be autoregulated by the expression of CXCR2 ligands in the skin. Of note, an IL-8/CXCL8-producing population of memory T cells that express CCR6 has been isolated from patients with acute generalized exanthematous pustulosis (AGEP), a condition induced most commonly by drugs (e.g., aminopenicillins) and characterized by small intraepidermal or subcorneal sterile pustules.[84] Similar T cells have been isolated from patients with Behçet's disease and pustular psoriasis.[78] It is possible that this subpopulation of T cells contributes to neutrophil accumulation in the stratum corneum (Munro's abscesses) in psoriasis and other inflammatory skin disorders characterized by neutrophil-rich infiltrates in the absence of frank infection.

CANCER

Chemokines may play a role in tumor formation and immunity in several distinct ways, including the control of angiogenesis and the induction of tumor immune responses.[85] CXC chemokines that express a three-amino-acid motif consisting of glu-leu-arg (ELR) immediately preceding the CXC signature are angiogenic while most non-ELR CXC chemokines, except SDF-1, are angiostatic. Interestingly, it is not clear that ELR^- chemokines actually bind to chemokine receptors in order to reduce angiogenesis. It has been proposed that they act by displacing growth factors from proteoglycans. In any event, the balance between ELR^+ versus ELR^- chemokines is thought to contribute to the complex regulation of angiogenesis at tumor sites. IL-8, a prototypical ELR^+ chemokine, can be secreted by melanoma cells and has been detected in conjunction with metastatic dissemination of this cancer,[86] which may be related to its ability to attract circulating tumor cells to primary tumors and to influence leukocyte and endothelial cell recruitment.[87,88] IL-8 may also act as an autocrine growth factor for melanoma[24] as well as several other types of cancer. Although CXCR1 and CXCR2 bind IL-8 in common, several other ELR^+ CXC chemokines also bind to and activate CXCR2.

Tumors, including melanoma, have long been known to secrete chemokines that can attract a variety of leukocytes. The question arises as to why this is not deleterious to the tumor itself. Breast cancers, for instance, are known to secrete macrophage chemotactic protein-1 (MCP-1), a chemokine that attracts macrophages through CCR2. Higher tissue levels of MCP-1 correlate with increasing number of macrophages within the tissue. While chemokines secreted by tumor cells do lead to recruitment of immune cells, this does not necessarily lead to increased clearance of the tumor.[89]

Inflammatory cells such as macrophages may actually play a critical role in cancer invasion and metastasis. Firstly, MCP-1 may increase expression of macrophage IL-4 through an autocrine feedback loop and possibly skew the immune response from Th1 to Th2. Interestingly, MCP-1-deficient mice show markedly reduced dermal fibrosis following dermal challenge with bleomycin, a finding of possible relevance to the pathogenesis of conditions such as scleroderma.[5] Secondly, macrophages may promote tumor invasion and metastasis.[90] The antitumor effects of specific chemokines may occur by a variety of mechanisms. ELR^- CXCR3 ligands such as IP-10 are potently antiangiogenic and may act as downstream effectors of IL-12-induced, NK cell-dependent angiostasis.[91] Of note, some cancer cells can synthesize LARC, attracting immature DC that express CCR6.[92] Experimentally, LARC has been transduced into murine tumors, where it attracts DC in mice and suppresses tumor growth in experimental systems.[93] Lastly, chemokines produced by tumor cells may attract $CD4^+CD25^+$ T regulatory cells (Tregs) that suppress host antitumor cytolytic T cells.[94]

Tumor metastasis is the most common cause of mortality and morbidity in cancer. With skin cancers such as melanoma, there is a propensity for specific sites such as brain, lung, and liver, as well as distant skin sites. Cancers may also metastasize via afferent lymphatics and eventually reach regional draining LN. The discovery of nodal metastasis often portends a poor prognosis for the patient. In fact, the presence of nodal metastases is one of the most powerful negative predictors of survival in melanoma.[95]

Chemokines may play an important role in the site-specific metastases of cancers of the breast and of melanoma[96] (Fig. 12-4). Human breast cancer as well as melanoma lines express the chemokine receptors CXCR4

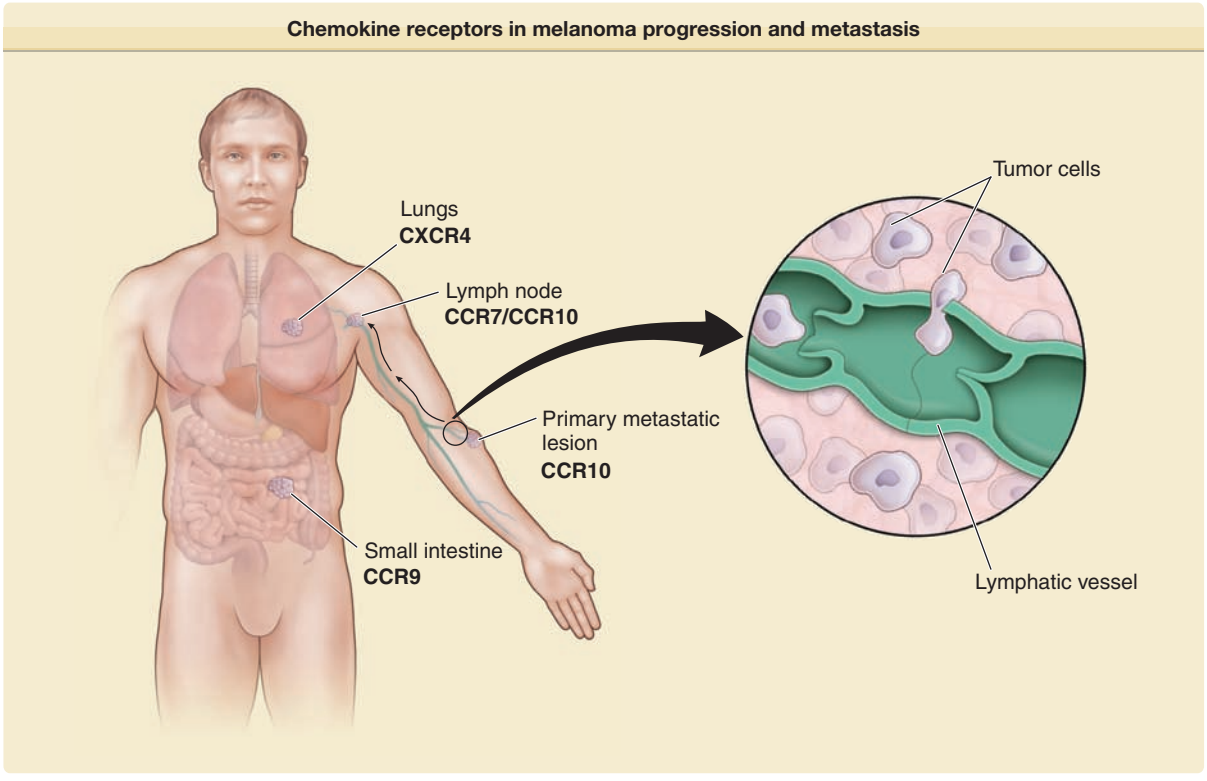

Figure 12-4 Chemokine receptors in melanoma progression and metastasis. Chemokine receptors play distinct roles in melanoma metastasis.[96] CCR10 may enhance survival of primary melanoma tumors and skin metastases. CCR7, CCR10, and, possibly, CXCR4 may contribute to lymph node metastasis. CXCR4 appears to be involved in primary tumor development and metastasis at distant organ sites such as the lungs. CCR9 has been implicated in melanoma small bowel metastasis in patients.

and CCR7, whereas normal breast epithelial cells and melanocytes do not appear to express these receptors.[97] CXCR4 is expressed in over 23 different solid and hematopoietic cancers. Broad expression of this receptor may be due to its regulation by hypoxia, a condition common to growing tumors, via the hypoxia inducible factor-1α transcription factor.[98] Notably stromal fibroblasts within human cancers express the CXCR4 ligand, CXCL12, which stimulates tumor growth as well as angiogenesis.[99] In several different animals of breast cancer[97] and melanoma metastasis,[29] inhibition of CXCR4 with antibodies or peptides resulted in dramatically reduced metastases to distant organs. Expression of CCR7 by cancer cells, including gastric carcinoma and melanoma, appears to be critical for invasion of afferent lymphatics and LN metastasis. CCR7-transfected B16 murine melanoma cells were found to metastasize with much higher efficiency to regional LN compared to control B16 cells after inoculation into the footpad of mice,[17] but CCR7 also directly stimulates primary B16 tumor development as well.[100] CCR9 may also play a role in melanoma metastasis to the small bowel, which shows high expression of the CCR9 ligand, CCL25.[19]

CCR10 is highly expressed by melanoma primary tumors[22] and is correlated with nodal metastasis in melanoma patients[101] and in experimental animal models (eFig. 12-4.1 in online edition).[22] Engagement of CCR10 by CTACK results in activation (via phosphorylation) of the phosphatidylinositol 3-kinase (PI3K) and Akt signaling pathways, leading to antiapoptotic effects in melanoma cells.[22] Because CTACK is constitutively produced by keratinocytes, it may act as a survival factor for both primary as well as secondary (metastatic) melanoma tumors that express CCR10. In fact, CCR10-activated melanoma cells become resistant to killing by melanoma antigen-specific T cells (eFig. 12-4.1 in online edition).[22] Interestingly, CCR4,[11] CXCR4,[102] and CCR10[23,103] have been implicated in the trafficking and/or survival of malignant T (lymphoma) cells to skin. Thus, a limited number of specific chemokine receptors appear to play distinct, nonredundant roles in facilitating cancer progression and metastasis (summarized in Fig. 12-4).

INFECTIOUS DISEASES

Although chemokines and chemokine receptors may have evolved as a host response to infectious agents, recent data suggest infectious organisms may have coopted chemokine- or chemokine receptor-like molecules to their own advantage in selected instances. A variety of microorganisms express chemokine receptors, including US28 by cytomegalovirus and Kaposi's sarcoma herpes virus (or human herpes virus-8) G-protein coupled receptor (GPCR). In the case of KSHV GPCR, this receptor is able to promiscuously

bind several chemokines. More importantly, it is constitutively active and may work as a growth promoter in Kaposi's sarcoma.[104]

The human immunodeficiency virus (HIV)-1, the causative agent of the acquired immunodeficiency syndrome (AIDS), is an enveloped retrovirus that enters cells via receptor-dependent membrane fusion (see Chapter 198). CD4 is the primary fusion receptor for all strains of HIV-1 and binds to HIV-1 proteins, gp120 and gp41. However, different strains of HIV-1 have emerged that preferentially use CXCR4 (T-tropic) or CCR5 (M-tropic) or either chemokine receptor as a coreceptor for entry. While other chemokine coreceptors can potentially serve as coreceptors, most clinical HIV-1 strains are primarily dual-tropic for either CCR5 or CXCR4.[3]

The discovery of a 32-base pair deletion (Δ32) in CCR5 in some individuals that leads to low levels of CCR5 expression in T cells and dendritic cells and correlates with a dramatic resistance to HIV-1 infection demonstrated a clear role for CCR5 in the pathogenesis of HIV-1 infection.[105] Interestingly, the frequency of Δ32 mutations in humans is surprisingly high, and the complete absence of CCR5 in homozygotes has only been associated with a more clinically severe form of sarcoidosis. Otherwise, these individuals are healthy. In fact, there is an association of less severe autoimmune diseases in patients with these mutations.[106]

LC reside in large numbers in the genital mucosa and may be one of the first initial targets of HIV-1 infection.[107] Since infected (activated) LC likely enter dermal lymphatic vessels and then localize to regional LN as described earlier, the physiologic migratory pathway of LC may also coincidentally lead to the transmission of HIV-1 to T cells within secondary lymphoid organs. CCR5 is expressed by immature or resting LC in the epidermis and is the target of CCR5 analogs of RANTES that block HIV infection.[108] Already, an FDA-approved small molecule inhibitor of CCR5, maraviroc, is available for use in treatment of HIV disease and may show fewer adverse effects than certain reverse transcriptase inhibitors.[109] CXCR4 antagonists may also be of clinical utility with T- or dual-tropic viruses.[110] A newly described autosomal dominant genetic syndrome comprised of *w*arts (human papilloma virus (HPV)-associated), *h*ypogammaglobulinemia, *i*nfections, and *m*yelokathexis (WHIM) is the result of an activating mutation (deletion) in the cytoplasmic tail of the CXCR4 receptor or in yet unidentified downstream regulators of CXCR4 function.[111,112] Bacterial infections are common because myelokathexis is associated with neutropenia and abnormal neutrophil morphology. The nearly universal presence of HPV infections associated with this syndrome can involve multiple common, as well as genital, wart subtypes (eFig. 12-4.2 in online edition) and suggest a critical role for normal CXCR4 function in immunological defense against this common human pathogen.

SUMMARY

The skin is rich in cells (keratinocytes, fibroblasts, endothelial cells, and immune cells) that are able to produce chemokines. Chemokines not only orchestrate the migration of inflammatory cells but also play roles in angiogenesis, cancer metastasis, and cellular proliferation. Other unanticipated biologic roles may ultimately be discovered. Just two of the promising therapeutic applications of chemokines (or molecules that mimic chemokines) may be in (1) preventing undesirable migration into the skin by preventing arrest of T cells or other inflammatory cells on activated endothelium, and (2) blocking the infection of dendritic cells and T cells by HIV-1 virus using CCR5 analogs. Signaling pathways are just beginning to be understood, and further work needs to be done to understand the regulation of these receptors, the specificity of intracellular activities, and the mechanism by which chemokine receptors work in the face of multiple chemokines present in many inflammatory sites.

Chapter 13 :: Allergic Contact Dermatitis

:: Mari Paz Castanedo-Tardan & Kathryn A. Zug

ALLERGIC CONTACT DERMATITIS AT A GLANCE

- Allergic contact dermatitis (ACD) is a cell-mediated (type IV), delayed type, hypersensitivity reaction caused by skin contact with an environmental allergen.
- Prior sensitization to a chemical is required for allergy to develop.
- The clinical manifestation of ACD is an eczematous dermatitis. The acute phase is characterized by pruritus, erythema, edema, and vesicles usually confined to the area of direct exposure. Recurrent contact to the allergen in a sensitized individual will result in chronic disease, characterized by lichenified erythematous plaques with variable hyperkeratosis and fissuring that may spread beyond the areas of direct exposure.
- Itch and swelling are key components of the history and can be a clue to allergy.
- The hands, feet, and face (including the eyelids) are some of the common sites for ACD.
- Patch testing is fundamental for the identification of causal allergens and is indicated for patients with persistent or recurrent dermatitis in whom ACD is suspected.
- Avoidance is the mainstay of treatment for ACD. Educating patients about avoidance of the allergen and its potentially related substances, and providing suitable alternatives are crucial to a good outcome.

As the largest organ in the human body, the skin is a complex and dynamic organ that serves among many other purposes, the function of maintaining a physical and immunologic barrier to the environment. Therefore, the skin is the first line of defense after exposure to a variety of chemicals. Allergic contact dermatitis (ACD) accounts for at least 20% or more of the new incident cases in the subgroup of *contact dermatitides* (irritant contact dermatitis accounts for the remaining 80%).[1] ACD, as the name implies, is an adverse cutaneous inflammatory reaction caused by contact with a specific exogenous allergen to which a person has developed allergic sensitization. More than 3,700 chemicals have been implicated as causal agents of ACD in humans.[2] Following contact with an allergen, the skin reacts immunologically, giving the clinical expression of eczematous inflammation. In ACD the severity of the eczematous dermatitis can range from a mild, short-lived condition to a severe, persistent, chronic disease. Appropriate allergen identification through proper epicutaneous patch testing has been demonstrated to improve quality of life as measured by standard tools,[3] as it allows for appropriate avoidance of the inciting allergen and possibly sustained remission of this potentially debilitating condition. Recognition of the presenting signs and symptoms, and appropriate patch testing are crucial in the evaluation of a patient with suspected ACD.

EPIDEMIOLOGY

A small but substantial number of studies have investigated the prevalence of contact allergy in the general population and in unselected subgroups of the general population. In 2007, Thyssen and colleagues[4] performed a retrospective study that reviewed the main findings from previously published epidemiological studies on contact allergy in unselected populations including all age groups and most publishing countries (mainly North America and Western Europe). Based on these heterogeneous published data collected between 1966 and 2007, the median prevalence of contact allergy to at least one allergen in the general population was 21.2%. Additionally, the study found that the most prevalent contact allergens in the general population were nickel, thimerosal, and fragrance mix. Importantly, the prevalence of contact allergy to specific allergens differs between various countries[5,6] and the prevalence to a specific allergen is not necessarily static, as it is influenced by changes and developments in the regional environment, exposure patterns, regulatory standards, and societal customs and values.

On a final note about epidemiology, contact allergy caused by ingredients found in personal care products (cosmetics, toiletries) is a well-known problem, with approximately 6% of the general population estimated to have a cosmetic-related contact allergy.[19,20] Contact allergy to ingredients in personal care products will be further discussed in this chapter.

AGE

Over the past decade, multiple studies have recognized contact dermatitis as an important cause of childhood dermatitis, and a common diagnosis among

children; being equally as likely in childhood as in adulthood,[21,22] although the most common allergens identified differ between the age groups. On the other hand, although fragrance mix allergy is an important sensitizer in all ages, certain studies, such as the 2001 Augsburg study, which was based on adults aged 28–75 years, have shown a significant increase in fragrance mix allergy with increasing age.[23] Similarly, Magnusson et al[24] demonstrated a high prevalence rate (4.7%) of *Myroxylon pereirae* (balsam of Peru—a marker for fragrance allergy) sensitization among 65-year-old Swedish patients. Similarly, a recent Danish study demonstrated the prevalence allergy to preservatives being higher among those aged 41–60 years.[25]

GENDER AND RACE

Because very few studies have looked at the induction of allergic contact sensitization in men and women under controlled circumstances, gender differences in the development of ACD are largely unknown. When the human repeat-insult patch testing method was used to assess induction rates for ten common allergens, women were more often sensitized to seven of the ten allergens studied.[26] With regard to frequency, Thyssen and colleagues found that the median prevalence of contact allergy among the general population was 21.8% in women versus 12% in men. When looking specifically at nickel sensitivity, the same study showed that the prevalence was much higher among women than men (17.1% in woman vs. 3% in men). This might be due to the fact that numerous studies have demonstrated that pierced ears are a significant risk factor for development of nickel allergy.[27–31] Thus, the higher prevalence of nickel allergy in women may be explained by the higher median prevalence of pierced ears in women in comparison with men (81.5% in women vs. 12% in men) of the population studied.

The role of race, if any, in the development of ACD to some potent allergens such as *para*-phenylenediamine (PPD), remains controversial.[32,33] Limited studies have suggested lower sensitizations rates to nickel and neomycin in African Americans compared to Caucasians. With regard to the patch-test protocol, the evaluation of positive reactions may be slightly more difficult in darker skin types (Fitzpatrick types V and VI), as erythema may not be as obvious, posing the risk of overlooking a mild positive allergic reaction. However, the edema and papules/vesicles are usually obvious and palpable; therefore palpation of the patch-test site can help to detect allergic reactions in patients with darker skin types. Finally, the darker the skin, the more difficult it is to mark the patch-test site after removal. For very dark skin, a florescent marking ink is probably best, the markings being located by a Wood's light in a darkened room.[34]

ETIOLOGY AND PATHOGENESIS

Allergic contact dermatitis represents a classic cell-mediated, delayed (type IV) hypersensitivity reaction. Such immunological reaction, results from exposure and subsequent sensitization of a genetically susceptible host, to an environmental allergen, which on reexposure triggers a complex inflammatory reaction. The resulting clinical picture is that of erythema, edema, and papulo-vesiculation, usually in the distribution of contact with the instigating allergen, and with pruritus as a major symptom Fig. 13-1.[35] To mount such reaction, the individual must have sufficient contact with a sensitizing chemical, and then have repeated contact with that substance later. This is an important distinction to irritant contact dermatitis (ICD) in which no sensitization reaction takes place, and the intensity of the irritant inflammatory reaction is proportional to the dose—concentration and amount of the irritant. In ACD, only minute quantities of an allergen are necessary to elicit overt allergic reactions. There are two distinct phases in the development of ACD: the sensitization phase and the elicitation phase.[36]

Figure 13-1 Erythematous papules and vesicles are characteristics of contact allergy in the acute stage.

SENSITIZATION PHASE

Most environmental allergens are small, lipophilic molecules with a low molecular weight (<500 Daltons). The unprocessed allergen is more correctly referred to as a hapten. Once the hapten penetrates the skin, it binds with epidermal carrier proteins to form a hapten–protein complex, which produces a complete antigen. Next, the antigen presenting cells (APC) of the skin (Langerhans cells and/or dermal dendritic cells), take up the hapten–protein complex and express it on its surface as an HLA-DR molecule. The antigen-presenting cell then migrates via the lymphatics to regional lymph nodes where it presents the HLA-DR–antigen complex to naive antigen-specific T cells that express both a CD4 molecule that recognizes the HLA-DR and more specifically a T-cell receptor CD3 complex that recognizes the processed antigen. The antigen can also be presented in the context of the MHC class I molecules, in which case it would be recognized by CD8 cells. Subsequently, the naive T cells are primed and differentiate into memory (also referred to as effector T cells) which undergo clonal expansion, acquire skin-specific homing antigens, and emigrate out of the

BOX 13-1 NEW DEVELOPMENTS IN CONTACT DERMATITIS

Emerging evidence suggests that innate immune cells such as Natural Killer (NK) cells play a significant role in ACD.

NK T cells (a hybrid between an NK cell and a conventional T cell) have been found to be necessary for the initiation of ACD and are also present in the elicitation phase of ACD.

Recent studies suggest that **Langerhans cells** (LC) that have been credited with an indispensable role in ACD may not be essential for the development of contact hypersensitivity. New studies of mice that lack LHCs suggest that they may even play a regulatory role in ACD.

Dermal dendritic cells may be the antigen presenting cells (APC) that complement epidermal LCs.

T-regulatory (T-reg) cells may be critical in the control of ACD (resolution of T-cell inflammation). Loss of T-reg cell activity may play a role in chronic inflammation.

Mast cells appear to be pivotal in determining the magnitude of the inflammatory reaction.

Keratinocytes play a role in all phases of ACD; from the initiation phase when their production of TNF-α after antigen exposure modulates APC migration and T-cell trafficking; through the peak of the inflammatory phase when they interact directly with epidermotrophic T cells; to the resolution of ACD through tolerogenic antigen presentation and the production of anti-inflammatory cytokines such as IL-10 and IL-16, which recruit T-regs.

From Gober MD, Gaspari AA: Allergic contact dermatitis. *Curr Dir Autoimmun* **10**:1, 2008.

lymph node into the circulation.[37,38] These clones of CD4+ Th1 and CD8+ type 1 cytotoxic T cells are then able to act as effectors on target cells presenting the antigen in the future.[39] The sensitization phase generally lasts 10–15 days and is often asymptomatic.[40] Subsequent exposure to the antigen, or rechallenge, leads to an elicitation phase. Such rechallenge can occur via multiple routes, including transepidermal, subcutaneous, intravenous, intramuscular, inhalation, and oral ingestion.[41]

ELICITATION PHASE

During this phase, both the APCs and the keratinocytes can present antigen and lead to subsequent recruitment of hapten-specific T cells. In response, the T cells release cytokines, including IFN-γ and TNF-α, which, in turn, recruit other inflammatory cells while stimulating macrophages and keratinocytes to release more cytokines.[42,43] An inflammatory response occurs as monocytes migrate into the affected area, mature into macrophages, and thereby attract more T cells. This localized proinflammatory state results in the classical clinical picture of spongiotic inflammation (redness, edema, papules and vesicles, and warmth). Recent advances in the knowledge of the pathophysiology of ACD have demonstrated the important role of the skin innate immunity in the sensitization process; have revisited the dogma that Langerhans cells are mandatory for ACD; and have addressed the nature, mode, and site of action of the regulatory T cells that control the skin inflammation (Box 13-1) (see also Chapter 10).[44,45] This new understanding may facilitate the development of strategies for tolerance induction, as well as the identification of novel targets for pharmacological agents for the treatment of ACD.

CLINICAL APPROACH

An algorithmic approach to the patient is described in the following sections.

CONSIDERATION OF THE DIAGNOSIS

The character and distribution of the dermatitis should raise the index of suspicion for ACD. Therefore, any patient who presents with an eczematous dermatitis should be regarded as possibly having ACD (Fig. 13-2). Additionally, one must also consider contact allergy in patients with other types of dermatitis (e.g., atopic) that is persistent and recalcitrant despite appropriate standard therapies, as well as in patients with erythroderma, or scattered generalized dermatitis.[46] Furthermore, it is important to note that patients with stasis dermatitis are at increased risk of developing ACD from topical medications and lotions which are often applied under occlusion over chronically inflamed and broken skin (Fig. 13-3). For that reason, ACD should always be in the differential of eczematous lesions surrounding leg ulcers. Finally, it is important to avoid some commonly held misconceptions about ACD that can alter a physician's ability to recognize contact dermatitis. These were described by Marks and DeLeo and include the following:

- ACD is not always bilateral even when the antigen exposure is bilateral (i.e., shoe or glove allergy).
- Even when exposure to an allergen is uniform (e.g., contact allergy to an ingredient of a cream that is applied on all of the face), eczematous manifestations are very often patchy.
- ACD can and does affect the palms and the soles.

Figure 13-2 Typical appearance of eczematous dermatitis compatible with ACD. **A.** Note the erythematous scaly plaques with some fissuring on the hands. **B.** Erythematous papules, scattered on the extensor forearms. This is a typical picture of contact allergy to a skin care product ingredient.

HISTORY TAKING

The first step in the diagnosis of ACD is a careful medical and environmental exposure history. History taking should begin with a discussion of the present illness focusing on the site of onset of the problem and the topical agents used to treat the problem (including over the counter and prescription medications). A past history of skin disease, atopy, and general health should be routinely investigated. This is followed by a detailed history of the usage of personal care products (soap, shampoo, conditioner, deodorant, lotions, creams, medications, hair styling products, etc.), and investigation of the patient's avocations or hobbies. The occupation should be ascertained as well, and if it appears contributory, or there are potential allergenic exposures, then a thorough occupational history should be taken. Occupations requiring frequent hand washing, glove use, or frequent chemical exposure should be prime suspects, among others.

Figure 13-3 Stasis dermatitis is a risk factor for the development of contact allergy. This is likely because of more frequent application of products that contain contact allergens to this area. Products without high frequency positive allergens are preferred in this area.

CLINICAL MANIFESTATIONS

CUTANEOUS FINDINGS

The classic presentation of ACD is a pruritic, eczematous dermatitis initially localized to the primary site of allergen exposure. Geometric or linear patterns or involvement of focal skin areas, may also be suggestive of an exogenous etiology (Fig. 12-4B). A linear or streaky array on the extremities, for example, often represents ACD from poison ivy, poison oak, or poison sumac. Occasionally, the actual sensitizing substance in these plants, an oleoresin named *urushiol* may be aerolized when the plants are burned, leading to a more generalized and severe eruption on exposed areas such as the face and arms. Transfer of the resin from sources other than directly from the plant (such as clothes, pets, or hands) may result in rashes on unexpected sites (i.e., genital involvement in a patient with poison ivy). Thus, relevant historic data gathered from thoughtful questioning may prove as useful as the distribution of the lesions.

It is important to note that lesions of ACD will vary morphologically depending on the stage of the disease. For example, during the acute phase, lesions are marked by edema, erythema, and vesicle formation. As the vesicles rupture, oozing ensues and papules and plaques appear. Stronger allergens often result in vesicle formation, whereas weaker allergens often lead to papular lesion morphology, with surrounding erythema and edema. Subacute ACD on the other hand, will present with erythema, scaly juicy papules and weeping; whereas chronic ACD can present with scaling, fissuring, and lichenification. A key symptom for allergy is pruritus, which seems to occur more typically with allergy, than a complaint of burning.[47]

Figure 13-4 ACD to *para*-phenylenediamine. **A.** Notice the eczema on the distribution of the hairline and behind the ears. **B.** Dermatitis on the forehead where the bangs came in contact with the skin of the same patient. **C.** *para*-Phenylenediamine, the most frequent relevant allergen in hair dye, is a strong sensitizer. It will darken the patch-test site. There is a strong edematous and vesicular reaction that is spreading, a 3+ reaction to this patch test.

Moreover, there are some noneczematous clinical variants of ACD that are infrequently observed.[48] These include among others:

- *Purpuric ACD* is mainly observed on the lower legs and/or feet and has been reported with a wide variety of allergens including textile dyes.
- *Lichenoid ACD* is considered a rare variant. Clinical features mimic lichen planus and has been associated with metallic dyes in tattoos. Oral lichenoid ACD from dental amalgams can resemble typical oral lichen planus.
- *Pigmented ACD* has been mainly described in populations from Asian ethnicity.
- *Lymphomatoid ACD* is based only on histopathological criteria (presence of significant dermal infiltrate displaying features of pseudolymphoma). Clinical signs which are nonspecific include erythematous plaques, sometimes very infiltrated, at the site of application of the contact allergen. Some examples include allergy to metal, allergy to hair dye, and to dimethylfumarate, a mold inhibitor found in sachets within some furniture implicated in causing a severe epidemic of ACD.

TOPOGRAPHIC APPROACH

Dermatitis distribution is usually the single most important clue to the diagnosis of ACD. Typically, the area of greatest eczematous dermatitis is the area of greatest contact with the offending allergen(s). Location, in fact, can be one of the most valuable clues as to which chemical might be the culprit of a patient's ACD. For instance, an eczematous dermatitis in the peri/infraumbilical area suggests contact allergy to metal snaps in jeans and belt buckles, whereas eczema distributed around the hairline and behind the ears suggests contact allergy to an ingredient(s) in hair products (hair dyes, shampoo, conditioners, styling products) (Fig. 13-4). Using the same rationale, eczema on the dorsum of the feet suggests contact allergy to products used to make shoe uppers like leather, rubber, or dyes, while eczematous dermatitis on the weight-bearing surfaces of the feet suggests contact allergy to products used to make insoles/soles like rubber and adhesive materials. Notably, facial, eyelid, lip, and neck patterns of dermatitis should always raise suspicion of a cosmetic-related contact allergy. However, for all of these presentations, correct identification of the

culprit chemical(s) will still require patch testing, since even the most astute and experienced clinician is, for the most part, unable to properly surmise the positive allergen(s) prior to testing. The pattern of dermatitis should be mainly used in determining whether or not to patch test, and which allergens and screening series to test.

Occasionally, the topographic approach does not hold, and the distribution can actually be misleading. This mainly refers to cases of ectopic ACD or airborne ACD. Ectopic ACD can follow two circumstances: *Auto transfer,* in which the allergen is inconspicuously transferred to other body sites by the fingers—the classical example being nail lacquer dermatitis located on the eyelids or lateral aspects of the neck; and *hetero-transfer,* in which the offending allergen is transferred to the patient by someone else (spouse, parent, etc.); this is described in the literature as connubial or consort ACD.

A discussion of allergens in the context of common patterns of presentation is briefly detailed below.

FACE. The face is a common site for ACD. Among patients with facial dermatitis, women are more commonly affected than men, particularly by cosmetic-associated allergens such as fragrances, PPD, preservatives, and lanolin alcohols (eFig. 13-4.1 in online edition).[49] Allergens can be applied to the face directly but can also be indirectly transferred from airborne or hand-to-face exposure. In addition to allergens found as ingredients in cosmetics, products used to apply them—such as cosmetic sponges, have also been reported to produce facial dermatitis in rubber-sensitive patients.[50] A similar situation is seen with nickel-plated objects used on the hair, such as bobby pins and curlers that may produce scalp and facial dermatitis in nickel-sensitive patients.

SCALP. Allergens applied to the scalp most often produce patterns of dermatitis on the forehead and lateral aspect of the face, eyelids, ears, neck, and hands; whereas the scalp remains uninvolved, suggesting that the scalp is particularly "resistant" to contact dermatitis. Nevertheless, patients exquisitely sensitive to certain ingredients in hair products such as PPD or glyceryl monothioglycolate may show a marked scalp reaction with edema and crusting. PPD is one of the most potent sensitizers known and is widely used as an ingredient in hair dyes. In general, PPD sensitization manifests on the face and scalp of female adult patients who had contact with a hair dye.[51–54] Glyceryl thioglycolate (GMT), on the other hand, is a chemical substance used in permanent wave solutions. Allergic sensitivity to GMT can manifest as intense scalp reactions with scaling, edema, and crusting.[55]

EYELIDS. The eyelids are one of the most sensitive skin areas, and are highly susceptible to irritants and allergens perhaps due to the thinness of the eyelid skin, as compared with the rest of the skin, and perhaps because they can accumulate the offending chemical in the skin folds. Transfer of small amounts of allergens used on the scalp, face, or hands can be enough to cause an eczematous reaction of the eyelids, while the primary sites of contact remain unaltered (eFig. 13-4.2 in online edition). Similarly, volatile agents may affect the eyelids first and exclusively, causing airborne eyelid contact dermatitis. Sources of contact dermatitis of the eyelids include cosmetics such as mascara, eyeliners and eye shadows, adhesive in fake eyelashes, and nickel and rubber in eyelash curlers. Furthermore, marked edema of the eyelids is often a feature of hair-dye dermatitis.[56] As mentioned earlier in this chapter, eyelids are also known for being a typical site for "ectopic contact dermatitis" caused by ingredients found in nail lacquer, such as tosylamide formaldehyde resin (TSFR), the chemical added to nail varnish to facilitate adhesion of the varnish to the nail and epoxy resin, also added to some nail polishes. Topical antibiotics (like bacitracin and neomycin) and certain metals such as gold[57] can also cause eyelid contact dermatitis. In fact, in the 2007 NACDG analysis of contact allergens associated with eyelid dermatitis,[58] gold was the most common allergen accounting for pure eyelid dermatitis. Notably, it has been observed that upon contact with hard particles such as titanium dioxide (used to opacify facial cosmetics, and in sunscreens as a physical blocker of ultraviolet light), gold found in jewelry may abrade, resulting in the release of gold particles that can then make contact with facial and eyelid skin, causing dermatitis.[59] Aside from gold, fragrances and preservatives have been found to be the main cosmetic allergens to cause dermatitis limited to the eyelids.[60]

LIPS. According to an NACDG study, approximately one-third of patients with cheilitis—without other areas of dermatitis—are typically found to have an allergen as a contributing factor.[61,62] Allergic contact cheilitis (ACC) has been reported to result from the use of a wide array of products including cosmetics such as lip balms, lipsticks, lip glosses, moisturizers, sunscreens, nail products, and oral hygiene products (mouthwashes, toothpastes, dental floss) (Fig. 13-5).[63–65]

Figure 13-5 Allergic Contact Cheilitis. Fragrances and flavorings are top among the most common causes of contact allergy in patch-tested patients with cheilitis.

ACC has a marked female predominance, with most studies reporting a range of 70.7%–90% female patients.[66] This is likely explained by the assumption that women wear more cosmetics and lip products than men. Most studies have reported fragrance allergens [such as fragrance mix and *Myroxylon pereirae* (Balsam of Peru)] as the most common cause of contact allergy in patch-tested patients with cheilitis.[67] Of note, some uncommonly reported allergens, namely, benzophenone-3 and gallates, may be relevant to a dermatitis localized to the lips. Benzophenone-3, a major constituent of many sunscreens, is also a common ingredient in many lip products and is increasingly reported as a culprit for ACC.[68,69] Gallates are antioxidants used in waxy or oily products such as lip balms, lipsticks, and lip glosses.[70]

NECK. The neck is also a highly reactive site for ACD. Cosmetics applied to the face, scalp, or hair often initially affect the neck. Nail-polish ingredients (tosylamide formaldehyde resin and epoxy resin) are common culprits in this region.[71] Furthermore, as a cultural practice, perfumes are sprayed on the neck. In a fragrance-sensitized individual, the practice of repeated application of fragrances to the anterior neck may result in the appearance of a dermatitic plaque on the neck, which has been coined the *"atomizer sign."*[72] Also, in this topographic area, metal allergy can manifest as chronic eczematous dermatitis from exposure to necklaces and jewelry clasps that contain nickel and/or cobalt.

TORSO. The torso can encounter fragrances, preservatives, surfactants, and other chemicals from the use of personal care products; yet it is also susceptible to allergens found in textiles. Textile-associated allergens include disperse dyes (azoanilines) and formaldehyde-releasers used as durable press chemical finishes (DPCF). In the past, finishes used to contain large amounts of free formaldehyde, which led to many cases of allergic contact dermatitis to clothing in the 1950s and 1960s. However, currently most finishes are based on modified dimethylol dihydroxyethyleneurea, which releases less formaldehyde. Importantly, recent studies have shown that the amount of free formaldehyde in most garments will likely be below the threshold for the elicitation of dermatitis for all but the most sensitive patients, and that the amount of free cyclized urea in clothes is unlikely to be high enough to cause sensitization.[73]

AXILLAE. Heat, humidity, and friction of the axillary fold may contribute to the leaching of textile resins and dyes and dermatitis accentuation in these areas.[74] The axillary region is also uniquely exposed to deodorants and antiperspirants. These products contain most notably the contact allergens fragrances and preservatives (formaldehyde releasers, parabens, etc.). A commonly observed effect with the use of these products is the sparing of the axillary vault, mainly secondary to perspiration diluting the allergens. Aerosolized exposure of the allergens through antiperspirant/deodorants in spray, may lead to scattering of the allergen and the resulting picture may be that of scattered satellite papules.

HANDS AND FEET. Hand dermatitis has a particularly high incidence secondary to the fact that the hands are the main means of interaction with the environment, with increased possibility for numerous allergen exposures. Hand dermatitis accounts for as much as 80% of the occupationally related skin diseases, especially in certain "wet work" occupations such as health care workers, food handlers, etc.[75] Thus, careful consideration should be given to occupation-specific exposures in the evaluation of patients with hand dermatitis. As an example, a hairdresser may be sensitized to ingredients in hair-care products such as PPD, glyceryl monothioglycolate, or cocamidopropyl betaine (a surfactant-detergent, commonly found in shampoos), whereas a construction worker may become allergic to chromium through exposure to wet cement. Clinical clues that should raise a higher index of suspicion of ACD include the involvement of the finger web spaces and the dorsal hands, as well as the predominance of pruritus as a symptom. Still the multifactorial etiology of hand dermatitis (irritant exposure, atopy, pompholyx or chronic vesicular hand eczema, psoriasis, dermatophyte infection, among others) adds to the complexity of both diagnosing and treating these patients. Chronic hand dermatitis is an indication for patch testing, as causal or contributing allergy can result in improvement or resolution of the problem. Similarly, the evaluation of foot dermatitis should include patch testing with the allergens most commonly associated with this condition. These include, rubber-related chemicals (such as mercaptobenzothiazole, carba mix, thiuram mix, mercapto mix, black rubber mix, and mixed dialkyl thioureas) potentially present as components of shoes and insoles; glues and adhesives used in shoe manufacturing like 4-*tert*-butylphenol formaldehyde resin; and potassium dichromate found in tanned leather-made shoes. Testing materials should also include topical antibiotics, corticosteroids, or antifungal medications (both over-the-counter and prescription) that may have been used by the patient to treat the affected area.

Other topographic areas affected by ACD include the oral mucosa, which may present with contact stomatitis from dental metals and the perianal area, which may react to sensitizing chemicals in proctologic preparations such as benzocaine.

SCATTERED GENERALIZED DERMATITIS

Patients with scattered generalized dermatitis (SGD) usually present a difficult diagnostic and therapeutic challenge. Patch testing can be a strategy for evaluating ACD as a potential relevant factor. In 2008, Zug and NACDG colleagues [76] examined the yield of patch testing as well as the relevant allergens in patients with SGD referred for patch testing. Of 10,061 patients studied during a period of 4 years, 14.9% had SGD.

Men and patients with a history of atopic eczema were more likely to have dermatitis in this distribution. Of the total of patients presenting with SGD, 49% had at least one relevant positive patch-test reaction. Preservatives, fragrances, propylene glycol, cocamidopropyl betaine, ethyleneurea melamine formaldehyde, and corticosteroids were among the more frequently relevant positive allergens.

SYSTEMIC CONTACT DERMATITIS

In 2001, members of the International Contact Dermatitis Research Group (ICDRG) developed the concept of the *allergic contact dermatitis syndrome* (ACDS).[77] This concept considers the various facets of contact allergy, including morphological aspects and staging by symptomatology. ACDS has three stages that can be defined (Table 13-1) and with many causes (Table 13-2).

Systemic contact dermatitis describes a systemic reactivation of allergic contact dermatitis; in other words, a cutaneous eruption in response to systemic (nontopical) exposure to an allergen.[78] In considering the chains of events resulting in the development of systemic reactivation of ACD, the ICDRG has suggested that the occurrence of some successive steps is necessary. Initially, direct skin contact with an allergen results in sensitization. Second, in some relatively uncommon cases, weeks or even years after that first episode of ACD, the patient is systemically exposed to exactly the same allergen, or to a related substance that is chemically closely related to it (cross-sensitization), elicitating a systemic reactivation of ACD. There are multiple routes of exposure for the elicitation of systemic contact dermatitis—subcutaneous, intravenous, intramuscular, inhalation, and oral ingestion. It is important then to note, that by definition, in systemic contact dermatitis, there is no occurrence of topical skin contact to the allergen. Clinically, systemic contact dermatitis has a wide spectrum of presentation, from a recall reaction (dermatitis at the site of prior topical sensitization), to widespread dermatitis and erythroderma. Other patterns that have been associated with systemic contact dermatitis include axillary vaults, upper inner thighs, and buttocks—sometimes described as "baboon syndrome,"[79] which has been associated with some internally ingested allergens, i.e., cashew nut shell oil causing a cross-reaction to the allergen urushiol. Dyshidrotic hand eczema/pompholyx are conditions in which oral challenges with nickel, and *Myroxylon pereirae* have demonstrated flaring of this type of hand eczema in some studies (eFig. 13-5.1 in online edition).[80] Of particular notoriety is the allergen *Myroxylon pereirae* also known as balsam of Peru, a substance derived from *Myroxolon balsamum*, a tree that is native to the country of El Salvador. Because the main components of *Myroxylon pereirae* (cinnamic acid, cinnamyl cinnamate, benzyl benzoate, benzoic acid, benzyl alcohol, and esterified polymers of coniferyl alcohol) are naturally derived, they have a significant number of natural cross-reactors. Certain foods, such as tomatoes and tomato-containing products, citrus fruit peel/zest, chocolate, ice cream, wine, beer, vermouth, dark colored sodas, and spices such as cinnamon, cloves, curry, and vanilla, have chemical ingredients related to balsam of Peru.[81] Consumption of these foods may result in a systemic reactivation of ACD in some patients allergic to balsam of Peru. Salam and Fowler drew attention to this ability of orally ingested balsam-related substances to induce systemic contact dermatitis, and reported that, in their study, remarkably almost half of the subjects with a positive patch test to *Myroxylon pereirae* who followed a balsam of Peru-reduction diet, had a significant to complete improvement of their dermatitis. Finally, some oral or IV medications may cause systemic reactivation of ACD in patients

TABLE 13-1
Stages of the Allergic Contact Dermatitis Syndrome

Stage 1	The skin symptoms are limited to the site (s) of application of contact allergen(s).
Stage 2	There is a regional dissemination of symptoms (via lymphatic vessels), extending from the site of application of allergen(s).
Stage 3	Can be further subdivided in **Stage 3A**: Corresponds to hematogenous dissemination of ACD at a distance. **Stage 3B**: Corresponds to systemic reactivation of ACD (nontopical trigger)

Data from Lachapelle JM: Dermato-allergolie de contact. *Nouv Dermatol (Strasbourg)* **20**:450, 2001 and Lachapelle JM, Maibach HI: *Patch Testing and Prick Testing: A Practical Guide*. Berlin, Germany, Springer-Verlag, 2003.

TABLE 13-2
Systemic Drugs that Can Cause Systemic Reactivation of ACD

Contact Allergen[a]	Related Drug with Potential to Cause Systemic Reactivation of ACD
Ethylenediamine dihydrochloride (stabilizer infrequently found in skin care products)	Aminophylline Piperazine antihistamines: hydroxyzine, cetirizine, levocetirizine and meclizine
Thiuram (rubber antioxidant)	Tetraethyl thiuram disulfide (generic name: disulfiram)
Thimerosal (mercury-derived preservative)	Piroxicam

[a]To which a patient had previously become sensitized by direct, topical application of the contact allergen to the skin.

previously sensitized to related allergens by direct skin contact[82–85] (Table 13-2).

FREQUENCY APPROACH

Because "frequent is frequent," the approach to a patient with suspected ACD can also be done taking into account the most likely culprits based on frequency data of a given region, and the patient's occupation or other individual exposures. This approach should not replace by any means actual patch testing; nevertheless, a working knowledge of the most common allergens can prove to be useful when evaluating a patient with suspected ACD. Next is a brief description of the most frequently patch-test positive allergens in North America.

NICKEL. Nickel is a ubiquitous metal used in a wide range of products including those that have a prolonged contact with the skin (costume jewelry, suspenders, zippers, button snaps, belt buckles, eyeglasses frames, cell phones, nickel-containing coins, keys, among many others). There is a well-documented rising incidence of nickel allergy in the United States and elsewhere, with high nickel sensitization rates documented in children.[86] Ear piercing at an early age, in addition to the trend of a greater number of other body piercings, are consistently linked to the rise in nickel sensitization in the recent decade.[87,88] Currently, nickel allergy is the most common cause of contact dermatitis in the industrial world, particularly affecting females.[89] Several studies have examined the striking discrepancy of sensitization incidence to nickel in females versus males and have associated this with ear piercing.[90,91] Classically, nickel contact dermatitis presents as an eruption on the earlobes, the neckline, the wristband, or the periumbilical area since those are common areas for exposure to nickel-containing jewelry or button snaps, zippers, and belt buckles. Facial dermatitis caused by nickel has also been reported to musical instruments and more recently to cell phones.[92] Furthermore, the presence of nickel in implantable medical devices and potential complications derived from nickel allergy is a rising subject of discussion. The relevance of nickel allergy in the failure of metal orthopedic implants and cardiac devices is not clear. Documented cases of joint replacement failure associated with nickel or other metal sensitivity are clearly rare, and arthroplasty prostheses rarely cause a problem in the nickel sensitive individual. Existing publications are largely retrospective and thus can only suggest a possible association of nickel allergy with implant failure rather than determine causation.[93] Similarly, eczematous reactions temporally related to joint replacement or implantation of other orthopedic devices (i.e., metallic plates and screws) although reported, are infrequent (eFig. 13-5.2 in online edition). More studies are needed in this area.

In an attempt to prevent the development of nickel sensitivity, Denmark in 1990, and the rest of the European Union in 1994, have regulated the amount on nickel that may be released from objects with direct and prolonged skin contact (≤0.5 μg nickel/cm^2/week; revision for 2004: ≤0.2 μg nickel/cm^2/week for items inserted into pierced parts of the body). Recent evidence indicates that the prevalence of nickel allergy is decreasing among young Danish females from 27.6% in 1985 to 16.8% in 2007.[94] The American Academy of Dermatology and the American Contact Dermatitis Society favor enacting similar legislation in the United States.

FRAGRANCES. Fragrances are aromatic compounds that impart a smell or odor. They can be natural (from botanical or animal products) or synthetic in origin. It has been estimated that between 1% and 4% of the general population is allergic to fragrances.[95,96] Fragrance allergy is one of the two top causes of contact allergy to personal care products; the typical sites of involvement include the face and hands, as well as behind the ears, neck, and axillae, in addition to a scattered generalized distribution of eczematous dermatitis.[97,98] Two of the main substances used by most patch-test groups for screening are among the top ten allergens in North America. The first is *fragrance mix I*, which is a mixture of eight fragrance allergens, and the second is *Myroxylon pereirae* (MP) also known as balsam of Peru (BOP), whose main components are fragrance ingredients.[99] MP is considered to be a good marker for fragrance allergy, able to identify approximately 50% of fragrance allergic individuals.[100] MP-related substances can be found in products such as cosmetics, perfumes, pharmaceutical preparations, toothpastes and mouthwashes, as well as in scents and flavorings for foods and drinks. Similarly, certain foods, such as the ones mentioned earlier in the chapter, contain chemical ingredients related to MP. Surgical adhesives used postprocedure to secure dressings also may cross-react and produce dermatitis in individuals sensitive to MP.

NEOMYCIN. Neomycin belongs to the aminoglycoside family of antibiotics commonly used in topical formulations for the prevention and treatment of superficial skin, ear, and eye infections. The frequency of neomycin sensitization in the general population is 1.1%,[101] while reported sensitization rates in selected patient populations referred for patch testing vary from as low as 1.1[102] to as high as 10%, the latter reported by the NACDG.[103] This high rate of sensitization in North America may be due to the availability of this antibiotic in numerous over-the-counter preparations, especially "triple antibiotic" creams and ointments.[104] Subgroups at higher risk include patients with stasis dermatitis and leg ulcers, anogenital dermatitis, and otitis externa. Because antibiotic preparations are applied to already damaged skin, ACD from neomycin is not always easily recognized. It often presents as persistence or worsening of a preexisting dermatitis.[105] Additionally, it may mimic cellulitis; the clue for contact allergy is itching rather than pain. An intensification of itch and the progression of lesions beyond the initial site of involvement may offer clues to the

Figure 13-6 This eczematous dermatitis was caused by the most frequent preservative allergen, quaternium-15, which was present in the patient's moisturizer.

correct diagnosis. Occupational dermatitis involving the hands can occur in nurses, physicians, pharmacists, dentists, and veterinarians.[106]

FORMALDEHYDE AND FORMALDEHYDE-RELEASING PRESERVATIVES. Formaldehyde is a colorless gas with preservative and disinfectant properties. Although there is a wide range of uses for formaldehyde-like cleansing products, glues, biocides, and photographic developers, currently it is rarely used *as-is* in personal care because it has demonstrated to be a frequent sensitizer.[107] Therefore, many manufacturers have replaced the use of formaldehyde with formaldehyde-releasing preservatives (FRPs) to preserve personal care products.[108] FRPs include quaternium-15, imidazolidinyl urea (Germall), diazolidinyl urea (Germall II), DMDM hydantoin (Glydant), 2-bromo-2-nitropropane-1, 3-diol (Bronopol), and tris nitromethane (Tris Nitro).[109] Of these, Quaternium-15 is the most common cosmetic preservative allergen (Figs. 13-6 and 13-7).[110–112]

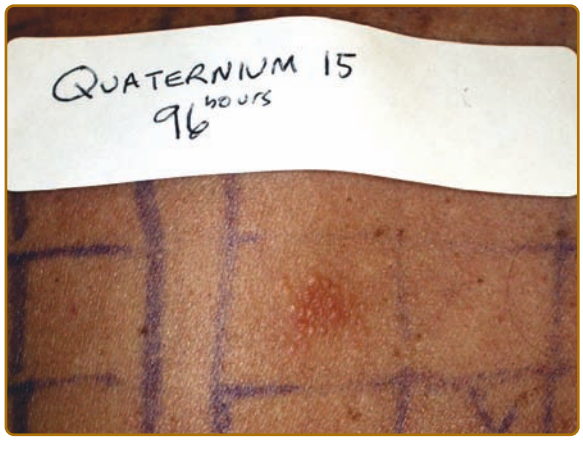

Figure 13-7 An example of a weak, 1+ reaction to quaternium-15.

COBALT. Cobalt is a metal which is often added to other metals to increase overall strength. Cobalt is commonly a contaminant present in nickel ores and is frequently a minor element in nickel compounds.[113] As with nickel, a majority of sensitization exposures result from contact with jewelry, clothing snaps, buckles, coins, keys, and other metal objects. Furthermore, it can also be found in prosthetic joint replacements, dental alloys, ceramics, paints, tattoo dyes, cement (mostly in Europe), and multivitamins containing vitamin B12 (cobalt is a main component of vitamin B12, Cyanocobalamine).[114] Concomitant allergy to nickel and cobalt is often observed among patients with dermatitis, probably as a result of cosensitization. In general, the best way of avoiding contact with metallic cobalt is by avoiding contact with nickel-plated objects that come in direct contact with the skin.

BACITRACIN. Bacitracin is a topical antibiotic frequently used for postoperative and general wound care by both the medical profession and the general public since it is readily available in over-the-counter preparations. Bacitracin is known to be a common sensitizer and can cause not only allergic contact dermatitis but also urticarial reactions and even, rarely, anaphylaxis.[115] It is important to note that despite its high prevalence, bacitracin is not included as a screening allergen in the currently available T.R.U.E. Test series, which will be further discussed briefly in this chapter. Interestingly, patients often show simultaneous sensitivity to bacitracin and neomycin, although the two substances are not chemically related, meaning there is coreactivity but not cross-reactivity between both substances. Independent sensitization probably occurs to both antibiotics, which are often used simultaneously in over-the-counter combinations.[116]

METHYLDIBROMOGLUTARONITRILE/PHENOXYETHANOL. Methyldibromoglutaronitrile/Phenoxyethanol (MDGN/PE) is a preservative combination also known as *Euxyl K400*. It has become an increasingly important sensitizing agent,[117] resulting in a ban on use in Europe, first from stay-on cosmetics in 2005, and later from rinse-off cosmetics in 2007, in an attempt to decrease the rates of contact allergy.[118] The use of MDGN/PE is not banned in cosmetics produced outside the European Union, and therefore toiletries sold elsewhere may contain MDGN/PE, albeit at a lesser concentration than had been allowed European formulations. Most allergic reactions to MDGN/PE are due to the use of personal care products containing the allergen, especially creams, lotions, wet wipes, and liquid soaps.

***para*-PHENYLENEDIAMINE.** PPD is an oxidizing agent used as a permanent hair dye. Both consumers and hairdressers alike are at risk for sensitization. As mentioned earlier in this chapter, contact allergy to PPD often presents as facial dermatitis near the

hairline, but it may also involve the eyelids and the neck, while the scalp may or may not be spared.[119] Once oxidized, PPD is no longer allergenic, thus, dyed hair itself does not pose further risk of allergic stimulation. This is in contrast to permed hair, in which the allergen, glyceryl monothioglycolate, retains ability to further stimulate dermatitis in the allergic individual (i.e., an allergic hairdresser cutting the hair of a client who has had GMT permanent waving applied to the hair weeks ago). PPD has the potential to cross-react with other *para*-amino group chemicals such as *para*-aminobenzoic acid (PABA), sulfonylureas, hydrochlorothiazide, benzocaine, procainamide, and certain azo and aniline dyes.[120,121] Additionally, PPD has gained notoriety for its use in adulterating natural henna to make "black henna," a substance increasingly used to make temporary tattoos.[122,123]

PATCH TESTING

ALLERGEN SELECTION

T.R.U.E. TEST. The commercially available patch-test screening tool with US Food and Drug Administration (FDA) approval is the Thin-layer Rapid Use Epicutaneous (T.R.U.E.) Test (Mekos Laboratories AS, Hillerod, Denmark). As of March 2010, there were 28 (plus 1 negative control) T.R.U.E. Test allergens organized into three panels (panels 1.1, 2.1, and 3.1). Of the top 30 most frequently positive NACDG screening allergens for the 2005–2006 period, Zug and NACDG colleagues found that 10 important allergens were not currently available for testing and identification with the T.R.U.E. Test panels: bacitracin, methyldibromoglutaronitrile, bronopol, cinnamic aldehyde, propylene glycol, DMDM hydantoin, iodopropynyl butylcarbamate, ethyleneurea/melamine formaldehyde, disperse blue 106, and amidoamine. Of these, bacitracin is likely the most important. Named Allergen of the Year in 2003 by the American Contact Dermatitis Society, bacitracin is now the seventh most frequently positive allergen according to prevalence data from this study group (Fig. 13-8).

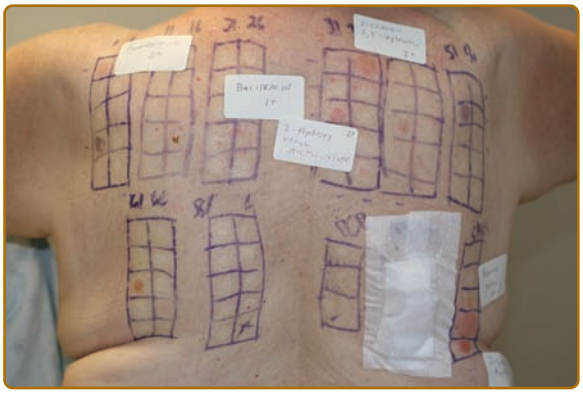

Figure 13-8 This patient had multiple relevant positive patch tests. Bacitracin, chloroxylenol, and 2-hydroxyethyl methacrylate are relevant to this patient's severe dermatitis but are not allergens on the currently available commercial screening series.

RESULT INTERPRETATION

Reading reactions elicited by the patch test is a crucial step in the patch-test procedure. Patches should be applied to healthy skin on the patient's back and left under occlusion for 48 hours (eFig. 13-8.2 in online edition). Traditionally, patch-test reading is carried out in most patch-test clinics twice: the day of patch-test removal 48 hours after application (day 2 = D2), and 96 hours after epicutaneous exposure (day 4 = D4), or day 7. It is important to note that certain allergens are acknowledged for being "late-reactors." For example, if neomycin or PPD allergies are suspected, additional readings at 5–7 days may be needed.[125] Likewise, some researchers have also found that readings for metals and corticosteroids should sometimes be delayed to 7 days.[126] The reason for this is that all these allergens are characterized as being "late-bloomers." On the other hand, a study by Geier and colleagues showed that by delaying readings to 7 days, some reactions to certain fragrances and preservative allergens may dissipate.[127] Therefore, the optimal protocol is probably to read the test at day 2 and day 4, the conventional way, and then on day 7 if allergies to metals, topical antibiotics (neomycin), and PPD are strongly suspected, or if the patient notes a newly developed reaction after day 4. Patients are instructed to report back to their physician should any additional positive reactions appear at day 5 or beyond to detect any late reactors or active sensitization that may have occurred. At each test reading, it is traditional to note the results as negative or positive, and grade the positive results on a quantitative scale. The ICDRG has recommended to score patch-test reactions according to the scoring system recommended by Wilkinson and colleagues[128] which is on a + to +++ scoring system; where + represents a weak nonvesicular reaction but with palpable erythema; ++ represents a strong (edematous or vesicular) reaction; and +++ represents an extreme (bullous or ulcerative) reaction (Figs. 12-6C and 13-7). Very weak or questionable reactions where there is only faint or macular (nonpalpable) erythema are recorded by a question mark (?+), and irritant reactions are recorded as "IR." Irritant patch-test reactions have varied clinical signs which are related to the nature and the concentration of the irritant[129] and are classically described as (1) erythematous reactions limited to the site of application of the chemical, with sharp, well-delineated margins; discretely scaly (may look "chapped") and usually not edematous. Among the patch-test allergens, fragrance mix, cocamidopropyl betaine, iodopropynyl butylcarbamate, glutaraldehyde, and thiuram mix are identified as the most common allergens to produce such marginal irritant reactions. (2) Purpuric reactions with petechial hemorrhage, which are seen in about 5% of patients tested to cobalt chloride. This is sometimes referred as *punctate purpura of cobalt* and should always be interpreted as an irritant reaction. Another top allergen that has been

observed to cause purpuric reactions during patch testing is PPD. (3) Pustular reactions: there can be a unique large pustule at the site of application (more characteristic of caustic, strong irritant reactions), or more commonly, small follicular pustules over an erythematous background. This type of reaction mainly occurs with metallic salts such as potassium dichromate, cobalt, nickel, gold, and copper, and mainly in atopic patients. Other patch-test reactions that should be interpreted with caution given their mild irritant potential include the preservatives formaldehyde, benzalkonium chloride, and iodopropynyl butylcarbamate (IPBC); the rubber allergen carba mix, fragrance chemicals such as fragrance mix I and propolis (bee glue); the foaming agent cocamidopropyl betaine; and the emulsifiers: oleamidopropyl dimethylamine and triethanolamine. It is important to mention that even paying close attention to the aforementioned morphological features, irritant reactions are still difficult to interpret, and the morphology of the patch-test response can still be a confusing guide to whether the response is allergic or irritant. When morphology is not enough, it is advisable to keep in mind that in general when the patch-test reaction is sufficiently strong, an irritant reaction will be early appearing (during the first reading), and promptly healing (often times the reaction is not as strong or sometimes not even present during the second reading). In contrast, a strong allergic reaction usually spreads, is more slowly disappearing, and is more clearly eczematous.

ASSIGNING CLINICAL RELEVANCE

The diagnosis of contact allergy is mainly determined by the outcome of patch testing. However, a positive test reaction is not necessarily an indicator of clinical disease, i.e., ACD, as the patch test only measures whether the individual is sensitized or not. Sensitization does not necessarily equate with clinical allergic disease. A good example of this point is the case of thimerosal. This mercuric preservative is unique in the sense that it commonly causes positive patch-test reactions but very seldom nowadays does thimerosal allergy account for the patient's dermatitis. Most allergic patients have presumably been sensitized to this preservative through vaccination but have no clinical disease associated with this sensitization.[130] Establishing the relevance of a positive patch-test result is critical. However, it should be noted that lack of relevance does not mean a patient is not allergic to the chemical in question, but more specifically that this chemical is not the causal agent for the dermatitis currently being evaluated. Therefore determination of current clinical relevance is essential in declaring ACD.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ACD includes a wide range of inflammatory skin disorders (Box 13-2).[135,136]

BOX 13-2 DIFFERENTIAL DIAGNOSIS OF ACD

DIAGNOSIS	DIAGNOSTIC CLUES
Irritant contact dermatitis (ICD)	Physical findings can be indistinguishable clinically; in general there is an absence of vesiculation (only very strong irritants produce vesicles) and burning exceeds itching. Does not spread beyond the area of contact with continued exposure.
Atopic dermatitis	Distribution of skin findings can be helpful; atopic patients can and do develop contact allergies. Worsening disease can indicate new contact allergy development.
Nummular dermatitis (ND)	Widespread ACD can assume this pattern in certain patients; nonetheless, the classical morphology of coin-shaped, well-demarcated plaques on the legs, dorsal hands, and extensor surfaces favors ND.
Seborrheic dermatitis	Greasy and scaly papulosquamous plaques usually located in the hair-bearing regions, glabella, and nasolabial folds.
Asteatotic eczema	Parchment-like patches with no edema or vesiculation on the lower legs.
Stasis dermatitis	Papulosquamous plaques with dyschromia located on the shins and medial surfaces of the lower legs, with presence of concomitant varicosities.
Pompholyx and/or dyshidrotic eczema	Deep-seated vesicles on palms, soles, sides of the fingers, and volar edges.
Psoriasis	When it presents in its classic form, diagnosis can be straightforward, however, when the lesions are few and limited to the hands and/or feet differentiation can be more difficult. Classical location and predominance in areas of trauma (Koebnerization) can be helpful as well as the presence (if any) of concomitant arthritis.
Mycosis fungoides (patch/plaque stage cutaneous T-cell lymphoma)	The well demarcated, atrophic, poikilodermatous, scaly patches and plaques of MF are usually found in nonsun-exposed areas of the skin, such as the trunk, breasts, hips, and buttocks (bathing suit distribution).

Histologically, the presence of eosinophilic spongiosis and multinucleate dermal dendritic fibrohystiocytic cells is especially suggestive of ACD, when encountered in the presence of a lymphocytic infiltrate, dermal eosinophils, and hyperkeratosis.[137]

COMPLICATIONS

COMPLICATIONS OF PATCH TESTING

Patch testing is considered a safe diagnostic procedure and unwanted effects are seldom encountered. The most common side effect is itching at the site of a positive test reaction, and irritation and pruritus from tape application. Less commonly, postinflammatory hypo- or hyperpigmentation can occur. Hyperpigmentation is more likely in darkly pigmented persons; it fades progressively with time and the use of topical corticosteroids. It is important to note that exposure to sunlight or artificial UV immediately following removal of patch tests especially to fragrance materials, can lead to hyperpigmentation of the patch-test site in relation with photosensitivity. Persistence of a positive reaction is another adverse reaction that may occur. A patch-test reaction that may persist for more than 1 month is that due to gold in a gold sensitive patient. Induction of a dermatitis flare-up at the original site of an existing or preexisting dermatitis (that was caused by the positive patch-test allergen) can also occur. This can be minimized by testing patients free of any current active dermatitis. Also, a positive patch-test reaction in a patient who has active psoriasis or lichen planus may reproduce these dermatoses at the patch-test sites (as a *Koebner phenomenon*), during the weeks following patch testing.[138] These lesions can be cleared with the use of topical corticosteroids. Finally, the possibility of becoming sensitized (active sensitization) to one of the tested allergens exists; however, it has proven to be low.[139] Serious adverse effects during patch testing such as anaphylactoid reactions from allergens known to cause a type I (immediate) hypersensitivity reaction such as bacitracin and neomycin are exceptionally rare.

COMPLICATIONS DERIVED FROM FAILURE TO PATCH TEST

The greatest hazard is omission to patch-test appropriate patients with dermatitis. Such omission potentially dooms the patient to repeated episodes of avoidable contact dermatitis. In 2004, the American Academy of Dermatology and the Society of Investigative Dermatology studied the burden of skin disease and estimated that 72 million people in the United States suffer from ACD.[140] It is the third most common reason for patients to seek consultation with a dermatologist, accounting for 9.2 million visits in 2004 alone. Likewise, in that same year, primary care physicians received 5 million visits for unexplained dermatitis or eczema.[141] Whereas many of these patients will respond readily to standard treatments, there will be others that demonstrate recalcitrant eczema. It has been estimated that approximately 16% of all chronic eczema patients would benefit from patch testing.[142] Clinical experience suggests this number is much larger. Based on those figures, it could be estimated that approximately 2.2 million patients each year in the United States would benefit from patch testing.

PROGNOSIS/CLINICAL COURSE

It is difficult to assess the actual prognosis of ACD because there is no standardized instrument for such evaluation. The disruption of work, ability to return to work, and improvement of dermatitis with time are among outcome measures that have been studied in patients with ACD. Recent study designs have aimed to capture the increasingly important outcome measure of health-related quality of life (QoL).[143] When different QoL assessment tools have been applied to populations of patients with ACD it has been demonstrated that ACD negatively impacts QoL significantly. Holness and colleagues[144] found that pain, itching, embarrassment, work interference, and sleep difficulties were the most significant effects in QoL of their patch-test population. Kadyk et al[145] found the greatest impact on emotions, followed by symptoms, functioning, and occupational impact. Similarly, Woo and colleagues[146] reported that patients with the final diagnosis of ACD had a mean baseline QoL equal to that of patients experiencing hair loss and psoriasis. Zug et al[147] found that patients referred for patch testing were severely affected by frustration, reported feeling annoyed, and had a great concern about the persistence of their skin problem. Notably a factor that is strongly predictive of a negative impact on QoL is hand involvement of ACD. Similarly, the extent of the disease[148] and the duration of symptoms before diagnosis are both correlated with a poor prognosis and recalcitrant disease.[149] On the other hand, increased patient knowledge has been associated with improved prognosis in some studies.[150,151] Much of this information is extrapolated from data regarding occupational contact dermatitis.

TREATMENT

Because allergen identification can be achieved through proper patch testing, there is a good potential for a sustained remission. Therefore, identification and removal of the inciting agent(s), and they are often multiple, should always be the goal in the diagnosis and treatment of ACD.[152]

Chapter 14 :: Atopic Dermatitis (Atopic Eczema)

:: Donald Y.M. Leung, Lawrence F. Eichenfield, & Mark Boguniewicz

ATOPIC DERMATITIS AT A GLANCE

- Prevalence peak of 15–20% in early childhood in industrialized countries.
- A chronic or chronically relapsing disorder with major features of:
  - Pruritus;
  - Eczematous dermatitis (acute, subacute, or chronic) with typical morphology and age-specific patterns;
  - Facial and extensor involvement in infancy; and
  - Flexural eczema/lichenification in children and adults.
- Commonly associated with the following:
  - Personal or family history of atopy (allergic rhinitis, asthma, atopic dermatitis).
  - Xerosis/skin barrier dysfunction.
  - Immunoglobulin E reactivity.
  - Genetic basis influenced by environmental factors with alterations in immunologic responses in T cells, antigen processing, inflammatory cytokines, host defense proteins, allergen sensitivity, and infection.

INTRODUCTION

Atopic dermatitis (AD) is a chronically relapsing skin disease that occurs most commonly during early infancy and childhood. It is frequently associated with abnormalities in skin barrier function, allergen sensitization, and recurrent skin infections. There is no single distinguishing feature of AD or a diagnostic laboratory test. Thus, the diagnosis is based on the constellation of clinical findings listed in Table 14-1.[1]

EPIDEMIOLOGY

Since the 1960s, there has been a more than threefold increase in the prevalence of AD.[2] AD is a major public health problem worldwide, with a prevalence in children of 10–20% in the United States, Northern and Western Europe, urban Africa, Japan, Australia, and other industrialized countries.[3] The prevalence of AD in adults is approximately 1–3%. Interestingly, the prevalence of AD is much lower in agricultural regions of countries such as China and in Eastern Europe, rural Africa, and Central Asia. However, the most recent data from the International Study of Asthma and Allergies in Childhood (ISAAC) Phase Three study confirms that AD is a disease with high prevalence, affecting patients in both developed and developing countries.[4] There is also a female preponderance for AD, with an overall female/male ratio of 1.3:1.0.

The basis for this increased prevalence of AD is not well understood. However, wide variations in preva-

TABLE 14-1
Features of Atopic Dermatitis

Major Features
Pruritus
Rash on face and/or extensors in infants and young children
Lichenification in flexural areas in older children
Tendency toward chronic or chronically relapsing dermatitis
Personal or family history of atopic disease: asthma, allergic rhinitis, atopic dermatitis
Other Common Findings
Dryness
Dennie–Morgan folds (accentuated lines or grooves below the margin of the lower eyelid)
Allergic shiners (darkening beneath the eyes)
Facial pallor
Pityriasis alba
Keratosis pilaris
Ichthyosis vulgaris
Hyperlinearity of palms and soles
White dermatographism (white line appears on skin within 1 minute of being stroked with blunt instrument)
Conjunctivitis
Keratoconus
Anterior subcapsular cataracts
Elevated serum immunoglobulin E
Immediate skin test reactivity

lence have been observed within countries inhabited by similar ethnic groups, suggesting that environmental factors are critical in determining disease expression. Some of the potential risk factors that may be associated with the rise in atopic disease include small family size, increased income and education both in whites and blacks, migration from rural to urban environments, and increased use of antibiotics, that is, the so-called Western lifestyle.[5,6] This has resulted in the "hygiene hypothesis" that allergic diseases might be prevented by "infection in early childhood transmitted by unhygienic contact with older siblings."[7] Given the increase in autoimmune diseases such as diabetes, abnormalities in T regulatory cells have also been implicated.

ETIOLOGY AND PATHOGENESIS

AD is a highly pruritic inflammatory skin disease that results from complex interactions between genetic susceptibility genes resulting in a defective skin barrier, defects in the innate immune system, and heightened immunologic responses to allergens and microbial antigens.[8]

DECREASED SKIN BARRIER FUNCTION

AD is associated with a marked decrease in skin barrier function due to the downregulation of cornified envelope genes (filaggrin and loricrin), reduced ceramide levels, increased levels of endogenous proteolytic enzymes, and enhanced transepidermal water loss.[9,10] Addition of soap and detergents to the skin raises its pH, thereby increasing activity of endogenous proteases, leading to further breakdown of epidermal barrier function. The epidermal barrier may also be damaged by exposure to exogenous proteases from house dust mites and *Staphylococcus aureus* (*S. aureus*). This is worsened by the lack of certain endogenous protease inhibitors in atopic skin. These epidermal changes likely contribute to increased allergen absorption into the skin and microbial colonization. Because epicutaneous, as compared to systemic or airway, sensitization to allergen results in higher level allergic immune responses, decreased skin barrier function could act as a site for allergen sensitization and predispose such children to the development of food allergy and respiratory allergy.[11]

IMMUNOPATHOLOGY OF ATOPIC DERMATITIS

Clinically unaffected skin of AD patients manifests mild epidermal hyperplasia and a sparse perivascular T cell infiltrate.[12] Acute eczematous skin lesions are characterized by marked intercellular edema (spongiosis) of the epidermis. Dendritic antigen-presenting cells [e.g., Langerhans cells (LCs), macrophages] in lesional and, to a lesser extent, in nonlesional skin of AD exhibit surface-bound immunoglobulin E (IgE) molecules. A sparse epidermal infiltrate consisting primarily of T lymphocytes is also frequently observed.

In the dermis of the acute lesion, there is an influx of T cells with occasional monocyte-macrophages. The lymphocytic infiltrate consists predominantly of activated memory T cells bearing CD3, CD4, and CD45 RO (suggesting previous encounter with antigen). Eosinophils are rarely present in acute AD. Mast cells are found in normal numbers in different stages of degranulation.

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. There is an increased number of IgE-bearing LCs in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. Mast cells are increased in number but are generally fully granulated. Neutrophils are absent in AD skin lesions even in the setting of increased *S. aureus* colonization and infection. Increased numbers of eosinophils are observed in chronic AD skin lesions. These eosinophils undergo cytolysis with release of granule protein contents into the upper dermis of lesional skin. Eosinophil-derived extracellular major basic protein can be detected in a fibrillar pattern associated with the distribution of elastic fibers throughout the upper dermis. Eosinophils are thought to contribute to allergic inflammation by the secretion of cytokines and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins.

CYTOKINES AND CHEMOKINES

Atopic skin inflammation is orchestrated by the local expression of proinflammatory cytokines and chemokines.[12] Cytokines such as tumor necrosis factor-α (TNF-α) and interleukin 1 (IL-1) from resident cells [keratinocytes, mast cells, dendritic cells (DCs)] bind to receptors on the vascular endothelium, activating cellular signaling pathways, which leads to the induction of vascular endothelial cell adhesion molecules. These events initiate the process of tethering, activation, and adhesion to vascular endothelium followed by extravasation of inflammatory cells into the skin. Once inflammatory cells have infiltrated into the skin, they respond to chemotactic gradients established by chemokines that emanate from sites of injury or infection.

Acute AD is associated with the production of T helper 2 type (Th2) cytokines, notably IL-4 and IL-13,[13] which mediate immunoglobulin isotype switching to IgE synthesis and upregulate expression of adhesion molecules on endothelial cells. The important role that Th2 cytokines play in the skin's inflammatory response is supported by the observation that transgenic mice genetically engineered to overexpress IL-4 in their skin develop inflammatory pruritic skin lesions similar to AD, suggesting that local skin expression of Th2 cytokines plays a critical role in AD. There has also been considerable interest in IL-31, which is a novel Th2 cytokine that induces severe pruritus and dermatitis in experimental animals. IL-31 has also been found to be increased in AD skin and serum levels of IL-31 correlate with severity of skin disease.[14]

In chronic AD, there is an increase in the production of IL-5, which is involved in eosinophil development and survival. Increased production of granulocyte macrophage colony-stimulating factor in AD inhibits apoptosis of monocytes, thereby contributing to the persistence of AD.[15] The maintenance of chronic AD also involves production of the Th1-like cytokines IL-12 and IL-18, as well as several remodeling-associated cytokines, including IL-11 and transforming growth factor-1.[16]

The skin-specific chemokine, cutaneous T cell-attracting chemokine [CTACK; CC chemokine ligand 27 (CCL27)], is highly upregulated in AD and preferentially attracts skin homing cutaneous lymphoid antigen $(CLA)^+$ CC chemokine receptor 10^+ ($CCR10^+$) T cells into the skin.[17] CCR4 expressed on skin homing CLA^+ T cells can also bind to CCL17 on the vascular endothelium of cutaneous venules. Selective recruitment of CCR4-expressing Th2 cells is mediated by macrophage-derived chemokine and thymus and activation-regulated cytokine, both of which are increased in AD. Severity of AD has been linked to the magnitude of thymus and activation-regulated cytokine levels. In addition, chemokines such as fractalkine, interferon (IFN)-γ-inducible protein 10, and monokine induced by IFN-γ are strongly upregulated in keratinocytes and result in Th1-cell migration toward epidermis, particularly in chronic AD. Increased expression of the CC chemokines, macrophage chemoattractant protein-4, eotaxin, and RANTES (regulated on activation, normal T cell expressed and secreted) contribute to infiltration of macrophages, eosinophils, and T cells into both acute and chronic AD skin lesions.

KEY CELL TYPES IN ATOPIC DERMATITIS SKIN

ANTIGEN-PRESENTING CELLS. DCs play an important role in detecting environmental allergens or pathogens via pattern recognition receptors such as Toll-like receptors (TLR). AD skin contains two types of high-affinity, IgE receptor-bearing (FcεR) myeloid DCs: (1) LCs and (2) inflammatory dendritic epidermal cells (IDECs). IgE-bearing LCs appear to play an important role in cutaneous allergen presentation to IL-4-producing Th2 cells.[18] In this regard, IgE-bearing LCs from AD skin lesions, but not LCs that lack surface IgE, are capable of presenting allergens to T cells. These results suggest that cell-bound IgE on LCs facilitates capture and internalization of allergens into LCs before their processing and antigen presentation to T cells. IgE-bearing LCs that have captured allergen likely activate memory Th2 cells in atopic skin, but they may also migrate to the lymph nodes to stimulate naïve T cells there to further expand the pool of systemic Th2 cells. Stimulation of FcεRI on the surface of LCs by allergens induces the release of chemotactic signals and recruitment of precursor cells of IDECs and T cells in vitro. Stimulation of FcεRI on IDECs leads to the release of proinflammatory signals, which contribute to amplification of the allergic immune response.

In contrast to other inflammatory skin diseases, such as allergic contact dermatitis or psoriasis vulgaris, very low numbers of plasmacytoid DCs (pDCs), which play an important role in host defense against viral infections, can be detected within the AD skin lesion.[19] pDCs in the peripheral blood of patients with AD have been shown to bear the trimeric variant of FcεRI on their cell surface, which is occupied by IgE molecules. The modified immune function of pDCs of patients with AD after FcεRI-mediated allergen stimulation might contribute to a local deficiency of type I IFNs, thereby contributing to increased susceptibility of AD patients toward viral skin infections such as eczema herpeticum.[20]

T CELLS. Skin homing memory T cells play an important role in the pathogenesis of AD, particularly during the acute phase of illness. This concept is supported by the observation that primary T-cell immunodeficiency disorders are frequently associated with eczematous skin lesions that clear after successful bone marrow transplantation.[21] Furthermore, in animal models of AD, the eczematous rash does not occur in the absence of T cells. In addition, treatment with topical calcineurin inhibitors (TCIs), which target activated T cells, significantly reduces the clinical skin rash of AD.[22]

Several studies have demonstrated the presence of Th2-like T cells in acute AD that produce cytokines that enhance allergic skin inflammation. During the chronic phase of AD, there is a switch to Th1-like cells that primarily produce IFN-γ. These Th1-like cells induce the activation and apoptosis of keratinocytes.[23] Recently, T regulatory (Treg) cells have been described as a further subtype of T cells that have immunosuppressive function and cytokine profiles distinct from both Th1 and Th2 cells.[24] Treg cells are able to inhibit the development of both Th1 and Th2 responses. Mutations in a nuclear factor expressed in Treg cells, FoxP3, result in IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome characterized by elevated serum IgE, food allergy, and dermatitis that may be eczematous or psoriasiform. A deficiency of resident Treg cells has also been reported in AD skin.[25] Interestingly, staphylococcal superantigens subvert Treg cell function and may thereby augment skin inflammation.[26]

There has also been considerable interest in the role of Th17 cells in the immunopathogenesis of AD.[27] These cells produce inflammatory cytokines such as IL-17 and are thought to play a role in host defense by inducing keratinocytes to produce antimicrobial peptides as well as promote neutrophil chemotaxis. Th17 cells are increased in the skin lesions of autoimmune diseases, such as psoriasis, where they may promote inflammatory responses, including neutrophil infiltration but also reduce skin infection.[28] Compared to psoriasis, AD skin lesions have significantly fewer T cells expressing IL-17, but increased numbers of IL-4$^+$ cells.[29] Furthermore, it has been found that the Th2 cytokines, IL-4 and IL-13, inhibit IL-17 induced generation of antimicrobial peptides.[30] Interestingly, an independent increase of IL-22 expressing cells, originally thought to be produced by Th17 cells, can be found in AD skin and it has been suggested that these may contribute to epidermal hyperplasia.[31]

KERATINOCYTES. Keratinocytes play a critical role in the augmentation of atopic skin inflammation. AD keratinocytes secrete a unique profile of chemokines and cytokines after exposure to proinflammatory cytokines. This includes high levels of RANTES after stimulation with TNF-α and IFN-γ.[32] They are also an important source of thymic stromal lymphopoietin (TSLP), which activates DCs to prime naïve T cells to produce IL-4 and IL-13 (i.e., promotes Th2 cell differentiation).[33] The importance of TSLP in AD pathogenesis is supported by the observation that mice genetically manipulated to overexpress TSLP in the skin develop AD-like skin inflammation. Skin-derived TSLP is also thought to trigger the development of asthma.[34,35]

Keratinocytes are critical to the skin's innate immune responses, expressing Toll-like receptors, producing proinflammatory cytokines and antimicrobial peptides (such as human β defensins and cathelicidins) in response to tissue injury or invading microbes.[36] Several studies have now demonstrated that AD keratinocytes produce reduced amounts of antimicrobial peptides and this may predispose such individuals to skin colonization and infection with *S. aureus*, viruses, and fungi. However, this defect appears to be acquired as the result of Th2-cytokine (IL-4, IL-10, and IL-13) mediated inhibition of TNF-α and IFN-γ-induced antimicrobial peptide generation.

GENETICS

AD is a complex disease that is familially transmitted with a strong maternal influence.[37] Genome-wide linkage studies of families with AD have implicated chromosomal regions that overlap with other inflammatory skin diseases such as psoriasis. Together with candidate gene studies, these have provided interesting insights into the pathogenesis of AD. Although many genes are likely to be involved in the development of AD, there has been particular interest in the potential role of skin barrier/epidermal differentiation genes and immune response/host defense genes.

Loss-of-function mutations in *FLG*, which encodes the epidermal barrier protein, filaggrin, have been demonstrated to be a major predisposing factor for AD,[38] as well as ichthyosis vulgaris, a common keratinizing disorder associated with AD (Figs. 14-1 and 14-2). Patients with filaggrin null mutations often have early onset, severe eczema, high level allergen sensitization, and develop asthma later in childhood. Of note, the filaggrin gene is found on chromosome 1q21 that contains genes (including loricrin and S100 calcium-binding proteins) in the epidermal differentiation complex, known to be expressed during terminal differentiation of the epidermis. DNA microarray analyses have demonstrated upregulation of S100 calcium-binding proteins and downregulation of loricrin and filaggrin in AD. Candidate gene approaches have also implicated variants in the *SPINK5* gene, which is expressed in the uppermost epidermis where its product, LEKT1, inhibits two serine proteases involved in desquamation and inflammation (stratum corneum tryptic enzyme and stratum corneum chymotryptic

Figure 14-1 Ichthyosis vulgaris commonly accompanies atopic dermatitis and is thought to be responsible for the barrier defect in a subset of patients. Note the larger scales on the lower extremities.

Figure 14-2 Hyperlinear palms.

enzyme). Stratum corneum tryptic enzyme and stratum corneum tryptic enzyme expression is increased in AD, suggesting that an imbalance of protease versus protease inhibitor activity may contribute to atopic skin inflammation.[9]

These observations establish a key role for impaired skin barrier function in the pathogenesis of AD, as impaired skin barrier formation allows increased transepidermal water loss and, importantly, increased entry of allergens, antigens, and chemicals from the environment resulting in skin inflammatory responses. It is important to note that these filaggrin mutations, and likely other mutations affecting the skin barrier, can occur in clinically normal individuals, and in patients with ichthyosis vulgaris without clinical evidence of skin inflammation. The majority of patients with AD outgrow their inflammatory skin disease by adolescence. Thus, AD is a complex trait that involves interactions between multiple gene products requiring environmental factors and the immune response to result in the final clinical phenotype. Chromosome 5q31-33 contains a clustered family of functionally related cytokine genes—*IL-3*, *IL-4*, *IL-5*, *IL-13*, and granulocyte macrophage colony-stimulating factor—which are expressed by Th2 cells. A case control comparison has suggested a genotypic association between the T allele of the 590C/T polymorphism of the IL-4 gene promoter region with AD. Because the T allele is associated with increased IL-4 gene promoter activity when compared to the C allele, this suggests that genetic differences in transcriptional activity of the *IL-4* gene influence AD predisposition. In addition, an association of AD with a gain-of-function mutation in the α subunit of the IL-4 receptor has been reported, providing further support of the concept that *IL-4* gene expression plays a role in AD. Functional mutations in the promoter region of the CC chemokines, RANTES, and eotaxin, as well as variants in IL-13, the α subunit of the high affinity cell surface receptor for IgE (FcεR1) found on basophils and mast cells suggest an overlapping of genetic basis with other atopic diseases.

Recent studies demonstrating a significant association between *TSLP* gene polymorphisms and AD provide further support for the importance of Th2 polarization in this disease.[37] The involvement of T cell γ interferon and *IL-18* genes support the role of $CD4^+$ T cells and dysregulation of *Th1* genes in the pathophysiology of AD. As well, reports of AD association with polymorphisms of the *NOD1* gene, which encodes cytosolic pathogen recognition receptor and Toll-like receptors, suggest an important role for host defense genes in the pathogenesis of AD. The reader is referred to Chapter 10 and reference 35 for a detailed discussion of the genetics of AD.

BASIS OF PRURITUS IN ATOPIC DERMATITIS

Pruritus is a prominent feature of AD, manifested as cutaneous hyperreactivity and scratching following exposure to allergens, changes in humidity, excessive sweating, and low concentrations of irritants. Control of pruritus is important because mechanical injury from scratching can induce proinflammatory cytokine and chemokine release, leading to a vicious scratch–itch cycle perpetuating the AD skin rash. The mechanisms of pruritus in AD are poorly understood. Allergen-induced release of histamine from skin mast cells is not an exclusive cause of pruritus in AD, because H_1 antihistamines are not effective in controlling the itch of AD.[39] However, recent studies demonstrating a potential role for H_4 receptors in skin pathobiology suggests that histamine may play a contributory role.[40] However, the observation that treatment with topical corticosteroids and calcineurin inhibitors is effective at reducing pruritus suggests that the inflammatory cells play an important role in pruritus.[41,42] Molecules that have been implicated in pruritus include T-cell-derived cytokines such as IL-31, stress-induced neuropeptides, and proteases which can act on protease-activated receptors, eicosanoids, and eosinophil-derived proteins.[43,44] The reader is referred to Chapter 103 for a detailed discussion of the pathophysiology of pruritus.

CLINICAL FINDINGS

The diagnosis of AD is based on the constellation of clinical features summarized in Table 14-1. AD typically begins during infancy. Approximately 50% of patients develop this illness by the first year of life and an additional 30% between the ages of 1–5 years. Between 50–80% of patients with AD develop allergic rhinitis or asthma later in childhood. Many of these patients outgrow their AD as they are developing respiratory allergy.

CUTANEOUS LESIONS

Intense pruritus and cutaneous reactivity are cardinal features of AD. Pruritus may be intermittent throughout the day but is usually worse in the early evening and night. Its consequences are scratching, prurigo papules (Fig. 14-3), lichenification (Fig. 14-4), and eczematous skin lesions. Acute skin lesions are

Figure 14-3 Prurigo papules in a patient with atopic dermatitis.

Figure 14-4 Lichenification and excoriations on the dorsal aspect of the hand in a child with atopic dermatitis.

characterized by intensely pruritic, erythematous papules associated with excoriation, vesicles over erythematous skin, and serous exudate (Fig. 14-5). Subacute dermatitis is characterized by erythematous, excoriated, scaling papules (Fig. 14-6). Chronic AD is characterized by (1) thickened plaques of skin, (2) accentuated skin markings (lichenification), and (3) fibrotic papules (prurigo nodularis; Fig. 14-7). In chronic AD, all three stages of skin reactions frequently coexist in the same individual. At all stages of AD, patients usually have dry, lackluster skin.

The distribution and skin reaction pattern vary according to the patient's age and disease activity. During infancy, the AD is generally more acute and primarily involves the face (Fig. 14-8), scalp, and the extensor surfaces of the extremities (Fig. 14-9). The diaper area is usually spared. In older children, and in those who have long-standing skin disease, the patient develops the chronic form of AD with lichenification and localization of the rash to the flexural folds of the extremities (Fig. 14-10). AD often subsides as the patient grows older, leaving an adult with skin that is prone to itching and inflammation when exposed to exogenous irritants. Chronic hand eczema may be the primary manifestation of many adults with AD (Fig. 14-11). Other associated features of AD are listed in Table 14-1.

LABORATORY TESTS

Laboratory testing is not needed in the routine evaluation and treatment of uncomplicated AD. Serum

Figure 14-6 Confluent erythematous papules on the cheeks of an infant with subacute atopic dermatitis. Chronic exposure to saliva and moist food at this location has been thought to contribute to the distribution.

Figure 14-7 Severe lichenification and hyperpigmented prurigo papules seen in a patient with chronic atopic dermatitis.

IgE levels are elevated in approximately 70–80% of AD patients. This is associated with sensitization against inhalant and food allergens and/or concomitant allergic rhinitis and asthma.[8] In contrast, 20–30% of AD patients have normal serum IgE levels. This subtype of AD has a lack of IgE sensitization against inhalant or food allergens. However, some of these patients may possess IgE sensitization against microbial antigens such as *S. aureus* toxins, and *Candida albicans* or *Malassezia sympodialis* can be detected. As well, some of these patients show positive reactions using the atopy patch test despite negative immediate skin tests.

The majority of patients with AD also have peripheral blood eosinophilia. Patients with AD have increased spontaneous histamine release from basophils. These findings likely reflect a systemic Th2 immune response in AD especially those patients who have elevated serum IgE levels. Importantly, the peripheral blood skin homing CLA^+ T cells in AD expressing either CD4 or CD8 spontaneously secrete IL-5 and IL-13, which functionally prolong eosinophil survival and induce IgE synthesis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Table 14-1 lists the clinical features of AD. Of the major features, pruritus and chronic or remitting eczematous dermatitis with typical morphology and distribution are essential for diagnosis. Other features, including allergy or elevated IgE, are variable, and some of the "associated features" in the table may not be useful discriminators of individuals with AD from the unaffected general population. Various diagnostic criteria have been proposed to assist with clinical diagnosis,

Figure 14-8 Edematous, erythematous eyelids with lichenification and hyperpigmentation in an adolescent with atopic dermatitis. Note the infraocular (Dennie–Morgan) folds.

definition of patients for clinical studies, and epidemiologic population studies.[45] A refined list of diagnostic criteria suitable for epidemiologic studies has been derived and validated by workers in the United Kingdom.[46]

Figure 14-10 Childhood atopic dermatitis with lichenification of antecubital fossae and generalized severely pruritic eczematous plaques.

Figure 14-11 Typical papules, vesicles, and erosions seen in atopic hand dermatitis.

Box 14-1 lists a number of inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations that share symptoms and signs with AD. These should be considered and ruled out before a diagnosis of AD is made. Infants presenting in the first year of life with failure to thrive, diarrhea, a generalized scaling erythematous rash, and recurrent cutaneous and/or systemic infections should be evaluated for severe combined immunodeficiency syndrome. Wiskott–Aldrich syndrome is an X-linked recessive disorder characterized by cutaneous findings almost indistinguishable from AD (see Chapter 143). It is associated with thrombocytopenia, variable abnormalities in humoral and cellular immunity, and recurrent severe bacterial infections. The hyper-IgE syndrome is characterized by elevated serum IgE levels, defective T-cell function, recurrent deep-seated bacterial infections, including cutaneous abscesses due to *S. aureus* and/or pruritic skin disease due to *S. aureus* pustulosis, or by recalcitrant dermatophytosis. A papulopustular eruption of the face and scalp may be seen in early life. Although *S. aureus* is an important pathogen in this disorder, infection with other bacteria, viruses, and fungi may occur, particularly when patients are on chronic antistaphylococcal antibiotic prophylaxis. Hyper-IgE is most commonly an autosomal dominant disorder due to mutations in *STAT3*, which also features pneumonia with pneumatocele formation, dental anomalies with retained primary teeth, bone fractures, and osteopenia. Autosomal recessive forms of hyper-IgE syndrome show severe eosinophilia, recurrent viral and bacterial infections, an increased risk of autoimmune disease, and serious neurologic manifestations, but not the pneumatoceles and dental or skeletal defects. To date, deficiencies of Tyk2 and dedicator of cytokinesis 8 protein (DOCK8) deficiency have been found, leading to a global defect in T-cell activation.[47]

It is important to recognize that an adult who presents with an eczematous dermatitis with no history of childhood eczema, respiratory allergy, or atopic family history may have allergic contact dermatitis. A contact

BOX 14-1 DIFFERENTIAL DIAGNOSIS OF ATOPIC DERMATITIS

MOST LIKELY

- Contact dermatitis (allergic and irritant)
- Seborrheic dermatitis
- Scabies
- Psoriasis
- Ichthyosis vulgaris
- Keratosis pilaris
- Dermatophytosis

CONSIDER

- Asteatotic eczema
- Lichen simplex chronicus
- Nummular dermatitis
- Juvenile palmar–plantar dermatosis
- Impetigo
- Drug eruptions
- Perioral dermatitis
- Pityriasis alba
- Photosensitivity disorders (hydroa vacciniforme; polymorphous light eruption, porphyrias)
- Molluscum dermatitis

LESS COMMON/RARE DISORDERS PREDOMINANT IN ADOLESCENTS AND ADULTS

- Cutaneous T-cell lymphoma (mycosis fungoides or Sézary syndrome)
- Human immunodeficiency virus-associated dermatoses
- Lupus erythematosus
- Dermatomyositis
- Graft-versus-host disease
- Pemphigus foliaceus
- Dermatitis herpetiformis
- Photosensitivity disorders (hydroa vacciniforme, polymorphous light eruption, porphyrias)

LESS COMMON/RARE DISORDERS PREDOMINANT IN INFANTS/CHILDREN

Metabolic/Nutritional

- Phenylketonuria
- Prolidase deficiency
- Multiple carboxylase deficiency
- Zinc deficiency (acrodermatitis enteropathica; prematurity; deficient breast milk zinc; cystic fibrosis)
- Others: biotin, essential fatty acids, organic acidurias

Primary Immunodeficiency Disorders

- Severe combined immunodeficiency disorder
- DiGeorge syndrome
- Hypogammaglobulinemia
- Agammaglobulinemia
- Wiskott–Aldrich syndrome
- Ataxia-telangiectasia
- Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome
- Hyperimmunoglobulin E syndrome (autosomal dominant and recessive forms)
- Chronic mucocutaneous candidiasis
- Omenn syndrome

Other Genetic Syndromes

- Netherton syndrome

Inflammatory, Autoimmune Disorders

- Eosinophilic gastroenteritis
- Gluten-sensitive enteropathy
- Neonatal lupus erythematosus

Proliferative Disorders

- Langerhans cell histiocytosis

allergen should be considered in any patient whose AD does not respond to appropriate therapy. Of note, contact allergy to topical glucocorticoids and TCIs has been reported in patients with chronic dermatitis. In addition, cutaneous T-cell lymphoma must be ruled out in any adult presenting with chronic dermatitis poorly responsive to topical glucocorticoid therapy. Ideally, biopsies should be obtained from three separate sites, because the histology may show spongiosis and cellular infiltrate similar to AD. Eczematous dermatitis has been also reported with human immunodeficiency virus as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyoses, and seborrheic dermatitis.

COMPLICATIONS

OCULAR PROBLEMS

Eye complications associated with severe AD can lead to significant morbidity. Eyelid dermatitis and chronic blepharitis are commonly associated with AD and may result in visual impairment from corneal scarring. Atopic keratoconjunctivitis is usually bilateral and can have disabling symptoms that include itching, burning, tearing, and copious mucoid discharge. Vernal conjunctivitis is a severe bilateral recurrent chronic inflammatory process associated with papillary hypertrophy, or cobblestoning of the upper eyelid

conjunctiva. It usually occurs in younger patients and has a marked seasonal incidence, often in the spring. The associated intense pruritus is exacerbated by exposure to irritants, light, or sweating. Keratoconus is a conical deformity of the cornea believed to result from chronic rubbing of the eyes in patients with AD and allergic rhinoconjunctivitis. Cataracts were reported in the early literature to occur in up to 21% of patients with severe AD. However, it is unclear whether this was a primary manifestation of AD or the result of the extensive use of systemic and topical glucocorticoids, particularly around the eyes. Indeed, more recent studies suggest that routine screening for cataracts in patients with AD may not be productive unless there is concern about potential side effects from steroid therapy.

INFECTIONS

AD can be complicated by recurrent viral skin infections that may reflect local defects in T-cell function.[48] The most serious viral infection is herpes simplex (see Chapter 193), which can affect patients of all ages, resulting in Kaposi varicelliform eruption or eczema herpeticum. After an incubation period of 5–12 days, multiple, itchy, vesiculopustular lesions erupt in a disseminated pattern; vesicular lesions are umbilicated, tend to crop, and often become hemorrhagic and crusted (Fig. 14-12). Punched out and extremely painful erosions result. These lesions may coalesce to large, denuded, and bleeding areas that can extend over the entire body.

Although smallpox infections have been eradicated worldwide since the late 1970s, threats of bioterrorism (with smallpox and other infectious agents) have made nations reconsider their policies toward initiating vaccination programs. In AD patients, smallpox vaccination (or even exposure to vaccinated individuals) (see Chapter 195) may cause a severe widespread eruption (called *eczema vaccinatum*) that appears very similar to eczema herpeticum. Thus, in patients with AD, vaccination is contraindicated unless there is a clear risk of smallpox. In addition, decisions regarding vaccination of family members should take into consideration the potential of eczema vaccinatum in household contacts.

Figure 14-12 Eczema herpeticum. Typical vesicles and crusting in a patient with disseminated disease.

Superficial fungal infections are also more common in atopic individuals and may contribute to the exacerbation of AD. Patients with AD have an increased prevalence of *Trichophyton rubrum* infections compared to nonatopic controls. There has been particular interest in the role of *M. sympodialis* (*Pityrosporum ovale* or *P. orbiculare*) in AD. *M. sympodialis* is a lipophilic yeast (see Chapters 188 and 189) commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* are commonly found in AD patients and most frequently in patients with head and neck dermatitis. In contrast, IgE sensitization to *M. sympodialis* is rarely observed in normal controls or asthmatics. Positive allergen patch-test reactions to this yeast have also been demonstrated. The potential importance of *M. sympodialis* as well as other dermatophyte infections is further supported by the reduction of AD skin severity in such patients after treatment with antifungal agents.

S. aureus is found in more than 90% of AD skin lesions. Honey-colored crusting, folliculitis, and pyoderma are indicators of secondary bacterial skin infection, usually due to *S. aureus*, that requires antibiotic therapy. Regional lymphadenopathy is common in such patients. The importance of *S. aureus* in AD is supported by the observation that patients with severe AD, even those without overt infection, can show clinical response to combined treatment with antistaphylococcal antibiotics and topical glucocorticoids. Although recurrent staphylococcal pustulosis can be a significant problem in AD, deep-seated *S. aureus* infections occur rarely and should raise the possibility of an immunodeficiency syndrome such as hyper-IgE syndrome. Methicillin-resistant *S. aureus* has become an increasingly important pathogen in patients with AD.[49]

HAND DERMATITIS

Patients with AD often develop nonspecific, irritant hand dermatitis. It is frequently aggravated by repeated wetting and by washing of the hands with harsh soaps, detergents, and disinfectants. Atopic individuals with occupations involving wet work are prone to develop an intractable hand dermatitis in the occupational setting. This is a common cause of occupational disability.

EXFOLIATIVE DERMATITIS

Patients with extensive skin involvement may develop exfoliative dermatitis (see Chapter 23). This is associated with generalized redness, scaling, weeping, crusting, systemic toxicity, lymphadenopathy, and fever. Although this complication is rare, it is potentially life threatening. It is usually due to superinfection, for example, with toxin-producing *S. aureus* or herpes simplex infection, continued irritation of the skin, or inappropriate therapy. In some cases, the withdrawal of systemic glucocorticoids used to control severe AD may be a precipitating factor for exfoliative erythroderma.

PROGNOSIS AND CLINICAL COURSE

The natural history of AD is not completely known because studies have been flawed in terms of inadequate sample size, an unclear definition of remission, inadequate length of follow-up, selection bias in the initial cohort, and excessive loss of patients to follow-up. Nevertheless, although the outcome of AD may be difficult to predict in any given individual, the disease generally tends to be more severe and persistent in young children. Periods of remission appear more frequently as the patient grows older. Spontaneous resolution of AD has been reported to occur after age 5 years in 40–60% of patients affected during infancy, particularly if their disease is mild. Although earlier studies suggested that approximately 84% of children outgrow their AD by adolescence, more recent studies have reported that AD disappears in approximately 20% of children followed from infancy until adolescence, but becomes less severe in 65%. In addition, more than one-half of adolescents treated for mild dermatitis may experience a relapse of disease as adults. Filaggrin mutations have been associated with higher rates of persistent atopic dermatitis into later childhood and adulthood.[50] Importantly, for occupational counseling, adults whose childhood AD has been in remission for a number of years may present with hand dermatitis, especially if daily activities require repeated hand wetting. The following predictive factors correlate with a poor prognosis for AD: widespread AD in childhood, associated allergic rhinitis and asthma, family history of AD in parents or siblings, early age at onset of AD, being an only child, and very high serum IgE levels.

TREATMENT

Successful treatment of AD requires a systematic, multipronged approach that incorporates education about the disease state, skin hydration, pharmacologic therapy, and the identification and elimination of flare factors such as irritants, allergens, infectious agents, and emotional stressors (Fig. 14-13).[51,52] Many factors lead to the symptom complex characterizing AD. Thus, treatment plans should be individualized to address each patient's skin disease reaction pattern, including the acuity of the rash, and the trigger factors that are unique to the particular patient. In patients refractory to conventional forms of therapy, alternative anti-inflammatory and immunomodulatory agents may be necessary.[53]

TOPICAL THERAPY

CUTANEOUS HYDRATION. Patients with AD have abnormal skin barrier function with increased transepidermal water loss and decreased water content and dry skin (xerosis) contributing to disease morbidity by the development of microfissures and cracks in the skin, which serve as portals of entry for skin pathogens, irritants, and allergens. *FLG* gene mutations have also been shown to result in decreased epidermal levels of natural moisturizing factor.[54] This problem can become aggravated during the dry winter months and in certain work environments. Warm soaking baths for approximately 10 minutes followed by the application of an occlusive emollient or topical medication to retain moisture can give such patients excellent symptomatic relief. Bathing without emollient use may result in drier skin.[55] Use of an effective emollient combined with hydration therapy helps to restore and preserve the stratum corneum barrier, and may decrease the need for topical glucocorticoids. Moisturizers are available in the form of lotions, creams, or ointments. Some lotions and creams may be irritating due to added preservatives, solubilizers, and fragrances. Lotions containing water may be drying due to an evaporative effect.

Hydrophilic ointments can be obtained in varying degrees of viscosity according to the patient's preference. Occlusive ointments are sometimes not well tolerated because of interference with the function of the eccrine sweat ducts and the induction of folliculitis. In these patients, less occlusive agents should be used.

Topical therapy to replace abnormal epidermal lipids, improve skin hydration, and decrease skin barrier dysfunction may be useful therapeutically. Studies have shown benefits of topical preparations with distinct compositions of lipids and ceramides, as well as a nonsteroidal cream containing palmitamide MEA, an essential fatty acid, and a hydrolipidic cream with glycyrrhetinic acid (MAS063ADP).[56,57] Further clinical studies to define the benefits relative to traditional moisturizers and topical anti-inflammatory agents will be helpful.

Hydration, by baths or wet dressings, promotes transepidermal penetration of topical glucocorticoids. Dressings may also serve as an effective barrier against persistent scratching, allowing more rapid healing of excoriated lesions.[58] Wet dressings, or "wet wraps" are recommended for use on severely affected or chronically involved areas of dermatitis refractory to therapy.[59] However, overuse of wet dressings may result in maceration of the skin complicated by secondary infection. Wet dressings or baths also have the potential to promote drying and fissuring of the skin if not followed by topical emollient use. Thus, wet dressing therapy is reserved for poorly controlled AD and should be closely monitored by a physician.

TOPICAL ANTI-INFLAMMATORY THERAPY

A recent study looked at TEWL, as well as several other parameters of epidermal barrier including stratum corneum hydration and dye penetration.[60] The authors found improvement in all parameters when AD patients were treated with both a topical steroid (betamethasone valerate 0.1% cream) and a topical calcineurin inhibitor (pimecrolimus 1% cream) applied to paired lesions of the upper extremities. Electron

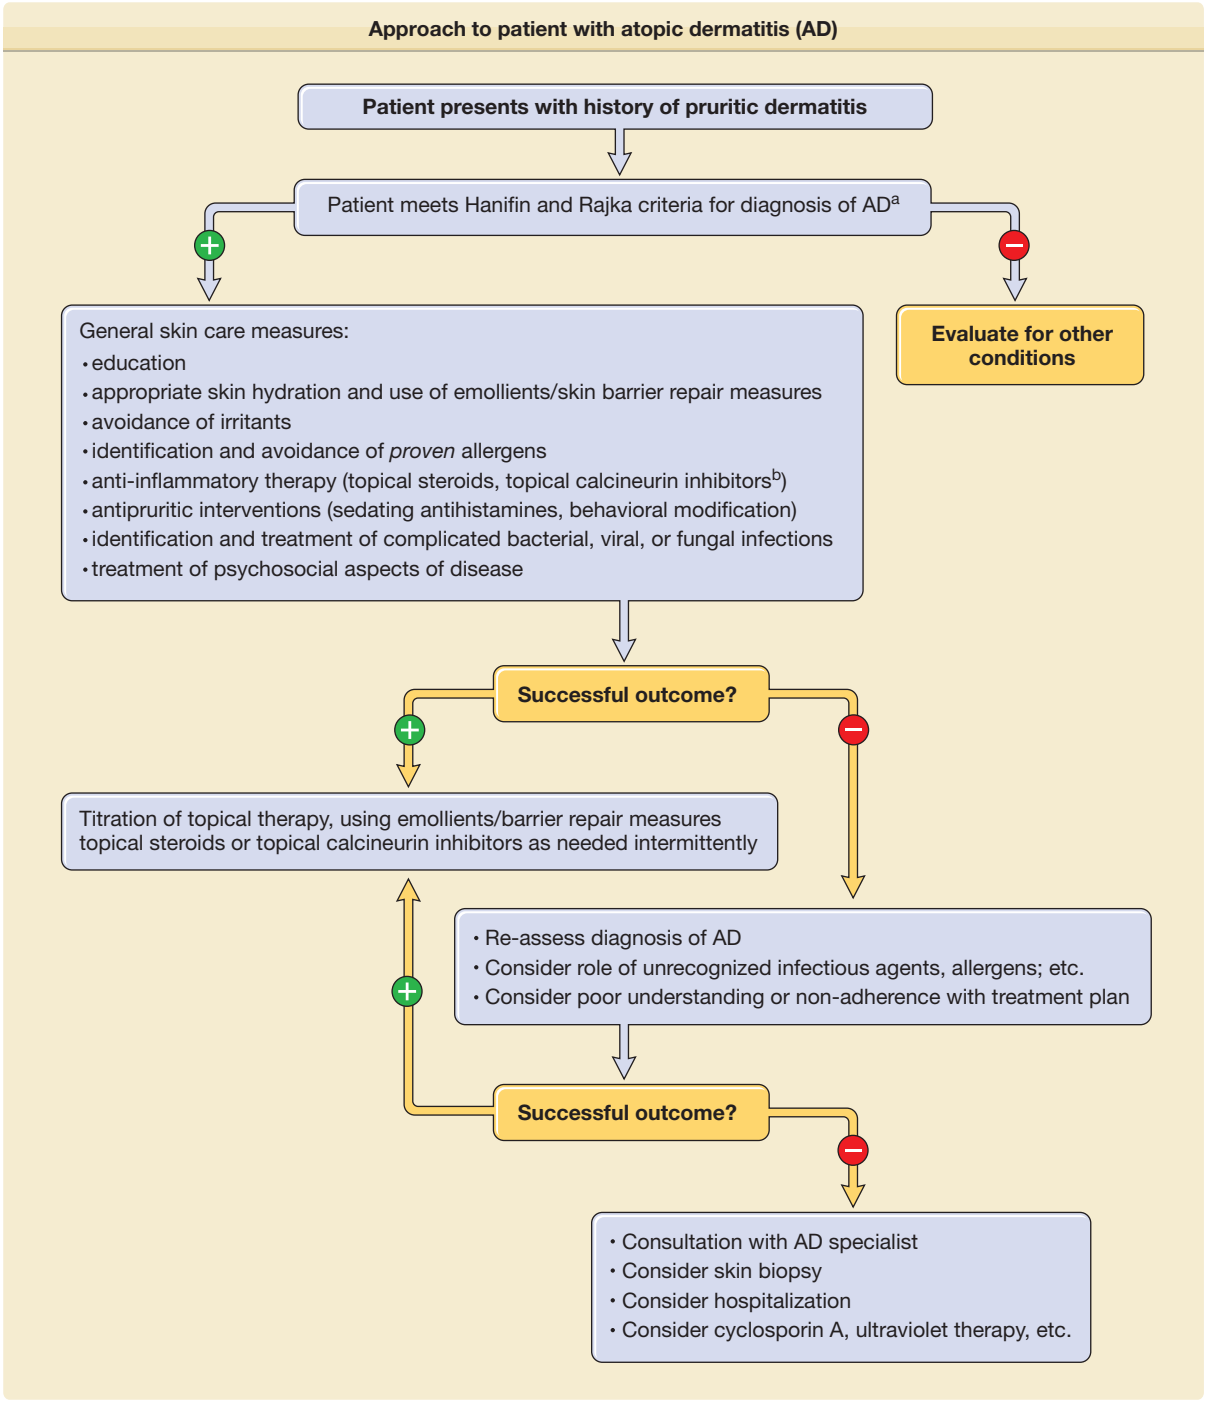

Figure 14-13 Approach to patient with atopic dermatitis (AD). [a]See Table 14-1. [b]Second-line therapy per black box warning.

microscopic evaluation of barrier structure showed prevalently ordered stratum corneum lipid layers and regular lamellar body extrusion in the calcineurin inhibitor-treated skin but inconsistent extracellular lipid bilayers and only partially filled lamellar bodies in the steroid-treated skin. Both treatments normalized epidermal differentiation and reduced epidermal hyperproliferation. Both anti-inflammatory therapies increased expression of filaggrin and involucrin in the skin. Betamethasone valerate was superior in reducing clinical symptoms and epidermal proliferation, but twice daily use over the 3-week period of the study led to epidermal thinning. The authors concluded that since pimecrolimus improved the epidermal barrier and did not cause cutaneous atrophy, it might be more suitable for long-term treatment of AD. However, the finding that the topical steroid was more effective in reducing clinical symptoms and inflammation

supports the use of topical steroids for acute intervention of AD flares.

TOPICAL GLUCOCORTICOID THERAPY. Topical glucocorticoids are the cornerstone of treatment for anti-inflammatory eczematous skin lesions. Because of potential side effects, most physicians use topical glucocorticoids only to control acute exacerbations of AD. However, recent studies suggest that once control of AD is achieved with a daily regimen of topical glucocorticoid, long-term control can be maintained in a subset of patients with twice weekly applications of topical fluticasone to areas that have healed but are prone to developing eczema.[61]

Patients should be carefully instructed in the use of topical glucocorticoids to avoid potential side effects. The potent fluorinated glucocorticoids should be avoided on the face, the genitalia, and the intertriginous areas. A low-potency glucocorticoid preparation is generally recommended for these areas. Patients should be instructed to apply topical glucocorticoids to their skin lesions and to use emollients over uninvolved skin. Failure of a patient to respond to topical glucocorticoids is sometimes due in part to an inadequate supply. It is important to remember that it takes approximately 30 g of cream or ointment to cover the entire skin surface of an adult once. To treat the entire body twice daily for 2 weeks requires approximately 840 g (2 lb) of topical glucocorticoids.

There are seven classes of topical glucocorticoids, ranked according to their potency based on vasoconstrictor assays. Because of their potential side effects, the ultrahigh-potency glucocorticoids should be used only for very short periods of time and in areas that are lichenified but not on the face or intertriginous areas. The goal is to use emollients to enhance skin hydration and low-potency glucocorticoids for maintenance therapy. Midpotency glucocorticoids can be used for longer periods of time to treat chronic AD involving the trunk and extremities. Newer formulations of topical steroids include gel formulations without alcohol bases that moisturize skin, and solutions, oils, foams, and shampoos that may be useful on hair-bearing surfaces.

Factors which influence topical glucocorticoid potency and side effects include the molecular structure of the compound, the vehicle, the amount of medication applied, the duration of application, occlusion, as well as host factors, including age, body surface area and weight, skin inflammation, anatomic location of treated skin, and individual differences in cutaneous or systemic metabolism. Side effects from topical glucocorticoids are directly related to the potency ranking of the compound and the length of use, so it is incumbent on the clinician to balance the need for a more potent steroid with the potential for side effects. In addition, ointments have a greater potential to occlude the epidermis, resulting in enhanced systemic absorption when compared to creams. Side effects from topical glucocorticoids can be divided into local side effects and systemic side effects resulting from suppression of the hypothalamic–pituitary–adrenal axis. Local side effects include the development of striae, skin atrophy, perioral dermatitis, and acne rosacea. The potential for potent topical glucocorticoid to cause adrenal suppression is greatest in infants and young children. Several topical steroid formulations have been specifically tested for safety and received specific US Federal Drug Administration (FDA) approval for use in younger children such as desonide hydrogel and nonethanolic foam, fluocinolone acetonide oil, and fluticasone 0.05% cream.[62–65] Mometasone cream and ointment are approved for children aged 2 years and older.

Because normal-appearing skin in AD shows evidence of immunologic dysregulation, the use of topical corticosteroids as maintenance therapy has been reported in several controlled studies.[66] Once control of AD with a once daily regimen was achieved, long-term control could be maintained with twice weekly application of fluticasone to previously involved areas. Given recent insights into skin barrier and immunologic abnormalities and colonization of normal-appearing skin in AD by *S. aureus*, it is important to appreciate that proactive therapy is an attempt to control residual disease, not just application of an active drug to nonaffected skin.[67]

TOPICAL CALCINEURIN INHIBITORS. Topical tacrolimus and pimecrolimus have been developed as nonsteroidal immunomodulators.[68] Tacrolimus ointment 0.03% has been approved for intermittent treatment of moderate to severe AD in children aged 2 years and older, with tacrolimus ointment 0.1% approved for use in adults; pimecrolimus cream 1% is approved for treatment of patients aged 2 years and older with mild–moderate AD. Both drugs have proven to be effective with a good safety profile for treatment up to 4 years with tacrolimus ointment[69] and up to 2 years with pimecrolimus cream.[70] A frequently observed side effect with TCIs is a transient burning sensation of the skin. Importantly, treatment with TCIs is not associated with skin atrophy,[71] thus they are particularly useful for the treatment of areas such as the face and intertriginous regions. Ongoing surveillance and recent reports have not shown a trend for increased frequency of viral superinfections, especially eczema herpeticum.[72] The long-term safety of TCIs has not been established. Rare cases of skin malignancy and lymphoma have been reported with topical tacrolimus, though the level of data quality and applicability of these reports was judged low in the report of a scientific consensus conference.[73] Importantly, a case-control study of a large database that identified a cohort of 293,253 patients with AD found no increased risk of lymphoma with the use of TCIs.[74] Twice to three times weekly maintenance therapy using tacrolimus ointment has also been reported in both adults and children with AD.[75,76]

IDENTIFICATION AND ELIMINATION OF TRIGGERING FACTORS

GENERAL CONSIDERATIONS. Patients with AD are more susceptible to irritants than are unaffected individuals. Thus, it is important to identify and

eliminate aggravating factors that trigger the itch–scratch cycle. These include soaps or detergents, contact with chemicals, smoke, abrasive clothing, and exposure to extremes of temperature and humidity. Alcohol and astringents found in toiletries are drying. When soaps are used, they should have minimal defatting activity and a neutral pH. New clothing may be laundered before wearing to decrease levels of formaldehyde and other added chemicals. Residual laundry detergent in clothing may be irritating. Using a liquid rather than powder detergent and adding a second rinse cycle facilitates removal of the detergent.

Recommendations regarding environmental living conditions should include temperature and humidity control to avoid problems related to heat, humidity, and perspiration. Every attempt should be made to allow children to be as normally active as possible. Certain sports, such as swimming, may be better tolerated than other sports involving intense perspiration, physical contact, or heavy clothing and equipment, but chlorine should be rinsed off immediately after swimming and the skin lubricated. Although ultraviolet (UV) light may be beneficial to some patients with AD, sunscreens should be used to avoid sunburn. However, because sunscreens can be irritants, care should be used to identify a nonirritating product.

SPECIFIC ALLERGENS. Foods and aeroallergens such as dust mites, animal danders, molds, and pollens have been demonstrated to exacerbate AD. Potential allergens can be identified by taking a careful history and carrying out selective skin-prick tests or specific serum IgE levels. Negative skin tests or serum tests for allergen-specific IgE have a high predictive value for ruling out suspected allergens. However, a normal total serum IgE level does not rule out the possibility of allergen-specific IgE being present. Positive skin or in vitro tests, particularly to foods, often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and elimination diets. Avoidance of foods implicated in controlled challenges results in clinical improvement. Extensive elimination diets, which in some cases can be nutritionally deficient, are rarely, if ever, required, because even with multiple positive skin tests, the majority of patients react to three or fewer foods on controlled challenge. In dust mite-allergic patients with AD, prolonged avoidance of dust mites has been found to result in improvement of their skin disease. Avoidance measures include use of dust mite-proof encasings on pillows, mattresses, and box springs; washing bedding in hot water weekly; removal of bedroom carpeting; and decreasing indoor humidity levels with air conditioning. Because there are many triggers contributing to the flares of AD, attention should be focused on identifying and controlling the flare factors that are important to the individual patient. Infants and young children are more likely to have food allergies, whereas older children and adults are more likely to be sensitive to environmental aeroallergens. Contact allergens have been increasingly recognized in AD. A recent study found that of children with relevant positive reactions, 34% had a diagnosis of AD.[77]

EMOTIONAL STRESSORS. Although emotional stress does not cause AD, it often exacerbates the illness. AD patients often respond to frustration, embarrassment, or other stressful events with increased pruritus and scratching. In some instances, scratching is simply habitual and less commonly associated with significant secondary gain. Psychological evaluation or counseling should be considered in patients who have difficulty with emotional triggers or psychological problems, contributing to difficulty in managing their disease. It may be especially useful in adolescents and young adults who consider their skin disease disfiguring. Relaxation, behavioral modification, or biofeedback may be helpful in patients with habitual scratching.[58]

INFECTIOUS AGENTS. Antistaphylococcal antibiotics are very helpful in the treatment of patients who are heavily colonized or infected with *S. aureus*.[78] Cephalosporins or penicillinase-resistant penicillins (dicloxacillin, oxacillin, or cloxacillin) are usually beneficial for patients who are not colonized with resistant *S. aureus* strains. Because erythromycin-resistant *Staphylococci* are common, erythromycin and newer macrolide antibiotics are usually of limited utility. Topical antimicrobials such as mupirocin, fusidic acid, or more recently retapamulin offers some utility in the treatment of impetiginized lesions. A Cochrane Database analysis of interventions for impetigo found that topical mupirocin and topical fusidic acid are equal to or more effective than oral treatment for patients with limited disease and that fusidic acid and mupirocin are of similar efficacy.[79] Patients should be cautioned against using topical antibiotics in an "as-needed" manner that can lead to resistant organisms.[80]

Use of neomycin topically can result in development of allergic contact dermatitis as neomycin is among the more common allergens causing contact dermatitis. However, in patients with extensive superinfection, a course of systemic antibiotics is most practical. Methicillin-resistant *Staphylococci* may require culture and sensitivity testing to assist in appropriate antibiotic selection. Baths with dilute sodium hypochlorite (bleach) may also benefit AD patients with superinfected eczema, especially those with recurrent MRSA, although they can occasionally be irritating. Of note, a controlled study of twice weekly bleach baths for 3 months showed clinical benefit, although skin colonization by *S. aureus* did not disappear, even when combined with intranasal mupirocin 5 days each month.[81]

Herpes simplex can provoke recurrent dermatitis and may be misdiagnosed as *S. aureus* infection. The presence of punched-out erosions, vesicles, and/or infected skin lesions that do not respond to oral antibiotics should initiate a search for herpes simplex. This

can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base, direct immunofluorescence assay, polymerase chain reaction identification of herpes genetic material, or by viral culture. For infection suspected to be caused by herpes simplex, topical anti-inflammatory agents might be discontinued, at least temporarily. Antiviral treatment for cutaneous herpes simplex infections is of critical importance in the patient with widespread AD because life-threatening dissemination has been reported. Acyclovir, 400 mg three times daily for 10 days or 200 mg four times daily for 10 days by oral administration (or an equivalent dosage of one of the newer antiherpetic medications), is useful in adults with herpes simplex confined to the skin. Intravenous treatment may be necessary for severe disseminated eczema herpeticum. The dosage should be adjusted according to weight in children.

Dermatophyte infections can complicate AD and may contribute to exacerbation of disease activity. Patients with dermatophyte infection or IgE antibodies to *Malassezia* may benefit from a trial of topical or systemic antifungal therapy.

PRURITUS. The treatment of pruritus in AD should be directed primarily at the underlying causes. Reduction of skin inflammation and dryness with topical glucocorticoids and skin hydration, respectively, often symptomatically reduce pruritus. Inhaled and ingested allergens should be eliminated if documented to cause skin rash in controlled challenges. Systemic antihistamines act primarily by blocking the H_1 receptors in the dermis, thereby ameliorating histamine-induced pruritus. However, histamine is only one of many mediators that can induce pruritus of the skin. Therefore, certain patients may derive minimal benefit from antihistaminic therapy. Some antihistamines are also mild anxiolytics and may offer symptomatic relief through tranquilizing and sedative effects. Studies of newer, nonsedating antihistamines show variable results in the effectiveness of controlling pruritus in AD, although they may be useful in the subset of AD patients with concomitant urticaria or concurrent allergic rhinitis.

Because pruritus is usually worse at night, the sedating antihistamines, for example, hydroxyzine or diphenhydramine, may offer an advantage with their soporific side effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H_1- and H_2-histamine receptor-blocking effects. It can be used in doses of 10–75 mg orally at night or up to 75 mg bid in adult patients. If nocturnal pruritus remains severe, short-term use of a sedative to allow adequate rest may be appropriate. Treatment of AD with topical antihistamines is generally not recommended because of potential cutaneous sensitization. However, short-term (1 week) application of topical 5% doxepin cream has been reported to reduce pruritus without sensitization. Of note, sedation is a side effect of widespread application of doxepin cream, and allergic contact dermatitis has been reported.

TAR PREPARATIONS

Coal tar preparations may have antipruritic and anti-inflammatory effects on the skin, although usually not as pronounced as those of topical glucocorticoids.[82] Tar preparations may be useful in reducing the potency of topical glucocorticoids required in chronic maintenance therapy of AD. Newer coal tar products have been developed that are more acceptable with respect to odor and staining of clothes than some older products. Tar shampoos can be beneficial for scalp dermatitis and are often helpful in reducing the concentration and frequency of topical glucocorticoid applications. Tar preparations should not be used on acutely inflamed skin, because this often results in skin irritation. Side effects associated with tars include folliculitis and photosensitivity. There is a theoretic risk of tar being a carcinogen based on observational studies of workers using tar components in their occupations; however, epidemiologic studies do not confirm similar outcomes when used topically.[83]

PHOTOTHERAPY

Natural sunlight is frequently beneficial to patients with AD. However, if the sunlight occurs in the setting of high heat or humidity, thereby triggering sweating and pruritus, it may be deleterious to patients. Broadband UVB, broadband UVA, narrowband UVB (311 nm), UVA-1 (340 to 400 nm), and combined UVAB phototherapy can be useful adjuncts in the treatment of AD. Investigation of the photoimmunologic mechanisms responsible for therapeutic effectiveness indicates that epidermal LCs and eosinophils may be targets of UVA phototherapy, with and without psoralen, whereas UVB exerts immunosuppressive effects via blocking of function of antigen-presenting LCs and altered keratinocyte cytokine production. Photochemotherapy with psoralen and UVA light may be indicated in patients with severe, widespread AD, although studies comparing it with other modes of phototherapy are limited. Short-term adverse effects with phototherapy may include erythema, skin pain, pruritus, and pigmentation. Long-term adverse effects include premature skin aging and cutaneous malignancies (see Chapters 237 and 238 for detailed discussion of phototherapy and photochemotherapy, respectively).

HOSPITALIZATION

AD patients who appear erythrodermic or who have widespread severe skin disease resistant to outpatient therapy should be hospitalized before considering systemic alternative therapies (see section "Systemic Therapy"). In many cases, removing the patient from environmental allergens or emotional stresses, intense patient education, and assurance of compliance with therapy results in a sustained improvement in their AD. Clearing of the patient's skin during

hospitalization also allows the patient to undergo allergen skin testing and appropriately controlled provocative challenges to correctly identify or rule out potential allergens.

SYSTEMIC THERAPY

Systemic therapies discussed below were reviewed in a consensus conference.[53]

SYSTEMIC GLUCOCORTICOIDS. The use of systemic glucocorticoids, such as oral prednisone, is rarely indicated in the treatment of chronic AD. Some patients and physicians prefer the use of systemic glucocorticoids to avoid the time-consuming skin care involving hydration and topical therapy. However, the dramatic clinical improvement that may occur with systemic glucocorticoids is frequently associated with a severe rebound flare of AD after the discontinuation of systemic glucocorticoids. Short courses of oral glucocorticoids may be appropriate for an acute exacerbation of AD whereas other treatment measures are being instituted. If a short course of oral glucocorticoids is given, it is important to taper the dosage and to begin intensified skin care, particularly with topical glucocorticoids and frequent bathing followed by application of emollients to prevent rebound flaring of AD.

CYCLOSPORINE. Cyclosporine is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine transcription. The drug binds to cyclophilin, an intracellular protein, and this complex, in turn, inhibits calcineurin, a molecule required for initiation of cytokine gene transcription. Multiple studies demonstrate that both children and adults with severe AD, refractory to conventional treatment, can benefit from short-term cyclosporine treatment. Various oral-dosing regimens have been recommended: 5 mg/kg has generally been used with success in short-term and long-term (1 year) use, whereas some authorities advocate body-weight-independent daily dosing of adults with 150 mg (low dose) or 300 mg (high dose) daily of cyclosporine microemulsion. Treatment with cyclosporine is associated with reduced skin disease and an improved quality of life (see Chapter 233 for further discussion). Discontinuation of treatment may result in rapid relapse of skin disease, although some patients may have sustained remission. Elevated serum creatinine or more significant renal impairment and hypertension are specific side effects of concern with cyclosporine use.

ANTIMETABOLITES. Mycophenolate mofetil is a purine biosynthesis inhibitor used as an immunosuppressant in organ transplantation, which has been used for treatment of refractory inflammatory skin disorders (see Chapter 233). Open-label studies report that short-term oral mycophenolate mofetil, 2 g daily, as monotherapy results in clearing of skin lesions in adults with AD resistant to other treatment, including topical and oral steroids and psoralen and UVA light. The drug has generally been well tolerated with the exception of one patient developing herpes retinitis that may have been secondary to this immunosuppressive agent. Dose-related bone marrow suppression has also been observed. Similar results were previously reported in another open study of ten patients with a mean reduction in the SCORAD (SCORing Atopic Dermatitis) index of 68% in all ten patients. Of note, not all patients benefit from treatment. Therefore, the medication should be discontinued if patients do not respond within 4 to 8 weeks. Dose finding and well-controlled studies are needed for this drug.

Methotrexate is an antimetabolite with potent inhibitory effects on inflammatory cytokine synthesis and cell chemotaxis. Methotrexate has been used for adult AD patients with recalcitrant disease, although controlled trials are lacking. Dosing more frequently than the typical weekly dosing for psoriasis has been advocated.[84] In open-label studies, initial improvement was observed after a period ranging from 2 weeks to 3 months (mean 9.95 weeks +/– 3.17).

Azathioprine is a purine analog with anti-inflammatory and antiproliferative effects. It has been used for severe AD, and several controlled trials have been reported in adults and children.[85,86] Myelosuppression is a significant adverse effect. Thiopurine methyl transferase levels may predict individuals at risk.[87]

OTHER THERAPIES

INTERFERON-γ. IFN-γ is known to suppress IgE responses and downregulate Th2 cell proliferation and function. Several studies of patients with AD, including a multicenter, double-blind, placebo-controlled trial[88] and two long-term open trials,[89,90] have demonstrated that treatment with recombinant human IFN-γ results in clinical improvement. Reduction in clinical severity of AD correlated with the ability of IFN-γ to decrease total circulating eosinophil counts. Influenza-like symptoms are commonly observed side effects early in the treatment course.

OMALIZUMAB. Treatment of patients with severe AD and elevated serum IgE levels with monoclonal anti-IgE has shown lack of efficacy in three adult patients[91] and significant improvement in three adolescent patients.[92] In an open study of 11 adult patients with high IgE levels treated with anti-IgE, some patients had very good clinical improvement, others had none and several had worsening of their AD based on change in SCORAD.[93] To date, specific markers have not been found to identify potential responders.

ALLERGEN IMMUNOTHERAPY. Unlike allergic rhinitis and extrinsic asthma, immunotherapy with aeroallergens has not proven to be efficacious in the treatment of AD. There are anecdotal reports of both disease exacerbation and improvement. A recent study of specific immunotherapy over 12 months in adults with AD sensitized to dust mite allergen showed improvement in SCORAD as well as reduction in

topical steroid use.[94] However, well-controlled studies are still required to determine the role for immunotherapy with this disease. More recently, a controlled study with sublingual immunotherapy showed benefit in a subset of children with AD sensitized to dust mite allergen.[95] This data need to be reproduced in a larger pediatric population, given the natural history of AD.

EXTRACORPOREAL PHOTOPHERESIS. Extracorporeal photopheresis consists of the passage of psoralen-treated leukocytes through an extracorporeal UVA light system. Clinical improvement in skin lesions associated with reduced IgE levels has been reported in a few patients with severe, resistant AD who were treated with extracorporeal photopheresis and topical glucocorticoids.[96]

PROBIOTICS. Perinatal administration of the probiotic *Lactobacillus rhamnosus* strain GG was shown to reduce the incidence of AD in at-risk children during the first 2 years of life.[97] Mothers were given either placebo or *Lactobacillus* GG daily for 4 weeks before delivery and then either the mother (if breast-feeding) or the infant continued with daily therapy for 6 months. In a follow-up study, the same group assessed the persistence of potential to prevent AD at 4 years.[98] The results suggest that the preventive effect of *Lactobacillus* GG on AD could extend beyond infancy.

In a second study, children with AD treated with two *Lactobacillus* strains for 6 weeks experienced improvement of their eczema compared to placebo-treated patients, although their SCORAD index did not change significantly.[99] The treatment response was found to be more pronounced in patients with positive skin-prick tests and elevated IgE levels. Another study of children with moderate to severe AD treated for 8 weeks with *L. fermentum* in a placebo-controlled study showed persistent improvement in SCORAD at 16 weeks.[100] These studies suggest that probiotics, or at least some *Lactobacillus* strains, may have preventative, lasting effects on the incidence of AD in a subset of patients. More research into subgroups of responders, optimal therapy [route (i.e., directly to infant or via mother's milk); length of treatment; strain of *Lactobacillus*], as well as mechanisms involved is clearly needed.[101]

A recent meta-analysis found a modest role for probiotics in children with moderately severe disease in reducing SCORAD (mean change from baseline, –3.01; 95% confidence interval, –5.36 to –0.66; P = .01).[102] Duration of probiotic administration, age, and type of probiotic used did not affect outcomes. Another meta-analysis found that current evidence is more convincing for probiotics' efficacy in prevention, rather than treatment of AD in children.[103] In contrast to earlier studies, supplementation with *Lactobacillus* GG during pregnancy and early infancy neither reduced the incidence of AD nor altered the severity of AD in affected children, but was associated with increased rate of recurrent episodes of wheezy bronchitis.[104] A Cochrane review concluded that probiotics are not an effective treatment for eczema in children and that probiotic treatment carries a small risk of adverse events.[105]

CHINESE HERBAL MEDICATIONS. Several placebo-controlled clinical trials have suggested that patients with severe AD may benefit from treatment with traditional Chinese herbal therapy (see Chapter 241). They had significantly reduced skin disease and decreased pruritus. However, the beneficial response of Chinese herbal therapy is often temporary, and effectiveness may wear off despite continued treatment. The possibility of hepatic toxicity, cardiac side effects, or idiosyncratic reactions remains a concern. The specific ingredients of the herbs also remain to be elucidated and some preparations have been found to be contaminated with corticosteroids. At present, Chinese herbal therapy for AD is considered investigational.

ORAL VITAMIN D. A pilot randomized, double-blind placebo-controlled study looked at the benefit of oral vitamin D supplementation in children with AD from February to March in Boston.[106] Eleven pediatric patients primarily with mild AD were treated with either vitamin D (1,000 IU ergocalciferol) or placebo once daily for a month. IGA score improved in four of six subjects in the vitamin D group (80%), as compared to one of five subjects in the placebo group (p = 0.04). In addition, there was a greater reduction in EASI score in the vitamin D, as compared to the placebo group, although the difference was not statistically significant. In addition, in a controlled study, 14 healthy subjects and 14 subjects with AD were supplemented with 4,000 IU per day of oral vitamin D_3 (cholecalciferol) for 3 weeks.[107] Expression of the AMP cathelicidin was significantly increased in the skin biopsies of AD lesions, as compared to those in healthy skin or uninvolved AD skin, suggesting a role for oral vitamin D in improving innate immune responses in AD patients.[108]

EDUCATION AS INTERVENTION

Education may be considered as a therapeutic intervention for the management of atopic dermatitis.[51,52] Intensive disease education has been shown in randomized, controlled trials to improve subjective quality-of-life and objective eczema severity scores.[109] Intensive education may include comprehensive "center-based" patient/family teaching, written "handouts," and care plans, patient/family support groups, and Internet-accessed media. Several resources available online are listed in Table 14-2.

:: Susan Burgin

NUMMULAR ECZEMA

NUMMULAR ECZEMA AT A GLANCE

- Also known as *discoid eczema*.
- A chronic disorder of unknown etiology.
- Papules and papulovesicles coalesce to form nummular plaques with oozing, crust, and scale.
- Most common sites of involvement are upper extremities, including the dorsal hands in women, and the lower extremities in men.
- Pathology may show acute, subacute, or chronic eczema.

EPIDEMIOLOGY

Nummular eczema is predominantly a disease of adulthood. Men are more frequently affected than women. The peak incidence in both males and females is around 50–65 years of age. There is a second peak in women around 15–25 years of age. Nummular eczema is rare in infancy and childhood. The peak age of onset in childhood is 5 years.[1]

ETIOLOGY AND PATHOGENESIS

The pathogenesis of nummular eczema is still unknown. The vast majority of patients with nummular eczema do not have a personal or family history of atopy,[2,3] although nummular plaques may be seen in atopic eczema. Numerous factors have been implicated as causal. The state of hydration of the skin in elderly patients has been shown to be decreased.[4] The role of infection previously received much attention in the literature. An internal focus of infection, including teeth, upper respiratory tract, and lower respiratory tract, was found in 68% of patients in one study.[5] Eleven of thirteen patients without a history of atopic eczema improved after odontogenic infections were treated.[6] A role for environmental allergens, such as the house dust mite and *Candida albicans* has also been touted.[4] Nummular eczema has been reported during therapy with isotretinoin and gold.[7,8] Generalized nummular eczema is seen in patients with hepatitis C undergoing combination therapy with interferon α-2b and ribavirin.[9,10] Mercury amalgam was implicated as a cause in two patients.[11]

CLINICAL FINDINGS

Well-demarcated coin-shaped plaques form from coalescing papules and papulovesicles. Pinpoint oozing and crusting eventuate, and are distinctive (Figs. 15-1 and 15-2). Crust may however cover the entire surface (Fig. 15-3). Plaques range from 1 to 3 cm

Figure 15-1 Nummular eczema. Coin-shaped plaques with pinpoint erosions and excoriations. (Image from Division of Dermatology, University of the Witwatersrand, Johannesburg, South Africa, with permission, from Professor D. Modi.)

Figure 15-3 Nummular eczema in a child. Crusted plaques. (Used, with permission, from P. Lio, M.D., Northwestern University's Feinberg School of Medicine, Chicago.)

in size. The surrounding skin is generally normal but may be xerotic. Pruritus varies from minimal to severe. Central resolution may occur, leading to annular forms. Chronic plaques are dry, scaly, and lichenified. The classic distribution of lesions is the extensor aspects of the extremities. In women, the upper extremities, including the dorsal aspects of the hands, are more frequently affected than the lower extremities.[2] Exudative discoid and lichenoid dermatitis of Sulzberger-Garbe may represent a variant of nummular dermatitis.[12]

Figure 15-2 Nummular eczema. Single plaque showing pinpoint erosions and crusting.

LABORATORY TESTS

Patch testing may be useful in chronic recalcitrant cases to rule out a superimposed contact dermatitis. In a series from India, just under half of 50 patients were patch-test positive to colophony, nitrofurazone, neomycin sulfate, and nickel sulfate.[13] Serum IgE levels are normal.

SPECIAL TESTS

Histopathologic changes are reflective of the stage at which the biopsy is performed. Acutely, there is spongiosis, with or without spongiotic microvesicles. In subacute plaques, there is parakeratosis, scale-crust, epidermal hyperplasia, and spongiosis of the epidermis (Fig. 15-4). There is a mixed cell infiltrate in the dermis. Chronic lesions may resemble lichen simplex chronicus microscopically.

DIFFERENTIAL DIAGNOSIS

See Box 15-1.

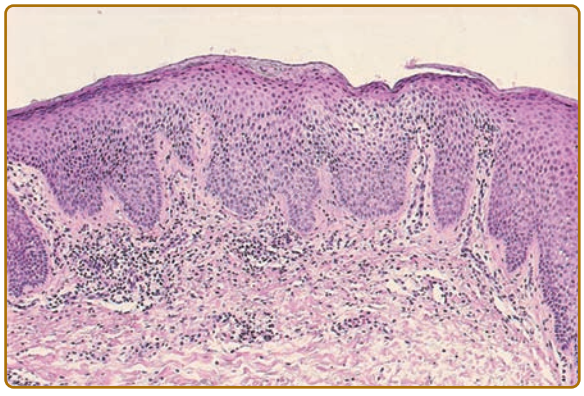

Figure 15-4 Histopathology of nummular eczema. Parakeratosis containing plasma and neutrophils (scale-crust) and psoriasiform epidermal hyperplasia with spongiosis are present, with a superficial dermal perivascular infiltrate of lymphocytes, macrophages, and eosinophils.

COMPLICATIONS

Nummular eczema may be complicated by secondary bacterial infection.

PROGNOSIS/CLINICAL COURSE

The course is usually chronic. Recurrence at prior sites of involvement is a feature of the disease.[5]

TREATMENT

Topical steroids in the mid- to high-potency range are the mainstay of treatment. The calcineurin inhibitors, tacrolimus and pimecrolimus, and tar preparations are also effective. Emollients can be added adjunctively if there is accompanying xerosis. Oral antihistamines are useful if pruritus is severe. Oral antibiotics are indicated when secondary infection is present. For widespread involvement, phototherapy with broad- or narrow-band ultraviolet B may be beneficial.

BOX 15-1 DIFFERENTIAL DIAGNOSIS OF NUMMULAR ECZEMA

Most Likely

- Allergic contact dermatitis
- Stasis dermatitis
- Atopic dermatitis
- Tinea corporis

Consider

- Impetigo
- Psoriasis (longstanding plaques)
- Mycosis fungoides (longstanding plaques)
- Paget's disease, when there is unilateral involvement of nipple/areola
- Other nummular dermatoses:
  - Fixed drug eruption
  - Pityriasis rotunda

Always Rule Out

- Tinea corporis

LICHEN SIMPLEX CHRONICUS/ PRURIGO NODULARIS

LICHEN SIMPLEX CHRONICUS AT A GLANCE

- A chronic, severely pruritic disorder characterized by one or more lichenified plaques.
- Most common sites of involvement are scalp, nape of neck, extensor aspects of extremities, ankles, and anogenital area.
- Pathology consists of hyperkeratosis, hypergranulosis, psoriasiform epidermal hyperplasia, and thickened papillary dermal collagen.

PRURIGO NODULARIS AT A GLANCE

- A pruritic disorder that runs a chronic course.
- Hyperkeratotic firm nodules vary in size from 0.5 to 3 cm and may be excoriated.
- Associations include atopic dermatitis, or systemic causes of pruritus.
- Pathology consists of hyperkeratosis, hypergranulosis, psoriasiform epidermal hyperplasia, thickened papillary dermal collagen, and characteristic neural hypertrophy.

EPIDEMIOLOGY

Lichen simplex chronicus affects adults, predominantly from ages 30 to 50. Females are affected more commonly than males. Prurigo nodularis may occur at any age, but most patients are between 20 and 60 years.[14] Men and women are equally affected. Patients with coexistent atopic dermatitis have been found to have any earlier age of onset (mean: 19 years) as compared to the nonatopic group (mean: 48 years).[15]

ETIOLOGY AND PATHOGENESIS

Lichen simplex chronicus is induced by rubbing and scratching secondary to itch. The prurigo nodule is induced by picking and scratching most commonly, but not always, in response to itch. Various factors incite itch in both disorders and not all are well understood. A variable association between lichen simplex chronicus and atopic disorders has been reported, ranging from around 26% to 75%.[16,17] Similarly, a subset of patients with prurigo nodularis has coexistent atopic eczema. Here, prurigo nodules occur in concert with subacute prurigo, lichenification, and xerosis. "Besnier prurigo" refers to the pruriginous nodules seen in atopic dermatitis. In the nonatopic nodular prurigo group, systemic causes of pruritus, including renal insufficiency, hyper- or hypothyroidism, liver failure, HIV disease, parasitic infection, or an underlying malignancy must be excluded. Hepatitis B and C have been reported as associations without liver failure.[18] Prurigo nodularis has also been reported to occur in the setting of celiac disease in the presence or absence of dermatitis herpetiformis.[19,20] The relationship between lichen simplex chronicus and radiculopathy has been preliminarily investigated.[21] Further studies are needed to clarify whether an association exists.

Environmental factors have been implicated in inducing itch, such as heat, sweat, and irritation associated with anogenital lichen simplex chronicus.[17] The presence of emotional or psychological factors in patients with prurigo nodularis and lichen simplex chronicus has been alluded to in the literature. One study of prurigo nodularis patients found that around half of 46 patients had a history of depression, anxiety, or other treatable psychological disorders.[22] Lichen simplex chronicus patients also had higher depression scores in one study.[23] Whether these emotional factors are secondary to the primary dermatologic disease or whether they are primary and causative, altering perception of itch, is unclear. It has been postulated that neurotransmitters that affect mood, such as dopamine, serotonin, or opioid peptides modulate perception of itch via descending spinal pathways.[14] Obsessive-compulsive disorder (OCD) has also been associated with picking in these disorders.[24]

At a microscopic level, increased numbers of Merkel cells are also seen adjacent to the dermal nerve fibers and mast cells in prurigo nodularis. It is thought that this complex may mediate the abnormally heightened perception of touch and itch in these patients. Nerve growth factor (NGF) is overexpressed in prurigo nodularis lesions and it has been implicated in the pathogenesis of the characteristic cutaneous neural hyperplasia seen.[25] NGF is produced and released by mast cells, which are increased in number and size on histologic sections. It upregulates the expression of neuropeptides, such as calcitonin gene-related peptide and substance P. These are thought to mediate inflammation and itch.[17]

CLINICAL FINDINGS

HISTORY. Severe itching is the hallmark of lichen simplex chronicus. Itching may be paroxysmal, continuous, or sporadic. Rubbing and scratching may be conscious and to the point of replacing the sensation of itch with pain, or may be unconscious, occurring during sleep. Itch severity is worse with sweating, heat, or irritation from clothing. Itching is also worse in times of psychological distress.[18]

CUTANEOUS LESIONS. In lichen simplex chronicus, repeated rubbing and scratching gives rise to a lichenified, scaly plaque with excoriations. Hyper- and hypopigmentation are seen with chronicity. Usually, only one plaque is present; however, more than one site may be involved. The most common sites of involvement are the scalp, the nape of the neck (especially in women), the ankles, the extensor aspects of the extremities, and the anogenital region.[26] The labia majora in women and the scrotum in men (Fig. 15-5) are the most common sites of genital involvement.[16] The upper inner thighs may also be affected.

Prurigo nodules vary in size from 0.5 to 3 cm and are firm to hard on palpation. The surface may be hyperkeratotic or crateriform. There is often overlying excoriation. Pruritus is usually severe. Limbs are affected in most cases, especially the extensor aspects (Fig. 15-6). The abdomen and sacrum were the next most common sites of involvement in one study.[22] Face and palms are rarely involved; however, nodules may occur on any site that can be reached by the patient. Lesions may vary in number from few to more than one hundred. Nodules resolve with postinflammatory hyper- or hypopigmentation with or without scarring.

RELATED PHYSICAL FINDINGS. In patients with atopic eczema, the intervening skin is often lichenified and xerotic. In nonatopic patients, cutaneous signs of underlying systemic disease or lymphadenopathy, signifying lymphoma, may be present.

LABORATORY TESTS

In patients with prurigo nodularis in whom an underlying systemic cause of pruritus is suspected, a complete blood count with differential count, renal, liver, and thyroid function tests may be ordered. A chest X-ray may be obtained to screen for lymphoma. HIV testing may also be indicated. The need for a more extensive evaluation may be individualized based on patient history and results of the aforementioned tests.

SPECIAL TESTS

On histopathologic sections, lichen simplex chronicus shows varying degrees of hyperkeratosis with para- and orthokeratosis, hypergranulosis, and psoriasiform epidermal hyperplasia. The papillary dermis shows thickening of collagen with coarse collagen bundles and vertical streaks. There is a variable inflammatory infiltrate around the superficial vascular plexus with lymphocytes, histiocytes, and eosinophils. A biopsy may also reveal a primary pruritic disorder that has led to secondary lichenification, such as psoriasis.

The epidermal findings in prurigo nodularis are similar to lichen simplex chronicus. The lesion is more

Figure 15-5 Lichen simplex chronicus of the scrotum: lichenification, hyper- and hypopigmentation with excoriation. (Image from Division of Dermatology, University of the Witwatersrand, Johannesburg, South Africa, with permission, from Professor D. Modi.)

Figure 15-6 Prurigo nodularis. (Used, with permission, from Professor D. Modi, Division of Dermatology, University of the Witwatersrand, Johannesburg, South Africa.)

papular with bulbous epidermal hyperplasia. Papillary dermal changes also resemble lichen simplex chronicus. There may be cutaneous neural hypertrophy with thickened nerve bundles and an increase in nerve fibers by S-100 staining. This finding was seen in the minority of cases in a recent study.[27]

DIFFERENTIAL DIAGNOSIS

See Boxes 15-2 and 15-3.

COMPLICATIONS

Sleep studies have shown that disturbances in the sleep cycle in lichen simplex chronicus are present. Non-REM sleep is disturbed and patients have an increased arousal index (brief awakenings from sleep) caused by scratching.[28]

PROGNOSIS/CLINICAL COURSE

Both diseases run a chronic course with persistence or recurrence of lesions. Exacerbations occur in response to emotional stress.

TREATMENT

Treatment is aimed at interrupting the itch–scratch cycle. Both components should be addressed. Systemic causes of itch should be identified and addressed. In

BOX 15-2 DIFFERENTIAL DIAGNOSIS OF LICHEN SIMPLEX CHRONICUS

Most Likely
- Lichenified atopic eczema
- Lichenified psoriasis
- Hypertrophic lichen planus

Consider
- Genital: extramammary Paget's disease

Always Rule Out
- Vulva, perianally: underlying lichen sclerosus, HPV, or tinea cruris
- Scrotum: underlying HPV or tinea cruris

BOX 15-3 DIFFERENTIAL DIAGNOSIS OF PRURIGO NODULARIS

Most Likely

- Perforating disease
- Hypertrophic lichen planus
- Pemphigoid nodularis
- Actinic prurigo
- Multiple keratoacanthomas

Consider

- Nodular scabies
- Dermatitis herpetiformis

both conditions, first-line measures to control itch include potent topical steroids as well as nonsteroidal antipruritic preparations such as menthol, phenol, or pramoxine. Emollients are an important adjunct. Intralesional steroids, such as triamcinolone acetonide, given in varying concentrations according to the thickness of the plaque or nodule are beneficial. Topical tacrolimus has been successfully employed as a steroid-sparing agent. Sedating antihistamines, such as hydroxyzine, or tricyclic antidepressants, such as doxepin, may be used to abolish nighttime itch in both conditions. Selective serotonin reuptake inhibitors (SSRIs) have been recommended for relief of daytime pruritus or in patients with OCD.[17]

Capsaicin, calcipotriene, and cryotherapy, with or without intralesional steroid injections, have all been successfully used in prurigo nodularis. Both broad- and narrow-band ultraviolet B, as well as topical or oral PUVA show efficacy and are indicated in widespread cases. The 308 nm excimer monochromatic light, UVA1 phototherapy, and naltrexone were all effective in small series.[29–31] Thalidomide and cyclosporine have also been shown to be beneficial.

The importance of avoiding scratching should be addressed with the patient. Nails should be kept short and occlusive measures, such as plastic films, topical steroid tape, or Unna boots in widespread cases may be needed.

Chapter 16 :: Vesicular Palmoplantar Eczema

:: Daven N. Doshi, Carol E. Cheng, & Alexa B. Kimball

VESICULAR PALMOPLANTAR ECZEMA AT A GLANCE

- An acute and/or chronic dermatitis clinically characterized by small to large blisters on the palms and soles.
- Histopathology characterized by spongiotic vesicles.
- Considered an endogenous dermatitis, distinct from dermatitis caused by exogenous factors such as contact, allergy, or irritation.
- Can be divided into four categories: (1) pompholyx, (2) chronic vesiculobullous hand dermatitis, (3) hyperkeratotic hand dermatitis, and (4) id reactions.
- Does not respond well to treatment.

Vesicular palmoplantar eczema is a dermatitis of the hands and feet characterized by small to large blisters clinically and spongiotic vesicles histologically. It can manifest as either an acute or a chronic dermatitis, or both. Because clinical and histologic presentations of the variants of hand dermatitis, including vesicular palmoplantar eczema, often overlap, making a precise diagnosis can be difficult. For example, patients with pompholyx, the most acute form of vesicular palmoplantar eczema, have been noted to have higher incidence rates of both atopy and contact dermatitis than controls.

With the preceding caveat in mind, vesicular palmoplantar eczema can be divided into four categories: (1) *pompholyx*, (2) *chronic vesiculobullous hand dermatitis*, (3) *hyperkeratotic hand dermatitis*, and (4) *id reactions* (see Chapter 17). These conditions can be grouped under the category of endogenous hand dermatitis, in contrast to dermatitis clearly caused by exogenous factors such as contact allergy or irritation.

Pompholyx is a term best reserved for acute explosive outbreaks of small to large vesicles and bullae on the palms and soles. It tends to occur more often in the spring and fall, and may be associated with stress. Other etiologic factors are less well established. *Cheiropompholyx* and *podopompholyx* are terms occasionally used to describe cases affecting the palms or soles, respectively. *Chronic vesiculobullous hand dermatitis*, also known as *dyshidrotic hand eczema* or *dyshidrotic hand dermatitis*, is usually characterized by small vesicles on the lateral aspects of the fingers. "Dyshidrosis," a dysfunction of the sweat gland, was long postulated to be a cause, but its role has been subsequently disproved. However, the terminology persists and is commonly used. A third category is chronic *hyperkeratotic hand dermatitis*, an entity that generally occurs on the central palms. Unlike the other classifications of vesicular palmoplantar eczema, vesicles do not dominate the clinical presentation. However, the spongiosis observed histologically is indistinguishable from the other categories. An *id reaction* is a vesiculobullous dermatitis, generally appearing on the lateral aspects of the fingers, elicited by an infection elsewhere in the body. The most common cause is a fungal infection. Treatment of the underlying causative factor usually leads to resolution. Endogenous hand dermatitis can be exacerbated by exogenous factors, most notably irritant dermatitis and allergic contact dermatitis. In addition, atopy may in some cases predispose to the development of vesicular palmoplantar eczema.

EPIDEMIOLOGY

Differences in classification and definition have made it difficult to assess the true incidence of the endogenous hand disorders. Most studies have focused on the prevalence of exogenous hand disorders as seen in occupational settings. Pompholyx is the least common presentation of hand dermatitis; in one population study, the 1-year prevalence of pompholyx was estimated to be 0.5%.[1] In the same study, hyperkeratotic hand dermatitis represented 2% of all hand dermatoses.[1] Other studies have noted prevalence rates ranging from 1% to 5%, with the variation in the frequency of vesicular hand eczema attributable in part to the lack of a common condition.[2,3,4]

ETIOLOGY AND PATHOGENESIS

With the exception of the id reaction, a direct cause of vesicular palmoplantar eczema is rarely identified. A number of etiologic factors have been associated with pompholyx, including atopy (see Chapter 14), contact allergy (see Chapter 13), psychological stress, and hot weather.[1] Pompholyx has also been reported after ingestion of piroxicam,[5] after ingestion of certain metals in predisposed or sensitized patients most commonly nickel, cobalt, and chromate[5] and after intravenous immunoglobulin therapy, with 39 cases reported to date.[6,7] There has also been a report of five cases of photo-induced pompholyx in patients with a reported history of photo-induced disease that was reproduced when the patients were phototested with an ultraviolet A (UVA) source.[5] Histologic evaluation confirmed the diagnosis of pompholyx and a true photosensitivity rather than photoaggravation. Additionally, there has been evidence of association of vesicular hand eczema following dermatophytid from tinea pedis.[8] In a study of 398 patients with hand eczema, those with culture positive tinea pedis were found to have an increased relative risk of 3.58 ($p < 0.05$) for vesicular hand eczema.[9]

EXACERBATING FACTORS

Contact allergy is common in patients affected with vesicular palmoplantar eczema, especially the chronic type, but the causal relationship is not always clear. There are cases in which contact allergy has exacerbated preexisting hand dermatitis and also reports that ingestion of certain metals, including nickel, cobalt, and chromium, have caused flares. However, in other cases, the causal relationship may be the reverse. The skin's impaired barrier function in vesiculobullous hand dermatitis (see Chapter 47) may in some cases lead to sensitization and a higher prevalence of contact dermatitis in the affected population. Investigations into the role of atopy (see Chapter 14) have yielded mixed results. Some studies have shown levels of personal or familial atopy as high as 50% in affected subjects, compared to 11.5% of controls, but other studies have demonstrated no difference in the prevalence in people with vesiculobullous hand dermatitis versus controls.[10]

CLINICAL FINDINGS

POMPHOLYX

Figure 16-1 is an algorithm showing the approach to the patient with vesicular palmoplantar eczema. Pompholyx can even be severe enough to neces-

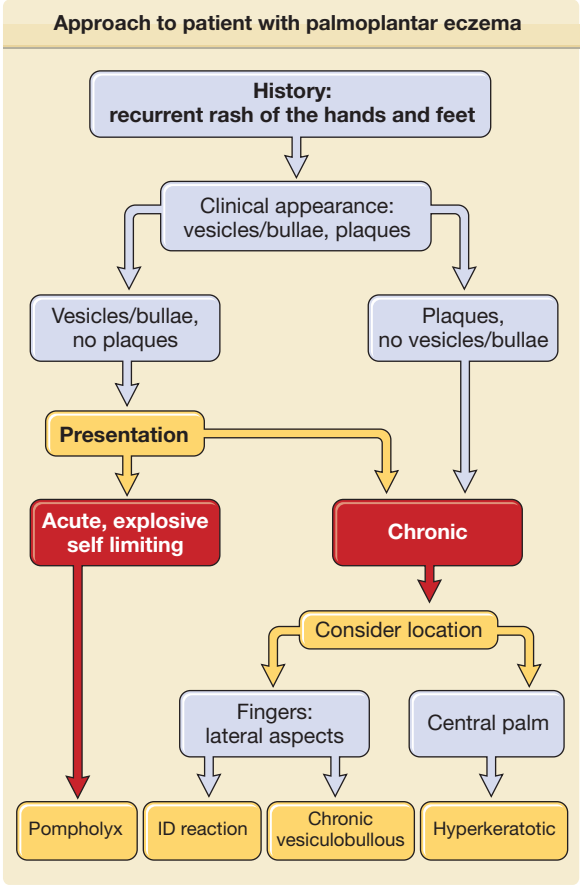

Figure 16-1 Approach to the patient with vesicular palmoplantar eczema.

sitate hospitalization. In true acute pompholyx, there is an explosive outbreak of deep-seated vesicles on the palms, the lateral aspects of the fingers (Fig. 16-2), and sometimes the soles, usually in a symmetric pattern. Discomfort and itching usually precede the development of the blisters, which have been described as having a "tapioca" appearance (see Fig. 16-3). Blisters may coalesce then desiccate and resolve without rupture (Fig. 16-4). Intact, large blisters can be drained, but should not be unroofed. However, large blisters may rupture spontaneously, leaving oozing or dried up erosions (Fig. 16-5).

This acute phase is generally followed by desquamation of the affected areas. Individual outbreaks are usually self-limited over 2–3 weeks, although they may recur. Secondary bacterial infection is common, often resulting in a local cellulitis, and can sometimes potentiate the development of lymphatic damage, resulting in lymphedema. Attacks are most common among adolescents and young adults and seem to be more common in the spring and summer months. Outbreaks have been shown to be associated with dermatophyte infection, contact dermatitis, in particular cosmetic and hygiene products, metals and internal reactivation from drugs, foods, or metals.

Figure 16-3 Chronic vesiculobullous hand dermatitis. There is a vesicular dermatitis on the lateral sides of the fingers. Note the tapioca-like, deep-seated vesicles.

Figure 16-2 Chronic dyshidrotic hand dermatitis of bilateral hands. There is hyperkeratosis of the palms and fingers sparing the dorsal hand. Deep-seated vesicles at different stages can be seen.

Figure 16-4 Cheiropompholyx. Apart from small vesicles, there are large bullae, some purulent; others have collapsed and are drying up.

Figure 16-5 Podopompholyx. Large blisters have ruptured leaving erosions that are drying up. Note large bulla on the arch of the right foot: The roof of the blister still contains tapioca-like vesicles. This is characteristic.

CHRONIC VESICULOBULLOUS DERMATITIS

Chronic vesiculobullous hand dermatitis is more common than pompholyx and more difficult to manage because of its relapsing course. The clinical presentation includes small 1- to 2-mm vesicles filled with clear fluid localizing to the lateral aspects of the fingers, palms, and soles as in pompholyx (see Fig. 16-3). As the condition becomes more chronic, the clinical appearance may evolve and subsequently appear more fissured and hyperkeratotic (as in Figs. 16-2 and 16-6). A clear history of vesicles or exacerbations characterized by blistering may help to narrow the classification of a given presentation of hand dermatitis.

HYPERKERATOTIC HAND DERMATITIS

Patients with hyperkeratotic hand dermatitis are usually male and generally present with chronic keratotic pruritic plaques, sometimes with fissures on the central palm (see Fig. 16-6). This condition may be the end result of contact allergy, excoriation, and irritation, but generally the cause is not identifiable, and contact allergy does not seem to play an important role. This hand dermatitis commonly occurs in middle-aged to elderly men and is often very refractory to treatment. Friction in lichen simplex chronicus may be an important factor in some cases. Plantar involvement is present in a minority of cases.

Figure 16-6 Hyperkeratotic hand dermatitis. There are pruritic keratotic plaques on the central palm: Occasional vesiculation and fissuring may occur.

Figure 16-7 Id reaction to tinea pedis. Erythematous, partially dried up vesicles on the foot. Lesions are very pruritic.

ID REACTION

(See Chapter 17)

In an id reaction, erythematous vesicles usually are seen on the lateral aspects of the fingers and the palms and are typically pruritic (Fig. 16-7). This eruption of vesicles is usually sudden and classically occurs in response to an intense inflammatory process, especially fungal infections, taking place somewhere else on the body. The id reaction is thought to be an allergic reaction to fungi or to some antigen created during inflammation. Treatment of the underlying infection results in resolution.

LABORATORY FINDINGS

In the diagnostic workup of vesicular palmoplantar eczema, it is important to first examine the feet to exclude a dermatophytid. Secondly, a potassium hydroxide examination of the hand should be performed to rule out tinea manuum. Finally, patch testing should be performed to rule out a contact dermatitis or a systemic reaction to a contact allergen. There are no *specific* laboratory findings characteristic of vesicular palmoplantar eczema, although IgE levels may be elevated in atopic patients.

PATHOLOGY

The histology of these entities depends on the chronicity of the disease. The primary vesicle appears

as an intraepidermal spongiotic vesicle that does not involve the acrosyringia on either conventional and electron microscopy. Lymphocytic infiltration is common in the epidermis, with a mixed infiltrate observed in the dermis. In more chronic cases, the epidermis may show hyperproliferation, hyperkeratosis, or even psoriasiform epidermal hyperplasia. Periodic acid-Schiff staining can be helpful in excluding fungal elements.

DIAGNOSIS

The diagnosis of vesiculobullous hand dermatitis is usually made on the basis of clinical presentation, history, and sometimes histology. Patch testing may be useful in helping to distinguish this entity from other palmoplantar disorders or in eliminating other exacerbating factors such as irritant exposure and contact allergy.

There are many other skin conditions of the hands and feet that can be difficult to distinguish from vesiculobullous hand dermatitis. Several of the diagnoses may also coexist.

DIFFERENTIAL DIAGNOSIS

(Box 16-1)

Allergic contact dermatitis (see Chapter 13) may be clinically indistinguishable from other forms of hand eczema, and patch testing should be considered for those with recurrent, atypical, or persistent forms of the disease. In a recent study of 422 patients with hand eczema, the ten most common allergens with positive patch testing were nickel, cobalt, thiuram mix, balsam of Peru (*Myroxylon pereirae* resin), formaldehyde, colophony, potassium dichromate, benzoyl peroxide, fragrances methylchloroisothiazolinone/methylisothiazolinone, and sesquiterpene lactone mix.[11,12] Although frequently considered, laundry detergents rarely cause allergic contact dermatitis. Irritants (see Chapter 48) are by far the most common causes of hand dermatitis that are often exacerbated by occupational exposures. The irritant dermatitis is usually symmetric and chronic, and affects the dorsal fingertips and web spaces.

Atopic hand dermatitis (see Chapter 14) is associated with a number of factors: hand dermatitis before age 15 years, persistent eczema on the body, dry or itchy skin in adult life, and widespread atopic dermatitis in childhood. The backs of the hands, particularly the fingers, are affected with erythema, vesiculation, crusting, excoriation, and scale.

Infections, most commonly from tinea, can mimic endogenous hand dermatitis. In cases of asymmetric or atypical cases, or in cases of small vesicles confined to the feet, a potassium hydroxide examination may be useful in ruling out primary tinea infection. In chronic cases of hand dermatitis, fungal and bacterial infections may be superimposed, and treatment may result in improvement of clinical symptoms. Herpes simplex may, in unusual cases, present as blisters on the hands.

Psoriasis and psoriasiform hand dermatitis (see Chapter 18) are most prominent over pressure points. Psoriasis can normally be distinguished by its sharply marginated, nummular, or circinate scaly plaques; relative lack of itching; silvery scales; and the presence of psoriasis elsewhere. Psoriasiform hand dermatitis can occur without a family or personal history of psoriasis. It is a diagnosis made primarily on clinical and histologic presentation. At times, however, it appears as though eczematous, hyperkeratotic, and psoriatic diatheses coexist. Repeated pressure or friction may cause hyperkeratosis in some individuals.

Pustular eruptions of the palms and soles (see Chapter 21) are generally easy to distinguish because, unlike the presentation of clear fluid-filled blisters and bullae of hand dermatitis, pustules are the primary lesions. For example, in pustular psoriasis, the vesicles are cloudy and painful.

Keratolysis exfoliativa (recurrent focal palmar peeling) is a chronic, asymptomatic, and noninflammatory peeling of the palms and soles, most commonly seen during the summer months. It is thought to occur more frequently in people with hyperhidrosis in these areas. Scaling usually starts from one to two fine points and expands outward to larger circular areas. The condition is usually self-limited and asymptomatic, requiring only emollients.

Bazex acrokeratosis paraneoplastica is a rare, acute, erythematous, scaling, vesiculobullous hand dermatitis with nail dystrophy associated with neoplasia, usually squamous carcinomas of the upper digestive or respiratory tracts, although there have been some reports of similar findings in patients with colon cancer and genitourinary tumors.

Other blistering diseases, such as pemphigoid, pemphigus, or epidermolysis bullosa, may affect the hands and feet, but usually do so in the setting of blisters elsewhere on the body.

BOX 16-1 DIFFERENTIAL DIAGNOSIS OF VESICULAR PALMOPLANTAR ECZEMA

Most Likely

- Allergic contact dermatitis
- Irritant contact dermatitis
- Atopic hand dermatitis
- Infections, commonly from tinea

Consider

- Bazex acrokeratosis paraneoplastica
- Psoriasis
- Psoriasiform hand dermatitis
- Pustular eruption of palms and soles
- Keratolysis exfoliativa
- Bullous disorders
- Herpes simplex (never bilateral)

BOX 16-2 TREATMENTS FOR VESICULAR PALMOPLANTAR ECZEMA

	TOPICAL	PHYSICAL	SYSTEMIC
First line	▪ Corticosteroids	▪ Ultraviolet A-1 ▪ Psoralen and ultraviolet A ▪ Narrowband ultraviolet B	▪ Prednisone ▪ Cyclosporine ▪ Mycophenolate mofetil ▪ Methotrexate ▪ Alitretinoin
Second line	▪ Drying agents ▪ Tacrolimus ▪ Pimecrolimus ▪ Retinoids ▪ Calcipotriene	▪ Grenz ray ▪ Iontophoresis ▪ Sympathectomy ▪ Intradermal botulinum toxin	▪ Entanercept
Third line			▪ Azathioprine

COMPLICATIONS

Secondary bacterial infection of the vesicles can result in cellulitis, lymphedema, and, in rare instances, septicemia.[13]

PROGNOSIS AND CLINICAL COURSE

Pompholyx tends to occur as intermittent explosive outbreaks and becomes less frequent in middle-aged individuals. The more chronic forms of vesicular palmoplantar eczema, however, are much more persistent and frustrating to manage and often require multiple therapeutic approaches over time.

TREATMENT

(Box 16-2)

Treatment of vesiculobullous hand dermatitis should be based on the acuity of the condition, the severity of the disease, the prominence of blisters versus chronic changes, and any relevant history that reveals possible cofactors.

TOPICAL THERAPY

Topical steroids, typically high potency (class 1 or 2), are usually first-line agents. They are often more effective if used under occlusion, although this approach may increase the chance of infection. Topical drying agents, such as Domeboro soaks, Burow's solutions (aluminum subacetate), or dilute potassium permanganate solution (1–8,000) may be useful in acute forms with a predominance of vesicles.

Nonsteroidal topical immunomodulating agents, such as tacrolimus and pimecrolimus, have been studied for treatment of individuals with mild to moderate chronic hand dermatitis with improvements from baseline.[5] Topical tacrolimus was shown to be as effective as momethasone furoate 0.1% ointment in a randomized, blinded trial in patients with vesicular pompholyx of the palms. After 2 weeks of treatment, the Dyshidrotic Eczema Area and Severity Index (DASI) was reduced by more than 50%.[14]

Hyperkeratotic palmar eczema is notoriously difficult to manage. Topical retinoids and calcipotriene, both of which act to regulate epidermal cell maturation, have anecdotally been shown to improve this category of hand dermatitis.[1]

SYSTEMIC THERAPY

For recurrent pompholyx and chronic vesicular dermatitis, oral prednisone may be required and is often effective if treatment is initiated early, at the onset of the itching prodrome. However, because of significant side effects, systemic glucocorticoids are typically inappropriate for long-term management. Intralesional and intramuscular steroid injections can also be considered for short-term use in acute episodes when intensive topical therapy fails.

Cyclosporine has been studied at dosing levels of 3 mg/kg/day and 5 mg/kg/day in the treatment of chronic vesicular dermatitis. Although patients showed improvement with treatment, relapses occurred shortly after discontinuation of cyclosporine.[15]

Mycophenolate mofetil has been used in the treatment of chronic vesicular dermatitis at dosing levels of 2–3 g/day (in divided doses). It has been anecdotally shown to improve chronic vesicular dermatitis that has been otherwise recalcitrant to corticosteroids, iontophoresis, and phototherapy. However, it has also been anecdotally shown to induce biopsy-proven dyshidrotic eczema.

Methotrexate has proven a useful therapy of a wide range of skin diseases. In chronic vesicular eczema,

it has been reported to partially or completely clear lesions at low doses ranging from 12.5 to 22.5 mg/week.[15] However, its wide spectrum of potential side effects remains a limiting factor to its use in this particular skin disease.

Alitretinoin, (9-*cis*-retinoic acid) is a novel retinoid with anti-inflammatory properties and one of the newer therapies under study for palmoplantar vesicular eczema. It is the only medication specifically approved for the treatment of adults with hand eczema unresponsive to topical steroids in some countries outside of the United States.[19] In a large controlled study with over 1,000 patients it was successful in the treatment of chronic hyperkeratotic hand eczema and offers another treatment option for patients refractory to treatments with corticosteroids, radiation therapy, tretinoin, isotretinoin, and acitretin.[20]

UVB, systemic, topical, and bathwater psoralen and UVA light with or without PUVA have been used in severe cases of chronic vesicular hand eczema. Studies evaluating the use of UVA-1 compared localized high-dose UVA-1 irradiation against topical cream psoralen UVA for the treatment of dyshidrotic eczema demonstrated that UVA-1 irradiation and topical PUVA showed similar beneficial responses.[23,24] In addition, the potential side effects noted with PUVA, such as phototoxic reactions and long-term carcinogenic risk, are theoretically reduced with UVA-1 therapy. UV therapy is thought to work by induction of apoptosis of T and B lymphocytes.

OTHER THERAPIES

Iontophoresis, sympathectomy, and intradermal botulinum toxin are effective therapies for hyperhidrosis and have been studied as treatments for chronic vesicular dermatitis.[15] Tap water iontophoresis with pulsed direct current showed no benefit for subjects with hand dermatitis over controls in time to improvement, but those who were treated had much longer remissions, by a factor of months.[6] Intradermal botulinum toxin A was shown to have a beneficial effect in patients with treatment-refractory vesicular dermatitis, especially in those patients whose condition was aggravated by hyperhidrosis.[25] This therapy may also be used in conjunction with topical corticosteroids.[26]

FUTURE THERAPIES

RADIATION THERAPY AND IMMUNOTHERAPY. The use of etanercept has also been shown in a case report to be successful in treatment of recalcitrant dyshidrotic eczema for a 4-month period before relapse occurred.[16]

Azathioprine has been shown to be efficacious in a study that included six patients with pompholyx; however, a separate case study of its use reported development of myelotoxicity.[17,18]

Superficial radiotherapy (Grenz ray) is still sometimes used at a few centers. This condition may be one of the last indications for this treatment modality, and has been shown to be successful in some patients with resistant chronic eczema of the hand in a double-blind study.[14] Megavoltage radiation therapy (1,200 cGy) has also been tried in patients with severe chronic vesicular hand dermatitis with moderate success in long-term remission.[21,22]

LEUOKOTRIENE INHIBITORS. Leukotriene receptor antagonists and inhibitors are oral medications that act by inhibiting proinflammatory mediators in the 5-lipoxygenase pathway and have been shown to block the effects of leukotrienes successfully in asthma, allergic rhinitis, and recently in atopic dermatitis. No specific trial has been reported yet with these medications on pompholyx.

Phosphodiesterases-4 (PDE4) modulate the release of inflammatory mediators and have recently been investigated as a novel therapeutic approach in the treatment of inflammation-associated diseases. Animal models of PDE4 inhibitors have displayed strong anti-inflammatory action in models of allergic contact dermatitis. The safety and efficacy in pompholyx has yet to be evaluated.

Tumor necrosis factor inhibitors (e.g., infliximab) have been successful for treatment of psoriatic arthritis and psoriasis, among other chronic inflammatory diseases. No data is available on pompholyx.

Two severity indices, (1) the dyshidrosis area and severity index and (2) the total sign and symptoms score, have been validated and may prove useful in clinical trials to better assess the effectiveness of these and future therapies.

PREVENTION

Prevention is a critical part of therapy in most cases, especially when known exacerbating factors are present. Avoidance of commonly encountered allergens, such as foods and plants, and irritants, such as soaps, solvents, acids, and alkalis, can be helpful. Vinyl gloves, rather than latex, are recommended because of the risk of either having an underlying allergy or of developing one in the setting of impaired barrier function. Patch testing may be considered for patients to identify relevant allergens. Modification of environmental exposure to exacerbating factors, such as friction and cold air, may also help with persistent or refractory disease. Frequent use of emollients, specifically novel barrier creams or ointments, help to preserve the normal skin-barrier function. Maintaining a low-cobalt diet has been suggested to decrease the number of dyshidrotic flares.[28]

Chapter 17 :: Autosensitization Dermatitis

:: Donald V. Belsito

AUTOSENSITIZATION DERMATITIS AT A GLANCE

- An acute disorder triggered by infection, stasis and contact dermatitides, ionizing radiation, blunt trauma, and retained suture material.
- Widespread, pruritic, usually papulovesicular eruption, most frequently affecting the extremities.
- Related features are those of the precipitating disorder.
- Pathology is nondiagnostic and most often consistent with an acute spongiotic process of the epidermis with a superficial, perivascular, lymphohistiocytic infiltrate of the dermis containing occasional eosinophils.

EPIDEMIOLOGY

Autosensitization dermatitis refers to a phenomenon in which an acute dermatitis develops at cutaneous sites distant from an inflammatory focus, and where the secondary acute dermatitis is not explained by the inciting cause of the primary inflammation. The classic presentation of autosensitization is that seen in patients with venous stasis disease,[1] where as many as 37% of patients have been reported to develop at least one episode of autosensitization,[2] and those with dermatophyte infections, where 4–5% reported having had dermatophytid reactions.[3]

ETIOLOGY AND PATHOGENESIS

The term *autosensitization dermatitis* was coined in 1921 by Whitfield to describe reaction patterns ranging from a generalized, erythematous, morbilliform, and urticarial eruption after blunt trauma to a generalized, petechial, papulovesicular dermatitis after the acute irritation of chronic stasis dermatitis.[4] Subsequently, the vesicular id reactions associated with infections caused by tuberculosis,[5] histoplasmosis,[6] dermatophytes,[7] and bacteria[8] were included under this rubric.[9–11] Noneczematous reaction patterns, including erythema multiforme[12] and neutrophilic lobular panniculitis,[13] have also been ascribed to autosensitization associated with various infections. Other precipitating factors for autosensitization have included the application of irritant or sensitizing chemicals,[14] ionizing radiation,[15,16] and retained suture material.[17]

Although the disease was originally thought to be due to autosensitization to epidermal antigens,[11] this concept has not been experimentally verified. In murine studies designed to determine whether keratinocyte-derived proteins can serve as antigenic carriers for hapten, Fehr et al[18] derived major histocompatibility complex-restricted, T-cell receptor α/β, $CD4^+$ T-cell clones that proliferated in response to keratinocyte extracts unconjugated to hapten. In these studies, such autoreactive T-cell clones could not be derived after treatment with irritants. Nonetheless, the authors speculated that T cells autoreactive to keratinocyte antigens may be generated during the course of contact hypersensitivity and lead to the development of an id reaction.

In the most extensive study to date,[1] only 4 of 81 patients with autosensitization dermatitis had serum antibodies cytotoxic to autologous or homologous skin. However, the role of such autoantibodies in mediating the disorder, even in these four patients, must be interpreted cautiously, given the high frequency of epidermal autoantibodies in the normal adult population.[19]

In an experiment in which guinea pigs were injected with autologous skin, Wilhelmj et al[20] reported dermatitis in 2 of 11 guinea pigs, but it was not clear whether these reactions were immunologic and, if so, what the

causal allergen(s) was. Other investigators using similar techniques have been unable to induce cutaneous disease in animals by means of epidermal extracts.[21] In contrast, 19 of 24 patients with active autosensitization who were intradermally challenged with water-soluble extracts of autologous epidermal scale developed a reaction.[22]

The term *autosensitization* is probably a misnomer. The disease is more likely due to a hyperirritability of the skin induced by either immunologic or nonimmunologic stimuli. Factors such as irritation, sensitization, infection, and wounding, which are known to precipitate autosensitization, have been reported to release a variety of epidermal cytokines.[23,24] Once hematogenously disseminated in sufficient amounts, these cytokines could heighten the sensitivity of skin to a variety of nonspecific, but otherwise innocuous, stimuli, producing a pattern of "spillover" reactions[25] that have been classically termed *autosensitization*. Such a hypothesis would account for (a) the results in humans of delayed-type hypersensitivity testing with autologous epidermal scale,[22] (b) the histopathologic findings noted in the disease (see section "Clinical Findings"), and (c) the activated T lymphocytes occasionally observed in the blood of patients with autosensitization.[26] The characteristic distribution of the disease might perhaps be explained if the skin overlying the arms and legs was found to contain increased numbers of, or more avid receptors for, various cytokines than the skin of the face or hands. Such a geographic variation in the distribution of bullous pemphigoid antigen has been observed and hypothesized to account for the clinical patterns of this autoimmune disease.[27] Application of modern biotechnological tools should provide insight into the mysteries of autosensitization.

CLINICAL FINDINGS

Typically, 1 to 2 weeks after an acute inflammation, an extremely pruritic, symmetric, scattered, erythematous eruption with macules, papules, and vesicles develops (Fig. 17-1). The eruption involves the forearms, thighs, legs, trunk, face, hands, neck, and feet in descending order of frequency.[2,11] During the evolution of the dermatitis, its morphology may change in a manner consistent with the chronicity (i.e., vesicles to scale). Histopathologically, the findings are not pathognomonic: spongiotic epidermal vesicles

Figure 17-1 Stasis dermatitis with autosensitization. An elderly woman with a long-standing history of stasis dermatitis presented with gradual worsening of the edema; pruritus; and multiple, punctate, superficial, excoriated ulcers overlying the medial malleoli (**A**). Nine days after the ulcers appeared, she developed an acute, extremely pruritic, erythematous, papulovesicular eruption over the forearms (**B**), which progressively involved the upper arms, upper torso, and hands. The acute papulovesicular dermatitis also involved the lower extremities and can be noted overlying the chronic stasis dermatitis (**A**).

BOX 17-1 DIFFERENTIAL DIAGNOSIS

Most Likely

- Allergic contact dermatitis
- Irritant contact dermatitis
- Atopic dermatitis
- Nummular dermatitis

Consider

- Polymorphous light eruption
- Pityriasis rosea
- Eruptive (guttate) psoriasis

Always Rule Out

- Infectious processes
  - Dermatophyte infections
  - Scabies and other mite infestations
  - Viral exanthems
- Drug eruptions

associated with a superficial, perivascular lymphohistiocytic infiltrate of the dermis, which may contain scattered eosinophils.[28] Immunophenotypic studies of skin have revealed that most of the lymphocytes in the epidermis are $CD3^+$ and $CD8^+$ T cells, whereas those in the dermis are primarily $CD4^+$.[25] In the majority of individuals with autosensitization,[1] deposition of antibody or complement in affected skin is not detected.

As previously mentioned, noneczematous autosensitization patterns have also been reported. Both erythema multiforme[12] and neutrophilic lobular panniculitis[13] have been reported to be induced by a variety of infectious processes. The histology in these cases is consistent with the reaction pattern for erythema multiforme and lobular panniculitis, respectively.

DIFFERENTIAL DIAGNOSIS

See Box 17-1.

PROGNOSIS AND CLINICAL COURSE

The eruption often persists and spreads until the underlying causative primary site of inflammation is treated.

TREATMENT

Treatment is best directed toward the inciting disease. The frequently weeping, vesicular eruption of autosensitization benefits from drying agents such as aluminum sulfate and calcium acetate. Given the likely involvement of cytokines and inflammatory mediators sensitive to glucocorticoids[29] or macrolactams,[30] systemic and/or topical treatment with these drugs may be helpful. To prevent the secondary effects of excoriation, pruritus must be controlled with topical antipruritic agents or oral antihistamines. However, one must remain alert to the possibility of inducing an allergy in existing dermatitic skin with topical medicaments.

Chapter 18 :: Psoriasis

:: Johann E. Gudjonsson & James T. Elder

PSORIASIS AT A GLANCE

- Worldwide occurrence: Affects 2%–3% of Americans; prevalence ranges from 0.1% to 3% in various populations.
- A chronic disorder with polygenic predisposition combined with triggering environmental factors such as trauma, infection, or medication.
- Erythematous scaly papules and plaques; pustular and erythrodermic eruptions occur.
- Most common sites of involvement are scalp, elbows, knees, hands, feet, trunk, and nails.
- Psoriatic arthritis occurs in 10%–25% of patients; pustular and erythrodermic forms may be associated with fever.
- Pathology is characterized by uniform elongation of the rete ridges, with dilated blood vessels, thinning of the suprapapillary plate, and intermittent parakeratosis. Epidermal and perivascular dermal infiltrates of lymphocytes, with neutrophils occasionally in aggregates in the epidermis.

EPIDEMIOLOGY

PREVALENCE

Psoriasis is universal in occurrence. However, its prevalence in different populations varies from 0.1% to 11.8%, according to published reports.[1] The highest reported incidences in Europe have been in Denmark (2.9%) and the Faeroe Islands (2.8%). A recent study of 1.3 million Germans found a prevalence of 2.5%.[2] Similar prevalence (ranging from 2.2% to 2.6%) has been measured in the United States. A higher prevalence in East Africans as opposed to West Africans may explain the relatively low prevalence of psoriasis in African-Americans (1.3% vs. 2.5% in white Americans).[3] The incidence of psoriasis is also low in Asians (0.4%), and in an examination of 26,000 South American Indians, not a single case was seen. Psoriasis is equally common in males and females.[4,5]

AGE OF ONSET

Psoriasis may begin at any age, but it is uncommon under the age of 10 years. It is most likely to appear between the ages of 15 and 30 years. Possession of certain HLA Class I antigens, particularly *HLA-Cw6*, is associated with an earlier age of onset and with a positive family history. This finding led Henseler and Christophers[6] to propose that two different forms of psoriasis exist: type I psoriasis, with age of onset before 40 years and HLA-associated, and type II, with age of onset after 40 years and lacking HLA associations, although many patients do not fit into this classification. There is no evidence that type I and type II psoriasis respond differently to treatment.

ETIOLOGY AND PATHOGENESIS

Psoriasis is a chronic inflammatory skin disease, with a strong genetic basis, characterized by complex alterations in epidermal growth and differentiation and multiple biochemical, immunologic, and vascular abnormalities, and a poorly understood relationship to nervous system function. Its root cause remains unknown. Historically, psoriasis was widely considered to be a primary disorder of keratinocytes. With the discovery that the T-cell specific immunosuppressant cyclosporine A (CsA) was highly active against psoriasis, research became more focused on T cells and the immune system. Nevertheless, accumulating evidence shows that keratinocytes are an integral part of the cutaneous immune reponse in psoriasis.[7]

PATHOGENESIS OF PSORIASIS

DEVELOPMENT OF LESIONS. Detailed light, electron microscopic, immunohistochemical, and molecular studies of involved and uninvolved skin of both newly appearing and established psoriatic lesions provide a useful framework for inferring cause-and-effect relationships between the many cellular events that take place in a psoriatic lesion. They are illustrated schematically in Fig. 18-1 and with actual photomicrographs in Fig. 18-2.

Uninvolved Psoriatic Skin. The normal-appearing skin of psoriatic patients has long been known to manifest subclinical morphologic and biochemical changes, particularly involving lipid biosynthesis.[67,68] These changes were predominantly found in the stratum corneum and included changes in the levels and composition of phospholipids, free α-amino acids, hydrolytic enzymes, and several dehydrogenases. These changes led to the use of the term "histochemical parakeratosis" to describe these findings.[67] Much more recent studies using microarray technology to search for differences in gene expression between normal and uninvolved psoriatic skin have identified groups of coordinately regulated genes involved in lipid biosynthesis and innate immune defense.[69]

Development of psoriatic lesions

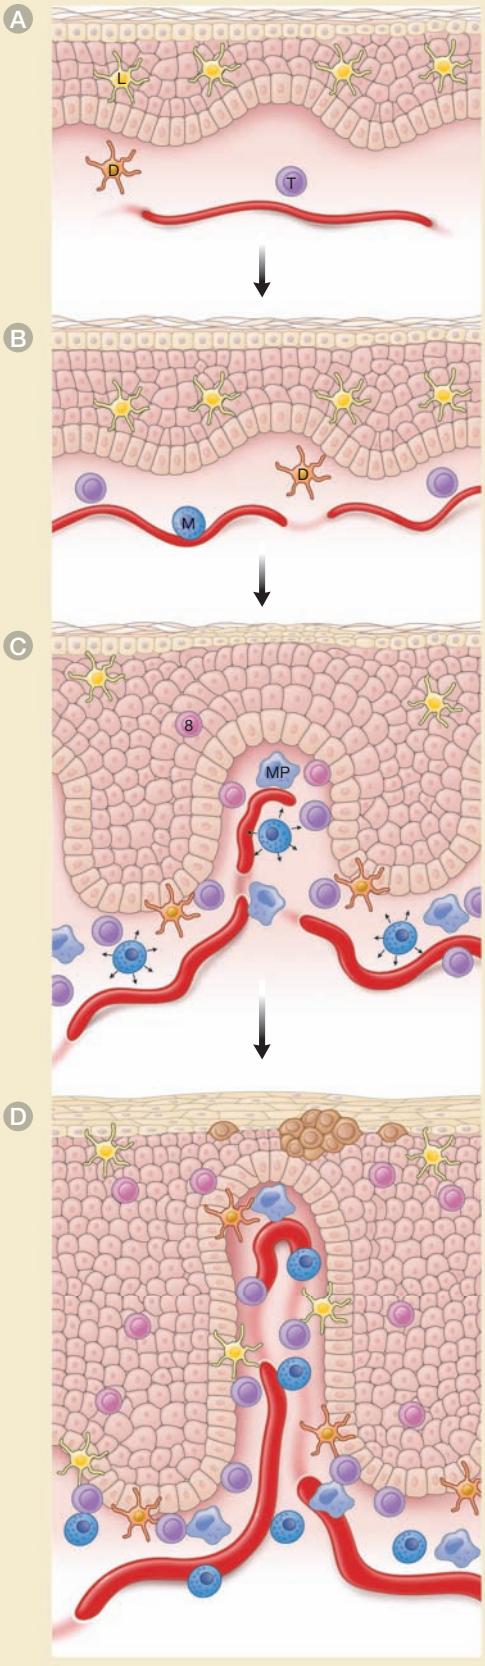

Figure 18-1 Development of psoriatic lesions. This figure depicts the transition from normal skin to fully developed lesion described in the text. Normal skin from a healthy individual (*panel* **A**) contains epidermal Langerhans cells, scattered immature dendritic cells (D), and skin-homing memory T cells (T) in the dermis. Normal-appearing skin from a psoriatic individual (*panel* **B**) manifests slight capillary dilatation and curvature, and a slight increase in the numbers of dermal mononuclear cells and mast cells (M). A slight increase in epidermal thickness is usually present. In chronic plaque psoriasis, the intensity of these changes may depend on distance from an established lesion. The transition zone of a developing lesion (*panel* **C**) is characterized by progressive increases in capillary dilatation and tortuosity, numbers of mast cells, macrophages (MP), and T cells, and mast cell degranulation (small arrows). In the epidermis, there is increasing thickness with increasingly prominent rete pegs, widening of the extracellular spaces, transient dyskeratosis, spotty loss of the granular layer, and parakeratosis. Langerhans cells (L) begin to exit the epidermis, and inflammatory dendritic epidermal cells (I) and $CD8^+$ T cells (8) begin to enter the epidermis. The fully developed lesion (*panel* **D**) is characterized by fully developed capillary dilatation and tortuosity with a tenfold increase in blood flow, numerous macrophages underlying the basement membrane, and increased numbers of dermal T cells (mainly $CD4^+$) making contact with maturing dermal dendritic cells (D). The epidermis of the mature lesion manifests markedly increased (approximately tenfold) keratinocyte hyperproliferation extending to the lower suprabasal layers, marked but not necessarily uniform loss of the granular layer with overlying compaction of the stratum corneum and parakeratosis, increased numbers of $CD8^+$ T cells, and accumulation of neutrophils in the stratum corneum (Munro's microabscesses).

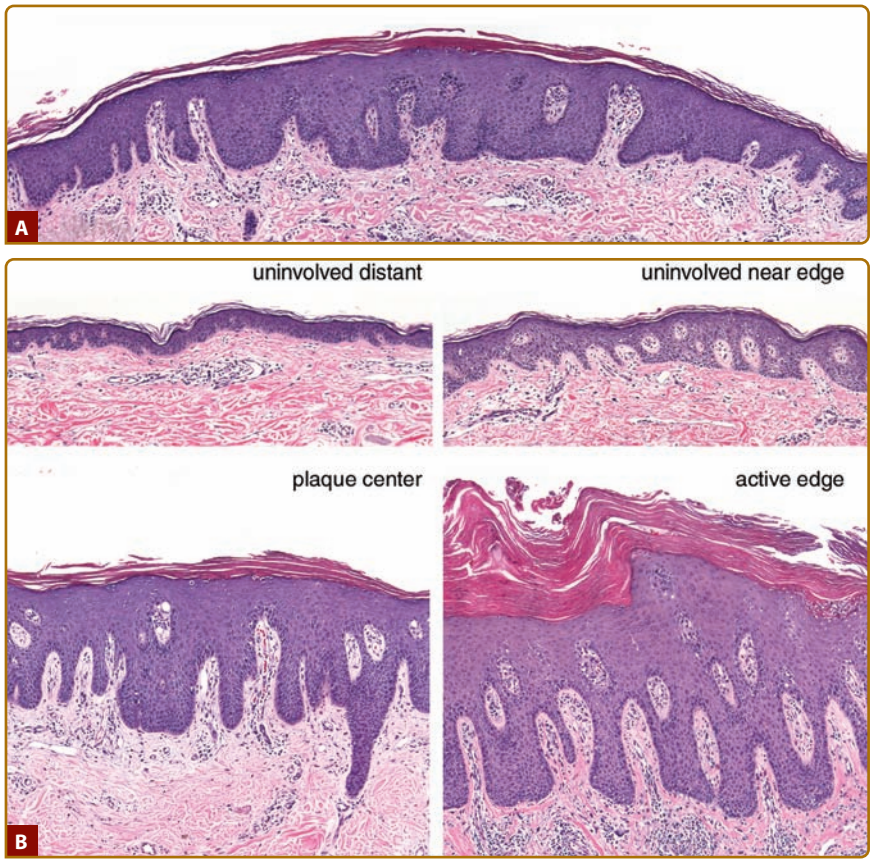

Figure 18-2 Histopathology of psoriasis. **A.** Pinpoint papule of psoriasis. In the transition from the edges to the center of the lesion, note progressive thickening of epidermis with elongation of rete pegs, increasing dilatation and tortuosity of vessels, and increasing mononuclear cell infiltrate. Also note the transition from basket-weave to compact stratum corneum with loss of granular layer in the center of the lesion. (4-mm punch biopsy, hematoxylin and eosin, scale bar = 100 µM.) **B.** Comparison of uninvolved versus involved skin. Four 4-mm biopsies were taken from the same individual sampled in **A** on the same day. "Uninvolved distant" skin was taken from the upper back 30 cm from the nearest visible lesion of psoriasis. "Uninvolved near edge" skin was taken 0.5 cm from the edge of a 20-cm plaque, which had been present for several years, according to the patient. "Center plaque" skin was taken from a relatively inactive (less red and scaly) area in the center of this plaque. "Involved edge" skin was taken from an active (more red and scaly) area about 1 cm inside the edge of the same plaque. In comparing "uninvolved distant" to "uninvolved near edge" skin, note that the latter manifests increased thickness and early elongation of the rete pegs, dilatation and early tortuosity of blood vessels, and increased numbers of mononuclear cells in the upper dermis, many of which are in a perivascular location. In this patient, "uninvolved near edge" skin also manifests an increased frequency of dyskeratotic keratinocytes, a finding that has been noted previously at the periphery of psoriatic lesions.[53] In comparing less active to more active areas of the plaque, note that the more active area manifests increased dermal mononuclear infiltrate, increased hyperkeratosis and parakeratosis, and Munro's microabscesses. (4-mm punch biopsies, hematoxylin, and eosin, scale bar = 100 µM.)

Initial Lesion. In the initial pinhead-sized macular lesions there is marked edema, and mononuclear cell infiltrates are found in the upper dermis.[70] These findings are usually confined to the area of one or two papillae. The overlying epidermis soon becomes spongiotic, with focal loss of the granular layer. The venules in the upper dermis dilate and become surrounded by a mononuclear cell infiltrate.[67] Similar findings have been described in early macules and papules of psoriasis[71] and in clinically normal-appearing skin 2–4 cm away from any active lesion in patients undergoing an acute flare of guttate psoriasis.[72]

Developing Lesion. Studies of the clinical margins of somewhat larger lesions (0.5–1.0 cm) reveal an approximately 50% increase in epidermal thickening in the "normal-appearing" skin immediately adjacent to lesions.[67] There is a large increase in the metabolic activity of epidermal cells, including the stratum corneum, increased DNA synthesis, an increased number of mast cells and dermal macrophages, and increased mast cell degranulation.[67,73,74] Subsequent studies revealed increased numbers of dermal T cells[75] and dendritic cells (DCs)[76] in both uninvolved and involved psoriatic skin relative to normal skin. Toward the center of the lesion, a "marginal zone" can be identified, with increasing band-like epidermal thickness, increasing parakeratosis and capillary elongation, and perivascular infiltration of lymphocytes and macrophages, without exudation into the epidermis. More centrally,

rete ridges begin to develop in the marginal zone, before finally transitioning into the fully developed psoriatic plaque. Squamous cells manifest enlarged extracellular spaces with only a few desmosomal connections. Parakeratosis is typically mounded or spotty.

Mature Lesion. Mature lesions of psoriasis are characterized by uniform elongation of rete ridges, with thinning of the epidermis overlying the dermal papillae.[67,71] Epidermal mass is increased three to five times, and many more mitoses are observed, frequently above the basal layer. About 10% of basal keratinocytes are cycling in normal skin, whereas this value rises to 100% in lesional psoriatic skin.[77] Widening of the extracellular spaces between keratinocytes persists but is less prominent than in developing lesions and is more uniform than the typical spongiosis of eczematous skin lesions. The tips of the rete ridges are often clubbed or fused with adjacent ones, with thin, elongated, edematous papillae containing dilated, tortuous capillaries. Parakeratosis, with accompanying loss of the granular layer, is often horizontally confluent but may alternate with orthokeratosis,[78] and hyperkeratosis is more extensive than in the transitional zone. The inflammatory infiltrate around the blood vessels in the papillary dermis becomes more intense but still consists of lymphocytes, macrophages, DCs, and mast cells. Unlike the initial lesion and the transitional zone, lymphocytes are observed in the epidermis of the mature lesion. Neutrophils exit from the tips of a subset of dermal capillaries (the "squirting papillae"), leading to their accumulation in the overlying parakeratotic stratum corneum (Munro's microabscesses) and, less frequently, in the spinous layer (spongiform pustules of Kogoj). Collections of serum can also be seen in the epidermis and the stratum corneum.[67,71]

CELLULAR PARTICIPANTS IN PSORIASIS

T Cells.[79,80] In 1984, it was demonstrated that the eruption of psoriatic skin lesions coincided with epidermal influx and activation of T cells,[75] and shortly thereafter it was further shown that resolution of psoriasis during phototherapy was preceded by depletion of T cells, predominantly from the epidermis.[81] Several studies found CsA to be highly effective in psoriasis,[82,83] and this effect was demonstrated to be primarily through blockade of T cells rather than keratinocytes.[84] Furthermore, psoriasis has been triggered or cured by bone marrow transplantation, depending on whether the donor or the host was psoriatic.[85,86] The role of T cells in psoriasis was functionally demonstrated in 1996 when it was shown that the psoriasis process could be induced by injecting activated autologous T cells into uninvolved psoriatic skin transplanted onto severe combined immunodeficient mice.[87] Available data indicate that the T-cell responses are antigen-specific rather than mediated by superantigens, as clonal populations of both $CD4^+$ and $CD8^+$ T cells have consistently been identified in psoriatic lesions.[88–91] However, most of the T cells in a psoriatic lesion are not clonally expanded and may accumulate in response to the cytokine environment of the lesion. There is virtually no evidence for B-cell involvement or antibody-mediated processes in psoriasis.

The best-characterized T cells are the $CD4^+$ and $CD8^+$ subsets. Predominantly of the memory phenotype ($CD45RO^+$), these cells express the cutaneous lymphocyte antigen (CLA), a ligand for E-selectin, which is selectively expressed on skin capillaries and therefore provides them with access to the skin.[92] $CD8^+$ T cells are predominantly located in the epidermis, whereas $CD4^+$ T cells are predominantly located in the upper dermis.[93,94] The cytokine profile of psoriatic lesions is rich in interferon (IFN)-γ,[95] indicative of T helper 1 (Th1) polarization of $CD4^+$ cells, and T cytotoxic 1 (Tc1) polarization of $CD8^+$ cells[96] (Fig. 18-3). Two other subsets of $CD4^+$ T cells, stimulated by IL-23 and characterized by production of IL-17 (Th17 cells) and/or IL-22 (Th22 cells), are also found in psoriatic lesions and have been shown to play a major role in maintaining chronic inflammation in psoriasis[97,98] as well as other autoinflammatory conditions.[99–101] While the majority of CD4 T cells are Th1, about 20% of them produce IL-17 (Th17) and ~15% produce IL-22 (Th22).[98] Similarly, $CD8^+$ epidermal T cells producing IFN-γ (Tc1), IL-17 (Tc17), and IL-22 (Tc22) are found in psoriasis.[98] These T-cell subsets have considerable functional plasticity and conversions of Tc17 to Tc1[102] and Th17 to Th1[103–105] have been described. In mice most Th17 cells also elaborate IL-22, which mediates dermal inflammation and epidermal hyperplasia after intracutaneous injection of IL-23.[106] However, in humans, this overlap is much less pronounced, with largely distinct populations of Th17 and Th22 cells.[98,107–109]

Regulatory T cells suppress immune responses in an antigen-specific fashion, and are responsible not only for downregulating successful responses to pathogens but also for the maintenance of immunologic tolerance.[110] Several different populations of regulatory T cells (T-regs) exist but the best characterized one is the $CD4^+$ $CD25^+$ subset.[111] A recent study of this subset in psoriasis demonstrated impaired inhibitory function and failure to suppress effector T-cell proliferation,[112] possibly due to a tissue environment rich in IL-6 produced by endothelial, dendritic, and Th17 cells.[113]

Natural killer T cells (NKT cells) are a heterogeneous subpopulation of T lymphocytes defined by coexpression of the T-cell receptor (TCR) and natural killer (NK) lineage markers such as CD16, CD56, CD57, CD94, and CD161. Unlike conventional T cells, NKT cells recognize glycolipid antigens in the context of the MHC Class I-like antigen-presenting molecule CD1d. NKT cells constitute only a small fraction of lymphocytes. Nevertheless, their ability to rapidly secrete large amounts of cytokines, including IFN-γ, IL-4, IL-2, IL-5, IL-10, IL-13, IL-17, and TNF-α, positions them as potentially important regulators of T-cell differentiation at sites of inflammation. While NKT cells are increased in psoriatic lesions relative to uninvolved or normal skin, their precise role in psoriasis remains unclear.[114]

Natural Killer Cells. Like NKT cells, NK cells are major producers of IFN-γ and serve as a bridge

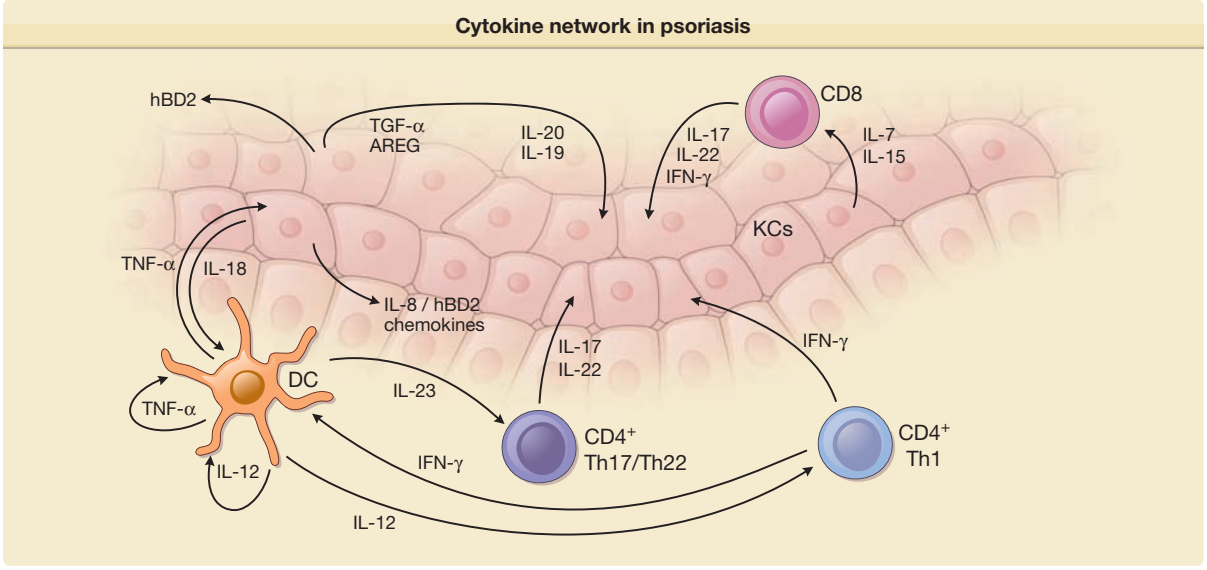

Figure 18-3 The cytokine network in psoriasis. IFN-γ is produced by Th1 cells, and TNF-α is produced by activated T-cells and DCs. IFN-γ amplifies the production of IL-23 by DC. In turn, IL-23 maintains and expands subsets of $CD4^+$ T cells, called Th17 and Th22 cells, which are characterized by production of IL-17 and IL-22, respectively. CD8+ T cells are predominantly found in the epidermis, and their entry into the epidermis is necessary for lesion development. IL-17, TNF-α, IFN-γ, and IL-22 synergistically promote activation of the innate keratinocyte defense response involving secretion of antimicrobial peptides such as human-β-defensin 2 (hBD-2), IL-8 and other chemokines, and growth factors such as TGF-α, AREG, IL-19, and IL-20. Keratinocytes also produce IL-7 and IL-15, which influence the survival and turnover of CD8+ T cells, and IL-18, which via IL-12 causes DC to further increase the production of IFN-γ by T-cells.

between innate and acquired immunity. Unlike NKT cells, NK cells do not express the T-cell receptor. NK cells are present in psoriasis,[115,116] and can trigger the formation of psoriasis lesions in a xenograft model system.[117] NK cells are regulated in part by killer immunoglobulin-like receptors (KIRs), which recognize HLA-C and other MHC Class I molecules. KIRs are a family of ~15 closely linked genes located on chromosome 19q13.4,[118] some of which stimulate and others of which inhibit NK cell activation. KIR genes have been associated with psoriasis[119–121] and psoriatic arthritis.[122,123] It has been proposed that susceptibility to psoriatic arthritis is determined by the overall balance of activating and inhibitory genotypes.[121,124] Although it is attractive to speculate that the association of psoriasis with *HLA-Cw6* might reflect a KIR-mediated dysregulation of NK cells, it is known that a number of other HLA-C protein alleles recognize the same inhibitory receptor (*KIR2DL1*), including HLA-Cw2, HLA-Cw4, HLA-Cw5, HLA-Cw15, and HLA-Cw17. Thus, it is not straightforward to explain the action of HLA-Cw6 in psoriasis on the basis of KIR recognition alone.

Dendritic Cells. Treatments directed primarily against key costimulatory molecules expressed by "professional" antigen-presenting DCs markedly improve psoriasis.[79] This suggests that T cells in psoriatic lesions are in constant communication with DCs, which have a role in both the priming of adaptive immune responses and the induction of self-tolerance[125] (see Chapter 10). Several subsets of DCs have been defined, and many of these are found in markedly increased numbers within psoriatic lesions.[125–128] Although DCs are believed to be central to the pathogenesis of psoriasis, the specific role of each subset is still somewhat unclear.

Langerhans Cells. Usually defined by a $Langerin^+$, $CD1a^+$ surface phenotype, Langerhans cells (LCs) are considered to be immature DCs (iDCs). LCs have a well-defined role as antigen-presenting cells (APCs) in contact dermatitis,[129] but their role in psoriasis is currently somewhat unclear. While the density of LC is decreased in lesional psoriasis in terms of cells per unit area,[126,130] the number of LC per unit length of epidermis is similar in normal, uninvolved, and lesional skin.[128] DCs lacking the characteristic Birbeck granule but positive for the maturation molecule DC-LAMP found in the dermis of psoriatic lesions could be derived from epidermal or dermal iDC.[131] Recently, LC have been shown to preferentially drive Th22 differentiation, relative to dermal DC.[132] Interestingly, migration of LCs in response to inflammatory cytokines is markedly impaired in uninvolved psoriatic epidermis relative to normal skin,[133] especially in type I (early onset) psoriasis.[134]

Dermal Dendritic Cells. Dermal DCs do not express activation markers in resting normal skin and in that context can be considered as another type of iDC that is similar to myeloid iDCs found in other tissues.[128,135] Immunophenotyping studies have revealed that the population of dermal DCs is quite complex, and that psoriasis lesions demonstrate a marked increase in the number and maturation state of dermal DC.[126,136,137]

Identified initially by strong expression of MHC Class II and/or factor XIIIa,[138] it is now appreciated that factor XIIIa+ cells are macrophages rather than DCs, and that the most reliable marker for myeloid-derived dermal DC is CD11c.[139] There appears to be three types of myeloid-derived ($CD11c^+$) DCs in psoriasis lesions.[128,139,140] The first is the population of "resident" dermal DCs that are also seen in normal skin. These $CD11c^+/CD1c^+$ DC account for about 10%–15% of DCs in psoriasis lesions. These cells are relatively more mature than inflammatory DCs (see Section "Inflammatory Dendritic Epidermal Cells"), but less so than fully mature DCs. The second population comprises mature DCs that are marked by DC-LAMP or CD83. The $DC\text{-}LAMP^+$ DCs form large aggregates with T cells in the dermis, whereas the $CD83^+$ DCs are more diffuse. It has been suggested that fully mature DCs may be the sustaining force for chronic T-cell activation in skin and the characteristics of these cells are very similar to those in lymph nodes.[128,139–141] The third population of myeloid DCs are the inflammatory DCs, which are $CD11c^+/CD1c^-$, and are less mature than the resident $CD1c^+$ subset. These cells make IL-23 and probably help drive Th17 differentiation.[142] About 80%–90% of DCs in psoriasis lesions are these relatively immature, inflammatory DCs and, interestingly, the total number of these cells can exceed the number of T cells in lesions. A subset of these inflammatory DC express high levels of TNF-α and iNOS, and by analogy to similar if not identical cells in mice, have been called "TIP-DC" (for TNF-α and iNOS-producing DC). Consistent with our recent genetic findings,[64] TIP-DCs are increased up to 30-fold in psoriatic lesions.[128] There appears to be substantial plasticity in this population of cells, as the cytokine milieu in atopic dermatitis promotes the emergence of dermal DC that chemotactically attract a different subset of T cells than those found in psoriasis.[143]

Inflammatory Dendritic Epidermal Cells. Thought to be either monocyte-derived iDCs,[144] or a variant of inflammatory myeloid DC that migrate into the epidermis,[145] inflammatory dendritic epidermal cells (IDECs) are distinguished from LCs by the lack of Birbeck granules and lower expression of CD1a. Unlike LCs, IDECs are nearly absent in normal skin, and their numbers are markedly increased in the epidermis of active psoriasis lesions, as well as a large number of other inflammatory dermatoses.[126,130]

Plasmacytoid Dendritic Cells. Plasmacytoid DCs (pDCs) are inefficient presenters of antigens to T cells. However, they regulate inflammation and link innate with adaptive immunity, producing large amounts of IFN-α when activated[146] (see Chapter 10). Absent from normal skin, pDCs are significantly increased in both uninvolved and involved psoriatic skin, but activated only in involved skin.[126,147] Interestingly, inhibition of pDCs was shown to prevent development of psoriasis in a mouse xenograft model.[147] Conversely, imiquimod, which has been reported to exacerbate psoriasis,[148] likely acts through this type I IFN system by binding to Toll-like receptor 7 on pDCs.[149] Although IFN-α appears to have a role in psoriatic lesional development and exacerbations,[147] its role in stable chronic plaque psoriasis has been questioned.[150]

Mast Cells. Mast cells have long been observed in initial and developing psoriasis lesions,[67] with prominent mast cell degranulation in both eruptive psoriasis[72] and in lesions reappearing after discontinuation of topical corticosteroid suppression.[74] Interestingly, skin-derived mast cell release of preformed and newly synthesized mediators is potently suppressed byCsA and tacrolimus,[151] suggesting that the antipsoriatic effects of these compounds could be mediated by mast cells as well as T cells. Recently, mast cells have been shown to be a major source of IL-17 production in both rheumatoid arthritis synovium[152] and in psoriatic lesions.[153]

Macrophages. Macrophages are prominent in initial and developing psoriasis lesions.[67] CD163 has recently been shown to be a reliable marker for skin-derived macrophages,[139] and as mentioned earlier, these cells also express Factor XIIIa.[154] A population of $CD11c^-$, $CD1a^+$, $CD68^+$ macrophages is found scattered just under the basement membrane, subadjacent to proliferating keratinocytes expressing the macrophage chemokine MCP-1 (CCL2).[155–157] These phagocytically active cells could be involved in generating fenestrations (holes) in the epidermal basement membrane.[158] Recent studies in two different mouse models of psoriasis, one dependent on and the other independent of T cells, showed that selective elimination of macrophages led to prompt improvement of lesions. These findings suggest that macrophages may play a key role in the pathogenesis of psoriasis, at least in part via production of tumor necrosis factor (TNF)-α, iNOS, and IL-23.[154,159–161]

Neutrophils. Although neutrophils are commonly seen in the upper epidermis of psoriatic lesions, they appear late during the development of lesions, their number is quite variable, and their role in the pathogenesis of psoriasis is unclear. Studies in one of the same mouse models used to implicate macrophages indicate that neutrophils are probably unnecessary for lesional development.[161]

Keratinocytes. As detailed below, keratinocytes are a major producer of proinflammatory cytokines, chemokines, and growth factors,[162] as well as other inflammatory mediators such as eicosanoids[163] and mediators of innate immunity such as cathelicidins, defensins, and S100 proteins.[164] Psoriatic keratinocytes are engaged in an alternative pathway of keratinocyte differentiation called *regenerative maturation*.[165] Regenerative maturation is activated in response to immunologic stimulation in psoriasis,[166] but the mechanism by which this occurs is presently unknown.

Other Cell Types. Other cell types, such as endothelial cells and fibroblasts, are also likely to be participants in the pathogenic process. Endothelial cells are

strongly activated in developing and mature lesions of psoriasis[67,71] and in addition to delivering a tenfold increase in blood flow to the lesion, they play a major role in controlling the flux of leukocytes and serum proteins into psoriatic tissue.[167–169] Fibroblasts support keratinocyte proliferation in a paracrine manner,[170] and this process is exaggerated in psoriasis.[171] Fibroblasts produce many chemotactic factors and support the migration of T cells out of psoriatic lesions.[172] Thus, fibroblasts may also be intimately involved in psoriasis by directing the localization of T cells.

SIGNALING MOLECULES IN PSORIASIS

Cytokines and Chemokines. The cytokine network in psoriasis is extremely complex, involving the actions and interactions of multiple cytokines, chemokines, and growth factors, and their receptors in addition to other mediators produced by multiple cell types. Combinations of cytokines and growth factors can result in effects that are not seen when these factors are studied individually. For example, T-cell clones isolated from psoriatic skin lesions are able to promote keratinocyte proliferation in an IFN-γ-dependent manner,[173,174] but by itself, IFN-γ has an antiproliferative effect on cultured keratinocytes.[175]

The most prominent cytokines currently thought to be involved in the pathogenesis of psoriasis are summarized in Fig. 18-3. Besides IFN-γ,[96,176] a plethora of cytokines and chemokines are upregulated in psoriasis, including the cytokines TNF-α,[177] IL-2,[95] IL-6,[178] IL-8,[179] IL-15,[180] IL-17,[181] IL-18,[182] IL-19, IL-20, IL-22,[183] IL-21,[184] IL-23,[97,100,101] and the chemokines MIG/CXCL9, IP-10/CXCL10, I-TAC/CXCL11, and MIP-3α/CCL20.[7,185] More complex abnormalities have been observed for other immunomodulatory cytokines and their receptors, including IL-1 and TGF-β.[186–188] IL-23 is currently believed to play a central role in the pathogenesis of psoriasis through its role in maintaining and expanding specific subsets of $CD4^+$ T cells characterized by production of IL-17 (Th17)[189] and IL-22 (Th22).[106] IFN-γ plays a role in amplifying this process by stimulating antigen-presenting cells to produce more IL-23.[190] The entry of activated, cytokine secreting, $CD8^+$ T cells into the epidermis promotes epidermal hyperplasia[191] and activation of keratinocyte innate defense response with resulting production of antimicrobial peptides, cytokines, chemokines, and growth factors (see Fig. 18-3). The other major cytokine producers in psoriatic lesions are DC and macrophages,[154] with additional contributions from mast cells, neutrophils, and endothelial cells. Overall, this creates a highly complex network of inflammatory signals between the main cellular participants.

Innate Immune Mediators. In addition to cytokines and chemokines, several mediators of innate immunity are abnormally expressed in psoriasis.[164] Prominent among the innate immune mediators are the antimicrobial peptides human β-defensin-2 (hBD-2) and cathelicidin (LL-37), both of which are much more highly overexpressed in psoriasis than in atopic dermatitis.[192,193] Notably, expression of HBD-2 and LL-37 is increased in response to proinflammatory and type I cytokines (TNF-γ, IL-1, and IFN-γ) and suppressed by type II cytokines (IL-4, IL-10, and IL-13).[194] These differences in antimicrobial peptide expression help to explain why approximately 30% of patients with atopic dermatitis have bacterial or viral infections, as opposed to only 7% of psoriasis patients, even though both conditions have a defective skin barrier.[195] They may also explain why psoriasis patients, though frequently colonized with *Staphylococcus aureus*, are not markedly improved by antibiotic treatment, whereas atopic dermatitis patients often obtain dramatic benefit from antibiotic therapy. The S100 proteins are a large family of dimeric low-molecular-weight proteins that bind calcium and other divalent cations. S100A2, S100A7 (psoriasin), and the S100A8/A9 heterodimer (calprotectin) are markedly overexpressed in psoriasis lesions.[196] These proteins exert chemotactic and antimicrobial activity, the latter through sequestration of zinc ions,[197,198] and have been shown to function as TLR4 ligands on $CD8^+$ T cells, upregulating IL-17 expression and inducing autoimmunity.[199] Nitric oxide is produced in large amounts by DCs in psoriasis, triggering multiple signal transduction events.[137] Finally, the complement component C5a is a potent chemoattractant for neutrophils and may contribute to the accumulation of neutrophils in the stratum corneum of psoriasis.[200] Interestingly, it is also the most potent chemoattractant for DCs in psoriatic scale extracts.[201] Many of these mediators are regulated in response to Toll-like receptors, providing a mechanism whereby the innate immune system can rapidly recognize a wide variety of pathogens according to their pathogen-associated molecular patterns[202] (see Chapter 10).

Eicosanoids. The role of eicosanoids in psoriasis remains unclear.[203] Levels of free arachidonic acid, leukotriene B4, 12-hydroxyeicosatetraenoic acid, and 15-hydroxyeicosatetraenoic acid are markedly increased in lesional skin, whereas levels of prostaglandins E and F2α are increased less than twofold.

Growth Factors. Multiple growth factors are overexpressed in psoriasis.[204] Members of the epidermal growth factor (EGF) family induce their own production in keratinocytes, including transforming growth factor-α, amphiregulin (AREG), and heparin-binding EGF-like growth factor.[205] Studies in xenografted mice found a reduction in epidermal hyperplasia after antibody-mediated neutralization of AREG.[206] Activation of the EGF receptor stimulates keratinocyte production of vascular endothelial growth factor (VEGF),[167] perhaps accounting for the long-standing observation that the angiogenic properties of normal and psoriatic skin associate with the epidermis.[207] Nerve growth factor (NGF) is also overexpressed by keratinocytes in psoriatic skin, and NGF receptors are increased in the peripheral nerves of lesional skin. Psoriasis has been shown to clear in denervated skin,[208] and psoriasis improved after NGF blockade in xenografted mice.[209] Moreover, direct connections have been documented between terminal nerve fibers and DCs in the skin, and

neuropeptides have been shown to modulate DC function.[210] Paracrine growth factors produced outside the epidermal compartment may also play an important role in stimulating epidermal hyperplasia in psoriasis, including insulin-like growth factor-1[211] and keratinocyte growth factor.[212]

Proteases and Their Inhibitors. The psoriatic lesion is characterized by marked overexpression of multiple classes of proteinases by both keratinocytes and leukocytes. Metalloproteinases release TNF-α, several EGF-like growth factors, and many other cytokines and growth factors from their membrane-anchored precursors.[213] Leukocyte-derived elastase has also been implicated in the release of EGF-like growth factors.[214] Serine proteases directly activate protease-activated receptors.[215] Each of these mechanisms may contribute to stimulation of keratinocyte proliferation. The protease inhibitors elafin, serpinB3, and serpinB13 (hurpin) are among the most markedly overexpressed genes in psoriatic lesions,[216,217] suggesting that homeostatic mechanisms are strongly engaged in an effort to regulate the proteolytic environment of psoriatic lesions.

Integrins. Several observations suggest an early role for α5 integrins and their ligand fibronectin in psoriasis. Fibronectin is increased in psoriatic epidermis,[218] and it has been suggested that fibronectin gains access to the epidermis via fenestrations in the epidermal basement membrane.[219] Fibronectin receptors (α5 integrins) are only weakly expressed in normal skin, but are strongly expressed in uninvolved as well as involved psoriatic skin,[219] and fibronectin selectively increases the proliferation of keratinocytes cultured from uninvolved psoriatic skin.[219] Receptors for collagen and laminin-5 (α2β1 and α3β1 integrins, respectively) are confined to the basal layer of normal skin but are strongly expressed in suprabasal keratinocytes as part of the regenerative maturation program.[220] Interestingly, forced expression of β1 integrins in the suprabasal compartment results in epidermal hyperplasia.[221] Finally, the entry and retention of $CD8^+$ T cells into the epidermis requires binding of type IV collagen by α1β1 integrin and binding of E-cadherin by αEβ7 integrin, respectively.[191,222]

Signal Transduction. As would be expected given this plethora of intercellular signaling alterations, multiple signal transduction mechanisms are dysregulated in psoriatic epidermis, including receptor tyrosine kinase, mitogen-activated protein kinase, Akt, STAT, Src family kinase, Wnt,[223] and NF-κB pathways. These abnormalities affect immunocyte activation and trafficking as well as keratinocyte responses of proliferation, differentiation, and survival. As described below, many of the susceptibility variants associated with psoriasis have a role in regulating these signaling pathways, particularly the NF-κB pathway.[34,64] This is a challenging area of research, as signal transduction experiments are typically conducted on cell lines in culture, whereas the phenotype of psoriasis requires intercellular interactions and differentiation conditions that can only be obtained *in vivo*. Animal models are helping to define signal transduction abnormalities at a functional level. Space does not allow detailed consideration of these pathways in psoriasis, nor of the animal models being used to study them. Interested readers are referred to several reviews for deta ils.[50,188,224–226]

PSORIASIS: INTEGRATING GENETICS AND IMMUNOLOGY

HLA-Cw6. (Fig. 18-4). As has been made clear by detailed fine mapping, genetic linkage, and association studies, HLA-C is by far the major genetic risk factor for psoriasis.[30,34,35,38,57] Because it presents antigens to $CD8^+$ T cells, HLA-Cw6 is an excellent candidate for functional involvement in psoriasis. Psoriasis has long been known to be triggered by streptococcal pharyngitis, and is the only infection that has been shown to trigger psoriasis in a prospective cohort study.[227] Because tonsillar T cells are cutaneous lymphoid antigen (CLA)-positive and recognize activated skin endothelium[228] they can traffic into the skin, explaining why the same CLA-positive T-cell clones are found in the tonsils and in the lesional skin of psoriatic patients.[229] $CD8^+$ T cells comprise at least 80% of the T cells in the epidermis of psoriatic lesions,[230] and epidermal invasion correlates with lesional development.[94,231,232] $CD8^+$ T cells selectively traffic to the epidermis because they express integrin α1β1 (also known as VLA-1), which binds to type IV basement membrane collagen,[191] as well as integrin αEβ7, which binds to keratinocyte E-cadherin.[222] Once in the epidermis, $CD8^+$ T cells "interrogate" peptides bound to HLA-Cw6 on the surface of dendritic APCs and/or keratinocytes. In normal immune responses, $CD4^+$ T cells provide critical help in processing and presentation of intracellular viral components and tumor antigens, in a process called *cross-priming*. While $CD4^+$ and $CD8^+$ memory T cells can traffic between the skin and lymph nodes and blood, increasing evidence suggest that they spend most of their time in the skin itself.[233] This may help to account for the characteristic distribution of psoriatic plaques, which tend to recur in the same places after therapeutic or spontaneous improvement.

As mentioned earlier, there is a very strong association between *HLA-Cw6* and guttate psoriasis. This form of psoriasis is often self-limiting[5,234] but can progress to chronic plaque psoriasis, which has a fluctuating inflammatory course in the absence of ongoing streptococcal infection. The transition from guttate to chronic plaque psoriasis likely reflects a transition from a self-limited cutaneous immune reaction triggered by streptococci encountered in the tonsils during a guttate flare, to a persistent and inappropriate immune reaction directed against host proteins in chronic plaque disease.[235] The mechanisms by which normal immunologic tolerance of self-proteins is broken during this transition remain to be elucidated.

Non-MHC Genes. (Fig. 18-5). As reviewed earlier, in the online edition, the advent of GWAS has identified an increasing number of convincing genetic association signals for psoriasis outside the MHC

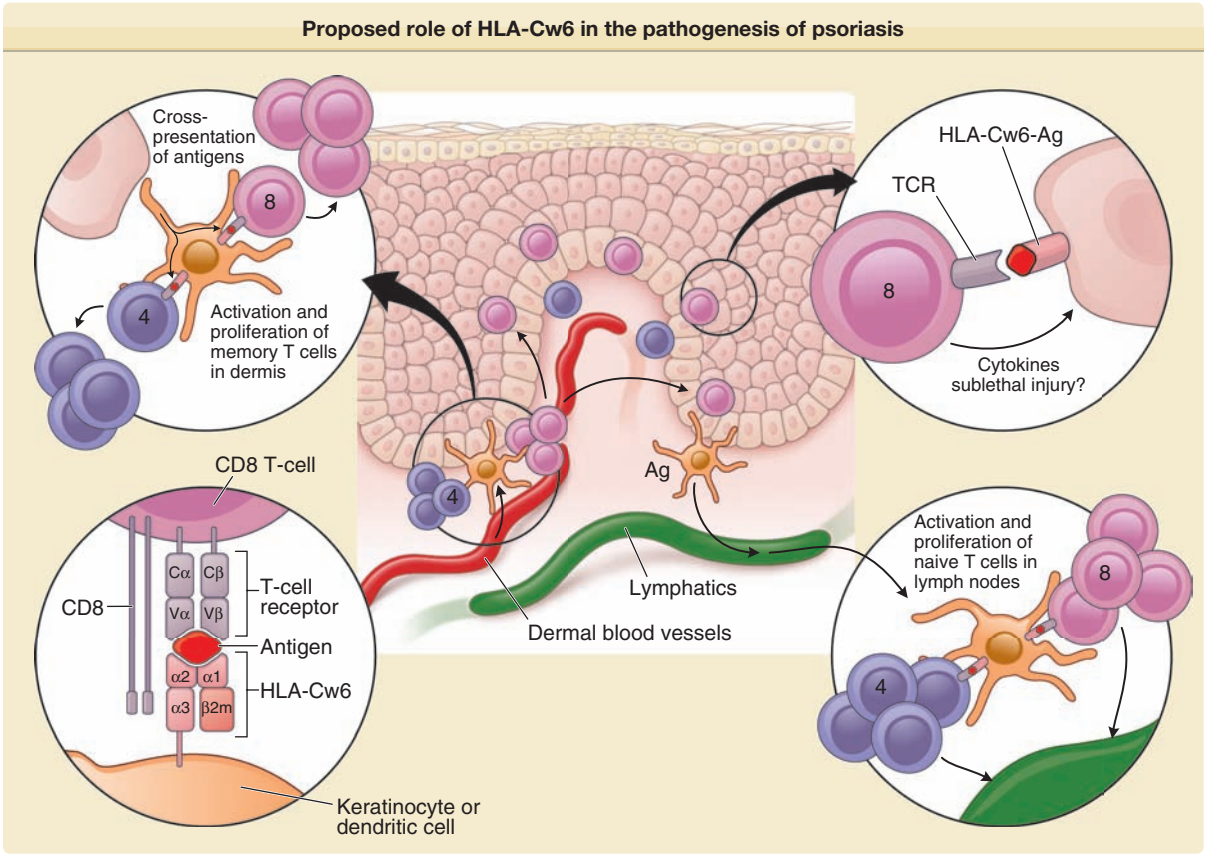

Figure 18-4 Proposed role of HLA-Cw6 in the pathogenesis of psoriasis. Antigen (Ag) in the binding pocket of HLA-Cw6 interacts with a T-cell receptor. The role of HLA-Cw6 in psoriasis is likely to be twofold. HLA-Cw6 is active in cross-presenting peptides on the surface of dendritic cells, allowing activation and clonal expansion of antigen-specific $CD8^+$ T cells. This process is dependent on $CD4^+$ T-cell help for cross-presentation of intracellular antigens and is likely to happen both in the dermis (activation of memory resident T cells) and local lymph nodes (activation of naive T cells). Subsequently, the $CD8^+$ T cells are able to migrate into the epidermis where they encounter HLA-Cw6 on the surface of the keratinocytes presenting those same pathogenic peptides. Activated CD8+ T-cells may recognize peptides presented by HLA-Cw6 on keratinocyte cell surface. Because these T-cells express perforin, they could directly damage keratinocytes in the traditional cytotoxic manner.[435] Activated $CD8^+$ T cells could also trigger the local release soluble factors, including cytokines, chemokines, eicosanoids, and/or innate immune mediators, which could further increase local inflammation and stimulate keratinocyte proliferation.[173] In response to either insult, keratinocytes could respond by elaborating autocrine growth factors such as TGF-α and AREG, thereby encouraging their own proliferation and survival.[436]

(Table 18-1). The genes contained within these associated regions fit very well with our current concepts of psoriasis pathogenesis. This integration is further reinforced by the pronounced clinical responsiveness of psoriasis to biological agents that specifically target the genetically implicated pathways. Most of the non-MHC associations identified thus far fall into four interconnected functional axes: (1) IFN-γ/IL-23/IL-17 signaling, (2) NF-κB signaling, (3) inflammatory DC function, and (4) keratinocyte differentiation. While the actual functional genetic variations that are ultimately responsible for these associations remain to be determined, these discoveries provide a rationale for biological and therapeutic dissection of the implicated pathways.

IFN-γ/IL-23/IL-17 Signaling. Three strong regions of association map near genes involved in IL-23 signaling: (1) *IL12B* (encoding the p40 subunit of IL-23 and IL-12), (2) *IL23A* (encoding the p19 subunit of IL-23), and (3) *IL23R* (encoding a subunit of the IL-23 receptor).[34,60,61] These associations are further supported by the impressive efficacy of biologics targeting the p40 subunit common to IL-12 and IL-23,[268] along with the fact that *IL12B* and *IL23A* are markedly overexpressed in psoriatic lesions, whereas *IL12A* is not.[269] IL-23 signaling promotes cellular immune responses by promoting the survival and expansion of a subset of IL-17-expressing T cells that protects epithelia against microbial pathogens.[270] Given the similarities between skin and gut as epithelial tissues, it is notable that inflammatory bowel disease (IBD) is clinically associated with psoriasis[271] and the same genetic variation in *IL23R* that increases risk for both diseases.[272] Ankylosing spondylitis (AS) is another HLA-Class I-associated autoimmune disorder that is clinically associated with IBD[273] and genetically associated with *IL23R*.[274] Psoriatic arthritis (PsA) shares a number of clinical

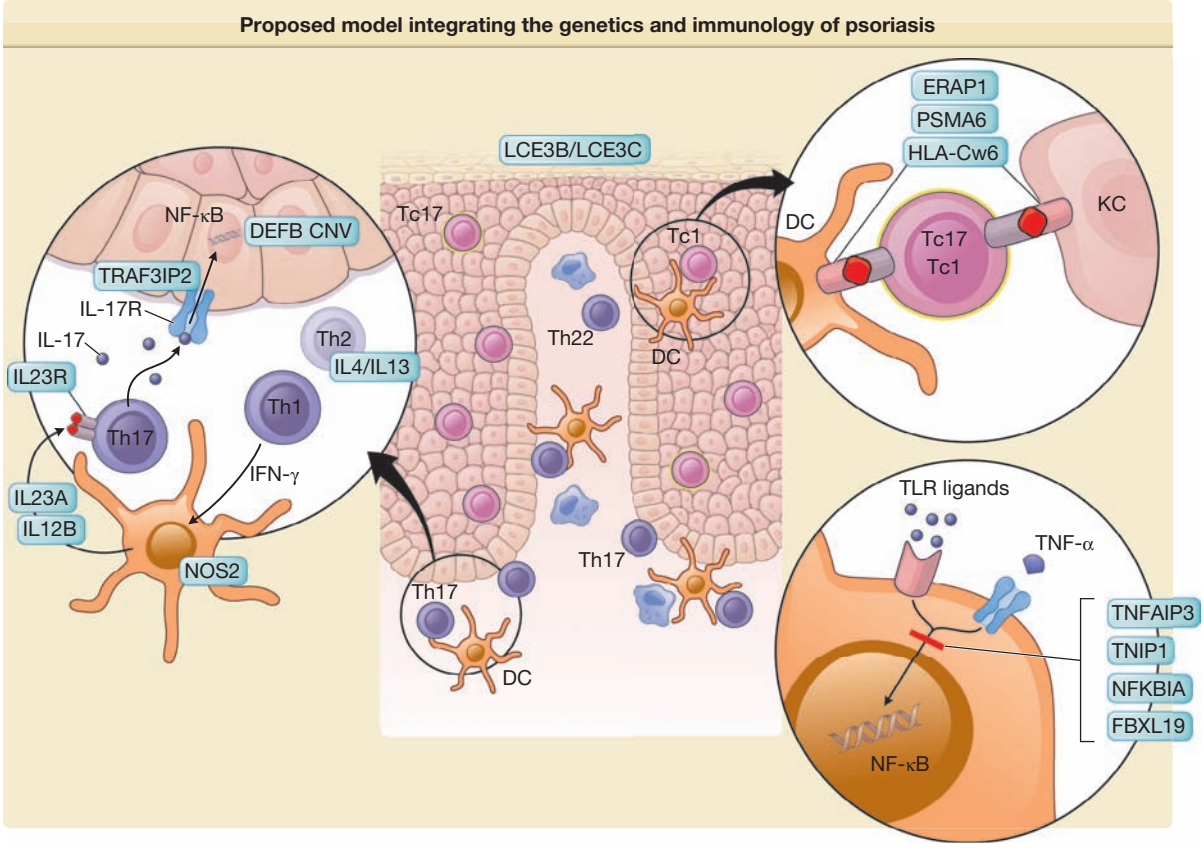

Figure 18-5 Proposed model integrating the genetics and immunology of psoriasis. The majority of the CD8+ T-cells (lilac) are located in the epidermis, whereas CD4+ T-cells (blue) predominate in the dermis along with antigen presenting cells/dendritic cells (DCs) (blue) and macrophages (Mφs)(light blue). Confirmed association signals are indicated by the likely candidate genes they contain. Please see text for additional details. (Adapted from Nair RP et al: Psoriasis bench to bedside: Genetics meets immunology. *Arch Dermatol* **145**(4):462-464, 2009, with permission.)

similarities with AS, and is genetically associated with *IL12B*, *IL23A*, and *IL23R*[34,275,276] (see Chapter 19).

IFN-γ is a major product of activated Th1 cells that stimulates DC to produce IL-23.[190] Several psoriasis susceptibility loci contain genes involved in interferon signaling (IFIH1, IL28R, and TYK2)[61] Together with IL-1, IL-23 promotes the survival and proliferation of IL-17-expressing T cells (Th17), thereby explaining why Th1 and Th17 are colocalized in psoriasis lesions and in many other sites of inflammation.[190] Given the well-known reciprocal relationship between Th1 and Th2 differentiation, it is notable that another psoriasis susceptibility region contains the *IL4* and *IL13* genes.[34,63] In addition to biasing T-cell differentiation away from Th1 and toward Th2, IL-4 inhibits Th17 cell development.[277] Both IL-4 and IL-13 are expressed at high levels in atopic dermatitis, but only at very low levels in psoriasis.[278] Moreover, treatment of psoriasis with IL-4 resulted in significant clinical improvement,[279] accompanied by reduced expression of IL-23 (but not of IL-12) and reduced numbers of Th17 cells.[280] The fact that significant genetic signals at both ends of this polarizing spectrum (IL-23, on the one hand, and IL-4/IL-13, on the other), with IFN-γ positioned between them, suggests that Th1-Th2-Th17 balance is a key functional and genetic determinant of psoriasis.

NF-κB Signaling. At least five psoriasis-associated genomic regions contain genes involved with controlling signaling through the transcription factor NF-κB: (1) *TNFAIP3*, (2) *TNIP1*, (3) *NFKBIA*, (4) *FBXL19*, and (5) *TRAF3IP2*.[34,58,59,61,64] TNF-α is a major activator of NF-κB signaling, and these associations are clinically reinforced by the dramatic therapeutic response of psoriasis to anti-TNF biologicals (see Section "Treatment"). *TNFAIP3* and *TNIP1*, respectively encode A20 and ABIN-1, which interact with each other to regulate the ubiquitin-mediated destruction of IKKγ/NEMO, a central nexus of NF-κB signaling.[281] *TNFAIP3* is genetically associated with rheumatoid arthritis (RA),[282,283] and both *TNFAIP3* and *TNIP1* are associated with systemic lupus erythematosus (SLE).[284–287] The polymorphisms implicated in RA and SLE show no association with psoriasis, suggesting that each of these common autoimmune diseases is driven by a different variant of the *TNFAIP3* gene. Interestingly, in mice, *Tnfaip3* is associated with atherosclerosis,[288] which is now known to be a major comorbidity of psoriasis.[289] *NFKBIA* encodes IκBα, which inhibits NF-κB signaling by sequestering it in the cytoplasm. *FBXL19* and *TRAF3IP2* are significantly more strongly associated with PsA than with purely cutaneous psoriasis.[58,64] *FBXL19* is structurally related to *FBXL11*, an F-box family mem-

[a]The most significant SNP in the associated region is shown.
[b]Risk allele frequencies and odds ratios are computed for the replication sample (discovery sample excluded due to the winner's curse phenomenon).
[c]*P*-value is calculated for the combined discovery and replication samples. Only genes that reached a genome-wide significance criterion of $p = 7 \times 10^{-8}$ are shown.
[d]Not applicable because the disease association is with copy number variation rather than SNP.

ber recently shown to inhibit NF-κB activity by lysine demethylation.[290] FBXL11 contains domains known to be required for demethylase activity, but FBLX19 does not.[291] Thus, FBXL19 might act as a dominant negative inhibitor of demethylase activity, thereby serving to activate NF-κB. *TRAF3IP2* encodes Act1, a ubiquitin ligase that interacts with TRAF (tumor necrosis factor receptor-associated factors) proteins and the IKK complex to activate NF-κB. Interestingly, Act1 is a key component of IL-17-mediated signaling through the IL-17 receptor, allowing the incorporation of TRAF6 into the IL-17 receptor signaling complex, with consequent activation of NF-κB.[292] Thus, Act1 may serve as a key link between the IFN-γ/IL-23/IL-17 axis on the one hand, and the NF-κB axis on the other.

Inflammatory DC Function. Beyond the major role of *HLA-Cw6* described earlier, it is noteworthy that two other regions of association contain genes whose products function in antigen presentation: (1) *PSMA6*, which encodes a proteosomal subunit involved in MHC Class I antigen processing,[64] and (2) *ERAP1*, an IFN-γ-inducible aminopeptidase that trims peptides for optimal binding to the MHC Class I peptide groove. As noted above, inflammatory DC produce large amounts of TNF-α and nitric oxide in addition to their well-recognized functions in antigen presentation. Thus, it seems more than coincidental that another novel region of association contains *NOS2*, which encodes iNOS, the enzyme responsible for nitric oxide production by DC. Reflective of the massive increase

in inflammatory dermal dendritic cells characteristic of psoriasis lesions, *NOS2* is markedly overexpressed in lesional skin.[64] In addition to iNOS, these inflammatory DC produce large amounts of TNF-α, which synergizes strongly with IL-17 to induce a marked increase expression of innate inflammatory mediators such as hBD2 by keratinocytes.[58]

Keratinocyte Differentiation. Given that hyperproliferation and altered differentiation of keratinocytes figure prominently in psoriasis pathophysiology, it is perhaps surprising that relatively few of the psoriasis-associated regions highlight genes that function primarily in keratinocytes. The most well-established association is an insertion–deletion polymorphism of the late cornified envelope genes *LCE3B* and *LCE3C*, which was independently discovered in European[65] and Chinese[57] populations. Located in the EDC, these genes are expressed very late during keratinocyte terminal differentiation[293] and are markedly overexpressed in psoriasis,[294] wound healing, and epidermal stress.[65,293] Another reported genetic association involving keratinocytes involves increased *DEFB4* copy number.[66] Whether or not this association is ultimately confirmed, it is notable that *DEFB4* is one of the most highly overexpressed genes in psoriatic lesions.[295] Finally, *TRAF3IP2* is known to function in epidermal cells, as shRNA-mediated knockdown of *TRAF3IP2* abrogates the TNF-α + IL-17-mediated upregulation of *DEFB4* in human keratinocytes.[58]

CLINICAL FINDINGS

Figure 18-6 is an algorithm showing clinical findings and treatment for psoriasis.

HISTORY

It is useful to determine the age at onset and the presence or absence of a family history of psoriasis, as younger age of onset and positive family history have been associated with more widespread and recurrent disease.[6,21] In addition, the physician should inquire about the prior course of the disease, as major differences exist between "acute" and "chronic" disease. In the latter form, lesions may persist unchanged for months or even years, whereas acute disease shows sudden outbreak of lesions within a short time (days). Likewise, patients have great variability in regard to relapses. Some patients have frequent relapses occurring weekly or monthly, whereas others have more stable disease with only occasional recurrence. The frequently relapsing patients tend to develop more severe disease with rapidly enlarging lesions covering significant portions of the body surface[296] and may require more rigorous treatment compared to those with more stable disease. Certain medications may worsen psoriasis (see Section "Treatment"). The physician should also inquire about joint complaints. Although osteoarthritis is extremely common and can coexist with psoriasis, a history of onset of joint symptoms before the fourth decade and/or a history of warm, swollen joints should raise the suspicion of psoriatic arthritis (see Chapter 19).

CUTANEOUS LESIONS[297]

The classic lesion of psoriasis is a well-demarcated, raised, red plaque with a white scaly surface (Fig. 18-7). Lesions can vary in size from pinpoint papules to plaques that cover large areas of the body. Under the scale, the skin has a glossy homogeneous erythema, and bleeding points appear when the scale is removed, traumatizing the dilated capillaries below (the Auspitz sign) (Fig. 18-8).[297] Psoriasis tends to be a symmetric eruption, and symmetry is a helpful feature in establishing a diagnosis. Unilateral involvement can occur, however. The psoriatic phenotype may present a changing spectrum of disease expression even within the same patient.

Koebner phenomenon (also known as the *isomorphic response*) is the traumatic induction of psoriasis on nonlesional skin; it occurs more frequently during flares of disease and is an all-or-none phenomenon (i.e., if psoriasis occurs at one site of injury it will occur at all sites of injury) (Fig. 18-9). The Koebner reaction usually occurs 7–14 days after injury, and approximately 25% of patients may have a history of trauma-related Koebner phenomenon at some point in their lives.[298] Estimates of lifetime prevalence rise as high as 76% when factors such as infection, emotional stress, and drug reactions are included.[4] The Koebner phenomenon is not specific for psoriasis but can be helpful in making the diagnosis when present.

CLINICAL PATTERNS OF SKIN PRESENTATION[297]

PSORIASIS VULGARIS, CHRONIC STATIONARY PSORIASIS, PLAQUE-TYPE PSORIASIS.

Psoriasis vulgaris is the most common form of psoriasis, seen in approximately 90% of patients. Red, scaly, symmetrically distributed plaques are characteristically localized to the extensor aspects of the extremities, particularly the elbows and knees, along with scalp, lower lumbosacral, buttocks, and genital involvement (see Fig. 18-7). Other sites of predilection include the umbilicus and the intergluteal cleft. The extent of involvement varies widely from patient to patient. There is constant production of large amounts of scale with little alteration in shape or distribution of individual plaques. Single small lesions may become confluent, forming plaques in which the borders resemble a land map (psoriasis geographica). Lesions may extend laterally and become circinate because of the confluence of several plaques (psoriasis gyrata). Occasionally, there is partial central clearing, resulting in ring-like lesions (annular psoriasis) (Fig. 18-10). This is usually associated with lesional clearing and portends a good prognosis. Other clinical variants of plaque psoriasis have been described depending on the morphology of

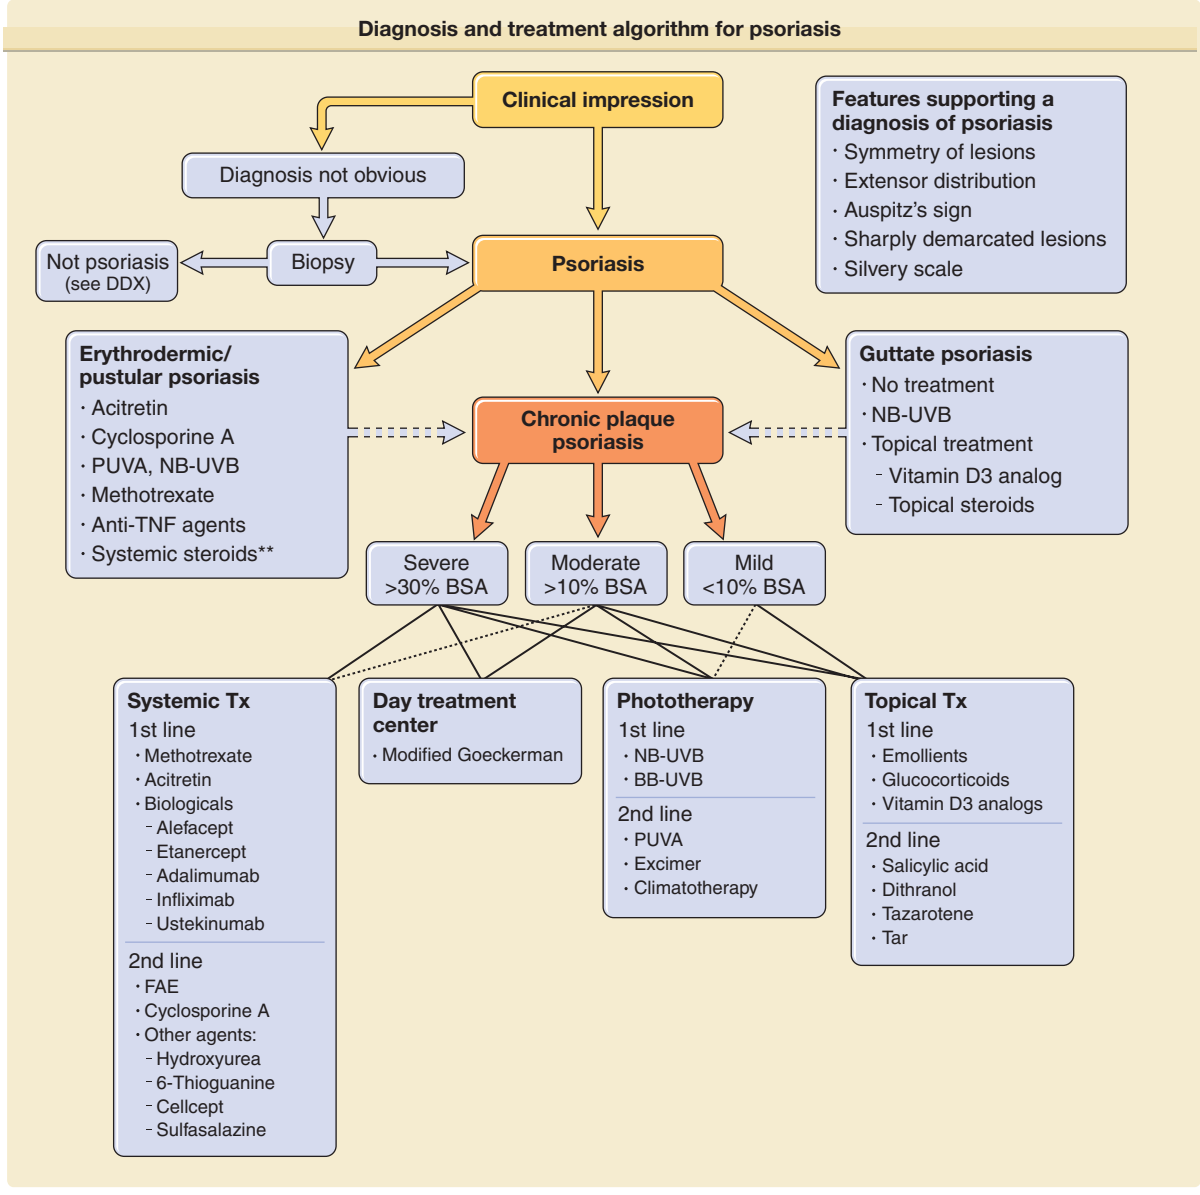

Figure 18-6 Diagnosis and treatment algorithm for psoriasis. The diagnosis of psoriasis is usually based on clinical features. In those few cases in which clinical history and examination is not diagnostic, biopsy is indicated to establish the correct diagnosis. The majority of psoriasis cases fall into three major categories: guttate, erythrodermic/pustular, and chronic plaque, of which the latter is by far the most common. Guttate psoriasis is often a self-limited disease with spontaneous resolution within 6–12 weeks. In mild cases of guttate psoriasis, treatment may not be needed, but, with widespread disease, ultraviolet B (UVB) phototherapy or narrowband UVB in association with topical therapy is very effective. Erythrodermic/pustular psoriasis is often associated with systemic symptoms and necessitates treatment with fast-acting systemic medications. The most commonly used drug for erythrodermic and pustular psoriasis is acitretin. In occasional cases of pustular psoriasis, systemic steroids may be indicated (**). *Dotted arrows* indicate that guttate, erythrodermic, and pustular forms often evolve into chronic plaque psoriasis. Therapeutic choices for chronic plaque psoriasis are typically based on the extent of the disease. Among the main treatment regimens (topical treatment, phototherapy, day treatment centers, and systemic treatments), first-line and second-line modalities are indicated by the *solid* and *dashed lines*, respectively. Individuals with conditions that limit their activities, including painful palmoplantar involvement and psoriatic arthritis, may require more potent treatments irrespective of the extent of affected body surface area. Likewise, psychological issues and the impact on quality of life should be taken into consideration. Within each treatment regimen, first-line and second-line choices are grouped. Cyclosporin A is not considered a first-line long-term systemic treatment due to its side effects, but short-term treatment can be helpful for induction of remission. If patients have incomplete response to or are unable to tolerate individual first-line systemic medications, combination regimens (Table 18-6), rotational treatments, or use of biologic therapies should be considered. BB-UVB = broadband UVB; BSA = body surface area; DDx = differential diagnosis; FAE = fumaric acid ester; NB-UVB = narrowband UVB; PUVA = psoralen, and UVA light; tx = therapy.

Figure 18-7 A–F. Chronic plaque psoriasis located at typical sites. Note marked symmetry of lesions. (Photos used with permission from Dr. Johann Gudjonsson and Mr. Harrold Carter.)

the lesions; particularly those associated with gross hyperkeratosis (see Fig. 18-10). *Rupioid psoriasis* refers to lesions in the shape of a cone or limpet. *Ostraceous psoriasis*, an infrequently used term, refers to a ring-like, hyperkeratotic concave lesion, resembling an oyster shell. Finally, elephantine psoriasis is an uncommon form characterized by thickly scaling, large plaques, usually on the lower extremities. A hypopigmented ring (Woronoff ring) surrounding individual psoriatic lesions may occasionally be seen and is usually associated with treatment, most commonly UV radiation or topical corticosteroids (see Fig. 18-10C). The pathogenesis is not well understood but may result from inhibition of prostaglandin synthesis.[299]

(Photo used with permission from Mr. Harrold Carter.) **B.** Flare of psoriasis on the back after a sunburn. Note sparing of sun-protected areas. (Photo used with permission from Dr. James Rasmussen.)

GUTTATE (ERUPTIVE) PSORIASIS. Guttate psoriasis (from the Latin *gutta*, meaning "a drop") is characterized by eruption of small (0.5–1.5 cm in diameter) papules over the upper trunk and proximal extremities (Fig. 18-11). It typically manifests at an early age and as such is found frequently in young adults. This form of psoriasis has the strongest association to HLA-Cw6,[26] and streptococcal throat infection frequently precedes or is concomitant with the onset or flare of guttate psoriasis.[300] However, antibiotic treatment has not been shown to be beneficial or to shorten the disease course.[301] Patients with a history of chronic plaque psoriasis may develop guttate lesions, with or without worsening of their chronic plaques.

SMALL PLAQUE PSORIASIS. Small plaque psoriasis resembles guttate psoriasis clinically, but can be distinguished by its onset in older patients, by its chronicity, and by having somewhat larger lesions (typically 1–2 cm) that are thicker and scalier than in guttate disease. It is said to be a common adult-onset presentation of psoriasis in Korea and other Asian countries.[141]

INVERSE (FLEXURAL) PSORIASIS. Psoriasis lesions may be localized in the major skin folds, such as the axillae, the genito-crural region, and the neck. Scaling is usually minimal or absent, and the lesions show a glossy sharply demarcated erythema, which is often localized to areas of skin-to-skin contact (Fig. 18-12). Sweating is impaired in affected areas.[302]

ERYTHRODERMIC PSORIASIS. (See also Chapter 23). Psoriatic erythroderma represents the generalized form of the disease that affects all body sites, including the face, hands, feet, nails, trunk, and extremities (Fig. 18-13). Although all the symptoms of psoriasis are present, erythema is the most prominent feature, and scaling is different compared with chronic stationary psoriasis. Instead of thick, adherent, white scale there is superficial scaling. Patients with erythrodermic psoriasis lose excessive heat because of generalized vasodilatation, and this may cause hypothermia. Patients may shiver in an attempt to raise their body temperature. Psoriatic skin is often hypohidrotic due to occlusion of the sweat ducts,[303] and there is an attendant risk of hyperthermia in warm climates. Lower extremity edema is common secondary to vasodilatation and loss of protein from the blood vessels into the tissues. High-output cardiac failure and impaired hepatic and renal function may also occur. Psoriatic erythroderma has a variable presentation, but two forms are thought to exist.[304] In the first form, chronic plaque psoriasis may worsen to involve most or all of the skin surface, and patients remain relatively responsive to therapy. In the second form, generalized erythroderma may present suddenly and unexpectedly or result from nontolerated external treatment (e.g., UVB, anthralin), thus representing a generalized Koebner reaction. Generalized pustular psoriasis [see Section "Generalized Pustular Psoriasis (von Zumbusch)"] may revert to erythroderma with diminished or absent pustule formation. Occasional diagnostic problems may arise in differentiating psoriatic erythroderma from other causes (see Chapter 23).

PUSTULAR PSORIASIS. Several clinical variants of pustular psoriasis exist: generalized pustular psoriasis (von Zumbusch type), annular pustular psoriasis, impetigo herpetiformis, and two variants of localized pustular psoriasis—(1) pustulosis palmaris et plantaris and (2) acrodermatitis continua of Hallopeau. In children, pustular psoriasis can be complicated by sterile, lytic lesions of bones[305,306] and can be a manifestation of the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis).[307]

Generalized Pustular Psoriasis (von Zumbusch). Generalized pustular psoriasis (von Zumbusch)

Figure 18-10 Unusual forms of plaque-type psoriasis **A.** Annular psoriasis on the flank. **B.** Rupioid psoriasis in an infant. Note cone-shaped lesions. **C.** Psoriatic patient undergoing modified Goeckerman therapy (ultraviolet B light, coal tar, and topical steroid), demonstrating Woronoff rings. **D.** Elephantine psoriasis of the lower extremities. Figure 18-12 Flexural psoriasis. Note the well-demarcated, beefy-red, shiny plaques in **A**. The infant in **B** is suffering from "napkin psoriasis." (Photos used with permission from Dr. Johann Gudjonsson and Mr. Harrold Carter.)

is a distinctive acute variant of psoriasis. It is usually preceded by other forms of the disease. Attacks are characterized by fever that lasts several days and a sudden generalized eruption of sterile pustules 2–3 mm in diameter (Fig. 18-14). The pustules are disseminated over the trunk and extremities, including the nail beds, palms, and soles. The pustules usually arise on highly erythematous skin, first as patches (Fig. 18-14C) and then becoming confluent as the disease becomes more severe. With prolonged disease, the fingertips may become atrophic. The erythema that surrounds the pustules often spreads and becomes confluent, leading to erythroderma. Characteristically, the disease occurs in waves of fevers and pustules. The

Figure 18-13 Erythrodermic psoriasis. The patient shown in panel **A** rapidly developed near-complete involvement and complained of fatigue and malaise. Note islands of sparing. Figure 18-14 Pustular psoriasis. **A** and **B**, von Zumbusch-type generalized pustular psoriasis. Note tiny pustules, 1–2 mm in diameter, on erythematous skin. **C** and **D**, localized pustular psoriasis of the leg and foot, respectively. **E**, resolving pustular psoriasis, note extensive areas of desquamation. (Photos **C**–**E** used with permission from Drs. Johann Gudjonsson, Trilokraj Tejasvi, and Neena Khanna.)

etiology of generalized psoriasis von Zumbusch type is unknown. Various provoking agents include infections, irritating topical treatment (Koebner phenomenon), and withdrawal of oral corticosteroids.[308] This form of psoriasis is usually associated with prominent systemic signs and can potentially have life-threatening complications such as hypocalcemia,[309] bacterial superinfection, sepsis, and dehydration.[310] Severe pustular psoriasis can be difficult to control and requires a potent treatment regimen with rapid onset of action to avoid life-threatening complications. Drugs commonly used include etretinate, methotrexate (MTX), cyclosporine, infliximab,[311,312] or oral corticosteroids (see Section "Treatment").[313] Cases of acute respiratory distress syndrome associated with generalized pustular psoriasis have been reported.[314] Two recent reports have identified recessive loss-of function mutations in the *IL36RN* gene encoding IL-36 receptor antagonist (IL-36ra) in patients with generalized pustular psoriasis. Consistent with the prominent inflammation associated with generalized pustular psoriasis, IL-36ra is an anti-inflammatory cytokine that inhibits signaling by three related IL-1 like proteins (IL-36alpha, beta, and gamma).[315,316]

Exanthematic Pustular Psoriasis. Exanthematic pustular psoriasis tends to occur after a viral infection and consists of widespread pustules with generalized plaque psoriasis. However, unlike the von Zumbusch pattern, there are no constitutional symptoms, and the disorder tends not to recur.[297] There is an overlap between

this form of pustular psoriasis and acute generalized exanthematous pustulosis, a type of drug eruption.

Annular Pustular Psoriasis. Annular pustular psoriasis is a rare variant of pustular psoriasis. It usually presents in an annular or circinate form. Lesions may appear at the onset of pustular psoriasis, with a tendency to spread and form enlarged rings, or they may develop during the course of generalized pustular psoriasis. The characteristic features are pustules on a ring-like erythema that sometimes resembles erythema annulare centrifugum. Identical lesions are found in patients with impetigo herpetiformis, an entity defined by some as a variant of pustular psoriasis occurring in pregnancy.[317] Onset in pregnancy is usually early in the third trimester and persists until delivery.[318] It tends to develop earlier in subsequent pregnancies. Impetigo herpetiformis is often associated with hypocalcemia.[309,319] There is usually no personal or family history of psoriasis.[320]

Localized Pustular Psoriasis Variants. Localized pustular psoriasis variants, including pustulosis palmaris et plantaris and acrodermatitis continua (of Hallopeau), are discussed in Chapter 21.

SEBOPSORIASIS. A common clinical entity, sebopsoriasis presents with erythematous plaques with greasy scales localized to seborrheic areas (scalp, glabella, nasolabial folds, perioral and presternal areas, and intertriginous areas). In the absence of typical findings of psoriasis elsewhere, distinction from seborrheic dermatitis is difficult. Sebopsoriasis may represent a modification of seborrheic dermatitis by the genetic background of psoriasis and is relatively resistant to treatment. Although an etiologic role of *Pityrosporum* remains unproven, antifungal agents may be useful.[321]

NAPKIN PSORIASIS. Napkin psoriasis usually begins between the ages of 3 and 6 months and first appears in the diaper (napkin) areas as a confluent red area (see Fig. 18-12B) with appearance a few days later of small red papules on the trunk that may also involve the limbs. These papules have the typical white scales of psoriasis. The face may also be involved with red scaly eruption. Unlike other forms of psoriasis, the rash responds readily to treatment and tends to disappear after the age of 1 year.

LINEAR PSORIASIS. Linear psoriasis is a very rare form. The psoriatic lesion presents as linear lesion most commonly on the limbs but may also be limited to a dermatome on the trunk. This may be an underlying nevus, possibly an inflammatory linear verrucous epidermal nevus (ILVEN), as these lesions resemble linear psoriasis both clinically and histologically. The existence of a linear form of psoriasis distinct from ILVEN is controversial.[322]

RELATED PHYSICAL FINDINGS

NAIL CHANGES IN PSORIASIS. (See also Chapter 89). Nail changes are frequent in psoriasis, being found in up to 40% of patients,[21] and are rare in the absence of skin disease elsewhere. Nail involvement increases with age, with duration and extent of disease, and with the presence of psoriatic arthritis. Several distinct changes have been described and can be grouped according to the portion of the nail that is affected (Table 18-2).[323]

TABLE 18-2
Nail Changes in Psoriasis

Nail Segment Involved	Clinical Sign
Proximal matrix	Pitting, onychorrhexis, Beau lines
Intermediate matrix	Leukonychia
Distal matrix	Focal onycholysis, thinned nail plate, erythema of the lunula
Nail bed	"Oil drop" sign or "salmon patch," subungual hyperkeratosis, onycholysis, splinter hemorrhages
Hyponychium	Subungual hyperkeratosis, onycholysis
Nail plate	Crumbling and destruction plus other changes secondary to the specific site
Proximal and lateral nail folds	Cutaneous psoriasis

Modified from Del Rosso JQ et al: Dermatologic diseases of the nail unit. In: *Nails: Therapy, Diagnosis, Surgery*, edited by RK Scher, CR Daniel. Philadelphia, W.B., Saunders, 1997, p. 172, with permission.

Nail pitting is one of the commonest features of psoriasis, involving the fingers more often than the toes (Fig. 18-15). Pits range from 0.5 to 2.0 mm in size and can be single or multiple. The proximal nail matrix forms the dorsal (superficial) portion of the nail plate, and psoriatic involvement of this region results in pitting due to defective keratinization. Other alterations in the nail matrix resulting in deformity of the nail plate (onychodystrophy) include leukonychia, crumbling nail, and red spots in the lunula. Onychodystrophy has a stronger association with psoriatic arthritis than other nail changes.[21] Oil spots and salmon patches are translucent, yellow–red discolorations observed beneath the nail plate often extending distally toward the hyponychium, due to psoriasiform hyperplasia, parakeratosis, microvascular changes, and trapping of neutrophils in the nail bed.[324,325] Unlike pitting, which is also seen in alopecia areata and other disorders, oil spotting is considered to be nearly specific for psoriasis. Splinter hemorrhages result from capillary bleeding underneath the thin suprapapillary plate of the psoriatic nail bed. Subungual hyperkeratosis is due to hyperkeratosis of the nail bed and is often accompanied by onycholysis (separation of the nail plate from the nail bed), which usually involves the distal aspect of the nail. Anonychia is total loss of the nail plate. Although nail changes are rarely seen in the localized pustular variant of pustulosis palmaris et plantaris,

Figure 18-15 Nail psoriasis. Panel **A** demonstrates distal onycholysis and oil drop spotting. Panel **B** demonstrates nail pitting. Panel **C** demonstrates subungual hyperkeratosis. Panel **D** demonstrates onychodystrophy and loss of nails in a patient with psoriatic arthritis. (Photos used with permission from Drs. Johann Gudjonsson and Allen Bruce, and Mr. Harrold Carter.)

anonychia can be seen in other forms of pustular psoriasis.

GEOGRAPHIC TONGUE. (See also Chapter 76). Geographic tongue, also known as *benign migratory glossitis* or *glossitis areata migrans*, is an idiopathic inflammatory disorder resulting in the local loss of filiform papillae. The condition usually presents as asymptomatic erythematous patches with serpiginous borders, resembling a map. These lesions characteristically have a migratory nature. Geographic tongue has been postulated to be an oral variant of psoriasis, as these lesions show several histologic features of psoriasis, including acanthosis, clubbing of the rete ridges, focal parakeratosis, and neutrophilic infiltrate. In addition, the prevalence of geographic tongue is increased in psoriatic patients.[326] However, geographic tongue is a relatively common condition and is seen in many nonpsoriatic individuals, so its relationship to psoriasis needs further clarification.

PSORIATIC ARTHRITIS. Arthritis is a common extracutaneous manifestation of psoriasis seen in up to 40% of patients. It has a strong genetic component, and several overlapping subtypes exist. This condition is discussed in Chapter 19.

LABORATORY TESTS

Although histopathologic examination is rarely necessary to make the diagnosis, it can be helpful in difficult cases. The histopathologic findings of guttate and chronic plaque psoriasis have already been described (see Section "Development of Lesions"). In early lesions of pustular psoriasis, the epidermis is usually only slightly acanthotic, whereas psoriasiform hyperplasia is seen in older and persistent lesions. Neutrophils migrate from dilated vessels in the upper dermis into the epidermis where they aggregate beneath the stratum corneum and in the upper Malpighian layer to form the spongiform pustules of Kogoj.

Other laboratory abnormalities in psoriasis are usually not specific and may not be found in all patients. In severe psoriasis vulgaris, generalized pustular psoriasis, and erythroderma, a negative nitrogen balance can be detected, manifested by a decrease of serum albumin.[327]

Psoriasis patients manifest altered lipid profiles, even at the onset of their skin disease.[328] Patients had 15% higher levels of high-density lipoproteins, and their cholesterol–triglyceride ratio for very low-density lipoprotein particles was 19% higher. Furthermore, plasma apolipoprotein-A1 concentrations were

11% higher in psoriasis patients. Whether these differences in lipid profile can explain or are contributing to an increased incidence of cardiovascular events in psoriasis remains to be seen.

Serum uric acid is elevated in up to 50% of patients and is mainly correlated with the extent of lesions and the activity of disease. There is an increased risk of developing gouty arthritis. Serum uric acid levels usually normalize after therapy.

Markers of systemic inflammation can be increased, including C-reactive protein, α_2-macroglobulin, and erythrocyte sedimentation rate. However, such elevations are rare in chronic plaque psoriasis uncomplicated by arthritis. Increased serum immunoglobulin (Ig) A levels and IgA immune complexes, as well as secondary amyloidosis, have also been observed in psoriasis, and the latter carries a poor prognosis.[329]

SPECIAL TESTS

Immunostaining techniques, fluorescence-activated cell sorting of dissociated cell suspensions, and assessment of T-cell receptor gene rearrangements have been of major importance in elucidating the pathogenesis of psoriasis and in characterizing the response to antipsoriatic therapies but are generally not required for diagnosis or management.

DIFFERENTIAL DIAGNOSIS

(Box 18-1)

COMPLICATIONS

Patients with psoriasis have an increased morbidity and mortality from cardiovascular events, particularly those with severe and long duration of psoriasis skin disease.[330,331] Risk of myocardial infarction is particularly elevated in younger patients with severe psoriasis.[289] In a recent study of 1.3 million German health care recipients, metabolic syndrome was 2.9-fold more frequent among psoriatic patients, and the most common diagnoses were hypertension (35.6% in psoriasis vs. 20.6% in controls) and hyperlipidemia (29.9% vs. 17.1%). The frequencies of rheumatoid arthritis

BOX 18-1 DIFFERENTIAL DIAGNOSIS OF PSORIASIS

PSORIASIS VULGARIS

Most Likely
- Discoid/nummular eczema
- Cutaneous T-cell lymphoma (CTCL)
- Tinea corporis

Consider
- Pityriasis rubra pilaris
- Seborrheic dermatitis
- Subacute cutaneous lupus erythematosus
- Erythrokeratoderma (the fixed plaques of keratoderma variabilis and/or progressive symmetric erythrokeratoderma)
- Inflammatory linear verrucous epidermal nevus
- Hypertrophic lichen planus
- Lichen simplex chronicus
- Contact dermatitis
- Chronic cutaneous lupus erythematosus/discoid lupus erythematosus
- Hailey–Hailey disease (flexural)
- Intertrigo (flexural)
- *Candida* infection (flexural)

Always Rule Out
- Bowen's disease/squamous cell carcinoma *in situ*
- Extramammary Paget's disease

GUTTATE

Most Likely
- Pityriasis rosea
- Pityriasis lichenoides chronica
- Lichen planus

Consider
- Small plaque parapsoriasis
- PLEVA
- Lichen planus
- Drug eruption

Always Rule Out
- Secondary syphilis

ERYTHRODERMIC

Most Likely
- Drug-induced erythroderma
- Eczema
- CTCL/Sézary syndrome
- Pityriasis rubra pilaris

PUSTULAR

Most Likely
- Impetigo
- Superficial candidiasis
- Reactive arthritis syndrome
- Superficial folliculitis

Consider
- Pemphigus foliaceus
- Immunoglobulin A pemphigus
- Sneddon–Wilkinson disease (subcorneal pustular dermatosis)
- Migratory necrolytic erythema
- Transient neonatal pustular melanosis
- Acropustulosis of infancy
- Acute generalized exanthematous pustulosis

[prevalence ratio (PR) 3.8], Crohn's disease (PR 2.1), and ulcerative colitis (PR 2.0) were also increased.[2] Psoriasis remained associated with after controlling for age, sex, smoking status, obesity, diabetes, and NSAID use.[332] Psoriasis patients have also been shown to have increased relative risk of both Hodgkin lymphoma and cutaneous T-cell lymphoma, especially in patients with more severe disease.[333]

Psoriasis is emotionally disabling, carrying with it significant psychosocial difficulties. Emotional difficulties arise from concerns about appearance, resulting in lowered self-esteem, social rejection, guilt, embarrassment, emptiness, sexual problems, and impairment of professional ability.[334] The presence of pruritus and pain can aggravate these symptoms. Psychological aspects can modify the course of illness; in particular, feeling stigmatized can lead to treatment noncompliance and worsening of psoriasis.[335] Likewise, psychological stress can also lead to depression and anxiety.[336] The prevalence of suicidal ideation and depression in patients with psoriasis is higher than that reported in other medical conditions and the general population.[337] Thus, although the disease is not threatening to life itself, psoriasis can very significantly impair quality of life.[338] A comparative study reported reduction in physical and mental functioning comparable with that seen in cancer, arthritis, hypertension, heart disease, diabetes, and depression.[339] According to a recent survey, 79% of patients with severe psoriasis reported a negative impact on their lives.[340]

PROGNOSIS AND CLINICAL COURSE

NATURAL HISTORY[297]

Guttate psoriasis is often a self-limited disease, lasting from 12 to 16 weeks without treatment.[297] It has been estimated that one-third to two-thirds of these patients later develop the chronic plaque type of psoriasis.[5,234] In contrast, chronic plaque psoriasis is in most cases a lifelong disease, manifesting at unpredictable intervals. Spontaneous remissions, lasting for variable periods of time, may occur in the course of psoriasis in up to 50% of patients. The duration of remission ranges from 1 year to several decades. In two separate studies, remission ranged from 17% to 55%. In another study of patients followed for 21 years, 71% had persistent lesions, 13% were free of the disease, and 16% had intermittent lesions.[297] The cause of spontaneous remission is unknown, but could reflect successful generation of self-tolerance under the model of immunologic self-reactivity discussed earlier (see Section "Psoriasis as an Autoimmune Disease").

Erythrodermic and generalized pustular psoriasis have a poorer prognosis, with the disease tending to be severe and persistent.[297]

MODIFYING FACTORS

OBESITY. It has been demonstrated that obese individuals are more likely to present with severe psoriasis (defined as >20% body surface area involvement).[341] However, obesity does not appear to have a role in defining the onset of psoriasis.[341]

SMOKING. Smoking (more than 20 cigarettes daily) has also been associated with more than a twofold increased risk of severe psoriasis.[342] Unlike obesity, smoking appears to have a role in the onset of psoriasis.[341] Recently, a gene–environment interaction has been identified between low activity of the cytochrome P_{450} gene *CYP1A1* and smoking in psoriasis.[343]

INFECTION. An association between streptococcal throat infection and guttate psoriasis has been repeatedly confirmed.[300,343] Streptococcal throat infections have also been demonstrated to exacerbate preexisting chronic plaque psoriasis.[227]

Severe exacerbation of psoriasis can be a manifestation of human immunodeficiency virus (HIV) infection.[345] Like psoriasis in general, HIV-associated psoriasis has a strong association with HLA-Cw6.[345] Interestingly, the prevalence of psoriasis in HIV infection is no higher than in the general population (1%–2% of patients),[346,347] indicating that this infection is not a trigger for psoriasis but rather a modifying agent. Psoriasis is increasingly more severe with progression of immunodeficiency but can remit in the terminal phase.[348,349] This paradoxical exacerbation of psoriasis may be due to loss of regulatory T cells and increased activity of the CD8 T-cell subset.[300] Psoriasis exacerbation in HIV disease may be effectively treated with antiretroviral therapy.[350] Psoriasis has also been associated with hepatitis C infection.[351]

DRUGS. Medications that exacerbate psoriasis include antimalarials, β blockers, lithium, nonsteroidal anti-inflammatory drugs, IFNs-α and -γ, imiquimod, angiotensin-converting enzyme inhibitors, and gemfibrozil.[352] Imiquimod acts on pDCs and stimulates IFN-α production,[147] which then strengthens both innate and Th1 immune responses. Exacerbations and onset of psoriasis have been described in patients receiving TNF inhibitor therapy. The majority of these cases are palmoplantar pustulosis, but about one-third develop chronic plaque psoriasis.[353] Lithium has been proposed to cause exacerbation by interfering with calcium release within keratinocytes, whereas β blockers are thought to interfere with intracellular cyclic adenosine monophosphate levels.[352] The mechanisms by which the remaining medications exacerbate psoriasis are largely unknown. Patients with active or unstable psoriasis should receive advice when traveling to countries where antimalarial prophylaxis is needed.

TREATMENT

GENERAL CONSIDERATIONS

A broad spectrum of antipsoriatic treatments, both topical and systemic, is available for the management of psoriasis. As detailed in Tables 18-3–18-6, it

TABLE 18-3
Topical Treatments for Psoriasis[359]

	Topical Steroids	Vitamin D Analogs	Tazarotene	Calcineurin Inhibitors
Mechanism of action	Bind to glucocorticoid receptors, inhibiting the transcription of many different AP-1- and NF-κB-dependent genes, including IL-1 and TNF-α.	Bind to vitamin D receptors, influencing the expression of many genes. Promote keratinocyte differentiation.	Metabolized to tazarotenic acid, its active metabolite,[361] which binds to retinoic acid receptors. Normalizes epidermal differentiation, exhibits a potent antiproliferative effect, and decreases epidermal proliferation.	Bind to FK506-binding protein (FKBP) and inhibit calcineurin, decreasing the activation of the transcription factor, NF-AT, with resultant decrease in cytokine transcription, including IL-2.
Dosing	10,000-fold range of potency. High-potency steroids are applied to affected areas twice daily for 2–4 weeks and then intermittently (weekends).	Calcipotriene, 0.005%, to affected areas twice daily. Often used alternating with topical steroids (i.e., vitamin D analogs on weekdays, topical steroids on weekends).	Available in 0.05% and 0.1% formulations, both as cream and gels. Apply every night to affected area.	Application to affected areas twice daily.
Efficacy	Very effective as short-term treatment.	Efficacy is increased by combination with topical steroids. Can be combined with various other therapies.	Efficacy is increased by combination with topical steroids.[361]	Effective for treatment of facial and flexural psoriasis[269] but minimally for chronic plaque psoriasis.[268]
Safety	Suppression of the hypothalamic–pituitary–adrenal axis (higher risk in children). Atrophy of the epidermis and dermis. Formation of striae. Tachyphylaxis.[258]	Development of irritation at the site of application is common.[258] Isolated reports of hypercalcemia in patients who applied excessive quantities.[363]	When used as monotherapy, significant proportion of patients develop irritation at the site of application.[364]	Burning sensation at the site of application. Case reports of development of lymphoma.
Contraindications	Hypersensitivity to the steroid, active skin infection.	Hypercalcemia, vitamin D toxicity.	Pregnancy, hypersensitivity to tazarotene.	Use only with caution for treatment of children younger than the age of 2 years.
Remarks/long-term use	Long-term use increases risk of side effects.	Calcipotriol is well tolerated and continues to be clinically effective with minimum of adverse effects in long-term use.[365,366]	Combination of steroid with tazarotene may reduce atrophy seen with superpotent topical steroids.[362] If added during phototherapy, the ultraviolet doses should be reduced by one-third.[258]	Due to anecdotal reports of association with malignancy, this class of medications recently received a black-box warning by the US Food and Drug Administration.
Pregnancy category	C	C	X	C

AP = activator protein; IL = interleukin; NF = nuclear factor; NF-AT = nuclear factor of activated T cells.

is notable that most if not all of these treatments are immunomodulatory. When choosing a treatment regimen (see Fig. 18-6) it is important to reconcile the extent and the measurable severity of the disease with the patient's own perception of his or her disease. In this context, it is notable that a recent study found that 40% of patients felt frustrated with the ineffectiveness of their current therapies, and 32% reported that treatment was not aggressive enough.[350] As psoriasis is a chronic condition, it is important to know the safety

TABLE 18-4
Phototherapy of Psoriasis[385]

	Narrowband UVB (NB-UVB; 310–331 nm)	Broadband UVB (BB-UVB)	Psoralen and UVA Light (PUVA)	Excimer Laser (308 nm)
Dosing	Dosage based on either the Fitzpatrick skin type or MED. Determine MED. Initial treatment at 50% of MED followed by three to five treatments weekly. Lubricate before treatment. Treatments 1–20; increase by 10% of initial MED. Treatments ≥21; increase as ordered by physician.[385] Maintenance therapy after >95% clearance: 1×/week for 4 weeks, keep dose the same 1×/2 weeks for 2 weeks, decrease dose by 25% 1×/4 weeks, 50% of highest dose.[385]	The dosage may be administered according to the Fitzpatrick skin type.[437] Initial treatment at 50% of MED followed by three to five treatments weekly. Treatment 1–10 increase dose by 25% of initial MED. Treatments 11–20; increase by 10% of initial MED. Treatments ≥21; increase as ordered by physician.[385]	Dose based on MPD is recommended. If MPD testing is impractical, a regimen based on skin type may be used. Initial dose 0.5–2.0 J/cm^2, depending on skin type (or MPD). Treat twice weekly, increments of 40% per week until erythema, then maximum 20% per week. No further increments once 15 J/cm^2 is reached.[369]	The dose of energy delivered is guided by the patient's skin type and thickness of plaque. Further doses are adjusted based on response to treatment or development of side effects.[385] Treatment usually given twice weekly.
Efficacy	>70% improvement in a split body study after 4 weeks of treatment. Nine out of eleven patients showed clearance.[368] More effective than BB-UVB.[274,275,368]	47% improvement in a split body study after 4 weeks, only 1 out of 11 patients showed clearance.[367]	Induces remission in 70%–90% of patients.[370–373] Less convenient than NB-UVB but may be more effective.[278]	High response rates. In one study, 85% of patients showed a ≥90% improvement in PASI after average 7.2 weeks of treatment[438] While in another study showed greater than 75% improvement in 72% of patients in an average of 6.2 treatments.[439]
Safety	Photodamage, polymorphic light eruption, increased risk of skin aging and skin cancers although lower than that for PUVA.[374]	Photodamage, polymorphic light eruption, increased risk of skin aging and skin cancers.	Photodamage, premature skin aging, increased risk of melanoma and nonmelanoma skin cancers, ocular damage. Eye protection required with oral psoralens.	Erythema, blisters, hyperpigmentation and erosions. Long-term side effects not yet clear but likely similar to NB-UVB.
Contraindications	Absolute: ■ Photosensitivity disorders. Relative: ■ Photosensitizing medications, melanoma, and nonmelanoma skin cancers.	Absolute: ■ Photosensitivity disorders. Relative: ■ Photosensitizing medications, melanoma, and nonmelanoma skin cancers.	Absolute: ■ Light-sensitizing disorder, lactation, melanoma. Relative: ■ Age <10 years, pregnancy, photosensitizing medications, nonmelanoma skin cancers, severe organ dysfunction.	Absolute: ■ Photosensitivity disorders. Relative: ■ Photosensitizing medications, melanoma, and nonmelanoma skin cancers.
Remarks	Effective as a monotherapy, but coal tar (Goeckerman regimen), anthralin (Ingram regimen), or systemic therapies may increase effectiveness in resistant cases.[367]	Coal tar (Goeckerman regimen), anthralin (Ingram regimen), or systemic therapies may increase effectiveness in resistant cases.	<200 total treatments (or <2000 J/cm^2 UVA) are recommended.[375] Combination with oral retinoids can reduce cumulative UVA exposure.	Normal skin is spared from unnecessary radiation exposure, as therapy is selectively directed toward lesional skin.[283]

MED = minimal erythema dose; MPD = minimal phototoxic dose; UVB = ultraviolet B; PASI = Psoriasis Area and Severity Index; UVA = ultraviolet A.

TABLE 18-5
Systemic Treatments for Psoriasis[390,398]

	Cyclosporine A	Methotrexate	Acitretin	Fumaric Acid Esters
Mechanism of action	Binds cyclophilin, and the resulting complex blocks calcineurin, reducing the effect of the NF-AT in T cells, resulting in inhibition of IL-2 and other cytokines.	Blocks dihydrofolate reductase, leading to inhibition of purine and pyrimidine synthesis. Also blocks AICAR transformylase, leading to accumulation of anti-inflammatory adenosine.[376]	Binds to retinoic acid receptors. May contribute to improvement by normalizing keratinization and proliferation of the epidermis.	Interferes with intracellular redox regulation, inhibiting NF-κB translocation. Skews the T-cell response toward a Th2-like pattern.[377]
Dosing	High-dose approach: ■ 5 mg/kg daily, then tapered. Low-dose approach: ■ 2.5 mg/kg daily, increased every 2–4 weeks up to 5 mg/kg daily.[378] Tapering is recommended on discontinuation.	Start with a test dose of 2.5 mg and then gradually increase dose until a therapeutic level is achieved (average range, 10–15 mg weekly; maximum, 25–30 mg weekly).[378]	Initiate at 25–50 mg daily and escalate and titrate to response.[378]	Initiate at low dose, and escalate dose weekly. After treatment response is achieved, the dose should be individually adjusted. The maximum dose is 1.2 g/day.[300]
Efficacy	Very effective, up to 90% of patients achieve clearance or marked improvement.[379,380]	May reduce the severity of psoriasis by at least 50% in more than 75% of patients.[261]	Modestly effective as monotherapy.[261]	80% Mean reduction in Psoriasis Area and Severity Index.[381]
Safety	Nephrotoxicity, HTN, immunosuppression. Increased risk of malignancy if before PUVA.	Hepatotoxicity, chronic use may lead to hepatic fibrosis. Fetal abnormalities or death, myelosuppression, pulmonary fibrosis, severe skin reactions. Rarely, severe opportunistic infections.	Hepatotoxicity, lipid abnormalities, fetal abnormalities or death, alopecia, mucocutaneous toxicity, hyperostosis.	GI symptoms, including diarrhea. Flushing ± headaches. Lymphopenia, acute renal failure.[300,381]
Monitoring	BP. Obtain baseline CBC, CMP, magnesium, uric acid, lipids, UA. Repeat tests every 2–4 weeks, then every month along with BP.[286]	Baseline CBC and LFTs. Monitor CBC and LFTs weekly until target dose is achieved, then every 4–8 weeks.[286] Liver biopsy every 1.5 g (high risk) to every 3.5–4.0 g (low risk) of cumulative dose or use procollagen III assay.	Baseline LFTs, CBC, lipids, pregnancy test. Repeat LFTs, CBC, lipids every week for 1 month then every 4 weeks. Pregnancy test every month for females. Spinal X-rays if symptoms.	Baseline CBC, CMP, UA. Repeat tests every month for the first 6 months and bimonthly thereafter.[300]
Contraindications	Absolute: ■ Uncontrolled HTN, abnormal renal function, history/current malignancy.	Absolute: ■ Pregnancy, lactation, bone marrow dysfunction, alcohol abuse.[390] Relative: ■ Hepatic dysfunction, hepatitis, renal insufficiency, severe infections, reduced lung function	Absolute: ■ Pregnancy during or within 3 years after termination of acitretin, breastfeeding.	Absolute: ■ Patients with chronic disease of the GI tract or renal disease. Pregnant or lactating women. Malignancy (or history of).[300]
Remarks/long-term use	Intermittent short-course treatments appear to be safer than chronic long-term use.[380,382]	With appropriate monitoring, long-term use appears to be safe.	Retinoids have been combined with PUVA and occasionally with UVB in an attempt to minimize the side effects and to improve therapeutic response.[261]	Not US Food and Drug Administration-approved for psoriasis but widely used in Europe. New formulations may reduce risk of GI symptoms.
Pregnancy category	C	X	X	C

(*continued*)

TABLE 18-5
Systemic Treatments for Psoriasis (Continued)

	Hydroxyurea	6-Thioguanine	Mycophenolate Mofetil	Sulfasalazine
Mechanism of action	Inhibits ribonucleotide diphosphate reductase, which converts ribonucleotides to deoxyribonucleotides, thus selectively inhibiting DNA synthesis in proliferating cells.	Purine analog that interferes with purine biosynthesis, thereby inducing cell cycle arrest and apoptosis.	A noncompetitive inhibitor of inosine monophosphate dehydrogenase, blocking *de novo* purine biosynthesis. Selectively cytotoxic for cells that rely on *de novo* purine synthesis (i.e., lymphocytes).	Anti-inflammatory agent, inhibits 5-lipoxygenase, molecular mechanism unclear.
Dosing	500 mg daily, increased to 1.0–1.5 g daily based on response and tolerance.[286]	Starting dose is 80 mg twice weekly, with 20-mg increments every 2–4 weeks. Maximum dose, 160 mg three times weekly.[286]	Doses often initiated at 500– 750 mg bid and then increased to 1.0–1.5 g bid.	Starting dose: 500 mg tid. If tolerated after 3 days, increase dose to 1 g tid. If tolerated after 6 weeks, increase dose to 1 g qid.[286]
Efficacy	In a study of 85 patients with extensive chronic plaque psoriasis, 61% had satisfactory remission.[383]	A small retrospective cohort study demonstrated >90% improvement in up to 80% of patients.[306]	Appears to be only moderately effective for treatment of psoriasis.[381,382]	Appears to be moderately effective treatment for severe psoriasis.[386]
Safety	Bone marrow suppression, macrocytosis. Teratogenicity and mutagenicity. Dermatologic side effects: lichen planus-like eruptions, exacerbation of postirradiation erythema, leg ulcers, and dermatomyositis changes.	Bone marrow suppression; GI complaints, including nausea and diarrhea; hepatic dysfunction. Instances of hepatovenous-occlusive disease have been reported.[306]	GI, including constipation, diarrhea, nausea and vomiting, bleeding. Myelosuppression, leukopenia. Headaches, HTN, peripheral edema. Infectious disease, lymphoma.	Headache, nausea, and vomiting, which occur in approximately one-third of patients. Rashes, pruritus, and hemolytic anemia (associated with G6PD deficiency).
Monitoring	Baseline CBC, CMP, LFTs. Repeat baseline tests weekly for 4 weeks then every 2–4 weeks for at least 12 weeks. Then repeat tests every 3 months.[286] Hold dosage if WBC $<2.5 \times 10^9$/L, platelet count is $<100 \times 10^9$/L or severe anemia.	Baseline CBC, CMP, LFTs. Repeat baseline tests weekly during dose escalation, then every 2 weeks. Hold if WBC $\leq 4.0 \times 10^9$/L, platelet count is $<125 \times 10^9$/L, or hemoglobin <110 g/L.[286]	Baseline CBC and CMP. Repeat laboratory tests weekly × 6 weeks, then every 2 weeks × 2 months, and then monthly. Monitor BP.	Baseline CBC, CMP, and G6PD. Repeat CBC and CMP weekly for 1 month, then every 2 weeks for 1 month, then monthly for 3 months, and then every 3 months.
Contraindi-cations	Absolute: ■ Prior bone marrow depression (leukopenia, thrombocytopenia, anemia), pregnancy, lactation. Relative: ■ Renal abnormalities.	Absolute: ■ Patients with inherited deficiency of thiopurine methyltransferase enzyme have increased risk of myelosuppression. Liver toxicity. Pregnancy.	Absolute: ■ Patients with severe infections, malignancy.[286]	Absolute: ■ Hypersensitivity to sulfasalazine, sulfa drugs, salicylates, intestinal or urinary obstruction, porphyria. Precaution in patients with G6PD deficiency.
Remarks/long-term use	Limited experience with long-term treatment.	Patients have been effectively maintained on treatment for up to 33 months.[387]	Limited experience with long-term treatment.	Limited experience with long-term treatment.
Pregnancy category	D	D	C	B

AICAR = 5-Aminoimidazole-4-carboxamide ribonucleotide; BP = blood pressure; CBC = complete blood cell count; CMP = comprehensive metabolic panel; G6PD = glucose-6-phosphate dehydrogenase; GI = gastrointestinal; HTN = hypertension; LFTs = liver function tests; NF = nuclear factor; NF-AT = nuclear factor of activated T cells; PUVA = psoralen and UVA light; Th = T helper; UA = urinalysis; UV = ultraviolet; WBC = white blood cell count.

TABLE 18-6
Combination Treatments for Psoriasis

	Topical Vitamin D3	Topical Cortico-steroids	Dithranol	Coal Tar	Tazarotene	Ultraviolet B (UVB)	Psoralen and UVA Light (PUVA)	Metho-trexate (MTX)	Cyclo-sporine A (CSA)
Etaner-cept[440,441]	+	+	±	±	+	++	±	+	±
Acitretin	++	+	+	+	+	++	++	–	±
CsA	++	+	+	+	+	±	–	±	
MTX	+	+	+	+	+	±	±		
PUVA	++	+	+	–	++	±			
UVB	+/++	+	+/++	+/++	++

Coal tar	+	+	+/++						
Dithranol	+	+							
Topical cortico-steroids	+/++								

– = contraindicated combination; ± = insufficient evidence; + = recommended combination; ++ = strongly recommended combination. Blank boxes are represented elsewhere in the table.
Reasons for contraindicated combinations: CsA with PUVA; increased risk of squamous cell carcinoma. Coal tar with PUVA, severe phototoxic responses. Acitretin with MTX, hepatotoxicity.
Adapted from van de Kerkhof PC: Therapeutic strategies: Rotational therapy and combinations. *Clin Exp Dermatol* **26**:356, 2001, with permission.

of a treatment during long-term use. In most treatments, the duration of a treatment is restricted because of the cumulative toxicity potential of an individual treatment, and, in some instances, treatment efficacy may diminish with time (tachyphylaxis). Some treatments, such as calcipotriol, MTX, and acitretin, can be regarded as appropriate for continuous use.[354] These treatments maintain efficacy and have low cumulative toxicity potential. In contrast, topical corticosteroids, dithranol, tar, photo(chemo) therapy, and cyclosporine are not indicated for continuous chronic use, and combinatorial or rotational treatments[354] are suggested. However, patients with stable chronic plaque psoriasis who respond well to local treatments may not require a change of treatment.[354] In cases of itchy/pruritic psoriasis, treatments with an irritative potential, such as dithranol, vitamin D_3 analogs, and photo(chemo) therapy, should be used cautiously, whereas treatments with potent anti-inflammatory effects, such as topical corticosteroids, are more appropriate.[354]

In patients with erythrodermic and pustular psoriasis, treatments with an irritant potential should be avoided, and acitretin, MTX, or short-course cyclosporine are the treatments of first choice.[354] See Boxes 18-2 and 18-3 for special considerations in the treatment of women of child-bearing potential and pregnancy and children.

TOPICAL TREATMENTS

(See Table 18-3.)[355,356]

Most cases of psoriasis are treated topically. As topical treatments are often cosmetically unacceptable and time-consuming to use, noncompliance is on the order of 40%.[357] In most cases, ointment formulations are more effective than creams but are less cosmetically acceptable. For many patients, it is worth prescribing both cream and ointment formulations; cream for use in the morning and ointment for nighttime.[358] Topical agents are also used adjunctively for resistant lesions in patients with more extensive psoriasis and who are concurrently being treated with either UV light or systemic agents.[359] It is worth noting that around 400 g of a topical agent is required to cover the entire body surface of an average-sized adult when used twice daily for 1 week.[360]

CORTICOSTEROIDS. Glucocorticoids exert many if not all of their myriad effects by stabilizing and causing nuclear translocation of glucocorticoid receptors, which are members of the nuclear hormone receptor superfamily. Topical glucocorticoids are commonly first-line therapy in mild to moderate psoriasis and in sites such as the flexures and genitalia, where other topical treatments can induce irritation. Improvement is usually achieved within 2–4 weeks, with maintenance treatment consisting of intermittent applications (often restricted to the weekends). Tachyphylaxis to treatment with topical corticosteroids is a well-established phenomenon in psoriasis.[361] Long-term topical corticosteroids may cause skin atrophy, telangiectasia, striae (Fig. 18-16D) and adrenal suppression.

BOX 18-2 TREATMENT OF WOMEN OF CHILD-BEARING POTENTIAL AND DURING PREGNANCY

- Special caution needs to be exercised when treating women of child-bearing potential and during pregnancy.
- Medications such as methotrexate and oral retinoids should be avoided or used with extreme caution and then only along with appropriate contraception.
- In selected cases, isotretinoin rather than acitretin may be the preferred agent due to its much shorter half-life.
- As methotrexate is fetotoxic and an abortifactant and retinoids are potent teratotoxins, the use of these agents is absolutely contraindicated in pregnancy.
- Many women experience improvement or remission during periods of pregnancy, thus decreasing the need for the more potent agents.
- If treatment is needed, emollients and other topical agents are first-line agents, often in association with ultraviolet B phototherapy.
- Many of the topical agents, such as topical steroids and calcipotriene, are pregnancy category C agents, and caution should be exercised with their use.
- Several of the biologic agents are category B and can be used in pregnancy. Likewise, cyclosporine A may be considered, as it is pregnancy category C and is nonteratogenic.
- Systemic psoralen and ultraviolet A light (PUVA) has been used on occasion in selected cases and appears to be safe.

BOX 18-3 TREATMENT OF CHILDREN

- Children represent a large fraction of psoriasis patients, as the disease commonly presents during childhood or adolescence.
- As for adults, first-line treatment is with topical agents, often in association with ultraviolet B phototherapy.
- Due to its carcinogenic risk and opportunity for long-term exposure, psoralen and ultraviolet A light is generally contraindicated in childhood.
- Likewise, the decision to treat with systemic agents should be carefully assessed, as the long-term potential side effect profile of many of the systemic agents is still unknown. However, many of the systemic agents have been used successfully in severe recalcitrant cases.

Another concern is that when topical steroids are discontinued, patients may rebound, sometimes worse than it was prior to treatment.[359] This class of agents is discussed in detail in Chapter 216.

VITAMIN D_3 AND ANALOGS.[362] Vitamin D exerts its actions by binding to the vitamin D receptor, another member of the nuclear hormone receptor superfamily. Vitamin D_3 acts to regulate cell growth, differentiation, and immune function, as well as calcium and phosphorous metabolism. Vitamin D has been shown to inhibit the proliferation of keratinocytes in culture and to modulate epidermal differentiation. Furthermore, vitamin D inhibits production of several proinflammatory cytokines by psoriatic T-cell clones, including IL-2 and IFN-γ.[363]

Analogs of vitamin D that have been used for the treatment of skin diseases are calcipotriene (also known as calcipotriol), tacalcitol, and maxacalcitol. In short-term studies, potent topical corticosteroids were found to be superior to calcipotriene. When compared with short-contact anthralin or 15% coal tar, calcipotriene was the more effective agent. The efficacy of calcipotriene is not reduced with long-term treatment.[364] Calcipotriene applied twice daily is more effective than once-daily use. Hypercalcemia is the only major concern with the use of topical vitamin D preparations. When the amount used does not exceed the recommended 100 g/week, calcipotriene can be used with a great margin of safety.[365] Vitamin D analogs are often used in combination with or in rotation with topical corticosteroids in an effort to maximize therapeutic effectiveness while minimizing steroid-related skin atrophy.

ANTHRALIN (DITHRANOL). Dithranol (1,8-dihydroxy-9-anthrone) is a naturally occurring substance found in the bark of the araroba tree in South America. It can also be synthesized from anthrone. Dithranol is made up in a cream, ointment, or paste. Dithranol is approved for the treatment of chronic plaque psoriasis. Its most common use has been in the treatment of psoriasis, particularly on plaques resistant to other therapies. It can be combined with UVB phototherapy with good results (the Ingram regimen). Most common side effects are irritant contact dermatitis and staining of clothing, skin, hair, and nails. Anthralin possesses antiproliferative activity on human keratinocytes along with potent anti-inflammatory effects. Classic anthralin therapy starts with low concentrations (0.05%–0.1%) incorporated in petrolatum or zinc paste and given once daily. To prevent autooxidation, salicylic acid (1%–2%) should be added. The concentration is increased weekly in individually adjusted increments up to 4% until the lesions resolve. Scalp psoriasis should be treated with great caution as anthralin can stain hair purple to green.

COAL TAR. The use of tar to treat skin diseases dates back nearly 2000 years. In 1925, Goeckerman introduced the use of crude coal tar and UV light for the treatment of psoriasis. Tar is the dry distillation product of organic matter heated in the absence of oxygen. Its mode of action is not understood, and, because of

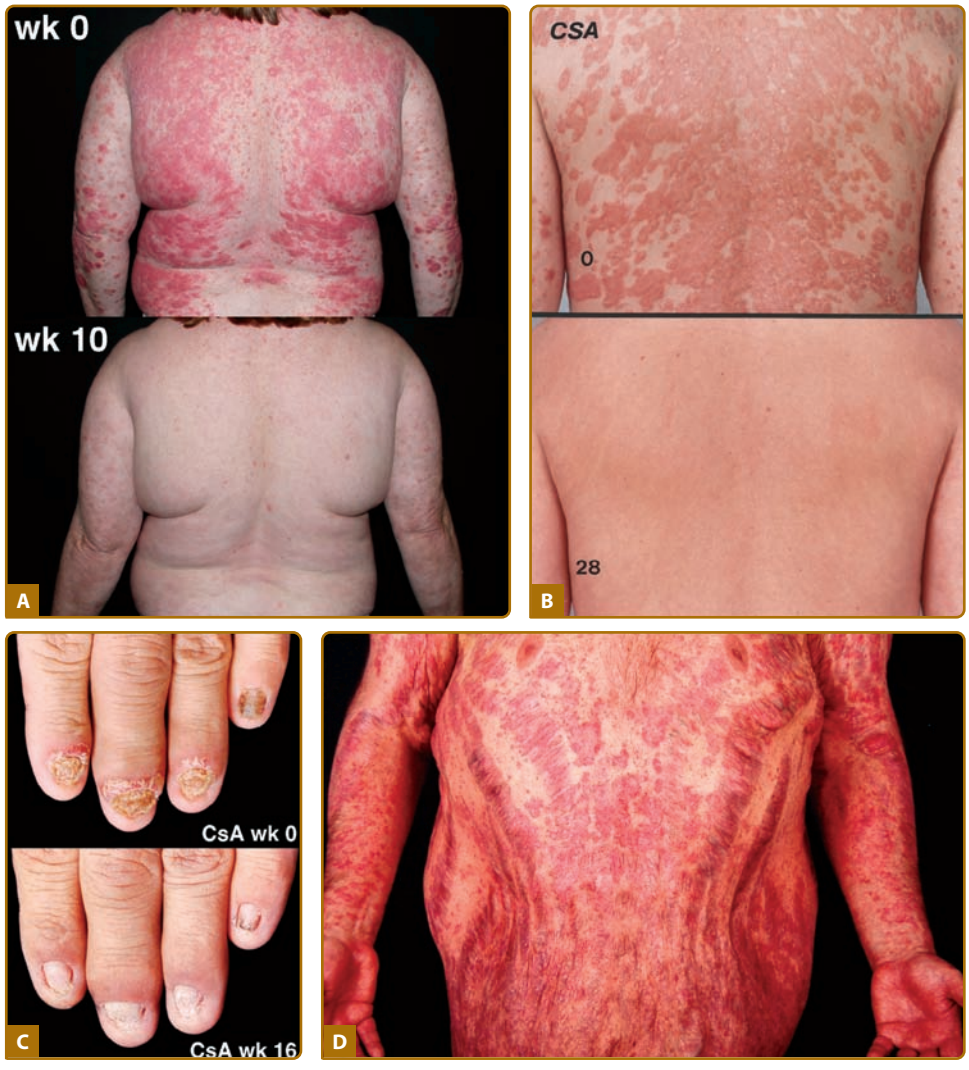

Figure 18-16 Positive and negative outcomes of psoriasis treatment. Panel **A** illustrates near-complete improvement of psoriasis after 10 weeks of infliximab therapy. Panel **B** illustrates marked improvement after 28 days of oral cyclosporine A treatment. Panel **C** illustrates marked reduction in nail dystrophy after 16 weeks of cyclosporine A treatment. Panel **D** illustrates severe atrophy with striae distensae after several years of treatment with potent topical steroid creams. (Photos used with permission from Mr. Harrold Carter.)

its inherent chemical complexity, tar is not pharmacologically standardized. It was recently suggested that carbazole, a coal-derived chemical, is the main active ingredient in tar.[366] Tar appears to exert its action through suppression of DNA synthesis and consequent reduction of mitotic activity in the basal layer of the epidermis, and some components in tar appear to have anti-inflammatory activity. Coal tar, in concentrations up to 20% (5%–20%) can be compounded in creams, ointments, and pastes. It is often combined with salicylic acid (2%–5%), which by its keratolytic action leads to better absorption of the coal tar.[297] Occasionally, patients become sensitive to the coal tar and develop allergic reactions. A folliculitis may occur after the use of coal tar. Furthermore, it has an unwelcome smell and appearance and can stain clothing and other items. Coal tar is carcinogenic.

TAZAROTENE. Tazarotene is a third-generation retinoid for topical use that reduces mainly scaling and plaque thickness, with limited effectiveness on erythema. It is thought to act by binding to retinoic acid receptors, but its molecular targets are unknown. It is available in 0.05% and 0.1% gels, and a cream formulation has been developed. When this drug is used as a monotherapy, a significant proportion of patients develop local irritation. This retinoid dermatitis is worse with the 0.1% formulation. Efficacy of this drug can be enhanced by combination with mid- to high-potency glucocorticoids or UVB phototherapy. When used in combination with phototherapy, it lowers the minimal erythema dose (MED) for both UVB and UVA. It has been recommended that UV doses be reduced by at least one-third if tazarotene is added in the middle of a course of phototherapy.[367]

TOPICAL CALCINEURIN INHIBITORS. (See Chapter 221.) Tacrolimus (FK-506) is a macrolide antibiotic, derived from the bacteria *Streptomyces tsukubaensis* that, by binding to immunophilin (FK506-binding protein), creates a complex that interacts and inhibits calcineurin, thus blocking both T-lymphocyte signal transduction and IL-2 transcription. Pimecrolimus is also a calcineurin inhibitor and works in a manner similar to tacrolimus and CsA.

In a study of 70 patients with chronic plaque psoriasis treated with topical tacrolimus, there was no improvement beyond that seen for placebo.[368] However, for treatment of inverse and facial psoriasis, these agents appear to provide effective treatment.[369,370] The main side effect of these medications is a burning sensation at application site. Anecdotal reports of lymph node or skin malignancy require further evaluation in controlled studies, and these drugs have a US Food and Drug Administration (FDA) "black-box warning."

SALICYLIC ACID. (See also Chapter 222.) Salicylic acid is a topical keratolytic agent. Its mechanism of action includes reduction of keratinocyte adhesion and lowering the pH of the stratum corneum. This results in reduced scaling and softening of the plaques,[371] thereby enhancing absorption of other agents. Therefore, salicylic acid is often combined with other topical therapies such as corticosteroids and coal tar. Topical salicylic acid decreases the efficacy of UVB phototherapy[359] and systemic absorption can occur, particularly in patients with abnormal hepatic or renal function and when applied to more than 20% of the body surface area. No placebo-controlled studies have been performed to verify the efficacy and safety of salicylic acid as a monotherapy.[359]

BLAND EMOLLIENTS. Between treatment periods, skin care with emollients should be performed to avoid dryness. Emollients reduce scaling, may limit painful fissuring, and can help control pruritus. They are best applied immediately after bathing or showering. The addition of urea (up to 10%) is helpful to improve hydration of the skin and remove scaling of early lesions. The use of liberal bland emollients over a thin layer of topical prescription treatments improves hydration while minimizing treatment costs.

PHOTOTHERAPY[372]

(See Table 18-4) (See Chapters 237 and 238.)

Phototherapy of psoriasis with artificial light sources dates back to 1925 when Goeckerman introduced a combination of topical crude coal tar and subsequent UV irradiation. In the 1970s, it was shown that broadband UVB radiation alone, if given in doses that produce a faint erythematous reaction, could clear the milder clinical forms of psoriasis. Major steps forward were the introduction of photochemotherapy with psoralen and UVA light (PUVA) in the 1970s and narrow band UVB (311–313 nm) in the 1980s.

The mechanism of action of phototherapy appears to involve selective depletion of T cells, predominantly those that reside in the epidermis.[166,230] The mechanism of depletion appears to involve apoptosis[373] and is accompanied by a shift from a Th1 immune response toward a Th2 response in the lesional skin.[374]

ULTRAVIOLET B LIGHT (290–320 nm). The initial therapeutic UVB dose lies at 50%–75% of the MED. Treatments are given two to five times per week. As peak UVB erythema appears within 24 hours of exposure, increments can be performed at each successive treatment. The objective is to maintain a minimally perceptible erythema as a clinical indicator of optimal dosing. Treatments are given until total remission is reached or until no further improvement can be obtained with continued treatment. The main side effects of UVB phototherapy are summarized in Chapter 237.

Narrowband (312 nm) UVB (NBUVB) phototherapy is superior to conventional broadband UVB (290–320 nm) with respect to both clearing and remission times.[375,376] Although early studies found NB-UVB to be as effective as psoralen and UVA light (PUVA),[377,378] a recent controlled trial found that PUVA was more effective, albeit less convenient.[379] On clearing, treatment is either discontinued or patients are subjected to maintenance therapy for 1 or 2 months. During this period, the frequency of UVB treatments is reduced while maintaining the last dose given at the time of clearing.[372]

Systemic drugs, such as retinoids, increase the efficacy of UVB light, particularly in patients with chronic and hyperkeratosis plaque-type psoriasis.[380,381] Because they are known to inhibit carcinogenesis in experimental animals, retinoids may possibly reduce the carcinogenic potential of UVB phototherapy.

PSORALEN AND ULTRAVIOLET A LIGHT. (See Chapter 238.) PUVA is the combined use of psoralens (P) and long-wave ultraviolet A radiation (UVA). The combination of drug and radiation results in a therapeutic effect, which is not achieved by the single component alone. Remission is induced by repeated controlled phototoxic reactions. A detailed account of PUVA therapy and its short-term and long-term side effects is to be found in Chapter 238.

EXCIMER LASER.[362] (See Chapter 239.) Supraerythemogenic fluences of UVB and PUVA are known to result in faster clearing of psoriasis,[383] however, the limiting factor for the use of such high fluences lies with the intolerance of the uninvolved surrounding skin as psoriatic lesions can often withstand much higher UV exposures.[384] The monochromatic 308-nm excimer laser can deliver such supraerythemogenic doses of light (up to 6 MED, usually in the range of 2–6 MEDs) to lesional skin, however, only focally. The dosing is guided by the patients' skin type and thickness of the plaque with subsequent doses based on the response to therapy or development of side effects.[385] In a study on 124 patients, 72% of study subjects achieved at least 75% clearing in an average of 6.2 treatments delivered twice weekly.[384] The role of this treatment seems to be indicated for patients with stable recalcitrant plaques particularly in the elbows and knee region.

PHOTODYNAMIC TREATMENT.[386] (See Chapter 238.) Photodynamic therapy has been tried for several inflammatory dermatoses, including psoriasis. In a randomized study on the effect of topical aminolevulinic acid-based photodynamic therapy, 29 patients demonstrated unsatisfactory clinical response and frequent occurrence of pain during and after treatment, prompting the authors to declare this as an inadequate treatment option for psoriasis.

CLIMATIC THERAPY.[387] It is well known that going to a sunny climate can improve psoriasis, although a small proportion of patients actually deteriorate. Patients should be warned not to overexpose themselves in the first few days, as sunburn may actually progress to psoriasis (Koebner phenomenon). The best-studied effects are from the Dead Sea area, and those therapeutic effects may be attributed, at least partially, to the unique climatic characteristic of that location. As it is situated 400 m below sea level, the evaporation of the sea forms an aerosol that stays in the atmosphere above the sea and surrounding beaches. This aerosol screens out the majority of the UVB rays but not the UVA. This mixture of UV light appears to be sufficient to clear psoriasis but without sunburn. Thus, patients can stay on the shores of the Dead Sea for long periods of time with greatly reduced risk of sunburn. This treatment is carried out over a period of 3–4 weeks, and improvements comparable to NB-UVB or PUVA treatments are observed. The main disadvantages of this treatment are time and expense.

SYSTEMIC ORAL AGENTS[388–390]

(See Table 18-5.)

METHOTREXATE. MTX is highly effective for chronic plaque psoriasis[389] and is also indicated for the long-term management of severe forms of psoriasis, including psoriatic erythroderma and pustular psoriasis.[388] For mechanisms of action, see Chapters 227 and 233. When first used for the treatment of psoriasis, MTX was thought to act directly to inhibit epidermal hyperproliferation via inhibition of dihydrofolate reductase (DHFR). However, it was found to be effective at much lower doses (0.1–0.3 mg/kg weekly) in the management of psoriasis, psoriatic arthritis, and other inflammatory conditions such as rheumatoid arthritis. At these concentrations, MTX inhibits the *in vitro* proliferation of lymphocytes, but not proliferation of keratinocytes.[391] It is now thought that the inhibition of DHFR is not the main mechanism of anti-inflammatory action of MTX, but rather the inhibition of an enzyme involved in purine metabolism [AICAR (5-aminoimidazole-4-carboxamide ribonucleotide) transformylase]. This leads to accumulation of extracellular adenosine, which has potent anti-inflammatory activities, particularly for neutrophils.[392] Consistent with a DHFR-independent mechanism of action, concomitant administration of folic acid (1–5 mg/day) reduces certain side effects, such as nausea and megaloblastic anemia, without diminishing the efficacy of antipsoriatic treatment.[393] The cellular targets of MTX action in psoriasis are still under investigation, but its mechanism of action may involve modulation of adhesion molecules, such as intercellular adhesion molecule 1, rather than induction of lymphocyte apoptosis.[394]

The very long half-life of MTX may account for its efficacy after weekly administration and may also help to explain why its onset of action is rather slow (therapeutic effects usually require 4–8 weeks to become evident). MTX is renally excreted and should therefore not be administered to patients with impairment in renal function, as MTX side effects are generally dose-related. Short-term toxicity and long-term concerns are discussed in Chapter 227.

In the most recent guidelines[395,396] it is suggested that patients be divided into two separate groups based on their risk factors for liver injury: the low-risk patients follow the American College of Rheumatology (ACR) guidelines and are not asked to undergo liver biopsy until they have reached a cumulative MTX dose of 3.5–4.0 g. In contrast, those patients with one or more risk factors continue to follow the previously published[397] more stringent guidelines requiring baseline liver biopsy either before treatment or after 2–6 months of treatment, and then at each cumulative MTX dose of 1.0–1.5 g.[395,398] The risk factors include current or past alcohol consumption, persistent abnormalities of liver function enzymes, personal, or family history of liver disease, exposure to hepatotoxic drugs or chemicals, diabetes mellitus, hyperlipidemia, and obesity.[395]

Some groups have recommended the use of amino terminal type III procollagen peptide (PIIINP) assay for screening of liver fibrosis.[292] Specific guidelines have been developed for monitoring PIIINP levels in psoriatic patients,[292] but the FDA has not yet approved the use of this assay for diagnostic use within the United States.

Another well-known side effect of MTX is myelosuppression, especially pancytopenia, which usually occurs in the setting of folate deficiency. Leucovorin calcium (folinic acid) is the only antidote for the hematologic toxicity of MTX. When an overdose is suspected, an immediate leucovorin dose of 20 mg should be given parenterally or orally, and subsequent doses should be given every 6 hours.[399] Pneumonitis can develop, and mucosal and skin ulcerations have also been reported in patients treated with MTX.[399,400]

Discontinuation of MTX treatment is required in the event of hepatotoxicity, hematopoietic suppression, active infections, nausea, and pneumonitis. MTX is also teratogenic and should therefore not be prescribed for women who are pregnant or breastfeeding. Several classes of drugs, including nonsteroidal anti-inflammatory drugs and sulfonamides, may interact with MTX to increase toxicity.

ACITRETIN.[401] Acitretin is a second-generation, systemic retinoid that has been approved for the treatment of psoriasis since 1997 and is discussed in Chapter 228.

The clinical forms most responsive to etretinate or acitretin as monotherapy include generalized pustular and erythrodermic psoriasis. Acitretin induces clearance of psoriasis in a dose-dependent fashion.

Overall, higher starting doses appeared to clear psoriasis faster.[402] The mechanism of action of retinoids for psoriasis is not fully understood.

The optimal initial dose of acitretin for psoriasis is reported at 25 mg/day, with a maintenance dose of 20–50 mg/day. Adverse effects, such as hair loss and paronychia, occur more frequently with higher initial dose (i.e., ≥50 mg/day). Most patients relapse within 2 months after discontinuing etretinate or acitretin. Acitretin should be discontinued if liver dysfunction, hyperlipidemia, or diffuse idiopathic hyperostosis develops.

CYCLOSPORINE A. Cyclosporine A (CsA) is a neutral cyclic undecapeptide derived from the fungus *Tolypocladium inflatum Gams*. Its mechanism of action and side effects are discussed in Chapter 233. The only formulation approved for treatment of psoriasis is available as an oral solution or in capsules. It is highly effective for cutaneous psoriasis and can also be effective for nail psoriasis (see Fig. 18-16B). CsA is particularly useful in patients who present with widespread, intensely inflammatory, or frankly erythrodermic psoriasis. Dosage ranges from 2 to 5 mg/kg/day.[403] Because the nephrotoxic effects of CsA are largely irreversible, CsA treatment should be discontinued if kidney dysfunction and/or hypertension occur. CsA-induced hypertension may be treated with calcium antagonists such as nifedipine.[404] The most common adverse effects noted in patients using CsA for short periods of time are neurologic, including tremors, headache, paresthesia, and/or hyperesthesia. Long-term treatment of psoriasis with low-dose CsA was found to increase risk of nonmelanoma skin cancers.[405] However, unlike organ transplant patients treated with higher doses of CsA, there is little or no increased risk of lymphoma.

FUMARIC ACID ESTERS. Fumaric acid was first reported in 1959 to be beneficial in the systemic treatment of psoriasis[406] and is licensed in Germany for treatment of psoriasis. Because fumaric acid itself is poorly absorbed after oral intake, esters are used for treatment. The esters are almost completely absorbed in the small intestine, and dimethyl fumarate is rapidly hydrolyzed by esterases to monomethyl fumarate, which is regarded as the active metabolite. The mode of action of fumaric acid esters (FAEs) in the treatment of psoriasis is not fully understood, but experimental data point toward a skewing of the Th1-dominated T-cell response in psoriasis to a Th2-like pattern and inhibition of keratinocyte proliferation.[406] Patients with severe concomitant disease, chronic disease of the gastrointestinal tract, chronic kidney disease, or with bone marrow disease leading to leukocytopenias or leukocyte dysfunction should not be treated. Likewise, pregnant or lactating women and patients with malignant disease (including positive history of malignancy) should be excluded from treatment. Prolonged therapy (up to 2 years) to prevent relapse in psoriasis patients with high disease activity is possible. Another therapeutic option is short-course intermittent therapy. FAEs are given until a major improvement is achieved and are then withdrawn. If a patient remains lesion-free during prolonged treatment, the FAE dose should be gradually decreased to reach the individual's threshold.[406] Therapy with FAEs can be stopped abruptly. Rebound phenomena have not been observed.[406]

SULFASALAZINE. Sulfasalazine is an uncommonly used systemic agent in the management of psoriasis. In the only prospective double-blind study on the efficacy of sulfasalazine in psoriasis, moderate effects were seen, with 41% of the patients showing marked improvement, 41% with moderate, and 18% with minimal improvement after 8 weeks of treatment.[407]

SYSTEMIC STEROIDS. (See Chapter 224.) In general, systemic steroids should not be used in the routine care of psoriasis. When systemic steroids are used, clearance of psoriasis is rapid, but the disease usually breaks through, requiring progressively higher doses to control symptoms. If withdrawal is attempted, the disease tends to relapse promptly and may rebound in the form of erythrodermic and pustular psoriasis.[408] However, systemic steroids may have a role in the management of persistent, otherwise uncontrollable, erythroderma and in fulminant generalized pustular psoriasis (von Zumbusch type) if other drugs are ineffective.

MYCOPHENOLATE MOFETIL. (See Chapter 233.) Mycophenolate mofetil is a prodrug of mycophenolic acid, an inhibitor of inosine-5′-monophosphate dehydrogenase. Mycophenolic acid depletes guanosine nucleotides preferentially in T and B lymphocytes and inhibits their proliferation, thereby suppressing cell-mediated immune responses and antibody formation. The drug is usually well tolerated with few side effects. Few studies have been done on this medication for psoriasis, but, in a prospective open-label trial on 23 patients with dosage between 2 and 3 g daily, a 24% reduction of the Psoriasis Area and Severity Index (PASI) was seen after 6 weeks, with 47% improvement at 12 weeks.[409]

6-THIOGUANINE. 6-Thioguanine is a purine analog that has been highly effective for psoriasis.[410] Apart from bone marrow suppression, gastrointestinal complaints including nausea and diarrhea can occur, and elevation of liver function tests is common.[388] Isolated instances of hepatic veno-occlusive disease have been reported.[411]

HYDROXYUREA. Hydroxyurea is an antimetabolite that has been shown to be effective as monotherapy, but nearly 50% of patients who achieve marked improvement develop bone marrow toxicity with leukopenia or thrombocytopenia. Megaloblastic anemia is also common but rarely requires treatment.[388] Cutaneous reactions affect most patients treated with hydroxyurea, including leg ulcers, which are the most troublesome.[412]

COMBINATION TREATMENTS

(See Table 18-6.)

Combination treatment may increase efficacy and reduce side effects, and so may result in a more substantial improvement, or alternatively, may permit

reduced doses to reach the same improvement as compared with monotherapy.[354] Data on combination of biologics with other systemic or topical agents are not yet widely available, but some combinations commonly used in the treatment of inflammatory arthritides, such as a combination of MTX and anti-TNF agents,[413] may be appropriate for treatment of recalcitrant psoriatic disease.

BIOLOGIC TREATMENTS[414–417]

(See Table 18-7.) (See also Chapter 234.)

Based on the continuous progress in psoriasis research and advances in molecular biology, a new class of agents—targeted biologic therapies—has emerged.[414,415] These agents are designed to block specific molecular steps important in the pathogenesis of psoriasis or have been transferred to the psoriasis arena after being developed for other inflammatory diseases. Currently, three types of biologics are approved or are in development for psoriasis: (1) recombinant human cytokines, (2) fusion proteins, and (3) monoclonal antibodies, which may be chimeric or humanized. Due to the risk of the development of antibodies to mouse sequences, humanized or fully human antibodies are preferred for clinical use.

Using internationally acknowledged safety and efficacy endpoints, the overall utility and benefit of biologics have been demonstrated based on the percentage of patients achieving at least a 50% improvement in PASI (PASI-50), a 75% improvement in PASI (PASI-75), the impact of treatment on quality of life, and safety and tolerability.[417] In general, these agents have antipsoriatic activity roughly comparable to that of MTX and lack its risk of hepatotoxicity. However, they are far more expensive, carry risks of immunosuppression, infusion reactions, and antibody formation, and their long-term safety remains to be evaluated. In the opinion of the authors, use of biologic agents should be reserved for treatment of severe psoriasis that is either unresponsive to MTX or in patients for whom the use of MTX is contraindicated.

ALEFACEPT. Alefacept is a human lymphocyte function-associated antigen (LFA)-3-IgG1 fusion protein designed to prevent the interaction between LFA-3 and CD2. The LFA-3-CD2 signal plays an important role in activation of T cells. The LFA-3 portion of alefacept binds to the CD2 receptor on T cells, blocking the interaction between LFA-3 and CD2, thus interfering with the activation of T cells, inducing apoptosis and modifying the inflammatory process. CD2 is upregulated on memory effector T cells, explaining the preferential depletion of these cells by alefacept.[418] One-third to one-half of psoriatic patients do not respond to alefacept; the reasons for this remain unclear. However, evidence indicates that repeated administration of alefacept leads to improved response, and that responses to alefacept are durable.[415]

EFALIZUMAB. Efalizumab (anti-CD11a) is a humanized monoclonal antibody developed for treatment of plaque psoriasis. It is directed against CD11a, the α subunit of LFA-1, and thus blocks the interaction of LFA-1 with its ligand intercellular adhesion molecule 1. This blockade inhibits T-cell activation, cutaneous T-cell trafficking, and T-cell adhesion to keratinocytes.[419,420] Some patients have shown evidence of exacerbation of the disease at the end of the dosing period.[421] This medication is not longer in clinical use as it was withdrawn from the market in 2009 after reports of an increased incidence of progressive multifocal leukoencephalopathy of approximately one in 500 treated patients.[422]

TUMOR NECROSIS FACTOR-α ANTAGONISTS. The clinical application of TNF antagonists in inflammatory diseases has exploded on the clinical realm in a manner reminiscent of the discovery of the activity of corticosteroids.[423] TNF-α is a homotrimeric protein that exists in both transmembrane and soluble forms, the latter resulting from proteolytic cleavage and release. It is still unclear which form is more important in mediating its proinflammatory activities or the relative importance of the two p55- and p75-kd TNF-α-binding receptors.[424]

Currently, four anti-TNF biologics are available in the United States. Infliximab is a chimeric monoclonal antibody that has high specificity, affinity, and avidity for TNF-α. An example of an excellent treatment outcome with infliximab is shown in Fig. 18-16A. Etanercept is a human recombinant, soluble, TNF-α receptor-Fc IgG fusion protein that binds TNF-α and neutralizes its activity. Adalimumab and golimumab are fully human recombinant IgG1 monoclonal antibodies and specifically targets TNF-α. Currently golimumab is only FDA-approved for psoriatic arthritis. Clinical trials have shown that each of these agents is well tolerated and appears suitable for long-term use in chronic plaque psoriasis. However, like all the targeted biologic therapies, they carry risks of immunosuppression, and their long-term safety requires further study.

Clinical studies have found infliximab and adalimumab to be slightly more effective than etanercept in the treatment of psoriasis. It is likely that the differential effects of these agents are associated with selectivity in their ability to perturb these receptor ligand interactions. It is known that infliximab, adalimumab, golimumab, and etanercept bind TNF differently; infliximab and adalimumab bind to both soluble and membrane-bound TNF, whereas etanercept binds primarily to soluble TNF.[425] Binding to membrane-bound TNF can induce a dose-dependent increase in apoptosis of T cells, but the relevance of this mechanism in psoriasis has not been evaluated.

ANTI-p40 (IL-12/IL-23 ANTAGONIST)

Ustekinumab is a human monoclonal antibody that binds the shared p40 subunit of IL-12 and IL-23 and prevents interaction with their receptors.[426] This treatment blocks IL-12, which is critical for Th1 differentiation, but its inhibitory effect on IL-23 may be more important. As described earlier, IL-23 supports chronic

TABLE 18-7
Biologic Treatments for Psoriasis[390,442]

	Alefacept	Ustekinumab	Etanercept	Infliximab	Adalimumab
Mechanism	Binds CD2 on T cells, blocking the CD2-LFA3 interaction, thus interfering with T-cell activation and causing T-cell apoptosis.	Binds p40 (the common subunit of IL-12 and IL-23). Blocks Th1 and Th17 differentiation and proliferation.	Human recombinant, soluble TNF-α receptor. Binds TNF-α and neutralizes its activity.	Chimeric monoclonal antibody that has high specificity, affinity, and avidity for TNF-α.	Fully human recombinant monoclonal antibody that specifically targets TNF-α.
Dosing	15 mg IM once weekly for 12 weeks. Multiple subsequent 12-week courses are possible in responders, with a minimum interval of 12 weeks between courses.	Subcutaneous injections. Weight based dosing. Individuals weighing <100 kg (220 lbs); 45 mg, >100 kg 90 mg. Injections at week 0, 4, and then every 12 weeks.	25- to 50-mg injections subcutaneously twice weekly. Commonly given as 50 mg BIW for 12 weeks followed by 50 mg weekly.	Intravenous infusions over 2 hours. 5–10 mg/kg at weeks 0, 2, and 6.	Initial dose of 80 mg, followed by 40 mg given every other week starting one week after the initial dose.
Efficacy	PASI-75 at 14 weeks (2 weeks after last dose) 24%. Patients who respond maintain improvement for extended periods of time. Repeat courses are safe and well tolerated.[388]	PASI-75 at 12 weeks, 67% and 71%–78% at week 28[443]	PASI-75 at 12 weeks, 34% and at 24 weeks, 44%.[393] For the 25 mg BIW vs. 49% and 59% for the 50 mg BIW dosing.[444]	PASI-75 at 10 weeks, 82% (5 mg/kg) and 91% (10 mg/kg).[394] At week 26 (following a single course), 57% of patients maintained PASI-50, and 50% maintained PASI-75.[394]	PASI-75 at 16 weeks, 71%[445]
Safety	Lymphopenia, malignancy, serious infections. Not recommended for human immunodeficiency virus-positive patients. Effects of live vaccines not studied.	Serious infections, increased risk of malignancy, reversible posterior leuko-encephalopathy syndrome. Live vaccinations not recommended.	Serious infections, exacerbation of MS, pancytopenia, malignancy, worsening congestive heart failure. Lupus-like symptoms (anti-dsDNA positive). Live vaccinations should not be given.	Infusion-related reactions, infections, worsening of MS, malignancy or lymphoproliferative disease, worsening heart failure. Lupus-like symptoms (anti-dsDNA positive). Live vaccinations should not be given.	Injection site reactions, infections, lupus-like syndrome, worsening heart failure, cytopenias, neurologic events.[396] Live vaccinations should not be given.
Monitoring	$CD4^+$ T-cell counts every 2 weeks during treatment.	Baseline PPD/ QuantiFERON-TB Gold	Baseline PPD/ QuantiFERON-TB Gold	Baseline PPD/ QuantiFERON-TB Gold.	Baseline PPD/ QuantiFERON-TB Gold.
Long-term administration	Up to nine courses have been administered over 4–5 years in small number of patients with incremental benefits.	Clinical trials have established safety up to 76 weeks.[443] Appears to be similar to TNF-α inhibitors	PASI response continues to increase to week 24. Large databases in patients with other immunologic diseases indicate safety.	As intermittent therapy. Large databases in patients with other immunologic diseases indicate relative safety.	Similar to other TNF-α inhibitors.
Pregnancy category	B	B	B	B	B

BIW = twice weekly; dsDNA = double-stranded DNA; LFA = lymphocyte function-associated antigen; MS = multiple sclerosis; PASI-50 = 50% improvement in Psoriasis Area and Severity Index; PASI-75 = 75% improvement in Psoriasis Area and Severity Index; PPD = purified protein derivative (of tuberculin); TNF = tumor necrosis factor.

inflammation mediated by Th17[99–101] and Th22 cells.[427] Clinical studies have found ustekinumab to be slightly more effective than etanercept in the treatment of psoriasis,[428] but direct comparison to infliximab or adalimumab has not been reported.

Numerous new drugs are currently in clinical trials for treatment of psoriasis as outlined in a comprehensive review.[429] As would be predicted from the immunological and genetic studies depicted in Figs. 18-3 and 18-5, a humanized monoclonal antibody directed against the IL-17 receptor appears to be highly effective in early clinical trials.[430]

Extensive guidelines are available for specific clinical scenarios, including severe scalp psoriasis,[431] intertriginous psoriasis,[432] concomitant hepatitis C or HIV infection,[396,433] and in erythrodermic psoriasis.[434]

PREVENTION

There is no known prevention for psoriasis.

Chapter 19 :: Psoriatic Arthritis

:: Dafna D. Gladman & Vinod Chandran

PSORIATIC ARTHRITIS AT A GLANCE

- Psoriatic arthritis (PsA) is an inflammatory arthritis associated with psoriasis and seronegative for rheumatoid factor.
- Genetic and environmental factors underlie susceptibility to PsA and immune-mediated inflammation leads to inflammation in musculoskeletal structures.
- Clinical features of PsA include peripheral and axial arthritis, enthesitis, dactylitis, and tenosynovitis.
- Extra-articular involvement in addition to skin and nail involvement may include conjunctivitis, uveitis, and inflammatory bowel disease.
- Investigations may reveal elevated acute phase reactants, although conventional tests such as erythrocyte sedimentation rate and C-reactive protein are normal in up to 50% of patients.
- Radiographs may reveal soft-tissue swelling, periostitis, erosions, pencil-in-cup change, ankylosis, sacroiliitis, or syndesmophytes.
- Pharmacotherapy is the mainstay of treatment, and antitumor necrosis factor agents are safe, efficacious, and effective.

DEFINITION AND CLASSIFICATION

Psoriatic arthritis (PsA) is an inflammatory musculoskeletal disease that affects people with psoriasis or their near relatives. It affects musculoskeletal structures such as the peripheral and axial joints, entheses, and tendon sheaths. The eye and mucous membranes are also often involved. Thus, the disease has varied manifestations that make diagnosis and assessment sometimes difficult.

The original case definition for PsA was provided by Moll and Wright in 1973.[1] They defined PsA as an inflammatory arthritis associated with cutaneous psoriasis, seronegative for rheumatoid factor. Rheumatoid factor is a marker for rheumatoid arthritis (RA); thus, the definition was meant to help distinguish PsA from RA, which at that time was a more recognized form of inflammatory arthritis. The CASPAR study group recently developed a new set of criteria for classification of PsA using data collected prospectively in patients with long-standing disease (Box 19-1).[2] The CASPAR criteria had specificity of 98.7% and sensitivity of 91.4% in the original study, with excellent sensitivity in both early and late disease. The criteria allow classifying patients even when they do not have current, past, or family history of psoriasis and are now used in epidemiologic and genetic studies in PsA.

ETIOLOGY AND PATHOGENESIS

GENETICS

PsA has a strong genetic component. The estimated recurrence risk ratio (λ) in first-degree relatives (FDRs) of probands with PsA ranges from 30.4 to 55, indicating a high genetic contribution to disease susceptibility.[8] Strong heritability was also demonstrated in a recent study from Iceland where patients known to have PsA in Reykjavik were linked to the Icelandic genealogy database.[9] FDRs to fourth-degree relatives of patients with PsA had relative risks of 39, 12, 3.6, and 2.3, respectively, reflecting a strong genetic component. The decrease of λ-1 more rapidly than by a factor of 2 with the degree of relationship indicates that multiple genes contribute to susceptibility with some interaction of effects. Genes associated with PsA include HLA alleles, MHC Class I related chain (MIC) genes, *TNFA*, *IL23R*, *IL1*, and killer-cell immunoglobulin-like receptor (KIR) genes. HLA-B13, -B16 and its splits -B38 and -B39, -B17, and -Cw6 are associated with psoriasis, with or without arthritis, -B27 and -B7 are specifically associated with PsA.[8] However, since most patients with PsA have cutaneous psoriasis it is difficult to determine whether genetic associations found in patients with PsA when compared to healthy controls is associated with psoriasis or with PsA. A recent genome-wide association study was able to investigate association with PsA and differences between PsA and psoriasis alone.[10] HLA-C, *IL12B*, and *TNIP1* were associated with PsA when compared to normal controls. There was a statistically significant difference between PsA and psoriasis alone at three loci [(1) HLA-C, (2) *IL12B*, and (3) *IL23R*]. HLA-C and *IL23R* were more strongly associated with psoriasis alone, and *IL12B* with PsA. A smaller GWAS also identified a novel PsA (and potentially psoriasis) locus on chromosome 4q27 that harbors the interleukin 2 (*IL2*) and interleukin 21 (*IL21*) genes.[11]

Genetic polymorphisms can also influence PsA phenotype. HLA-B39 alone, HLA-B27 in the presence of HLA-DR7, and HLA-DQ3 only in the absence of HLA-DR7, confers increased risk for disease progression.[12] TNF polymorphisms are associated with erosive disease and joint damage progression in early PsA.[13] The

BOX 19-1 THE CASPAR CRITERIA

To meet the CASPAR (ClASsification criteria for Psoriatic ARthritis) criteria*, a patient must have inflammatory articular disease (joint, spine, or entheseal) with three points from the following categories:

- Evidence of current psoriasis, a personal history of psoriasis, or a family history of psoriasis. Current psoriasis is defined as psoriatic skin or scalp disease present today as judged by a rheumatologist or dermatologist. A personal history of psoriasis is defined as a history of psoriasis that may be obtained from a patient, family physician, dermatologist, rheumatologist, or other qualified health care provider. A family history of psoriasis is defined as a history of psoriasis in a first- or second-degree relative according to patient report.
- Typical psoriatic nail dystrophy including onycholysis, pitting, and hyperkeratosis observed on current physical examination. A negative test result for the presence of rheumatoid factor by any method except latex but preferably by enzyme-linked immunosorbent assay or nephelometry, according to the local laboratory reference range.
- Either current dactylitis, defined as swelling of an entire digit, or a history of dactylitis recorded by a rheumatologist. Radiographic evidence of juxtaarticular new bone formation, appearing as ill-defined ossification near joint margins (but excluding osteophyte formation) on plain radiographs of the hand or foot.

*Current psoriasis is assigned a score of 2; all other features are assigned a score of 1. From Taylor W et al: Classification criteria for psoriatic arthritis. *Arthritis Rheum* **54**(8):2665-2673, 2006.

interleukin-4 receptor gene (*IL4R*) I50V SNP is associated with erosive PsA, although the association was not consistently shown.[14,15]

PATHOGENESIS

The immune system, especially the lymphocytes, play an important role in the pathogenesis of PsA. The traditional model of the pathogenesis is that autoimmunity directed against a common skin and joint autoantigen(s) leads to chronic autoreactive T-cell driven inflammation. Genetic susceptibility predisposes the T-cell receptor repertoire to recognition of target self-peptides expressed in target tissues. Prior response to exogenous ligands encoded by pathogens as well as prior episodes of inflammation result in expansion of memory effector CD8+ T cells that recognize stress-related self-antigens and initiates and maintains pathways of inflammation mediated by the expression of transcription factors such as nuclear factor-κB and activator protein-1, resulting in skin and synovial inflammation.[18] The primary defects in this model involve expression of an autoantigen, binding of autoantigen peptides by MHC Class 1 molecules leading to initial clonal activation and expansion of an adaptive immune response. However, recent imaging, histological, and genetic studies have made us reconsider this view, especially with respect to joint and nail diseases. Clinically unrecognized enthesitis is commonly seen in PsA and in psoriasis without arthritis.[19] Enthesitis is associated with adjacent osteitis or bone and synovial inflammation. Nail disease is a marker for PsA in patients with psoriasis, since it occurs in almost 90% of patients with PsA, but less than 50% of those with psoriasis alone. The nail is closely related to the distal interphalangeal (DIP) joints and the related extensor tendon insertion sites, and the association between DIP joint disease, adjacent nail lesions, and entheseal inflammation was recently demonstrated.[20] It is proposed that the synovial membrane and entheses form a "synovioentheseal complex," and that enthesitis is the unifying pathologic lesion that may explain the varied clinical manifestations of PsA.[21] In this model, tissue specific factors, including microtrauma, lead to regional innate immune activation and persistent inflammation. The genetic association of PsA with Class 1 HLA alleles and *KIR* genes as well as the association between juvenile PsA and Mediterranean Fever (*MEFV*) and NLR family, pyrin domain containing 3 (*NLRP3*) genes indicate that PsA is closer to the "autoinflammatory" end rather than the "autoimmune" end of the spectrum of immune-mediated diseases.[22] Disease localization in autoinflammatory diseases is determined predominantly by the innate immune response to local tissue specific factors.

There is also evidence that the monocyte–macrophage system plays a major role in the initiation and perpetuation of joint inflammation. Monocytes differentiate into macrophages, osteoclasts, Langerhans cells, or dendritic cells in response to microenvironmental signals.[23] In entheseal tissues, monocytes are the principal cells that infiltrate fibrocartilage. Monocytes are also present in the synovial lining of psoriatic joints, and they infiltrate the subsynovial lining. An increased frequency of circulating osteoclast precursors was identified in the circulation and synovial tissues of PsA patients. These precursors, derived from circulating CD14+ monocytes, differentiate into osteoclasts after exposure to monocyte colony stimulating factor (M-CSF) and receptor activator of nuclear factor κB ligand (RANKL) expressed by synovial lining cells in inflamed psoriatic synovium, and is responsible for bone erosions. The frequency of circulating osteoclast precursors in PsA patients decline rapidly following treatment with anti-TNF agents and may explain its antierosive effects.

CLINICAL FINDINGS

The CASPAR classification criteria define PsA as an inflammatory musculoskeletal disease that can involve the joints, spine or entheses. Clinical features of PsA include peripheral arthritis, axial arthritis (spondylitis),

Figure 19-1 Swelling and erythema of the left third metacarpophalangeal joint (*arrow*) indicating inflammatory arthritis in a patient with psoriatic arthritis.

enthesitis, dactylitis, and tenosynovitis. The typical features of inflammatory arthritis are joint pain, swelling, stiffness, redness, and reduction in mobility. The arthritis of PsA is often of gradual onset and involves one or more joints. Typically early PsA is oligoarticular (affecting less than five joints) (Fig. 19-1). Early PsA often involves the joints of the lower limbs, but any joint of the body may be affected. Oligoarticular PsA subsequently evolves into polyarthritis. Joints that are typically affected in patients with PsA include the DIP joints (Fig. 19-2). Commonly the nails near these affected joints demonstrate the nail changes that are typical for psoriasis. The distribution of the joint involvement in PsA is often asymmetric. However, as the number of joints affected increases, there is a tendency toward symmetry.[26] Patients with PsA have less pain than those with RA.[27] Therefore, they may be oblivious to the degree of inflammation in their joint. In addition to peripheral arthritis, PsA affects the axial joints in 30%–50% of patients with PsA. Axial inflammatory arthritis presents with inflammatory back and/or neck pain, typically associated with stiffness and worse after periods of prolonged inactivity such as nighttime sleep. Inflammatory axial pain and stiffness usually improve with activity. However, evidence of radiographic involvement of the axial joints may be present in a substantial proportion of patients presenting with peripheral PsA in the absence of axial symptoms.[28] Axial arthritis leads to restriction in the mobility of the spine. The process can lead to a completely fused and immobile spine, sometimes called "bamboo spine."

Dactylitis, defined as inflammatory swelling of an entire finger or toe, is a characteristic manifestation of PsA (Fig. 19-3). This is due to inflammation of the joints, tendons, bones, and soft tissues in the digit(s). Persistent dactylitis leads to destruction of the joints in that digit. Dactylitis is a marker of severity of psoriatic arthritis. Enthesitis, defined as inflammation at the entheses (site where ligaments or tendons attach to bone), is another important manifestation of PsA. The most common sites to be affected by enthesitis are the plantar fascia on the sole of the feet (plantar fasciitis) and Achilles tendon insertion at the back of the heel (Achilles enthesitis). Enthesitis can also affect other sites including tendon insertion sites on the patella, shoulder, elbows, pelvis, spinous processes, and chest wall. Tenosynovitis, or inflammation of the tendon sheath, may affect tendons in the hands, wrists, and around the ankles. (Box 19-2).

The category of asymmetric oligoarthritis includes those patients with four or less joints affected by arthritis. The joints involved are usually of the lower limbs and there is lack of symmetry. In the category of sym-

Figure 19-3 Dactylitis of the third toe (*arrow*) in a patient with psoriatic arthritis.

BOX 19-2 PATTERNS OF PsA ACCORDING TO MOLL AND WRIGHT*

Five patterns of PsA were originally described by Moll and Wright.* These include the following:

1. Asymmetric oligoarthritis
2. Symmetric polyarthritis similar to rheumatoid arthritis
3. Spondyloarthritis
4. Distal interphalangeal joint arthritis
5. Arthritis mutilans

*From Moll JM, Wright V: Psoriatic arthritis. *Semin Arthritis Rheum* **3**:55, 1973.

metric polyarthritis, five or more joints are involved in a symmetric fashion. Therefore, it is sometimes difficult to distinguish it from RA. The spondyloarthritis category includes patients with predominant involvement of the spine (axial arthritis), similar to the involvement in patients with AS. As the name suggests, the category of distal interphalangeal joint arthritis includes those patients with predominant involvement of the DIP joints. Arthritis mutilans describes a category with severe arthritis leading to shortening and destruction of fingers and toes (see eFig. 19-3.1 in online edition). Although, these categories were described initially, it was soon realized that as the longer the duration of the disease the higher the number of joints involved and the involvement becomes more symmetric. Distal joint involvement also is common and is seen in all categories. Arthritis mutilans is also a manifestation of severity of the arthritis process and not an exclusive category. Therefore, experts nowadays tend to classify the disease as peripheral arthritis alone, peripheral arthritis with axial arthritis, and axial arthritis alone.[29]

SKIN INVOLVEMENT. Most patients with PsA have psoriasis vulgaris. In about 70% of people with PsA, psoriasis develops first and the arthritis manifests itself after a variable duration, on average within 10 years. However, in about 15%, both arthritis and psoriasis develops simultaneously, and in the remaining, the arthritis develops first, and cutaneous psoriasis manifests itself a few years later. Patients seen in dermatology clinics and those hospitalized with psoriasis have high prevalence of PsA compared to patients with psoriasis seen in the community. Patients reporting greater extent of psoriasis also reported a higher prevalence of PsA when surveyed in a telephone interview.[30] Thus, patients with more severe psoriasis may have a higher prevalence of PsA. However, most patients attending rheumatology clinics for their arthritis have only mild to moderate psoriasis.

NAIL INVOLVEMENT. Psoriatic nail dystrophy usually manifests as pitting and onycholysis (see Chapter 18). Although 40% of patients with psoriasis without PsA have nail lesions, nail involvement is much more frequent in patients with PsA affecting close to 90% of patients.[31] Thus, nail lesions are the only clinical feature that distinguishes patients with psoriatic arthritis from those with uncomplicated psoriasis. The nail bed is closely linked to the DIP joints; nail involvement is associated with arthritis of these joints.

EXTRA-ARTICULAR MANIFESTATIONS. Apart from the involvement of the skin, nails, and joints, people with PsA also have involvement of other important organs. Eye involvement is not infrequent. Conjunctivitis is occasionally seen and uveitis may occur in 2.3% of patients.[32] Mucous membrane inflammation presents with painful mouth ulcers and urethritis. Inflammatory bowel disease in PsA may resemble Crohn disease and/or ulcerative colitis and can cause abdominal pain, loose stools, and bleeding.

LABORATORY INVESTIGATIONS. Laboratory tests are usually done at diagnosis and periodically thereafter. However, there is to date no diagnostic test for PsA. The acute phase reactants [erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)] are often normal. ESR and/or CRP are raised in less that 50% of people with PsA. Rheumatoid factor is usually negative and helps exclude RA. HLA-B*27 is positive in 20% of patients with PsA. Radiological investigations (X-ray, ultrasonography, and magnetic resonance imaging) can provide important clues to diagnosis and to the extent of inflammation and damage. However, only the presence of periostitis and new bone formation near joint margins may be considered reasonably specific to PsA.[2] Although, these tests are not by themselves diagnostic, they help in ruling out other conditions that may mimic PsA. Synovial fluid if obtained demonstrates inflammation and helps exclude crystal arthritis and infections. Investigations such as blood count, and liver and kidney functions are often obtained to monitor side effects of drug therapy.

RADIOLOGIC FEATURES OF PsA. Imaging is an important modality in the assessment of patients with PsA. Imaging complements clinical assessment and helps in confirming the diagnosis as well as in determining disease severity. The various modalities used in assessment of PsA include X-rays, ultrasound, computerized-tomography scan (CT scan), magnetic resonance imaging (MRI), and bone scan.

Plain Radiographs (X-rays). X-rays are the mainstay in the radiologic assessment of PsA. X-rays are relatively cheap, easily available, and can be read by most physicians. Once PsA is suspected clinically, radiographs of the hands, feet, pelvis, spine, and other affected joints are done to look for changes suggestive of PsA. X-rays are also used to assess disease severity, as well as to follow disease progression. Radiographic changes generally reflect damage to the joints rather than acute inflammation. In early disease, X-rays of the hands and feet show soft tissue swelling around the joints involved. If dactylitis is present, soft tissue swelling will involve the whole finger or toe. In more severe disease, erosions develop near the joint margin and are markers of disease severity (Fig. 19-4). Erosions may be paramarginal, in contrast to RA were

Figure 19-4 Radiograph of the feet of a patient with psoriatic arthritis showing solitary large erosion at the head of the fourth metatarsal bone (*arrow*).

the erosions are usually marginal. In PsA erosions are often accompanied by new bone formation. The combination of erosions and new bone formation at joint margins is characteristic of PsA (Fig. 19-5). Following the development of erosions there may be joint space narrowing, and finally total joint destruction may occur, either total joint lysis and the so called "pencil-in-cup" change or complete bony bridging through the joint termed ankylosis (Fig. 19-6).

X-rays of the pelvis often show changes reflecting the presence of sacroiliitis. Earliest notable changes include widening of the joint space, which is often difficult to appreciate (eFig. 19-6.1 in online edition). Subsequently,

Figure 19-5 Radiograph of the hands of a patient with psoriatic arthritis showing erosions, joint space narrowing and new bone formation at the wrists, carpometacarpal, metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints.

erosions develop, followed by sclerosis and subsequent bony bridging across the joints, ultimately leading to complete fusion of the joint (eFig. 19-6.2 in online edition). X-rays of the neck and the back often show changes that reflect consequences of inflammation at the spinal joints. The earliest changes on lateral view of the spine include shiny vertebral corners, erosions, and squaring of vertebrae. This is followed by bone bridging, or marginal syndesmophytes, beginning from the ends of the vertebrae across the disc space. Complete bony bridging can occur. If most of the vertebrae are bridged, it is called "bamboo" spine. These changes closely resemble the changes in AS (Fig. 19-7). Often in PsA, the syndesmophytes can develop from sites away from the vertebral body. The presence of these "nonmarginal" syndesmophytes is characteristic of PsA (eFig. 19-7.1 in online edition). The changes described can at occur at any site—cervical and lumbar vertebrae are frequently involved. In the cervical spine, occasionally atlanto-axial subluxation may be present and can lead to serious consequences.

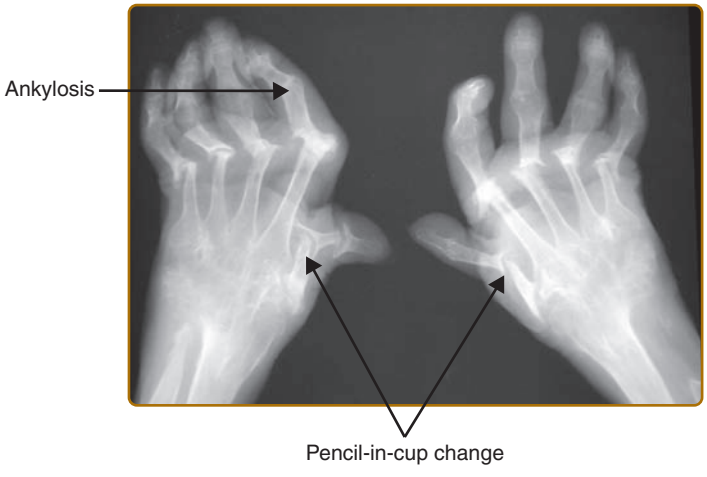

Figure 19-6 Advanced destructive changes in the hand joints including pencil-in-cup change and ankylosis in a patient with psoriatic arthritis.

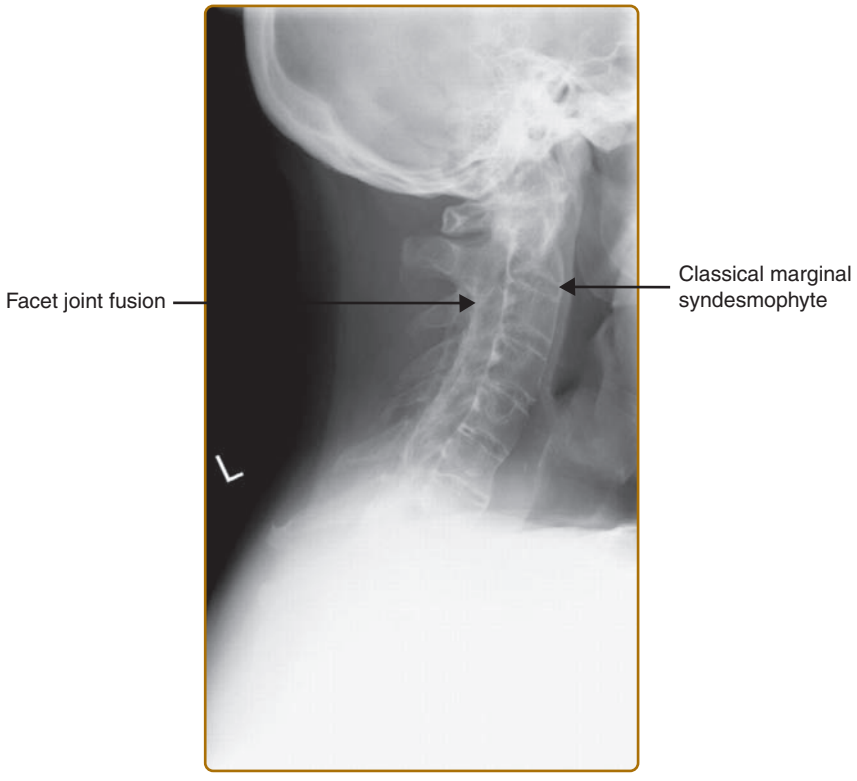

Figure 19-7 Lateral radiograph of the cervical spine showing anterior marginal syndesmophytes and fusion of the facet joints in a patient with psoriatic arthritis.

ULTRASOUND IMAGING. Ultrasound combined with Doppler evaluation, can detect active inflammation in joints and entheses. Ultrasound can also detect erosions before they appear on X-rays especially in the hand joints. It can also be used to guide injections into joints.[33]

MAGNETIC RESONANCE IMAGING (MRI). MRI scans along with contrast can detect active inflammation. MRI can also show erosions in the bone even before they are seen on plain X-rays.[34] Bone edema which often precedes the development of overt erosions is also detected easily. MRI scans are also very useful in detecting active inflammation in the spine and MRI changes are usually evident much before any abnormality is visualized on X-rays.[34] Thus, MRI evaluation is crucial in the diagnosis of early disease, especially affecting the spine.

COMPUTERIZED TOMOGRAPHY. CT scans are most useful when joints or the spine need to be evaluated in detail, especially when an MRI is unavailable or contraindicated. CT scans also give a detailed view of the joints. Bones are viewed better than in MRIs. However, CT scans involve considerable exposure to radiation.

COURSE AND PROGNOSIS

PsA has a variable course and prognosis. While some patients do well with small number of joints involved, and no significant damage, others progress very quickly, developed marked joint damage and disability.[35] Over 10 years of follow-up, 55% of the patients had at least five clinically damaged joints.[36] By the time patients present to a PsA clinic, 67% have at least one erosion.[31] Even in early disease, of 129 patients seen within 5 months of onset of symptoms 47% developed erosions within the first 2 years.[37] Factors associated with progression of joint damage include the number of actively inflamed and damaged joints at presentation, the ESR at presentation, and the number of actively inflamed joints at each visit.[38–41] There are patients with PsA who achieve remission, defined as no actively inflamed joints for 12 months.[42] In a longitudinal observation cohort 17.6% of the patients achieved remission, but only six patients had a complete remission with no actively inflamed joints, no damage, and off therapy. The period of remission lasted for 2.6 years, after which 52% of the patients flared. Thus, active disease must be treated aggressively, particularly in the presence of erosive changes. Quality of life and function of patients with PsA are reduced compared to the general population.[43,44] PsA patients have worse quality of life and function than patients with psoriasis alone.[45]

COMORBIDITIES. Patients with psoriasis and PsA have an increased prevalence of cardiovascular disease (CVD). In patients with PsA, the standardized prevalence ratio of hypertension, myocardial infarction, and angina is higher than the general population.[46–48] For other comorbidities, see Chapter 18.

MORTALITY IN PsA. Although population-based studies have shown that PsA is not associated with increased mortality, clinic-based studies have shown that patients with PsA have an elevated mortality risk, although the risk seems to have declined over the last decade.[49] The four leading causes of death are diseases of the circulatory or respiratory system, malignancies, and injuries/poisoning. Evidence of previously active and severe disease, as manifested by the prior use of medications and by radiologic changes as well as an elevated ESR at presentation, are prognostic indicators for death.[50]

EARLY DIAGNOSIS

PsA has an unpredictable clinical course. Radiographic damage can occur within 2 years of disease onset in almost half of patients with PsA, and the disease usually follows a chronic, progressive course.[37,51] With the availability of effective therapy it is hoped that early diagnosis will help prevent damage. Since cutaneous psoriasis precedes or occurs simultaneously with joint disease in 85% of patients with PsA, screening patients with psoriasis for PsA has the potential to help detect PsA early.[52]

Several screening tools have been recently developed.[53] The Psoriasis and Arthritis Questionnaire (PAQ) and its modification, Psoriatic Arthritis Screening and Evaluation (PASE) questionnaire, Psoriasis Epidemiology Screening Tool (PEST) questionnaire, and Psoriasis and Arthritis Screening Questionnaire (PASQ) were developed specifically to screen for PsA in patients with psoriasis, whereas the Toronto Psoriatic Arthritis Screen (ToPAS) was developed for use in the general population as well as in patients with psoriasis. The PASE, PEST, and ToPAS questionnaires have high sensitivity and specificity. Imaging studies using scintigraphy, MRI, and ultrasound have also shown abnormalities in subjects with psoriasis, who do not have overt PsA.[19,54,55] Soluble biomarkers have also been evaluated as a marker for screening for PsA in patients with psoriasis; C-reactive protein and Matrix Metalloproteinase-3 have shown promise.[56,57] Circulating osteoclast precursors are elevated in patients with PsA and psoriasis, and decrease with anti-TNF therapy.[58] In prospective studies, clinical predictors for PsA in patients with psoriasis include presence of scalp or intergluteal/perianal psoriasis, ≥3 affected sites, and presence of nail dystrophy.[59]

DIFFERENTIAL DIAGNOSIS. A number of arthritic conditions may occur in patients with psoriasis and these must be differentiated from PsA (Table 19-1). Since psoriasis is a common condition, occurring in 2%–3% of the population, and rheumatoid arthritis, the most common form of inflammatory arthritis, may occur in 1% of the population, the co-occurrence of rheumatoid arthritis and psoriasis would be expected by chance alone in 2 in 10,000 people. Since RA, like PsA is inflammatory in nature, the differentiation may be difficult. Osteoarthritis, which is the commonest form of arthritis, occurs in about 5% of the population and it may coexist with psoriasis. While osteoarthritis is not usually an inflammatory form of arthritis, it affects the DIP joints, a site commonly affected in patients with PsA. Patients with PsA also have increased prevalence of hyperuricemia and gout, and occasionally gouty arthritis may mimic PsA. PsA also has to be distinguished from other SpA.[60]

TABLE 19-1
Differential Diagnosis of Arthritis in Patients With Psoriasis

Manifestation	PsA	RA	Gout	Osteoarthritis
Age at onset	36s	40s	Any age	Over 50
M:F	1.1:1	1:3	3:1	1:1
Joint affected	Proximal and distal interphalangeal joints, small and large	Proximal interphalangeal and metacarpophalangeal joints, small and large	Toes, knees ankles	Weight bearing, distal hands
Symmetry	Usually asymmetric	Symmetric	Usually asymmetric	May be symmetric
Redness over joint	Yes	No	Yes	No
Spinal disease	Yes, inflammatory	No	No	Yes, degenerative
Dactylitis	Yes	No	Podagra	No
Enthesitis	Yes	No	No	No
Nodules	No	Yes, extensor surfaces	Tophi	Heberden's and Bouchard's
Psoriasis	100%	1–3%	1–3%	1–3%
Nail lesions	87%	No	No	No

The diagnosis of PsA is considered when a patient presents with inflammatory musculoskeletal disease. This may be in the form of arthritis, dactylitis, enthesitis, or spondylitis. The presence of cutaneous psoriasis is an important clue and this should be looked for carefully, especially in hidden regions such as the scalp, umbilicus, below breasts, or in the natal cleft. Nails should be carefully inspected for changes of nail psoriasis as the evidence of psoriasis may be present in the nail only. The pattern of involvement in PsA is often asymmetric. This is not usually the case in RA, which tends to be symmetric. A characteristic pattern of PsA is the "ray" pattern—involvement of all joints in a particular finger or toe, as opposed to joints beside one another. The "ray" distribution is typical for PsA, and is not usually seen in either RA or OA. The presence of dactylitis is an important feature. It is a typical feature for PsA and is not seen in RA. The only other arthritic condition that may manifest with dactylitis is reactive arthritis, which is not associated with psoriasis but where psoriasis-like lesions can occur (see Chapter 20). Spinal involvement presenting as inflammatory neck or back pain with or without restriction of mobility is present in about half of the patients with PsA, especially in well-established disease. It is not a feature of RA. The presence of spinal and peripheral arthritis makes the diagnosis of PsA very likely, and virtually rules out RA.

The diagnosis of PsA may sometimes be made even in the absence of psoriasis. If the above characteristic features are present even without cutaneous psoriasis, the diagnosis may be considered. The diagnosis is especially likely if there is a family history of psoriasis or PsA. The diagnosis may also be made if characteristic radiographic features such as "pencil-in-cup" changes, bony ankylosis, new bone formation close to sites of erosions, and nonmarginal syndesmophytes are present.

Laboratory tests have only a minor role to play in making the diagnosis of PsA. Characteristically, rheumatoid factor test is negative, although a positive test does not rule out the diagnosis. Elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) is present only in about half of the patients. However, these are markers of severity. ESR is a predictor of progression of joint damage and mortality, and CRP is a predictor of progression of radiological damage.[38,41,50] Other tests usually done are routine tests such as blood counts, and liver and kidney function tests. Although these tests are not important in making a diagnosis, they give important information on the presence of comorbid conditions and are important in monitoring treatment. If synovial fluid can be aspirated from the joint, it can be tested to confirm inflammation and to rule out other causes of inflammation like infection and crystals. Synovial biopsies, usually done using an arthroscope, show evidence of chronic inflammation, and are sometimes required to rule out chronic infection. As outlined above, imaging is most important in making a diagnosis of PsA.

TREATMENT

Pharmacotherapy is the cornerstone of management of PsA. Drug therapy depends on the severity and stage of the arthritis and severity of skin disease. Patients should ideally be under the care of a team of health professional comprising rheumatologists, dermatologists, physiotherapists, and occupational therapists. However, if the primary problem is skin disease and the arthritis is mild, the subject may be managed by a dermatologist after a complete assessment by a rheumatologist. Periodic assessment by a rheumatologist in such cases would be ideal. On the other hand, if the primary problem is joint disease, the rheumatologist should primarily manage the patient, with the dermatologist confirming the diagnosis of psoriasis and providing input if skin disease remains poorly controlled.

Drug therapy for psoriatic arthritis may be classified as in Box 19-3.

BOX 19-3 DRUG THERAPY FOR PsA

- Symptom modifying therapy
- Therapy with "Disease modifying" Antirheumatic Drugs (DMARDs)
- Therapy with biologic agents

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

NSAIDs are useful in the treatment of PsA and give relief to symptoms such as pain and stiffness. However, NSAIDs do not prevent disease progression, and may worsen skin lesions. They may be used as sole therapy in treating mild PsA and for symptomatic management of pain, inflammatory swelling and morning stiffness. With the recent reports of increased risk of myocardial infarction and stroke with long term use of COX-2 inhibitors, the use of nonselective NSAIDs like naproxen, ibuprofen, diclofenac, indomethacin, or aspirin (with or without misoprostol/H2-blockers/proton pump inhibitors) is preferable. If symptoms persist, or if more joints accrue after adequate trials with two different NSAIDs, Disease Modifying Antirheumatic Drug (DMARD) use should be considered.

CORTICOSTEROIDS

Corticosteroid therapy in the form of intra-articular injections of corticosteroids (triamcinolone, methylprednisolone) into the joints either at the bedside in the clinic or under ultrasound guidance is often used for rapid relief of symptoms when only one or a few joints are affected. This form of therapy has been proven effective in PsA.[66] Oral corticosteroids are used occasionally for symptom relief when there is polyarthritis or when there is inadequate response to NSAIDs and there is significant disability. However, glucocorticosteroids need to be used with extreme caution with slow taper, since psoriasis worsens in many instances and could occasionally evolve into more severe forms like pustular psoriasis. Treatment with oral steroids is usually resorted to as short-term therapy, until other

longer acting drugs take effect. Long-term steroid therapy is associated with significant toxicity such as high blood pressure, cataracts, weight gain, diabetes, osteoporosis, and avascular necrosis of bone.

DISEASE MODIFYING DRUG THERAPY

There is a paucity of clinical trials with traditional disease modifying agents (DMARDs) in PsA.[67] A recently published systematic review and meta-analysis of efficacy and toxicity of DMARDs and biological agents for PsA showed that treatment was more effective than placebo (RR = 0.35; 95% CI 0.25, 0.49) but caused more toxicity (RR = 2.33; 95% CI 1.61, 3.37).[67]

METHOTREXATE. Although methotrexate is used most commonly to treat PsA, oral methotrexate (MTX) has been evaluated in only one RCT.[68] This 12-week placebo-controlled trial of low-dose oral MTX given at a dose of 2.5–5.0 mg every 12 hours in three consecutive doses per week was terminated early after recruiting only 37 patients. MTX significantly improved physician global assessment, but there were no significant effects on tender and swollen joint scores, patient global assessment, and ESR. However, a retrospective analysis of PsA patients treated with MTX for 24 months therapy compared to a matched cohort not thus treated did not show any difference in radiographic progression scores in the two groups.[69] A reappraisal from the same cohort showed that in the last decade treatment with MTX has changed to include patients with shorter disease duration and less damage, at increased dose, and that there may be better response with less progression of damage.[70] In spite of lack of evidence from RCTs, based on efficacy in RA and psoriasis, rheumatologists have been using MTX as a first-line DMARD. Patients on MTX require regular monitoring of blood counts, liver function tests, and creatinine. Significant test abnormalities require adjustment of dose or treatment cessation. Although liver toxicity can occur in the absence of abnormal serum liver function tests, regular liver biopsies are not typically ordered by rheumatologists as they may be by dermatologists. The occurrence of liver fibrosis and cirrhosis seem to be higher in patients with psoriasis when compared to patients with RA, reflected in the differing guidelines in rheumatology and dermatology. There is increased prevalence of obesity, metabolic syndrome and type-2 diabetes in patients with psoriasis. Patients with psoriasis treated with MTX and having risk factors for liver disease, especially diabetes type 2 or obesity, are at higher risk of developing severe liver fibrosis compared to those without such risk factors, even when lower cumulative methotrexate doses are given.[71] These risk factors are important for nonalcoholic steatohepatitis even when there is no exposure to MTX. Thus it is unclear whether weekly low-dose MTX independently increases risk for cirrhosis. In clinical practice, it will thus be prudent to get serial liver biopsies after a cumulative MTX dose of 1.5 g especially in those patients who have risk factors for fibrosis and cirrhosis such as obesity, metabolic syndrome, type 2 diabetes, viral hepatitis, and significant alcohol use.

SULFASALAZINE. Five RCTs have evaluated sulfasalazine (SSZ) in the treatment of PsA; its benefits were moderate.[67] In the largest of these, 221 PsA patients were treated with SSZ, 2 g/day, for 36 weeks.[72] The psoriatic arthritis response criteria (PsARC) developed specifically for this study showed statistically significant improvement in the treatment group (57.8% for SSZ compared with 44.6% for placebo, $P = 0.05$). But, the only individual measure within the responder index to do so was the patient global assessment, and longitudinal analysis revealed only a trend favoring SSZ treatment. A systematic review revealed that the effect size for SSZ was less than 0.2, the level required to confirm response.[73] SSZ has not been shown to prevent progression of joint damage.[74]

CYCLOSPORINE A. Cyclosporine A (CsA) is effective in controlling psoriasis. A three-arm RCT comparing CsA 3 mg/kg/day added to standard therapy, SSZ 2 g/day added to standard therapy, and standard therapy alone, showed that CsA was well tolerated and was more efficacious that standard therapy and SSZ.[76] In the most recently published RCT, CsA was compared to placebo as an add-on treatment, in patients with PsA demonstrating an incomplete response to MTX monotherapy. There was significant improvement at 12 months in the swollen joint count, C-reactive protein, PASI, and synovitis detected by high-resolution ultrasound. There was no improvement in the Health Assessment Questionnaire or pain scores.[77] Thus, CsA has a role in the management of PsA either on its own or as an add-on treatment to MTX. However, it is not well tolerated. Its effect on joint damage has not been assessed.

GOLD. Although not shown to protect from progression of joint damage, Gold has been used in the treatment of PsA, with intramuscular gold being more efficacious.[78] With significant concern about toxicity, slow mode of action, problems with availability, and availability of more effective drugs, it is seldom used nowadays.

ANTI-TNF AGENTS. (See also Chapter 234.) Anti-TNF agents have revolutionized the management of PsA. There are currently four agents marketed for the treatment of PsA. In the placebo-controlled portion of the phase 3 Etanercept trial in PsA ($n = 205$), ACR 20 response was achieved by 59% of Etanercept treated patients versus 15% in the placebo group ($P < 0.0001$).[81] Skin response, as measured by the PASI score in patients with body surface area (BSA) involvement at least 3% showed a 75% improvement in 23% and 3%, respectively at 24 weeks ($P = 0.001$). Measures of function and quality of life significantly improved. Significant inhibition of progression of joint space narrowing and erosions was shown. In the open label extension of this study, at 2 years, effectiveness was maintained.

The drug was well tolerated. A more recent trial compared Etanercept 50 mg twice weekly for 12 weeks, followed by 50 mg weekly, compared with 50 mg weekly throughout in 752 patients with psoriasis affecting >10% of body surface area and at least two swollen and tender joints.[82] There was no difference in the response to arthritis at week 12 or 24, although the skin response was better at week 12. No difference in skin response was evident at week 24. Dactylitis and enthesitis also showed improvement from baseline.

In the IMPACT II phase 3 study, Infliximab in 200 PsA patients showed significant benefit. At week 14, 58% of Infliximab-treated patients and 11% of placebo patients achieved an ACR 20 response ($P < 0.001$). Presence of dactylitis and enthesitis decreased significantly in the Infliximab group. At 24 weeks, PASI 75 was achieved by 64% of the evaluable treatment group and 2% of the placebo group ($P < 0.001$).[83] Infliximab also significantly inhibits radiographic progression, and improves function and quality of life.[83,84]

In the phase 3 Adalimumab Effectiveness in Psoriatic Arthritis Trial (ADEPT), 313 subjects were studied.[85] At 12 weeks, 58% of patients receiving Adalimumab 40 mg every other week achieved ACR 20 response compared with 14% of patients receiving placebo ($P < 0.001$). PASI 75 was achieved by 59% in the Adalimumab-treated group and 1% in the placebo group ($P < 0.001$) in those 69 patients in each group who were evaluable for PASI scoring. Radiographic progression of disease was significantly inhibited, and there was improvement in disability and quality of life scores.[85]

The latest anti-TNF agent to be approved for PsA is Golimumab. In the GO-REVEAL trial, 405 patients active PsA were randomly assigned to receive subcutaneous injections of placebo (Golimumab 50 mg or Golimumab 100 mg every 4 weeks.[86] At week 14, 51% of patients receiving Golimumab 50 mg and 45% of patients receiving Golimumab 100 mg achieved an ACR 20 response, compared with 9% of patients receiving placebo ($P < 0.001$ for all comparisons). Among the 74% of patients in whom at least 3% of the body surface area was affected by psoriasis at baseline, 40% of those in the Golimumab 50 mg group and 58% of those in the Golimumab 100 mg group had at least 75% improvement in the PASI at week 14, compared with 3% of placebo-treated patients ($P < 0.001$ for both doses). Improvement was also demonstrated in the HAQ score, SF-36, NAPSI, and enthesitis. There was no difference in the arthritis outcomes between the two doses of Golimumab and it is marked only for PsA at a monthly dose of 50 mg. Significant improvement in dactylitis was seen only in the 100 mg dose, although a trend was evident with the 50 mg dose.[86] Golimumab was also shown to inhibit progression of radiographic damage.[87]

Thus, the anti-TNF agents have shown the greatest efficacy of any treatment to date in the various clinical aspects of PsA. Their efficacy in joint disease activity, inhibition of structural damage, function, and quality of life are similar, and they are well tolerated, with injection site reactions being the most significant. On comparing with traditional DMARDs, anti-TNF agents had the best efficacy/toxicity ratio (number needed to harm/number needed to treat = 0.25); tolerability was least with gold and leflunomide, and poor with SSZ.[67] There are no direct head-to-head trials comparing the efficacy of various anti-TNF agents in PsA. However, a meta-analysis of anti-TNF RCTs showed that the three anti-TNF agents [(1) Infliximab, (2) Etanercept, and (3) Adalimumab] were significantly more effective than placebo.[88] There were no significant differences between anti-TNF agents and placebo in the proportions of patients experiencing withdrawal for any reason, due to adverse events, serious adverse or upper respiratory tract infections. Pooled rates for injection site reactions were significantly higher for Adalimumab and Etanercept than for placebo, but there was no significant difference in the proportion of patients experiencing infusion reactions with Infliximab compared against placebo. Indirect analysis did not demonstrate any significant differences between the anti-TNF agents.[88]

Data from biologics registries that have been maintained in Europe suggest that drug survival (the length of time a patient continues to take a particular drug) of anti-TNF agents is significantly higher in SpA compared to RA.[89,90] Concomitant MTX was associated with better drug survival in RA and PsA, but not for AS.[90,91] There is a tendency toward shorter persistence with treatment for Infliximab when compared with Etanercept and Adalimumab.[91,92] Risk factors for drug discontinuation include female sex, comorbidity, using Infliximab rather than Etanercept, and absence of concomitant therapy with MTX.[91,92]

USTEKINUMAB. (See also Chapter 234.) Ustekinumab is a human monoclonal antibody that inhibits receptor binding of IL-12 and IL-23 has been shown to be very efficacious in treating psoriasis and is marketed for this indication.[93] A phase 2 trial in 146 subjects with PsA showed that at week 12, 42% of patients in active arm and 14% in the placebo arm achieved an ACR 20 response ($p = 0.0002$).[94] Of 124 participants with psoriasis affecting 3% or more body surface area, 52% in the active arm and three of 5% in the placebo arm had a PASI 75 response ($p < 0.0001$). The drug was well tolerated.[94] A larger phase 3 trial is underway.

ANTI T CELL AGENTS. (See also Chapter 234.) Alefacept is a fully human lymphocyte function associated antigen-3/immunoglobulin G1 fusion protein that targets memory-effector T cells is an effective therapy for psoriasis.[95] In combination with MTX, Alefacept is efficacious in PsA. In a phase 3 trial with 185 patients, 54% of patients in the Alefacept plus MTX group achieved an ACR 20 response, compared with 23% of patients in the placebo plus MTX group ($P \leq 0.001$) at week 24.[96] In patients with psoriasis involving ≥3% BSA ($n = 87$), a PASI 50 response at week 14 was achieved by 53% of patients receiving Alefacept plus MTX compared with 17% of those receiving placebo plus MTX ($P < 0.001$).[96] Alefacept in combination with MTX is thus a treatment option in patients failing standard therapy.

Abatacept (CTLA4-Ig) is a recombinant human fusion protein that binds to the CD80/86 receptor on an antigen-presenting cell, thus blocking the second

signal activation of the CD28 receptor on the T-cell. It is approved for use in RA.[97] Results from a phase 2 study using Abatacept in PsA show that Abatacept at 10 mg/kg significantly improved ACR 20 and physical function in PsA patients. Abatacept treatment also resulted in less joint damage by MRI evaluation.[98]

SURGICAL PROCEDURES

There are few studies addressing surgery in patients with PsA. It has been reported that about 7% of the patients with PsA require surgery and that the likelihood of surgery increased with disease duration.[99] The average disease duration at the time of surgery was 13 years. The most common surgical procedure was total hip replacement followed by total knee replacement. Joint replacement in the metacarpophalangeal joints was also performed, followed by fusion surgery for the fingers, wrists, and ankles. Few patients had synovectomies, including knee, wrist, and elbow. The majority of the patients had only one procedure, but in 28% several procedure were performed. The upper and lower extremities were involved in a similar number of patients with few patients having both upper and lower extremity surgery. Surgery was predicted by the number of actively inflamed joints and the extent of X-ray damage at presentation to the clinic. Patients with the highest number of severely affected joints both clinically and on radiographs were more likely to have surgery. Although patients who had surgery had more severe disease, their health outcomes were not worse than those who did not have surgery.[99] In another study of the type and outcome of reconstructive surgery for different patterns of psoriatic arthritis over a 10-year period was studied.[100] The patients were divided into three groups: (1) distal joint involvement, (2) oligoarticular, and (3) polyarticular. It was shown that the majority of patients had polyarticular disease. The majority of the operations done in this group of patients included complex hand and foot reconstruction, followed by hip replacements, and surgical fusion of different joints. In the oligoarticular group most of the procedures involved joint replacement, usually the hip or knee. Patients with distal arthritis had fusions in the distal joints. Patients with polyarticular disease had lower level of physical functioning according to the scores on the physical function domain of a quality of life questionnaire. Patients with severe axial arthritis may develop marked deformity of the spine and on occasion require surgery to correct this deformity. While there are no reported studies specifically describing spinal surgery in patients with PsA, the procedures are similar to those performed in patients with AS.

RECOMMENDATIONS FROM GRAPPA

Based on formal literature reviews of therapies for peripheral joints, spine, skin and nails, enthesitis, and dactylitis, the GRAPPA group has developed a treatment grid categorizing each domain as mild, moderate, or severe based on measures of disease severity and impact on function and quality of life in order to help clinicians with treatment decisions.[101] GRAPPA recommends that all domains of the disease be considered to define severity of "psoriatic disease." The worst individual domain should guide the management of all domains of PsA. Thus, if the skin domain is severe, but the peripheral arthritis is mild, the patient is classified as heaving severe disease and treated for severe psoriasis as appropriate. GRAPPA has also suggested treatment strategies applicable to patients worldwide.

Chapter 20 :: Reactive Arthritis

:: John D. Carter

REACTIVE ARTHRITIS AT A GLANCE

- Reactive arthritis is one of the spondyloarthritides. It is an inflammatory syndrome that typically begins 1–4 weeks after certain genitourinary or gastrointestinal infections.
- Most patients do not have the "classic triad" of symptoms (synovitis, urethritis, and conjunctivitis) and other organs are often involved (namely the skin).
- Key clinical features are asymmetric arthritis of a few joints, most often large joints of the lower extremities, often accompanied by axial arthritis and enthesitis typically at the Achilles tendon or plantar fascia and sacroiliac joints.
- Psoriasiform lesions on the soles—keratoderma blenorrhagicum—or penis—circinate balanitis—occur in one-third of patients and inflammatory eye disease is present in a similar proportion. Urethritis may occur with or without urogenital infection.
- HLA-B27 appears to increase disease susceptibility and chronicity of reactive arthritis, but recent data suggest it might portend more fulminate symptoms thereby serving as a diagnostic bias.
- *Chlamydia, Salmonella, Campylobacter, Shigella,* and *Yersinia* are definitive triggers of reactive arthritis, but other infections may also act as initiators.
- Although reactive arthritis often is self-limited in weeks to months, as many as 30%–50% of patients will develop chronic disease that often waxes and wanes.

ETIOLOGY AND PATHOGENESIS

TRIGGERING ORGANISMS

Bacteria that commonly cause ReA are *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, and *Chlamydia trachomatis*. Indeed, these organisms represent the definitive triggers of ReA; however many other infectious agents have been implicated as potential causes (Box 20-1). *Chlamydia trachomatis* (Ct) is the most common etiologic agent causing ReA in the United States.[14,22] Despite the obvious difference of initial route of infection (i.e., gastrointestinal vs. genitourinary), another distinction exists. The postdysentery form of ReA is always preceded by a symptomatic infection, and recent data suggest the more severe the initial gastrointestinal infection, the more likely ReA develops.[23–25] However, an initial Ct infection is often asymptomatic.[26–28] Recent data suggest that an initial asymptomatic Ct infection is a common cause of ReA.[29] In this study, the majority of patients diagnosed with uSpA, because of no known preceding infection prior to the onset of their arthritis, were found to be polymerase chain reaction (PCR) positive for Chlamydiae on synovial tissue analysis. This is in keeping with previous data suggesting that 78% of subjects who develop ReA after a venereal infection had an asymptomatic infection.[30] A number of published studies also indicate that *Chlamydophila (Chlamydia) pneumonaie* (Cpn), a related respiratory pathogen, is another causative agent in ReA, albeit at a lower frequency.[31–33]

Chlamydiae are Gram-negative, obligate intracellular organisms. The attack rate of ReA after a Ct infection is approximately 5%.[30] Synovial tissue analyses from patients affected with postchlamydial ReA have shown that these organisms traffic from the initial site of infection to the synovium. These synovium-based Chlamydiae exist in a morphologically aberrant but metabolically active viable state termed chlamydial persistence.[34,35] The pattern of gene expression is attenuated and significantly different than that seen during normal active infection. For example, during persistence of Ct expression of the major outer membrane protein (*omp1*) gene and several genes required for the cell division process are severely downregulated. This is coupled with differential regulations of the three paralog genes specifying *Chlamydia trachomatis* heat shock proteins (HSP)-60 [(1) Ct110, (2) Ct604, and (3) Ct755].[36] The exact role that these synovium-based persistent Chlamydiae play in terms of disease pathogenesis or disease propagation is not completely understood. Of note, it has been demonstrated that these same persistent Chlamydiae traffic to other end organs, specifically the skin in patients with suspect keratoderma blenorrhagicum.[37]

Other recent data relating to *Chlamydia*-induced ReA force us to reconsider our traditional paradigms. Because these pathogens are responsible for genital infections, it was logical to assume that the genital strains of *C. trachomatis* were responsible for triggering ReA. However, there are several serovars of *C. trachomatis*, specifically serovars A through K. Serovars A, B, and C are ocular (trachoma) serovars and the remainders (serovars D through K) are genital. Remarkably, a recent study analyzing the chlamydial serovars of 36 subjects with known *C. trachomatis*-induced ReA demonstrated that all 36 synovial tissue samples were positive for the ocular serovars, not the genital serovars.[38] It

BOX 20-1 TRIGGERING MICROBES OF REACTIVE ARTHRITIS

DEFINITE CAUSES

Postvenereal

Chlamydia trachomatis

Postenteric

Salmonella (*S. enteritidis*, *S. typhimurium*, *S. bovismorbificans*, *S. blockley*)
Shigella (*S. flexneri*, *S. dysenteriae*, *S. sonnei*, *S. boydii*)
Campylobacter (*C. jejuni*, *C. coli*)
Yersinia (*Y. enterocolitica*, *Y. pseudotuberculosis*)

PROBABLE CAUSES

Chlamydophila (Chlamydia) pneumoniae
Ureaplasma urealyticum
Bacille Calmette-Guérin (intravesicular)

POSSIBLE CAUSES

Bacillus cereus
Brucella abortus
Clostridium difficile
Escherichia coli
Helicobacter pylori
Hafnia alvei
Lactobacillus
Neisseria meningitidis serogroup B
Pseudomona
Intestinal parasites (*Strongyloides stercolis*, *Taenia saginata*, *Giardia lamblia*, *Ascaris lumbricoides*, *Filariasis*, and *Cryptosporidium*)

OTHER TYPES OF INFLAMMATORY ARTHRITIS IN WHICH BACTERIA MAY PLAY A CAUSATIVE ROLE

Borrelia burgdorferi (Lyme disease)
Propionbacterium acnes (SAPHO)
Streptococcus sp. (poststreptococcal reactive arthritis)
Trophyrema whippelii (Whipple's disease)

Reprinted with permission from Carter JD: Reactive arthritis: Defined etiologies, emerging pathophysiology, and unresolved treatment. *Infect Dis Clin North Am* **20**:827, 2006.

is known that genital infection with the ocular strains do occur, but are rare.[39,40] The infrequent rate of genital infections with the ocular strain might explain the low attack rate of ReA in patients with acute chlamydial infections.

HOST FACTORS

Reactive arthritis represents the classic interplay of host and environment. The environmental triggers outlined above play and undeniable role in disease genesis; the concept of bacterial persistence lends speculative support that these pathogens might also play a role in disease propagation. Certain bacterial serovars or species might be particularly arthritogenic or more prone to dissemination. However, genetic susceptibility also clearly plays a role. Because ReA is one of the spondyloarthritides, much of the focus on host genetics has centered on HLA-B27. There are also data indicating that patients with HIV are at increased risk for ReA and the symptoms can improve with antiretroviral HIV therapy.[57]

The prevalence of HLA-B27 and reactive arthritis varies around the world.[58] In Caucasian populations, HLAB27 is present in 7%–9% of individuals. Older literature suggested that as many as 70%–80% of patients with ReA were HLA-B27 positive.[59,60] However, several large epidemiological studies of ReA now dictate that, in reality, about 30%–50% of ReA patients are positive for this antigen.[45,61–67] More recent data even suggest there might be no association with HLA-B27 and ReA.[25,47,64] The vast majority of data regarding the prevalence of HLA-B27 in ReA comes from epidemiological studies of postenteric ReA after outbreaks with certain enteric pathogens. Therefore, the true prevalence of HLA-B27 in postchlamydial ReA is less well defined.

The possibility exists that HLA-B27 plays more of a role with phenotypic disease expression rather than a true genetic susceptibility locus. Several large ReA studies demonstrate that HLA-B27 positive patients have more severe symptoms, thereby making the condition more clinically apparent.[23] This haplotype might also increase one's risk for developing the complete triad of symptoms.[68] It should also be noted that the variation in the prevalence of HLA-B27 in various studies described above could, at least in part, be explained by the potential role that HLA-B27 plays on phenotypic expression. The studies cited above suggesting that HLA-B27 has little to no role in disease susceptibility include patients with milder symptoms, whereas the previous studies demonstrating a higher HLA-B27 prevalence only include patients with more fulminate symptoms sometimes requiring the complete triad of symptoms.

Whether HLA-B27 is more important in disease susceptibility or clinical expression, it clearly plays a role in ReA. Many theories exist regarding its pathophysiologic role, but none are proven. Since HLA-B27 is a Class I histocompatability antigen, it has been postulated that HLA-B27 presents arthritogenic microbial peptides to T cells stimulating an autoimmune response, so called molecular mimicry.[69] Conversely, B27 itself may serve as the autoantigen that is targeted by the immune system.[70] It is also possible that exposure to the triggering bacteria may subvert self-tolerance to the B27 antigen.[71] Another theory suggests that the role of HLA-B27 may be to enhance invasion of the causative organisms into human intestinal epithelial cells in patients with postenteric ReA.[72] Vast data demonstrate that misfolding of HLA-B27 can lead to the unfolded protein response enhancing the production of interleukin-23;[73] however this unfolded pro-

tein response has not been definitively linked to ReA. HLA-B27 has multiple alleles that could influence host response and disease susceptibility. One study suggests that although HLA-B*2705 is the most common allele observed in B27-positive ReA patients, this allele is seen less frequently than in the other SpA's and in B27 healthy controls.[74]

While HLA-B27 is important to pathogenesis in ReA, it is not the sole determinant. Clearly patients who are HLA-B27 negative can develop ReA. It has been suggested that HLA-B*5703 increases the risk for the classic triad of symptoms in patients who develop ReA.[75] Gene expression analyses suggest that proangiogenic factors account for genetic susceptibility of ReA.[76] Much remains to be learned about other HLA loci or even non-HLA genes that might be important in the pathophysiology of ReA.

PATHOPHYSIOLOGY

It is apparent that the causative bacteria of ReA are incorporated intracellularly, either in-part or in-whole, then taken from the site of initial infection and trafficked to the synovium. However, what governs this process is not yet evident. It is also not clear if their presence in the affected organs represents a trigger for an autoimmune response, or if these organisms are the source for the inflammatory process. It appears that this phenomenon of cellular uptake, trafficking, and host tolerance is multifactorial in nature.

Although the causative organisms are intracellular pathogens, the process of cellular uptake is not entirely apparent. Indeed the specific mechanisms for cellular uptake of these microbes are probably different for each organism. In the case of Chlamydiae, the quest to find a specific extracellular ligand has been unsuccessful. Intriguing recent data suggest that there might not be a specific chlamydial ligand, rather these pathogens might utilize a different ligand entirely. Apolipoprotein E (ApoE4) that is adherent to the surface of chlamydial elementary bodies (EB) attaches to the host cell low-density lipoprotein (LDL) receptor family carrying the EB with it.[77] However, this only appears to be true of *C. pneumoniae*, not *C. trachomatis*. In the case of *Salmonella*, type 1 fimbriae mediate the attachment of this organism to the cell leading to internalization.[78]

Toll-like receptors (TLR) are a key component of the innate immune system. Because they are among the first line of defense against microbes and they recognize extracellular pathogens, they could play a role in ReA. All of the definitive triggering organisms are Gram-negative with a lipopolysaccharide (LPS) component to their cell wall, and TLR-4 recognizes LPS. TLR-4 deficient mice exposed to *Salmonella* demonstrate dramatically increased bacterial growth and demise.[79] Other animal data have shown that effective host clearance of Ct depends on appropriate TLR-4 expression by neutrophils.[80] However, recent human data suggest that TLR-2, not TLR-4, is important in determining ReA disease susceptibility after a *Salmonella* infection.[81]

In terms of cytokine response in ReA, it appears that both Th1 and Th2 are important, but the Th2 pathway predominates. Although ReA patients have higher serum TNF-α (Th1) than normal controls,[82] lower levels of TNF-α have been demonstrated in ReA compared to other types of inflammatory arthritis.[83–85] Synovial fluid analyses from patients with ReA demonstrate higher levels of IL-10 and lower levels of TNF-α and IFN-γ (favoring a Th2 profile).[84,85] Interestingly, in terms of postchlamydial ReA, lower levels of these same two cytokines (TNF-α and IFN-γ) have been associated with increased chlamydial replication and overall bacterial burden in vitro.[86–88] The suppression of Th1 cytokines is likely mediated through suppression of IL-12 synthesis.

Data also exist suggesting that these cytokine levels can change over time. ReA patients with a disease duration of greater than 6 months secreted significantly less TNF-α.[83] Temporal relationships of these different Th1 and Th2 cytokines might also be important in disease manifestations. Slight changes in the Th1/Th2 balance may explain the relapsing course that is frequently seen chronic ReA. Animal data also suggest that blunting of the initial cytokine response of TNF-α, IFN-γ, and Interleukin-4 (IL-4) to an acute chlamydial infection leads to decreased bacterial clearance.[89] Therefore, lower initial responses of these Th1 cytokines may increase the likelihood of developing ReA. These animal data provide an interesting potential correlate to the fact that asymptomatic chlamydial infections in humans can often lead to ReA.

CLINICAL MANIFESTATIONS

In spite of the fact that ReA has several distinct etiologic agents and the apparent differences in the pathophysiology depending on the triggering microbe, the clinical features of ReA are congruent regardless of the initiating infection. The clinical syndrome that encompasses ReA can involve many different organ systems, although it has a predilection for the synovium, urethra, eye, and the skin (Box 20-2). The symptoms start within 1–4 weeks of the initial infection. However, as stated with Chlamydiae, the inciting infection could be asymptomatic obfuscating the diagnosis. It has traditionally been felt that the vast majority of cases of ReA resolve spontaneously within weeks to months, but more recent data suggest that 30%–50% of cases can become chronic.[45,61–67] One series suggested that 63% of patients develop chronic symptoms.[18] In general, if a patient experiences symptoms of longer than 6 months duration, then they are felt to have chronic disease (Box 20-3). Typically, patients have more significant symptoms during the acute phase; these can include constitutional symptoms (malaise, fatigue) and fever. If the symptoms persist, then the long-term manifestations tend to be milder. In these chronic cases, it is not unusual for the symptoms to wax and wane.

ReA is often misdiagnosed or underdiagnosed. The reasons are varied, but an overreliance on the "classic" clinical triad of symptoms lends to this underdiagnosis. Some of the earliest descriptions of ReA included

BOX 20-2 CLINICAL MANIFESTATIONS OF ReA

ACUTE SYMPTOMS

Articular

Most commonly present with oligoarthritis, but can also present with polyarthritis or monoarthritis

Axial	*Frequently involved* Sacroiliac joints Lumbar spine *Occasionally involved* Thoracic spine (usually seen in chronic ReA) Cervical spine (usually seen in chronic ReA) Cartilaginous joints (symphysis pubis; sternoclavicular and costosternal joints)
Peripheral	*Frequently involved* Large joints of the lower extremities (especially knees)
Dactylitis (sausage digit)	Very specific for a spondyloarthropathy

Enthesitis

Hallmark feature: inflammation at the transitional zone where collagenous structures such as tendons and ligaments insert into bone.

Common sites: plantar fasciitis, Achilles tendonitis; but any enthesis can be involved.

Mucosal

Oral ulcers (generally painless)

Sterile dysuria (occurs with both postvenereal and postdysentery forms)

Cutaneous

Keratoderma blenorrhagicum	Pustular or plaque-like rash on the soles and/or palms Grossly and histologically indistinguishable from pustular psoriasis Can also involve nails (onycholysis, subungal keratosis, nail pits), scalp, extremities
Circinate balanitis	Erythema or plaque-like lesions on the shaft and/or glans of penis

Ocular

Conjunctivitis	Typically during acute stages only
Anterior uveitis (iritis)	Often recurrent
Rarely described	Scleritis, pars planitis, iridocyclitis, and others

Cardiac

Pericarditis (uncommon)

patients with this triad of symptoms. For many years, clinicians felt this triad was necessary for the diagnosis. In 1976, the concept of "Incomplete Reiter syndrome" was introduced describing a case series of 13 patients, who were predominately HLA-B27 positive, and presented with oligoarthritis, heel pain, periostitis, dactylitis, and mucocutaneous lesions, but no urethritis or conjunctivitis.[90] It is now apparent that the majority of cases do not involve the three classic organ systems.

ARTICULAR

ReA nearly always involves an inflammatory arthritis. It is unclear if some patients with other symptoms of ReA, such as recurrent uveitis or enthesitis without arthritis, might represent cases of ReA as well. Patients with ReA can develop an inflammatory arthritis that involves the axial skeleton and/or the peripheral joints.

The axial arthritis of ReA (Box 20-2) presents as pain and stiffness in the low back and/or buttocks. A classic feature is prolonged pain and stiffness in the morning or after periods of rest or inactivity. These symptoms tend to improve with activity or exercise. The cause of the pain includes inflammation in the synovial portion of the sacroiliac joints and enthesitis of these same joints, pelvis, and lumbar spine. The combination of synovitis and enthesitis of the sacroiliac joints results in one of the classic features of ReA, i.e., sacroiliitis. These symptoms

BOX 20-3 CLINICAL MANIFESTATIONS OF ReA

CHRONIC SYMPTOMS (≥6 MONTHS)

Articular

Axial	Sacroiliac joints Lumbar spine Thoracic spine Cervical spine Cartilaginous joints (symphysis pubis; sternoclavicular joints)
Peripheral	Large joints of the lower extremities (especially knees)
Dactylitis (sausage digit)	Very specific for a spondyloarthropathy

Enthesitis

Chronic inflammation can cause collagen fibers to undergo metaplasia forming fibrous bone

Chronic enthesitis leads to radiographic findings:

- Plantar/Achilles spurs
- Periostitis
- Nonmarginal syndesmophytes
- Syndesmoses of the sacroiliac joints

Mucosal

Sterile dysuria

Cutaneous

Keratoderma blennorrhagicum

Circinate balanitis

Ocular

Anterior uveitis (iritis)	Often recurrent
Rarely described	Scleritis, pars planitis, iridocyclitis, and others

Cardiac

Aortic regurgitation

Valvular pathologies

might be more pronounced during the acute phase of the illness. It is important to note that sacroiliitis can often be documented on plain radiographs, but these imaging studies might be of lesser utility in patients with acute symptoms since radiographic evidence of sacroiliitis can take weeks to months to develop. In patients with a high index of suspicion of acute disease and normal plain radiographs, advanced imaging with magnetic resonance imaging (MRI) might prove useful (Fig. 20-1). Such advanced imaging can show evidence of early inflammatory sacroiliitis that might be otherwise missed by conventional radiographs.[91] Plain radiographs remain the imaging investigation of choice for patients with chronic disease. ReA patients with radiographic sacroiliitis typically have unilateral or bilateral asymmetric findings.

The axial inflammatory arthritis of ReA involves the thoracic and cervical spine less often than the lumbar spine. If present, symptoms are similar including prolonged pain and stiffness in the morning and improvement with activity. In addition to sacroiliitis, patients can also develop spinal changes on plain radiographs. The most typical finding is nonmarginal syndesmophytes (eFig. 20-1.1 in online edition). These are thick, bridging, comma-shaped bony growths between vertebral bodies. These are most often seen in patients with chronic disease. Finally, the axial symptoms can include inflammation in cartilaginous joints, such as the symphysis pubis or sternoclavicular joints, with resultant radiographic changes.

The peripheral arthritis of ReA most often is an inflammatory oligoarthritis; there is a predilection for the large joints of the lower extremities. However, patients can also present with a polyarthritis or even monoarthritis. This clinical picture involving one or a few joints, particularly of the lower extremities contrasts with other types of inflammatory arthritis, such as rheumatoid arthritis, that typically present with a symmetrical polyarthritis. As with the axial symptoms, these tend to be more pronounced during the acute stage and can relapse and remit. In patients with more chronic or severe cases the small joints of the hands and feet can be involved. Radiographic features of peripheral joints in patients with chronic disease can include erosive changes, periostitis, and possibly even "pencil-in-cup" deformities most often associated with psoriatic arthritis.

Dactylitis (sausage digit) is a valuable diagnostic clue for potential ReA (Fig. 20-2). Dactylitis represents diffuse inflammation of an entire finger or toe. While not specific to ReA, if present, it is strongly suggestive of a spondyloarthropathy. Besides the spondyloarthropathies, only a few conditions, namely sarcoidosis and gout, cause dactylitis. One series suggested that ReA was the most common diagnosis in patients presenting with dactylitis; 28% of ReA patients had this finding as part of their constellation of symptoms.[92]

ENTHESITIS

Enthesitis, or fibrocatilagenous enthesitis, is inflammation at the transitional zone where collagenous structures such as tendons, ligaments, and joint capsules insert into bone. This is a hallmark feature of ReA (as well as for other types of spondyloarthritis). There are two main phases of enthesitis: (1) subchondral osteitis and (2) reparative ossification. The inflammation starts in the intraosseous portion of the enthesis, eventually destroying the bone and cartilage plate. The defect is rapidly filled with newly formed bone that extends to the terminal part of the tendon producing an enthesophyte (eFig. 20-2.1 in online edition). Common types of enthesitis in ReA are Achilles tendonitis and plantar fasciitis, but inflammation can occur at any enthesis.

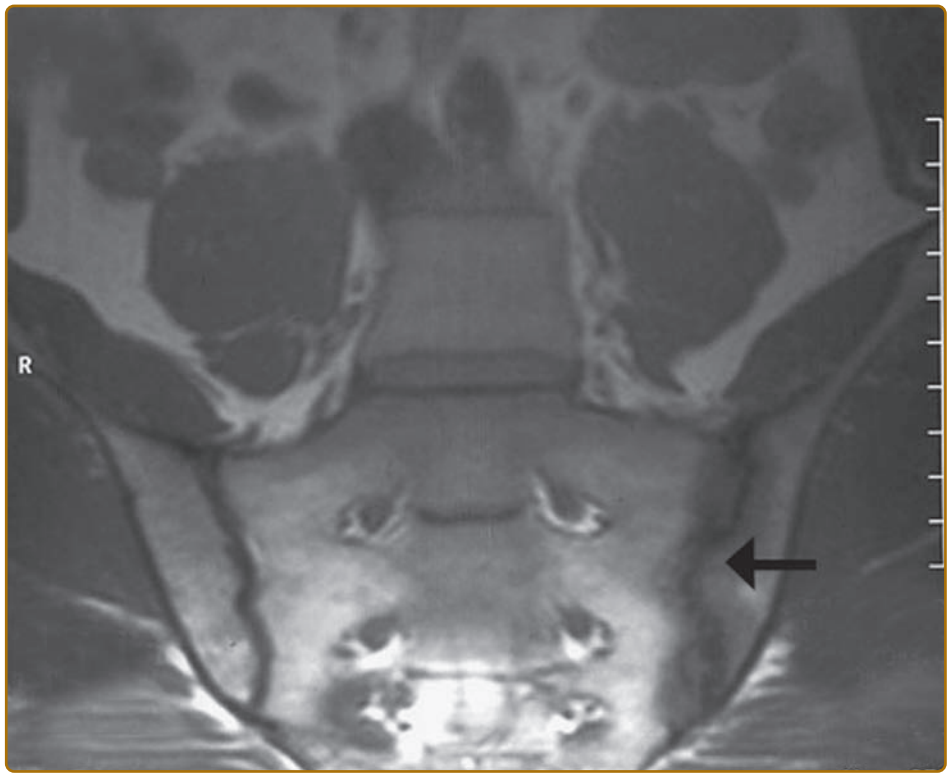

Figure 20-1 Magnetic resonance image showing unilateral sacroiliitis.

Figure 20-2 Dactylitis of second toe (sausage toe).

Sacroiliitis represents a combination of synovitis and enthesitis.[93] A recent report of >6,000 cases of culture-confirmed infections with bacterial enteric pathogens revealed that enthesitis was the most common finding in those individuals who developed ReA.[25]

CUTANEOUS

Dermatologic manifestations of ReA are several. The two most common are keratoderma blenorrhagicum and circinate balanitis. Keratoderma blenorrhagicum is a pustular or plaque-like rash that most often occurs in a palmoplantar distribution (Fig. 20-3). These

Figure 20-3 Keratoderma blennorrhagicum.

typically begin as erythematous macules or vesicles. These vesicles are often pustular in nature, but they can also be hemorrhagic; over time they can become thickened or papular forming a horny excrescence. These chronic lesions can become hyperpigmented and may coalesce. Rarely these lesions can occur in a more general distribution involving the entire body[94]; this is felt to be more likely in the setting of HIV. Interestingly, keratoderma blenorrhagicum is clinically and histologically indistinct from pustular psoriasis.[95] Histologic findings include hyperkeratosis and parakeratosis, elongation and hypertrophy of the rete ridges, general epidermal hyperplasia, and extensive neutrophilic infiltration with formation of microabscesses and spongiform pustules. Recently it has been demonstrated that these lesions are PCR positive for *Chlamydia trachomatis* in patients with suspected *Chlamydia*-induced ReA.[37]

Circinate balanitis is a cutaneous manifestation of ReA involving the penis. These are erythematous, pustular, or plaque-like lesions that most often involve the glans of the penis, but they can include the shaft and rarely the scrotum (Fig. 20-4). It has been suggested that these lesions on the glans can exhibit different characteristics depending on whether the patient is circumcised or not. In circumcised males, hyperkeratotic plaques are most typical and in uncircumcised patients they often begin as vesicles or pustules that may coalesce into a circinate pattern (Fig. 20-4).[96] Females with ReA can rarely get ulcerative vulvitis that has similar appearance to circinate balanitis.

Patients with ReA may also have nail involvement, which is similar to psoriasis and presents as onycholysis, subungal keratotic debris, transverse ridges, periungual scaly lesions, and nail pitting. These changes occur in about 20%–30% of ReA patients.[96] The relationship between distal interphalangeal arthritis and nail involvement is well recognized in psoriatic arthritis,[97] the same is also likely to be true for ReA, but there are no definitive data in this regard.

The true prevalence of keratoderma blenorrhagicum and circinate balanitis in patients ReA remains somewhat uncertain. Previous data have suggested that they occur in about 10%[98] and 50%[99] of patients, respectively and it was felt that they are more common in patients who are HLA-B27 positive.[100] However, as is the case with ReA in general, it is not clear if this genetic marker truly increases the occurrence of these cutaneous manifestations or if it has served as a diagnostic bias. More recent data demonstrate that circinate balanitis more strongly correlates with a previous chlamydial infection than previously thought.[101] In this same study, there was no apparent association with HLA-B27 and the majority of patients had no other signs or symptoms of ReA. The fact that these lesions are also clinically and histological indistinct from pustular psoriasis can also obfuscate the diagnosis.

Figure 20-4 Circinate balanitis.

OCULAR

(Boxes 20-2 and 20-3)

Although the original "classic triad" of symptoms of ReA included eye involvement, conjunctivitis was specifically mentioned. Not only do patients with ReA develop conjunctivitis, they often develop iritis/anterior uveitis. Although both conditions can occur at any time during the condition, it has traditionally been felt that conjunctivitis most often occurs during the early stage and less frequently becomes chronic whereas iritis/anterior uveitis occurs both as an acute and chronic (intermittent) problem. However, a long-term study of 25 ReA subjects with eye involvement at the time of diagnosis demonstrated that long-term ocular complications included conjunctivitis and anterior uveitis in 96% and 92% of patients, respectively.[102] Other long-term complications were seen in this study including posterior uveitis (64%), keratitis (64%), cataract (56%), intermediate uveitis (40%), scleritis (28%), cystoid macular edema (28%), papillitis (16%), and glaucoma (16%). These data suggest that patients with ocular involvement at the time of diagnosis are at increased risk for many long-term ocular complications; perhaps this risk is higher than previously appreciated.

MUCOSAL

(Boxes 20-2 and 20-3)

Mucosal involvement of the mouth, oral pharynx, and tongue can occur in patients with ReA, but these are infrequent. If they occur, typical lesions on the oropharnyx include diffuse erythema, macules, and plaques. They are often painless and might go unnoticed by the patient. Such lesions will sometimes present with bleeding. Lesions involving the tongue are most often circinate or annular in appearance. More

common mucosal manifestations include intestinal inflammatory lesions that resemble those of inflammatory bowel disease. One study found that 67% of subjects with ReA had histologic evidence of ileocolitis, even in the absence of gastrointestinal symptoms.[103] This finding might be higher in patients with postenteric ReA. Finally, it is well described that patients with ReA develop sterile dysuria. Interestingly this occurs with equal frequency in both postvenereal and postenteric ReA. This sterile dysuria can become a chronic intermittent problem for some patients. Prostatitis, cystitis, and pelvic inflammatory disease have also been described.[104,105]

CARDIAC

(Boxes 20-2 and 20-3)

Cardiac involvement from ReA is rare. There are sparse reports of ReA patients developing pericarditis, aortic regurgitation, or valvular pathologies. When they occur, they are more likely in chronic disease. These manifestations are rare enough in the acute setting that routine echocardiography is not recommended.[106] Electrocardiographic abnormalities can occur in the acute setting with significant arrhythmias occurring in approximately 5% of patients.[107]

DIAGNOSIS

Diagnostic criteria are broad and rely on clinical symptoms.[100,108] Difficulties with these diagnostic criteria have been raised.[109] The traditional disease definition also suggests that ReA represents a sterile inflammatory arthritis, but data presented above, specifically pertaining to Chlamydiae, challenge this paradigm. Although not pathognomonic for the condition, the documentation of the DNA presence of one of the causative organisms by PCR in synovial tissue or fluid of patients who fulfill the clinical criteria for ReA represents the most accurate means of diagnosing the condition.[110] Unfortunately, such synovial tissue analysis is not readily available for the majority of clinicians. Stool and urogenital sampling for the causative organisms in patients with chronic disease have been analyzed, but many patients test negative limiting the utility of this approach.[111,112] Serologic testing for antibodies to the causative organisms is unreliable. Because more than half of affected patients are HLA-B27 negative, this genetic antigen should not be utilized as a diagnostic tool. Therefore, at the current time we are left without a practical diagnostic test. Recognition of an underlying spondyloarthritis and identifying one of the triggering infections remains the most practical means of diagnosis ReA until better diagnostic tests are widely available. A diagnostic algorithm is shown in Figure 20-5.

TREATMENT

In the setting of acute or mild ReA, treatment is most often symptomatic and conservative. It is important to remember that many of the symptoms of acute ReA are self-limiting. The initial treatment of choice for the arthritis is nonsteroidal anti-inflammatory (NSAIDs). Not only is there a breadth of clinical experience with NSAIDs demonstrating their efficacy, there are also two randomized trials that have formally evaluated their use in ReA. The first was a double-blind crossover study comparing azapropazone to indomethacin in patients with both psoriatic arthritis and ReA.[113] Both medications were efficacious with a trend favoring indomethacin. Neither medication helped with the skin manifestations of either condition. The second was another double-blind crossover study comparing ketoprofen to indomethacin in 50 patients with ReA.[114] Both drugs were efficacious in treating the articular symptoms with no significant difference between the two. There were slightly more adverse events with indomethacin in both studies. Corticosteroids are quite helpful in patients with more severe articular symptoms. It has been suggested that systemic corticosteroids might be more efficacious in the treatment of peripheral articular symptoms rather than the axial symptoms.[115] Because ReA often involves one or few joints, intra-articular corticosteroids are often a useful treatment strategy.

Initial treatment of many of the extra-articular features of ReA includes topical corticosteroids. These have been utilized to treat iritis/uveitis, keratoderma blenorrhagicum, and circinate balanitis.[115] Given the similarities between the cutaneous manifestations of ReA and psoriasis, it is not surprising that other medications used to treat psoriasis have been advocated as potential treatments for keratoderma blenorrhagicum and/or circinate balanitis. Data suggest that topical calcipotriene is a useful treatment modality for keratoderma.[116] Emollients, keratolytics, coal tar, and phototherapy have also been advocated for keratoderma blenorrhagicum. In severe cases of keratoderma blenorrhagicum and circinate balanitis methotrexate (low-dose regimen as for psoriasis) and etretinate (0.5 mg/kg body weight) have been found to be beneficial but no formal clinical trials have been performed!

In spite of the fact that ReA often remits, as many as 30%–50% of patients will develop chronic disease. Both the articular and extra-articular features can persist. Because ReA can lead to pathologic sequelae (e.g., joint damage, visual impairment, skin disfigurement) resulting in decreased health-related quality of life, more definitive treatments have been sought. Paralleling the opposing schools of thought regarding the true role bacterial persistence plays in the pathophysiology of the disease, both traditional disease modifying antirheumatic drugs (DMARDs) and antibiotics have been assessed as potential therapeutic options. The latter have been studied in both acute and chronic disease, whereas the former are most often reserved for patients with chronic symptoms.

Several DMARDs have been advocated as treatments for ReA. These include sulfasalazine, methotrexate, azathioprine, and cyclosporine. Surprisingly, only one of these, sulfasalazine, has been formally evaluated in prospective clinical trials. Sulfasalazine

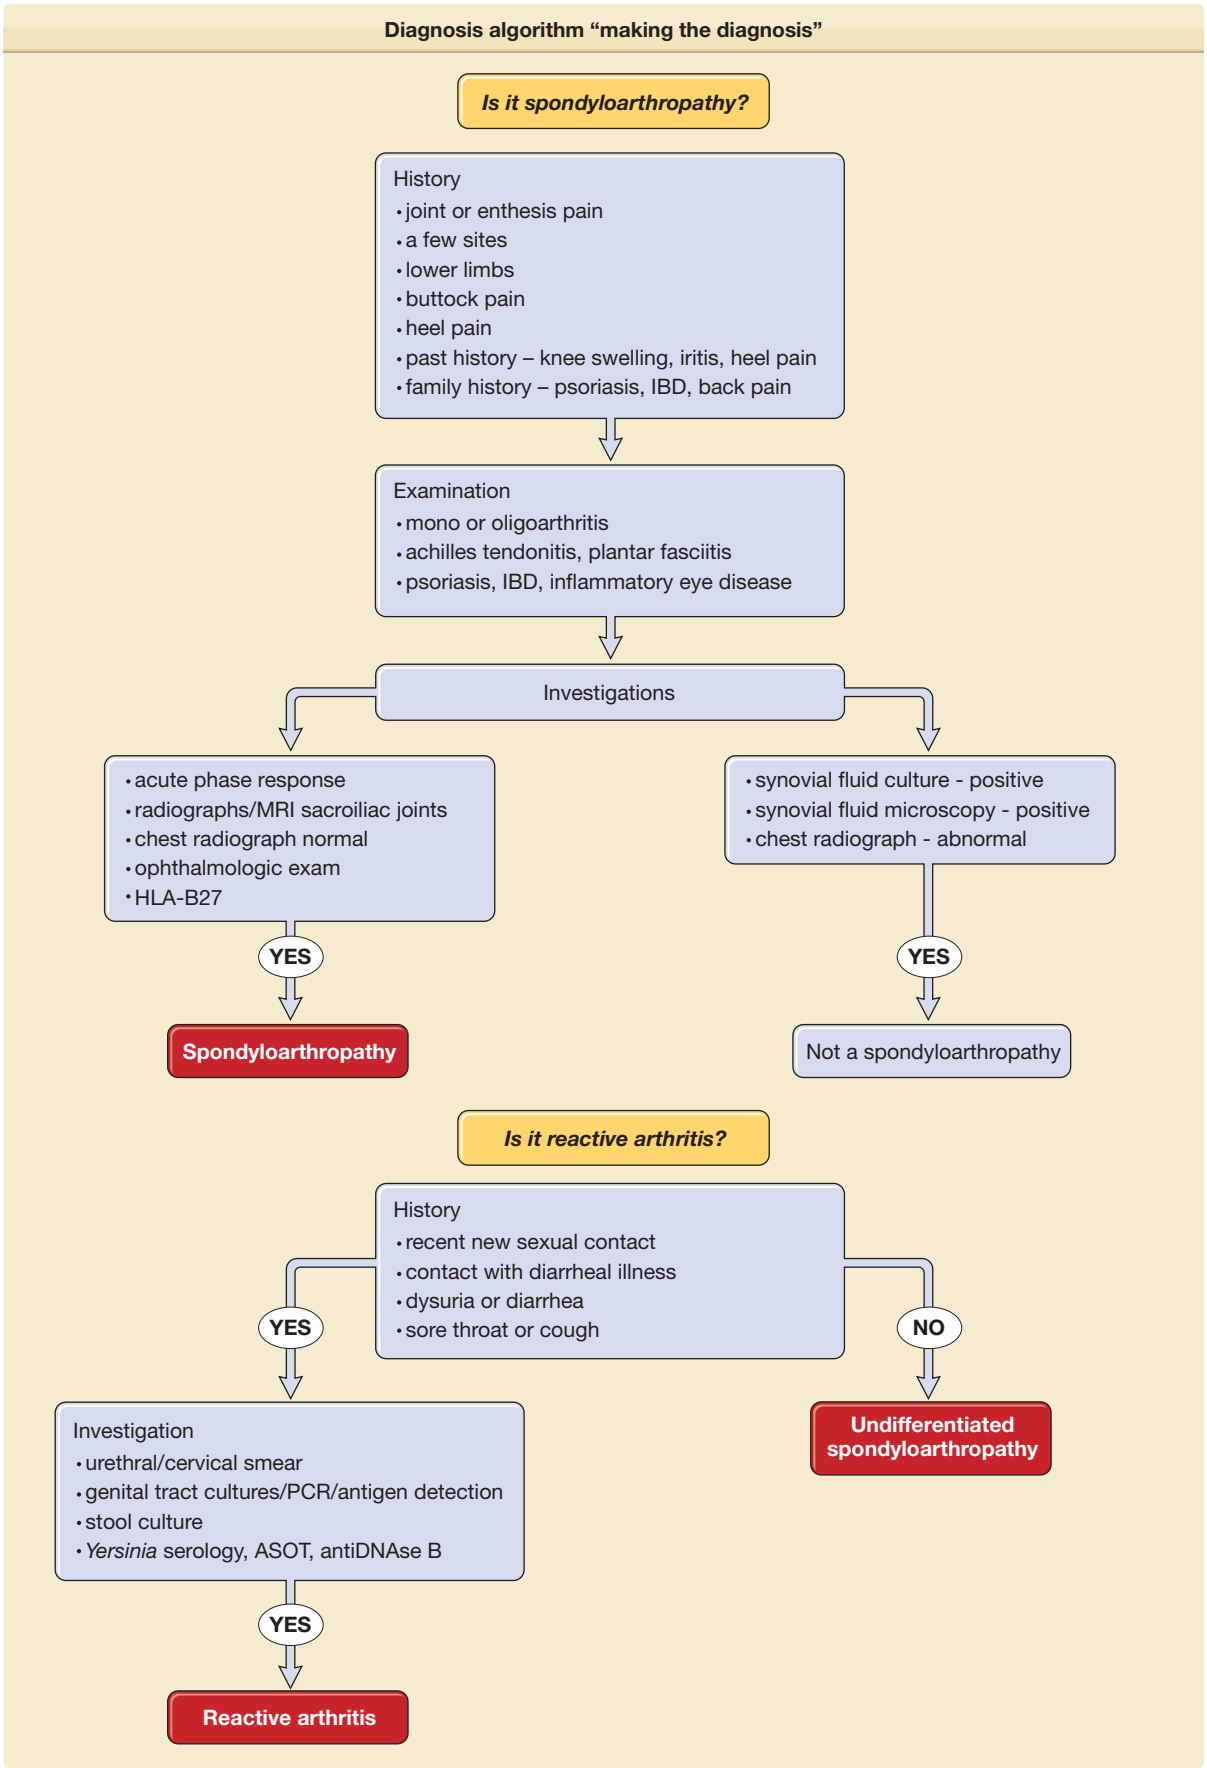

Figure 20-5 Diagnostic algorithm "making the diagnosis." Anti-DNAse B = antideoxyribonuclease B; ASOT = antistreptolysin O titer; IBD = inflammatory bowel disease; MRI = magnetic resonance imaging; PCR = polymerase chain reaction.

has been studied as a potential treatment for both acute and chronic ReA. In the acute ReA study, there was no significant difference between sulfasalazine and placebo in terms of pain, number of swollen joints, and erythrocyte sedimentation rate (ESR) after 6 months of therapy.[117] In addition, there was no apparent efficacy difference in patients regarding the initial triggering infection, HLA-B27 status, or presence/absence of axial arthritis. However, it is important to remember that acute ReA often remits spontaneously, so this potentially confounds these data. Sulfasalazine has also been studied in the setting of chronic ReA.[118] In this study, all patients had failed NSAIDs and were followed for 36 weeks' duration. There was a trend favoring sulfasalazine over placebo in terms of overall response. Sulfasalazine fared significantly better than placebo in some of the secondary endpoints including a longitudinal analysis and ESR.

The tumor necrosis factor (TNF)-α antagonists have demonstrated remarkable success treating several types of inflammatory arthritis including other types of spondyloarthritides, namely ankylosing spondylitis and psoriatic arthritis. Therefore it might seem logical that they would be useful therapeutic agents for ReA. However, several studies suggest that ReA is more of a Th2 driven disease.[83–85] Conversely, ReA patients have higher serum TNF-α levels than normal controls.[82] Adding to this complexity, it has been suggested that the Th1 versus Th2 predominance depends on the cell analyzed (synovial fluid derived T-cell clones vs. synovial fluid mononuclear cells).[82] It should also be noted that, in the case of chlamydial persistence, chlamydial replication is inversely proportional to TNF-α levels.[86–88] There are no randomized trials in ReA to accurately assess the efficacy of anti-TNF therapy, but several case reports and a small open label study suggest clinical benefit with these drugs in the treatment of ReA.[119–122] It might also be noteworthy that a rare, but defined, adverse event of anti-TNF therapy, in general, includes the onset of de novo psoriasis.[123] The similarities of keratoderma blenorrhagicum and pustular psoriasis are well described. The majority of these cases of anti-TNF therapy induced psoriasis occurs on the palms and/or soles and is pustular in nature. Three reported cases have been shown to be PCR positive for *Chlamydia trachomatis* on lesional skin biopsies.[37] The exact pathophysiology of these de novo cases of psoriasiform lesions remains unknown.

The fact that certain bacterial organisms are responsible for the genesis of ReA makes the notion of using antibiotics plausible. Data have demonstrated that the causative bacterial organisms traffic to the synovium and in the case of persistent synovium-based Chlamydiae, specifically, these organisms exist in a viable, albeit aberrant, state. This important difference in postchlamydial and postenteric ReA suggests a potential difference in antimicrobial response.

The first prospective, double-blind trial assessed antibiotics in the setting of acute ReA.[124] In this trial, 3 months of therapy with lymecycline significantly decreased the duration of illness in those subjects with postchlamydial ReA, but not those with the postenteric variety. This led to several studies assessing the utility of long-term treatment with various antibiotics, including ciprofloxacin, azithromycin, and doxycycline, in the ensuing years that produced negative results.[67,125–128] However, the initial concept that postchlamydial and postenteric ReA might behave differently in terms of therapeutic response was somewhat lost in these follow-up studies. More recently, data have suggested that a prolonged course of combination antibiotics is an efficacious treatment specifically for chronic postchlamydial ReA. Initially, an open-label comparison of doxycycline with rifampin versus doxycycline monotherapy suggested superiority with the former.[65] A double-blind, placebo-controlled follow-up study demonstrated that 6-month courses of doxycycline with rifampin and azithromycin with rifampin were significantly better than placebo.[129] In this study, all patients had to be PCR positive for Chlamydiae in order to be randomized to treatment. Significantly more patients on combination antimicrobial therapy converted to PCR negative compared to those treated with placebo after 6 months of therapy.

CONCLUSION

In terms of chronic diseases, ReA is unique in that the etiologic agents are known. This insight into disease initiation has led to significant advances in the understanding of this condition but much remains to be learned regarding its pathophysiology. In an almost ironic fashion, the definitive nature of disease genesis is juxtaposed with convoluted evolution regarding disease terminology and the original overreliance on the "classic triad" of symptoms; these issues have now been clarified. However, there remains ambiguity regarding a definitive therapeutic approach. Ongoing studies will hopefully answer the latter.

Chapter 21 :: Pustular Eruptions of Palms and Soles

:: Ulrich Mrowietz

PALMOPLANTAR PUSTULOSIS AT A GLANCE

- Chronic inflammatory disorder with sterile pustule formation.
- Affects only palms and soles.
- Disabling in severe cases.
- High rate of recurrence.
- Often resistant to treatment.
- Can be part of SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome.

Pustular eruptions of the palms and soles include palmoplantar pustulosis (PPP), acrodermatitis continua (Hallopeau disease), and infantile acropustulosis. The entities present with chronic and persistent eruptions of sterile, purulent vesicles.

A drug-induced rash clinically resembling PPP has been described in patients treated with tumor necrosis factor-α (TNF-α)-antagonists.

PALMOPLANTAR PUSTULOSIS

PPP is a chronic pustular dermatosis localized on the palms and soles only. High resistance to treatment and a high recurrence rate are characteristic. Histologically, it is characterized by intraepidermal vesicles filled with neutrophils.

Although many textbooks describe PPP along with psoriasis, it has an entity of its own.

The involvement of palms and soles has a great impact on life quality and the ability to work.

EPIDEMIOLOGY AND GENETICS

PPP has a worldwide distribution. It is a rare condition, but the exact incidence is not known. Females show a higher prevalence than males, with a ratio of approximately 3:1. Onset of the disease occurs mostly between the ages of 20 and 60 years; rarely, the condition occurs after the sixth decade of life, and in 10% of the patients the onset is before the age of 20 years.

HLA typing of patients with PPP reveals no increased frequency of any of the known psoriasis-linked alloantigens.[1] In a direct comparison among chronic-plaque psoriasis, guttate psoriasis, and PPP, the three major candidate genes within the PSORS1 region [(1) *HLA-Cw*6*, (2) *HCR*WWCC*, and (3) *CDSN*5*] showed a high association to guttate and chronic plaque psoriasis, not, however, to PPP.[2] Investigation of the apolipoprotein E alleles e2, e3, and e4 in chronic plaque and guttate psoriasis as well as in PPP in acitretin responders and nonresponders showed that the frequency of the e4 allele was significantly higher in the psoriasis groups but not in PPP patients as compared to healthy controls.[3] In chronic plaque psoriasis and psoriatic arthritis an association with TNF-α-238 and -308 promoter polymorphisms have been found; however, the association has not been found in PPP.[4] Studies from Japan provide evidence for phenotypic and genetic heterogeneity of PPP according to its association/provocation with tonsillitis. In patients in whom PPP was not associated with tonsillitis, the phenotype frequency of the TNF-β2 allele of the TNF-β gene and of the allele B of the TNF-α gene was significantly higher as compared to controls.[5]

Genetic association studies in a Caucasian cohort revealed that genes encoding for cytokines of the IL-10 family, namely, IL-19, IL-20, and IL-24 show haplotypes conferring increased risk for PPP.[6]

These findings further substantiate the notion that PPP and psoriasis represent different entities.

ETIOLOGY AND PATHOGENESIS

The cause of PPP is not known. An imbalance of the protease/antiprotease system in the skin consisting of decreased antileukoprotease (elafin/SKALP) activity in pustular psoriasis has been discussed as a possible mechanism of pustule formation.[7] Exacerbation of PPP has been observed after patch testing with metals and was accompanied by elevated leukotriene B4 levels in plasma and pustules.[8]

In a long-term survey from Japan, the incidence of PPP was found to be positively correlated to heavy smoking (more than 20 cigarettes per day), tonsillitis, and seasonal factors such as high humidity and high temperature.[9,10]

The most striking association in PPP is smoking. In two Swedish surveys, 95% of PPP patients were smokers at onset of disease and cessation of smoking was the most important measure to treat the disease.[11,12] There is evidence from immunohistochemical studies that nicotinic acetylcholine receptors are modulated in lesional skin from smoking PPP patients when compared to disease-free smokers and healthy controls suggesting an abnormal response to nicotine in PPP.[13] The possible involvement of neutrophils infiltrating sweat glands and ducts expressing choline acetyltransferase and the α-3 and α-7 nicotinic acetylcholine receptors as a target for nicotine/smoking was discussed as an important mechanism for manifestation and/or maintenance of PPP.[14]

Investigating the tissue of tonsils of PPP-patients a unique formation of lymphoid follicles surrounded

by reticular crypt epithelial cells was found which was absent in tonsils of controls.[15] Culturing crypt epithelial cells it was shown that p53-related expression factors contributed to an upregulation of *IL-6* gene expression. The possible importance of IL-6 for PPP has been emphasized previously and it has been shown that tonsillectomy leads to improvement of lesions.[16] In another study, the expression of inducible costimulator (ICOS), a costimulatory receptor on activated T cells was higher in the tissue of tonsils of PPP-patients as compared to controls.[17] Tonsillectomy or treatment of dental foci resulted in a marked and sustained improvement of lesions suggesting a major role of focal infections as a trigger for PPP. The role of T cells in the tonsils for PPP is further substantiated by the demonstration of an increased expression of cutaneous lymphocyte-associated antigen (CLA) on CD3+ T cells in tonsils and in diseased skin together with an enhanced expression of the CLA-ligand E-selectin.[18]

Grafting involved PPP-skin onto SCID/CB-17 mice injected with lymphocytes from tonsils of PPP patients together with heat shock protein 60 induced high antiheat shock protein 65-IgG levels together with an increase of IL-6 and interferon α.[19] Recruitment of lymphocytes seems to be mediated by the chemokine CCL20/MIP3 α the receptor of which, CCR6, is significantly expressed on tonsilar T cells of PPP patients as compared to controls. Indeed, Tonsillectomy resulted in a decreased CCR6 expression on peripheral PPP T cells.[20]

The observation of either PPP or new onset psoriasis in patients treated with anti-TNF-α agents is not yet understood[21] but a shift from a TNF-α-driven immune response toward an interferon-dominated inflammatory response is discussed.[22] In an animal model, the neutralization of TNF-α-induced skin inflammation resulted in an increased expression of IL-1β, IL-6, IL-17, IL-21, and IL-22 and a suppression of FoxP3-positive regulatory T cells.[23] In the light of the importance of T cells and IL-6 for the development of PPP this shift may at least in part explain this appears relevant.

CLINICAL FINDINGS

The primary lesions are pustules of nearly equal size measuring two to four mm in diameter. Crops of pustules usually arise within a few hours on otherwise normal-appearing palmar and plantar skin (Fig. 21-1). Involvement is usually symmetric but unilateral location on palms and/or soles can be seen. Single lesions then become surrounded by an erythematous ring. Sometimes, the pustules extend to the dorsa of the fingers, the feet, or over the volar wrists (see Fig. 21-1C). Episodes of new pustular eruptions occur at varying intervals and remain strictly confined to the sites of predilection.

As pustules become older, their yellow color changes to dark brown, so that in untreated PPP, the lesions show various shades of color (see Fig. 21-1). Dried pustules are shed within approximately 8 to 10 days.

Symptoms include itching or a burning sensation, which may precede new crops of lesions. However, in severe eruptions, pain and the inability to stand, walk, or do manual work may greatly reduce the quality of life.

DISEASE ASSOCIATIONS. (Box 21-1.) An association of PPP and osteoarthritis of the anterior chest wall was first described in Japan.[24] As reported by Swedish authors, involvement of the manubriosternal joint is present in 6% and of the sternoclavicular joints in 10% of patients.[25] Scintigraphic investigations showed sternocostoclavicular joint involvement to be present in 16 of 73 (22%) patients.[26] For this condition, the term *SAPHO* (synovitis, acne, pustulosis, hyperostosis, osteitis) has been established.[27] Clinical manifestations of SAPHO syndrome are similar when they occur either with severe acne (mostly acne conglobata) or PPP (see Chapter 80). The primary lesion consists of a sterile abscess containing neutrophils. The site of predilection is the anterior chest wall. Involvement of the sacroiliacal joints may occur.[28]

PPP is also seen in patients with chronic recurrent multifocal osteomyelitis as well as with noninfectious inflammatory bone lesions.

An association of PPP with gluten-sensitivity has been suggested as far back as 1991.[29] In a more recent study of 123 patients with PPP IgA-antibodies against gliadin were found in 18% of patients and against tissue transglutaminase in 10%, respectively.[30] In these patients CD3+ and CD8+ T cells were increased in numbers in duodenal biospsies. In 6% of patients diagnosis of celiac disease was made. Patients who tested positive for any of the antibodies showed total or nearly total clearance of skin lesions when they adhered to a gluten-free diet.

HISTOPATHOLOGY. Histologically, there is an intraepidermal cavity filled with polymorphonuclear leukocytes associated with spongiform changes within the surrounding epidermis (Fig. 21-2). Eosinophils and mast cells are present in increased numbers in PPP biopsies from lesional skin. Another hallmark is the inability to visualize the epidermal part of the eccrine duct in PPP specimens indicating an involvement of the acrosyringium.[31]

LABORATORY FINDINGS. The lesions of PPP are sterile; a moderately increased white blood cell count may occasionally be observed, but all other laboratory tests are usually normal. In patients with an infectious trigger, infection-associated laboratory parameters, such as C-reactive protein, may be increased. Increased levels of antigliadin and/or tissue transglutaminase antibodies may be found.

BOX 21-1 DISEASE ASSOCIATIONS OF PPP

- SAPHO syndrome
- Chronic recurrent multifocal osteomyelitis and noninfectious inflammatory bone lesions
- Gluten sensitivity

Figure 21-1 Palmoplantar pustulosis. **A** and **B.** Groups of pustules measuring 2 to 4 mm in diameter occur on erythematous skin on palms and soles. Both feet and both hands are normally affected symmetrically but can also be found on one side only. **C** and **D.** Lesions may occasionally spread beyond the predilection sites, and pustules may appear on the wrists. Within several days after pustule formation, lesions dry, flatten, and acquire a brownish color. This may be followed by eczematous changes with scaling and fissuring.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(Box 21-2)

PPP is a distinct entity. The course of the disease, together with the characteristic morphology, permits the proper diagnosis. The disease must be differentiated from dyshidrotic eczematous dermatitis (pompholyx), especially when pustules due to secondary infection are present (see Chapter 16). In that condition, the onset is also acute, but clear vesicles of various sizes are scattered on the palms, soles, and volar and interdigital aspects of the fingers. These may coalesce and secondarily become pustular because of secondary bacterial infection.

Pustular variants of tinea of the palms and soles or pustules developing in infected scabies may resemble

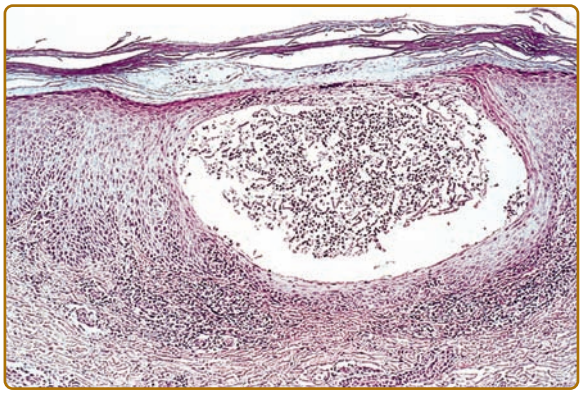

Figure 21-2 Histologically, there is a spongiform pustule and a moderate lymphohistiocytic infiltrate.

PPP. Bacterial cultures or demonstration of hyphae or mites clearly separate these entities from PPP.

Rare clinical variants such as vesicopustular mycosis fungoides palmaris et plantaris,[32] localized pustular vasculitis,[33] or palmoplantar involvement of generalized pustular psoriasis may also resemble PPP.

PROGNOSIS/CLINICAL COURSE

The clinical course of PPP is highly unpredictable. In patients with active disease with ongoing development of fresh pustules at the beginning of treatment relapse within a few days after cessation of any therapy or dose-reduction is highly likely. In phases of remission fewer pustules are produced, but the skin may remain erythematous and hyperkeratotic, sometimes resembling eczema. Cessation of smoking may help to extend disease-free intervals and to decrease activity of PPP.

TREATMENT

PPP is difficult to treat and all reported treatments have a high recurrence rate. Treatment modalities of PPP are summarized in Box 21-3.

In patients with limited disease or only focal lesions topical therapy with corticosteroids (potent and super-potent) is the treatment of choice. Increased efficacy can be obtained by occlusive therapy. When PPP involves larger parts of palms and/or soles systemic treatment with or without additional topical therapy should be initiated.

In a meta-analysis of several trials a modest efficacy of retinoids (etretinate/acitretin) or PUVA (oral, topical, bath) was established when compared to placebo. The addition of a retinoid to PUVA (re-PUVA) resulted in increased efficacy. Cyclosporine showed good evidence of improvement up to clearance but no data support was given for long-term cyclosporine therapy.[34]

In a recent open trial in 52 patients with PPP 35% could be controlled by topical therapy. In those patients requiring systemic therapy acitretin was found most efficacious followed by colchicine and methotrexate.[35] Efficacy of fumaric acid ester therapy in PPP has been described.[36]

In six female PPP-patients oral itraconazole (100 mg/day for 4 weeks followed by 100 mg every other day for 4 weeks) lead to a complete clearance in three out of six and in mild improvement in the other three patients. All patients relapsed within 1 month after cessation of therapy but therapeutic response could be regained in two of the three former responders.[37]

In an open trial in 15 patients 15 mg alefacept i.m. weekly for 16 weeks was found to be successful in the majority of cases.[38] However, in another series of 15 PPP patients alefacept 15–30 mg weekly was found efficacious only in some cases with a maximum response at week 10.[39] There is debate as to whether TNF-α antagonists may be beneficial in PPP. Whereas in chronic plaque type psoriasis and generalized pustular psoriasis the anti-TNF-α monoclonal antibody infliximab was found to be highly effective, this agent was found to be both beneficial and to worsen PPP.[40,41] In the SAPHO syndrome, infliximab led to a complete remission of osteoarticular disease but PPP deteriorated during treatment.[42] In a small placebo-controlled trial in 15 PPP-patients etanercept given 2 × 50 mg weekly s.c. for 6 months only few patients showed a significant clinical response.[43]

BOX 21-2 DIFFERENTIAL DIAGNOSIS

Most Likely

- Dyshidrotic eczema with secondary bacterial infection
- Pustular tinea of palms and soles

Consider

- Keratoderma blenorrhagicum in Reiter disease
- Involvement of palms and soles in generalized pustular psoriasis
- Infected scabies with pustulation
- Vesicopustular mycosis fungoides of palms and soles
- Localized pustular vasculitis

MANAGEMENT AND PREVENTION

(See Box 21-4)

Cessation of smoking and, according to data mainly generated in Asian countries, tonsillectomy may help to prevent new eruptions of PPP. In patients tested positive for antigliadin and/or tissue transglutaminase antibodies and/or with proven celiac disease a gluten-free diet seems to be a preventive measure.

ACRODERMATITIS CONTINUA (HALLOPEAU)

Acrodermatitis continua is a rare, sterile, pustular eruption of the tips of the fingers or toes that slowly extends proximally. Continuous pustulation leads to nail destruction and atrophy of the distal phalanx.

BOX 21-3 TREATMENTS FOR PALMOPLANTAR PUSTULOSIS AND ACRODERMATITIS CONTINUA[a]

	TOPICAL		PHYSICAL	SYSTEMIC	
First line	Potent and superpotent steroids Calcipotriol	bid, plastic film occlusion bid	PUVA (Bath—4/week psoralen and ultraviolet light	Acitretin	0.5 mg/kg/bw/day
Second line	Anthralin Tazarotene	Once daily bid		Methotrexate Cyclosporine	10–25 mg/wk 3–5 mg/kg/bw, when effective individual titration of dose
Third line				Fumaric acid esters[b] Colchicine Itraconazole Alefacept[c] TNF-α-antagonists	According to dose-escalation scheme, corresponding to a maximum of 720 mg of dimethylfumarate/day 1–2 mg/day 100 mg/day for 4 weeks followed by 100 mg every other day for 4 weeks 15–30 mg/weekly Dosing as recommended for psoriasis

[a]For treatment of acrodermatitis continua no data are available besides case-reports for some of the recommended treatments.
[b]Registered in Germany only.
[c]Registered in United States, Canada, and Switzerland only.

In 1888, Crocker described a relapsing bullous and pustular eruption on hands and feet; this was further delineated by Hallopeau.[44,45] Acrodermatitis continua is now classified as a form of acropustular psoriasis.

EPIDEMIOLOGY

There are no data on the prevalence or incidence of acrodermatitis continua.

BOX 21-4 MANAGEMENT OF PALMOPLANTAR PUSTULOSIS AND PREVENTION

  - Gluten-free diet
- ***In smokers***
  - Refer patients to antismoking programs
- ***Also consider***
  - Tonsillectomy

ETIOLOGY AND PATHOGENESIS

The etiology of acrodermatitis continua remains enigmatic. Even triggering factors have not been described yet. Pustule formation may involve similar pathways as discussed for PPP, but due to the rarity of the disease this has not been studied.

CLINICAL FINDINGS

Acrodermatitis continua most often begins at the tips of one or two fingers (Fig. 21-3), less often on the toes. The nail folds are affected very early, and trauma is thought to play an initiating role. The first signs consist of small pustules, which, on bursting, leave an erythematous, shiny area in which new pustules develop. These then tend to coalesce, forming polycyclic lakes of pus. As the disease extends proximally, the affected area shows either glossy erythema or a crusted, keratotic, and fissured surface with newly formed pustules underneath (see Fig. 21-3). Pustulation of the nail bed and the nail matrix almost always occurs and quite often leads to loss of the nail plate or severe onychodystrophy (see Fig. 21-3). Acrodermatitis continua of long duration may show complete destruction of the nail matrix and thus lead to anonychia. The skin becomes shiny and

Figure 21-3 **A.** Acrodermatitis continua demonstrating acral pustule formation and subungual lakes of pus with destruction of the nail plate. **B.** Repeated eruptions lead to nail loss and severe atrophy. Note micropustulation within the atrophic epidermis of the distal phalanges.

severely atrophic, and there is atrophic thinning of the distal part of the phalanx.

The disease may remain confined to the original site, sometimes up to several years, but more often it spreads proximally to cover the hand, dorsum of forearm, or foot. In such instances more than one extremity is involved. Acrodermatitis continua may be associated with generalized pustular psoriasis of the Zumbusch type (see Chapter 18).

HISTOPATHOLOGY. The main histopathologic feature of acrodermatitis continua is a subcorneal cavity filled with neutrophils. Epidermal cell necrosis and spongiosis does not occur, but the roof and shoulder zones adjacent to the pustule show aggregated leukocytes between the epidermal cells, forming spongiform pustules. There is a moderate lymphohistiocytic infiltrate in the upper dermis, together with focal edema.

Lesions of long duration show severe atrophy of the papillary dermis and thinning of the epidermis.

LABORATORY FINDINGS. Systemic abnormalities are absent, and laboratory tests are usually within normal ranges. The pustules are sterile. In advanced cases, X-ray may reveal atrophy of the distal phalanx and arthropathy of the interphalangeal joints.

DIFFERENTIAL DIAGNOSIS

Acrodermatitis continua at an early stage must be differentiated from acute paronychia caused by bacteria or fungi and from herpetic lesions (see Chapter 193). Cultures and smears help rule out infectious causes. The distal localization and the tendency of the pustules to become confluent, forming denuded, erythematous, or crusted lesions, distinguishes acrodermatitis continua from PPP or pustular dyshidrotic eczema. Atrophy and loss of nails do not occur in these conditions. Contact dermatitis with secondary infection and pustulation has less clearly defined margins, runs a different clinical course, and lacks the persistence typical for acrodermatitis continua.

PROGNOSIS/CLINICAL COURSE

Acrodermatitis continua shows a chronic course with a tendency of the lesions to spread proximally. Spontaneous improvement is rare, and episodes of acute pustulation occur without apparent cause. The development of pustules at other sites, or even the eruption of generalized pustular psoriasis, supports the idea that acrodermatitis continua is a variant of psoriasis. When uncontrolled, irreversible destruction of the complete nail apparatus occurs.

TREATMENT

As in pustular psoriasis, no specific drug is able to induce lasting remissions. Potent or superpotent topical steroids, preferentially under occlusion, are useful in blocking pustulation. Caution is advised in cases already showing atrophy. PUVA suppresses the eruption of new pustules and can be employed for long periods as maintenance treatment (see Chapter 238).

Treatment with a combination of systemic acitretin and local calcipotriol/calcipotriene was successful in one patient in a left–right comparison.[46] In recalcitrant patients, dapsone may be tried.[47] Recently, topical treatment with tacrolimus 0.1% ointment alone or in sequential combination with calcipotriol was found successful.[48] Numerous case reports describe the successful use of anti-TNF-α agents in acrodermatitis continua.[49] With respect to the recalcitrant nature of the diseases combination therapy of adalimumab, etanercept, or infliximab with either acitretin or methotrexate may be advisable in order to maintain treatment response when stopping anti-TNF-α-therapy while continuing acitretin or methotrexate.

In principle, regimens used for treatment of PPP may also be used for therapy of acrodermatitis continua (see Box 21-3). The therapeutic result lasts as long as the drugs are given, and relapses occur after withdrawal.

PREVENTION

There are no data on preventive measures for acrodermatitis continua.

INFANTILE ACROPUSTULOSIS

Infantile acropustulosis is discussed in Chapter 107.

Chapter 22 :: Seborrheic Dermatitis

:: Chris D. Collins & Chad Hivnor

SEBORRHEIC DERMATITIS AT A GLANCE

- Both infantile and adult forms exist.
- It is characterized by sharply demarcated, yellow to red to brown, greasy or bran-like scaling patches and plaques.
- Lesions favor scalp, ears, face, presternal chest, and intertriginous areas.
- Flares occur when sebaceous glands are most active (first few months of life, and post puberty).
- Generalized and erythrodermic forms rarely occur.
- The etiology is unclear but there are associations with *Malassezia* yeasts, sebum secretion and composition, and certain drugs.
- May be a cutaneous marker of HIV and AIDS, especially when severe, atypical, and therapy-resistant.

INTRODUCTION

Seborrheic dermatitis is a common, chronic papulosquamous disorder affecting infants and adults alike. It is characteristically found in regions of the body with high concentrations of sebaceous follicles and active sebaceous glands including the face, scalp, ears, upper trunk, and flexures (inguinal, inframammary, and axillary).[1] Less commonly involved sites include interscapular, umbilical, perineum, and the anogenital crease.[2] The dermatitis presents with pink to erythematous, superficial patches and plaques with a yellow, branny and sometimes greasy scale. Excessive flaking on the face and scalp can lead to social embarrassment which can have a negative impact on one's quality of life, especially in women, younger patients, and those with a higher educational level.[3] Mild forms are most commonly encountered, but severe psoriatic and erythrodermic forms can be seen as well.[1] Seborrheic dermatitis is one of the most common dermatoses seen in human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) patients along with certain neurological disorders such as Parkinson disease.[4,5] These patients tend to have widespread, erythrodermic, and treatment resistant forms. Severe forms are also seen with immunosupression in premature infants and congestive heart failure patients.[6,7] African-Americans and other darkly pigmented races are susceptible to the annular or petaloid variant of seborrheic dermatitis, which may be confused for discoid lupus, secondary syphilis, or sarcoidosis.[8] A rare pityriasiform variety of seborrheic dermatitis with ovoid scaling patches can be seen on the trunk and the neck, mimicking pityriasis rosea and secondary syphilis. A higher incidence of seborrheic dermatitis is also seen in patients with alcoholism and endocrinologic diseases that lead to obesity.[9]

EPIDEMIOLOGY

Seborrheic dermatitis is separated into two age groups, an infantile self-limited form primarily during the first 3 months of life and an adult form that is chronic. A male predominance is seen in all ages, without any racial predilection, or horizontal transmission. The prevalence of seborrheic dermatitis is 3%–5% of young adults, and 1%–5% of the general population, although its lifetime incidence is significantly higher.[10]

ETIOLOGY AND PATHOGENESIS

The exact pathogenesis of seborrheic dermatitis is yet to be fully elucidated, but this dermatosis is commonly linked with the yeast *Malessezia*, immunologic abnormalities, sebaceous activity, and patient susceptibility.[14,15] The amount of sebum produced is not an essential factor, as not all patients with seborrheic dermatitis will have increased levels of sebum production. On the other hand, some patients with elevated sebum levels may not have seborrheic dermatitis either.[16] Patients with seborrheic dermatitis show higher skin surface lipid levels of triglycerides and cholesterol, but lower levels of free fatty acids and squalenes. Both *Malassezia* species and the resident flora *Propionobacterium acnes* have lipase activity resulting in transformation of triglycerides into free fatty acids.[17] All seven species of *Malassezia* are lipophilic except the zoophilic species, *Malassezia pachydermatis*. The free fatty acids and reactive oxygen radicals produced in turn have antibacterial activity that alters the normal skin flora. Some authors believe this disturbance in flora, lipase activity, and free oxygen radicals may be more closely linked to seborrheic dermatitis than an altered immune response.[18]

IMMUNOLOGY

Many patients have normal levels of *Malassezia* species on the skin, but have an abnormal immune response to it resulting in a depressed helper T cell response and less production of phytohemagglutinin and concanavalin when compared to control subjects.[19,20] Levels of antibodies are the same in both patients with and without seborrheic dermatitis. *Malassezia* species also play a role in the inflammatory response with stimulation of the alternative complement pathway.[21] A disturbed lymphocytic cellular immune response to *Malassezia*, results in elevated levels of interleukin (IL)-10, with a drop in IL-2 and interferon-γ.[22] Both normal and elevated levels of antibodies to *Malassezia furfur* can be seen in patients with seborrheic dermatitis. *Malassezia* can lead to inflammation on the skin from metabolic products produced and complement activation via the direct and alternative pathways.

PHYSICAL FACTORS

Seasonal fluctuations in humidity and temperature are noted to flare this disease, particularly with low humidity and cold temperatures in the winter and early spring, with some relief in the summer.[23] Facial PUVA (psoralen plus ultraviolet radiation) treatments and facial trauma (i.e., scratching) are also reported to trigger seborrheic dermatitis as well.[24]

MICROBIAL EFFECTS

The pathogenesis of seborrheic dermatitis has been disputed since it was originally described over a hundred years ago. The presence or imbalance of microbial flora likely plays a role in the disease. Although some patients may have cultures showing *Candida albicans, Staphylococcus aureus, Propionobacterium acnes*, and other aerobic bacteria, none have been linked to the pathogenesis of seborrheic dermatitis.[25] Infants commonly have secondary contamination and infection with *Candida* species. The pathogenic role of *Malassezia furfur* (previously known as *Pityrosporum ovale*) is also controversial. The number of yeasts on the skin does not directly correlate with the severity of seborrheic dermatitis also. Patients with both dandruff and seborrheic dermatitis generally have abundant yeast counts when compared to controls supporting the role of yeast in the disease. A higher rate of seborrheic dermatitis is also seen in patients with *Pityrosporum folliculitis* and tinea versicolor.[26] Clearance of seborrheic dermatitis with antifungals and recurrence following cessation of therapy also supports the premise that *Malassezia* species is pathogenic.[27]

DRUGS

Several drugs are known to trigger seborrheic dermatitis like eruptions including griseofulvin, cimetidine, lithium, methyldopa, arsenic, gold, auranofin, aurothioglucose, buspirone, chlorpromazine, ethionamide, haloperidol, interferon-α, phenothiazines, stanozolol, thiothixene, psoralen, methoxsalen, and trioxsalen.

NEUROTRANSMITTER ABNORMALITIES

Many neurologic disorders have been associated with seborrheic dermatitis, with most of them resulting in some facial immobility and sebum accumulation. These include Parkinson's, Alzheimer's, syringomyelia, epilepsy, cerebrovascular infarcts, postencephalitis, mental retardation, poliomyelitis, quadriplegia, trigeminal nerve injury and other facial nerve palsies.[28] The fact that administration of L-dopa improves seborrheic dermatitis in some Parkinson patients, and some neuroleptic drugs that induce Parkinsonian symptoms can induce seborrheic dermatitis suggests that neurotransmitters may play a role in this dermatitis.[29] Depression and emotional stress have also been reported to trigger seborrheic dermatitis.[30] A high rate of this dermatitis is also seen among combat troops.[31] In summary, these groups of patients do not have increased rates of sebum, but rather excessive accumulation of sebum on the skin.

ABERRANT EPIDERMAL PROLIFERATION

Patients with seborrheic dermatitis may have epidermal hyperproliferation or dyskeratinization related to increased activity of calmodulin, which is also seen in psoriasis.[32] This explains why patients with seborrheic dermatitis improve while being treated with a

number of different cytostatic medications such as azeleic acid.[12]

NUTRITIONAL DISORDERS

Seborrheic dermatitis has not been proven to be associated with any vitamin deficiency. Patients with zinc deficiency (acrodermatitis enteropathica, and acrodermatitis enteropathica like conditions) may have an eruption that appears similar to seborrheic dermatitis and improves with zinc supplementation, while seborrheic dermatitis patients do not improve with zinc supplementation.[33] Infants with deficiency in biotin, holocarboxylase, biotinidase, and free fatty acids may also have seborrheic-like dermatitis. But again, biotin supplementation has not been substantiated to improve seborrheic dermatitis.[34]

GENETIC FACTORS

A family history of seborrheic dermatitis is often reported, but only recently has a mutation (*ZNF750*) encoding a zinc finger protein (C2H2) been described resulting in a seborrhea-like dermatitis. This Israeli Jewish Moroccan family presented with an autosomal dominant seborrhea-like dermatosis.[35]

PSORIASIS AND SEBORRHEIC DERMATITIS

The controversial term *sebopsoriasis* is often used in patients when there appears to be an overlap of psoriasis and seborrheic dermatitis. It tends to localize to the scalp, face, and presternal chest as seen with seborrheic dermatitis. However, the margins tend to be better defined, more erythematous and with thicker scales than those seen with seborrheic dermatitis. The biopsy can be indistinguishable from psoriasis, similar to the chronic form of seborrheic dermatitis.[36]

CLINICAL FINDINGS

In all patients with seborrheic dermatitis, there is a so-called seborrheic stage, which is often combined with a gray–white or yellow–red skin discoloration, prominent follicular openings, and mild to severe pityriasiform scales. Several forms can be distinguished (Table 22-1).

TABLE 22-1
Clinical Patterns in Seborrheic Dermatitis

INFANTILE: Scalp (cradle cap), trunk (flexures and napkin area), Leiner's disease (nonfamilial and familial C3/C5 dysfunction).
ADULT: Scalp, face, eyelids (blepharitis), trunk (petaloid, pityriasiform, flexural, eczematous, follicular, generalized, erythrodermic).

PROGNOSIS AND CLINICAL COURSE

Self-limited with a good prognosis in infants compared to chronic and relapsing in adults. There is no evidence to suggest infants with seborrheic dermatitis will have disease as adults. Generalized flares and erythroderma can sometimes occur.[37]

SEBORRHEIC DERMATITIS IN INFANTS COMPARED TO ADULTS

The infantile form occurs during the first few weeks to 3 months of life, is self-limited, and corresponds to the time when the neonate produces sebum, which then regresses until puberty.[38] It is commonly concentrated on the vertex of the scalp (i.e., cradle cap) with adherent, yellow–brown, greasy scale, which can sometimes spread to the entire scalp with inflammatory, erythematous, and oozing crusts. Lesions can be seen on the face, neck and can be disseminated to the trunk and extremities with inflammatory glistening plaques in intertriginous sites such as the axillae and groin (Fig. 22-1). A differential diagnosis should be undertaken in any infant with a widespread form of seborrheic dermatitis (Box 22-1). Atopic dermatitis patients tend to have lesions on the forearms and shins, while sparing the axillae. Lesions isolated to the diaper region suggest seborrheic dermatitis. Radioallergosorbent assay test screening to egg whites, milk antibodies,

Consider

- Scabies, psoriasis

Rule Out

- Langerhans cell histiocytosis

soybean, and total immunoglobulin E levels, may be helpful in discerning infantile seborrheic dermatitis from atopic dermatitis. Some authors believe that infantile seborrheic dermatitis is actually a variant of atopic dermatitis rather than a separate entity. Extensive involvement plus lesions on the palms and soles with severe pruritis suggests scabies. Infantile psoriasis can also be extensive, with erythematous plaques and scale, with less scale in intertriginous sites. Extensive involvement with moist erythematous plaques and petechial lesions of intertriginous sites and the scalp suggests Langerhans cell histiocytosis (Letterer–Siwe) and should be biopsied for confirmation and treated appropriately.

The adult form on the other hand, tends to be chronic and can persist from the fourth through the seventh decades of life, with a peak at age 40. Lesions may also be seen on the face with prominent symmetry (Fig. 22-2), particularly medial eyebrows, forehead, upper eyelids, nasolabial folds (Fig. 22-3), and lateral nares. Other sites commonly involved include retroauricular regions, external auditory canal, auricle, and conchae bowl (Fig. 22-4), scalp (Fig. 22-5), occiput, and neck. The presternal region of the chest, upper back (Fig. 22-6), and umbilicus can be involved as well, and can be petaloid or arcuate with fine pink scale. Intertriginous sites such as axillary and inguinal regions show less scale and mimic intertrigo. See Box 22-2 for site-specific differential diagnosis of seborrheic dermatitis. Erythema and pruritis are common, as well as burning or tingling sensitivity reported as well, particularly on the scalp. *Pityrosporum folliculitis* can be seen as well with diffuse monomorphic tiny pustules and papules with peripheral erythema on the trunk. Diagnosis can be confirmed with a KOH (potassium hydroxide) preparation. Immunocompromised patients more commonly get this form of folliculitis. The adult form typically begins during puberty corresponding with androgen activity, which

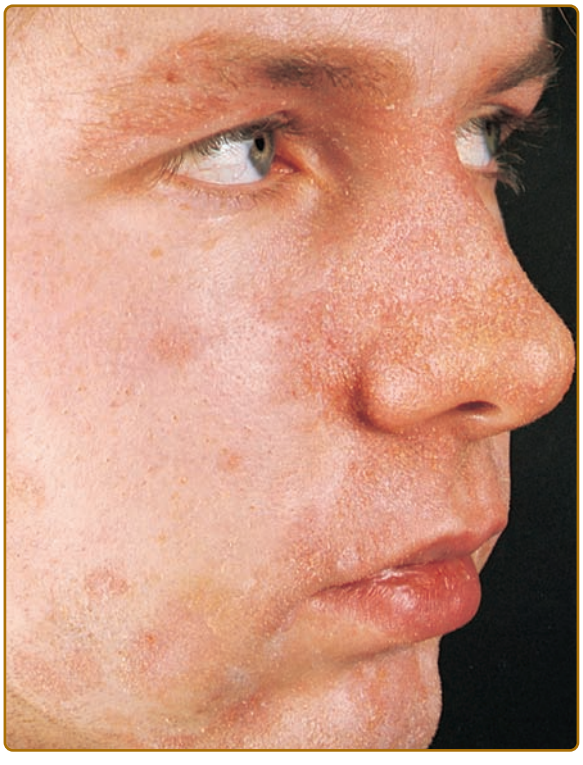

Figure 22-2 Seborrheic dermatitis with involvement of nasolabial folds, cheeks, eyebrows, and nose.

Figure 22-3 Seborrheic dermatitis of the nasolabial fold.

Figure 22-4 Seborrheic dermatitis of the ear: external canal, concha bowl, and auricle.

Figure 22-5 Seborrheic dermatitis of the scalp, ear, sideburn area, beard, and face with diffuse scale and inflammation.

results in an increase in size and activity of sebaceous glands. Prepubertal patients tend to not get seborrheic dermatitis because of this lack of androgen stimulation of sebaceous glands, and have also not been shown to have excessive colonization of *Malessezia* species.

ERYTHRODERMA DESQUAMATIVUM (LEINER'S DISEASE)

Leiner first described this controversial condition in 1908, dermatitis seborrhoides infantum, and is considered a severe, widespread, erythrodermic form of infantile seborrheic dermatitis.[39] These patients have symptoms of fever, anemia, diarrhea, vomiting, weight loss, and sometimes death if not treated properly with intense IV hydration, temperature regulation, and antibiotics if they have secondary bacterial infection. There is both a familial and nonfamilial form of Leiner's. The hereditary form has been associated with deficiencies of complement C3, C5, and phagocyte malfunction therefore resulting in defective opsonization of bacteria. Patients with the hereditary form may necessitate treatment with fresh frozen plasma and whole blood to supplement these complement deficiencies.[40]

Figure 22-6 Seborrheic dermatitis of the upper back.

BOX 22-2 SITE-SPECIFIC DIFFERENTIAL DIAGNOSIS OF SEBORRHEIC DERMATITIS

Scalp*	Psoriasis, atopic dermatitis, impetigo, tinea capitis* (mimics dandruff in children)
Face	Psoriasis, rosacea, contact dermatitis, impetigo, discoid lupus, sarcoid (petaloid type in African-Americans), drug-induced photosensitivity
Ear canal	Psoriasis, contact dermatitis
Eyelids	Atopic dermatitis, psoriasis, *Demodex folliculorum* infestation
Chest, back	Pityriasis rosea, tinea versicolor, subacute cutaneous lupus, psoriasis vulgaris
Groin, buttock	Intertrigo (fungal, candidal, erythrasma), glucagonoma, extramammary Paget's disease, zinc deficiency
Intertriginous	Inverse psoriasis, candidiasis, erythrasma, contact dermatitis, tinea intertrigo, Langerhans cell histiocytosis (Letterer Siwe in infants)
Generalized*	Scabies, secondary syphilis, pemphigus foliaceous, pemphigus erythematosus, Leiner's (infants), drug eruption
Erythrodermic*	Psoriasis, contact dermatitis, pityriasis rubra pilaris, drug eruption, mycosis fungoides (Sezary syndrome), lichen planus, chronic actinic dermatitis, HIV, Hodgkin's disease, paraneoplastic syndrome, leukemia cutis

*Diffuse scalp dermatitis or inflammatory alopecia in children warrants fungal culture, KOH prep. Widespread truncal types warrant scabies prep and RPR to rule out syphilis. Erythrodermic type should be biopsied.

PITYRIASIS AMIANTACEA

Pityriasis amiantacea was first described by Alibert in 1832, and is also known as asbestos scalp, tinea asbestina, keratosis follicularis amiantacea, and porrigo

Figure 22-7 Pityriasis amiantacea. Masses of sticky silvery scales adhere to the scalp and cause matting of hairs they surround.

amiantacea.[41] The use of the term tinea amiantacea is discouraged since tinea capitis is rarely associated with pityriasis amiantacea. This is a localized or diffuse condition, in which inflammation and massive silvery scaling of the scalp results in thick, matted, sticky hair (Fig. 22-7). This condition can occur at any age, especially adolescents and young females. It is most commonly seen with psoriasis (35%), and eczematous conditions like seborrheic dermatitis and atopic dermatitis (34%).[42] Case reports of patients with lichen planus and Darier's have had associated pityriasis amiantacea.[43] Middle-aged females with lichen simplex chronicus can have patches of pityriasis amiantacea as well. Alopecia may result and is nonscarring unless secondary scalp infection occurs with *Streptococcus* or *Staphylococcus* and should be treated appropriately. Staphylococcal isolates in the matted hairs can be found in up to 96% of patients.[42] Young females commonly have concomitant postauricular scale and fissures.

SEBORRHEIC DERMATITIS IN HIV AND AIDS PATIENTS

Patients with HIV and AIDS have severe and extensive seborrheic dermatitis (Fig. 22-8) that tends to be refractory to standard therapy.[44] Treatment with 400 mg of oral ketoconazole daily for 2 weeks may be necessary. The initial facial eruption may appear as a butterfly rash, similar to the acute facial eruption associated with systemic lupus erythematosus. The histopathology also differs from seborrheic dermatitis in HIV seronegative patients in that they have much more parakeratosis, necrosis, lymphocytes, and focal leukocytosis.[45] Seborrheic dermatitis usually occurs when CD4+ counts are between 200–500 cells/mm^3 and as one of the earliest skin manifestations of HIV patients.[46]

HISTOPATHOLOGY

Depending on the stage of the lesion biopsied, the changes seen include acute, subacute, and chronic spongiotic dermatitis. In acute lesions there is folliculocentric scale crust composed of orthokeratosis and focal parakeratosis with scattered neutrophils, mild focal

Figure 22-8 **A** and **B.** Widespread unusual distribution pattern of seborrheic dermatitis in a patient with AIDS. **A.** Moist patches on the centrofacial region, beard and scalp. **B.** Moist lesions on the chest. In patients with AIDS, the disease responds poorly to conventional therapy.

TABLE 22-2
Histopathologic Differences Between Classic Seborrheic Dermatitis and AIDS-Associated Seborrheic Dermatitis

Classic Seborrheic Dermatitis	AIDS-Associated Seborrheic Dermatitis
Epidermis	
Limited parakeratosis	Widespread parakeratosis
Rare necrotic keratinocytes	Many necrotic keratinocytes
No interface obliteration	Focal interface obliteration with clusters of lymphocytes
Prominent spongiosis	Sparse spongiosis
Dermis	
Thin-walled vessels	Many thick-walled vessels
Rare plasma cells	Increased plasma cells
No leukocytoclasis	Focal leukocytoclasis

From Soeprono FF et al: Seborrheic-like dermatitis of acquired immunodeficiency syndrome: A clinicopathologic study. *J Am Acad Dermatol* **14**:242, 1986, with permission.

spongiosis, and a sparse superficial perivascular infiltrate of lymphocytes and histiocytes. Subacute lesions show mild psoriasiform hyperplasia and numerous yeast species in the stratum corneum in addition to the above findings. Chronic lesions show even more psoriasiform hyperplasia and crusting scales in a folliculocentric distribution, superficial dilation of capillaries and venules, and minimal spongiosis. The chronic form may be difficult to distinguish from psoriasis clinically and pathologically, but the folliculocentric distribution supports seborrheic dermatitis.

HIV and AIDS patients with seborrheic dermatitis show histopathologic findings consistent with severe, chronic seborrheic dermatitis (Table 22-2). Patients with pityriasis amiantacea show, spongiosis, mild exocytosis of lymphocytes and acanthosis. The asbestos-like scale seen is due to a thick layering of hyperkeratosis and parakeratosis surrounding the outer hair shafts. Patients with dandruff (pityriasis simplex capillitii, aka pityriasis capitis) show minimal parakeratotic foci of scale, without any spongiosis or inflammatory infiltrates.[47]

TREATMENT

INFANTILE SEBORRHEIC DERMATITIS

This benign, self-limited form responds readily to shampoos, emollients, and mild topical steroids. Infants with prolonged inflammation on the scalp or intertriginous areas can be treated with low potency topical corticosteroids (hydrocortisone 1% cream or lotion for a few days), followed by topical imidazoles (2% ketoconazole cream, lotion, or 1% shampoo). Aggressive removal of scale with keratolytics or mechanical removal is discouraged to prevent further inflammation. However, mild baby shampoos, with or without 3% salicylic acid applications, can help remove thick, stubborn scale on the scalp. Secondary infections with candidiasis or *Staphylococcus* should be treated appropriately. Infants with seborrheic dermatitis do not respond to dietary alterations or restrictions (milk-free, etc.) and vitamin supplementation that may help patients with atopic dermatitis.[38,48–51]

ADULT SEBORRHEIC DERMATITIS

Adults tend to have chronic and recurrent disease, and as such, the patients should be informed that the aim of treatment will be to control rather than cure the disease. Scalp seborrheic dermatitis can be treated with shampoos containing zinc pyrithione, selenium sulfide (1%–2.5%), imidazoles (1%–2% ketoconazole shampoo, creams, lotions, or foams), ciclopirox (cream, gel, and shampoo), salicylic acid (shampoos, creams), coal tar (creams, shampoos), or mild detergents. Dandruff (pityriasis simplex capillitii) involves the face and scalp as well with extensive scale, but shows minimal to no inflammation and erythema. Dandruff responds to more frequent shampooing or a longer period of lathering. Shampoos may be used on the scalp, beard and chest, but may flare the disease if used on the face or other intertriginous areas if left on for extended periods. Xanthotrichia or yellow hair has been reported in patients using selenium sulfide shampoo. Severe and thick scale on the scalp can respond to overnight application of topical corticosteroids (low-, mid-, or high-potency creams, lotions, or foams depending on the severity) with shower cap occlusion as needed, Baker's P&S solution, tar shampoo, or salicylic acid (ointment or shampoo, especially for patients with pityriasis amiantacea). Alternative effective treatments include coconut oil compound (ointment combination of coal tar, salicylic acid and sulfur). Patients should avoid aggressive manipulation. Hair sprays and hair pomades should be stopped. Treatment of any underlying secondary microbial infection should be treated as well. Patients with severe inflammatory disease that fail the above regimens may respond to a 1-week course of systemic glucocorticoids (prednisolone 0.5 mg/kg body weight/day), while cautioning the patient of side effects and informing them of potential rebound flares following discontinuation of the medication.[52–57]

Treatment of the face, trunk, and ears includes short courses of low potency topical glucocorticoids (Class IV or lower) to suppress the initial inflammation. Excessive and long-term topical corticosteroid application should be discouraged as well to prevent steroid acne, steroid rosacea, perioral dermatitis, and rebound phenomenon. Topical calcineurin inhibitors (pimecrolimus and tacrolimus) have anti-inflammatory and antifungal (tacrolimus) properties without the long-term side effects of topical corticosteroid use. Topical antifungals such as ketoconazole, miconazole, fluconazole, itraconazole, econazole, bifonazole, climbazole, ciclopirox, and ciclopiroxolamine have all been used with varying success. Sulfur or sulfonamide combinations, or propylene glycol topical have also been used. Benzoyl peroxide wash 5%–10% can be used as

well. Recommend patients to avoid alcohol-containing solutions that flare the disease. Aluminum acetate solution can be used to maintain seborrheic otitis externa. Patients with seborrheic blepharitis can be treated with warm to hot compresses and washing with baby shampoo followed by gentle cotton tip debridement of thick scale. Avoid ocular glucocorticoids. Ophthalmic sodium sulfacetamide ointment can be used for resistant seborrheic blepharitis.[58–68]

There are many other alternative treatments. Oral antifungals should be reserved for severe and refractory cases due to potential drug interactions and side effects. Allylamines may also be effective including topical butenafine and naftifine cream for mild cases versus oral terbinafine for extensive involvement. Lithium succinate and lithium gluconate, both available in some countries, have antifungal properties that can be used for treatment as well. Vitamin D3 analogs (calcipotriol cream or lotion) have both anti-inflammatory and antifungal properties and can be used in selected patients as well. Other alternatives include topical metronidazole cream or gel, once to twice daily. Oral isotretinoin in low doses (2.5–5 mg daily; or 0.1–0.3 mg/kg/day) over 3–5 months can be used in refractory disease, of course while observing requirements in child-bearing females. Phototherapy with narrowband ultraviolet B or psoralen plus ultraviolet A can also be used in severe and refractory disease, but may be ineffective if patients have thick hair.[17,69,74]

ACKNOWLEDGMENTS

We would like to thank Gerd Plewig and Thomas Jansen for their previous editions of this chapter on seborrheic dermatitis and the use of their format, tables, boxes, and photos while revising this chapter.

Chapter 23 :: Exfoliative Dermatitis

:: Jane Margaret Grant-Kels, Flavia Fedeles, & Marti J. Rothe

EXFOLIATIVE DERMATITIS AT A GLANCE

- Exfoliative dermatitis (ED) is defined as diffuse erythema and scaling of the skin involving more than 90% of the total body skin surface area.
- Systemic and potentially life-threatening complications include fluid and electrolyte imbalance, thermoregulatory disturbance, fever, tachycardia, high-output failure, hypoalbuminemia, and septicemia.
- Common underlying etiologies are psoriasis, atopic dermatitis, and other spongiotic dermatoses, drug hypersensitivity reactions, and cutaneous T-cell lymphoma (CTCL). The cause of ED is unknown (idiopathic) in approximately 20% of cases.
- Diagnostic workup includes a complete history and physical examination, with careful analysis of pertinent clinical clues and dermatohistopathology. Other laboratory workup is often required and determined by clinical clues.
- Management of ED involves combining symptomatic relief with addressing the underlying etiology and potential systemic complications. Inpatient hospitalization is required in acute cases.
- Prognosis is variable and depends primarily on the underlying etiology. Drug-induced ED has the best prognosis while malignancy-associated ED has the highest mortality.

EPIDEMIOLOGY

Several large studies have reported a widely varied incidence of exfoliative dermatitis (ED) ranging from 0.9 to 71.0 per 100,000 outpatients.[1–4] A male predominance has been described, with a male-to-female ratio of approximately 2:1 to 4:1. Any age group can be affected, and with most studies excluding children, the average age of disease onset varies from 41 to 61. ED is a rare disease in children, and only little epidemiologic data is available for pediatric populations. One study found 17 patients, recorded over a 6-year period, with a mean age of onset of 3.3 years and a male-to-female ratio of 0.89:1.[5] ED occurs in all races.[6]

A preexisting dermatosis plays a role in more than one-half of the cases of ED. Psoriasis is the most common underlying skin disease (almost one-fourth of the cases). In a recent study of severe psoriasis, ED was reported in 87 of 160 cases.[7]

ETIOLOGY AND PATHOGENESIS

Establishing the etiology of ED can be challenging since it can be caused by a variety of cutaneous and systemic diseases (Table 23-1). A compilation of 18 published studies[1,2,4,6,8–21] from various countries on ED shows that a preexisting dermatosis is the most frequent cause in adults (52% of ED cases; range, 27%–68%) followed by drug hypersensitivity reactions (15%), and cutaneous T-cell lymphoma (CTCL) or Sézary syndrome (5%). No underlying etiology is identified in approximately 20% of ED cases (range, 7%–33%) and these cases are classified as idiopathic.

Psoriasis is the most common underlying skin disease to cause ED (23% of cases), followed by spongiotic dermatitis (20%). Possible triggers for psoriatic ED include the following:

- Medications, such as lithium, terbinafine, and antimalarials
- Topical irritants including tars
- Systemic illness
- Discontinuation of potent topical or oral corticosteroids, methotrexate, or biologics (efalizumab)[22,23]
- Infection including human immunodeficiency virus (HIV)
- Pregnancy
- Emotional stress
- Phototherapy burns

Less common causes of ED in adults include immunobullous disease; connective tissue disease; infections, including scabies and dermatophytes; pityriasis rubra pilaris (PRP) (4% of dermatoses); and underlying malignancy. Even in patients with underlying dermatoses, it is critical to consider other possible etiologies. In one case series, malignancy-related ED was identified in seven patients, five of whom had a preexisting dermatosis.[11] In about 5%–10% of idiopathic ED cases, erythrodermic CTCL was ultimately diagnosed.[24] Solid organ malignancies as well as hematologic and reticuloendothelial malignancies may manifest as ED.

In neonates and infants, the differential diagnosis includes dermatoses (such as psoriasis, atopic dermatitis, and seborrheic dermatitis), drugs, and infection (particularly staphylococcal scalded-skin syndrome). In addition, several congenital disorders including the ichthyoses, both bullous and nonbullous congenital ichthyosiform erythroderma, Netherton syndrome, and immunodeficiencies should be considered (Box 23-1).

Topical and systemic medications are implicated in a significant percentage of ED cases (15%; range, 4%–39%) and the introduction of new drugs is likely to increase the incidence of ED. Both allopathic and naturopathic medications have been suggested to cause ED and the list is constantly expanding (Table 23-2). The most commonly implicated drugs include calcium channel blockers, antiepileptics, antibiotics (penicillin family, sulfonamides, vancomycin), allopurinol, gold, lithium, quinidine, cimetidine, and dapsone. However, most of the drugs are reported in single case reports. In addition to drugs, the contrast medium iodixanol (Visipaque) used during percutaneous coronary interventions has recently been reported to cause ED.[25]

Currently, the pathogenic mechanisms of ED have not been elucidated. It is not well understood how a preexisting dermatosis progresses to ED, an underlying disease manifests as ED, or the de novo ED develops. While the clinical presentation is similar in patients with diverse etiologies of ED, it is likely that different pathways lead to the common end result of skin-selective recruitment of inflammatory cells.

Cytokines, chemokines, and their receptors are believed to play an important role in the pathogenesis of ED. A study of cytokine profile in dermal infiltrates showed that there may be differences in pathophysiologic mechanisms between benign ED and Sézary syndrome—a T helper 1 cytokine profile was found in benign ED while a T helper 2 cytokine profile was found in Sézary syndrome.[26] In a recent report, an overexpression of both T helper 1- and T helper 2-related chemokine receptors (CCR4, CCR5, and CXCR3) was found in ED of inflammatory origin, while a selective overexpression of CCR4 was found in Sézary syndrome,[27] suggesting that Sézary syndrome is a T helper 2 disorder and that different pathways may contribute to skin homing of reactive lymphocytes in different etiologies of ED. Another study showed that Sézary syndrome and inflammatory ED are characterized by different memory T-cell subset expression, further suggesting different pathophysiologic mechanisms.[28]

The interaction between adhesion molecules and their ligands is important during inflammatory and immunological responses. Increased circulating levels of adhesion molecules (intercellular adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin) have been reported in benign reactive ED secondary to psoriasis and atopic dermatitis compared to controls.[29] In contrast, no differences in expression levels of these molecules on endothelial cells were found in different types of ED, leading to the hypothesis that there are similarities in end-stage immunologic pathways in different types of ED.[30]

TABLE 23-1
Diseases Associated With Exfoliative Dermatitis

Dermatoses	Systemic	Infections	Malignancy	Congenital
▪ Spongiotic dermatitis ▪ Atopic dermatitis[a] ▪ Seborrheic dermatitis[2] ▪ Contact dermatitis ▪ Stasis dermatitis ▪ Bullous ▪ Pemphigus foliaceus[69] ▪ Paraneoplastic pemphigus[74] ▪ Bullous pemphigoid ▪ Hailey–Hailey[77] ▪ Papulosquamous ▪ Psoriasis[a] ▪ Generalized pustular psoriasis[87] ▪ Pityriasis rubra pilaris[a] ▪ Impetigo herpetiformis[93] ▪ Photosensitive ▪ Chronic actinic dermatitis ▪ Actinic reticuloid[97] ▪ Adverse drug[a] ▪ Acute generalized exanthematous pustulosis ▪ Toxic epidermal necrolysis ▪ Other ▪ Pseudolymphoma[103] ▪ Erythema gyratum repens[107] ▪ Perforating folliculitis[109] ▪ Radiation recall dermatitis[111] ▪ Senile erythroderma with hyper-IgE[115]	▪ Dermatomyositis[43–48] ▪ Subacute cutaneous lupus[49–51] ▪ Acute graft-versus-host disease[56,a] ▪ Postoperative transfusion induced[59] ▪ Thyrotoxicosis[60] ▪ Sarcoidosis[64–67] ▪ Hypercalcitonemia[70] ▪ Idiopathic hypereosinophilic syndrome[75] ▪ Monoclonal gammopathy of undetermined significance[76] ▪ Hemophagocytic histiocytosis, viral associated[78,79]	▪ Bacterial ▪ Tuberculosis[52] ▪ Congenital syphilis[57] ▪ Viral ▪ Hepatitis C[61] ▪ Human immunodeficiency virus ▪ Human herpesvirus 6[71] ▪ Fungal ▪ Dermatophyte[14,18] ▪ Histoplasmosis[80–82] ▪ Congenital cutaneous candidiasis[84] ▪ Parasite ▪ Norwegian scabies[88] ▪ Toxoplasmosis[90] ▪ Leishmaniasis[94] ▪ Toxin-mediated infections ▪ Staphylococcal scalded-skin syndrome[a] ▪ Toxic shock syndrome	▪ Solid tumors ▪ Lung[14,17,18,53,54] ▪ Prostate[14,18,58] ▪ Thyroid[14] ▪ Liver[14,62] ▪ Gallbladder[68] ▪ Melanoma[18,72] ▪ Breast[18] ▪ Ovary[18] ▪ Fallopian tube[83] ▪ Esophagus[85] ▪ Stomach[17,86] ▪ Rectum[18] ▪ Colon[91] ▪ Thymus[95] ▪ Buschke–Loewenstein tumor[96] ▪ Lymphoproliferative ▪ Cutaneous T-cell lymphoma[a] ▪ Sézary syndrome ▪ Papuloerythroderma of Ofuji ▪ Hodgkin lymphoma[12,14,15,100] ▪ B-cell lymphoma[102] ▪ (Cutaneous) anaplastic large cell lymphoma[104,105] ▪ Angioimmunoblastic T-cell lymphoma[108] ▪ Castleman disease[110] ▪ Acute myeloid leukemia M6[112] ▪ Acute myelomonocytic leukemia[116] ▪ Adult T-cell leukemia[117] ▪ T-cell prolymphocytic l eukemia[118] ▪ Chronic lymphocytic leukemia[12] ▪ Chronic myelogenous leukemia[119] ▪ Chronic eosinophilic leukemia[120] ▪ Myelodysplasia[121] ▪ Premalignant myeloproliferative disorder[122] ▪ Multiple myeloma[34] ▪ Reticulum cell sarcoma[8] ▪ Angioimmunoblastic lymphadenopathy[123] ▪ Cutaneous lymphoid hyperplasia ▪ Hypereosinophilic syndrome[124–126] ▪ Mastocytosis (type II–IV)[127,128] ▪ Histiocytosis[129] ▪ Rosai–Dorfman disease	▪ Immunodeficiency ▪ Common variable hypogammaglobulinemia[55] ▪ Wiskott–Aldrich syndrome ▪ Severe combined immunodeficiency ▪ Omenn syndrome[63] ▪ Leiner disease ▪ Hyperimmunoglobulin E (hyper-IgE) syndrome[73] ▪ Secretory IgA deficiency ▪ Metabolic ▪ Maple syrup urine disease ▪ Neutral lipid storage disease ▪ Essential fatty acid deficiency ▪ Propionic acidemia[89] ▪ Holocarboxylase synthetase deficiency[92] ▪ Ichthyosis ▪ Bullous congential ichthyosiform erythroderma ▪ Nonbullous congenital ichthyosiform erythroderma ▪ Netherton syndrome[98] ▪ Conradi–Hünermann syndrome[99] ▪ Epidermolytic hyperkeratosis ▪ Keratitis, ichthyosis, and deafness[101] ▪ Lamellar ichthyosis ▪ Lethal congenital erythroderma[106] ▪ Sjögren–Larsson syndrome ▪ Other ▪ Ankyloblepharon–ectodermal dysplasia–clefting syndrome (AEC)[113,114]

[a]Most common diseases.

BOX 23-1 DIFFERENTIAL DIAGNOSIS

Most Likely

- Spongiotic dermatitis (20%–24%) (atopic, 9%; contact dermatitis, 6%; seborrheic dermatitis, 4%; chronic actinic dermatitis, 3%)
- Psoriasis (23%)
- Drug hypersensitivity reaction (15%)
- Cutaneous T-cell lymphoma (5%)
- Idiopathic (approximately 20%)

Consider

- Contact dermatitis
- Immunobullous disease (superficial pemphigus, bullous pemphigoid, paraneoplastic pemphigus)
- Infection (scabies, dermatophytosis)
- Toxin-mediated (toxic shock syndrome, staphylococcal scalded-skin syndrome)
- Chronic actinic dermatitis
- Pityriasis rubra pilaris
- Collagen vascular disease
- Paraneoplastic (solid tumors and hematologic)
- Primary immunodeficiency
- Congenital ichthyoses

Always Rule Out

- Cutaneous T-cell lymphoma
- Drug-induced hypersensitivity syndrome
- Paraneoplastic

The complex interaction between adhesion molecules and cytokines likely contributes to the significantly increased mitotic and epidermal turnover rate in ED. The scaling of ED skin is a reflection of decreased transit time through the epidermis and leads to significant loss of protein, amino acids, and nucleic acids. Protein loss may increase by 25%–30% via scaling in psoriatic ED, and 10%–15% in nonpsoriatic ED.[31] Additionally, protein-losing enteropathy may contribute to hypoalbuminemia.

Some patients with chronic idiopathic ED have been reported to develop CTCL that has led to concern that patients with chronic idiopathic ED may be at increased risk for progression to mycosis fungoides or Sézary syndrome.[18,32] The chronic T-cell stimulation in these patients has been suggested to promote the development of CTCL.[33–37] Recently, a premalignant or pre-Sézary-like condition has been described in elderly patients with chronic or relapsing ED without progression to hematologic malignancy characterized by a monoclonal expansion of $CD4^+CD7^-CD26^-$ lymphocytes.[34] The term monoclonal T-cell dyscrasia of undetermined significance (MTUS), a T-cell equivalent to monoclonal gammopathy of undetermined significance, has been proposed for this condition, which is believed to be probably benign.[34] However, chronic idiopathic ED may also represent primary chronic, undiagnosed CTCL. Indeed, in up to 10% of idiopathic ED cases, erythrodermic CTCL is ultimately diagnosed.[24]

A role for immunoglobulin (Ig) E in ED has been proposed based on the observation of increased IgE levels in many types of ED. For example, it has been theorized that elevations in IgE in psoriatic ED may point to a change from a T helper 1 cytokine profile in psoriasis to a T helper 2 cytokine in psoriatic ED.[38] This secondary mechanism is different than the primary overproduction of IgE in atopic dermatitis. Hyper-IgE syndrome is an immune deficiency that has been associated with ED, and has high IgE production due to selective insufficient interferon-γ secretion.[39] The mechanisms related to this elevation of IgE may be related to the underlying disease process or to the manifestation of the disease as ED. Again, the mechanisms of IgE elevation appear to be different in different types of ED.

Recently, it has been theorized that *Staphylococcus aureus* colonization or another antigen, such as toxic shock syndrome toxin-1, may play a role in the pathogenesis of ED.[40,41] Research on the immunopathogenesis of toxin-mediated infection demonstrates staphylococcal pathogenicity islands encoding superantigens (see Chapter 177). These islands carry the genes for the toxins of toxic shock syndrome and staphylococcal scalded-skin syndrome.[42] 83% of patients with ED were noted to have *S. aureus* colonization in the nares, while 17% had colonization in the skin; however, only one in six patients was *S. aureus* enterotoxin positive.[41] (See Tables 23-1 and 23-2.)

CLINICAL FINDINGS

Figure 23-1 is an algorithm showing the approach to a patient with ED.

HISTORY

A detailed history of a patient who presents with ED is an important tool for diagnosing the underlying etiology. The patients may have a history of dermatoses (psoriasis, atopic dermatitis) or a systemic medical condition. A thorough medication history should be elicited, including naturopathic and over the counter therapies. Patients with history of psoriasis and atopic dermatitis should be queried specifically regarding use of topical and systemic corticosteroids, methotrexate, and other systemic medications; topical irritants; systemic illness; infection; phototherapy burns; pregnancy; and emotional stress. ED patients commonly report thermoregulatory disturbances, malaise, fatigue, and pruritus; these symptoms are not specific to any etiology.

The onset of symptoms is important to assess different etiologies of ED. Primary skin diseases have a slower course while drug reactions usually have a rapid onset and resolution. One exception is ED associated with drug hypersensitivity reactions due to anticonvulsants, antibiotics, and allopurinol. This reaction develops in 2–5 weeks after medication is started

TABLE 23-2
Drugs Implicated in Exfoliative Dermatitis[a]

Antibiotics
- Aztreonam
- Cefoxitin[130,131]
- Doxycycline[123]
- Gentamicin[136]
- *Isoniazid*[2,12,15]
- Minocycline
- Neomycin
- *Penicillin*[8,12,14,15]
- Ribostamycin[145]
- Rifampin
- *Streptomycin*[2,14]
- Sulfasalazine[153,154]
- *Sulfonamides*[12,14]
- Teicoplanin[158]
- Thiacetazone[2]
- Tobramycin[163]
- Trimethoprim[1,164]
- Vancomycin[166,167]

Antivirals
- Dideoxyinosine[171]
- Indinavir[173]
- Interferon α [176]
- Zidovudine[178]

Antilepromatous
- Clofazimine[183]
- *Dapsone*[185–190]

Antifungals
- Nystatin[197]
- Terbinafine[201]
- Ketoconazole[205]
- Griseofulvin[207]

Antiepileptics
- *Carbamazepine*[10,17,209,210]
- Lamotrigine[214]
- *Phenytoin*[12,17,215,216]
- *Phenobarbital*[219]
- Aztreonam

Anti-inflammatory
- Aspirin
- Celecoxib[132]
- Diflunisal[135]
- Metamizole[137]
- Phenylbutazone[2]
- Piroxicam[140]

Cardiac drugs
- Amiodarone[143]
- Captopril[146]
- Diltiazem[148,149]
- Enalapril[151]
- Isosorbide dinitrate[12]
- Mexiletine
- Nifedipine[159]
- Nitroglycerin[161]
- Practolol[1]
- *Quinidine*[8,17]
- Verapamil[168]

Chemotherapy
- Bevacizumab[172]
- Carboplatin[174]
- Cisplatin[177]
- Denileukin diftitox[179]
- Doxorubicin[182]
- Fluorouracil
- Imatinib[191–193]
- Mitomycin C[195]
- Pentostatin[198]
- Vinca alkaloids[202]

Diabetic
- *Sulfonylureas*
- Chlorpropamide[208]

Psychiatric
- *Barbiturates*
- Bupropion[217]
- Chlorpromazine[1]
- Desipramine[221]
- Escitalopram[222]
- Etumine[10]
- Fluoxetine[224]
- Imipramine[221]
- Lithium[225]
- *Phenothiazines*
- Methylphenidate[226]
- Aspirin

Other
- *Allopurinol*[1,10,12,17]
- *Antimalarials*[8,12,14,133,134]
- Arsenicals
- Bacille Calmette-Guérin immunization[138]
- Bromodeoxyuridine[139]
- Cimetidine[141]
- Clodronate[142]
- Codeine[14,144]
- Efalizumab[147]
- Ephedrine[150]
- Epoprostenol[152]
- Erythropoietin[155,156]
- Ethylenediamine[157]
- Fluindione[160]
- Furosemide[162]
- *Gold*[1,8,14,17]
- Homeopathic medicine (NatMur200)[165]
- Hypericum (St. John's wort)[169]
- Interleukin 2[170]
- Iodine[14]
- Leflunomide[175]
- Mercurials[14,15]
- Omeprazole[180,181]
- Phenolphthalein[14]
- Propolis[184]
- Pseudoephedrine[194]
- Ranitidine[196]
- Retinoids[199,200]
- Rhus (lacquer)[203,204]
- Roxatidine acetate hydrochloride[206]
- Terbutaline[12]
- Tetrachloroethylene[14]
- Thalidomide[211–213]
- Thiazide[12]
- Timolol eye drops[218]
- Tocilizumab[220]
- Tramadol
- Tumor necrosis factor-α[170]
- Valiya narayana[223]
- Allopurinol[1,10,12,17]

[a]Most commonly implicated drugs are in italics.

and may remain ongoing after discontinuation of the medication. Associated signs of a possible drug etiology include fever, lymphadenopathy, organomegaly, edema, leukocytosis with eosinophilia, and liver and renal dysfunction.[153,215]

History and clinical presentation alone may not be sufficient to diagnose ED due to internal malignancy. Important clues for this diagnosis are an absence of prior skin disease, gradual onset, and a lack of response to standard therapies. A history of transplant should raise suspicion of CTCL, as it has been found that there is a higher frequency of ED secondary to CTCL in post-transplant patients.[227]

CUTANEOUS LESIONS

The classic presentation of ED is erythematous patches that increase in size and coalesce into generalized red erythema with a shiny appearance. By definition, ED involves more than 90% of the patient's skin surface (Fig. 23-2). A few days after the onset of erythema, fine

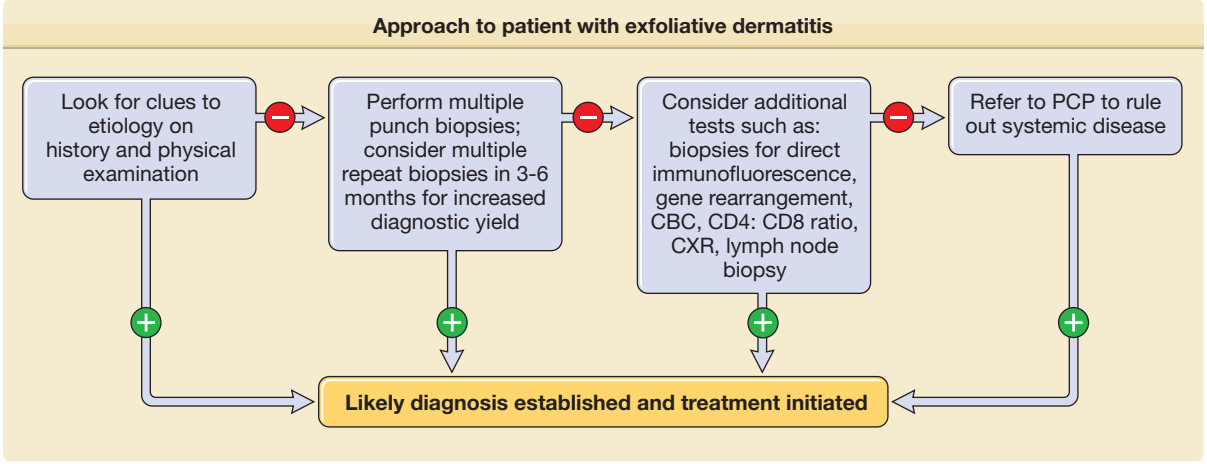

Figure 23-1 Approach to patient with exfoliative dermatitis. CBC = complete blood cell count; CXR = chest X-ray; PCP = primary care physician.

white or yellow scaling begins, classically arising in the flexures. Plate-like scaling may occur acutely and on the palms and soles. The scaling progresses further, giving the skin a dull red appearance. With chronicity, edema and lichenification lead to skin induration. Ectropion and epiphora may develop secondary to chronic periorbital involvement (Fig. 23-3). Palmoplantar keratoderma (Fig. 23-4) has been noted in up to 80% of patients with chronic ED.[18]

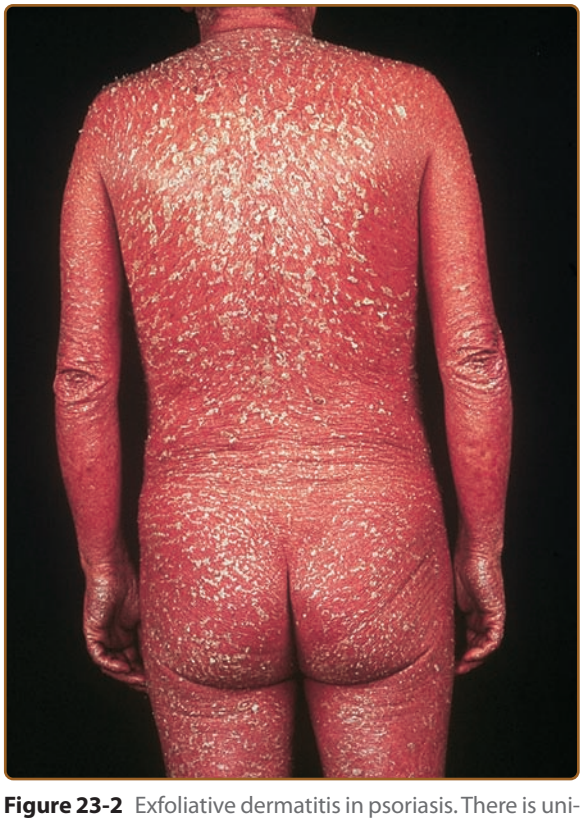

Figure 23-2 Exfoliative dermatitis in psoriasis. There is universal erythema, thickening of the skin, and heavy scaling. The patient had fatigue, malaise, and was shivering.

Some patients develop involvement of their hair and nails. Scaling of the scalp, alopecia, and in some cases, diffuse effluvium can be seen. Nail changes may include onycholysis, subungual hyperkeratosis, splinter hemorrhages, paronychia, Beau's lines, and, occasionally, onychomadesis.[2] Shore-line nails with alternating bands of nail plate discontinuity represent drug-induced ED reflecting the periods of time the drug was used.[228]

Sparing of the nose and paranasal areas (the "nose sign") has been described in some studies. Areolar sparing has been noted in some cases of CTCL, drug reactions, "eczema," psoriasis, photosensitivity, and PRP.[229] Typically, there is not mucosal involvement. Eruptive seborrheic keratoses may arise in patients with ED.[230–232] The keratoses often resolve spontaneously as the ED subsides.

The cutaneous lesions may suggest the underlying etiology of ED. For example, in early psoriatic ED, classic psoriatic plaques may be seen. Gottron's papules, heliotrope rash, and muscle weakness may be present in ED caused by dermatomyositis. Papuloerythroderma of Ofuji typically spares the abdominal skin folds (the "deck chair" sign).

Figure 23-4 Pityriasis rubra pilaris exfoliative dermatitis with keratoderma. Note keratoderma with an orange hue and thickening of the thumbnails.

SPECIFIC FEATURES OF UNDERLYING DISEASES

Features of underlying diseases may aid in diagnosis (see Table 23-3 and eFigures 23-4.1–23-4.4 in online edition).

RELATED PHYSICAL FINDINGS

Related physical findings due to ED of any etiology may include the following:

- Tachycardia due to increased blood flow to the skin and fluid loss due to disrupted epidermal barrier.
- High-output cardiac failure has been infrequently reported secondary to the high-flow state in ED.[233]
- Thermoregulatory disturbances can result in hyperthermia or less commonly hypothermia; however, most patients complain of feeling chilly.
- Generalized lymphadenopathy occurs in more than one-third of patients.[2,12,15] The clinician must distinguish between dermatopathic lymphadenopathy and lymphoma. If lymphadenopathy is prominent, a lymph node biopsy may be required.
- Hepatomegaly may occur in about one-third of patients [2,12,15] and is more commonly seen in drug-induced ED.
- Splenomegaly has also been rarely reported[12] and is most commonly associated with lymphoma.
- Peripheral pedal or pretibial edema may occur in up to 54% of patients.[15,32] Rarely, facial edema has been reported in drug-induced ED.

LABORATORY TESTS

Laboratory tests are most often not diagnostic and not specific. Common laboratory abnormalities found in ED patients include anemia, leukocytosis, lymphocytosis, eosinophilia, increased IgE, decreased serum albumin, and an elevated erythrocyte sedimentation rate. Fluid loss may lead to electrolyte abnormalities and abnormal renal function (elevated creatinine level). Elevated IgE levels have been noted in patients with ED unrelated to atopic dermatitis,[10,12,18] including in 81.3% of psoriatic ED patients.[38] Eosinophilia is nondiagnostic and has been found in 20% of ED patients.[17] However, when highly elevated eosinophil counts are noted, the possibility of associated Hodgkin disease must be investigated.

It is very important to differentiate benign erythrodermic inflammatory diseases from Sézary syndrome. In cases where erythrodermic CTCL is suspected, a thorough evaluation of skin, blood, and lymph node samples is required for definitive diagnosis. Studies have shown that a level of 20% or more circulating Sézary cells is a useful diagnostic criterion for Sézary syndrome, whereas less than 10% is nonspecific.[17,32] Exceptions do occur, such as in certain severe drug-induced reactions that can mimic Sézary syndrome (as hydantoin hypersensitivity).[234] Several benign dermatoses, including psoriasis, atopic dermatitis, discoid lupus, lichen planus, and "parapsoriasis" show the presence of Sézary cells in numbers less than 10%.[235] Demonstration of a clonal T cell receptor gene rearrangement is recommended for a sensitive and specific differentiation of Sézary syndrome from other etiologies of ED.

In a recent study, quantitative real-time polymerase chain reaction analysis of the expression values of five genes [(1) *STAT4*, (2) *GATA-3*, (3) *PLS3*, (4) *CD1D*, and (5) *TRAIL*] has proven useful for molecular diagnosis of Sézary syndrome[236] (see Chapter 145). Several molecular markers of Sézary cells have been recently studied (Twist, EphA4, T-plastin). In one report, CD158K/KIR3DL2, a killer immunoglobulin-like receptor normally expressed by subsets of circulating T CD8+ lymphocytes and natural killer cells, has been

TABLE 23-3
Specific Features of Underlying Disease Process[a]

Underlying Disease Process	Clinical Clues	
Idiopathic erythroderma ("red man syndrome")	Elderly men Chronic and relapsing course Dermatopathic lymphadenopathy	Pruritus Palmoplantar keratoderma
Psoriasis (see Chapter 18)	History of localized disease Personal or family history of psoriasis Classic psoriasiform plaques on elbows, knees, sacrum, etc. Well-circumscribed plaques at margins of erythroderma (eFig. 23-4.3 in online edition)	Large lamellar scales Psoriatic nail changes: pits, oil drop sign, onycholysis, subungual hyperkeratosis Collarettes of scale suggestive of ruptured pustules of pustular psoriasis Psoriatic arthritis
Atopic dermatitis (see Chapter 14)	History of localized disease, most often moderate to severe Personal or family history of atopy (atopic dermatitis, asthma, rhinoconjunctivitis) Marked pruritus	Classic atopic lesions in antecubital and popliteal fossae Lichenification and prurigo nodularis Excoriations Focal skin atrophy from years of use of potent topical steroids
Spongiotic dermatitis of other etiologies, such as contact dermatitis (see Chapter 13) (eFig. 23-4.1 in online edition) or stasis dermatitis (see Chapter 174)	Distribution of original skin lesions History of contactant History of preexisting venous disease	
Drug reaction (see Chapter 41)	Recent start of new drug, or use of frequently implicated drug Rapid onset of rash and progression to exfoliative Dermatitis	Lymphadenopathy Organomegaly Fever
Cutaneous T-cell lymphoma (see Chapter 145)	Severe debilitating pruritus Fissured, painful keratoderma Hepatosplenomegaly	Lymphadenopathy Alopecia Leonine facies
Immunobullous disease Pemphigus foliaceus and fogo selvagem (see Chapter 54) Bullous pemphigoid (see Chapter 56) Paraneoplastic pemphigus (see Chapter 55)	 Flaccid blisters Collarettes of scale at sites of previous blisters Superficial erosions and crusts Tense blisters (early lesions) Deep erosions and superficial ulcers Urticarial plaques Mucosal erosions and crusting prominent Rash resembles erythema multiforme Failure to thrive (i.e., cachexia)	 Pruritus Elderly patient
Paraneoplastic ED	Failure to thrive (i.e., cachexia)	
Pityriasis rubra pilaris (see Chapter 24)	Initial lesion: seborrheic dermatitis-like eruption of the scalp Worsening postsun exposure Generalized salmon-colored slightly infiltrated erythema (eFig. 23-4.4 in online edition)	Islands of sparing (eFig. 23-4.4 in online edition) Palmoplantar keratoderma, often orange (Fig. 23-4) Follicular pink papules of elbows, wrists, dorsal fingers or in skin spared from ED
Chronic actinic dermatitis (see Chapter 91)	Photo-accentuation	
Acute graft-versus-host disease (see Chapter 28)	History of bone marrow transplantation or blood transfusion	Initial lesion: palmar erythema Progression to toxic epidermal necrolysis
Dermatomyositis (see Chapter 156)	Gottron papules Heliotrope sign Poikiloderma	Periungual telangiectasia Muscle weakness
Sarcoidosis (see Chapter 152)	Apple jelly papules, plaques, and/or nodules	
Norwegian scabies (see Chapter 208)	Down syndrome or nursing home patient Burrows	Massively thickened nails Keratoderma

ED = exfoliative dermatitis.
[a]Features of underlying diseases may aid in diagnosis.

found to be useful as a molecular marker of Sézary syndrome in skin samples of patients with ED.[237] Another study suggests that Sézary syndrome may be differentiated from inflammatory ED based on different memory T-cell subset expression and that CD27 expression may be helpful as an additional diagnostic tool.[28]

Immunophenotyping of skin lymphocytes may be a helpful adjunct study in differentiation of Sézary syndrome from actinic reticuloid. Sézary patients show a clonal $CD4^+$ predominance while in patients with underlying actinic reticuloid,[238] there is a $CD8^+$ lymphocyte predominance. More specifically, $CD28^+/CD5^+/NKa^-/CD4^+$ T cells with reduction of CD3, CD4, CD7, CD2, and/or T-cell receptor α/β supports the diagnosis of Sézary syndrome in ED patients.[239] The nuclear contour index may also be a helpful investigation for the same differentiation.

HISTOPATHOLOGY

The histopathology findings differ depending on the underlying etiology (Table 23-4). Multiple skin punch biopsies over time are required in addition to clinical evaluation to make a diagnosis. The biopsy specimens often reveal a nonspecific picture that includes hyperkeratosis, parakeratosis, acanthosis, and a chronic inflammatory infiltrate, which may mask features of the underlying etiology. The histologic features may vary depending upon the stage of the disease and the severity of inflammation. One-third of biopsy specimens of erythroderma fail to reveal the underlying diagnosis.[240] The histologic features of the underlying disease may be more subtle than usually seen in that disease entity when unassociated with ED.[240] When dermatopathologists blinded to clinical information reviewed biopsies of erythroderma,[241] an accurate diagnosis was made only 50% of the time. Therefore, multiple punch biopsies obtained simultaneously and repeated over time are recommended to maximize the possibility of histopathologic diagnosis. Direct immunofluorescence, various special stains, immunoperoxidase studies, immunophenotyping, and gene rearrangement studies may be required to determine the underlying cause.

SPECIAL TESTS

Laboratory testing is driven by the patient's medical history and clinical presentation. In addition to multiple skin biopsies, lymph node biopsies may be required to differentiate dermatopathic lymphadenopathy from lymphomatous involvement. Radiologic workup should be undertaken if the condition is thought to be paraneoplastic. If a lymphoproliferative disease is considered as a possible cause of the ED, a thorough evaluation should be done that includes CD4:CD8 ratios, Sézary cell counts, immunophenotyping of skin and blood, and analysis of T-cell clonality by cytogenetics or T-cell receptor gene analysis.

COMPLICATIONS

A variety of metabolic and physiological changes occur in ED, including fluid and electrolyte imbalances, thermoregulatory disturbance, high-output cardiac failure,[233] cardiogenic shock,[242] acute respiratory distress syndrome,[243] decompensation of chronic liver disease,[244] and gynecomastia.[245] Hypoalbuminemia is common since there is an increase of protein loss via scaling (by 10%–15% in nonpsoriatic ED and up to 25%–30% in psoriatic ED[31]) as well as increase in metabolism and decrease in protein synthesis.[246] These processes lead to a negative nitrogen balance, muscle wasting, and edema.

Another common complication in ED is body temperature dysregulation. Increased skin perfusion combined with increased transepithelial water loss and loss of heat due to increased metabolic rate[247] leads to hypothermia. Furthermore, the capillaries cannot respond appropriately to temperature changes via vasoconstriction and vasodilation. Fluid and electrolytes loss from leaky capillaries leads to fluid and electrolyte imbalances. The shunting of blood to the skin may lead to high-output cardiac failure, which is of particular concern in patients with cardiac conditions and the elderly.[233]

There is an increased susceptibility to bacterial colonization in ED due to inflammation, fissuring, and excoriation of the skin. Sepsis may occur occasionally. Staphylococcal sepsis in particular is especially a risk for patients with CTCL and HIV-positive ED.[40,243,248]

PROGNOSIS AND CLINICAL COURSE

There are many factors affecting the clinical course and prognosis of ED, such as the underlying etiology, patient's comorbidities, age, speed of onset, and early therapy. In drug-induced ED, the course is usually rapid and upon discontinuation of the offending drug the ED clears readily and patients recover completely.[1] An important exception to this is the severe systemic hypersensitivity reactions that develop usually within 2–5 weeks after the medication is started and may persist for weeks after discontinuation of the drug. When the underlying etiology is a primary skin disease as in psoriatic and atopic ED, typically improvement takes weeks to months; however, chronic and persistent cases occur. Recurrence of psoriatic ED occurs in 15% of patients after initial resolution.[133]

ED can prove fatal especially in the very young and the elderly. Variable mortality rates (from 3.73% to 64%) have been reported in studies over the past 51 years.[4,10,12,14,16,20] In early series of ED, high mortality rates were reported in patients with severe drug reactions, lymphoproliferative malignancy, pemphigus foliaceus, and idiopathic ED.[8] The causes of death were complications such as sepsis, pneumonia, and cardiac failure.[8,14,20] Lower mortality rates have been reported in more recent studies with most deaths occurring in

TABLE 23-4
Histologic Clues of Underlying Disease

Disease	Diagnostic Features	Special Tests
Actinic reticuloid	Atypical mononuclear cells admixed amongst inflammatory cells Superficial and deep perivascular, interstitial, and lichenoid lymphocytic infiltrate Overlying lichen simplex chronicus With or without spongiosis	Immunophenotyping to differentiate actinic reticuloid from Sézary syndrome Predominance of CD8+ lymphocytes in skin and peripheral blood
Atopic dermatitis	Superficial perivascular lymphocytic infiltrate with eosinophils Spongiosis Occasional eosinophilic spongiosis Parakeratosis With or without lichen simplex chronicus	
Contact dermatitis	Same as atopic dermatitis	Patch testing, as appropriate Patch testing may be attempted when patient has partial clearing either spontaneously or with treatment
CTCL/Sézary	Atypical mononuclear cells singly and linearly along the basal cell layer Intraepidermal nests of atypical cells (Pautrier's microabscesses) Spongiosis absent or minimal Often lichenoid infiltrate	Immunophenotyping to detect clonal T-cell population in skin (and blood)
Dermatomyositis/ Subacute cutaneous lupus erythematosus	Interface dermatitis with vacuolar alteration Epidermal atrophy Colloid bodies Increased dermal mucin	Direct immunofluorescence ANA Muscle enzymes
Dermatophytosis	Hyphae within stratum corneum Mounds of parakeratosis Neutrophils in stratum corneum Papillary dermal edema	KOH scraping PAS stain Culture
Drug eruption, morbilliform type	Interface dermatitis Vacuolar alteration Necrotic keratinocytes at all levels of epidermis Perivascular and interface inflammation with eosinophils	
Acute graft-versus-host disease	Vacuolar alteration Dyskeratosis in close proximity to epidermal lymphocyties ("satellite cell necrosis") Subepidermal clefting possible	Direct immunofluorescence
Idiopathic	Nonspecific Usually subacute or chronic spongiotic dermatitis-like changes	
Lymphoprolifereative disease	Nodular or diffuse infiltrate of monomorphous mononuclear cells Lower dermal cellular infiltrate usually denser than that of the upper part Neoplastic mononuclear cells often within adnexal structures and walls of blood vessles	Immunophenotyping
Paraneoplastic	Nonspecific and variable changes	
Pemphigoid	Subepidermal bulla Dermal eosinophils Eosinophilic spongiosis	Direct immunofluorescence
Pemphigus	Intraepidermal bulla Acantholysis Eosinophilic or neutrophilic spongiosis	Direct immunofluorescence

(continued)

TABLE 23-4
Histologic Clues of Underlying Disease (Continued)

Disease	Diagnostic Features	Special Tests
Paraneoplastic pemphigus	Suprabasal acantholysis Necrotic keratinocytes Vacuolar alteration with lichenoid lymphotcytic infiltrate	Direct immunofluorescence
Pityriasis rubra pilaris	Epidermal hyperplasia Horizontal and vertical alternating orthokeratosis and parakeratosis Dilated plugged follicular infundibulum	
Psoriasis	Psoriasiform epidermal hyperplasia Confluent parakeratosis layered with neutrophils Spongiform pustules Hypogranulosis Dilated tortuous papillary blood vessels	
Sarcoidosis	Naked tubercles (dermal granulomas with little or no mantle of surrounding lymphocytes)	Chest X-ray
Scabies	Superficial and deep perivascular and interstitial inflammation Many eosinophils Frequent spongiosis Stratum corneum with mite or excreta and crusting possible	Scraping of burrows to identify a mite or excreta
Seborrheic dermatitis	Spongiotic psoriasiform dermatitis Parakeratosis and neutrophils at lips of the follicular ostia	
Stasis with autoeczematization	Spongiotic dermatisis Often eosinophils Lower leg biopsies demonstrate thick-walled superficial blood vessels, extravasated red blood cells, and siderophages	
Infantile exfoliative dermatitis ichthyoses Nonbullous congenital ichthyosiform erythroderma (Lamellar ichthysosis) Bullous congenital ichthyosiform erythroderma	Changes of the specific type of inherited ichthyosis (epidermolytic hyperkeratosis) Can be nondiagnostic changes Nondiagnostic Orthohyperkeratosis and acanthosis Epidermolytic hyperkeratosis Massive orthohyperkeratosis Acanthosis Hypergranulosis	Electron microscopy Genetic testing Translgutaminase-1 deficiency in cultured keratinocytes Genetic testing to detect mutations in *TGM1* Electron microscopy: cholesterol clefts and lipid droplets in the stratum corneum Mutations in keratin genes *KRT1* and *KRT10*
Netherton syndrome	Nondiagnostic Parakeratotic hyperkeratosis Diminished or absent granular layer Acanthosis PAS may stain stratum corneum strongly eosinophilic	Electron microscopy: premature lamellar body secretion Foci of electron-dense material in intracellular spaces of stratum corneum

patients with malignancy-associated ED,[1,12,17] usually due to underlying disease progression, treatment complications, or sepsis.[12] In a recent study, an average of 30-month follow-up of 80 ED patients demonstrated a death rate of 3.75% (3 of 80 patients) with deaths due to pneumonia in patients with pemphigus foliaceus and Sézary syndrome.[16]

ED secondary to malignancy including CTCL is most often chronic and refractory. For mycosis fungoides and Sézary syndrome-related ED, positive prognostic factors include age younger than 65 years, symptom duration greater than 10 years before diagnosis, absence of evidence of lymphoma involving a lymph node, and the absence of circulating Sézary cells in mycosis fungoides.[249] Mean survival ranges from 1.5 to 10.2 years based on these prognostic indicators.[249]

Idiopathic ED patients often have chronic symptoms and recurrences, which require long-term steroid therapy. Complete remission occurs in one-third of idiopathic ED patients and partial remission in one-half of patients.[18,32] Patients with chronic idiopathic ED are at increased risk of evolution to the diagnosis

of CTCL.[10,12,18,32] A proportion of patients with chronic ED have been shown to have a monoclonal T-cell dyscrasia, which may indicate a possible premalignant or pre-Sézary-like condition (monoclonal T-cell dyscrasia of undetermined significance).[35]

In pediatric patients presenting with fever and ED, certain parameters (older age, vomiting, presence of focal infection, specific laboratory values) can be used to predict which patients are likely to develop hemodynamic deterioration.[250] Predictors of developing toxic shock syndrome in this population included age ≥3 years, ill appearance, elevated creatinine, and hypotension on arrival.[250]

TREATMENT

The treatment of ED is summarized in Box 23-2. Patients presenting acutely with ED may require inpatient management due to significant fluid and electrolyte imbalance and hemodynamic or respiratory compromise. However, most patients can be managed on an outpatient basis. Regardless of etiology, the initial management involves fluid, electrolyte, and nutritional replacement. Children presenting with erythroderma and fever should be hospitalized and managed aggressively since they are likely to develop hemodynamic deterioration.[250]

The patient should be nursed in a warm (preferably 30°C–32°C) and humid environment for comfort and skin moisture, as well as to prevent hypothermia. Gentle local skin care, including oatmeal baths and wet dressings to weeping or crusted lesions, bland emollients, and low-potency topical steroids should be started. High-potency topical steroids[251] and topical immunomodulators, such as tacrolimus,[252] should be avoided as systemic absorption may occur due to the increased skin permeability and large surface area

BOX 23-2 THERAPY

	TOPICAL	SYSTEMIC	DOSAGE
First line	Oatmeal baths	Sedating antihistamines	
	Wet dressings	Systemic antibiotics if secondary infection	
	Bland emollients	Diuretics for peripheral edema	
	Low-potency corticosteroids	Fluid and electrolyte replacement	
Second line (once etiology established)	Single agent	Corticosteroids for drug hypersensitivity reactions, immunobullous disease, atopic dermatitis.	1–2 mg/kg/day with taper
		Cyclosporine for psoriasis, atopic dermatitis	4–5 mg/kg/day
		Methotrexate for psoriasis, atopic dermatitis, pityriasis rubra pilaris	5–25 mg qwk depending on renal function and response to treatment
		Acitretin for psoriasis, pityriasis rubra pilaris	25–50 mg qd
		Mycophenolate mofetil for psoriasis, atopic dermatitis, immunobullous disease	1–3 g qd
		Infliximab for psoriasis and pityriasis rubra pilaris	5–10 mg/kg
		Etanercept for psoriasis and pytirasis rubra pilaris	25 mg SC two times/week
	Combination therapy	Methotrexate and infliximab for psoriasis	2.7–4.4 mg/kg infliximab and 5–7.5 mg/week methotrexate
		Infliximab and acitretin for psoriasis and pityriasis rubra pilaris	5 mg/kg infliximab and 0.3–0.6 mg/kg acitretin (psoriasis) 5 mg/kg infliximab and 0.2 mg/kg/day acitretin (pityriasis rubra pilaris)
		Cyclosporine and etretinate for psoriasis	3.5–4 mg/kg/day cyclosporine and 0.5–0.6 mg/kg/day etretinate

involved. Other topical irritants such as anthralin, tar, hydroxyl acid moisturizers, and vitamin D analogs should also be avoided.

Antihistamines can be administered for sedation and antipruritic effects. Systemic antibiotics are required for patients with evidence of localized and systemic secondary infection. Septicemia secondary to *Staphylococcus* infection is often a complication of ED and requires aggressive antibiotic and supportive treatment. Even patients without evidence of secondary infection may benefit from systemic antibiotic therapy as bacterial colonization may exacerbate ED. Pedal and periorbital edema should be treated with diuretics and adequate fluid intake should be maintained. All nonessential and possible offending medications should be discontinued, including drugs such as lithium and antimalarials that may trigger a flare in patients with underlying psoriasis. Folate supplementation and a diet of 130% of normal dietary requirements for protein are recommended to replace nutrient losses.[31,253]

Determining the underlying etiology early is essential for definitive treatment of ED as ED may be refractory to therapy until the cause is treated. Consensus treatment recommendations for erythrodermic psoriasis have been recently put forth by the National Psoriasis Foundation.[254] Therapy should be based on the severity of disease and underlying comorbidities. Systemic agents such as methotrexate, cyclosporine, acitretin, mycophenolate mofetil, and azathioprine can be helpful as single agents or in combination.[254] Experience with biologics, although limited so far, is very promising. A number of small case series and reviews suggest that infliximab alone or in combination with methotrexate can lead to rapid and dramatic control of psoriatic ED and high rates or remission.[255–259] There are emerging data suggesting that etanercept may also be effective[260,261] as well as single case reports of adalimumab[262] and alefacept[263] being successfully used in psoriatic ED. Currently, there is no data to support a role of ustekimumab in the treatment of erythrodermic psoriasis, although given its good efficacy for plaque-type psoriasis it may eventually prove to be useful. Systemic steroids should be avoided given the danger of rebound erythrodermic flare and exacerbation of the disease. A recent case series supports the use of infliximab in patients with erythrodermic and recalcitrant chronic plaque psoriasis who have failed multiple therapies including biologics.[264]

Etanercept has also been used as a steroid-sparing agent with relief of pruritus in Sézary syndrome in two patients.[265] However, etanercept should be used with caution in these patients because of risk of further immunosuppression. Options for treatment of CTCL include topical corticosteroids, psoralen plus ultraviolet A (UVA), total skin electron beam irradiation, systemic chemotherapy including CHOP-like regimens (*c*yclophosphamide, *h*ydroxydaun*o*mycin, vincristine, and *p*rednisone), interferon-α, extracorporeal photochemotherapy, and biologics such as monoclonal antibodies (alemtuzumab),[266,267] bexarotene (selective retinoic X receptor retinoid),[268,269] and denileukin diftitox.

Systemic corticosteroids are useful for drug hypersensitivity reactions. In severe and persistent cases, intravenous Ig may be used. Cyclosporine, methotrexate, azathioprine, mycophenolate mofetil, and systemic corticosteroids may be helpful for spongiotic (eczematous) dermatitis. PRP usually responds to systemic retinoids or methotrexate. Recently, case reports and case series have showed that tumor necrosis factor (TNF)-α antagonists (infliximab, etanercept, adalimumab) alone or in combination therapy can be very useful in the treatment of adult-onset PRP[270–277] and juvenile PRP.[278,279] Papuloerythroderma of Ofuji has been treated with topical and systemic corticosteroids, cyclosporine, interferon, etretinate, and most recently with a combination of retinoid plus psoralen and UVA light.[280] Rituximab has proven useful in the treatment of erythrodermic pemphigus foliaceus in a recent case report.[281]

When the underlying cause of ED is unknown, empiric therapy with systemic agents, including methotrexate, cyclosporine, acitretin, mycophenolate mofetil, and systemic corticosteroids, has been used. It should be emphasized that a strong suspicion for psoriatic ED precludes systemic corticosteroid use due to risk for a rebound flare. Immunosuppressive drugs should not be used until CTCL has been ruled out with the most current laboratory testing.

PREVENTION

Prevention of ED depends on controlling the underlying cause. Medications and irritants that have previously caused ED should be avoided. It is important that the patients maintain careful records of allergies including potentially cross-reactive medications, such as topical agents (e.g., ED occurring secondary to systemic gentamicin use in a patient with known contact allergy to neomycin[136] and ED secondary to pseudoephedrine use in a patient with a contact allergy to phenylephrine).[194] Systemic steroids should be avoided in patients with psoriasis to prevent rebound flares. Educating patients with underlying diseases (e.g., psoriasis, atopic dermatitis) about possible triggers of ED (irritants, abrupt discontinuation of certain therapies) may also be helpful to prevent ED.

Chapter 24 :: Pityriasis Rubra Pilaris

:: Daniela Bruch-Gerharz & Thomas Ruzicka

PITYRIASIS RUBRA PILARIS AT A GLANCE

- A papulosquamous disorder of unknown etiology that often progresses to erythroderma and causes a disabling keratoderma of the palms and soles.
- The disease is subclassified into six types including both hereditary and acquired forms.
- The typical features of pityriasis rubra pilaris include follicular hyperkeratosis and a reddish orange, scaling dermatitis with islands of normal skin.
- Confusion with psoriasis presents the major problem in diagnosis, particularly in early phases of the disease.
- Histopathological examination reveals hyperkeratosis, alternating vertical and horizontal parakeratosis, and a mild superficial perivascular lymphocytic infiltrate.
- No single therapy is universally effective, and some cases do not respond to multiple therapies. The most successful treatment options are retinoids, photochemotherapy (PUVA), and antimetabolites (methotrexate).

EPIDEMIOLOGY

Pityriasis rubra pilaris is a rare, chronic disorder with an estimated incidence ranging from 1 in 5,000 to 1 in 50,000 dermatology patients. The age distribution is bimodal with peak incidences in the first and fifth decades of life. The disease occurs in all races and affects the sexes equally.[1]

ETIOLOGY AND PATHOGENESIS

Although an underlying dysfunction in vitamin A metabolism has been suggested, the etiology and pathogenesis of pityriasis rubra pilaris are still poorly understood. Thus, the role of vitamin A deficiency remains uncertain as attempts to produce keratotic lesions by vitamin A deprivation have been unsuccessful. Moreover, the deficiency of retinol-binding protein as an underlying pathogenic mechanism resulting in inadequate transport of vitamin A to the skin has yet to be ascertained. There are some cases in which pityriasis rubra pilaris may result from immune system dysregulation and abnormal response to various antigenic triggers.[2] A report of an exanthematous form of juvenile pityriasis rubra pilaris that followed an upper respiratory infection and initially resembled Kawasaki disease supports the hypothesis of a superantigen-mediated process. Finally, genetic factors with an autosomal dominant pattern of inheritance have been supposed to play a critical role for the induction of pityriasis rubra pilaris. Nevertheless, affected relatives are not observed in the classical acute-onset disease and are infrequent in other variants.

CLINICAL FINDINGS

CUTANEOUS LESIONS

Pityriasis rubra pilaris is generally believed to comprise more than a single entity and a classification scheme based on clinical characteristics and course has been proposed by Griffiths[1] (Table 24-1).

Type I (classic adult) is the most common subtype with over 50% of all cases. Characteristically, patients present with an eruption of follicular hyperkeratotic papules that spread in cephalocaudal direction (Fig. 24-1). As the disease further evolves, a reddish

TABLE 24-1
Classification Scheme of Pityriasis Rubra Pilaris (Types I–V According to Griffiths[1])

Type	Description	%	Clinical Characteristics	Distribution	Course
I	Classic adult	>50	**Erythroderma** with islands of normal skin ("nappes claires"), follicular hyperkeratosis, waxy diffuse **palmoplantar keratoderma**	Generalized, beginning on the head and neck, then spreading caudally	Often resolves within an average period of 3 years
II	Atypical adult	5	Combination of **follicular hyperkeratosis** and **ichthyosiform lesions** on the legs, sparse scalp hair	Generalized	Long duration (>20 years)
III	Classic juvenile	10	**Similar to type I** but appears in years 1 or 2 of life	Generalized	Often resolves within an average period of 1–2 years
IV	Circumscribed juvenile	25	Prepubertal children; well-demarcated scaly, **erythematous plaques on the elbows and knees**, resembling localized psoriasis	Localized	Uncertain, some cases clear in the late teens
V	Atypical juvenile	5	Begins in first few years, accounts for most familial cases; **follicular hyperkeratosis**, **scleroderma-like appearance of the hands and feet**	Generalized	Chronic course, improvement with retinoids but relapses when stopped
VI	HIV-associated	NA[a]	**Similar to type I** with variable beginning; associated with acne conglobata, hidradenitis suppurativa and lichen spinulosus	Generalized	May respond to antiretroviral triple therapy

[a]Data not available.

Figure 24-1 Acuminate follicular papules of pityriasis rubra pilaris. Close-ups of discrete (**A**) and confluent (**B**) lesions.

Figure 24-2 Generalized pityriasis rubra pilaris (**A**) with a reddish orange, scaling dermatitis, and islands of normal skin ("nappes claires"), shown in more detail in (**B**).

orange, scaling dermatitis appears that often progresses to a generalized erythroderma over a period of 2–3 months (Fig. 24-2). A diagnostic hallmark of pityriasis rubra pilaris are sharply demarcated islands of unaffected skin ("nappes claires") in a random distribution (Fig. 24-2B). Many patients develop a waxy, diffuse, yellowish keratoderma of the palms and soles (Fig. 24-3).[3] Nail changes are not uncommon and include distal yellow–brown discoloration, nail plate thickening, splinter hemorrhages, and subungual hyperkeratosis. Eventually, the mucous membranes may be affected with a diffuse whitish appearance of the buccal mucosa as well as lacy white plaques and erosions. Hair and teeth are normal.

Type II is an atypical variant with onset in adult age. Areas of follicular hyperkeratosis as well as ichthyosiform scaling, especially on the legs, dominate the clinical picture. This variant lacks the typical cephalocaudal progression observed in type I, and there is less tendency for the patients to become erythrodermic. Sparseness of the scalp hair is occasionally seen.

Type III (classic juvenile) typically begins in years 1 or 2 of life and shows all the morphological features of type I (Fig. 24-4).

Type IV (circumscribed juvenile) affects approximately 25% of the patients. This type usually presents several years after birth and is characterized by well-demarcated hyperkeratotic erythematous plaques on the elbows and knees, resembling localized psoriasis. According to Griffith,[1] these lesions do not progress to the widespread types I and III. Yet, some cases show marked palmoplantar keratoderma.

Type V is an atypical variant of juvenile pityriasis rubra pilaris that usually presents in the first few years of life and has a more chronic course. This type is distinguished by follicular hyperkeratosis with only minimal erythema and a scleroderma-like appearance of the hands and feet. Most cases of familial pityriasis rubra pilaris belong to this type, which may even represent a different clinical entity sharing features with several poorly defined ichthyotic disorders such as follicular ichthyosis and the erythrokeratodermas.

Other reports have described a **type VI** variant associated with HIV infection. The clinical features of this variant are similar to type I but with increased severity and additional manifestations of acne conglobata, hidradenitis suppurativa, and lichen spinulosus.

RELATED FINDINGS

There have been rare cases of a pityriasis rubra pilaris-like eruption, clinically and histologically, in patients with dermatomyositis, often associated with internal neoplasia. Concomitant rheumatologic disorders, mainly inflammatory polyarthritis, have also been reported. In addition, numerous other noncutaneous diseases were considered to be related to pityriasis rubra pilaris, which are probably all fortuitous.

Figure 24-3 Keratoderma in pityriasis rubra pilaris. Palmar (**A**) and plantar (**B**) erythema and waxy hyperkeratosis are frequent manifestations. Sometimes, there is an orange–yellow tint.

PATHOLOGY

Pathological findings in pityriasis rubra pilaris vary according to the duration of the disease. The findings are most likely to be diagnostic in the acute phase, when hyperkeratosis, acanthosis with broad short rete ridges and alternating orthokeratosis and parakeratosis oriented in both horizontal and vertical directions can be observed. Usually, there is a sparse superficial, perivascular lymphocytic infiltrate in the underlying dermis. Keratinous plugs of the follicular infundibula as well as perifollicular areas of parakeratosis may also be present. A prominent granular layer and dilated, but not tortuous capillaries are features that help to distinguish pityriasis rubra pilaris from psoriasis, its most important differential diagnosis.

DIFFERENTIAL DIAGNOSIS

See Box 24-1.

Figure 24-4 Juvenile pityriasis rubra pilaris. **A.** Confluence of lesions leads to extensive erythroderma. **B.** Characteristic scattered islands of unaffected skin are evident. So is the plantar hyperkeratosis.

BOX 24-1 DIFFERENTIAL DIAGNOSIS OF PITYRIASIS RUBRA PILARIS

Most Likely
- Localized
  - Psoriasis
  - Ichthyosis
- Generalized
  - Psoriasis
  - Erythrokeratoderma

Consider
- Localized
  - Follicular eczema
  - Lichen planus acuminatus
  - Keratosis pilaris
- Generalized
  - Pityriasis lichenoides chronica
  - Ichthyosiform erythroderma

Always Rule Out
- Generalized (therapy-resistant cases)
- HIV infection
- Cutaneous T-cell lymphoma

COMPLICATIONS

Systemic symptoms are uncommon except when generalized erythroderma occurs, and then they are comparable to those seen in exfoliative dermatitis (see Chapter 23). Occasionally, a mild ectropion may develop when the face becomes uniformly erythematous. Even though rare, moderate to severe pruritus or burning sensations may occur.

PROGNOSIS/CLINICAL COURSE

The classic adult disease (type I) usually remits completely within an average of 3 years. However, recurrences are recognized in up to 20% of patients, sometimes after long periods of subclinical disease. In the classic juvenile variant (type III) spontaneous clearing is commonly observed in 1 to 2 years. However, the atypical variants (type II and IV) have a less favorable prognosis for remission, some cases of type IV improve in late teens. Moreover, there is little or no tendency of type V to resolve spontaneously, improvements with retinoids have been described but relapses occurred when treatment was withdrawn. Clinical manifestations in the HIV-associated type VI are severe and occasionally fatal, with death occurring due to complications of cutaneous sepsis.

TREATMENT

(Box 24-2)

BOX 24-2 TREATMENTS FOR PITYRIASIS RUBRA PILARIS

FIRST LINE

Topical
- Emollients (water-in-oil emulsion)
- Keratolytics (salicylic acid, urea)
- Vitamin D3 (calcipotriol)

Physical
- Photochemotherapy (topical or systemic PUVA)
- Extracorporeal photopheresis

Systemic
- Retinoids (0.5–0.75 mg/kg acitretin/day)
- Methotrexate (10–25 mg weekly)
- Triple antiretroviral therapy[7] (HIV-associated variant)

SECOND LINE

Topical
- Glucocorticoids (medium to high potency)
- Vitamin A analogs (tazarotene)

Physical
- UVA1 phototherapy
- UVB (narrowband) phototherapy
- UVB phototherapy

Systemic
- Azathioprine (100–150 mg/day)
- Cyclosporine A (5 mg/kg/day)
- Fumaric acid esters[4]
- TNF-α antagonists[6]

Patients with pityriasis rubra pilaris are often irresponsive to multiple therapies, both topical and systemic.[3] Because of the relative rarity of the disease and its variable course, the chances for clinical trials assessing treatment options have been limited. Previous treatment strategies, which relied on megadoses of oral vitamin A or the anabolic steroid stanazol, proved to be largely ineffective.

Currently, oral retinoids are the first line of therapy in patients with pityriasis rubra pilaris. Isotretinoin has been reported to be of some value, although a comprehensive review suggests that acitretin may be more effective in clearing patients. Accordingly, most patients are treated first with acitretin. Alitretinoin, a novel panagonist retinoid (see Chapter 228), might be an alternative option for systemic treatment in patients refractory to conventional therapy. Treatment with methotrexate, using the guidelines established for psoriasis, has shown variable rates of success. Some cases respond well to photochemotherapy (PUVA), some may flare, and others require combination treatment with retinoids or methotrexate. In patients with severe symptoms, effective amelioration of the disease may require extracorporeal photopheresis but there are no evidence-based data.

Immunosuppressive agents are of inconsistent benefit. Thus, controversy persists about the role of cyclosporine in the treatment of pityriasis rubra pilaris. While most studies show lack of efficacy, several cases of adult-type pityriasis rubra pilaris showed significant clearance in 2–4 weeks. Some patients are helped by azathioprine, but this effect is also inconsistent. The use of glucocorticosteroids in the management of pityriasis rubra pilaris has been studied, but there is no evidence to suggest a beneficial effect. Whether phototherapy can be effective is controversial. Ultraviolet B (UVB) irradiation, which is efficiently used for psoriasis, has not been helpful or even worsened pityriasis rubra pilaris. UVA1 phototherapy may be a satisfactory alternative.

When conventional treatment strategies fail, new therapeutic approaches may include the use of immunomodulatory drugs. Fumaric acid esters were reported as successful in inducing remission in a patient with juvenile pityriasis rubra pilaris unresponsive to the usual treatment options.[4] Kerr and Ferguson reported a patient with type II adult-onset pityriasis rubra pilaris resistant to multiple therapies whose condition improved markedly with high-dose human intravenous immunoglobulin (IVIg) infusions.[5] Moreover, there is accumulating evidence indicating that blockade of tumor necrosis factor (TNF-α), which is beneficial in psoriasis and psoriasis–arthritis, is effective in the adult- and juvenile-onset types of pityriasis rubra pilaris as well.[6]

Topical treatment with keratolytics (where possible under an occlusive plastic dressing) has proved a valuable mode of adjuvant therapy in pityriasis rubra pilaris. For symptomatic relief, emollients and antihistamines provide significant benefit. Topical therapy with calcipotriol showed encouraging results. Its disadvantage is that total body treatment for the erythrodermic patient could be toxic. Success has been reported with topical aminonicotinamide 1%, although it is not commonly used.[3]

Pityriasis rubra pilaris associated with HIV infection has responded to triple antiretroviral therapy.[7]

Present therapeutic options (including drug doses) for pityriasis rubra pilaris used in adults and children are listed in Box 24-2.

PREVENTION

Pityriasis rubra pilaris is a rare, but socially and psychologically disabling condition, occurring in children and adults of both sexes. Suicide remains a risk in patients with generalized disease. Therefore, knowledge of the clinical pattern and cutaneous findings is crucial for an early therapeutic intervention, and may prevent protracted illness and serious complications in this clinically challenging condition.

Chapter 25 :: Parapsoriasis and Pityriasis Lichenoides

:: Gary S. Wood, Chung-Hong Hu, & Rosemarie Liu

PARAPSORIASIS

PARAPSORIASIS AT A GLANCE

- Also known as parapsoriasis en plaques.
- Parapsoriasis occurs worldwide and affects mainly adults.
- Large-plaque parapsoriasis (LPP) and small-plaque parapsoriasis (SPP) are recognized.
- Large and small "plaque" lesions actually present as flat patches rather than infiltrated plaques.
- Lesions are chronic and favor nonsun-exposed skin; LPP may be poikilodermatous.
- Pathology consists of superficial, mostly $CD4^+$ T-cell infiltrate; dominant clonality is more common in LPP than in SPP.
- LPP appears to exist on a continuum with patch-stage mycosis fungoides (MF) and progresses to overt MF at a rate of approximately 10% per decade.
- SPP has minimal risk of progression to overt MF in the experience of most experts.
- Treatment options include topical corticosteroids; ultraviolet B (UVB) irradiation, and psoralen and ultraviolet A (UVA) irradiation; excimer laser; and topical cytotoxic drugs.

HISTORICAL ASPECTS

The term parapsoriasis was coined originally by Brocq in 1902.[1] As shown in Table 25-1, the currently accepted classification of parapsoriasis includes large- and small-plaque forms of parapsoriasis en plaques (often referred to simply as *parapsoriasis*) as well as acute and chronic forms of pityriasis lichenoides [known today as *pityriasis lichenoides et varioliformis acuta* (PLEVA) and *pityriasis lichenoides chronica* (PLC), respectively].[2] Pityriasis lichenoides was first described in 1894 by Neisser[3] and Jadassohn.[4] In 1899, Juliusberg delineated the chronic form and named it PLC.[5] Mucha redescribed the acute form in 1916 and distinguished it from the chronic form.[6] Habermann named the acute variant PLEVA in 1925.[7] Mucha–Habermann disease is synonymous with PLEVA. Some authors regard lymphomatoid papulosis as a variant of pityriasis lichenoides, whereas others consider it to be a separate disease.[2,8–10] Lymphomatoid papulosis is discussed in Chapter 145 as part of the spectrum of $CD30^+$ cutaneous lymphoproliferative disorders.

EPIDEMIOLOGY

Large-plaque parapsoriasis (LPP) and small-plaque parapsoriasis (SPP) are, in general, diseases of middle-aged and older people, with a peak incidence in the fifth decade. Occasionally, lesions arise in childhood and may be associated with pityriasis lichenoides. SPP shows a definite male predominance of approximately 3:1. LPP is probably more common in males, but the difference is not as striking as in SPP. Both occur in all racial groups and geographic regions.

ETIOLOGY AND PATHOGENESIS

It is likely that a complete understanding of the pathogenesis of parapsoriasis will develop with our understanding of the pathogenesis of both chronic dermatitis and mycosis fungoides (MF), because parapsoriasis appears to bridge these disorders. The T cells that mediate most inflammatory skin diseases belong to the skin-associated lymphoid tissue (SALT).[11] These T cells express the cutaneous lymphocyte-associated antigen and traffic between the skin and the T-cell domains of peripheral lymph nodes via the lymphatics and bloodstream. MF (see Chapter 145) has been shown to be a neoplasm of SALT T cells. Sensitive polymerase chain reaction (PCR)-based tumor clonality assays have underscored the SALT nature of MF tumor clones by showing that they can continue to traffic after neoplastic transformation[12] and can even participate in delayed-type hypersensitivity reactions to contact allergens.[13] This implies that rather than being a skin lymphoma per se, MF is actually a SALT lymphoma, i.e., a malignancy of a T-cell circuit rather than of one particular tissue. Trafficking of MF tumor cells has been detected even in patients with very early stage disease whose lesions were consistent clinicopathologically with LPP.[12,14] Therefore, it can be said that at least in some cases LPP is a monoclonal proliferation of SALT T cells that have the capacity to traffic between the skin and extracutaneous sites.

TABLE 25-1
Classification of Parapsoriasis

1. Parapsoriasis en plaques
   A. Large-plaque parapsoriasis variants: poikilodermatous, retiform
   B. Small-plaque parapsoriasis variant: digitate dermatosis
2. Pityriasis lichenoides
   A. Pityriasis lichenoides chronica (Juliusberg)
   B. Pityriasis lichenoides et varioliformis acuta (Mucha–Habermann)

This view is also supported by the presence of structural and numerical chromosomal abnormalities in the peripheral blood mononuclear cells of patients with LPP.[15] In this context, LPP can be regarded as the clinically benign end of the MF disease spectrum, which eventuates in transformed large cell lymphoma at its malignant extreme. To say that these diseases belong to the same disease spectrum is not to say that they are biologically equivalent disorders. To lump them all together simply as "MF" would be to ignore their distinctive clinicopathologic features, which are likely due to genetic and/or epigenetic differences, such as the *p53* gene somatic mutations observed in some cases of large cell transformation of MF.[16–18] It is likely that several such differences separate these clinicopathologically defined disorders in a stepwise fashion analogous to the sequential acquisition of somatic mutations that occurs in the colon cancer disease spectrum as colonic epithelial cells progress through normal, hyperplastic, in situ carcinoma, invasive carcinoma, and metastatic carcinoma stages.[19,20]

A unifying feature of the parapsoriasis group of diseases is that all of them appear to be cutaneous T-cell lymphoproliferative disorders: LPP,[12,21–28] SPP,[23,28,29] pityriasis lichenoides,[28,30–32] and lymphomatoid papulosis[23,33–35] have all been shown to be monoclonal disorders in many cases.[36] These relationships suggest that progression from LPP through the various stages of the MF disease spectrum is accompanied by an increasing gradient of dominant T-cell clonal density resulting from mutations that confer increasing growth autonomy to the neoplastic T-cell clone.[37] Interestingly, analysis of peripheral blood has demonstrated that clonal T cells are often detectable in patients with LPP/early MF[27,28] or SPP,[28,38] which again supports the systemic SALT nature of these "primary" skin disorders.

Dominant clonality as seen in the parapsoriasis disease group, follicular mucinosis, pagetoid reticulosis, and certain other disorders does not equate to clinical malignancy. In fact, most patients with these diseases experience a benign clinical course, and in some cases the disease resolves completely. In addition, other types of chronic cutaneous T-cell infiltrates sometimes exhibit dominant clonality, including primary (idiopathic) erythroderma and nonspecific chronic spongiotic dermatitis. This has given rise to the concept of clonal dermatitis,[14,39] originally described in the context of clonal nonspecific chronic spongiotic dermatitis but later expanded to include other nonlymphomatous cutaneous T-cell infiltrates that harbor occult monoclonal T-cell populations. Several cases of clonal dermatitis, some of which have progressed to MF, have been identified.[14,21,39] We suspect that for each disease with a potential for progression to MF, the principal risk may reside in the subset showing clonal dermatitis, because this is the subset in which dysregulation has begun to occur.

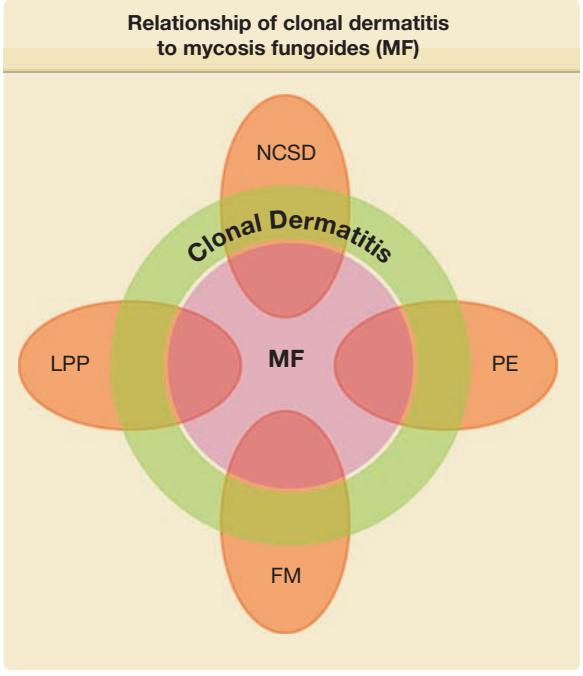

Figure 25-1 The relationship of clonal dermatitis to mycosis fungoides (MF) and various types of chronic dermatitis. The proportions of each entity that represent clonal dermatitis and mycosis fungoides vary with each disease and are not drawn to scale. FM = follicular mucinosis; LPP = large-plaque parapsoriasis; NCSD = nonspecific chronic spongiotic dermatitis; PE = primary erythroderma.

The postulated relationships among MF, clonal dermatitis, and selected types of chronic dermatitis are depicted in Fig. 25-1. Each of the entities shown is postulated to be at risk for MF through a clonal dermatitis intermediate. In this model, MF becomes the final common pathway for the clonal evolution of neoplastic T cells emerging from the polyclonal SALT T-cell populations present in each of the various precursor diseases.

Various viruses have been proposed to play a role in the pathogenesis of MF. None has been substantiated thus far. The most recent virus implicated in both LPP and MF is HHV-8; however, conflicting reports await resolution.[40–42]

CLINICAL FINDINGS

CUTANEOUS LESIONS. LPP lesions are either oval or irregularly shaped patches or very thin plaques that are asymptomatic or mildly pruritic. They are usually well marginated but may also blend imperceptibly into the surrounding skin. The size is variable, but typically most lesions are larger than 5 cm, often measuring

Figure 25-2 Large-plaque parapsoriasis. Irregularly shaped patches of variable size on the arm of a 16-year-old girl.

BOX 25-1 DIFFERENTIAL DIAGNOSIS OF POIKILODERMA

- Large-plaque parapsoriasis
- Dermatomyositis
- Lupus erythematosus
- Chronic radiation dermatitis
- Bloom syndrome
- Rothmund–Thomson syndrome
- Dyskeratosis congenita
- Xeroderma pigmentosum

more than 10 cm in diameter. Lesions are stable in size and may increase in number gradually. They are found mainly on the "bathing trunk" and flexural areas (Fig. 25-2). Extremities and the upper trunk, especially the breasts in women, also may be involved. They are light red–brown or salmon pink, and their surface is covered with small and scanty scales. Lesions may appear finely wrinkled—"cigarette paper" wrinkling. Such lesions exhibit varying degrees of epidermal atrophy. Telangiectasia and mottled pigmentation also are observed when the atrophy becomes prominent (Fig. 25-3). This triad of atrophy, mottled pigmentation, and telangiectasia defines the term *poikiloderma* or *poikiloderma atrophicans vasculare*, which also may be seen in other conditions (Box 25-1).

Retiform parapsoriasis refers to a rare variant of LPP that presents as an extensive eruption of scaly macules and papules in a net-like or zebra-stripe pattern that eventually becomes poikilodermatous (Fig. 25-4).

SPP characteristically occurs as round or oval discrete patches or very thin plaques, mainly on the trunk (Fig. 25-5). The lesions measure less than 5 cm in diameter; they are asymptomatic and covered with fine, moderately adherent scales. The general health of the patient is unaffected. A distinctive variant with lesions of a finger shape, known as *digitate dermatosis*,[43] has yellowish or fawn-colored lesions (Fig. 25-6). It follows lines of cleavage of the skin and gives the appearance of a hug that left fingerprints on the trunk. The long axis of these lesions often measures greater than 5 cm. Chronic superficial dermatitis is a synonym for SPP.[44] Digitate lesions with a yellow hue were referred to in the past as *xanthoerythrodermia perstans*.[2]

Figure 25-3 Large-plaque parapsoriasis. Poikilodermatous variant.

Figure 25-4 Large-plaque parapsoriasis. Retiform variant.

Figure 25-5 Small-plaque parapsoriasis. Small, discrete patches less than 5 cm in diameter.

LABORATORY TESTS

HISTOPATHOLOGY. In early LPP lesions, the epidermis is mildly acanthotic and slightly hyperkeratotic with spotty parakeratosis. The dermal lymphocytic infiltrate tends to be perivascular and scattered (Fig. 25-7). In the more advanced lesions one observes an interface infiltrate with definite epidermotropism. These invading lymphocytes may be scattered singly or in groups, sometimes associated with mild spongiosis. In addition, the poikilodermatous lesions show atrophic epidermis, dilated blood vessels, and melanophages (Fig. 25-8). Immunohistologic studies have revealed similar features in LPP and early MF, including a predominance of $CD4^+$ T-cell subsets, frequent CD7 antigen deficiency, and widespread epidermal expression of Class II HLA (HLA-DR).[22–24,45–48]

SPP exhibits mild spongiotic dermatitis with focal areas of hyperkeratosis, parakeratosis, scale crust, and exocytosis. In the dermis, there is a mild superficial perivascular lymphohistiocytic infiltrate and dermal edema (Fig. 25-9). There is no progression of the histologic features with time. Immunohistologic studies reveal a predominantly $CD4^+$ T-cell infiltrate with nonspecific features resembling those seen in various types of dermatitides.[47]

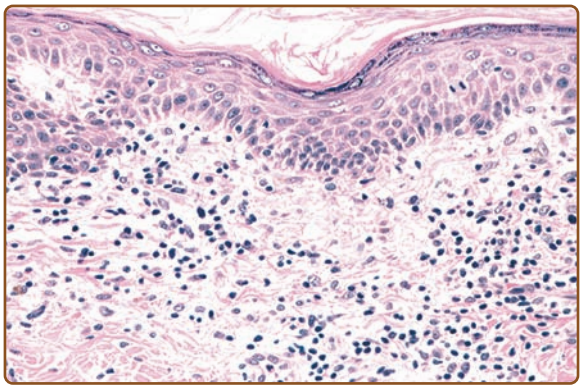

Figure 25-7 Large-plaque parapsoriasis. Mildly hyperkeratotic and focally parakeratotic epidermis with moderately dense superficial perivascular infiltrate. Lymphoid cells are mostly small, cytologically normal lymphocytes, and there is focal single-cell epidermotropism. (Used with permission from Helmut Kerl, MD.)

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

LPP is distinguished from SPP by the larger size, asymmetric distribution, and irregular shape of its

Figure 25-6 Small-plaque parapsoriasis. Digitate dermatosis variant. Typical "fingerprint" patches on the flank. Note that their length often exceeds 5 cm.

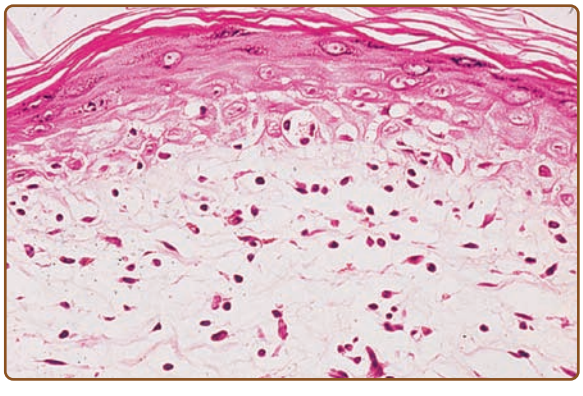

Figure 25-8 Large-plaque parapsoriasis. Atrophic variant. Sparse superficial lymphoid infiltrate with mild epidermotropism and epidermal atrophy.

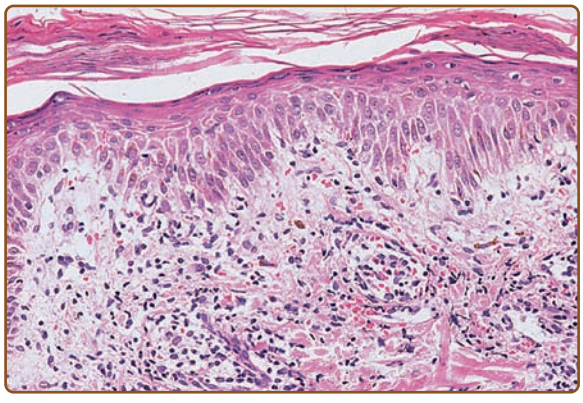

Figure 25-9 Small-plaque parapsoriasis. Superficial perivascular lymphoid infiltrate, mild spongiosis, parakeratosis, and focal scale crust.

lesions, which are less discrete and often poikilodermatous. LPP may be clinically and histopathologically indistinguishable from the patch stage of MF. Both LPP and SPP are readily distinguished from more advanced infiltrated plaques of MF because parapsoriasis lesions are, by definition, not thicker than patches or at most very thin plaques. This is so because the English equivalent of the French term *plaques* is *patches*, i.e., lesions that are essentially flat and devoid of induration or palpable infiltration.[49] Failure to appreciate this important distinction has led to considerable confusion and misuse of the terms *large-plaque parapsoriasis* and *small-plaque parapsoriasis* by some individuals. These designations more appropriately might be thought of as *large-patch parapsoriasis* and *small-patch parapsoriasis*.

The degree to which LPP is differentiated from early MF depends primarily on the histopathologic criteria used to diagnose the latter disorder. Unfortunately, there are no universally accepted minimal criteria for the diagnosis of MF; however, one set proposed by the International Society for Cutaneous Lymphoma is presented in Table 25-2.[50] This algorithm is based on a holistic integration of clinical, histopathologic, immunopathologic, and clonality data. It differs significantly from many prior approaches because it does not rely solely on histopathologic features.[51] Assuming that histopathologic examination does not disclose features diagnostic of some other dermatosis, these criteria allow lesions to be classified as either patch-stage MF or not. For the practical purposes of clinical management, patients presenting clinically with patch lesions whose features result in a score of four points or more are considered to have unequivocal MF. Obviously, the more liberal the criteria, the more cases could be considered to be MF. However, there will always be some cases that fail to meet any specific set of criteria, and the designation *LPP* is a useful term to apply to them because it guides treatment and follow-up and conveys an understanding that the risk of dying from lymphoma is small.

The clinical and/or histopathologic differential diagnosis of LPP also includes those collagen vascular diseases and genodermatoses exhibiting poikilodermatous features, lichenoid drug eruptions, secondary syphilis, chronic radiodermatitis, and occasionally several other diseases tabulated in Box 25-2. These

TABLE 25-2
Algorithm for the Diagnosis of Patch-Stage Mycosis Fungoides (Four Points are Required)

Parameter	2 Points	1 Point
Clinical: Persistent, progressive patches and plaques ± Nonsun-exposed distribution Variation in size and shape Poikiloderma	Any two	Any one
Histopathologic: Superficial dermal T-cell infiltrate ± Epidermotropism Nuclear atypia	Both	Either
Immunopathologic: CD2, CD3, or CD5 <50% CD7 <10% Epidermal–dermal discordance	Not applicable	Any one
Molecular biologic: Dominant T-cell clonality	Not applicable	Present

Note: Epidermotropism implies the lack of significant spongiosis (intraepidermal lymphoid cells associated with spongiosis is termed *exocytosis* rather than *epidermotropism*). Discordance refers to differential antigen expression between the epidermis and dermis, as opposed to the biopsy specimen as a whole.

BOX 25-2 DIFFERENTIAL DIAGNOSIS OF LARGE-PLAQUE PARAPSORIASIS (LPP) AND SMALL-PLAQUE PARAPSORIASIS (SPP)

Most Likely

- LPP
  - Tinea corporis
  - Plaque-type psoriasis
  - Contact dermatitis
  - Subacute cutaneous lupus erythematosus
- SPP
  - Nummular dermatitis
  - Pityriasis rosea
  - Plaque and guttate psoriasis
  - Pigmented purpuric dermatoses
  - Pityriasis lichenoides chronica

Consider

- LPP
  - Xerotic dermatitis
  - Atopic dermatitis
  - Dermatomyositis
  - Drug eruption
  - Erythema dyschromicum perstans
  - Pigmented purpuric dermatoses
  - Early inflammatory morphea
  - Atrophoderma of Pasini–Pierini
  - Erythema annulare centrifugum
  - Pityriasis rubra pilaris
  - Genodermatoses with poikiloderma
  - Chronic radiodermatitis
- SPP
  - Tinea versicolor
  - Seborrheic dermatitis
  - Drug eruption

Always Rule Out

- LPP
  - Mycosis fungoides
- SPP
  - Mycosis fungoides
  - Secondary syphilis

generally can be distinguished by their associated clinical findings. Histopathologic differentiation among these diseases is covered largely in the discussion of pseudo-MF in Chapter 146.

SPP, when it presents with its distinctive digitate dermatosis lesions parallel to skin lines in a truncal distribution, stands out from other types of parapsoriasis. Individual SPP lesions may show some superficial resemblance to PLC. SPP is distinguished from psoriasis by the absence of the Auspitz sign (see Chapter 18), micaceous scale, nail pits, and typical psoriatic lesions involving the scalp, elbows, and knees. Histologically, its mild spongiotic dermatitis and absence of other characteristic features distinguish it from PLC, psoriasis, and several of the other entities listed in Box 25-2. Clinical features are also important, such as the herald patch of pityriasis rosea and the papulovesicular coin-shaped patches favoring the lower extremities in nummular dermatitis.

Sometimes patients with MF may exhibit small patches of disease at presentation; however, these lesions typically have histopathologic features at least consistent with MF and generally are associated with larger, more classic lesions of MF elsewhere on the skin. They also may show poikilodermatous features not seen in SPP. Furthermore, the presence of well-developed, moderate to thick small plaques, as seen in some MF patients, is incompatible with the diagnosis of SPP because the latter disorder includes only lesions that are no more than patches or very thin plaques. It is also important to recognize that partially treated or early relapsing lesions of MF may show only nonspecific features that should not be taken as evidence of a pathogenetic link to SPP or any other dermatosis.

COMPLICATIONS

LPP can be associated with other forms of parapsoriasis and overt cutaneous lymphomas as detailed elsewhere in this chapter. Both LPP and SPP occasionally can develop areas of impetiginization secondary to excoriation.

PROGNOSIS AND CLINICAL COURSE

Both LPP and SPP may persist for years to decades with little change in appearance clinically or histopathologically. Approximately 10%–30% of cases of LPP progress to overt MF.[2,52–54] In this context, LPP represents the clinically benign end of the MF disease spectrum, with transformation to large cell lymphoma at the opposite extreme. The rare retiform variant is said to progress to overt MF in virtually all cases.[2]

In contrast to LPP with its malignant potential, SPP is a clinically benign disorder in the experience of most experts. Patients with this disease as defined in this chapter rarely develop overt MF.[11,44,55,56] Despite this fact and what most observers consider to be its nonspecific histopathologic features, some authors favor lumping SPP within the MF disease spectrum as a very early, nonprogressive variant.[55,57] This issue has been debated at length.[31,57,58] A few studies report progression from SPP to MF in about 10% of cases but may have used different criteria than described in this chapter.[53,54]

TREATMENT

Patients with SPP should be reassured and may forego treatment. The disease may be treated with emollients,

BOX 25-3 TREATMENT OF LARGE-PLAQUE PARAPSORIASIS AND SMALL-PLAQUE PARAPSORIASIS

FIRST LINE

- Emollients
- Topical corticosteroids
- Topical tar products
- Sunbathing
- Broadband UVB phototherapy
- Narrowband UVB phototherapy

SECOND LINE

(Mainly for large-plaque parapsoriasis cases considered to be early mycosis fungoides)

- Topical bexarotene
- Topical imiquimod
- Psoralen and UVA phototherapy
- Topical mechlorethamine
- Topical carmustine (BCNU)
- Excimer laser (308 nm)

topical tar preparations, topical corticosteroids, and/or broadband or narrowband UVB phototherapy (Box 25-3).[59] Response to therapy is variable. Patients should initially be examined every 3–6 months and subsequently every year to ensure that the character of the process is stable.

LPP requires more aggressive therapy: high-potency topical corticosteroids with phototherapy such as broadband UVB, narrowband UVB, or psoralen and UVA (PUVA). The goal of treatment is to suppress the disorder to prevent possible progression to overt MF. Other methods of treatment, such as topical nitrogen mustard, have been used, particularly for the poikilodermatous type. Localized lesions may respond to excimer laser (308 nm).[60,61] The patient should be examined carefully every 3 months initially and every 6 months to 1 year subsequently for evidence of progression. Repeated multiple biopsies of suspicious lesions should be performed. Cases that satisfy the clinicopathologic criteria for early MF can be treated with broadband UVB, narrowband UVB, PUVA, topical nitrogen mustard, topical bexarotene gel, topical imiquimod, or topical carmustine (BCNU).[62] Electron-beam radiation therapy generally is reserved for more advanced, infiltrated lesions of MF.

PREVENTION

Because LPP and SPP are uncommon diseases that appear to affect patients randomly, there are no known preventive measures.

PITYRIASIS LICHENOIDES

PITYRIASIS LICHENOIDES AT A GLANCE

- Pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC) represent two ends of a disease spectrum; both entities and intermediate forms can coexist.
- All forms are characterized by spontaneously resolving, temporally overlapping crops of papules.
- PLEVA papules last for weeks and may develop crusts, vesicles, pustules, or ulcers.
- PLC papules persist for months and develop scales.
- All forms contain interface, cytolytic T-cell infiltrates with variable epidermal destruction.
- In PLEVA, $CD8^+$ cells predominate.
- In PLC, $CD8^+$ or $CD4^+$ cells predominate.
- Dominant T-cell clonality can be detected in all forms, more often in PLEVA than in PLC.
- Treatment depends on severity and ranges from topical steroids, systemic antibiotics, UV irradiation, and psoralen and UVA to systemic immunosuppressants.

EPIDEMIOLOGY

Pityriasis lichenoides affects all racial and ethnic groups in all geographic regions.[63–68] It is more common in children and young adults but can affect all ages with seasonal variation in onset favoring fall and winter. There is a male predominance of 1.5:1 to 3:1. PLC is three to six times more common than PLEVA.

ETIOLOGY AND PATHOGENESIS

The etiology of pityriasis lichenoides is unknown. Some cases have been associated with infectious agents such as *Toxoplasma gondii*,[69,70] Epstein-Barr virus,[70,71] cytomegalovirus,[70,71] parvovirus B19,[70,72,73] and human immunodeficiency virus.[74,75] At least one case was linked repeatedly with estrogen–progesterone therapy, another with chemotherapy drugs, and a third with radiocontrast iodide.[76–78] It is uncertain

whether these agents are actively involved in disease pathogenesis or merely coincidental bystanders; however, several cases associated with toxoplasmosis have cleared fairly quickly in response to specific therapy.[69] A tenfold higher level of maternal keratinocytes have been reported in the epidermis of children with PL compared to controls.[79]

Immunohistologic studies have shown a reduction in $CD1a^+$ antigen-presenting dendritic (Langerhans) cells within the central epidermis of pityriasis lichenoides lesions.[80] Keratinocytes and endothelial cells are $HLA\text{-}DR^+$, which suggests activation by T-cell cytokines.[80] $CD8^+$ T cells predominate in PLEVA, whereas either $CD8^+$ or $CD4^+$ T cells predominate in PLC.[80–82] Many of these T cells express memory proteins (CD45RO) and cytolytic proteins (TIA-1 and granzyme B).[72,73] Dominant T-cell clonality has been demonstrated in about half of PLEVA cases and a minority of PLC cases.[32,83,84] In aggregate, these findings raise the possibility that pityriasis lichenoides is a variably clonal cytolytic memory T-cell lymphoproliferative response to one or more foreign antigens. Deposition of immunoglobulin M, C3, and fibrin in and around blood vessels and along the dermal–epidermal junction in early acute lesions suggests a possible concomitant humoral immune response, although this could be a secondary phenomenon.

The relationship of pityriasis lichenoides to lymphomatoid papulosis remains controversial[10,51,80] (see also Chapters 145 and 146). Common features include dominant T-cell clonality and spontaneous resolution of papular, predominantly lymphoid lesions. Furthermore, individual lesions with the clinicopathologic characteristics of either pityriasis lichenoides or lymphomatoid papulosis can coexist in the same patient, either concurrently or serially. It remains to be determined whether this can be explained as an artifact of sampling lymphomatoid papulosis lesions at various stages of their evolution. The presence of large $CD30^+$ atypical lymphoid cells is the hallmark of lymphomatoid papulosis (at least types A and C).[84] Furthermore, these cells are typically $CD4^+$ and often lack one or more mature T-cell antigens such as CD2, CD3, and CD5. These features serve to distinguish lymphomatoid papulosis from pityriasis lichenoides. Although occasional $CD30^+$ cells can be seen in a wide variety of dermatoses, the presence of any appreciable number should favor lymphomatoid papulosis over pityriasis lichenoides as a matter of definition. It may be that the "PLC-PLEVA" and "lymphomatoid papulosis–$CD30^+$ anaplastic large cell lymphoma" disease spectra are intersecting rather than overlapping entities, i.e., although pityriasis lichenoides is a distinct cutaneous T-cell disorder, it is possible that it may sometimes serve as fertile soil for the development of the $CD30^+$ T-cell clone characteristic of lymphomatoid papulosis.

CLINICAL FINDINGS

CUTANEOUS LESIONS. PLC and PLEVA exist on a clinicopathologic continuum.[2,51] Therefore, individual patients may exhibit a mixture of acute and chronic lesions sequentially or concurrently. In addition, lesions representing clinical or histopathologic intergrades between the extremes may also occur at any time.

Figure 25-10 Pityriasis lichenoides chronica. Polymorphous appearance ranging from early erythematous papules to scaling brown–red lesions and tan-brown involuting, flat papules, and macules.

Lesions are often asymptomatic but can be pruritic or burning, especially in the more acute cases. PLC typically presents as recurrent crops of erythematous scaly papules that spontaneously regress over several weeks to months (Fig. 25-10). PLEVA manifests as recurrent crops of erythematous papules that develop crusts, vesicles, pustules, or erosions before spontaneously regressing within a matter of weeks (Fig. 25-11). The more severe ulcerative variant is known as *pityriasis lichenoides with ulceronecrosis and hyperthermia (PLUH)* or *febrile ulceronecrotic Mucha–Habermann disease (FUMHD)*.[85] It presents as purpuric papulonodules with central ulcers up to a few centimeters in diameter (Fig. 25-12). Some have proposed that this severe variant is actually an overt T-cell lymphoma.[31] Pityriasis lichenoides lesions tend to concentrate on the trunk and proximal extremities, but any region of the skin and even mucous membranes can be involved. Rare regional or segmental lesion distributions have been described,[10,86] as has rare conjunctival nodular inflammation.[87] Although there are usually numerous coexistent lesions, occasionally only a small number of lesions will be present at any one time. All forms of pityriasis lichenoides can result in postinflammatory hypopigmentation or hyperpigmentation.[63] Chronic lesions can resolve with

Figure 25-11 Pityriasis lichenoides et varioliformis acuta. **A.** Adolescent with multiple erythematous papules and crusted lesions in various stages of evolution. **B.** Larger papulovesicular and hemorrhagic, crusted lesions in an adult. Note varioliform scars adjacent to active lesions on posterior thigh and leg. **C.** Pustules, crusts, and necrotic-centered papules with erythematous, indurated base.

postinflammatory hypopigmentation, sometimes presenting as idiopathic guttate hypomelanosis. Chronic lesions rarely lead to scars. In contrast, acute lesions result in deeper dermal injury and consequently often resolve leaving varioliform (smallpox-like) scars. The presence of lesions in various stages of evolution imparts a polymorphous appearance that is characteristic of pityriasis lichenoides.

Figure 25-12 Pityriasis lichenoides, ulceronecrotic, hyperacute variant. Large necrotic eschar with halo erythema developing in febrile patient with antecedent pityriasis lichenoides et varioliformis acuta.

LABORATORY TESTS

Miscellaneous nonspecific abnormalities in blood test results occur but are of little practical value. Leukocytosis and a decreased CD4/CD8 ratio can occur.

HISTOPATHOLOGY. As with the morphology of the clinical lesions, pityriasis lichenoides can exhibit a range of histopathologic features encompassing acute, chronic, and intermediate lesional variants (Figs. 25-13 and 25-14). All cases of pityriasis lichenoides contain an interface dermatitis that is denser and more wedge shaped in the acute lesions. The infiltrate is composed mainly of lymphocytes with a variable admixture of neutrophils and histiocytes. There is exocytosis, parakeratosis, and extravasation of erythrocytes. Epidermal damage ranges from intercellular and extracellular edema in less severe cases to extensive keratinocyte necrosis, vesicles, pustules, and ulcers. The acute variants can exhibit lymphocytic vasculitis with fibrinoid degeneration of blood vessel walls.

Occasional $CD30^+$ lymphoid cells and occasional atypical lymphoid cells may be seen as a nonspecific finding in many cutaneous lymphoid infiltrates. The

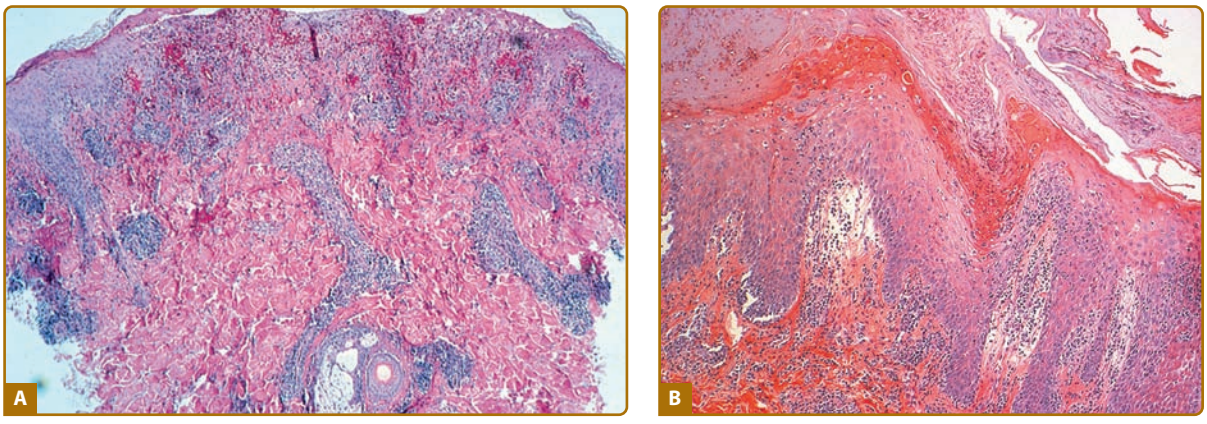

Figure 25-13 Pityriasis lichenoides et varioliformis acuta. **A.** Ulcerated papule with epidermal necrosis, hemorrhage, and superficial and deep perivascular lymphocytic infiltrate. Hematoxylin and eosin (H&E) stain. **B.** Parakeratosis and crust with marked spongiosis and epidermal necrosis. Lymphocyte exocytosis and basal hydropic changes. H&E stain.

presence of an appreciable numbers of these cells is not consistent with classic pityriasis lichenoides of any type and should raise concern for the lymphomatoid papulosis–CD30$^+$ anaplastic large cell lymphoma disease spectrum.[30] Other immunohistologic features and the clonality of pityriasis lichenoides are discussed in Section "Etiology and Pathogenesis" under Section "Pityriasis Lichenoides."

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pityriasis lichenoides includes many papular eruptions (Box 25-4). Those that develop crusts, vesicles, pustules, or ulcers are grouped with PLEVA, whereas those that form predominantly scaly papules are grouped with PLC. Most of them can be excluded based on history and typical clinicopathologic features. A few, such as secondary syphilis and virus-associated lesions, can also be excluded based on serologic tests. Among the most challenging diseases to distinguish from pityriasis lichenoides are lymphomatoid papulosis and macular or papular variants of MF.[88–91] As detailed earlier, the presence of large atypical lymphoid cells (often CD30$^+$) differentiates lymphomatoid papulosis from pityriasis lichenoides.[84] Macular or papular variants of MF are rare. They exhibit classic histopathological features of MF, including small atypical epidermotropic lymphoid cells with convoluted nuclei and a band-like superficial dermal lymphoid infiltrate.[90]

COMPLICATIONS

Secondary infection is the most common complication of pityriasis lichenoides. PLEVA may be associated with low-grade fever, malaise, headache, and arthralgia. Patients with PLUH/FUMHD can develop high fever, malaise, myalgia, arthralgia, and gastrointestinal and central nervous system symptoms. Occasionally, debilitated patients may die.[85,92] PLC has been associated uncommonly with LPP in children.[44] Despite their sometimes dominant T-cell clonal nature, PLC and PLEVA are considered clinically benign disorders

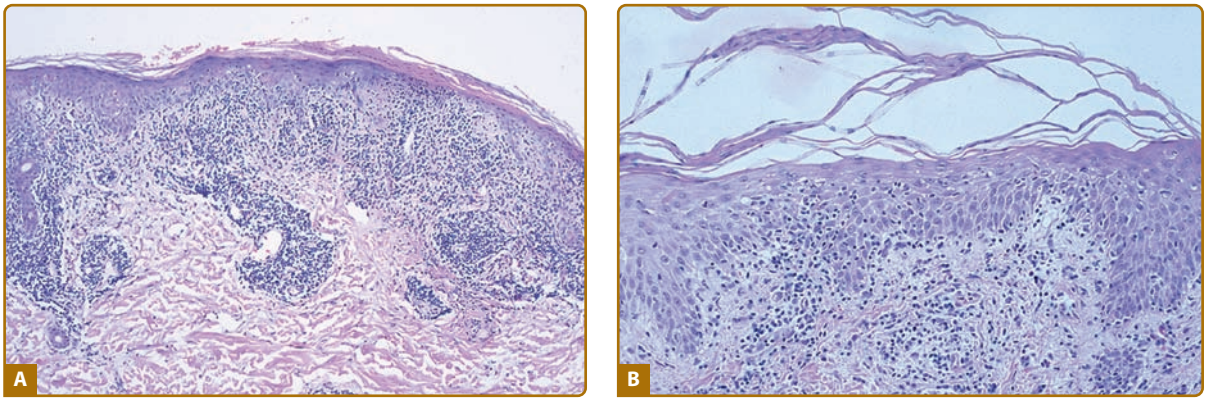

Figure 25-14 Pityriasis lichenoides chronica. **A.** Compact parakeratosis, lymphocytic exocytosis, occasional eosinophilic necrotic keratinocytes, edema, and diffuse lymphocytic infiltrate localizing to epidermal–dermal interface and perivascular sites within the dermis. Hematoxylin and eosin (H&E) stain. **B.** Parakeratosis, spongiosis, and a predominant mononuclear cell infiltrate in the epidermis and dermis with papillary edema. H&E stain.

BOX 25-4 DIFFERENTIAL DIAGNOSIS OF PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA (PLEVA) AND PITYRIASIS LICHENOIDES CHRONICA (PLC)

Most Likely

- PLEVA
  - Arthropod bites, stings, infestations
  - Leukocytoclastic vasculitis
  - Viral exanthem (e.g., varicella-zoster, herpes simplex)
- PLC
  - Pityriasis rosea
  - Drug eruption
  - Guttate psoriasis

Consider

- PLEVA
  - Folliculitis
  - Rickettsiosis
  - Erythema multiforme
  - Dermatitis herpetiformis
- PLC
  - Spongiotic dermatitis, papular variant
  - Small-plaque parapsoriasis
  - Lichen planus
  - Gianotti–Crosti syndrome

Always Rule Out

- PLEVA
  - Lymphomatoid papulosis
  - Secondary syphilis
- PLC
  - Lymphomatoid papulosis
  - Mycosis fungoides (papular variant)
  - Secondary syphilis

BOX 25-5 TREATMENT OF PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA AND PITYRIASIS LICHENOIDES CHRONICA

FIRST LINE

- Topical corticosteroids
- Antibiotics (erythromycin 500 mg PO 2–4 × daily[96]; tetracycline 500 mg PO 2–4 × daily,[97] minocycline 100 mg PO twice daily; azithromycin 500 mg PO on day 1 and 250 mg PO on days 2–5 bimonthly[93])
- Phototherapy (sunbathing, UVB,[90] UVA + UVB,[98] narrowband UVB[99])

SECOND LINE

- Topical tacrolimus[100,101]
- Prednisone (60/40/20 mg PO taper, 5 days each)[102]
- Methotrexate (10–25 mg PO weekly)[103,104]
- Phototherapy (UVAI, psoralen + UVA)
- Cyclosporine (2.5–4 mg/kg/day total dose divided into twice-daily PO doses; use the minimum)[75]
- Retinoids (e.g., acitretin 25–50 mg PO daily)[105]
- Photodynamic therapy[94]
- Bromelain (pineapple extract)[95]

without significant linkage to lymphomas or other malignancies.

PROGNOSIS AND CLINICAL COURSE

Pityriasis lichenoides has a variable clinical course characterized by recurrent crops of lesions that spontaneously resolve. The disorder may resolve spontaneously within a few months or, less commonly, persist for years. PLEVA usually has a shorter duration than PLC. Although the conclusion was not confirmed by subsequent investigation, one report suggested that the duration of pityriasis lichenoides in children correlated better with its clinical distribution than with the relative abundance of acute and chronic lesions, which often coexisted.[67] From longest to shortest duration, the distribution of lesions ranged from peripheral (distal extremities) to central (trunk) to diffuse.

TREATMENT

The mainstay of traditional therapy has been a combination of topical corticosteroids and phototherapy (Box 25-5). Systemic antibiotics in the tetracycline and erythromycin families are used primarily for their anti-inflammatory rather than antibiotic effects. One newer option is azithromycin.[93] Cases with minimal disease activity may not require any treatment. Photodynamic therapy has been used successfully for PLC.[94] The more acute the clinical course and the more severe the individual lesions, the more systemic therapy is indicated. Methotrexate is often effective in relatively low doses. Calcineurin inhibitors and retinoids may also be beneficial. Severe cases of PLEVA and PLUH often require systemic corticosteroids or similar drugs to gain control of systemic symptoms. Topical and systemic antibiotics may be needed to treat secondary infections complicating ulcerated skin lesions. These agents are often selected initially to cover Gram-positive pathogens, but subsequent use should be guided by culture results. Bromelain, a pineapple extract, cleared PLC lesions in 8/8 cases.[95]

PREVENTION

There are no known preventive measures.

Chapter 26 :: Lichen Planus

:: Mazen S. Daoud & Mark R. Pittelkow

LICHEN PLANUS AT A GLANCE

- Worldwide occurrence: Less than 1%.
- Lesions: Symmetric, grouped, erythematous to violaceous, flat-topped, polygonal papules.
- Distribution: Widespread, predilection for flexural aspects of arms and legs.
- Variants: Based on configuration, morphology of lesion, and site of involvement.
- Pathology: Basal epidermal keratinocyte damage and lichenoid interface lymphocytic reaction.

Lichen planus (Greek *leichen*, "tree moss"; Latin *planus*, "flat") is a unique, common inflammatory disorder that affects the skin, mucous membranes, nails, and hair. The appearance of lichen planus-like lichenoid dermatoses has been likened to the scurfy, finely furrowed, dry excrescences of the symbiotic vegetation known as *lichen*. Although this morphologic comparison may be antiquated, lichen planus is a distinctive entity with prototypic "lichenoid" papules that show distinctive color and morphology, develop in typical locations, and manifest characteristic patterns of evolution. Microscopic features are also distinctive, although the microscopic pattern of inflammation and skin response is shared by several dermatoses. The term *lichenoid reaction*[1] is the histologic description used to capsulize the pathologic characteristics of skin diseases resembling lichen planus.

The four Ps—(1) purple, (2) polygonal, (3) pruritic, and (4) papule—is the mnemonic device often used to recall the constellation of symptoms and skin findings that characterize lichen planus.

HISTORICAL ASPECTS

EPIDEMIOLOGY

The exact incidence and prevalence of lichen planus are unknown, but the overall prevalence is believed to be somewhat around 1% of the general population. Estimates between 0.14% and 1.27% have been reported worldwide and approximately 0.44% in the United States. No racial predilection has been observed.[2,3]

At least two-thirds of cases occur between the ages of 30 and 60 years of age. No sexual predilection is evident. Females are usually affected in their 50s and 60s, whereas males develop lichen planus at a somewhat earlier age. The disease is less common in the very young and the elderly. The development of lichen planus may be affected by seasonal or environmental factors.[2]

Fewer than 100 cases of familial lichen planus have been reported. The familial form tends to be more protracted and severe and presents in erosive, linear, or ulcerative patterns or with atypical features affecting young adults and children.[4] Some believe that the familial form represents a separate, unique dermatosis.

Different HLA haplotypes were reported in familial lichen planus, including HLA-B7, -Aw19, -B18, and -Cw8. In nonfamilial lichen planus, HLA-A3, -A5, -A28, -B8, -B16, and -Bw35 are more common.[5] HLA-B8 is more common in patients with oral lichen planus as a sole manifestation, and HLA-Bw35 is more strongly associated with cutaneous lichen planus.

ETIOLOGY AND PATHOGENESIS

It is evident that specific immunologic mechanisms control the development of lichen planus. T-cell mediated pathologic alterations involving proinflammatory and counterregulatory mechanisms function in the pathogenesis of lichen planus.[6] No consistent alterations in immunoglobulins (Igs) have been shown in lichen planus, and humoral immunity most likely is a secondary response in immunopathogenesis.

Cell-mediated immunity, on the other hand, plays the major role in triggering the clinical expression of the disease. Both $CD4^+$ and $CD8^+$ T cells are found in lesional skin of lichen planus. Progression of disease may lead to preferential accumulation of $CD8^+$ cells. The majority of lymphocytes in the infiltrate of lichen planus are $CD8^+$ and CD45RO (memory) positive cells and express the α–β T-cell receptor (TCR), and in a minority, the γ–δ receptor. This later cell subtype is not normally found in healthy skin. These cells are considered responsible for the development of the most characteristic change observed in the lichenoid reaction, namely, apoptosis.[7] The inflammatory process that leads to apoptosis is complex and not fully understood. The epithelium–lymphocyte interaction can be divided into three major stages: (1) antigen recognition, (2) lymphocyte activation, and (3) keratinocyte apoptosis.

LICHEN PLANUS-SPECIFIC ANTIGEN RECOGNITION

It is evident that the majority of T cells in the infiltrate of lichen planus, both within the epithelium and adjacent to damaged basal keratinocytes, are activated $CD8^+$ cytotoxic lymphocytes. Evidence from oral lichen planus suggests that $CD8^+$ lesional T cells recognize a lichen planus-specific antigen associated with major histocompatibility complex (MHC) class I on lesional keratinocytes. The nature of this antigen is unknown. Theoretically, the antigen may be an autoreactive peptide, thus classifying lichen planus as an autoimmune disease. Alternatively, it may represent an exogenous antigen such as an altered protein, drug, contact allergen, viral or infectious agent, or an unidentified immunogenic target. Innate immune responses that become activated by exogenous stimuli in a genetically susceptible individual may trigger the development of lichen planus and, further, involves a small but significant lesional population of $CD56^+CD16^-$ NK lymphocytes that secrete interferon-γ, tumor necrosis factor (TNF)-α, and only minimal amounts of IL-22, IL-17, or IL-4.

The role of T-helper (CD4) cells in the pathogenesis of lichen planus is not fully defined. T cells may become activated via professional antigen-presenting cells such as Langerhans cells, dendritic cells, or accessory cells such as epidermal keratinocytes in association with members of the MHC II and specific cytokines. T-helper lymphocytes may also propagate $CD8^+$ cytotoxic lymphocytes through cellular cooperation and release of cytokines.

The nature of antigenic stimulation is not known. Contact sensitizers such as metals could act as haptens and elicit an immunologic response. Enhanced lymphocyte reactivity to inorganic mercury, a component of dental amalgam, has been found in patients with oral lichenoid reactions. Low-grade chronic exposure to mercury, and possibly to other metals such as gold, may stimulate a lymphocytic reaction that manifests as lichen planus. A list of contact chemicals and drugs that can elicit lichenoid reactions is discussed in Section "Drug-Induced Lichen Planus." With more widespread use of biologics for various chronic inflammatory diseases, cases of lichenoid, interface dermatitis are being recognized and implicate dysregulated cytokine production, including upregulation of type-I interferon expression in the setting of tumor necrosis factor (TNF)-α blockage.[8] The role of infection in the development of lichen planus has been repeatedly raised over the years. Though provocative, no conclusive evidence has molecularly linked lichen planus to any of the following infections or microorganisms: syphilis, herpes simplex virus 2, human immunodeficiency virus (HIV), amebiasis, chronic bladder infections, hepatitis C virus (HCV), *Helicobacter pylori*, or human papillomavirus.

CYTOTOXIC LYMPHOCYTE ACTIVATION

Following antigen recognition, $CD8^+$ T cells are activated. Activated cytotoxic lymphocytes undergo lesional tissue clonal expansion, leading to oligoclonal and occasionally to monoclonal proliferation as detected by analysis of the TCR-γ chain gene products.

Activated lymphocytes, both by helper subsets (Th1 and Th2) and cytotoxic-suppressor cells, release soluble mediators (cytokines and chemokines), such as interleukin (IL)-2, IL-4, IL-10, interferon (IFN)-γ, tumor necrosis factor (TNF)-α, and transforming growth factor-β1, that attract lymphocytes and regulate their biologic activities within and adjacent to the epithelium. Both pro- and anti-inflammatory cytokines, i.e., mixed Th1 and Th2 cytokine products, are generated simultaneously. The balance between lymphocytic activation and down regulation determines the clinical behavior of the disease. IFN-γ, produced by T-helper cells during the antigen recognition stage, induces keratinocytes to produce lymphotoxin-α and TNF-α, and to upregulate MHC class II, thus increasing interactions with T-helper cells. Furthermore, IFN-γ upregulates the expression of intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 by basal keratinocytes, Langerhans cells, and other

macrophage-dendritic cells. IFN-γ and IL-4 are elevated in saliva from oral lichen planus. Intercellular adhesion molecule-1 is a ligand for the β_2-integrin, leukocyte function-associated antigen-1, on the surface of lymphocytes, which further enhances the interaction of these lymphocytes with the antigen-presenting cells. Laminin-5 and collagen types IV and VII are increased in lesional lichen planus and serve as ligands for β1-integrin on the surface of lymphocytes, thus allowing for enhanced association of lymphocytes with the basement membrane. Integrin α3 is present on activated, skin-homing T cells and may localize these effector cells to the epidermal–dermal interface and basement membrane, which contain epiligrin/laminin-5, a ligand for this integrin. This close interaction between lymphocytes and basement membrane targets metalloproteinases produced by lymphocytes to alter extracellular matrix proteins and integrins, and the process eventuates in apoptosis, basement membrane disruption, reduplication, and subepidermal cleft formation (see Section "Pathology"). TNF-α upregulates the expression of matrix metalloproteinase (MMP)-9 mRNA in lesional T lymphocytes, thus further enhancing basement membrane disruption (see Section "Keratinocyte Apoptosis").[9]

Keratinocytes also participate in the response by producing IL-1β, IL-4, IL-6, granulocyte–macrophage colony-stimulating factor, and TNF-α. These cytokines further activate tissue macrophages and peripheral blood mononuclear cells and upregulate expression of cell surface adhesion molecules and migration activity. Keratinocyte-produced cytokines also upregulate expression of specific keratin genes. Keratin (K)17, usually restricted to adnexal structures, is variably expressed in the basal and suprabasal layers of the interfollicular epithelium of affected epidermis. K6 and K16 also become detectable in the basal and suprabasal layers. K4 and K13 are reduced in the suprabasal compartment in areas with orthokeratosis, associated with increased production of K1 and K10.

KERATINOCYTE APOPTOSIS

The exact mechanisms used by activated cytotoxic T cells to trigger apoptosis of keratinocytes are not completely known. Possible mechanisms include: (1) T-cell secreted TNF-α binding to the TNF-α R1 receptor on the keratinocyte surface, (2) T-cell surface CD95L (Fas ligand) binding CD95 (Fas) on the keratinocyte, and (3) T-cell secreted granzyme B entering the keratinocyte via perforin-induced membrane pores. In lichen planus, granzyme B predominates in lesional epidermis versus perforin in graft-versus-host disease.[10] All these mechanisms may activate the keratinocyte caspase cascade, resulting in keratinocyte apoptosis. Caspase 3 is frequently found to be elevated in both cutaneous and oral lichen planus lesional skin.[11]

Recruited lymphocytes may further contribute to apoptosis via a different mechanism, the loss of a basement membrane-derived cell survival signal that normally prevents the onset of apoptosis. Hence, basement membrane disruption may trigger apoptosis. Principle mediators are the MMPs, a family of zinc-containing endoproteinases that primarily function to degrade connective tissue matrix proteins. The action of these enzymes is also regulated by inhibitors such as tissue inhibitors of metalloproteinases (TIMPs) (see Chapter 63). It has been shown that lesional T cells in lichen planus have higher MMP-9 levels than peripheral blood T cells. Lesional T-cell MMP-9 activity increases following stimulation with TNF-α, but not TIMP-1, an inhibitor for MMP-9. These observations suggest that T-cell secreted MMP-9 disrupts epithelial basement membranes, blocking cell survival signals to keratinocytes and inducing apoptosis.

Various other environmental, behavioral, or infectious factors have been observed on occasion to be associated with the development or exacerbation of lichen planus. However, no well-established association has been documented between emotional stress, tobacco use, or oral or gastrointestinal candidiasis and development of lichen planus.

SPECIFIC AND GLOBAL GENE RESPONSES.

Recent studies using microarray technologies to examine and characterize in greater detail various inflammatory and immune-mediated skin diseases have provided considerable new insights into mechanisms mediating-specific inflammatory responses, including lichen planus, oral lichen planus, lichen planopilaris as well as lichenoid eruptions, and interface dermatitis. Lichen planus was distinguished from atopic dermatitis, psoriasis, and healthy skin by elevated expression of type I interferon-induced genes and a specific cytokine expression pattern.[12] CXCL9, the ligand for CXCR3 was the most significant marker for lichen planus. In the scarring alopecias, specifically lichen planopilaris, microarray analysis implicates the loss of peroxisome proliferator-activated receptor (PPAR) γ expression in contributing to proinflammatory lipid accumulation and inflammatory cell infiltration leading to pilosebaceous destruction.[13] Recently, Brn2, a transcription factor expressed by keratinocytes as well as lymphocytes, when overexpressed in epidermis, has been found to not only cause epidermal changes characteristic of lichen planus but also inflammatory, interface cellular reactivity.[14]

CLINICAL FINDINGS

CUTANEOUS LESIONS

The classic cutaneous lesion of lichen planus is a faintly erythematous to violaceous, flat-topped, polygonal papule, sometimes showing a small central umbilication (Fig. 26-1). Papules are grouped and tend to coalesce. A thin, transparent, and adherent scale may be discerned atop the lesion. Fine, whitish puncta or reticulated networks referred to as *Wick-ham striae* are present over the surface of many well-developed papules (see Fig. 26-1). These are considered to be highly characteristic and are more easily observed after applying oil, xylene, or water and visualizing the

Figure 26-1 Flat-topped, polygonal, sharply defined papules of violaceous color, grouped and confluent. Surface is shiny and reveals fine white lines (Wickham striae). Note pigmentation of resolving lesions.

Figure 26-2 Generalized lichen planus. Small, flat-topped violaceous papules, some grouped, some disseminated, becoming confluent on the trunk.

lesions with a magnifying lens or a handheld dermatoscope. The surface alteration may result from localized thickening of the keratohyalin-containing cell layers of the stratum granulosum, although a focal increase in the activity of lichen planus may account for the morphologic alteration of Wickham striae.

Lichen planus usually develops over several weeks. Sometimes multiple lesions develop rapidly with dissemination following the initial appearance. In generalized disease (Fig. 26-2), the eruption often spreads within 1–4 months from onset. The initial lesions almost always appear on the extremities, especially the legs.

The lesions are usually distributed symmetrically and bilaterally over the extremities. Lichen planus tends to involve the flexural areas of the wrists, arms, and legs (see Fig. 26-1). The thighs, lower back, trunk, and neck may also be affected. Oral mucous membranes (Fig. 26-3) and the genitalia (Fig. 26-4) are additional sites of involvement. The face is usually spared in classical cases, and palmoplantar involvement is unusual. Inverse lichen planus usually affects the axillae, groin, and inframammary areas.

Lichen planus tends to be quite pruritic, although some patients are completely asymptomatic. The degree of pruritus is generally related to the extent of involvement, with more intense pruritus in generalized form. An exception is hypertrophic lichen planus, which is more localized but extremely pruritic. Oral involvement is generally asymptomatic unless erosions or ulcers developed, after which it becomes extremely painful. In the acute, evolving stages of the disease, scratching, injury, or trauma may induce an isomorphic (Koebner) response (Fig. 26-5). Lichen planus usually heals with hyperpigmentation (see Fig. 26-1), which is more prominent among patients with darker skin color. Hypopigmentation uncommonly develops after resolution of lesions.

Most reports of lichen planus in children have come from the Indian subcontinent, suggesting that children

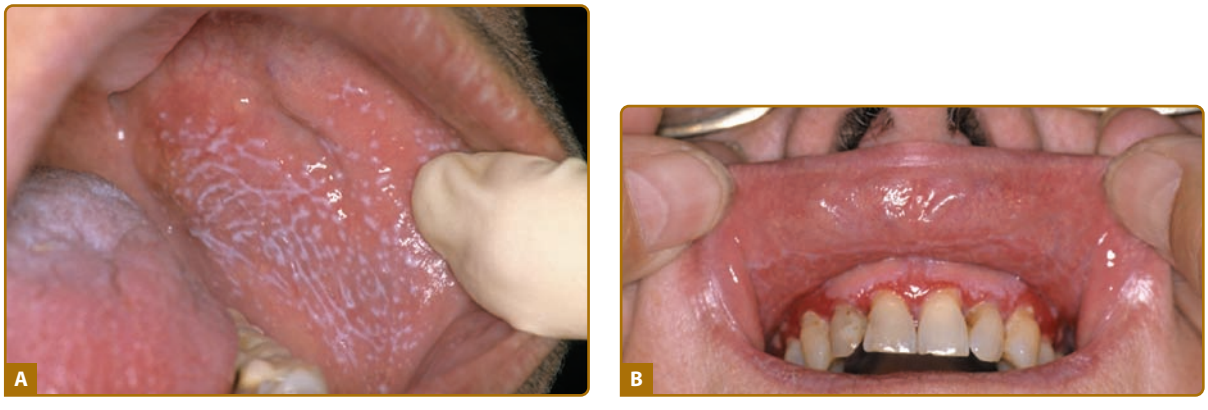

Figure 26-3 Mucosal lichen planus. **A.** A typical lace-like whitish reticulated pattern of oral lesions is seen on the buccal mucosa. **B.** Erosive gingivitis. Here lichen planus manifests as painful erosions on the gingiva.

Figure 26-4 Lichen planus on the penis. Agminate pattern of lesions involving the glans, sulcus, and meatus (not seen) of the penis.

of South Asian origin are more susceptible to developing lichen planus.[15] Although the clinical and pathologic features of childhood lichen planus are similar to those in adults, scalp, nail, and hair involvement are not common. Mucous membrane involvement, thought to be rare, may occur in up to one-third of patients. The hypertrophic variant occurs in one-fourth of children with lichen planus.

Figure 26-5 Lichen planus. Linear pattern with Koebner response adjacent to clustered papules on the flexural wrist.

CLINICAL VARIANTS

Many variations in the clinical presentation have been described and are generally categorized according to (1) the configuration of lesions, (2) the morphologic appearance, or (3) the site of involvement. These variations are patterned by subtle or unknown properties of the disease. The prototypic papule can be altered or modified in configuration, morphology, or anatomic distribution.

CONFIGURATION OF LESIONS

Annular Lichen Planus. Annular lesions occur in approximately 10% of cases and commonly develop as arcuate groupings of individual papules that develop rings or peripheral extension of clustered papules with central clearing. They tend to occur in blacks and are more common on the penis and scrotum (see Chapter 75). It occurs also when larger lesions on trunk and extremities reach 2–3 cm in diameter and become hyperpigmented with a raised outer rim. Actinic lichen planus (see below), seen in subtropical zones on sun-exposed, dark-skinned young adults and children, is frequently annular in shape.

Linear Lichen Planus. Papules of lichen planus may develop a linear pattern secondary to trauma (koebnerization) (see Fig. 26-5) or, rarely, in less than 0.2% of cases as a spontaneous, isolated eruption, usually on the extremities following Blaschko lines. The segmental formation is thought to be due to a postzygotic mutation that affects one of the genes predisposing its development that lead to the formation of a keratinocyte clone that is more susceptible to development of lichen planus.[16] Drug-induced linear lichen planus has also been reported.[17,18]

It is important to differentiate linear lichen planus from nevus unius lateris, lichen striatus, inflammatory linear verrucous epidermal nevus, linear psoriasis, and linear Darier–White disease, which have different presentations clinically and histopathologically.

MORPHOLOGY OF LESIONS

Hypertrophic Lichen Planus. Hypertrophic lichen planus (*lichen planus verrucosus*) usually occurs on the extremities, especially the shins and interphalangeal joints, and tends to be the most pruritic variant (Fig. 26-6).[19] Lesions are thickened and elevated, purplish or reddish-brown in color, and hyperkeratotic. Occasionally, verrucous plaques develop. Lesions may show accentuated and elevated follicular induration and chalk-like scale. This variant usually heals with scar formation and hyper- or hypopigmentation. Chronic venous insufficiency is frequently present.

Atrophic Lichen Planus. The atrophic variant is rare and is characterized by the presence of a few

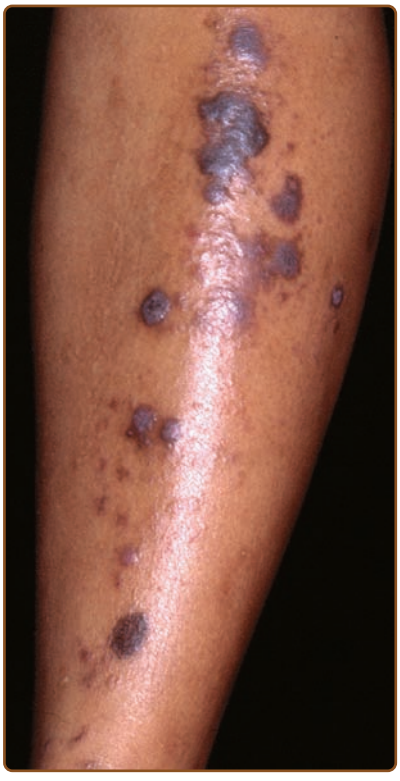

Figure 26-6 Hypertrophic lichen planus in the pretibial region of a dark-skinned individual. Lesions are almost nodular and very dark with the violaceous sheen of lichen planus. Lesions may later become hyperkeratotic.

well-demarcated, white-bluish papules or plaques, sometimes more erythematous, with central superficial atrophy.[2] The lesions are a few millimeters wide but may coalesce to form larger plaques. They are most common on the lower extremities or trunk. The lesions often resemble *lichen sclerosus et atrophicus*. However, the histologic features are diagnostic.

Vesiculobullous Lichen Planus. The development of vesicles and bullae in lichen planus is rare. (Fig. 26-7). The bullae, which appear most commonly on the extremities, arise from existing papules of lichen planus and rarely from normal-appearing skin. They may appear suddenly during an acute flare of disease and are usually associated with mild constitutional symptoms. These lesions usually resolve in a few months.

Figure 26-7 Vesiculo-bullous lichen planus. Vesicles and bullae with violaceous-erythematous papules and plaques on the foot.

Figure 26-8 Erosive–ulcerative lichen planus showing erosions, ulcers, and granulation tissue and scarring of toes, interdigital web spaces, and soles.

Bulla arising in oral lichen planus can lead to painful erosions. Histologically, subepidermal separation is present in addition to typical features. Bullae formation does not necessarily indicate a longer duration of the disease. Bullae arising from normal skin are more characteristic of *lichen planus pemphigoides* and should be differentiated by direct and indirect immunofluorescence (see below).

Erosive and Ulcerative Lichen Planus. A rare variant presents with chronic, painful bullae and ulcerations of the feet with often, cicatricial sequelae (Fig. 26-8). Patients typically have nails, and mucosal involvement in addition to classical skin lesions, which often aids in establishing the diagnosis. Permanent loss of toenails and cicatricial alopecia of the scalp are common. Squamous cell carcinoma (SCC) may develop in lesions of ulcerative lichen planus.[20]

Erosions and ulcerations may also develop in more severe cases of oral lichen planus.

Follicular Lichen Planus. Follicular lichen planus may occur alone or in association with other forms of cutaneous or mucosal lichen planus.[16] The term *lichen planopilaris* has been used to describe this distinctive variant, but other terms include *lichen planus follicularis*, *peripilaris*, and *acuminatus*. Individual keratotic follicular papules and studded plaques are seen. Sites of predilection include the trunk and medial aspects of the proximal extremities.[21] Follicular lichen planus may affect the scalp with the development of cicatricial alopecia (see Section "Lichen Planus of the Scalp"; Fig. 26-9). The triad of follicular lichen planus of skin (lichen planus spinulosus) and/or scalp, multifocal cicatricial alopecia of the scalp, and nonscarring alopecia of the axillary and pubic areas, has been described as Graham–Little–Piccardi–Lassueur (or Graham–Little–Feldman) syndrome. Sometimes more typical lesions of the skin and nails are seen. Other variants of follicular lichen planus include the *lichen planus follicularis tumidus* with oval pseudotumoral plaques of the mastoid area, postmenopausal frontal fibrosing alopecia,[22] and lichen planoporitis, with the lichenoid

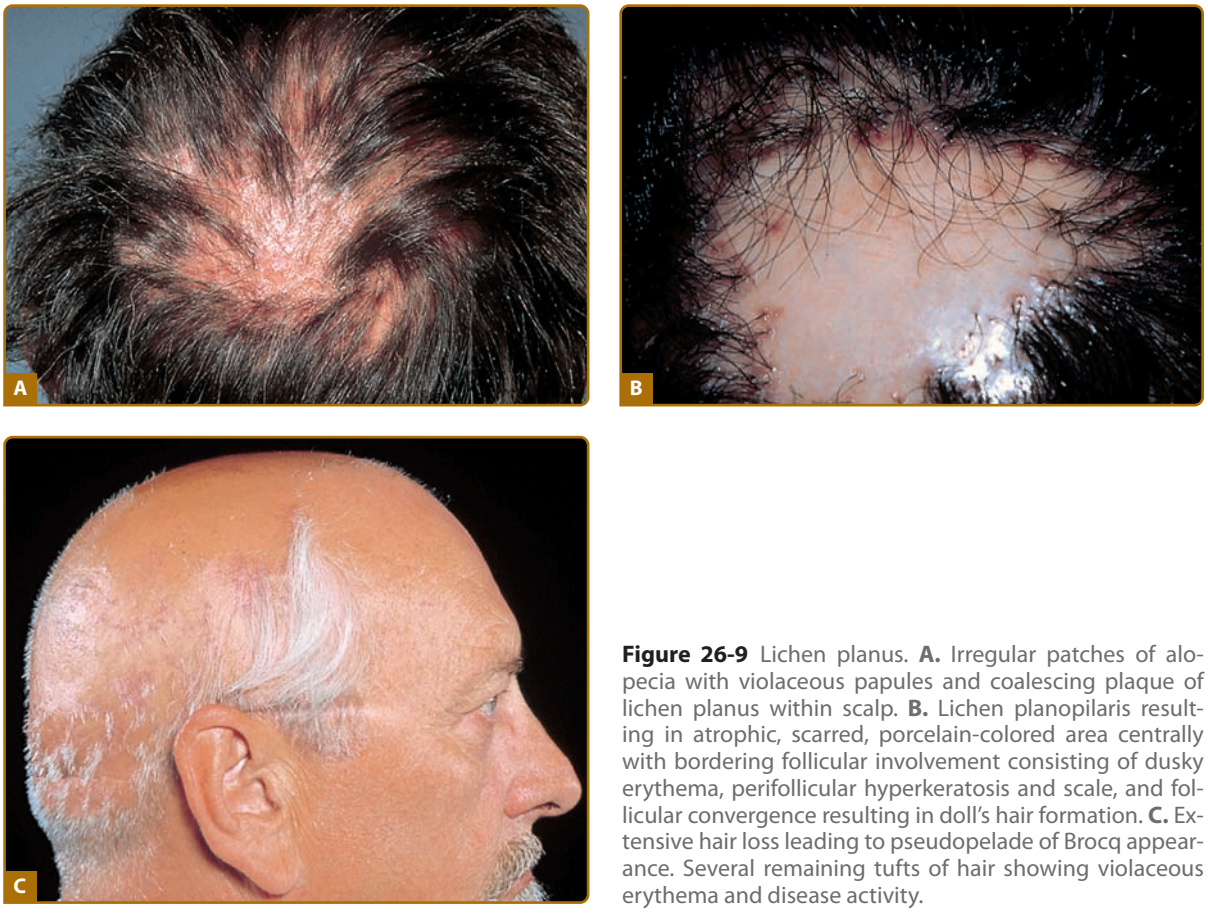

Figure 26-9 Lichen planus. **A.** Irregular patches of alopecia with violaceous papules and coalescing plaque of lichen planus within scalp. **B.** Lichen planopilaris resulting in atrophic, scarred, porcelain-colored area centrally with bordering follicular involvement consisting of dusky erythema, perifollicular hyperkeratosis and scale, and follicular convergence resulting in doll's hair formation. **C.** Extensive hair loss leading to pseudopelade of Brocq appearance. Several remaining tufts of hair showing violaceous erythema and disease activity.

reaction centered over the acrosyringium and eccrine ducts entering the epidermis.

Lichen Planus Pigmentosus. This variant is characterized by hyperpigmented, dark-brown macules in sun-exposed areas and flexural folds. This entity tends to occur in patients with darker pigmented skin. Histologically, an atrophic epidermis, a vacuolar alteration of the basal cell layer with a scarce lymphohistiocytic lichenoid infiltrate, and pigment incontinence are seen. This variant bears significant similarity to ashy dermatosis or *erythema dyschromicum perstans*. It may represent an overlap in the phenotypic spectrum of lichenoid inflammation in darkly pigmented skin, with ethnic and genetic factors influencing the expression of disease (see Chapter 75).[23] In cases where the inflammatory phase was minimal, such as lichen planus "invisible de Gougerot," the pigmentation may be the only sign of the disease.

Actinic Lichen Planus. Also known as *lichen planus subtropicus*, *lichen planus tropicus*, *summertime actinic lichenoid eruption*, *lichen planus actinicus*, *lichen planus atrophicus annularis*, and *lichenoid melanodermatosis*. Actinic lichen planus affects young people of the Middle East in spring and summer, where sunlight appears to have a precipitating effect. Exposed areas of the face, dorsal hands and arms, and the nape of the neck are usually affected. Papules are hyperpigmented with violaceous-brown color and a thready, rolled edge showing well-defined borders. Annular lesions are common, but pigmented and linear forms were seen.[24,25] Typical lichen planus lesions may be present over the extremities. Pruritus and scaling are minimal.

Other Variants. A perforating variant has been described in which transepidermal elimination of lichen planus-like inflammatory tissue is observed. Guttate lichen planus is another variant that resembles guttate psoriasis but with the characteristic lichenoid histology. Exfoliative and exanthematous forms are very rare and may represent manifestations of lichenoid drug reactions (Fig. 26-10). The rare entity of invisible lichen planus describes lesions that are not perceptible with visible light illumination but become apparent with Wood's lamp examination. Pruritus is present and biopsy evaluation shows lichenoid histology. This entity may be a minimal variant of lichen planus "invisible de Gougerot."

SITE OF INVOLVEMENT

Lichen Planus of the Scalp. Lichen planopilaris (LPP) or follicular lichen planus may affect the scalp in a distinctive clinical and histologic pattern that affect women more than men.[26–30] LPP can be subdivided into three variants: (1) classic LPP, (2) frontal fibrosing alopecia, and (3) Lassueur–Graham–Little–Piccardi

Figure 26-10 Lichen planus-like eruption. Generalized violaceous papules with superficial scale coalescing to form erythematous variant. History of associated drug exposure leading to lichenoid reaction.

syndrome. In classic LPP, individual keratotic follicular papules that coalesce and merge over the scalp to form patches are typically seen. Perifollicular erythema and acuminate keratotic plugs are characteristic features. Follicular-centered lesions are usually observed under close inspection of the scalp and orifices, particularly at the margins of the alopecic area or within patches still bearing hair. Cutaneous, nail, or mucous membrane involvement with lichen planus may also be present. Patients present with uni- or multifocal hair loss that may be extensive and sometimes involve the entire scalp (see Fig. 26-9). The condition can have major psychological impact on affected individuals.

End-stage disease is characterized by a nondescript scarring alopecia that has led to the use of several clinical terms describing the entity: *lichen planopilaris*, *folliculitis decalvans et atrophicus*, *lichen spinulosus at folliculitis decalvans*, and Graham–Little syndrome.

Frontal fibrosing alopecia is an uncommon condition characterized by progressive frontotemporal recession due to inflammatory destruction of hair follicles. It is more common in postmenopausal women, but it can occur in younger women. It may be associated with mucocutaneous lichen planus. Recession of the hairline may progress inexorably over many years, but this is not inevitable.[22,31]

Pseudopelade of Brocq is a rare clinical syndrome of scarring alopecia and fibrosis, in which distinct pathologic features are absent. It is generally accepted that pseudopelade of Brocq is the end stage of follicular fibrosis caused by a primary inflammatory dermatosis such as lichen planus, lupus erythematosus, pustular-scarring forms of folliculitis, or fungal infections, including favus, scleroderma, and sarcoidosis.

Mucosal Lichen Planus. Lichen planus can affect the mucosal surfaces of mouth, vagina, esophagus, conjunctiva, urethra, anus, nose, and larynx. Its prevalence is estimated at approximately 1% of the adult population. Oral involvement occurs in approximately 60%–70% of patients with lichen planus. It may be the only manifestation in 20%–30% of patients.

In *oral lichen planus*, different types have been described, including reticular, plaque-like, atrophic, papular, erosive/ulcerative, and bullous forms (see Fig. 26-3).[32,33] The reticular pattern is considered the most common, but patients with erosive form are more likely to seek medical help due to the symptomatology (pain and burning sensation) and chronicity. Most patients have more than one type. The buccal, gingival, and glossal mucosae are the most commonly affected areas. The palate, floor of the mouth, retromolar pads, and lips may also be affected. Gingival involvement may take the form of gingival stomatitis or desquamative gingivitis, and could be the sole presentation in 8% of oral lichen planus. On the other hand, lichen planus is the most common cause for desquamative gingivitis.[34]

Oral lichenoid reaction is similar clinically and histologically to oral lichen planus, however, with identifiable etiology. Differentiating these two entities is often difficult. It is usually seen on the buccal mucosa adjacent to amalgam dental fillings.[35,36] Patch tests frequently show positive reactions to mercury, gold, and other metals.[37,38]

Bilateral reticular keratotic or atrophic changes of the buccal mucosa and lichenoid atrophic patches over the dorsal tongue have been described in patients with HIV infection. The eruptions usually follow zidovudine or ketoconazole intake.

Esophageal Lichen planus is rare and affects the proximal esophagus. It manifests as progressive dysphagia and odynophagia. Endoscopic findings can include lacy white papules, pinpoint erosions, desquamation, pseudomembranes, and stenosis. Histologically, it shows parakeratosis, epithelial atrophy, and lack of hypergranulosis. Squamous cell carcinoma of esophagus may develop after longstanding disease.[39,40]

Male genitalia are involved in 25% of cases, and the glans penis is most commonly affected, with annular lesions frequently present (see Fig. 26-4). *Anal lesions* of mucosal lichen planus present with leukokeratosis, hyperkeratosis, fissuring, and erosions (Fig. 26-11).

Vulvar and vaginal lichen planus is present in over half of patients with oral lichen planus.[41] Clinically, the condition is often asymptomatic unless erosions develop.

Figure 26-11 Lichen planus. Perianal leuko- and hyperkeratosis with hypertrophic, folded violaceous epithelium, fissures, and healing biopsy site.

Burning, itching, pain and abnormal discharge then become common.[42] Examination reveal patches of leukoplakia or erythroplakia, sometimes with erosions, and, occasionally, as a more generalized desquamative vaginitis. Vaginal adhesions and labial agglutination may result.

The *vulvo-vaginal gingival syndrome* is characterized by involvement of vulvar and gingival tissues. Erythema and erosions of the gingivae and tongue and, occasionally, white reticulated plaques, is associated with desquamation and erosions of vulva and vagina.[43]

Conjunctival lichen planus may manifest as cicatricial conjunctivitis. Histologically, irregular thickening with reduplication of the basement membrane is seen. Direct immunofluorescence distinguishes ophthalmic lichen planus from cicatricial pemphigoid.

Lichen Planus of the Nails. (See also Chapter 89.) Nail involvement occurs in 10%–15% of patients.[44] Lichen planus limited to the nails is uncommon, and the initial involvement is followed, in many cases, by the development of typical lesions elsewhere. Lichen planus of nails is infrequent in children. Thinning, longitudinal ridging, and distal splitting of the nail plate (onychoschizia) are the most common findings. Onycholysis, longitudinal striation (onychorrhexis), subungual hyperkeratosis, or even absence (anonychia) of the nail plate can also be seen. Twenty-nail dystrophy (trachyonychia) may represent an isolated nail finding of lichen planus. Psoriasis and alopecia areata can also lead to these distinctive nail changes. Nail loss may result from ulcerative lichen planus involving the nail unit. Pterygium or forward growth of the eponychium with adherence to the proximal nail plate is a classic finding of lichen planus of the nail (Fig. 26-12). An atrophic cicatrizing form of lichen planus with random and progressive nail loss in Asians and blacks has also been reported. The tenting or pup-tent sign is observed as a result of nail bed involvement that elevates the nail plate and may cause longitudinal splitting.[2]

Inverse Lichen Planus. The inverse pattern occurs only rarely and is characterized by red-brownish, discrete papules, and nodules. The eruption occurs mainly in the flexural areas such as axillae, inframammary, groin, and, less likely, the popliteal and antecubital areas. Koebnerized lesions are occasionally present.

Figure 26-12 Lichen planus. Classic pterygium formation and tenting of several fingers with loss of nail plates.

Palmoplantar Lichen Planus. This is a rare variant that is difficult to diagnose if present as an isolated finding. Very pruriginous, erythematous, scaly plaques with or without hyperkeratosis are characteristic. Lesions are often seen on the internal plantar arch. Yellowish, compact keratotic papules or papulonodules are seen on the lateral margins of the fingers and hand surfaces; however, they are less likely to affect the fingertips. They appear like callosities with an inflammatory, erythematous halo. The lesions resemble psoriasis vulgaris, warts, calluses, porokeratosis, hyperkeratotic eczema, tinea, or secondary syphilis.[45] Palmoplantar lichen planus may also present as erosive–ulcerative type (see Section "Erosive and Ulcerative Lichen Planus").

SPECIAL FORMS OF LICHEN PLANUS OR LICHENOID ERUPTIONS

Drug-Induced Lichen Planus. Lichen planus-like or lichenoid eruptions describe a group of cutaneous reactions identical or similar to lichen planus (see Fig. 26-10).[46] *Lichenoid drug eruptions* have been reported after ingestion, contact, or inhalation of certain chemicals (Table 26-1). They may be localized or generalized with eczematous papules and plaques and variable desquamation. They typically manifest postinflammatory hyperpigmentation and alopecia, and do not exhibit classic Wickham striae. The eruptions usually appear symmetrically on the trunk and extremities, unlike the flexural distribution of classic lichen planus. Mucous membrane involvement is less common and is often associated with specific drugs and chemicals. A *photodistributed pattern* is often found in sun exposed areas, and several drugs frequently induce this reaction (see Table 26-1).

The latency period for development of a lichenoid drug eruption by these agents varies from months to a year or more based on the dosage, host response, previous exposure, and concomitant drug administration. Resolution of the eruptions is quite variable, but most disappear in 3–4 months, except in gold-induced lichenoid eruption that may require up to 2 years after discontinuation. For many inciting drugs, the severity and extent of the eruption influences the rate of clearance. Occasionally, the lichenoid drug eruption disappears or may recur intermittently despite continuation of treatment.

Lichenoid contact dermatitis may result from contact with compounds such as color film developers, dental restoration materials, metals (e.g., mercury, silver, and gold), and aminoglycoside antibiotics.[46] *Oral lichenoid drug eruptions* are mostly related to dental restoration metals such as mercury, silver, and gold.

Lichen Planus–Lupus Erythematosus Overlap Syndrome. This is a rare variant characterized by lesions that share features of lichen planus and lupus erythematosus. Atrophic plaques and patches with hypopigmentation and a livid red to blue–violet color with telangiectasia and minimal scaling are characteristic. Transient bullae may develop. Classic lesions of lichen planus, photosensitivity,

TABLE 26-1
Agents Inducing Lichen Planus and Lichenoid Reactions

Common inducers
- Gold salts
- β blockers
- Antimalarials
- Diuretics; Thiazide, Furosemide, Spironolactone
- Penicillamine

Less common
- ACE inhibitors
- Calcium channel blockers
- Sulfonylurea
- Nonsteroidal anti-inflammatory drugs
- Ketoconazole
- Tetracycline
- Phenothiazine
- Sulfasalazine
- Carbamazepine
- Lithium
- Antituberculosis
- Iodides
- Radiocontrast media
- Radiotherapy
- Antipsoriatic therapy: Etanercept, Infliximab, Adalimumab
- Omalizumab

Inducers of lichen planus by contact
- Color film developers
- Dental restorative materials
- Musk ambrette
- Nickel
- Gold

Inducers of photodistributed lichenoid eruption
- 5-Fluorouracil (Efudex)
- Carbamazepine (Tegretol)
- Chlorpromazine (Compazine, Thorazine)
- Diazoxide (Proglycem)
- Ethambutol
- Pyritinol
- Quinine
- Quinidine (Quinaglute)
- Tetracycline
- Thiazide
- Furosemide (Lasix)

Inducers of oral lichen planus and lichenoid eruption
- Allopurinol (Zyloprim)
- ACE inhibitors
- Cyanamide
- Dental restorative materials, Mercury, Silver, Gold
- Gold salts
- Ketoconazole (Ketoconazole)
- Nonsteroidal anti-inflammatory drugs
- Penicillamines (Cuprimine)
- Sulphonylurea
- Interferon-α and Ribavirin

ACE = angiotensin-converting enzyme.

Figure 26-13 Lichen planus–lupus erythematosus overlap syndrome. Lichenoid lesions involving dorsal hand and forearm with direct immunofluorescence evidence of lupus erythematous.

pruritus, and follicular plugging are also not common. Lesions may develop anywhere, but are most common on the extremities (Fig. 26-13). Some patients with this overlap syndrome may progress to systemic lupus erythematosus. In other instances, laboratory evaluation may reveal only a weak-positive antinuclear antibody. This disease variant is characterized by a prolonged course and lack of response to treatment. Histologically, a lichenoid reaction typical for lichen planus and histologic features of lupus erythematosus are usually present in the same biopsy.[47] By direct immunofluorescence, cytoid bodies staining with IgG, IgM, and C3 intraepidermally or at the dermal–epidermal junction, as seen in classic lichen planus, are most common. Linear to granular deposition of IgM and C3 (as seen in lupus erythematosus, but not in lichen planus) and shaggy deposition of fibrinogen at the basement membrane zone, typical of lichen planus have been observed occasionally.[47]

Lichen Planus Pemphigoides. *Lichen Planus Pemphigoides* is characterized by the development of tense blisters atop lesions of lichen planus or the development of vesicles de novo on uninvolved skin or oral mucosa (Fig. 26-14). It is important to differentiate this entity from bullous lichen planus, in which blisters develop in lesions of long-standing lichen planus as a result of intense lichenoid inflammation and extensive liquefaction degeneration of basal keratinocytes. The etiology of this variant is not clear. It was proposed that basal cell keratinocyte damage by lymphocytes in lichen planus may unmask hidden antigenic

Figure 26-14 Lichen planus pemphigoides. Lichenoid maculopapular erythema, erosions, and bullae with direct immunofluorescence showing features of bullous pemphigoid. Indirect immunofluorescence also was positive.

determinants and lead to autoantibody formation and induction of bullous lesions. Captopril was described to induce this entity also.[48] Histologic findings resemble those of lichen planus. Direct immunofluorescence shows linear deposition of IgG and C3 at the dermal–epidermal junction.[49] Sera from these patients react with the epidermal side of NaCl-split human skin. Circulating IgG autoantibodies react to the major noncollagenous extracellular domain (NC16A) of the 180-kDa bullous pemphigoid antigen within the basement membrane zone. Further mapping showed that lichen planus pemphigoides serum reacts with amino acids 46–59 of domain NC16A, a protein segment that was previously shown to be unreactive with bullous pemphigoid sera. This newly described epitope is designated *MCW-4*.[50]

Lichenoid Reaction of Graft-Versus-Host Disease. (See Chapter 28.) Chronic graft-versus-host disease (GVHD) (occurring 100 days after transplant) may present as a lichenoid eruption indistinguishable clinically and histologically from lichen planus. Lichenoid GVHD favors the trunk, buttocks, hips, thighs, palms, and soles. In oral mucosa, xerostomia and oral ulcerations are occasionally seen. Histologically, the findings in lichen planus and oral GVHD are similar, although more infiltrating $CD3^+$ T lymphocytes are present in oral lichen planus than in GVHD.[52] Natural killer cells, Leu-8-positive T cells (homing receptor: CD62L, LECAM), CD25-positive lymphocytes, and the CD4:CD8 ratio were not different. Langerhans cells are often increased in both conditions.

Lichenoid Keratosis. Lichenoid keratoses are brown to red, scaling maculopapules found on sun-exposed skin of extremities. Histologic features of lichen planus are present, with the additional finding of focal parakeratosis. They frequently occur with solar lentigo, seborrheic keratosis, and actinic keratosis and likely represent an "involuting lichenoid plaque."[53]

RELATED FINDINGS

Lichen planus is seen with increased frequency in association with liver diseases such as autoimmune chronic active hepatitis, primary biliary cirrhosis, and postviral chronic active hepatitis.[55] The association with primary biliary cirrhosis is observed regardless of treatment with D-penicillamine, a drug that may cause an exacerbation of lichen planus.

Hepatitis C infection has been implicated in triggering lichen planus. The prevalence of HCV infection varied between 16% and 29% in southern European patients with lichen planus.[56,57] On the other hand, many studies from northern Europe and the United States did not substantiate any link.[58,59] Genetic factors controlling disease susceptibility and prevalence of certain HCV genotypes in certain geographic areas may have significantly influenced these results. No strong link between hepatitis B infection and lichen planus is shown.[60] Lichen sclerosus is seen in 16% of cases of erosive vaginal lichen planus.[41]

There is no evidence to link lichen planus to diabetes mellitus, autoimmune diseases, or internal malignancies. Cases of severe erosive gingivitis and stomatitis with histologic appearance of lichen planus in association with internal malignancies may represent cases of paraneoplastic autoimmune multiorgan syndrome (PAMS) or paraneoplastic pemphigus (see Chapter 55).

LICHEN PLANUS AND MALIGNANT TRANSFORMATION

There has been considerable controversy as to whether oral lichen planus inherently harbors malignant potential.[61,62] It is currently believed that the risk of malignant transformation is fairly low (Fig. 26-15). Risk factors that increase the likelihood of developing oral cancer are long-standing disease, erosive or atrophic types, tobacco use, and possibly esophageal involvement. It is generally accepted that about 2% of patients with oral lichen planus develop SCC.[32] The majority of these cases are in situ carcinoma or with microinvasive pattern. The most common site for cancer is the tongue, followed by buccal mucosa, gingiva, and, rarely, the lip. Clinically, the lesions appear as indurated, nonhealing ulcers, or exophytic lesions with a keratotic surface. Red atrophic plaques could also be seen and often correlate with SCC in situ. Advanced cases could result in nodal metastases and occasionally death.

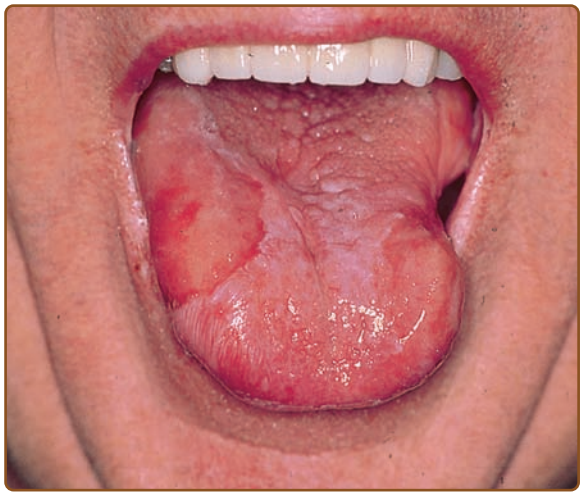

Figure 26-15 Lichen planus and squamous cell carcinoma. Long-standing oral lichen planus with scarring changes of tongue. Circumscribed erythroplakia and erosions of the right lateral tongue was biopsied and confirmed squamous cell carcinoma.

The risk of skin malignancy in cutaneous lichen planus is extremely low. Most patients developing SCC in cutaneous lichen planus had a history of either arsenic or X-ray exposure.

LABORATORY TESTS

No specific abnormalities of laboratory analyses are seen in lichen planus. The total white blood cell count and lymphocytes may be decreased. This could be related to cytokine activation and local trafficking of cells to skin or other tissue compartments.

Patch tests in patients with oral or cutaneous lichen planus usually reveal positive results in a majority of patients.[63] Sensitivity to mercury and gold is often positive in one-half of the cases. Chromate, flavoring agents, acrylate, and thimerosal are common sensitizers. Avoidance of these clinically relevant sensitizers results in amelioration of disease. Dyslipidemia is more common in patients with lichen planus than controls.[64]

PATHOLOGY

The two major pathologic findings in lichen planus are (1) basal epidermal keratinocyte damage and (2) lichenoid-interface lymphocytic reaction. The epidermal changes include hyperkeratosis, wedge-shaped areas of hypergranulosis, and elongation of rete ridges that resemble a sawtooth pattern (Fig. 26-16). Multiple apoptotic cells or colloid-hyaline (Civatte) bodies are seen at the dermal–epidermal junction. Eosinophilic colloid bodies are present in the papillary dermis. A band-like lymphocytic infiltrate is seen in the papillary dermis that abuts the epidermis. Plasma cells are more prominent in mucous membrane specimens. Few eosinophils are seen in drug-induced lichen planus or lichenoid drug eruptions. Melanin pigmentation is invariably present and is more pronounced in

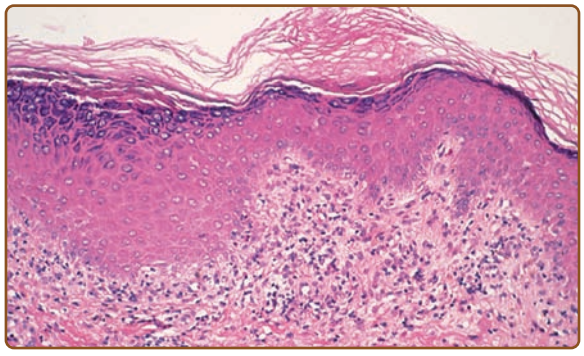

Figure 26-16 Lichen planus. Typical hyperkeratosis, hypergranulosis, early sawtooth changes, and lichenoid interface reaction of classic lichen planus.

older, waning lesions, in dark-skinned individuals and lichen planus pigmentosus. Separation of the epidermis in small clefts (Max Joseph cleft formation) is occasionally seen (Fig. 26-17).

Direct immunofluorescence shows numerous apoptotic cells at the dermal–epidermal junction (60%) staining with IgM and, occasionally, with IgG and IgA. Shaggy deposition of fibrinogen at the dermal–epidermal junction (55%) is characteristic of lichen planus (Fig. 26-18).[65] Immunocytochemical studies show that the majority of the cells in the infiltrate are T lymphocytes, with scattered B lymphocytes. An increased density of Langerhans cells, dermal dendritic cells, and histiocytes have also been seen, especially in early active lesions.

The presence of abundant plasma cells and eosinophils in the infiltrate, focal parakeratosis and hypogranulosis, and the presence of cytoid bodies high in the stratum corneum favor lichenoid tissue eruptions. Furthermore, lymphocytic infiltration is less dense. The differential diagnosis of lichen planus is shown in Boxes 26-1 and 26-2.

PROGNOSIS AND CLINICAL COURSE

Lichen planus is an unpredictable disease that typically persists for 1–2 years, but which may follow a chronic, relapsing course over many years.[66] The duration

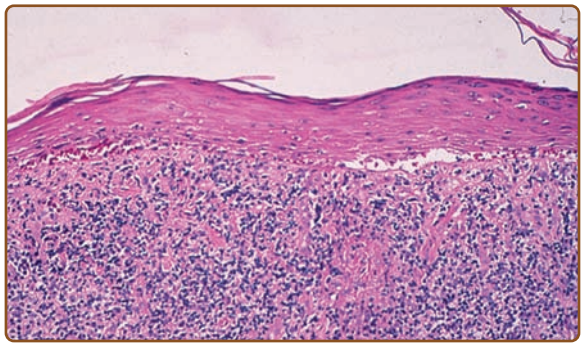

Figure 26-17 Lichen planus. More extensive epidermal alterations with hydropic changes, thinned epidermis, focal wedge-shaped hypergranulosis, compact orthokeratosis, and pronounced lichenoid inflammation with focal hemorrhage.

varies according to the extent and site of involvement and morphology of lesions. Generalized eruptions tend to have a rapid course and heal spontaneously faster than limited cutaneous disease. Lichen planopilaris is one of the most chronic and often progressive disease variants with little potential for hair regrowth after follicular inflammation and destruction. Hypertrophic lichen planus typically follows a protracted, unremitting course. Spontaneous regression is also an uncommon feature of oral lichen planus. The mean

BOX 26-1 DIFFERENTIAL DIAGNOSIS OF LICHEN PLANUS

Classic	Psoriasis
	Drug eruption

duration for oral lichen planus is 5 years. The reticular variant has a better prognosis than erosive disease that does not heal spontaneously. Generally, the duration of disease conforms to the following order, from shortest duration to longest duration: (1) generalized, (2) cutaneous, (3) cutaneous + mucous membrane, (4) mucous membrane, (5) hypertrophic, and (6) lichen planopilaris.

Relapse of disease occurs in 15%–20% of cases and tends to occur in the same area as the initial episode. Recurrences are more common in generalized lichen planus and are usually of shorter duration.

TREATMENT

Management of lichen planus can be challenging and discouraging for both the patient and physician. Lichen planus may be associated with only minor symptoms or may cause considerable discomfort and disability. Hence, treatment options should be assessed for attendant risks and benefits and tailored to the extent and severity of disease. Avoidance of exacerbating drugs, unless necessary, and minimizing trauma to skin and mucosal tissues are routinely recommended.

Various drugs have been proposed for the treatment of mucosal and cutaneous lichen planus and the majority of these consist of small series of patients or anecdotes.[67] Many of the advocated treatments lack conclusive evidence for efficacy.

MUCOSAL LICHEN PLANUS

(Box 26-3)

GENERAL MEASURES. For oral lichen planus, good oral hygiene and regular personal and professional dental care need to be encouraged. Replacement of amalgam or gold dental restorations with composite material is frequently of considerable benefit in patients with oral lichenoid reactions, even in the apparent absence of relevant patch test results. Chronic lesions on the buccal mucosa in contact with metal or other contact sensitizers frequently heal promptly after replacement. Occasionally, lesions at sites distant to oral lesions may also clear after removal of metal restorations. Gingival lesions may respond less favorably. The decision to undergo removal and restoration is often difficult and usually depends on the chronicity, severity, and clinical and patch-test evidence for involvement by the metal/prosthesis as well as the level of frustration of the patient.

Topical Steroids. Topical steroids are the first-line therapy in mucosal lichen planus.[67–69] Use of occlusive materials suitable for mucous membranes, such as Orabase, may provide protection, sustained tissue contact with the medication, and alleviate the discomfort associated with erosive lesions. Triamcinolone acetonide (0.1%), Fluocinonide gel, 0.1% fluocinolone acetonide, and 0.025% clobetasol propionate in Orabase showed good results.[70] Application four to six times a day is recommended. Treatment is often complicated by oral candidiasis. The use of chlorhexidine gluconate mouthwashes and topical anticandidal medications is recommended during therapy.[71]

Topical corticosteroids are sometimes compounded with anesthetics to provide symptomatic benefit for patients with difficulty eating and chewing, for

example, Intralesional Triamcinolone acetonide 10 mg/mL or at diluted concentrations, if effective and safe.[72]

Glucocorticoids containing vaginal and rectal suppositories are usually helpful for mucosal involvement in these areas. Topical ultrapotent corticosteroid is an effective treatment for erosive lichen planus of the vulva, giving relief of symptoms in 71%.[73]

Systemic Glucocorticoids. Systemic glucocorticoids provide effectiveness in erosive oral and vulvovaginal lichen planus to achieve rapid relief during periods of exacerbations.[74] Systemic dosing can be used alone, or, more commonly, in conjunction with topical glucocorticoids. Prednisone dose range from 30 to 80 mg/day, tapered over 3–6 weeks, and Betamethasone 5 mg on two consecutive days per week show benefit. Relapses are common after dose reduction or discontinuation. Higher doses are often needed for esophageal lichen planus in addition to intralesional steroid injection and mechanical dilatation.[75] Oral candidiasis is a common complication.

Retinoids. Topical retinoic acid (tretinoin gel) has been shown to be effective in erosive as well as plaque-like oral lesions, however, site irritation often makes it less attractive. Isotretinoin gel is also effective, especially in nonerosive oral lesions. However, recurrence is common after discontinuation of therapy.[76] Topical retinoids are often used in conjunction with topical glucocorticoids. Although not proven in clinical trials, this may improve the efficacy and lessen the side effects.

Etretinate orally has been used at 75 mg/day (0.6–1.0 mg/kg/day) in erosive oral lichen planus with significant improvement in the majority of patients. Relapses are common after discontinuation of medication.[77] Two-thirds of patients showed marked improvement or complete remission within 8 weeks of instituting acitretin, 30 mg/day.[78] The topical use of isotretinoin gel is effective also in oral disease.[79]

Tacrolimus and Pimecrolimus. Tacrolimus, effective in erosive mucosal disease, provides rapid relief from pain and burning with minimal side effects.[80,81] It is at least equally effective to clobetasol propionate 0.05% ointment and triamcinolone acetonide 0.1% paste in the treatment of oral lichen planus.[82–84]

Pimecrolimus 1% cream was shown to be as effective as triamcinolone acetonide 0.1% paste in treating oral lichen planus, and proved to be effective in treating vulvar disease.[85–87]

Cyclosporine. Topical application of cyclosporine, 100 mg/mL, 5 mL three times daily has shown benefit for oral lichen planus. Application modalities include mouthwashes and manual administration with local massage. Topical cyclosporine washes seem to be effective in oral lichen planus, especially the severe erosive forms,[88,89] but they do not appear to be better than local glucocorticoid therapy.[90] Lack of effectiveness in a few cases, high cost of this medication, and lack of proper commercial formulation for topical application limit its use. Oral cyclosporine at dose regimens of 3–10 mg/kg/day has been used for severe ulcerative disease and in cases with esophageal involvement.[91]

Miscellaneous. *Antifungal agents* (e.g., fluconazole, itraconazole) are useful in reducing candidal overgrowth associated with glucocorticoids use.

Hydroxychloroquine at 200–400 mg/day for at least 6 months is also used cautiously because antimalarials are implicated as possible inducers of lichen planus.[92]

Thalidomide should be reserved for cases recalcitrant to other remedies. The dose could be started at 50 mg/day and increased gradually to 200 mg/day.[93]

Dapsone can be used orally at 100–200 mg daily and has proved effective in two-thirds of patients with cutaneous and oral disease.

Extracorporeal photochemotherapy twice a week for 3 weeks and then tapered has had favorable results.[94,95] Alefacept at 15 mg every week for 12 weeks and Efalizumab (no longer on market) 0.7 mg/kg subcutaneously at week 0 followed by 1.0 mg/kg weekly from week 1 to week 11 exhibited therapeutic response in erosive lichen planus.[96–98] Frequent topical hyaluronic acid gel preparation (0.2%) appears to be of some benefit.[99] Aloe vera gel is also effective in improving the symptoms.[100] Topical rapamycin (1 mg/mL) twice a day for 3 months may be effective in some refractory erosive cases.[101]

Successful treatment of severe long-standing erosive vulvovaginal lichen planus using 10–15 mg of oral methotrexate once weekly in conjunction with topical clobetasol dipropionate 0.05% ointment and tacrolimus 0.03%–0.10% ointment within 4–8 weeks.[102]

CUTANEOUS LICHEN PLANUS

(Box 26-4)

TOPICAL GLUCOCORTICOIDS. A large variety of topical and systemic therapies are available for the treatment of cutaneous lichen planus, and this range of options may be attributed to the chronicity, symptomatology, and variable responsiveness of the dermatosis. *Topical glucocorticoids* are typically used for limited cutaneous disease. Potent topical glucocorticoids with occlusion, are often needed.

Intralesional triamcinolone acetonide (5–10 mg/mL) is effective in treating oral and cutaneous lichen planus. This may also be used in lichen planus of the nails with injection of the proximal nail fold every 4 weeks. Regression of lesions occurs within 3–4 months. For hypertrophic lichen planus, higher concentrations of intralesional glucocorticoid (10–20 mg/mL) may be required. Regular and close observation should be performed to monitor for any signs of atrophy or localized hypopigmentation that should prompt cessation of therapy. Intralesional injection is of special value in lichen planopilaris.[27]

Systemic glucocorticoids are often useful and effective in doses greater than 20 mg/day (e.g., 30–80 mg prednisone) for 4–6 weeks with subsequent taper over 4–6 weeks. Symptoms are often alleviated, and patients in the early stages of evolution or experiencing a flare have marked benefit and attenuation or aborted progression of disease. In lichen planopilaris, potent topical glucocorticoids in conjunction with oral glucocorticoids,

BOX 26-4 TREATMENT FOR CUTANEOUS LICHEN PLANUS

	TOPICAL		PHYSICAL	SYSTEMIC	
First line	▪ Topical steroids ▪ Intralesional steroids ▪ Tacrolimus ▪ Pimecrolimus	1–2 per day 5–20 mg/mL Variable Variable	▪ Psoralen and ultraviolet A light Broad band UVB Narrow band UVB	▪ Systemic steroids ▪ Etretinate ▪ Acitretin ▪ Isotretinoin	30–80 mg/day 10–75 mg/day 25–50 mg/day 20–40 mg/day

30–40 mg/day, for at least 3 months, seems to be successful. Relapse typically occurs following discontinuation. Long-term, chronic continuation of oral or injected glucocorticoids is contraindicated in most cases because of the high risk of complications.

RETINOIDS. The systemic retinoids demonstrate anti-inflammatory activity and have been used in the treatment of lichen planus. Remission and marked improvement was achieved with 30 mg/day of acitretin for 8 weeks.[78] Oral tretinoin is used at 10–30 mg/day with marked improvement and mild side effects.[103] Low-dose etretinate (10–20 mg/day) use has been associated with complete remission of cutaneous, oral, and nail lichen planus after 4–6 months of treatment. Prompt beneficial response was noted with the use of 75 mg/day of etretinate,[104] but side effects of retinoids are dose related and may limit use of higher dose therapeutic regimens.

PHOTOCHEMOTHERAPY. Psoralen and ultraviolet A (PUVA) light photochemotherapy is usually successful in generalized cutaneous lichen planus.[105] It has been used in conjunction with oral glucocorticoids to hasten the response. Trioxsalen, 50 mg added to 150 L of water, then exposing the patients to UVA after 10 minutes of bathing gave good results.[106] UVA-1 phototherapy may also benefit more protracted lichen planus. UVB, both broad and narrow band, are safe and efficient treatment options for generalized disease.[107–109]

IMMUNOSUPPRESIVE AGENTS. *Systemic cyclosporine* has been used successfully in recalcitrant lichen planus.[110] The administered dose can range from 3 to 10 mg/kg/day. Pruritus usually disappears after 1–2 weeks. Clearance of the rash is seen in 4–6 weeks. Low doses (1.0–2.5 mg/kg/day) are probably sufficient to achieve remission. Adverse effects as well as relapse after discontinuation of the drug, limit its use to severe cases.[111]

Azathioprine is useful in recalcitrant, generalized cutaneous lichen planus and in lichen planus pemphigoides.[112] *Methotrexate* is of value in generalized and erosive vulvar lichen planus.[113] *Mycophenolate mofetil* was effective at reducing the signs and symptoms of active lichen planopilaris in 83% of patients who had failed multiple prior treatments after at least 6 months of treatment.[114] Similar results are seen with mycophenolate mofetil at a dose of 1500 mg twice daily.[115] Cyclophosphamide should be reserved for refractory cases due to its toxicity.

MISCELLANEOUS. *Hydroxychloroquine* is effective in decreasing symptoms and signs in Lichen planopilaris and its variant frontal fibrosing alopecia in 69% and 83% of patients after 6 and 12 months of treatment, respectively.[116] It is also the main treatment in actinic lichen planus at 200–400 mg/day in addition to sun protection.[24]

Thalidomide can be used in lichen planus unresponsive to other therapies.[117,118] Oral *metronidazole* 500 mg twice daily for 1–2 months also reportedly clears the majority of cases of generalized lichen planus.[119]

Based on the benefit in bullous pemphigoid, combination therapy with *tetracycline* or *doxycycline* and *nicotinamide* has been reported as useful in the treatment of

lichen planus pemphigoides.[120] Tetracycline should be considered in lichen planopilaris.[27]

A case of generalized Lichen planus with oral involvement was treated with adalimumab, a tumor necrosis factor (TNF) antagonist with good results[121] and Alefacept.[122]

Low-molecular-weight heparin in low doses has lymphoid antiproliferative and immunomodulatory properties.[123,124] At a dose of 3 mg weekly, heparin injections have been reported to significantly improve the symptoms of pruritus and activity of the disease. Four to six injections of heparin induced complete regression of lesions within 4–10 weeks. Cutaneous involvement and reticulated oral lesions had the best response. Oral erosive lichen planus showed minimal improvement with this regimen.

Skin grafting has been beneficial in the management of ulcerative lichen planus of the feet that is recalcitrant to other treatments.

Chapter 27 :: Lichen Nitidus

:: Mazen S. Daoud & Mark R. Pittelkow

LICHEN NITIDUS AT A GLANCE

- Small, glistening, flesh-colored to pink or reddish-brown papules of unknown etiology.
- Distinctive, circumscribed infiltrate of lymphocytes and histiocytes in papillary dermis situated directly beneath thinned epidermis.
- There is no associated systemic disease.
- Prognosis is good.

Lichen nitidus (Latin nitidus, "shiny" or "glistening") is an uncommon, usually asymptomatic cutaneous eruption first described by Felix Pinkus in 1901 and further characterized by him in 1907.[1,2] Lichen nitidus consists of small, glistening, flesh-colored to pink or reddish-brown papules that may be limited to the penis, genitalia, abdomen, and extremities or, less frequently, may occur as a generalized condition. The histopathologic findings are characteristic. Although the condition is often chronic, the prognosis is good, and no clearly associated systemic illnesses have been documented.

EPIDEMIOLOGY

Epidemiologic characteristics of lichen nitidus have not yet been defined completely. Lichen nitidus occurs infrequently and has been reported to affect blacks more than Caucasians; children and young adults more than the elderly; and males more than females. The incidence is estimated to be approximately 3.4 cases/10,000 population, based on a 25-year survey of skin diseases in African-Americans.[3] The crude ratio of lichen nitidus to lichen planus is 1.7:100, based on pathologic diagnosis of cases evaluated over several decades at the Mayo Clinic.

ETIOLOGY AND PATHOGENESIS

Once considered a tuberculoid reaction, lichen nitidus is currently regarded as a disorder of unknown etiology. The relationship between lichen nitidus and lichen planus has been debated for many years.[4] The coexistence of both diseases in some patients, development of lichen planus following generalized lichen nitidus,[5] and the clinical similarities to small lichen planus papules were used to support the view that lichen nitidus is a variant of lichen planus. However, most experienced clinicians, as well as research studies, favor the separation of these two diseases as distinct entities based on both clinical and immunodermatopathologic differences and the characteristic and distinctive histologic changes. Table 27-1 summarizes some of these differences and similarities. Another etiologic theory of lichen nitidus proposes that an allergen may cause epidermal and dermal antigen-presenting cells (e.g., Langerhans cells) to activate a cell-mediated response, initiate lymphocyte accumulation, and form discrete inflammatory papules. The presence of large numbers of Langerhans cells in the infiltrate supports this theory.[6] Specific cytokines produced by the inflammatory cells influence the immune response and may shift the T lymphocyte response toward the T helper 2 subset that has the potential to produce the superficial dermal granulomas seen in lichen nitidus.[7] Functional impairment in cellular immunity has been reported in generalized lichen nitidus,[8] and lichenoid photoeruptions similar to lichen nitidus were seen in a patient with HIV infection.[9] Rare cases of lichen nitidus associated with atopic dermatitis, Crohn's disease, and juvenile chronic arthritis have been reported. Induction of allergic contact dermatitis by topical application of dinitrochlorobenzene in a patient with lichen nitidus cleared the eruption, presumably by altering the cellular immunity, cellular infiltration, and cytokine expression.[7]

A rare familial presentation of lichen nitidus has been reported, although no genetic factors of the disease have been identified.[10]

CLINICAL FINDINGS

Lichen nitidus is composed of multiple, discrete, smooth, and flat, round papules. Individual papules are 1–2 mm in size, flesh-colored to slightly pink or, in blacks, hypopigmented, with a glistening appearance (Fig. 27-1). Sometimes, minimal scale is present or can be elicited by rubbing the surface of the papules. Occasionally, the papules are grouped and the isomorphic or Koebner phenomenon is observed. Lesions may occur anywhere over the skin surface; however, the most frequent sites of predilection are the flexural surfaces of the arms and the wrists, lower abdomen, breasts, the glans and shaft of the penis, and other areas of the genital region. Infrequently lichen nitidus is a generalized eruption.

Rare sites of involvement include mucous membranes, nails, palms, and soles. Rare clinical variants include vesicular, hemorrhagic and purpuric, spinous follicular, linear, generalized, and lichen nitidus actinicus types.[11–16] (See Table 27-2.)

TABLE 27-1
Comparison of Features Between Lichen Nitidus and Lichen Planus

	Lichen Nitidus	Lichen Planus
Incidence	Rare	Common
Lesion		
Size	Usually 1–2 mm	Variable, usually larger
Shape	Round	Polygonal
Color	Flesh, pink, red–brown	Erythematous to violaceous
Wickham striae	Absent	Present
Mucosal changes	Rare	Variably present
Pruritus	Uncommon	Usually present, marked
Histopathology		
Hyperkeratosis	Variable and focal	Usually present
Parakeratosis	Mostly present	Not found
Infiltrate	Focal in one to three papillary bodies	Band-like, extends through many rete ridges
Lymphocytes	Variable	Vast majority of cells
Histiocytes	Variable, almost always present	Almost none
Giant cells	Occasional	None
Dyskeratotic	Occasional	Very common
Immunopathology		
Cytoids	Usually negative	Immunoglobulin M and other conjugates
Basement membrane	Usually negative	Fibrinogen, other conjugates
Immunohistochemistry		
$CD4^+$ lymphocytes	Majority of cells	Majority of cells
$CD68^+$ cells	Common	Uncommon

Figure 27-1 Lichen nitidus. **A.** Pinpoint to pinhead, discrete, dome-shaped papules over upper back, shoulder, and arm. Side-lighting, as performed here, enhances visualization of multiple small lesions. **B.** Individual papules, flesh- to pink-colored over chest and arm, becoming more grouped over anterior axilla.

Actinic lichen nitidus appears in patients with dark skin in areas with significant sun exposure such as face and arms. It can recur with repetitive exposure to the sun and show seasonal pattern.[17] It has been reported in the literature under summertime lichenoid actinic eruptions.[18] Palmoplantar involvement may manifest several morphologic forms that range from pinpoint papules to keratoderma.[19] Bilateral hyperkeratosis of palms and soles with erythema, fissuring, and a texture resembling fine sandpaper has been observed.[14,19] Occasionally, minute keratotic spicules on the palmar surfaces or multiple pinpoint papules that extend to the dorsa of the extremities occur (Fig. 27-2). Nail abnormalities usually manifest as longitudinal, beaded ridging, and terminal splitting with or without irregular pitting.[20] Lichen nitidus is usually asymptomatic; however, pruritus is occasionally present and sometimes intense. There are no constitutional symptoms or systemic abnormalities associated with the disease.

PATHOLOGY

A dense mass of infiltrating lymphohistiocytic cells is situated immediately below the epidermis and results in widening of the papillary dermis with elongation and the appearance of embracement by neighboring rete ridges (Fig. 27-3). The overlying epidermis is thinned and occasionally demonstrates central parakeratosis without hypergranulosis. This is a characteristic diagnostic finding, when observed (see Fig. 27-3B). Minimal hydropic degeneration with few dyskeratotic cells is usually observed. Occasionally, the epidermis may partially detach from the dermis. Colloid bodies are rarely seen. The dermal infiltrate is well circumscribed and composed of closely associated histiocytes, few lymphocytes, and occasional foreign body or Touton-type giant cells. Usually, no plasma cells or eosinophils are seen. Palmar lesions may show a deep parakeratotic plug. Transepithelial elimination of the inflammatory infiltrate has been described (perforating lichen nitidus).[21] Purpuric or hemorrhagic lesions are associated with capillary wall degeneration and red blood cell extravasation.[12]

The majority of the cells in the infiltrate are T lymphocytes ($CD4^+$ cells predominate over $CD8^+$)

TABLE 27-2
Rare Forms of Lichen Nitidus

Site of Involvement	Clinical Variant
Generalized	Actinic
Palmar	Vesicular
Plantar	Hemorrhagic
Linear	Spinous follicular
Nail involvement	Perforating
	Purpuric

Figure 27-2 Lichen nitidus. Wrist and palmar involvement with development of hyperkeratotic lesions.

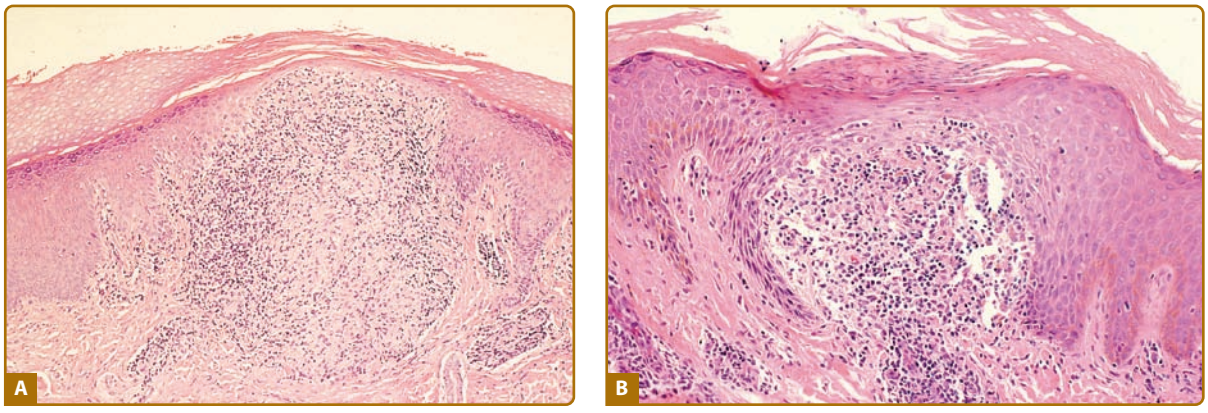

Figure 27-3 Lichen nitidus. **A.** Distinctive, circumscribed infiltrate of papillary dermis situated directly beneath thinned epidermis. Many histiocytes mingle with lymphocytes that are enveloped by bordering rete ridges. (Hematoxylin and eosin × 40.) **B.** Central parakeratosis, epidermal thinning, and loss of granular layer with focus of granuloma-appearing, inflammatory cells and reactive, finger-like extensions of epidermis. (Hematoxylin and eosin × 80.)

intermixed with few to many histiocyte–macrophages (CD68 positive), as well as epidermal Langerhans cells and indeterminate cells (S100 protein positive). Direct immunofluorescence examination of lichen nitidus is usually negative.[22]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of lichen nitidus is summarized in Box 27-1.

PROGNOSIS AND CLINICAL COURSE

Lichen nitidus is typically a focal, asymptomatic, chronic inflammatory reaction that eventually resolves spontaneously after months to 1 year in two-thirds of patients or, less frequently, over a few years. Rarely, the eruption may persist indefinitely. New lesions may continue to develop as older lesions resolve. Lesions heal without scar formation or pigmentary abnormalities.

TREATMENT

Because the disease is asymptomatic and self-limiting, no intervention is required in most cases. Treatment of lichen nitidus is warranted when it is associated with protracted pruritus, become generalized or for cosmetic reasons.[23] Topical glucocorticoids may yield favorable results. A short course of oral glucocorticoids may also be helpful and hasten resolution of more extensive, generalized, or symptomatic disease.[24] Psoralen and ultraviolet A light (UVA),[25] UVA and UVB phototherapy,[24] astemizole,[26] acitretin or etretinate,[20,27] low-dose cyclosporine,[28] and oral itraconazole[29] have also been used successfully when indicated for more problematic disease. Oral retinoids and local PUVA are effective treatments in palmoplantar type.[19]

Narrowband UVB could be a safe and effective treatment in generalized lichen nitidus.[30,31] Tacrolimus ointment was also reported to be effective after 1 month of therapy.[32] History of exposure to tuberculosis in the setting of lichen nitidus should be investigated and, when appropriate, treated with antituberculous medications.[33] Low-molecular-weight heparin was used safely and successfully at weekly dose of 3 mg subcutaneously.[34] Various treatment modalities are summarized in Table 27-3.

BOX 27-1 DIFFERENTIAL DIAGNOSIS OF LICHEN NITIDUS

Most Likely

- Lichen planus
  - CD8 lymphocytes predominate
  - No granulomatous inflammation
- Psoriasis
  - Plaques have silvery scale
- Verruca plana
  - Variable in size
  - Verrucous surface
  - Fewer lesions than lichen nitidus
  - Less likely to involve multiple anatomic areas
- Keratosis pilaris
  - More keratotic and scaling
  - Hand dermatitis
  - Palmoplantar involvement of lichen nitidus

Consider

- Lichen spinulosus
- Papular eczema
- Lichen scrofulosorum
- Lichenoid syphilitic lesions
- Bowenoid papulosis
- Sarcoidosis
- Lichen amyloidosus

TABLE 27-3
Treatment of Lichen Nitidus

	Topical	Physical	Systemic
First line	Topical steroids Sun protection for actinic type Topical tacrolimus	Narrowband UVB Local PUVA UVA and UVB phototherapy	Antihistamines
Second line		Psoralen plus UVA	Oral steroids Oral retinoids Cyclosporine 4 mg/kg/day Itraconazole Antituberculous agents Astemizole Enoxaparin Sodium 3 mg SC weekly

Chapter 28 :: Graft-Versus-Host Disease

:: Edward W. Cowen

GRAFT-VERSUS-HOST DISEASE AT A GLANCE

- Acute graft-versus-host disease (GVHD) is a serious and potentially life-threatening sequelae of allogeneic hematopoietic stem cell transplantation. Skin manifestations range from a mild, asymptomatic exanthem-like eruption to full-thickness skin loss resembling toxic epidermal necrolysis. Hepatic involvement is characterized by elevated total bilirubin. Gastrointestinal disease manifests as abdominal pain, nausea/vomiting, and secretory diarrhea.
- The most important risk factor for chronic GVHD is a history of acute GVHD. Traditionally, acute features present prior to day 100 posttransplantation, and chronic manifestations after 100 days; however, overlap between "classic" acute and chronic features may occur.
- Chronic GVHD of the skin is remarkably variable in clinical presentation. Epidermal involvement may resemble lichen planus, keratosis pilaris, or psoriasis. Sclerotic changes may resemble lichen sclerosus, morphea, systemic sclerosis, or eosinophilic fasciitis.
- The pathogenesis of chronic GVHD is poorly understood and nearly every organ system is at risk. The skin, oral mucosa eyes, gastrointestinal tract, and lungs are most frequently involved. In many cases, organ system disease resembles known autoimmune conditions.
- Optimal dermatologic management of chronic GVHD of the skin requires an understanding of other organ involvement, infection status, and cancer relapse risk. Close communication with the transplant physician and a "team approach" to multispecialty management is needed.

EPIDEMIOLOGY

Approximately 50,000 hematopoietic stem cell transplantation (HCT) procedures are performed worldwide each year for an expanding array of hematologic malignancies and marrow failure syndromes, metabolic disorders, and immunodeficiencies. HCT may utilize autologous, syngeneic, or allogeneic donor hematopoietic stem cell (HC). During autologous transplantation the patient's own HC are returned to the patient following preparative chemotherapy. Syngeneic transplantation is the transfer of HC between identical twins. Allogeneic HCT (allo-HCT) is the transfer of HC from a related (nonidentical) or unrelated donor to a recipient. Graft-versus-host disease (GVHD) is the primary cause of nonrelapse-related morbidity and mortality in allo-HCT and also rarely occurs following transplantation of solid organs or transfusion of blood products.

Transplantation regimens have advanced rapidly since the first successful allo-HCT was performed in 1968.[1] Peripheral blood, rather than bone marrow, is now the primary source of donor HC at many transplant centers, and reduced intensity (nonmyeloablative) conditioning has permitted older patients and others who would not tolerate myeloablative chemotherapy a chance for cure with HCT. More recently, umbilical cord blood has gained prominence as a stem cell source in both pediatric and adult HCT. Donor leukocyte infusions (DLI), the administration of additional donor HC to the recipient weeks or even months after HCT, are also frequently utilized to augment graft-versus-malignancy effect.

These evolving trends in HCT, in conjunction with other known donor/recipient risk variables (Box 28-1), contribute to a wide range of reported GVHD incidence. Nevertheless, the degree of HLA-mismatch between donor and recipient remains the single most important predictor of GVHD.[2] Acute GVHD develops in approximately 40% of fully matched sibling donor HCT, whereas 80% of mismatched unrelated HCT result in acute GVHD.[3,4] Risk estimates of chronic GVHD also vary widely and confounding factors such as improving early posttransplant survival may be influencing the apparent trend in increasing chronic GVHD incidence.[5] The most significant additional risk factor for chronic GVHD is a history of antecedent acute GVHD.[5]

Skin involvement is often the first indicator of acute GVHD (81%), followed by gastrointestinal (54%) and liver disease (50%).[6] Similarly, the majority of patients who develop chronic GVHD manifest skin symptoms at some point in their disease course. The risk of chronic skin involvement is increased by the use of peripheral blood HCT (PB-HCT) compared with bone marrow HCT (BM-HCT). At one center, approximately 90% of patients who developed chronic GVHD following PB-HCT manifested skin symptoms.[7] In most published reports, the incidence of sclerotic versus nonsclerotic chronic skin manifestations has not been differentiated. Although sclerotic involvement is less common than "lichenoid" GVHD and tends to occur later post-HCT, sclerotic features, particularly deep-seated fascial changes, may have an insidious onset, and "lichenoid" involvement is not a prerequisite to the development of sclerotic features. In one series of 196 patients post-HCT, only 7 (3.6%) developed sclerotic manifestations (mean 2.0 years after HCT).[8] In a review of 133 patients who survived at least 4 months after allo-HCT, the 5-year cumulative incidence of sclerotic GVHD was 10.5% (15.5% among patients with chronic GVHD). In this series, only 21% manifested "lichenoid" changes prior to the onset of skin sclerosis.[9] In a referral setting for patients with primarily refractory disease at the NIH, 81/110 (74%) consecutive patients had skin involvement, 58/110 (53%) of whom had sclerotic manifestations.[10]

BOX 28-1 MAJOR RISK FACTORS FOR THE DEVELOPMENT OF GRAFT-VERSUS-HOST DISEASE

HLA-incompatibility
Patient age (elderly > adult > pediatric)
Female donor (especially multiparous)/male recipient
Stem cell source (peripheral blood > bone marrow > cord blood)
T-cell replete graft
Unrelated donor
Donor leukocyte infusion
Interruption or rapid tapering of immunosuppression

ETIOLOGY AND PATHOGENESIS

In 1966, Billingham proposed three basic requirements for GVHD: (1) immunocompetent transplanted cells, (2) host antigens recognizable by the transplanted cells and lacking in the donor, and (3) a host incapable of mounting an immune response to the transplanted cells.[11] The immunocompetent cells are now known to be T-cells, which target human leukocyte antigens (HLAs) expressed on host tissues. GVHD still develops in 40% of recipients of HLA-identical grafts, however. In this setting, GVHD is due to mismatch of key minor histocompatibility antigens (e.g., HY, HA-3).[12] Tissue damage from the recipient's underlying disease, infection, and pretransplant conditioning also plays a key role in induction of the inflammatory response through pro-inflammatory cytokine production and antigen-presenting cell (APC) activation.[13,14]

Following activation of host APCs, T-cell activation and differentiation drives the response in acute GVHD. This appears to be primarily a Th1-driven process with massive release of interferon-γ, interleukin-2 (IL2), and TNF-α.[14] Genetic polymorphisms in tumor necrosis factor (TNF)-α, interleukin-10, interferon-γ, and transforming growth factor (TGF)-β have been linked to increased risk and severity of GVHD.[15–17] Although many therapies for acute GVHD target IL-2 or its receptor (CD25), these approaches (calcineurin inhibitors, daclizumab) may have the unintended

consequence of adversely impacting the $CD4^+CD25^+$ regulatory T-cell population.[14,18] Decreased T-regulatory cells are associated with severity of acute GVHD and poor response to GVHD treatment.[19] The final effector phase of acute GVHD is characterized by cell damage via cytotoxic T-cells, natural killer cells, and soluble inflammatory mediators, including TNF-α, interferon γ, and interleukin-1.[14]

In comparison to acute GHVD, the pathophysiology of chronic GVHD is less well understood. Features of alloimmunity and autoimmunity and the broad spectrum of disease manifestations implicate multiple immunological pathways beyond T-cell alloreactivity. In fact, in contrast to acute GVHD, T-cell depletion of the graft does not necessarily reduce the incidence of chronic disease.[20] Murine models of GVHD have demonstrated both Th1 and Th2 responses, depending on the setting; however, these models typically demonstrate specific aspects of GVHD, but do not recapitulate the full breadth of immunological and clinical abnormalities seen in human disease.[21]

The role of B-cell function in chronic GVHD has garnered renewed interest following the success of the anti-CD20 antibody rituximab in chronic GVHD.[22] Autoantibody formation (e.g., antinuclear antibody, anti-ds DNA antibody) is a frequent finding in chronic GVHD, although the antibodies lack the specificity of typical autoimmune disease. B-cells may play several key roles in facilitating the T-cell response in chronic GVHD. Acting as APCs, B-cells prime T-cells to respond to minor histocompatibility antigens (mHA), and high-titers of antibodies directed against mHA are associated with cGVHD.[23,24] Similarly, soluble levels of B-cell activating factor of the TNF family (BAFF), a cytokine which inhibits apoptosis of B-cells and promotes differentiation into plasma cells, correlate with cGVHD activity. [25,26]

The mechanisms responsible for chronic GVHD-induced fibrosis in the skin and elsewhere (e.g., bronchiolitis obliterans) remains uncertain. A two-phase model has been proposed in which the innate pathway is activated through Toll-like receptors, leading to an alloreactive T-cell response. This is followed by a fibrotic phase driven by platelet-derived growth factor (PDGF) and PDGF receptor (PDGFR), which in turn activates TGF-β.[21] TGF-β is a potent profibrotic cytokine, capable of stimulating collagen production, abrogating metalloproteinase activity, and sensitizing fibroblasts to a constitutive-activated state via autocrine signaling.[27] Furthermore, stimulatory antibodies directed against PDGFR have been identified by one group in patients with chronic GVHD as well as patients with systemic sclerosis.[28,29] This has led to significant interest in imatinib mesylate, a multikinase inhibitor with potent activity against PDGFR signaling (and other receptors), for the treatment of GVHD-related fibrosis.[30,31] However, to date, detection of PDGFR antibodies in sclerotic skin disease has not been replicated by other groups,[32] and administration of imatinib prior to the onset of GVHD does not appear to eliminate the risk of developing skin sclerosis.[33] The mechanism of action of imatinib therefore, remains unclear, and other mechanisms, including T-cell inhibition[34] and inhibition of fibrosis via "nonclassic" pathways downstream of TGF-β, such as cellular Abelson (c-Abl) may be relevant.[27]

CLINICAL FINDINGS

HISTORY

Accurate diagnosis of acute GVHD requires clinicopathologic correlation. Because the skin eruption (and histology) may be nonspecific at the time of first presentation, a careful history is invaluable. Key donor/recipient characteristics include degree of HLA-match, use of related versus unrelated donor, and T-cell depletion of the graft. Reduced-intensity conditioning may delay the onset of acute GVHD symptoms beyond the 100-day period.[35] The timing of neutrophil engraftment, new medication exposures, and evidence of other organ involvement (e.g., elevated total bilirubin, diarrhea) provide additional data for clinicopathologic correlation.

Features of acute GVHD following recent blood transfusion should raise concern for transfusion-associated GVHD (TA-GVHD). TA-GVHD is an often fatal sequelae of administration of cellular blood products to immunocompromised HCT recipients, and therefore all blood products in these patients are now irradiated. TA-GVHD may also occur following transfusion of unirradiated blood products to children with congenital immunodeficiency, including Wiskott—Aldrich and ataxia-telangiectasia, as well as in the immunocompetent setting. In the latter scenario, the diagnosis may be easily missed. TA-GVHD in the immunocompetent setting follows transfusion of an unirradiated blood product that contains donor lymphocytes that are homozygous for the HLA haplotype of the recipient. A history of blood product transfusion from a relative or genetically similar population is an important feature. For example, in Japan, the estimated risk of randomly receiving blood from a homozygous donor is 1 in 874.[36] In this form of TA-GVHD, the donor lymphocytes in the blood product are not recognized as foreign, leading to a GVHD reaction similar to classic acute GVHD. Beginning 10 days after transfusion, fever and skin rash (histologically consistent with GVHD) develops, followed by liver dysfunction and diarrhea. Death from pancytopenia usually occurs within several weeks.[37]

As with acute disease, a new diagnosis of chronic GVHD is best made based on history, cutaneous examination, and histology. A previous history of acute GVHD is the single greatest risk factor for chronic disease. Because acute symptoms may develop after 100 days posttransplant and chronic symptoms may develop before then, the revised classification of acute and chronic GVHD symptoms includes additional subtypes of GVHD with overlapping features or timing of acute and chronic symptoms (Fig. 28-1).[38] Recent tapering of immunosuppressant medication or DLI given to augment the graft-versus-malignancy response are two common triggers of skin activity. DLI, in particular may present with an acute GVHD skin eruption consistent

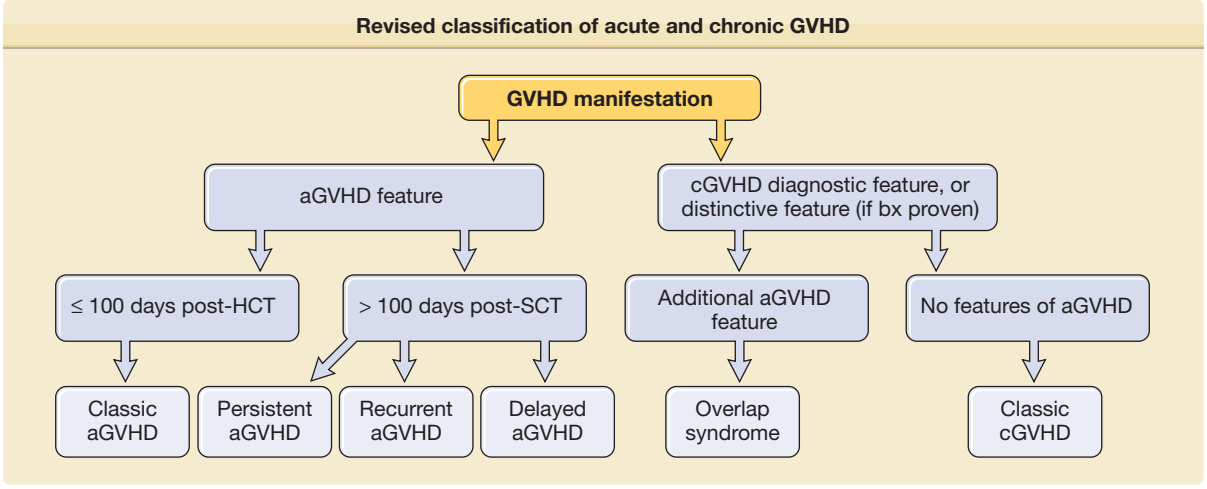

Figure 28-1 Revised classification of acute and chronic GVHD. (Adapted from Filipovich AH et al: National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report. *Biol Blood Marrow Transplant* **11**(12):945-956, 2005.)

with acute GVHD rather than the papulosquamous eruption of chronic disease (Fig. 28-2D). Cutaneous or systemic infection may also induce a flare of skin GVHD, as will drug exanthems, which can result in a diagnostic challenge given the clinical and histologic similarities between viral exanthem, drug eruption, and GVHD.[39] Important clues to sclerotic and fascial disease includes a history of edema of an extremity, muscle cramping, decreased flexibility, and complaints of skin tightness, particularly at the waistband and brassiere-line.[10] Although GVHD in other organ systems may not necessarily flare in synchrony with skin involvement, the presence of other organ system involvement is helpful when the cutaneous features are nondiagnostic. Common GVHD symptoms include oral and ocular sicca and oral pain, particularly with spicy foods. Also common, but less specific, are symptoms of fatigue, poor appetite, and weakness. Dysphagia may indicate the presence of esophageal strictures or webbing. Bronchiolitis obliterans manifests as dry cough, wheezing, and dyspnea, but requires pulmonary function tests and computerized tomography (CT) scans to rule out infection and other etiologies. Finally, it is important to remember that despite the phenotypic variability in chronic GVHD of the skin, not every skin manifestation in a patient after HCT is due to GVHD, so a careful dermatologic history to detect other possible diagnoses is prudent.

CUTANEOUS LESIONS

Acute GVHD initially presents with erythematous-dusky macules and papules of the volar and plantar surfaces and ears that may rapidly become a diffuse morbilliform exanthema (Fig. 28-2A and 28-2B; Box 28-2). Very early involvement may manifest as erythema limited to hair follicles (Fig. 28-2C). Pruritus is variable and is not useful to distinguish acute GVHD from other causes. Erythroderma may develop, and, in severe cases, spontaneous bullae with skin sloughing resembling toxic epidermal necrolysis. Widespread erythrodermic involvement, particularly the presence of skin sloughing portends a very poor prognosis. In contrast to chronic disease, postinflammatory pigmentary changes following acute GVHD are uncommon.

In appreciation of the tremendous variability in clinical presentation of chronic skin GVHD, it is no longer useful to dichotomize chronic GVHD of the skin into either "lichenoid" or "sclerodermoid" categories. In the transplant community, the term "lichenoid" has been utilized to denote any involvement of the skin in which erythema or scaling is present; however,

BOX 28-2 ACUTE GVHD ORGAN SYSTEM MANIFESTATIONS

SKIN
- Erythema of palms, soles, ears
- Perifollicular erythema
- Generalized exanthem
- Bullae/necrolysis

GASTROINTESTINAL
- Abdominal pain
- Anorexia
- Ileus
- Mucositis
- Vomiting
- Secretory diarrhea

LIVER
- Endothelialitis
- Pericholangitis
- Cholestatic hyperbilirubinemia

Figure 28-2 Spectrum of acute graft-versus-host skin manifestations. Acute cutaneous graft-versus-host reaction. Erythematous macules involving the ears (**A**), palms (**B**), and soles are characteristic of early cutaneous involvement. **C.** Follicular graft-versus-host disease. Perifollicular invovlement is an early manifestation of skin involvement. **D.** GVHD-associated necrolysis. Acute GVHD with bullae formation and skin sloughing following donor leukocyte for relapsed acute lymphoblastic leukemia 10 months following allogeneic HCT.

"lichenoid" is a histologic pattern, not a clinical one, and, therefore, usage of it is best reserved to pathologic description. Futhermore, although chronic GVHD may resemble lichen planus (Fig. 28-3), other patterns are frequently observed, such as poikiloderma (Fig. 28-4) and skin lesions resembling lupus erythematosus, keratosis pilaris, or psoriasis.[40] Postinflammatory hyperpigmentation is common following the resolution of epidermal involvement, particularly in darkly pigmented individuals, and may persist for many months after the skin disease becomes quiescent.

The fibrotic changes of chronic GVHD are also remarkably variable, and the term "sclerodermoid" is an inadequate descriptor of the varied sclerotic tissue abnormalities in the dermis, subcutaneous tissue, and fascia (Fig. 28-5). As in systemic sclerosis, an

Figure 28-3 Lichen planus-like chronic GVHD. Reticulate violaceous plaques with dry scale on the posterior neck and upper back.

Figure 28-4 Poikilodermic chronic GVHD. Hypopigmentation, hyperpigmentation, and erythema on the chest and proximal arms.

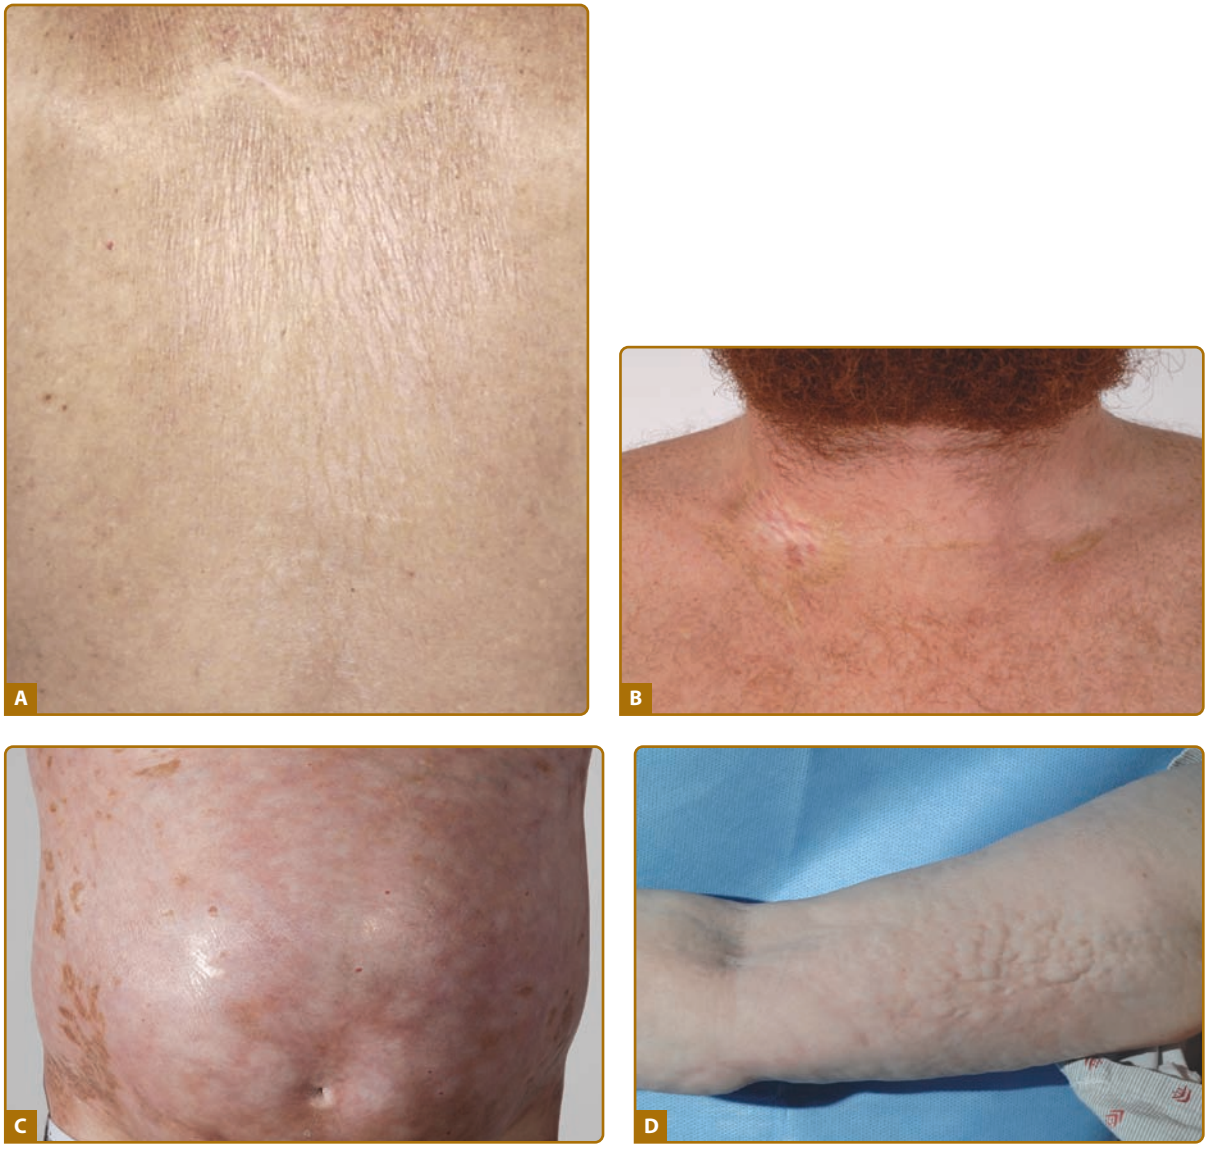

Figure 28-5 Clinical spectrum of sclerotic GVHD skin manifestations. **A.** Guttate white plaques on the upper back resembling lichen sclerosus. **B.** Morphea-like sclerotic plaques at sites of previous indwelling line placement near the clavicle (isotopic response). **C.** Diffuse dermal sclerosis resembling scleroderma on the anterior torso with patchy hyperpigmentation. **D.** Subcutaneous fibrosis of chronic GVHD. There is prominent rippling with a firm nodular texture extending along the medial arm resembling eosinophilic fasciitis. There is associated decreased range of motion at the elbow.

edematous phase may herald the onset of skin fibrosis, but fingers and toes are usually spared and the typical acral to proximal progression characteristic of systemic sclerosis is not seen in chronic GVHD. In constrast to systemic sclerosis, facial involvement is rarely involved in sclerotic-type GVHD. As mentioned above, fibrosis may occur primarily in the upper dermis, through the full-thickness of dermis, or in the subcutaneous fat and fascia. Early superficial fibrotic involvement resembles lichen sclerosus, often manifesting as porcelain-white atrophic plaques on the upper back (Fig. 28-5A). A common pattern of GVHD-associated fibrosis involves patchy sclerotic plaques with hypo- and hyperpigmentation mimicking morphea. Sclerosis of this type may exhibit an isomorphic response, localizing to the sites of minor skin trauma, particularly the waistband area, or may develop at sites of previous scar formation (Fig. 28-5B).[41] Diffuse dermal involvement may result in a "pipe-stem" appearance of the lower extremities with marked reduction in limb volume and overlying shiny hidebound skin with loss of hair resembling scleroderma (Fig. 28-5C). Deeper involvement of the subcutaneous fat results in irregular hyperpigmented sclerotic plaques with intervening areas of edematous skin closely resembling deep morphea/morphea profunda.[42] Bullae may develop at sites of fibrosis, particularly on the lower legs, as a result of dermal edema, as has been described in bullous morphea profunda.[43] Patchy hyperpigmentation ("leopard spots") may be visible prior to the diagnosis of dermal sclerotic involvement.[44]

Primary involvement of the subcutaneous fat and fascia results in a diffuse firm, rippled pattern to the skin resembling eosinophilic fasciitis (Fig. 28-5D).[45] Features of overlying epidermal GVHD involvement and pigmentary changes may be absent. Fascial involvement is often most visible on the medial arms and thighs and be accentuated by abduction and supination of the arm. Prominent "grooving" demarcating fascial bundles and along the path of superficial vessels may be observed. Careful palpation of the skin is helpful in detecting deep-seated irregularities in skin texture and differentiation from cellulite. Dermal fibriosis or fascial involvement without overlying dermal thickening may lead to progressive loss of joint range of motion and contracture formation.

Nail involvement in chronic GVHD typically results in longitudinal ridging and thin, easily broken nails. Partial or complete anonychia and dorsal pterygium formation may occur. Other unusual skin sequelae of chronic GVHD include milia formation, porokeratosis, often on the buttock area,[46] angioma formation at sites of skin sclerosis,[47] nipple hyperkeratosis,[48] vitiligo,[49] and alopecia, either diffuse or focal areas of alopecia areata.[50]

Different manifestations of sclerotic and and non-sclerotic skin disease may be present in the same individual, making accurate quantification of disease activity challenging. The chronic GVHD NIH Consensus Development Project provided more precise terminology for organ system involvement and defined features specific for diagnosis of chronic GVHD in the setting of HCT (Box 28-3). Diagnostic cutaneous features of GVHD include poikiloderma, lichen-planus-like lesions, and sclerotic skin changes.[38]

RELATED PHYSICAL FINDINGS

Acute GVHD is primarily a disorder of the skin, GI tract, and liver (Box 28-2), typically presenting with skin rash, new onset elevation of total bilirubin, and/or voluminous diarrhea. By contrast, chronic GVHD is remarkably diverse in its breadth of organ system manifestations (Box 28-3). The most frequently affected sites are skin and nails, oral mucosa, eyes, liver, lungs, and marrow (usually thrombocytopenia).[5] Esophageal webs/strictures, vagino-vulvar disease, myositis, nephrotic syndrome, and pericarditis are less frequent sequelae of chronic disease.

Mucosal disease is second only to skin involvement in frequency in chronic GVHD. Mucoceles are common, as are erosions, lichen-planus-like changes with Wickham's striae, and sicca symptoms. Dryness and violaceous erythema of the lips are common. Genital involvement significantly impairs sexual function and quality of life and may be overlooked if a specific examination and directed questions regarding genital symptoms are not undertaken. Involvement of the penis may induce phimosis. Vulvo-vaginal involvement presents as erythema, erosions/fissures, vestibulitis, vaginal stenosis, labial resorption, or complete agglutination of the introitus leading to hematocolpos (Fig. 28-6).[51]

Figure 28-6 Severe chronic GVHD of the vulva. The labia minora are partially resorbed with residual vulvitis and atrophic mucosa. Surrounding reticulate hyperpigmentation of the nonmucosal skin is consistent with postinflammatory changes of chronic GVHD.

BOX 28-3 SIGNS AND SYMPTOMS OF CHRONIC GVHD BASED ON NIH CONSENSUS CRITERIA

SKIN AND MUCOSAL INVOLVEMENT

Skin
- Alopecia
- Angiomatous papules
- Bullae
- **Erythema**
- Hypo- or hyperpigmentation
- Ichthyosis-like
- Keratosis-pilaris-like
- **Lichen planus-like[a]**
- Lichen sclerosus-like[a]
- Maculopapular
- **Morphea-like[a]**
- Poikiloderma[a]
- Scleroderma-like[a]
- Sweat impairment
- Ulceration

Nails
- Brittleness
- **Longitudinal ridging or splitting**
- Onycholysis
- Pterygium unguis

Subcutaneous tissue
- Fasciitis[a]
- Panniculitis

Oral mucosa
- Erythema
- Gingivitis
- Hyperkeratotic plaques[a]
- **Lichen planus-like[a]**
- **Mucocele**
- Mucosal atrophy
- Mucositis
- Pseudomembrane
- Restriction of oral opening from sclerosis[a]
- Ulcer
- Xerostomia

Genital mucosa
- Lichen planus-like[a]
- Vulvar erosions/fissures
- Vaginal scarring/stenosis[a]

OTHER ORGAN SYSTEM INVOLVEMENT

Cardiovascular
- Pericardial effusion
- Cardiac conduction abnormality
- Cardiomyopathy

Ophthalmologic
- Blepharitis
- Cicatricial conjunctivitis
- Confluent punctuate keratopathy
- **Keratoconjunctivitis sicca**
- Photophobia

Gastrointestinal
- Esophageal web[a]
- Esophageal stricture/stenosis[a]
- Exocrine pancreatic insufficiency

Hematopoeitic
- Eosinophilia
- Hypo-/hypergammaglobulinemia
- Lymphopenia
- **Thrombocytopenia**

Hepatic
- Elevated total bilirubin
- Elevated alkaline phosphatase
- **Elevated transaminases**

Musculoskeletal
- Arthralgia
- Arthritis
- Edema
- Myalgia
- Myositis/polymyositis

Neurologic
- Peripheral neuropathy

Pulmonary
- **Bronchiolitis obliterans +/– organizing pneumonia[a]**
- Pleural effusion

Renal
- Nephrotic syndrome

Rheumatologic
- Autoantibodies
- Myasthenia gravis

[a]Diagnostic features of cGVHD based on NIH Consensus Criteria. Other signs and symptoms listed are not considered sufficient to establish a diagnosis of chronic GVHD without further testing or evidence of other organ system involvement. The most common GVHD manifestations are shown in **bold.**

Adapted from Filipovich AH et al: National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report. *Biol Blood Marrow Transplant* **11**(12):945-956, 2005.

HISTOPATHOLOGY. The histological grading scale for acute GVHD is shown in Table 28-1. The hallmark feature of acute GVHD is the presence of necrotic keratinocytes accompanied by a dermal lymphocytic infiltrate (usually sparse) and basal vacuolar alteration (Fig. 28-7). Early GVHD involvement with follicular erythema correlates with involvement limited to the hair follicle. Subepidermal cleft formation (Grade III) is indicative of more severe involvement, whereas complete separation of epidermis

TABLE 28-1
Histologic Grading of Acute GVHD

Histologic Grading Scheme for Acute Cutaneous Graft-Versus-Host Reaction	
Grade	**Description**
0	Normal skin or changes not referable to graft-versus-host disease
1	Basal vacuolization of the dermalepidermal junction
2	Basal vacuolization, necrotic epidermal cells, lymphocytes in the dermis and/or epidermis
3	Subepidermal cleft formation plus grade 2 changes
4	Separation of epidermis from dermis plus grade 2 changes

Adapted from Lerner KG et al: Histopathology of graft-versus-host reaction (GVHR) in human recipients of marrow from HLA-matched sibling donors. *Transplantation* **18**:367, 1974.

from dermis (Grade IV) correlates with clinical findings resembling toxic epidermal necrolysis. Grade IV involvement may be impossible to differentiate histologically from drug-induced toxic epidermal necrolysis and requires careful clinical correlation. The presence of eosinophils has been used in the past to argue against a diagnosis of GVHD; however, the presence of scattered eosinophils may lead to a false diagnosis of drug eruption[52] and, unless very large numbers of eosinophils are present, this feature cannot be used as a reliable indicator of a drug hypersensitivity reaction.[53] Engraftment syndrome is a poorly understood phenomenon at the time of neutrophil engraftment following autologous-HCT or allo-HCT characterized by a nonspecific erythematous skin eruption, fever, and pulmonary edema.[54] Histologically, it may not be possible to distinguish engraftment rash from early (Grade I) acute GVHD.

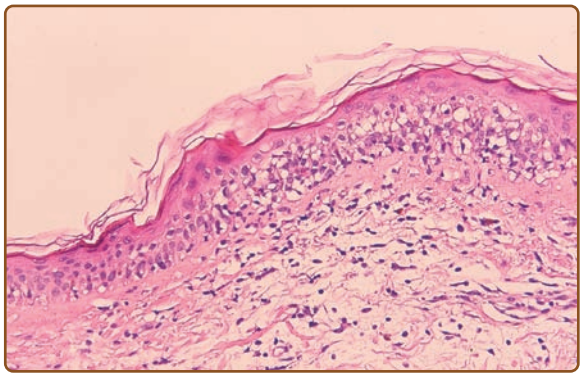

Figure 28-7 Histopathologic features of acute cutaneous graft-versus-host disease, Grade II. Inflammation of the upper dermis is present, with extension of lymphocytes into the dermis and interface change.

Epidermal changes in chronic GVHD may be indistinguishable from those of acute disease (Fig. 28-8A). Acanthosis and wedge-shaped hypergranulosis may be seen. Sclerotic involvement of the upper dermis may resemble lichen sclerosus, with atrophy, hyperkeratosis, follicular plugging, and pale, homogenized appearance of the upper dermis collagen (Fig. 28-8B).[45] If epidermal changes of GVHD are not present, dermal fibrosis with thickened collagen bundles and loss of periadnexal fat involvement may be indistinguishable from morphea/scleroderma. Subcutaneous and fascial involvement accordingly demonstrates changes in the fat septae and fascia, including thickening, edema, and fibrosis. Variable lymphocytes, histiocytes, and eosinophils may be seen.[45]

Histology of involvement of the oral mucosa reflects similar interface changes as those seen in epidermal GVHD, but without associated acanthosis.[55] Lymphocytic infiltration of the salivary glands resembles changes seen in Sjögren's syndrome.

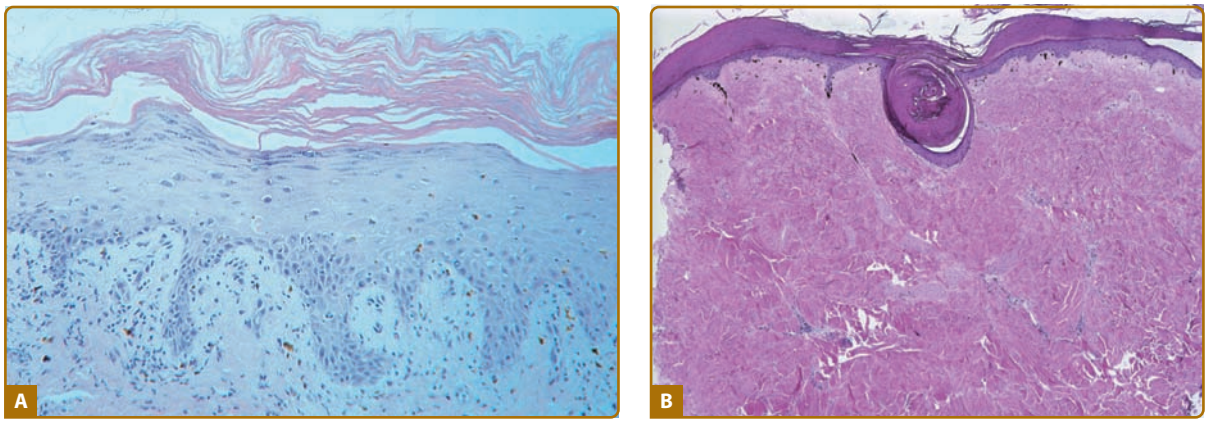

Figure 28-8 Histologic features of epidermal and sclerotic-type chronic cutaneous graft-versus-host disease. **A.** Histopathologic features of a lichen planus-like reaction. Acanthosis, hypergranulosis, hyperkeratosis, and pointed rete ridges are present. The inflammatory infiltrate is less dense than that usually seen in idiopathic lichen planus. **B.** Sclerotic-type GVHD. There is mild, compact hyperkeratosis or the epidermis with keratin plugging. There is hyalinization of the collagen throughout the dermis with loss of appendegeal structures.

LABORATORY TESTS

Diagnosis of acute GVHD skin involvement is based on histopathologic correlation, particularly exclusion of drugs and infectious causes. The presence of a normal leukocyte count is indicative of engraftment but no specific laboratory testing is diagnostic. Liver function testing and total bilirubin levels and quantification of diarrhea volume are used in conjunction with skin disease to stage the disease (Table 28-2).

Although autoimmune markers are seen in the majority of patients after alloHCT, their presence is generally not specific for the development of chronic GVHD manifestations, with the possible exception of sclerotic disease. In one study, elevated ANA titer was detected in 70% of patients with limited chronic disease and 94% of patients with extensive chronic disease compared to 23.5% of patients who did not develop chronic GVHD.[56] The presence of more than one autantibody also correlated with risk of extensive disease ($p = 0.04$); however, ANA titer does not correlate with disease severity. In this study, the presence of a nucleolar ANA pattern also indicated a potential association with sclerotic disease ($p = 0.06$).[56] In another multivariate analysis limited to sclerotic-type chronic GVHD patients, the presence of autoantibodies and serum eosinophilia were both associated with increased risk of sclerotic-type chronic GVHD.[9]

Identifying specific biomarkers of disease activity is an area of research emphasis in acute and chronic GVHD.[57] Plasma levels of elafin, a protease secreted in response to IL-1 and TNF-α, was recently identified as a candidate marker capable or differentiating acute GVHD skin from rashes of other etiologies. In this study, immunohistochemical staining of skin biopsies for elafin also discriminated acute GVHD from drug exanthem, suggesting a potential diagnostic application of this biomarker.[58]

SPECIAL TESTS (INCLUDING IMAGING STUDIES)

Suspicion of subcutaneous sclerotic and fascial disease and myositis may be confirmed by magnetic resonance imaging, particularly in cases in which definitive sclerotic changes are not observed or when a fascial or muscle biopsy is deferred.[45,59,60]

DIFFERENTIAL DIAGNOSIS

See Box 28-4.

COMPLICATIONS

Skin erosions and ulceration due to chronic GVHD may lead to secondary infection. Sclerotic changes resulting in restriction in joint function lead to functional disability and joint contractures. Restrictive lung disease may result from sclerotic involvement of the torso. HCT survivors are at increased risk for melanoma[61] and nonmelanoma[62] skin cancer due to previous exposure to ionizing radiation, GVHD-associated immunodysregulation, and immunosuppressive treatment for GVHD. The risk of cutanous squamous cell carcinoma (SCC) may also be increased by long-term treatment with voriconazole, a potent photosensitizer, which may be employed for antifungal treatment or prophylaxis.[63] Multiple SCC have also been reported after PUVA for GVHD.[64]

PROGNOSIS/CLINICAL COURSE

Although the presence of GVHD is associated with decreased risk of malignancy relapse, GVHD is also a cause of significant morbidity and mortality, particularly

TABLE 28-2
Staging and Grading of Acute GVHD Clinical and Laboratory Manifestations

Stage	Skin	Liver	Gut
1	Rash <25% BSA	Bilirubin 2 mg/dL to <3 mg/dL	Diarrhea 500–1,000 mL/day or persistent nausea
2	Rash 25%–50% BSA	Bilirubin 3–6 mg/dL	Diarrhea 1,000–1,500 mL/day
3	Rash >50% BSA	Bilirubin 6–15 mg/dL	Diarrhea >1,500 mL/day
4	Erythroderma w/bullae formation	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus

BOX 28-4 DIFFERENTIAL DIAGNOSIS OF GRAFT-VERSUS-HOST DISEASE

Acute GVHD

Drug eruption
Rash of engraftment syndrome
Transient acantholytic dermatosis
Toxic epidermal necrolysis (for Stage IV disease)
Viral exanthem

Chronic GVHD

Epidermal involvement
- Drug eruption
- Lichen planus
- Pityriasis lichenoides chronica
- Psoriasis

Sclerotic involvement
- Eosinophilic fasciitis
- Lichen sclerosus
- Morphea
- Nephrogenic systemic fibrosis
- Radiation dermatitis
- Systemic sclerosis

in patients who develop refractory disease. A number of systemic risk factors portend a poor prognosis, including a history of progressive involvement from acute to chronic GVHD,[65] thrombocytopenia (fewer than 100,000 cells/mL),[66] elevated bilirubin,[67] older age, gastrointestinal symptoms, and lack of response to therapy at 6 months.[68] The two primary dermatologic features associated with poor prognosis are extensive (>50%) skin involvement[69] and "lichenoid" skin histology.[65]

TREATMENT

MANAGEMENT OF ACUTE GVHD

Treatment of acute GVHD is usually undertaken in the hospital, given the proximity to the date of HCT and the need for close observation. Patients with mild (Grade I) skin involvement without hepatic or gastrointestinal symptoms may respond to high-potency topical steroids. However, more severe skin involvement or the presence of internal organ involvement necessitates treatment with systemic corticosteroids (methylprednisone 2 mg/kDa/day). Patients with skin sloughing require meticulous skin care, infection surveillance, and fluid management similar to toxic epidermal necrolysis. Approximately 50% of patients respond to systemic corticosteroids—however, those who require salvage therapy typically receive one or more immunosuppressive agents, including calcineurin inhibitors (tacrolimus, cyclosporine), mycophenolate mofetil, and sirolimus, which are of variable success (Box 28-5).[70] Phototherapy (PUVA,[71] NB-UVB,[72]

BOX 28-5 SYSTEMIC TREATMENT OF ACUTE CUTANEOUS GVHD

FIRST LINE
- Corticosteroids (IV methylprednisone 2 mg/kg/day)[112,113]
- Tacrolimus (usually on prophylactic treatment)[114]
- Cyclosporine (usually on prophylactic treatment)[115]

SECOND LINE
- Mycophenolate mofetil[116,117]
- Etanercept[74,118]
- Infliximab[119,120]
- Denileukin diftitox[121]
- Pentostatin[122]
- Antithymocyte globulin[123,124]

OTHER SALVAGE THERAPY
- Extracorporeal photopheresis[125,126]
- Alefacept[127]
- Mesenchymal stem cell therapy[76,77]
- Anti-CD25 antibodies
- Daclizumab[128]
- Inolimomab[129]
- Baxiliximab[130,131]
- ABX-CBL (anti-CD147)[132]
- Anti-CD3 (visilizumab)[133]
- Anti-CD52 (alemtuzumab)[134,135]
- Psoralen plus UVA (PUVA)[71,136]
- Narrowband-UVB[72]
- Ultraviolet A1 (340–400 nm)[73]

UVA1[73]) has also been used in small series for acute GVHD, but is logistically challenging in the inpatient setting and should be administered cautiously to avoid inducing erythema.

Extracorporeal photopheresis (ECP), anti-TNF–α therapy, and multipotent mesenchymal stromal cells (MSC) are additional strategies that have shown recent success for the treatment of acute skin GVHD. In a review of salvage therapies for acute GVHD, 60%–76% of patients with skin involvement responded to ECP; however, responses decreased with increasing skin severity.[70] Levine et al[74] demonstrated complete remission (CR) of skin symptoms in 81% of patients treated with steroids and etanercept compared to steroids alone (CR = 47%). Similarly, infliximab has also shown variable success in acute treatment-refractory skin GVHD (33%–60%).[70] Finally, preliminary reports of the success of MSC, bone marrow-fibroblast derived cells capable of differentiation into adipocytes, chondrocytes, and osteoblasts, in patients with refractory acute GVHD has generated significant interest in this novel therapy.[75–77] In a 2008 study, 39/55 (71%) of participants with steroid-resistant acute GVHD sustained a complete or partial response to MSC infusion.[77] Responses were seen regardless of MSC source (HLA-matched, haploidentical, or third party unmatched

donors), and immunogenicity was not observed. The immunomodulatory mechanism of MSC is unclear, but may be through induction of regulatory T-cells.[78,79] Several MSC studies are underway for the treatment or prophylaxis of acute and chronic GVHD as well as for other chronic conditions, including Crohn's disease, multiple sclerosis, systemic sclerosis, and lupus erythematosus.

MANAGEMENT OF CHRONIC GVHD

Among the myriad topical, phototherapy-based, and systemic treatments that have been used in patients with chronic GVHD who cannot be tapered from systemic corticosteroids or who are steroid-refractory, no single treatment has demonstrated proven superiority (Table 28-3). Determination of a preferred second-line agent has been complicated by poor understanding of the disease process and a lack of high-quality clinical trials. The need to spur clinical trial development in the field of chronic GVHD was acknowledged by the chronic GVHD NIH Consensus Project, which included a standardized system of organ system assessments and recommendations for clinical trial design[80] Unfortunately, validated measures of cutaneous disease activity are still lacking, and the most common skin assessments tools, body surface estimates and use of Rodnan scoring (derived from systemic sclerosis trials) are not applicable for all manifestations of chronic GVHD skin activity.[81] Ideally, dermatologic collaboration in future therapeutic trials will permit better quantification of cutaneous disease response.

The dermatologist should play a key role in the multidisciplinary approach to chronic GVHD management, beginning with careful assessment of the subtype and extent of skin involvement. Together with an understanding of other organ system activity, infection risk, relapse risk, and GVHD prognostic risk factors, a decision regarding the appropriateness of topical, physical (e.g., phototherapy), and systemic therapy can then be made. If systemic therapy is prescribed by the transplant physician, periodic dermatologic monitoring is advised to differentiate adverse drug reactions or other new skin disease from GVHD,[82] to assess cutaneous disease response, and to monitor for infection and skin malignancy.

Nonsclerotic lichen-planus like and other papulosquamous chronic GVHD manifestations may respond well to topical steroid treatment and serve to reduce exposure to systemic immunosuppression.[83] Topical emollients and antipruritic agents may provide relief of pruritus and skin irritation; however, oral antihistamines may worsen sicca symptoms in patients with oral and ocular dryness. Choi and Nghiem[84] described a response to topical tacrolimus 0.1% ointment in 13/18 patients with chronic GVHD; however, all patients eventually required other therapy to control their skin disease. Subsequent reports have also described response to topical pimecrolimus 1% cream.[85,86] Topical calcineurin inhibitors are particularly useful for treatment of areas at high risk of skin atrophy, such as the face (including the lips) and intertriginous surfaces. Topical tacrolimus may not be tolerable at sites of significant inflammation or erosions. Hydroquinone in combination with tretinoin and topical dexamethasone has anecdotally been reported to improved periocular lichenoid type chronic GVHD and hyperpigmentation.[87] Topical tretinoin may also benefit milia formation following GVHD skin activity.

Phototherapy may be of benefit for both sclerotic and nonsclerotic chronic GVHD, but data are limited to anecdotal cases and a small number of noncontrolled case series. Vogelsang[88] described improvement in 31/40 patients treated with PUVA.[88] Three patients in this series had skin sclerosis—two demonstrated

[b]Bath-PUVA.

transient benefit, but developed severe phototoxicity, and the third did not respond to treatment. Smaller series with PUVA-bath (6 patients),[89] narrow-band UVB (10 patients, pediatric),[90] and UVB (5 patients),[91] have also described chronic GHVD responses, primarily in patients with "lichenoid" disease. Over the last several years, however, there has been growing experience with UVA1 for sclerotic skin conditions, suggesting potential application in chronic GVHD. Longer wavelength UVA1 (340–400 nm) does not require psoralen ingestion/topical application and penetrates deeper into the dermis than full spectrum UVA. Several reports have described skin softening following UVA1 treatment of lichen sclerosus,[92] localized morphea,[93–95] and sclerotic-type GVHD.[73,96–98] Wetzig et al[73] used medium-dose UVA-1 phototherapy in seven patients with lichenoid GVHD and three with sclerotic GVHD. All three patients with sclerotic GVHD demonstrated partial response or improvement. Ständer et al[97] described softening of skin lesions, improved joint mobility, and healing of skin erosions in five adult patients with medium-dose UVA-1 and one child treated with low-dose UVA-1. Calzavara Pinton et al[98] described five patients with sclerotic involvement treated with MD UVA-1 therapy leading to complete resolution in three patients and partial response in two patients. UVA-1 may accentuate pigmentary abnormalities.[99] Although UVA-1 is not yet widely available in the Unites States, it appears to be well tolerated, acceptable for pediatric use,[96] and is not associated with persistent photosensitivity or potential gastrointestinal issues that may occur with oral psoralen use.

Phototherapy may be appropriate for patients with limited epidermal or sclerotic disease in whom systemic therapy is not otherwise warranted (e.g., without internal organ system involvement), or in whom systemic immunosuppressive therapy is contraindicated (e.g., active infection); however further controlled trials are needed to directly compare phototherapy modalites and to determine the optimum dose and treatment schedule. Skin cancer risk assessment and concurrent use of photosensitizing medications should also be considered. Multiple squamous cell carcinomas have been reported following PUVA treatment for chronic GVHD [64] and the risk of melanoma is elevated in patients following HSCT.[61] Photosensitizing medication use is common, including voriconazole therapy, which may further increase the risk of squamous cell carcinoma formation in the setting of chronic GVHD.[63]

Extracorporeal photopheresis (ECP) is another option for patients with cutaneous disease, particularly patients with extensive or sclerotic involvement. During ECP, the white cell compartment of the blood is removed from the patient via pheresis, mixed with 8-methyoxypsoralen, irradiated with UVA light, and then returned to the patient. In a retrospective review of 71 chronic GVHD patients who were treated with ECP, 59% of patients with cutaneous involvement responded, including 67% of those patients categorized as sclerotic involvement.[100] ECP may be particularly useful for patients with deep-seated sclerotic involvement of the subcutaneous tissue and fascia. Although GVHD-related fasciitis resembles eosinophilic fasciitis (EF), in contrast to EF, it does not respond well to steroid therapy and may result in significant long-term functional disability. Several case reports describe successful use of ECP for EF,[101] and GVHD-related fasciitis.[41,102,103] ECP is a time-consuming procedure and requires a dedicated pheresis center which is not available at all medical facilities. As with phototherapy, the optimal frequency and duration of ECP treatment is unclear. Typically, intensive treatment (2× weekly or every other week) is initiated, followed by an attempt to decrease frequency if a response is achieved.

Limited data are available supporting the use of systemic retinoids for chronic GVHD. Marcellus et al[104] reported improvement in 20/27 evaluable patients with sclerotic disease treated with etretinate; however, six patients could not tolerate the treatment due to scaling or skin breakdown. Ghoreschi et al[105] described PUVA-bath treatment in 14 patients with sclerotic-type GVHD, five of whom received concurrent treatment with isotretinoin 10–20 mg/daily. Overall improvement was reported in 7/14 patients; however, skin ulceration was a significant issue in both PUVA-bath only and combination treatment groups, and the small sample size precluded statistical comparison between groups.[105] Further prospective studies are needed to determine the tolerability and efficacy of systemic retinoid therapy.

Imatinib mesylate, a multikinase inhibitor with activity against bc-abl, c-kit, PDGFR, and other kinases, has been reported to benefit patients with sclerotic GVHD in a small number of case reports.[30,31,106] The drug is generally well tolerated in the setting of treatment for chronic myelogenous leukemia; however, the tolerability and efficacy of the drug in chronic GVHD is an area of ongoing clinical trial investigation. Common side effects include peripheral and periorbital edema, myalgia, and fatigue. Second generation agents with similar targeted tyrosine kinase inhibitory activity (nilotinib, dasatinib) also hold potential as therapeutic options for sclerotic disease, as does the use of MSC, based on the experience with acute GVHD. Recently, a single case of sclerotic-type GVHD was reported with a response to MSC therapy.[107]

TREATMENT OF CHRONIC ORAL AND VULVO-VAGINAL DISEASE

Limited oral mucosal disease can be controlled with application of high-potency topical corticosteroid gel (fluocinonide gel 0.05%, clobestasol gel 0.05%). Refractory lesions may respond to intralesional triamcinolone injection (0.3–0.4 mL/L cm^2).[83] Topical application of tacrolimus 0.1% ointment may also be used;[108] however, systemic absorption has been reported[109] and, therefore, serum tacrolimus levels are reasonable following initiation of intra-oral treatment. Generalized oral disease can significantly impair oral intake and quality of life and often result in the need for systemic intervention. Corticosteroid rinses (dexamethasone 0.5 mg/mL; prednisolone 15 mg/mL) are beneficial

for widespread involvement and should be swished in the mouth 4–6 minutes 4–6 times daily.[83] Cyclosporine and azathioprine rinses may also be used for refractory disease, but require pharmacy compounding. As mentioned above, patients with salivary gland disease should avoid oral antihistamines as well as other xerogenic medications (SSRIs, tricyclic antidepressants). Dental hygiene is very important in patients with decreased salivary function and home fluoride treatment is frequently recommended. Salivary stimulants (e.g., sugar-free gum) and sialogogue therapy (cevimeline, pilocarpine) are recommended for patients with severe salivary gland dysfunction.[83] Although sclerotic involvement of perioral skin involvement is uncommon, in this setting aggressive systemic therapy is indicated.

Genital erosions and fissures associated with chronic vulvo-vaginal disease may be treated with clobetastol proprionate ointment nightly, which should be tapered to a maintenance level of 2–3 times weekly. If estrogen is not contraindicated, hormone replacement via topical cream, vaginal ring, or oral replacement may improve genital skin integrity. Limited vaginal scarring/synechiae can be treated with dilators or manual lysing; however, thick vaginal scarring may require surgical intervention.[110]

PREVENTION

GVHD prevention begins prior to transplantation with the selection of the most closely HLA-matched donor, the GVHD prophylaxis regimen and, in some cases, manipulation of the T-cell content of the graft. T-cell depletion is accomplished through ex vivo T-cell negative selection or enrichment of the $CD34^+$ stem cell population, or through in vivo treatment with anti-T-cell therapy. The benefits of T-cell depletion, however, are offset by higher rates of graft failure, cancer relapse, and infection.[14] Prophylactic immunosuppressive therapy is initiated concomitantly with the administration of the hematopoietic graft, but, as with T-cell depletion, such therapy must be balanced with potential for diminished graft-versus-leukemia/lymphoma effect and long-term infection risks. In general, available strategies for the prevention of acute GVHD are rarely effective in the prevention of chronic GVHD, emphasizing the distinct pathophysiology of these two GVHD manifestations. Ideally, personalized immunogenomics will evolve to allow careful titration of T-cell graft content and prophylactic immunosuppression to maximize graft acceptance and graft-versus-leukemia effect and at the same time minimize infection risk and other complications associated with long-term immunosuppression.

Similar to solid-organ transplantation, skin cancer screening and patient education regarding photoprotective measures is a key preventive strategy in patients with chronic GVHD.[83] Patients are also at elevated risk of systemic infection, and therefore, implementation of preventive infectious disease recommendations and careful monitoring for cutaneous infection, particularly in patients with chronic skin erosions/ulcerations, is prudent.[83] Finally, patient education regarding early signs of skin sclerosis and fascial involvement, including skin tightness, edema, muscle cramping, and range of motion restriction, may facilitate early diagnosis and initiation of treatment.

Chapter 29 :: Skin Disease in Acute and Chronic Immunosuppression

:: Benjamin D. Ehst & Andrew Blauvelt

SKIN DISEASE IN ACUTE AND CHRONIC IMMUNOSUPPRESSION AT A GLANCE

- Skin manifestations in patients who have hematologic malignancies, have undergone bone marrow transplantation, or are immunosuppressed by drugs are common and varied.
- Many of these skin diseases occur in immunocompetent individuals as well.
- In patients with acute immunosuppression, infections occur that are normally controlled by neutrophils and macrophages.
- In patients who have long-term immunosuppression, T-cell function is impaired and skin diseases are often similar to those seen in patients with human immunodeficiency virus infection.
- Salient dermatologic features particularly associated with immunosuppression are important diagnostic signs and indicators for therapy.

Impairment of the body's immune system results from a variety of causes, including natural aging, ultraviolet radiation, diabetes, malnutrition, cancer, and iatrogenic suppression. While few skin conditions appear solely in immunocompromised individuals, clinical presentations may be morphologically atypical, follow unusual clinical courses, or prove harder to treat than in individuals with intact immunity. This chapter focuses on dermatologic manifestations in immunosuppressed patients without human immunodeficiency virus (HIV) disease, predominantly in those with immunosuppression induced by drugs, conditions surrounding solid organ and bone marrow transplantation, and hematologic malignancy. Skin manifestations of HIV disease are described in Chapter 198. Other chapters cover graft-versus-host disease (see Chapter 28), skin signs associated with primary immunodeficiency disorders (see Chapter 143), and detailed side effects of medications, including corticosteroids, cancer chemotherapeutic agents, immunosuppressants, and cytokines (see Chapters 224, 227, 233, and 234). The salient clinical features particularly associated with immunosuppression are emphasized here.

While a variety of inflammatory skin diseases and paraneoplastic processes occur in the setting of immunosuppression, infections, and malignancy are most commonly seen and are discussed herein. When approaching an immunocompromised patient, it is helpful to determine the time frame of the immune loss as well as the specific immune defect. This chapter is divided into two major subsections based on this concept: acute immunosuppression and chronic immunosuppression. When patients are acutely immunosuppressed, usually from iatrogenic ablation of the immune system or from acute leukemia, infections occur that are normally controlled by innate immunity, which typically involve neutrophils and macrophages. In chronically immunosuppressed individuals, such as organ transplant patients and those taking corticosteroids on a long-term basis, T-cell function is impaired, and diseases will often be similar to those observed in HIV disease. Thus, it is helpful to understand the underlying immune defects associated with the medical conditions of each patient (Table 29-1), because it helps to focus the history taking and physical examination toward skin manifestations of specific pathogens.

In ill-immunosuppressed patients, disease often manifests in the skin. Appropriate evaluation and diagnosis of skin lesions are critical to the overall health of these individuals, because the skin is often a window to more severe systemic illness. In particular, unusual presentations of infection with typical pathogens and infections with rare opportunistic pathogens are common in these patients. Diagnosis is also made more difficult by the variety of organisms that share similar morphologies and the wide variety of morphologic presentations of a single organism (Table 29-2). This makes prompt clinical evaluation and extensive use of skin biopsy and culture necessary to make an accurate diagnosis and initiate prompt treatment to obviate significant morbidity and mortality.

ACUTE IMMUNOSUPPRESSION

The prototype of an acutely immunosuppressed patient needing dermatologic evaluation is the neutropenic patient undergoing chemotherapy around the time of hematopoietic transplantation. Pancytopenia and neutropenia in particular predispose to invasive infections caused by Gram-negative and -positive bacteria and the fungal organisms *Candida* and *Aspergillus*.[1] These complications from many cancer therapies often pose a more immediate threat to survival than the malignancy itself. In the past two decades, overall mortality due to infection among patients undergoing hematopoietic transplantation has decreased significantly with the use of better prophylaxis and nonmyeloablative regimens, but still represents an ongoing risk to survival. The causes of infection-related death

TABLE 29-1
Opportunistic Infections that are Commonly Associated with Specific Underlying Immune Defects

Immune Defect	Usual Conditions	Common Bacterial Pathogens	Common Viral Pathogens	Common Fungal Pathogens
Defective cell-mediated immunity	Organ transplantation, metastatic cancer, Hodgkin disease, glucocorticoid, or cyclosporine therapy	*Listeria, Salmonella, Nocardia, Mycobacterium avium-intracellulare, M. tuberculosis, Legionella*	Cytomegalovirus, herpes simplex virus, varicella zoster virus	*Candida, Cryptococcus, Histoplasma, Coccidioides*
Defective humoral immunity	Multiple myeloma, chronic lymphocytic leukemia	*Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis*	Enteroviruses	—
Neutropenia	Cancer chemotherapy, acute leukemia, adverse drug reaction	Aerobic Gram-negative bacteria; *Staphylococcus aureus, Streptococcus viridans, Staphylococcus epidermidis*	Herpes simplex virus	*Candida, Aspergillus*
Defective neutrophil function	Chronic granulomatous disease, myeloperoxidase deficiency	Catalase-positive bacteria: *S. aureus, Escherichia coli*	—	*Candida*
Hyposplenism	Splenectomy, hemolytic anemia	*S. aureus, Streptococcus*	—	*Candida*
Defective complement components	Congenital or acquired deficiencies	*S. pneumoniae* (C2, C3, C5 alternate), *H. influenzae* (C2, C3, alternate), *S. aureus* (C5), Enterobacteriaceae (C5), *Salmonella*(alternate), *N. meningitidis* (C6–C8)	—	—
Skin barrier disruption	Intravascular catheters, decubitus ulcers, burns	*Staphylococcus, M. fortuitum,* Gram-negative bacteria, anaerobes	—	*Candida, Aspergillus, Mucor*

have remained relatively stable, with death due to bacterial infections being the most common (36%), followed by deaths due to infection by viruses (31%), fungi (28%), and parasites (5%).[2,3] Infections in the acute period following solid organ transplantation are less opportunistic and tend to reflect the usual nosocomial pathogens associated with surgical procedures and hospitalization.[4]

BACTERIAL INFECTIONS

Bacteria are responsible for most infections during acute neutropenic episodes. Empiric antimicrobial therapy for fever and neutropenia was first introduced in the 1970s when 60%–70% of infections were due to Gram-negative bacteria such as *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella* species. Dramatic shifts have occurred since that time, such that over 50% of bacterial infections in cancer patients are now caused by Gram-positive organisms, and 75%–80% in patients that are bacteremic.[5,6] The use of indwelling intravascular catheters, medications predisposing to mucositis, and prophylactic fluoroquinolones are all thought to play a role in the shift to Gram-positive organisms, such as coagulase-negative staphylococci, *Staphylococcus aureus*, Enterococcus species, and viridians group streptococci.[7] The emergence of drug-resistant organisms, including methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *Enterococcus*, as well as polymicrobial infections also complicates the situation.[6]

Routine cellulitis from staphylococcal and streptococcal organisms is a common manifestation of skin infection in the acutely immunocompromised host. Muted clinical signs and symptoms can be found in this population, so care must be taken to rule out deeper involvement as occurs in necrotizing fasciitis.[8] Bacteremia may result from skin and soft-tissue infections such as folliculitis, furuncles, and wound infections. Bone marrow transplant patients and other patients with neutropenia are prone to streptococcal bacteremia and may develop facial flushing, a widespread erythematous, petechial or purpuric eruption of macules and papules, and desquamation of the palms and soles.[9] Staphylococcal scalded-skin syndrome, which typically occurs in children (see Chapter 177), can occur in immunosuppressed adults.[10]

Ecthyma gangrenosum is one of the more specific clinical signs of bacteremia and is characterized by a painful erythematous to dusky nodule or plaque that rapidly develops a central pustule or hemorrhagic vesicle, followed by necrosis (Fig. 29-1). The groin, perianal area, and axillae are the most common locations. There may be one or many lesions. Classically described in patients with *Pseudomonas* septicemia, it is now recognized that other bacterial and fungal organisms, including *S. aureus*, *Aeromonas hydrophilia*, *Serratia marcescens*, *K. pneumoniae*, *E. coli*, *Aspergillus*, and *Mucor* species, can also cause similar lesions.[11,12] Necrosis is secondary to underlying focal vasculitis, which can be observed in skin biopsy specimens. Diagnosis is made by culture of the organism from skin or blood.

Figure 29-1 Ecthyma gangrenosum secondary to *Pseudomonas aeruginosa* infection in a bone marrow transplant patient.

Patients with neutropenia, cystic fibrosis, or extensive burns are particularly susceptible to systemic *P. aeruginosa* infection (see Chapter 180).[13] The mortality rate of *P. aeruginosa* bacteremia in transplant patients is high at upwards of 40%.[14] Other cutaneous manifestations of *P.* septicemia may appear initially as grouped vesicles, cellulitis, subcutaneous nodules, petechiae, purpura, or folliculitis.[15] Progression to ulcerative and necrotic lesions that are more characteristic of ecthyma gangrenosum may occur. Primary cutaneous infection, usually at the site of a medical procedure, can also cause ecthyma gangrenosum-like lesions. As is common with other infections in neutropenic patients, primary lesions can lead to bacteremia and should be treated aggressively.

FUNGAL INFECTIONS

In the acute transplant setting, invasive fungal infections are less common than bacterial infection, but cause much greater mortality. Mortality rates range from 40% to close to 100%, especially when treatment is delayed.[16] Prolonged neutropenia is a significant risk factor and recovery from disseminated fungal infections is rare unless neutropenia resolves. Candidiasis and aspergillosis represent the two most common invasive fungal infections that occur in patients who are undergoing cytotoxic chemotherapy or stem cell transplantation or who have acute myeloproliferative disorders.[17] However, they are not unique to the neutropenic patient and are encountered in settings such as surgical and neonatal intensive care units, and in patients with cell-mediated immune dysfunction such as those undergoing long-term immunosuppression after solid organ transplantation. Additional risk factors for opportunistic fungal infection include hyperalimentation, antibiotic use, hyperglycemia, corticosteroid use, and central venous catheter use. Other fungal organisms causing infection in hosts with acute neutropenia include *Trichosporum* species, *Fusarium* species, and organisms in the Zygomycetes class.[18]

CANDIDIASIS. Candidiasis (see Chapter 189) remains the most common opportunistic fungal infection worldwide, although its role in invasive infections is changing in certain immunosuppressed populations.[19] *Candida* species still account for more than half of invasive fungal infections in solid organ transplant recipients, but aspergillosis has become more common in hematopoietic stem cell transplant recipients.[20–22] Historically, most candidal infections were due to *Candida albicans*, but there has been an emergence of other organisms in recent years, including *C. glabrata*, *C. krusei, C. parapsilosis*, and *C. tropicalis*.[17] In certain populations of patients with hematologic malignancy or stem cell transplantation, non-*C. albicans* species now predominate, so awareness of local and regional patterns of infection is important.[20,23]

The classic triad of fever, myalgias, and erythematous skin lesions in a septic patient not responding to antibiotic therapy is highly suggestive of disseminated candidiasis. Fungi may seed numerous organs, causing myositis, meningitis, endocarditis, pneumonitis, cerebritis, esophagitis, bursitis, osteomyelitis, arthritis, and endophthalmitis. Cutaneous lesions are present in only 5%–10% of individuals with disseminated candidiasis.[15,24] Lesions are characteristically painless, nonblanching, discrete, erythematous macules, papules, or nodules (Fig. 29-2) and may develop central purpuric, pustular, or necrotic changes. Involvement is usually generalized, but occasional patients have very few lesions limited to the proximal extremities. The major clinical differential diagnosis includes infections caused by other opportunistic pathogens and drug eruptions. Histologically, periodic acid-Schiff-positive yeast forms are seen in the dermis, usually in association with vascular damage and mild inflammation. *Candida* can be grown from sterile skin lesion samples in approximately 50% of patients. Tissue scrapings from dermal skin can be obtained at the time of biopsy with a scalpel or small-diameter curette for slide examination and can be an invaluable aid in making a rapid diagnosis in an acutely ill patient.

Figure 29-2 Early cutaneous lesion of disseminated candidiasis in a neutropenic patient after chemotherapy for non-Hodgkin lymphoma.

The treatment of choice for presumed disseminated candidiasis is usually intravenous liposomal amphotericin B, although the new class of echinocandins are also being evaluated.[25,26] Culture results are again important since *C. glabrata*, *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are showing resistance to fluconazole, and *C. krusei* is naturally resistant.[22] Newer azoles, including voriconazole and posaconazole, are effective against *Candida* species, although breakthrough infections with resistant *C. glabrata* have already been reported with voriconazole (see Chapter 232).[27]

ASPERGILLOSIS. While aspergillosis remains the second most common cause of opportunistic fungal infection in immunosuppressed patients as a whole, it has now surpassed *Candida* as the most common cause of invasive fungal infection in hematopoietic stem cell transplant patients and certain hematologic malignancies.[15,16,20] Incidence rates vary in different immunosuppressed groups, but may reach 25% in acute leukemia and organ transplant patients.[28] Persistent neutropenia and neutrophil dysfunction are risk factors for disseminated infection. Infection rates are also high for patients undergoing allogeneic stem cell transplantation, and risk factors in this group are expanded to include immunosuppression for graft-versus-host disease prophylaxis, graft-versus-host disease itself, and other infectious diseases, especially cytomegalovirus (CMV) infection. Invasive infection with *Aspergillus* was classically seen during acute periods of neutropenia, but shifts in conditioning regimens and other strategies to promote earlier engraftment have led to infections after 30–40 days posttransplantation.[20] This observation emphasizes that immune defenses other than those mediated by granulocytes are important for protection against invasive fungal infections, and against *Aspergillus* infections in particular.

The incidence of invasive aspergillosis is also increasing in nonclassic immunocompromised hosts such as critically ill patients in the intensive care unit. Environmental factors also clearly contribute to the development of aspergillosis, especially in primary cutaneous disease. These include hospital construction (which increases spore counts in ventilation systems), the use of indwelling catheters (which provide portals of entry for organisms), and contamination of tape and arm boards used to secure catheters. Mortality rates have improved with the introduction of newer antifungal agents, but remain higher than 50% in stem cell and organ transplant recipients.[28,29]

A. fumigatus is the most common cause of disseminated infections, although emerging strains of *A. flavus*, *A. niger,* and *A. terreus* are accounting for more disease.[20] Reports suggest that *A. flavus* is associated most commonly with primary cutaneous disease.[30] *A. terreus* is more likely to be resistant to amphotericin B, and multiple tri-azole resistant *A. fumigatus* has been described.[28]

Primary cutaneous aspergillosis often develops at paronychial locations, sites of intravenous catheters, or under areas of occlusion. Lesions initially appear as

Figure 29-3 Ecthymatous lesion of primary cutaneous aspergillosis in a child after bone marrow transplantation. (Used with permission from Jonathan Alexander, MD, Portland, OR.)

small cellulitic areas and progress quickly to necrotic ulcers with black eschars (Fig. 29-3) due to the angioinvasive nature of the organism. In patients with *Aspergillus* sinusitis, necrotic ulcers with black eschars can occur in the anterior nares and on the nasal septum, palate, and skin overlying the nasal bridge. MRI may be useful in diagnosing the underlying sinusitis, and prior treatment with amphotericin B does *not* exclude the diagnosis as surgical treatment may be needed in this setting.[31–33]

Pulmonary, and less often primary cutaneous or sinus, infection can easily become invasive and lead to disseminated disease in immunocompromised hosts. Patients with disseminated aspergillosis often present with unremitting fever despite antibiotic use. The central nervous system, heart, kidneys, and gastrointestinal tract may also be involved. Cutaneous manifestations of disseminated aspergillosis are uncommon, occurring in only 5%–10% of patients.[30] Lesions begin as single or multiple painful, erythematous papules, nodules, or plaques. They rapidly expand and develop central hemorrhagic vesicles or bullae, then eschar. In tissue sections, diagnosis can be made by demonstration of nonpigmented septated hyphae that branch at acute angles. Blood culture results often are not positive or reliable because *Aspergillus* is found commonly as a laboratory contaminant. Voriconazole has become the first-line agent for treatment of invasive aspergillosis. Alternatives include caspofungin, liposomal amphotericin B, itraconazole, and posaconazole.[29] Surgical removal of isolated lesions of primary cutaneous aspergillosis can be attempted, although this may not necessarily prevent secondary disseminated infection in patients with persistent neutropenia.

ZYGOMYCOSIS. Zygomycosis is the third most common opportunistic fungal infection in immunosuppressed hosts, and may account for closer to 50% of invasive fungal infections in certain populations such as renal transplant patients.[18] The term *zygomycosis* is used to describe a group of fungal infections caused by ubiquitous Zygomycetes found in soil and decaying matter. Infections in humans are mostly caused by the order Mucorales (mucormycosis) and include the genera of *Mucor*, *Rhizopus*, *Absidia*, *Rhizomucor*, and *Cunninghamella*. The term *zygomycosis* is now preferred over *mucormycosis* because it is broader and more relevant when organisms are not identifiable. Like aspergillosis, zygomycosis is rare in individuals without underlying immunodeficiency or predisposing conditions. Host defenses usually prevent the germination of spores unless the inoculation is too great, as in trauma or surgical wounds. Chronic medical conditions that affect macrophage function, such as diabetes or corticosteroid-induced immunosuppression, lead to an inability to inhibit spore germination, and these patients are at increased risk of infection. Additional risk factors besides immunosuppression include iron overload, burns, intravenous illicit drug use, and malnourishment. Recently, the use of voriconazole in immunosuppressed patients with presumed or diagnosed aspergillosis may account for part of the increase in zygomycotic infections.[27]

Primary infection can occur by inhalation, by direct inoculation into damaged skin, or by ingestion. Patients with prolonged neutropenia present most often with pulmonary disease and dissemination. The mortality rate in these individuals is very high, approaching 100%.[34] Diabetic patients with sustained hyperglycemia and metabolic acidosis are predisposed to primary rhinocerebral (66%) and pulmonary (16%) infections.[35] Malnutrition and gastrointestinal disease predispose patients to primary gastrointestinal tract infection. Wounds and burn injuries predispose to primary cutaneous infection. Each type of primary infection can lead to hematogenous spread and disseminated infection of numerous organs (especially the brain).

The clinicopathologic hallmarks of cutaneous zygomycosis are vascular invasion, ischemic infarction, and necrosis, which result in painful erythematous nodules and plaques that ulcerate rapidly and form central black eschars.[34] Clinical manifestations of primary cutaneous disease can range from necrotic papules to cellulitis, to subcutaneous nodules with rapid extension and dissemination especially in neutropenic patients.[36] Rhinocerebral zygomycosis typically begins with facial edema and erythema (Fig. 29-4), bloody nasal discharge, and ulceration of the palate or nasal septum. Within a few days, necrotic skin lesions, headache, focal neurologic defects, exophthalmos, and altered vision develop and can progress to seizures, stupor, coma, and death. Disseminated disease from a noncutaneous primary site infrequently presents with skin findings.[36]

Diagnosis of zygomycosis is usually made by demonstration of nonseptated hyphae (with branching at right angles) within infected tissue. The treatment of choice for disseminated disease is lipid preparations of

Figure 29-4 Rapidly progressing zygomycosis in a man with diabetes.

intravenous amphotericin B and surgical debridement. Some advocate the addition of posaconazole. If possible, reversal or removal of underlying predisposing conditions should be attempted.[18]

FUSARIOSIS. *Fusarium* is a filamentous mold found in soil and plants belonging to the fungal group of hyalohyphomycoses. Disseminated infections are found in severely immunocompromised individuals, whereas immunocompetent patients have localized lesions at areas of skin breakdown. Neutropenic patients are particularly susceptible to infection and rapid dissemination.[31] The source of infection in patients undergoing acute immunosuppressive therapy is often the skin, especially from cellulitis developing at the site of onychomycosis, local trauma, or insect bites. Nasal sinuses are another source of primary infection that can lead to dissemination following acute immunosuppression.[18] In disseminated disease, patients present with multiple painful erythematous papules and nodules, some with central necrosis. Lesions are often at different stages of development, and a specific presentation of papules evolving into target-like lesions with a ring of normal-appearing skin and an outer rim of erythema has been observed.[31] Skin lesions in disseminated disease often precede fungemia and are found in approximately 75% of patients making dermatologic evaluation valuable.[8] The mortality rate in patients who are persistently neutropenic is about 80%, compared with 30% in patients whose immune systems recover. Disease in solid organ transplant recipients may occur later than in patients with hematologic malignancies. Newer triazole antifungals such as voriconazole have some efficacy against infection with *Fusarium* species, for which treatment options have traditionally been limited. Surgical resection of localized skin infection is useful. Granulocyte transfusions may also play a role in treatment.[18]

TRICHOSPORONOSIS. *Trichosporon beigelii*, a yeast-like organism that causes white piedra in the tropics, may produce acute systemic infection in immunosuppressed patients, most commonly in the setting of neutropenia.[31] *Trichosporon* is an emerging pathogen in organ transplant recipients as well.[18] Patients with disseminated trichosporonosis are acutely ill. They may have fever, hypotension, pulmonary infiltrates, renal involvement, and hepatosplenomegaly. Skin lesions occur in 30% of patients and appear similar to cutaneous lesions of disseminated candidiasis (multiple red papules that may ulcerate). Definitive diagnosis is made by culture, and the treatment of choice is fluconazole or itraconazole; amphotericin B resistance is common.[18]

VIRAL INFECTIONS

Viral infections are predominantly associated with defects in cellular immune function and are not typically expected to cause problems in patients whose main immunologic defect is neutropenia.[4] The most common viral infection that occurs in patients who are undergoing induction chemotherapy for lymphoma or an acute leukemia or who are in the first few weeks after a hematopoietic stem cell transplantation is reactivation of latent herpes simplex virus (HSV) infection (see Chapter 193).[37] Clinical presentations in acutely immunosuppressed patients include an increased severity of oral mucositis, intraoral ulcers outside of the gingival margin, and necrotizing gingivitis. Pneumonitis can occur from either contiguous spread from the oropharynx or from viremia.[37] Antiviral prophylaxis with acyclovir is very effective in preventing disease during chemotherapy and following hematologic and solid organ transplantation. When disease does occur in transplant patients, approximately 10% of cases are resistant to acyclovir because of a mutation in the gene coding for thymidine kinase, which is the enzyme required for efficacy of acyclovir, valacyclovir, and famciclovir (see Chapter 231).[38] The treatment of choice in these patients is foscarnet, although reports of resistance to both agents is increasing.[37,39,40]

Reactivation of varicella zoster virus (VZV) (see Chapter 194) usually occurs 3 months or longer after transplantation and is relatively rare in the acutely immunosuppressed patient. VZV infection in adults with leukemia or after solid organ transplantation is rarely primary, but more often represents reactivation of latent virus. In this setting, patients are at increased risk for both skin and systemic dissemination of virus (Fig. 29-5).[41] Before the use of antiviral prophylaxis in bone marrow transplantation, disseminated primary varicella or zoster infection was associated with mortality rates of 30%.[42]

CHRONIC IMMUNOSUPPRESSION

Patients with chronic immunosuppression include those that are iatrogenically immunosuppressed because they are taking medications that impair the

Figure 29-5 Disseminated varicella zoster virus in a patient after induction chemotherapy.

immune system and those with chronic diseases that are associated with immune dysfunction, such as diabetes mellitus. Moreover, individuals with cancer often have immune system defects before aggressive cytotoxic, radiation, or surgical therapy.[43] For example, tumors can secrete immunosuppressive factors (e.g., transforming growth factor-β1 and interleukin-10) or induce T-cell anergy, which help them evade normal immune responses and lead to further systemic immunosuppression.

The population of patients taking long-term immunosuppressive medications is growing as solid organ transplantation becomes a therapeutic option for many human diseases and the survival of patients in the short and long term has improved. These individuals require lifelong therapy with immunosuppressive drugs to maintain function of the transplanted organ. Cyclosporine, tacrolimus, sirolimus, prednisone, mycophenolate mofetil, azathioprine (see Chapters 227 and 233), and the newer agents daclizumab and basiliximab are the drugs used most commonly to prevent graft-versus-host disease, predominately by inhibiting cell-mediated immunity (i.e., T-cell function).[44] Humoral immunity (i.e., B-cell function) remains relatively intact in these patients. Thus, opportunistic diseases in most transplant patients are dominated by viral and fungal infections, intracellular bacterial infections, and virus-associated malignancies—conditions that are controlled predominantly by cell-mediated immune mechanisms in immunocompetent hosts.

BACTERIAL INFECTIONS

MYCOBACTERIAL INFECTIONS. Atypical mycobacteria (see Chapter 184) are ubiquitous organisms found in soil and water. The most common organisms in this group include *Mycobacterium marinum*, *M. chelonae*, *M. fortuitum*, *M. abscessus*, *M. kansasii*, *M. haemophilum*, and *M. avium-intracellulare*. Before the epidemic of acquired immunodeficiency syndrome (AIDS), most cases occurred in persons with underlying pulmonary disease. However, nontuberculous mycobacterial infections after transplantation are increasing in frequency and severity, with the highest incidence (up to 5%) seen in recipients of hematopoietic stem cell transplants. One-third present with catheter-related infections, although skin lesions are rare in this population. Skin involvement is the most commonly reported manifestation of nontuberculous mycobacterial infections in solid organ recipients except lung and heart transplant recipients, who are more likely to have pulmonary involvement. One-third of these patients have localized or disseminated cutaneous disease and the rapid growing species *M. chelonae*, *M. fortuitum*, and *M. abscessus* are most commonly isolated.[45,46] Median time to infection varies depending on the type of transplant, ranging from 4 months posttransplant in stem cell recipients, to 30 months in heart recipients.

Atypical mycobacterial infections in the skin are characterized by diverse morphologies, including reddish brown nodules and plaques (eFig. 29-5.1 in online edition), abscesses (Fig. 29-6), and ulcers.[47] *M. avium-intracellulare* and *M. haemophilum* commonly cause disseminated infection, which can involve the lungs, lymph nodes, liver, spleen, bone marrow, and skin. Organisms can be identified by special stains or by culture of specimens from affected skin. Specific antimycobacterial antibiotic treatment regimens are complex and depend on the mycobacterial species, results of sensitivity testing, extent and severity of disease, and presence or absence of underlying immune defects.[45,46]

M. tuberculosis infection is a common worldwide problem, especially in individuals with impaired immunity. For example, individuals receiving high-dose corticosteroids are prone to active pulmonary tuberculosis. Cutaneous tuberculosis is usually more common in the setting of immunosuppression. Specifically, scrofuloderma (tuberculous lymphadenitis with extension to overlying skin) and numerous cutaneous lesions of miliary tuberculosis may occur more commonly in patients with underlying immune defects.[48]

Figure 29-6 *Mycobacterium chelonae* infection in a patient receiving long-term, high-dose glucocorticoid treatment.

NOCARDIOSIS. *Nocardia* species (see Chapter 185) are ubiquitous filamentous bacteria found in soil. While *N. asteroides* was historically considered the most common species associated with human disease, the recent availability of molecular diagnostics has allowed recategorization such that infections are now reported with a variety of species, including *N. farcinica*, *N. nova*, *N. brasiliensis*, *N. asteroids sensu strictu*, and *N. cyriacigeorgica*, among others.[49] Species identification is important as some show more virulence and antimicrobial resistance than others (e.g., *N. farcinica*), and infection patterns may differ (e.g., *N. brasiliensis* is often the cause of primary cutaneous disease). Infection can be seen in immunocompetent hosts, but the majority of infections (60%) involve patients with immune compromise, particularly those receiving long-term corticosteroid therapy (the most important risk factor), solid organ or bone marrow transplant recipients, cancer patients, AIDS patients, intravenous drug users, and individuals with chronic pulmonary disease.[50,51] Infections in patients treated with rituximab and tumor necrosis factor-α inhibitors have also been reported. In transplant patients, the mean onset of infection is 9 months after transplantation, although it can occur as early as 1 month afterward. Before the use of cyclosporine to prevent rejection, infection rates were much higher in transplant recipients, and this decline is attributed to decreased use of corticosteroids.[49]

Most cases of nocardiosis in transplant patients (approximately 80%) present as primary pulmonary disease and dissemination occurs in up to 40% of cases. The brain is commonly involved with disseminated infection, while approximately a third of cases show cutaneous involvement. Rarely, the skin is the primary location of infection.[49] Several types of skin lesions have been described, including lower extremity subcutaneous nodules with pustules (Fig. 29-7), erythema nodosum-like disease, abscesses with sinus tract formation, mycetoma, sporotrichoid nodules, and cellulitis.[8,52,53] Diagnosis is based on demonstration of Gram-positive, partially acid-fast, branching bacilli in tissue or tissue exudates, or is determined by tissue culture, although it often takes several weeks for organisms to grow. Molecular techniques may now aid in identification as well. The treatment of choice remains trimethoprim-sulfamethoxazole (TMP-SMX); however, the severely ill or those with cerebral or disseminated infection may benefit from the addition of amikacin and/or imipenem. Numerous other antibiotics have been reported to be efficacious as well, such as linezolid, minocycline, other carbapenems, and third-generation cephalosporins. In addition, incision and drainage of cutaneous abscesses should be performed.[50] The duration of treatment and the use of long-term prophylactic therapy to prevent primary or recurrent disease in transplant patients or patients on chronic corticosteroids are currently under debate. For instance, breakthrough infections in solid organ and hematopoietic transplant patients receiving traditional thrice weekly doses of TMP-SMX have occurred, and general resistance to sulfonamides is increasing.[51,54]

Figure 29-7 Nocardiosis in a man with glioblastoma.

BACILLARY ANGIOMATOSIS. Bacillary angiomatosis (see Chapter 182) is caused by infection with the bacterium *Bartonella henselae* or *B. quintana* and usually occurs in AIDS patients and other immunocompromised hosts.[55] Cutaneous lesions appear as painful, dome-shaped vascular papules and nodules (often resembling pyogenic granulomas). Disseminated infection may occur and involve the liver, spleen, bone marrow, and brain. Fever and lymphadenopathy may be present. Patients often have a history of scratches or bites by cats, the natural reservoir for *B. henselae* and *B. quintana*. Diagnosis is made by demonstration of pleomorphic bacilli in tissue specimens with Warthin–Starry silver stain. Preferred treatments include oral erythromycin or azithromycin, or doxycycline.[56]

OTHER BACTERIAL INFECTIONS. (See Chapters 177–180.) Cellulitis caused by *Streptococcus pyogenes*, *Streptococcus pneumoniae*, or *S. aureus* may progress rapidly and cause necrotizing fasciitis in immunosuppressed patients (Fig. 29-8). Solid organ recipients also may develop recurrent cellulitis of the elbow, a condition termed "transplant elbow" that has been attributed to staphylococcal infection.[8,57]

Individuals with underlying complement deficiencies (loss of late-phase components C5–C9) or alcoholism are susceptible to infection with *Neisseria meningitidis*.[58] Patients have acute septicemia, meningitis, disseminated intravascular coagulation, and widespread petechiae and purpura (Fig. 29-9).

Persons with underlying hepatic disease (commonly alcoholic cirrhosis or hepatitis) are prone to infection with *Vibrio vulnificus*, a Gram-negative bacillus commonly found in seawater, shellfish, clams, and oysters.[59] Infection occurs by ingestion of contaminated seafood or by direct cutaneous inoculation after contact with contaminated seawater. Patients classically present with rapidly evolving septicemia and painful cellulitis, bullae, or ulcers on the lower extremities (Fig. 29-10). *Aeromonas* can cause a similar picture in immunosuppressed patients.[15,60]

Capnocytophaga canimorsus is a commensal bacterium found in the saliva of dogs and cats that is transmitted to humans by bites or scratches. Hosts particularly susceptible to septicemia and widespread organ

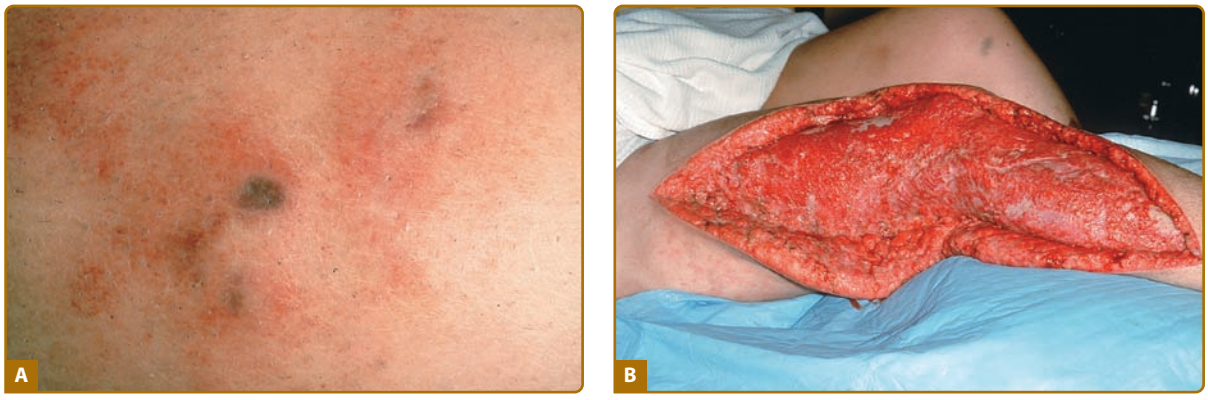

Figure 29-8 Early (**A**) and late [after surgical debridement (**B**)] lesions of necrotizing fasciitis caused by *Streptococcus pyogenes* in an intravenous drug abuser with underlying Job syndrome.

involvement include alcoholics, asplenic patients, and those taking glucocorticosteroids. Skin lesions occur commonly and include widespread macules, papules, purpura, and gangrene. Septicemia carries a mortality rate of 10%–50%.[61,62]

In immunosuppressed patients, *Salmonella* species have been associated with cutaneous abscesses and necrotizing fasciitis of the head and neck.[63]

FUNGAL INFECTIONS

CANDIDIASIS. Although mucocutaneous candidiasis (see Chapter 189) is less serious than disseminated candidiasis in the setting of acute immunosuppression (as described earlier), it is a significant source of morbidity in hosts with chronic cell-mediated immune dysfunction. Studies in organ transplant recipients suggest rates of oral candidiasis anywhere between 7% and 64%, depending on the type of transplant and the location of the study population.[41,64] Patients with chronic mucocutaneous candidiasis have specific underlying immune deficits in fighting candidal infections, including alterations in dendritic cells and the T helper type 17 cells (Th17), and usually have chronic widespread disease without systemic involvement.[65–67]

Patients with oral mucosal candidiasis most commonly have pseudomembranous, white, friable plaques that leave a raw, erythematous undersurface when scraped. Less common oral lesions include erythematous or atrophic plaques as well as angular cheilitis. Esophageal involvement should be suspected in any patient with oral candidiasis complaining of pain or difficulty swallowing. Moist intertriginous areas are common locations of cutaneous lesions and are characterized by tender erythematous papules and plaques, often with satellite pustules. Onychomycosis and paronychia caused by *Candida* species are common in patients with chronic mucocutaneous candidiasis. For mucocutaneous disease, topical therapy with nystatin or clotrimazole and oral fluconazole are the treatments of choice. Prophylactic treatment with fluconazole is

Figure 29-9 Acute meningococcemia in a man with acquired complement deficiency.

Figure 29-10 *Vibrio vulnificus* infection in an alcoholic patient after minor trauma sustained while swimming in the ocean.

Figure 29-11 White superficial onychomycosis in a renal transplant patient receiving cyclosporine.

often recommended for patients at high risk for infection, such as those who have recently undergone organ transplant surgery, although as noted before resistance to this agent is increasing.[68]

DERMATOPHYTOSIS. Dermatophytoses (see Chapter 188) are common uncomplicated infections in normal hosts, but immunosuppressed patients may have widespread, aggressive infection that can be resistant to topical and systemic therapy.[31,69] The overall incidence of dermatophyte infection is likely not higher in immunocompromised patients compared to normal hosts.[70] Specific presentations seen in immunocompromised patients include multiple lesions, a wide distribution, tinea capitis in adults, and Majocchi granuloma. Manifestations more suggestive of immunosuppression include both white superficial onychomycosis and proximal subungual onychomycosis. In the former, the surfaces of affected nails have a white, chalky appearance (Fig. 29-11), and hyphae are observed readily in superficial nail plate scrapings. These conditions should prompt a search for underlying immune deficiency.[31,69]

CRYPTOCOCCOSIS. *Cryptococcus neoformans* (see Chapter 190) is a yeast-like encapsulated fungus that is ubiquitous and is found commonly in soil enriched with bird feces. Primary infection is almost always via the respiratory tract by inhalation of airborne spores and usually is asymptomatic in healthy individuals. Organ transplant recipients are now the population at highest risk of developing disseminated disease, because improved antiretroviral agents have decreased the incidence in those with HIV disease.[71] Patients receiving high-dose systemic corticosteroids are another group susceptible to hematogenous spread and disseminated infection, while incidences in those with diabetes mellitus, chronic lymphocytic leukemia, chronic myeloid leukemia, multiple myeloma, and Hodgkin disease are lower. Cryptococcal disease in hematopoietic stem cell transplant recipients is very rare.[72] The central nervous system is most commonly involved during dissemination, although infection may occur in many organs including the lungs, bone marrow, heart, liver, spleen, kidneys, thyroid, lymph nodes, adrenal glands, and skin.

Cutaneous lesions occur in up to 20% of patients with disseminated infection, however, skin lesions may be present in two-thirds of organ transplant patients receiving tacrolimus.[73] In transplant patients, erythematous, edematous, warm, painful plaques on the extremities (clinically indistinguishable from bacterial cellulitis) have been reported most frequently (Fig. 29-12A).[74] Umbilicated papules (resembling molluscum contagiosum), nodules, pustules, vesicles, and ulcers also may occur (Fig. 29-12B).[75] Oral mucosal cryptococcal nodules and ulcerations also have been described. Lesions may be isolated or multiple and can be quite painful.

Figure 29-12 Cellulitis and subsequent necrosis (**A**) and molluscum-like lesions (**B**) of cutaneous cryptococcosis. (Used with permission from Jonathan Alexander, MD, Portland, OR and Yale Residents' slide collection, respectively.)

Although primary skin disease may occur in the absence of pulmonary infection, diagnosis of cutaneous cryptococcosis always warrants an investigation for systemic infection, especially because disseminated disease may not always be evident clinically.[76] Cerebrospinal fluid can be assessed for cryptococcal polysaccharide antigens. Budding encapsulated yeasts can be identified readily in skin biopsy specimens as well as in material obtained by a scraping of skin lesions. The yeast stain red with periodic acid-Schiff and mucicarmine stains and black with methenamine silver stain. India ink can be used to accentuate the capsule in a skin scraping. *Cryptococcus* can be isolated in culture of cutaneous tissue. The treatment of choice for cryptococcosis is a lipid formulation of amphotericin B with or without flucytosine. Fluconazole is used as alternative primary treatment and is the treatment of choice for prophylaxis in individuals at high risk for recurrent infection.[77]

HISTOPLASMOSIS. *Histoplasma capsulatum* (see Chapter 190) is a dimorphic fungus found in soil endemic to the central and eastern regions of the United States. As with cryptococcosis, inhalation of airborne spores causes primary pulmonary infection that usually leads to self-limited disease in otherwise healthy individuals. Disseminated disease is rare and most often occurs in individuals with deficiencies in cell-mediated immunity. In addition to pneumonia, immunosuppressed hosts may show fever, renal failure, central nervous system involvement, hepatosplenomegaly, lymphadenopathy, and myelosuppression.[78]

Mucocutaneous lesions occur in 5%–25% of patients with disseminated infection and may be an initial sign of disease. The head and neck region are favored and the oropharynx is the most common site. Mucosal lesions present with nodules or plaques that progress to ulcers with indurated borders. Skin findings are diverse and include molluscum-like papules, acneiform papules and pustules, and cellulitis.[15,79] The organism grows very slowly in culture so diagnosis is best achieved by direct examination of tissue. Numerous small, oval, yeast-like fungi can be seen within the cytoplasm of dermal macrophages. Antigen testing is also available, but cross-reaction can occur with blastomycosis and other fungal infections (though not with cryptococcus). The treatment of choice for disseminated histoplasmosis in an immunosuppressed host is intravenous amphotericin B. For patients who are not acutely ill, oral itraconazole may be used; itraconazole is also recommended for immunosuppressed patients to prevent recurrent disease.[78]

COCCIDIOIDOMYCOSIS. *Coccidioides immitis* (see Chapter 190), the causative agent of coccidioidomycosis, is endemic to soil in the southwestern United States, and infection is usually acquired through inhalation of spores, which causes pulmonary disease.[78] Although progressive primary infection may occur in immunosuppressed patients, reactivation of a prior, clinically unapparent infection is more common. The risks of dissemination and fatal infection are greater among men, pregnant women, non-Caucasians, and immunosuppressed patients with defects in cell-mediated immunity. Thus, disseminated coccidioidomycosis can occur in any immunocompromised patient who lives or has lived previously in an endemic area.

Immunosuppressed patients with disseminated disease may have fever, pneumonia, bone involvement, skin lesions, and/or meningitis. Mortality remains high at around 30%, but has improved with targeted prophylaxis in the organ transplant population.[80] Primary cutaneous lesions of coccidioidomycosis are extremely rare and usually resolve in healthy individuals, whereas lesions persist in immunocompromised patients. Morphologies are varied and include multiple verrucous papules, abscesses, and ulcerated papules and plaques. Nonspecific findings seen in systemic disease include erythema multiforme, urticaria, a maculopapular rash, and erythema nodosum.[15]

Definitive diagnosis of coccidioidomycosis is made by culture or demonstration of characteristic endosporulating spherules in smears or biopsy specimens. Serologic studies may prove helpful, but may give false-negative results in the immunocompromised. In disseminated infections in immunosuppressed hosts, treatments for life-threatening disease include amphotericin B until infection is controlled, followed by itraconazole or fluconazole. Immunosuppressed patients with meningeal disease may require lifelong therapy.[81]

BLASTOMYCOSIS. *Blastomyces dermatitidis* (see Chapter 190) is endemic to the soil of the Ohio and Mississippi river valleys. Infection is acquired through inhalation of spores. Immunosuppressed patients are prone to disseminated disease involving the lungs, bone, genital tract, and skin, although infection in this population is still rare. Skin is the most common extrapulmonary site of involvement.[15,78] Lesions appear as verrucous or ulcerated plaques with serpiginous borders located on the head, neck, or distal extremities. Ulcerative lesions begin as subcutaneous nodules and pustules.[82] Diagnosis is made on demonstration of broad-based, budding, thick-walled yeasts in exudates or skin scrapings from the edges of lesions or by tissue culture. In life-threatening disseminated infection, intravenous amphotericin B is the treatment of choice, whereas less severe disease is treated with oral itraconazole.[83]

OTHER FUNGAL INFECTIONS. *Alternaria* is a common saprophytic fungus that can cause opportunistic infection in the setting of organ transplantation, Cushing syndrome, autoimmune bullous disease, and lymphoproliferative disorder. Over half of the patients reported to have cutaneous alternariosis were taking systemic corticosteroids, and secondary increased skin fragility has been implicated as a risk factor. There are two routes of infection: traumatic inoculation and secondary colonization of a preexisting skin lesion. Presentations include indurated plaques, ulcers, and pustules.[84,85]

Penicillium marneffei is a dimorphic fungus that is endemic to Southeast Asia (see Chapter 190). Most infections are associated with HIV disease, but cases

in immunosuppressed patients residing or traveling to endemic areas have occurred.[86] Tinea versicolor and folliculitis caused by *Pityrosporum ovale* (also known as *Malassezia furfur;* see Chapter 189) may be more prevalent, widespread, and persistent in immunosuppressed hosts. In addition, *Pityrosporum* has been reported to cause indwelling catheter-associated fungemia in immunosuppressed hosts, especially in those receiving parenteral lipid preparations.[8]

VIRAL INFECTIONS

HERPES VIRUS INFECTION. Herpes viruses (see Chapters 193 and 194) include HSV-1, HSV-2, VZV, CMV, Epstein–Barr virus (EBV), human herpes virus 6 (HHV-6), HHV-7, and Kaposi sarcoma-associated herpes virus (KSHV or HHV-8). Infections are most prevalent in patients with acquired defects in cell-mediated immunity. Herpes viruses infect hosts for life and remain dormant in the nuclei of latently infected cells. Suppression of immunity often leads to reactivation (i.e., a latent to lytic switch).

Recurrent HSV-1, HSV-2, and VZV infections are common in cancer and posttransplant patients, with the majority experiencing reactivation with at least one of these three viruses. Clinically apparent HSV outbreaks occur in up to 68% of organ transplant patients not on prophylaxis.[87] Herpes zoster (recurrent VZV infection) is most likely to occur during the first year after transplantation with a 20–100-fold increased incidence in immunocompromised patients (approximately 10% incidence).[37,88] Although presentations can be identical to those in immunocompetent hosts, lesions atypical in morphology and distribution often occur. For example, in immunosuppressed hosts recurrent lesions due to HSV or VZV may be isolated, nondermatomal, disseminated, necrotic, ulcerative, or verrucous (Figs. 29-13 and 29-14). In the mouth, chronic recurrent HSV infection can form white plaques and can be confused clinically with candidiasis. Lesions can occur in atypical locations, such as the tongue. Severe pain often is associated with both skin and oral lesions, and postherpetic pain is common. Protracted clinical courses of recurrent HSV or VZV infection are also more common in the setting of immunosuppression. In short, any painful, eroded lesion in an immunocompromised patient, regardless of its distribution or age, should be evaluated for both HSV and VZV by Tzanck preparation, immunofluorescence testing for viral antigen, polymerase chain reaction testing, and/or viral culture. Importantly, systemic infection involving the lungs, central nervous system, liver, heart, and gastrointestinal tract may occur. Treatment with systemic acyclovir or a related antiherpesviral drug is always necessary. Prophylactic treatment to prevent recurrent episodes should be considered for individual patients if warranted. Foscarnet is the drug of choice for acyclovir-resistant viruses.[37]

Reactivation and recurrent disease associated with CMV are major causes of morbidity and mortality in patients with marked immunosuppression, occurring in 20%–60% of transplant recipients depending

Figure 29-13 Severe chronic herpes simplex infection in a patient receiving long-term, high-dose glucocorticoids for autoimmune disease.

Figure 29-14 Severe recurrent varicella zoster virus infection in a child with acute lymphocytic leukemia.

on the type of transplant and other risk factors.[37,89] Disease is most commonly caused by reactivation of preexisting CMV infection, although CMV may be transmitted from donor to host in solid organ transplantation. CMV also exerts indirect effects in transplant patients, contributing to an increase in graft loss and risk of other opportunistic infections. CMV retinitis, gastroenteritis, hepatitis, and pneumonitis are the most common clinical disease manifestations. Cutaneous lesions can occur in 10%–20% of patients and are varied and nonspecific, including ulcers, papules, vesicles, petechiae, and morbilliform eruptions. Oral ulcers caused by CMV, particularly on the lateral aspects of the tongue, are most common. Painful, punched-out perianal ulcers have been reported and coinfection with HSV can occur. Tzanck preparations of specimens from the bases of ulcers may show multinucleated giant cells, and CMV-infected dermal endothelial cells may be seen in tissue sections by routine microscopy, appearing as large cells with intranuclear inclusions surrounded by clear halos (owl-eye nuclei). In addition, CMV can be cultured from infected skin. The treatment of choice for systemic CMV disease is intravenous ganciclovir, although intravenous foscarnet, cidofovir, or CMV immunoglobulin also may be effective.[37,41] Prophylaxis of at-risk transplant patients is routine.[39]

HHV-6 and HHV-7, herpes viruses closely related to CMV, can also cause widespread multiorgan infection in immunosuppressed individuals. Disease itself is usually mild, but indirect effects of viral reactivation may allow other infections to occur and contribute to allograft failure.[90]

Unlike the other herpes virus infections, EBV and KSHV infections are associated with malignancies in the setting of immunosuppression. Specifically, chronic reactivated EBV infection is associated with non-Hodgkin lymphoma and other lymphoproliferative disorders, whereas chronic KSHV infection is associated with Kaposi sarcoma (KS), primary effusion lymphoma, and the plasmablastic variant of Castleman disease. Their neoplastic potential is discussed further later. Oral hairy leukoplakia is a unique presentation of EBV reactivation within oral mucosal epithelial cells, classically seen in patients with AIDS, but also seen in other immunosuppressed individuals (see Chapter 198).[37] Lesions appear as adherent, white, corrugated plaques on the lateral aspects of the tongue. Histologically, there is hyperkeratosis and vacuolated suprabasal epithelial cells. Oral hairy leukoplakia may respond to topical podophyllin or high-dose acyclovir, although it is usually asymptomatic and does not require treatment. It has been regarded as a poor prognostic indicator in HIV-infected individuals, but the clinical significance of oral hairy leukoplakia in transplant patients is not known.

HUMAN PAPILLOMAVIRUS INFECTION. Warts (see Chapter 196) caused by human papillomavirus (HPV) infection are a common problem in post-transplant patients and in others receiving long-term immunosuppressive drug therapy. The prevalence of warts increases with longer duration of immune compromise, with up to 95% of individuals affected 5 years after transplant surgery.[91] In this setting, lesions may be numerous, persistent, and difficult to eradicate. The morphology of the lesions may be typical or atypical. Atypical lesions appear as scaly macules and plaques, occur more commonly in sun-exposed areas, and are associated with HPV types observed in patients with epidermodysplasia verruciformis (e.g., HPV types 5 and 8). Several studies have reported that systemic retinoids (i.e., isotretinoin or acitretin) can prevent or decrease wart formation and prevent a variety of premalignant and malignant cutaneous lesions in post-transplant patients. In these patients, the association between HPV infection and cutaneous genital and non-genital squamous cell carcinoma (SCC) is complex, as discussed later.

HUMAN POLYOMAVIRUS INFECTION. Polyomaviruses are small double-stranded DNA viruses found in a variety of species including humans. The first two described, BK virus (BKV) and JC virus (JCV), were identified in the 1970s and cause nephropathy in kidney transplant patients and progressive multifocal leukoencephalopathy in immunosuppressed individuals, respectively. Neither produce skin lesions.[92] In 2008, another polyomavirus was identified in tumors from patients with the neuroendocrine tumor Merkel cell carcinoma (MCC; see Chapter 120 and later in this chapter), subsequently termed Merkel cell polyomavirus (MCPyV).[93] MCPyV can be found in 24%–89% of MCC with the highest rates in North American and European populations. Integration of the virus into MCC tumor genomes suggests a direct oncogenic role of MCPyV.[94] Risk factors for MCC include advanced age and excessive sun exposure, and the incidence is greatly increased in the setting of immunosuppression, especially in organ transplant recipients.[95]

PARASITIC INFESTATIONS: CRUSTED SCABIES

Crusted (or Norwegian or keratotic) scabies infestation (see Chapter 208) typically occurs in the settings of mental deficiency, malnutrition, or immunosuppression. Clinically, patients present with multiple widespread, thick, gray, or yellowish scaly plaques (eFig. 29-14.1 in online edition), with numerous mites present within lesions. Unlike in common scabies, pruritus may be minimal. Several courses of treatment with topical permethrin, as well as keratolytics, may be necessary to cure patients. Oral ivermectin is useful in these patients.[96]

CANCER

NONMELANOMA SKIN CANCER. Nonmelanoma skin cancer (NMSC; see Chapters 114 and 115) is the most common malignancy in adult solid organ transplant patients and causes significant morbidity and mortality. The overwhelming majority of these neoplasms are SCCs; however, the incidence of basal cell carcinomas and other cutaneous malignancies is

also increased.[97] For SCC, the risk may be 200 times higher in transplant patients than in the general population and increases exponentially with length of immunosuppression.[98,99] The cumulative incidence is a staggering 80% after 20 years of immunosuppressive therapy in renal transplant patients residing in Australia with its large amount of ultraviolet exposure.[100] The incidence of other epithelial proliferative diseases, including actinic keratoses, keratoacanthomas, porokeratosis, appendageal tumors, and sebaceous carcinomas, is greatly increased as well.

The pathogenesis of NMSC in posttransplant patients is multifactorial and has been studied and reviewed extensively.[99,101–103] Prior history of NMSC was the most important predictor of risk in one comprehensive study.[104] The distribution of lesions and the populations at highest risk suggest that sun exposure is one of the most important risk factors.[105] Risk also increases with age and is greater for those with fair skin type, those living near the equator, and those with documented histories of significant sun exposure. In addition, gene mutations in the tumor suppressor gene *p53* characteristic of those caused by ultraviolet radiation are found within NMSC in transplant patients.[106,107] The commonly used immunosuppressive medications, including azathioprine and the calcineurin inhibitors cyclosporine and tacrolimus, are not only directly carcinogenic, but their additional effects on the immune system diminish immune surveillance mechanisms that potentially serve to eradicate precancerous lesions. On the other hand, sirolimus which blocks the mammalian target of rapamycin (m-TOR) pathway, has chemoprotective effects, including blocking tumor growth and angiogenesis.[108] Switching from a calcineurin inhibitor to sirolimus-based therapy reduces the rates of internal malignancies and skin cancer in renal transplant patients.[109]

The role of HPV infection in organ transplant recipients is unclear. HPV is known to cause cervical and anal SCC and can be detected in cutaneous cancers of transplant patients (Fig. 29-15). Furthermore, epidermodysplasia verruciformis-associated HPV types (5, 8, and others) have been detected in cutaneous SCC, and there is suspicion that infections by these viruses may occur at an increased rate in immunosuppressed patients. However, asymptomatic infection has been identified in the general population, and thus it is unclear whether these HPV types are transcriptionally active and pathogenic in forming skin cancers in the setting of immunosuppression.[103,110–112]

Importantly, SCC in posttransplant patients can be clinically aggressive leading to increased morbidity and mortality than in the normal population. Local invasion, recurrence after primary treatment, and distant metastases are not uncommon and are all associated with a higher rate of mortality in organ transplant recipients.[113,114] Oral mucosal leukoplakia and oral SCC also occur more commonly in immunocompromised individuals.[99] Lip lesions are particularly common, which suggests a pathogenic role for sunlight in lesion formation.

Careful and regular examination of skin and oral mucosa by both patients and dermatologists is required for all transplant patients, with an emphasis on monitoring of potentially premalignant lesions (e.g., actinic keratoses, porokeratosis, leukoplakia) for morphologic changes and initiation of treatment as indicated. Ideally, patients would be treated for precancerous lesions before transplant surgery. All transplant patients should be advised to maximize sun precautions.[115] Oral retinoids, especially acitretin, have been used successfully to decrease the occurrence of new SCCs and actinic keratoses in transplant patients, but can be difficult to tolerate.[116] A range of dosages has been used, and good effects with minimal side effects have been reported at daily dosages of 0.2–0.4 mg/kg/day.[117] It is a common clinical observation that when the medication is discontinued, numerous cancerous lesions arise (described as a rebound effect).[118] Thus, when retinoids are considered for prophylaxis of NMSC, they should be considered as a long-term treatment.

Figure 29-15 Caucasian renal transplant patient with warts, actinic keratoses, and squamous cell carcinomas. (Used with permission from Jonathan Alexander, MD, Portland, OR.)

Recent studies have demonstrated that voriconazole, an oral broad-spectrum antifungal frequently used for the long-term management of chronically immunosuppressed patients, is associated with photosensitivity, accelerated photoaging, pseudoporphyria cutanea tarda, aggressive squamous cell carcinoma and melanoma. This accelerated cancer risk occurs in both children and adults. Thus, strict photoprotective measures should be recommended when voriconazole is used for prevention or treatment of fungal diseases.[119,120]

MELANOMA. The incidence of melanoma (see Chapter 124) and widespread atypical melanocytic nevi may be increased in transplant recipients and in other immunosuppressed patients.[97] In particular, children who have had transplants appear to be at higher risk for the development of melanoma (15% of all skin cancers) compared with adults (6% of all skin cancers).[121] Most melanomas arise from precursor nevi

in these patients. Melanomas have also been reported to originate from donor organs causing metastatic disease in graft recipients.[122]

LYMPHOMA. Lymphoproliferative disorders (see Chapter 145) are common devastating complications following transplantation and are often related to EBV-mediated proliferation of B-cells. Extranodal involvement is common, including involvement of the gastrointestinal tract, lungs, central nervous system, the transplanted organ, and skin.[4,123] Cutaneous lesions present as violaceous macules to firm papules and plaques, similar to presentation in immunocompetent individuals. Lymphoma with purely cutaneous involvement is rare after transplantation. Most reported cases represent lymphomas of B-cell origin and are occasionally $CD30^+$. The presence of EBV is often detected. Prognosis is generally better if there is cutaneous involvement alone, perhaps due to the ease of detection.[37,124] Cutaneous T-cell lymphomas account for 30% of cases of cutaneous lymphomas in transplant patients. EBV is not associated with development in these patients. Clinical presentation is similar to that in nontransplant patients, except that there is an increased incidence of erythroderma. Prognosis is also worse than for cutaneous T-cell lymphoma in the general population.[125]

KAPOSI SARCOMA. The occurrence of KS (see Chapter 128) is increased in patients receiving immunosuppressive therapy after organ transplantation, with an incidence of 0.5%–5%. Risk factors in transplant recipients include male sex and Mediterranean, Jewish, Arabic, Caribbean, or African descent, as in the classic form of the disease.[37,126] All cases of KS, regardless of clinical or geographic setting, are associated with KSHV infection. The vast majority of patients with posttransplant KS are KSHV seropositive before transplantation. Rarely, posttransplant KS can occur when KSHV-infected organs are transplanted into KSHV seronegative recipients.[126,127]

Clinically, skin lesions of posttransplant KS are identical to other forms of KS. As in classic KS, transplant-associated disease is found most commonly on the lower legs and feet, although the groin and oral cavity are also common locations. Typically, early KS lesions are deep red to violaceous macules or patches. With time, lesions develop into papules, plaques, nodules, or tumors. Visceral involvement occurs in 25% of renal transplant patients and 50% of those with heart or lung transplants.[128] Reduction in immunosuppressive treatment often causes disease regression, although these patients remain at risk for developing KS at a later time if immunosuppressive therapy is reinstituted. Recently, regression of KS lesions in transplant patients after switching to a sirolimus-based regimen have been reported.[129] Additional treatments include local excision or radiation therapy, intralesional therapy, and systemic chemotherapy.

MERKEL CELL CARCINOMA. MCC (see Chapter 120) is an unusual, aggressive skin cancer of neuroendocrine cells (Fig. 29-16). The incidence of MCC is increased and the cancer presents at a younger age in transplant recipients.[95] Sentinel lymph node biopsy is becoming part of the standard of care in this population due to the high rate of lymph node metastases. Wide surgical resection and adjuvant radiation is recommended. The mortality rate is high at 56% at 2 years after diagnosis, which is nearly twice the rate for immunocompetent individuals. Less than 10% of individuals with distant metastasis survive longer than 3 years. There are early suggestions that MCC tumors positive for MCPyV DNA convey a better disease course than those lacking evidence of viral oncogenesis.[92,130,131]

SECTION 5

Inflammatory Diseases Based on Neutrophils and Eosinophils

Chapter 30 :: Regulation of the Production and Activation of Neutrophils

:: Steven M. Holland

REGULATION OF THE PRODUCTION AND ACTIVATION OF NEUTROPHILS AT A GLANCE

- Human bone marrow commits enormous resources to the creation of neutrophils, producing approximately 10^{11} daily with a circulating half-life of approximately 7.5 hours and tissue survival for 1–2 days.
- Neutrophils are absolutely required for the prevention of infection and are not yet amenable to significant external replacement therapy.
- The neutrophil not only plays a central role in host defense, it can be responsible for significant tissue damage as well.
- The pathophysiology of the neutrophil indicates pathways, which can be exploited to enhance protection from infection. Selective abrogation of those pathways that are injurious in certain settings is also possible.
- Regulation of neutrophil responses in the skin is a major concern.

NEUTROPHILS

This section presents an overview of neutrophil biology and function and uses a few well-characterized defects of myeloid function as illustrations.

ONTOGENY AND DEVELOPMENT

Similar to other components of the hematopoietic system, the neutrophil is ultimately derived from a pluripotent hematopoietic stem cell. The development of the myeloid stem cell is largely determined by ambient cytokines and reflected in its surface markers, morphology, and functional characteristics. The myeloblast is fully committed to the neutrophil lineage and is the first morphologically distinct cell in neutrophil development. Subsequent stages of neutrophil development occur under the influence of granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF). Four to six days are required for maturation through the mitotic phase to the myelocyte, and 5–7 days more for the myelocyte to develop into a mature neutrophil, including the metamyelocyte and band stages, before emerging as a fully developed neutrophil. Development of neutrophils through the myelocyte stage normally occurs exclusively in the bone marrow, which is composed of approximately 60% developing neutrophils. The mature neutrophil measures 10–12 μm and has a highly condensed, segmented, multilobulated nucleus, usually with three to five lobes. Although 10^{11} neutrophils are generated daily, this number can rise tenfold in the setting of infection. The calculated circulating granulocyte pool is 0.3×10^9 cells/kg blood and the marginated pool is 0.4×10^9 cells/kg blood, comprising only 3% and 4% of the total granulocyte pool, respectively. The bone marrow releases 1.5×10^9 cells/kg blood/day to this pool but keeps 8.8×10^9 cells/kg blood in the marrow in reserve. An additional reserve of immature and less competent neutrophils, 2.8×10^9 cells/kg blood, is also available.

G-CSF is critically important for neutrophil production.[1] Mice deficient in G-CSF show reduced neutrophil numbers and cannot upregulate neutrophil numbers in response to infection. Interestingly, G-CSF production is under the influence of IL-17, a cytokine of importance in regulation of epithelial defenses.

BIOLOGIC FUNCTIONS

GRANULE CONTENT AND FUNCTION. (Table 30-1.) Neutrophils are characterized by cytoplasmic granules and partially condensed nuclei. Granules are first found at the promyelocyte stage.[2] Primary (azurophilic) granules are the first to arise, measure

TABLE 30-1

approximately 0.8 µm in diameter, and contain numerous antimicrobial products including lysozyme, myeloperoxidase, and defensins.[3] Primary granules are only synthesized at the promyelocyte stage. The promyelocyte gives rise to the myelocyte, the last cell of the neutrophil lineage with proliferative potential. Therefore, cytokines or agents that increase total neutrophil production must act at or before the myelocyte stage. The smaller eosinophilic secondary (specific) granules appear during the myelocyte stage. These granules measure about 0.5 µm in diameter and contain lactoferrin, collagenase, gelatinase, vitamin B_{12}-binding protein, and complement receptor 3 (CR3; CD11b/CD18). $gp91^{phox}$ and $p22^{phox}$ comprise the specific granule component cytochrome b_{558}, defects in which cause chronic granulomatous disease (CGD), characterized by infections with particular catalase-producing bacteria. Gelatinase also cleaves and potentiates the activity of the chemokine interleukin-8 (IL-8). Because primary granules are synthesized early and distributed to daughter cells during division, they are eventually outnumbered by about 3:1 by the specific granules, which are produced throughout the myelocyte stage.

Granules fuse in a sequential fashion with incoming phagocytic vacuoles, such as those containing ingested bacteria. Secondary granules fuse to the phagosome within the first 30 seconds after ingestion and release their enzymes, many of which function best at neutral or alkaline pH. By 3 minutes after ingestion, the primary granules have fused to the phagolysosome leading to rapid lowering of the intravacuolar pH. For objects too large to be ingested, or certain stimuli, degranulation to the cell surface occurs with release of granule contents into the surrounding environment. This can be inferred by detection of lactoferrin levels in blood.

An example of disordered granule biogenesis is Chédiak–Higashi syndrome (CHS), a rare autosomal recessive disorder with abnormal pigmentation due to a generalized abnormality of primary granule and lysosome formation (see Chapter 143).

NEUTROPHIL-SPECIFIC GRANULE DEFICIENCY. Neutrophil-specific granule deficiency is a rare, autosomal recessive condition clinically characterized by a profound susceptibility to bacterial infections. There is a paucity or absence of neutrophil-specific granules, specific granule proteins (e.g., lactoferrin) and their respective messenger RNAs, and very low levels of the primary granule products defensins and their messenger RNAs. Specific granule deficiency is due to loss of the transcriptional factor CCAAT/enhancer binding protein ε (CEBPε), which is essential in normal myeloid development. Acquired abnormalities of neutrophil granules are seen in some myeloid leukemias, in which primary granule contents may be aberrantly accumulated (e.g., Auer rods in acute myelogenous leukemia).

TISSUE TRAFFICKING

CHEMOATTRACTANTS AND CHEMOTAXIS. Metchnikoff discovered over a century ago that

neutrophils move toward very slight gradients of chemical signals, now termed *chemoattraction*. The "classic" chemoattractants are *N*-formylmethionyl-leucyl-phenylalanine (fMLF), complement factor 5a (C5a), leukotriene B_4, and platelet-activating factor (PAF). More recently, chemokines (*chemo*attractant cyto*kines*), a class of small (<10 kDa) extremely active chemoattractant proteins have been identified (see Chapter 12).

IL-8 is a potent chemoattractant and neutrophil activator (see Chapter 12). Its blockade by neutralizing antibody in rabbit models of pulmonary inflammation prevented neutrophil accumulation and reperfusion injury, confirming its central role in neutrophil recruitment to sites of inflammation. Cellular sources for IL-8 include neutrophils, monocytes, T cells, B cells, natural killer cells, basophils, eosinophils, fibroblasts, endothelial cells, keratinocytes, and smooth muscle. Exudative neutrophils are particularly effective at synthesizing IL-8, probably through a calcium-regulated mechanism.

Exuberant neutrophil function is implicated in Sweet syndrome (acute febrile neutrophilic dermatosis) as shown by the frequent association of the syndrome with hematologic malignancies, dysmyelopoiesis, and sometimes with the use of G-CSF (see Chapter 32).

The classic chemoattractants and chemokines use similar receptors that have in common seven transmembrane regions, an extracellular amino terminal domain, and transduce their signals through pertussis toxin-sensitive heterotrimeric G proteins. These are the same type of receptors through which light, neuropeptides, and neurotransmitters signal. Chemoattractant receptor signaling entails exchange of bound guanine diphosphate for guanine triphosphate by the α subunit of the heterotrimeric G protein, which in turn leads to the dissociation of the β–γ subunit of the complex, stimulation of phospholipase C, and generation of inositol triphosphate and diacylglycerol from phosphatidylinositol bisphosphate. Inositol triphosphate stimulates the release of calcium from intracellular "calciosomes," whereas diacylglycerol activates protein kinase C. Extracellular calcium also enters the cell, preparing it for subsequent movement, generation of oxidants, and secretion of vesicles.

Ras-related guanosine triphosphatases of the ρ superfamily are also involved in actin cytoskeletal regulation and adhesion. Phosphatidylinositol 3-kinase is activated by rho and ras and is necessary for the neutrophilic respiratory burst, adhesion, endothelial transmigration, and chemotaxis. Mitogen-activated protein (MAP) kinases are serine/threonine kinases that include p38, Erk1, Erk2, and Jnk and are involved in neutrophil signaling and adhesion. Inhibition of p38 impairs chemotaxis and tumor necrosis factor (TNF)-α-mediated superoxide production, adhesion, and release of secondary granules. Erk activation is required for neutrophil homotypic aggregation. Salicylates inhibit neutrophil adhesion through Erk inhibition.

Several chemokine receptors also function as requisite human immunodeficiency virus (HIV) coreceptors. Mutations in the chemokine receptor CCR5 that are protective against HIV infection led to development of chemokine receptor blockers for treatment of HIV infection (maraviroc and vicriviroc).

ADHESION. Neutrophils exist as free-flowing (those which are sampled on blood drawing) and marginated cells (those which are attached to the endothelium or are traversing the lung, skin, or other tissues). Neutrophils rolling along the endothelium recognize sites of activation (e.g., chemokine expression), adhere to those sites, and traverse the endothelium to enter the tissue and fight infection. Leukocyte physical interaction with endothelium and other leukocytes is mediated by integrins, selectins, and intercellular adhesion molecules (ICAMs; Fig. 30-1).

Elaboration of chemoattractants or display of activation markers on endothelium triggers leukocyte high affinity binding by β_2 integrins, heterodimeric surface molecules largely stored in the secondary granules of neutrophils that are displayed on the cell surface upon leukocyte activation. There are three β_2 integrin heterodimers comprised of different α chains, CD11a, -b, and -c, and a common β chain, CD18. Each CD11/CD18 complex has separate and overlapping activities. CD11a/CD18 [leukocyte function-associated molecule 1 (LFA-1)] binds to other leukocytes and mediates tight adhesion to the endothelium through ICAM-1 and ICAM-2. CD11b/CD18 (Mac-1, Mo-1, or CR3) binds to the inactivated form of the third component of complement (C3bi) and thereby facilitates complement-mediated phagocytosis. CD11b/CD18 also binds to bacteria directly, to fibrinogen, and to endothelium through ICAM-1. The divalent cations Ca^{2+} and Mg^{2+}/Mn^{2+} mediate adhesion through β_2 integrin "A" domains containing a metal ion-dependent adhesion site. CD11b/CD18 may also induce the expression of the β_1 integrin very late antigen 6 [VLA-6 (CD49f/CD29)], derived from neutrophilic granules, to aid in tissue infiltration. The integrin-associated protein (CD47), expressed on neutrophils and endothelial and epithelial cells, is also involved in the transendothelial and transepithelial migration of neutrophils.[4] Metalloproteinases may be involved in cleavage of L-selectin, allowing neutrophil migration through the basement membrane.

Absence of CD18 causes lack of CD18/CD11 heterodimers and is called *leukocyte adhesion deficiency type 1* (*LAD1*). Neutrophils lacking CD18 roll normally along the endothelium but are unable to stick to the vessel wall or exit the circulation after chemotactic stimulation. Absence of LFA-1 (CD11a/CD18) makes neutrophils unable to bind tightly to and traverse activated endothelium to infected areas. Therefore, LAD1 patients have chronic neutrophil leukocytosis, partly from inability of neutrophils to bind tightly to endothelium and exit the circulation, thus leading to a reduction in the marginated pool and an increase in the circulating pool of neutrophils. Poor neutrophil penetration to sites of bacterial invasion leads to necrotic ulcers that lack neutrophils on biopsy. Absence of Mac-1 (CD18/CD11b or CR3) leads to inability to perform complement-mediated phagocytosis, although antibody-mediated phagocytosis remains intact.

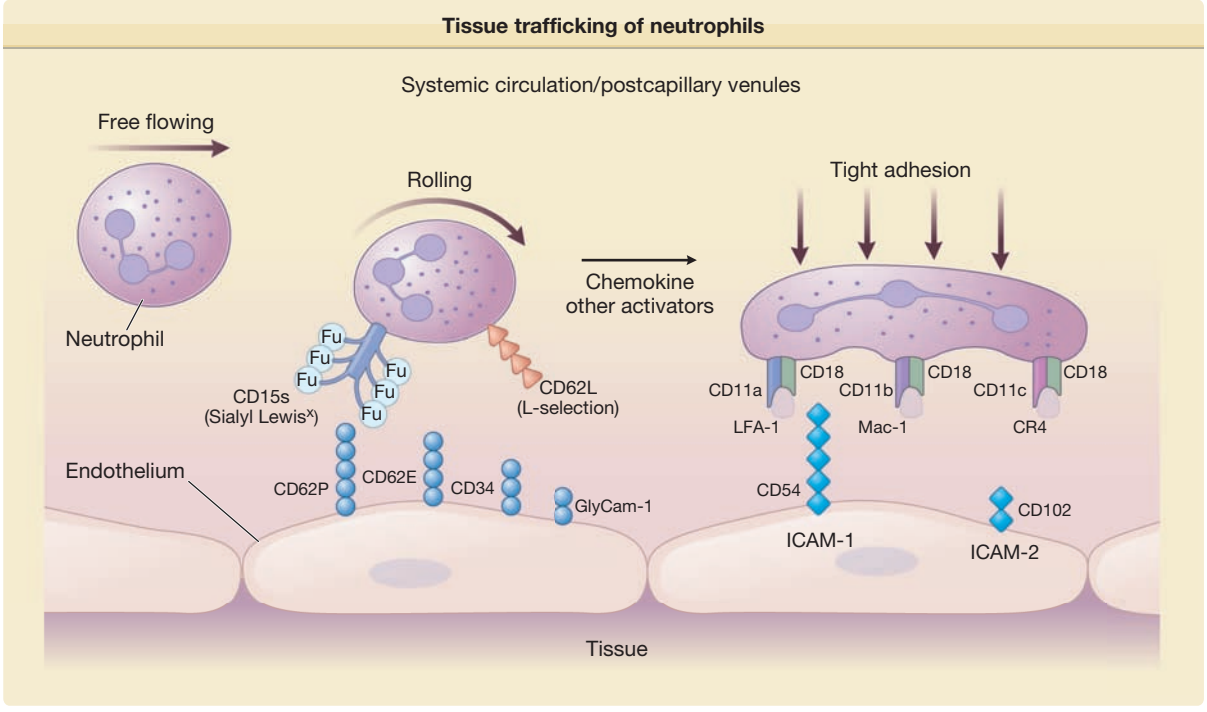

Figure 30-1 Tissue trafficking of neutrophils. The interaction of selectins and integrins on the leukocyte surface with their endothelial addressins is depicted (neutrophils on the top and eosinophils on the bottom). The leukocytes are in a laminar flow pattern. Following tissue signals that activate endothelial selectins and glycoproteins, a subset of leukocytes begin to roll along the vascular wall. For the neutrophil, this typically involves the interaction of CD15s with CD62P (P-selectin) and CD62E (E-selectin) on the endothelial cell or CD62L (L-selectin) with CD34 or glycosylation-dependent cell adhesion molecule 1 (GlyCAM-1) on the endothelial cell. Abnormalities in fucosylation of CD15s cause leukocyte adhesion deficiency 2 (LAD2). Activation of leukocytes by chemoattractants leads to the expression of integrins with higher avidity conformations. In the case of the neutrophil, the relevant integrins are the β_2 family members [lymphocyte function-associated antigen 1 (LFA-1), Mac-1, and CR4]; whereas eosinophils express a more limited number of β_2 family members (LFA-1 and Mac-1), but also express a β_1 integrin VLA-4 and β_7 integrin ($\alpha_4\beta_7$). The β_2 integrins bind to ICAM-1 and ICAM-2, whereas the β_1 and β_7 integrins bind VCAM-1 and mucosal addressin cell adhesion molecule-1 (MadCAM-1), respectively. Defects in CD18, the β chain of the β_2 integrins, lead to the inability of neutrophils to exit the circulation at sites of infection and is called leukocyte adhesion deficiency 1. Interestingly, eosinophils, monocytes, and lymphocytes are observed at sites of infection in these patients, as these cells can use β_1 integrins to mediate the firm adhesion step required for leukocyte transendothelial migration. See figure in Chapter 31 for a similar analysis of eosinophil function.

LAD1 is diagnosed by fluorescent-activated cell sorting (FACS), which shows levels of CD18 and its coexpressed molecules CD11a, CD11b, and CD11c. Severe LAD1 (<0.5% of normal protein expression) is a disorder manifested by delayed umbilical stump separation, umbilical stump infection, persistent leukocytosis in the absence of active infection (>15,000/μL), and severe, destructive periodontitis with the loss of teeth and alveolar bone. Recurrent infections of the skin, upper and lower airway, bowel, perirectal area, and septicemia are common and usually due to *Staphylococcus aureus* or Gram-negative rods. Severe LAD1 patients should receive bone marrow transplantation in early childhood. Moderate LAD1 (2.5%–10.0% of normal protein expression) patients tend to be diagnosed later in life and have fewer life-threatening infections. Leukocytosis, delayed wound healing, and periodontal disease are still common.

Neutrophil "rolling" along the endothelium is mediated through selectins, surface glycoproteins on the endothelium, and sialyl-Lewis X (CD15s), a surface glycoprotein on neutrophils (see Fig. 30-1). Endothelial cells express E-selectin (CD62E) and P-selectin (CD62P), whereas leukocytes express L-selectin (CD62L). Although endothelial E-selectin and P-selectin bind to the sialyl-Lewis X (CD15s) antigen on neutrophils, the neutrophil molecule L-selectin probably binds to distinct antigens on endothelium, including CD34, and is highly sensitive to glycosylation. L-selectin is shed by neutrophils on activation, thereby allowing neutrophil migration into sites of inflammation. Cross-linking of L-selectin on neutrophils results in superoxide generation and may result in upregulation of TNF-α, IL-8, and tyrosine phosphorylation and activation of MAP kinase. LAD2 is the disease that occurs when CD15s is improperly fucosylated. These patients have neutrophilia, recurrent

pulmonary, periodontal, and cutaneous infections, and abnormal chemotaxis. The defect is in the gene *SLC35C1*, a GDP-fucose transporter. Because the disease affects sugar transport it is now classified as a congenital disorder of glycosylation (CDG), and known as CDG IIc. Interestingly, although infections are common early in life, LAD2 (CDG IIc) patients appear to improve with age. Administration of oral fucose to some patients with LAD2 has been inconsistently therapeutic. Most patients also have mental retardation, short stature, distinctive facies, and the Bombay (hh) blood phenotype, indicating the multiple systems in which fucosylation is critical. LAD3 (previously known as LAD1 variant) is associated with a syndrome like Glanzmann's thrombasthenia, and is due to mutations in *KINDLIN3 (FERMT3)*, a molecule responsible for β1, β2, and β3 integrin activation in leukocytes and platelets leading to recurrent infections and bleeding.

The CD18 integrin pathway is critical for inflammation in the skin, but not necessary for accumulation of neutrophils in the lung or peritoneum. Therefore, although CD18-dependent pathways are critical for cutaneous inflammation, CD18-independent pathways exist for pulmonary and peritoneal inflammation. Further, in the setting of congenital absence of CD18, compensatory pathways exist in the mouse to respond to peritoneal inflammation.

PHAGOCYTOSIS. Phagocytosis is the culmination of object recognition, binding, signaling, adherence, cytoskeletal remodeling, engulfment, and membrane fusion. Two mechanisms are well characterized, one mediated by immunoglobulin and the other mediated by complement.

Receptors for the Fc portions of immunoglobulin G [IgG (FcγR)] are present on many components of the cellular immune response, including neutrophils, monocytes, macrophages, eosinophils, and basophils. FcγRI (CD64) is a receptor for IgG1 and IgG3 on monocytes, macrophages, and eosinophils and is upregulated on neutrophils after interferon-γ (IFN-γ) stimulation. FcγRII (CD32) binds IgG with rather low affinity, and prefers IgG1 and IgG3. FcγRIII (CD16) binds IgG1 and IgG3 with intermediate affinity. Neutrophil FcγRIIIB is bound to the membrane through a glycan phosphatidyl inositol linkage, which is largely cleavable by phosphatidyl inositol-specific phospholipase C. As FcγRIIIB has no cytoplasmic domain, its role in signal transduction may be through association with FcγRII. Cross-linking of these receptors by antibody leads to rapid engulfment of targets with the release of granule contents and oxygen metabolites into the phagolysosome. If the target is too large, degranulation occurs against the antibody-coated surface.

The complement receptors CR1 and CR3 are expressed on the surfaces of neutrophils, eosinophils, and basophils. Complement receptor 1 is designated *CD35* and is found on many cell types. It binds C3b and enhances its degradation to C3dg by factor I, thereby removing that molecule from further activation of the alternative pathway. CR3, CD11b/CD18, binds iC3b and fibrinogen as well as certain bacteria, parasites, and fungi. CR1 and CR3 are not per se able to stimulate phagocytosis, but in the presence of a second signal, such as one given through FcγR or by cytokines, phagocytosis proceeds.

MECHANISMS OF KILLING. Neutrophil granules contain enzymes and proteins for killing ingested bacteria and fungi. Some of these bactericidal mechanisms are dependent on the generation of oxygen metabolites for microbicidal activity, but others are not. In addition to mobilizing their own resources, neutrophils produce a multitude of cytokines that stimulate and attract other phagocytes as well as lymphocytes.

OXYGEN-INDEPENDENT PATHWAYS. Bactericidal/permeability-increasing protein (BPI) is a highly potent antibacterial granule protein synthesized and stored in the primary granules. It is a highly basic (isoelectric point >9.6) protein of 452 amino acids and approximately 58 kDa. Sequence homology to lipopolysaccharide (LPS)-binding protein, a critical endotoxin binding acute-phase reactant, suggests that it acts by directly binding to LPS. BPI is cytotoxic to Gram-negative bacteria at concentrations as low as 10^{-9} M, but much less effective against Gram-positive organisms. Binding to LPS leads to insertion of BPI into the outer membrane of the organism and eventual insertion into the inner membrane. Arrest of bacterial growth is solely dependent on the *N*-terminal half of the molecule. The *C*-terminal fragment serves as an anchor to the membrane. BPI appears to act inside the phagolysosome. Not all Gram-negative rods are sensitive to BPI, especially *Burkholderia (Pseudomonas) cepacia* and *Serratia marcescens*, pathogens in patients who lack oxidative killing.

Defensins are small (<4 kDa) cationic proteins in the primary granules of neutrophils involved in killing ingested Gram-positive and Gram-negative bacteria. Defensins are synthesized during the promyelocyte/myelocyte stage as prepropeptides, stored predominantly in a dense subset of the primary granules as propeptides, and released during neutrophil degranulation. Defensins prefer an actively metabolizing target and can kill transformed mammalian cells as well as prokaryotes and yeasts. Defensins and BPI act synergistically against Gram-negative bacteria. Defensins are reduced in CHS but absent in specific granule deficiency.

Proteinase 3 is the antigen against which the antineutrophil cytoplasmic antibody is directed in Wegener granulomatosis (see Chapter 164). It is found predominantly in primary granules but is also in secondary and secretory granules. Synthesis and surface display are upregulated by cytokines such as TNF-α. Elastase is a myeloid serine protease in primary granules that has remarkable roles in host defense. Mice with elastase defects have decreased resistance to Gram-negative bacteria. However, human neutrophil elastase deficiency causes the syndromes of severe congenital neutropenia and cyclic neutropenia. Phospholipase A2

is also found in neutrophil granules, where its various isoforms act both directly and synergistically with BPI to kill intracellular bacteria.

Lactoferrin is an iron-binding protein present in specific granules and in mucosal secretions. When released into the phagolysosome, lactoferrin binds iron and inhibits the growth of phagocytosed bacteria and some fungi. The mechanisms through which lactoferrin exerts its antimicrobial action probably include the depletion of iron from an organism's environment, but iron binding-independent antimicrobial activities and direct immunomodulatory effects are also reported. Lactoferrin is readily released into the circulation after burns and experimental endotoxemia, presumably from neutrophil degranulation.

OXYGEN-DEPENDENT PATHWAYS. Neutrophils can produce toxic oxygen metabolites through the reduced nicotinamide dehydrogenase phosphate (NADPH) oxidase complex, which typically is assembled in the wall of the phagolysosome. The NADPH oxidase catalyses the addition of an electron to molecular oxygen, leading to the formation of superoxide anion. Superoxide in turn is converted to hydrogen peroxide by superoxide dismutase. Inside the phagolysosome, the primary granule component myeloperoxidase converts hydrogen peroxide to hypohalous acid by the addition of a halogen (chloride in neutrophils forms bleach, bromide in eosinophils). The NADPH oxidase is a multiprotein complex, which is maintained in separate membrane-bound and cytosolic compartments. On cell activation, the cytosolic components translocate to the phagolysosome membrane, resulting in an active NADPH oxidase, which can produce the respiratory burst.

The components of the NADPH oxidase are named *phox* (*ph*agocyte *ox*idase) proteins. $p22^{phox}$ and $gp91^{phox}$ are the α and β chains, respectively, of the cytochrome b558 complex, which resides in the wall of the secondary granule. The cytosolic compartment contains three factors, $p47^{phox}$, $p67^{phox}$, $p40^{phox}$ and the small guanine nucleotide (guanine triphosphate) binding protein *rac*. Assembly of the NADPH complex is caused by diverse stimuli. $p47^{phox}$ and $p67^{phox}$ contain *src*-homology type 3 domains (SH3 boxes), which bind to proline-rich targets in themselves and in other members of the NADPH complex. Stimulation leads to structural changes in $p47^{phox}$ that promote its interaction with $p22^{phox}$ through $p47^{phox}$ SH3 domains and $p22^{phox}$ *C*-terminal proline-rich sequences.

Pathologic mutations in the five required components impair the generation of phagocyte superoxide and cause CGD, a disease characterized by recurrent life-threatening infections with bacteria and fungi and exuberant granuloma formation (see Chapter 143).[5]

PHARMACOLOGIC MANIPULATION

When neutrophils are overrecruited into neutrophilic dermatoses, they can produce reactive oxygen intermediates, activate proteinases, and release chemotactic cytokines, which can contribute to tissue injury and inflammation. Therefore, it makes sense to aim treatment to suppress the generation of reactive oxygen intermediates, to inhibit neutrophil adhesion and chemotaxis, and to suppress the release of lysosomal enzymes and chemotactic factors.

Dapsone is often used for chronic neutrophilic dermatoses such as dermatitis herpetiformis, subcorneal pustular dermatosis, or erythema elevatum diutinum (see Chapter 225). Dapsone suppresses neutrophil adherence and subsequent migration, is a successful scavenger of reactive oxygen intermediates, and interferes with the myeloperoxidase-halide system and leukocyte-mediated cytotoxicity. Thalidomide reduces inflammation through inhibition of TNF-α and subsequent neutrophil–endothelial adhesion and reactive oxidant generation (see Chapter 235). Dapsone and thalidomide both inhibit the proinflammatory cytokine TNF-α, which activates neutrophils through upregulation of complement receptors (CR3, CR4) and endothelial adhesion molecules, ICAM-1 and E-selectin. Colchicine inhibits neutrophil chemotaxis, release of lysosomal enzymes, and production of reactive oxidants and is therefore considered for Sweet syndrome and neutrophilic bullous dermatoses. Antibiotics such as tetracyclines, macrolides, and metronidazole also have antioxidant properties and interfere with neutrophil chemotaxis. In addition to its antioxidant activity, sulfasalazine induces neutrophil apoptosis and enhances adenosine release at sites of inflammation, making it especially useful in pyoderma gangrenosum.

Chapter 31 :: Regulation of the Production and Activation of Eosinophils

:: Kristin M. Leiferman, Lisa A. Beck, & Gerald J. Gleich

EOSINOPHILS AT A GLANCE

- Eosinophils are bone marrow-derived cells that circulate transiently and normally account for up to 6% (up to 400–600 per mm^3) of circulating blood leukocytes.
- Eosinophils primarily are tissue dwelling cells, but only in certain tissues in humans, with an average tissue life span of 2–5 days that may be increased with eosinophil survival factors for up to 14 days.
- As proinflammatory cells, the presence of eosinophils within most tissues is associated with pathological states that include infections, allergic reactions and atopic diseases, fibrotic disorders, reactive eosinophilias, and hypereosinophilic syndromes.
- Eosinophils play a role in innate and adaptive immune responses, which may explain why they are present in normal, noninflamed tissues such as the gastrointestinal tract and lymphoid tissues.
- This section reviews the biologic actions of eosinophils with particular focus on what controls eosinophil production, activation, and tissue trafficking.
- Pharmacologic manipulation of eosinophil inflammation is possible as new, more specific strategies are emerging.

EOSINOPHILS

ONTOGENY AND DEVELOPMENT

Eosinophils develop in the bone marrow from multipotential, stem cell-derived $CD34^+$ myeloid progenitor cells in response to eosinophilopoietic cytokines and growth factors (see Fig. 31-1). They are released into the circulation as mature cells.[1–3] Important stimulatory cytokines and growth factors for eosinophils include interleukin (IL)-3, granulocyte macrophage colony stimulating factor (GM-CSF), and IL-5. Activated T cells likely are the principal sources of IL-3, GM-CSF, and IL-5 that induce eosinophil differentiation in bone marrow. However, depending on pathogenic stimuli, eosinophilopoietic cytokines may be released by other cell types, including mast cells, macrophages, natural killer cells, endothelial cells, epithelial cells, fibroblasts, and even eosinophils, themselves.[4] IL-3 and GM-CSF are pluripotent cytokines that have effects on other hematopoietic lineages. IL-5 is the most selective eosinophil-active cytokine, but it is relatively late acting. Although it is both necessary and sufficient for eosinophil differentiation, IL-5 demonstrates maximum activity on the IL-5 receptor (IL-5R)-positive eosinophil progenitor pool that first is expanded by earlier acting pluripotent cytokines such as IL-3 and GM-CSF[4]; expression of the high affinity IL-5R is a prerequisite for eosinophil development. Exodus from the bone marrow also is regulated by IL-5. IL-3, GM-CSF, along with IL-5, promote survival, activation, and chemotaxis of eosinophils through binding to receptors that have a common β chain (CD131) with IL-5R, and unique α chains. See eTable 31-0.1 in online edition for designations of many factors involved in eosinophil biology.

INTERACTIONS OF EOSINOPHILIC FACTORS AND CYTOKINES AND INTRACELLULAR SIGNALING

The interactions of eosinophilopoietic factors with their receptors stimulate a cascade of complex biochemical events through signal transduction. Signaling events progress in four steps: (1) juxtamembranous signaling in which membrane-anchored tyrosine kinases and lipid kinases are activated; (2) signal interfacing which serves to transduce juxtamembranous signals to cytosolic signals; (3) mobile signaling in which cytosolic signaling molecules translocate from the receptor site to other cellular compartments including the nucleus, mitochondria, and cytoskeleton; and (4) transcription activation resulting from nuclear translocation and initiation of gene transcription. Studies have shown the pivotal role of IL-5 in immune responses involving eosinophils through receptor-driven signaling.[20] IL-5 binds to the α chain of the IL-5R and induces recruitment of the common β (βc) chain to IL-5R. Janus kinase (JAK)2 tyrosine kinase is constitutively associated with IL-5Rα, and JAK1 tyrosine kinase with IL-5Rβc; both are activated with IL-5 binding as part of the juxtamembranous step. Lyn and Fes are other tyrosine kinases involved in the first step; these tyrosine kinases also are activated by IL-3 and GM-CSF. Adaptor proteins, *src* homologues and

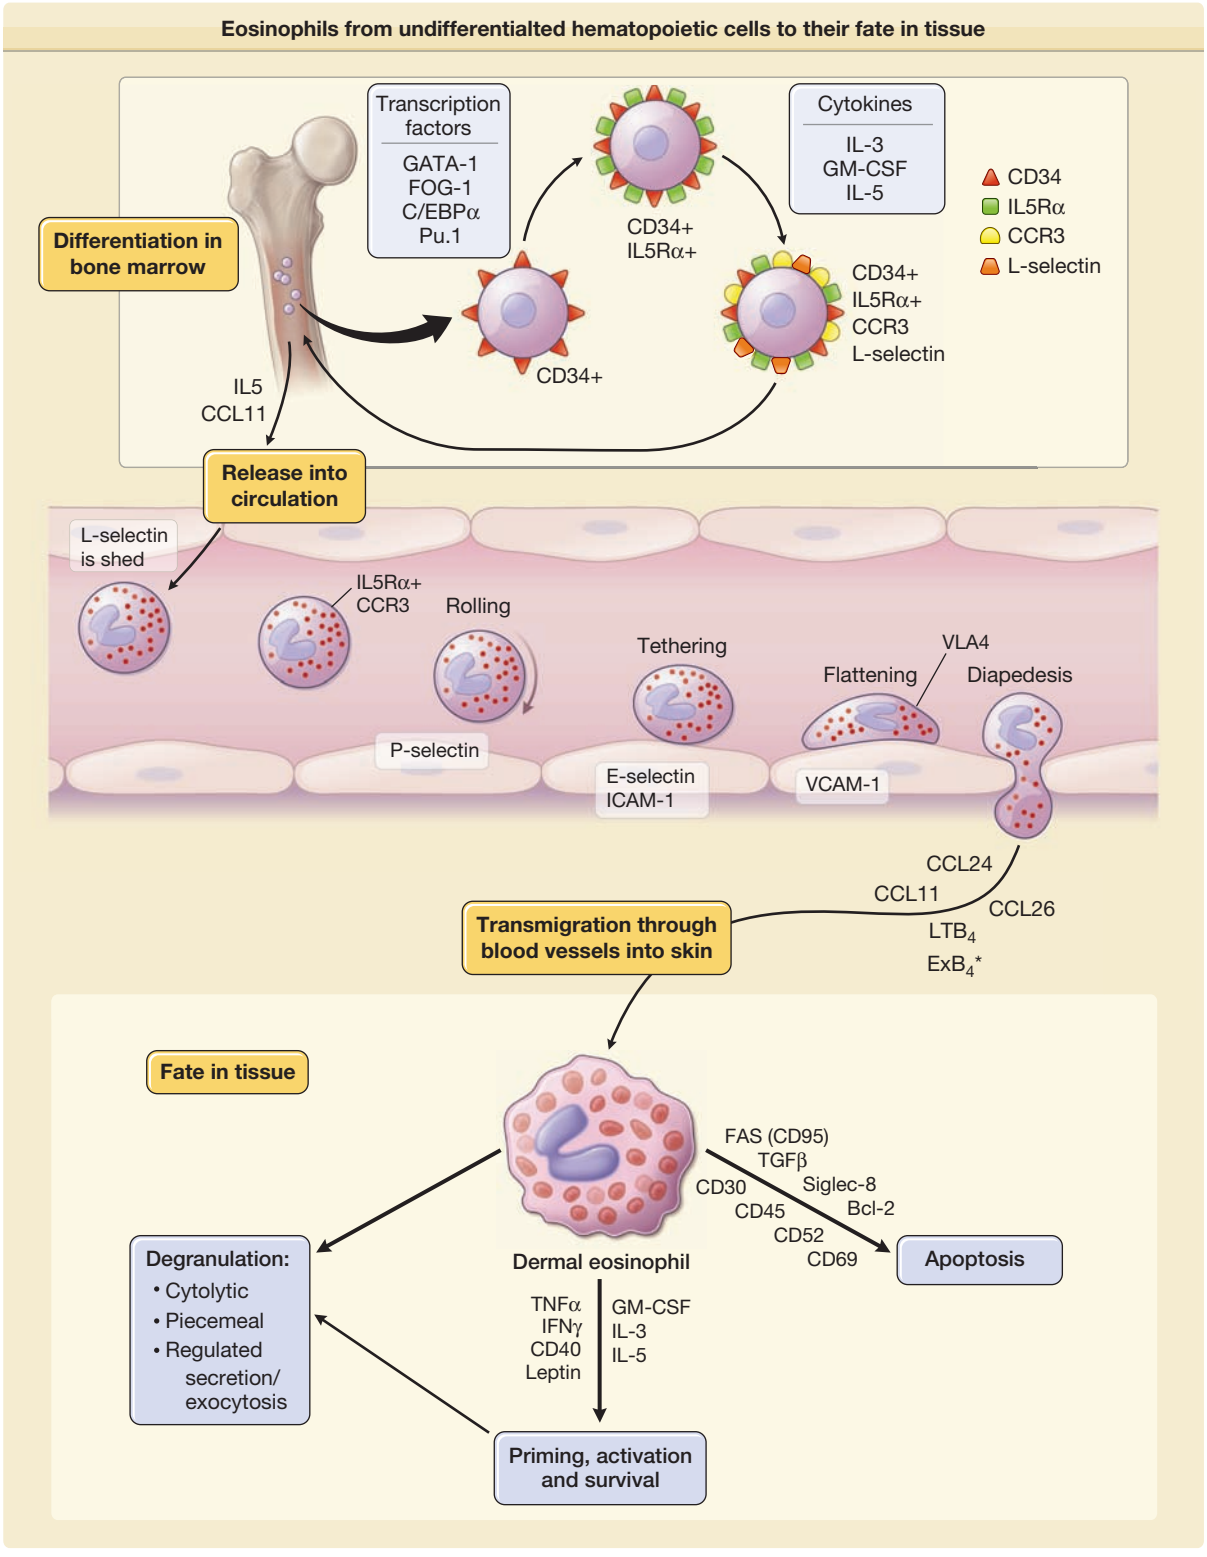

Figure 31-1 Eosinophils from undifferentiated hematopoietic cells to their fate in tissue. The images depict the eosinophil's life from differentiation in the bone marrow to vascular transmigration to their fate in tissue with key factors noted. ExB_4 likely has activities comparable with those of LTB_4.

collagen (Shc), SH2-containing phosphatase-2 (SHP-2), growth factor receptor-bound protein 2 (Grb2), Vav, and lipid kinases, phosphatidylinositol 3-kinase (PI-3K), function in the interfacing step. The activation of JAK2 and signal transducer and activator of transcription (STAT) 5 is essential for IL-5 dependent signal transduction. The Ras GTPase-extracellular signal-regulated kinase (Ras-ERK) and also known as Ras-mitogen-activated protein kinase (Ras-MAPK) pathway, in addition to the JAK2-STAT5 pathway, is important in IL-5 signaling in the mobile step. The JAK-STAT and Ras-MAPK pathways converge at various levels in IL-5 signaling of eosinophils. IL-5 induces the expression of cytokine-inducible SH2 protein (CIS) and JAK-binding protein (JAB), which is one of the negative feedback loops in the regulation of IL-5 signaling. Multiple other interactive signal transduction pathways induce and regulate gene expression for eosinophil growth, development, activation, and survival.[21,22] Much of the discovery in these pathways has been in murine systems with presumed general applicability to humans. However, at least part of the immune response to IL-5 in mice is NOT part of the biological effect in humans, i.e., in mice, IL-5 enhances several functions of B cells, including immunoglobulin production, growth, and differentiation, whereas human B-cells are influenced by IL-5 only in the presence of specific cytokines and under certain conditions.[20] However, human IL-5 does act on T cells by increasing the expression of IL2Rα and augmenting cytotoxic T cell generation.[23]

EOSINOPHIL ULTRASTRUCTURE AND GRANULE CONTENT

(See Fig. 31-2)

Mature eosinophils are 12–17 μm in diameter and, therefore, slightly larger than neutrophils. They typically have a bilobed nucleus with highly condensed peripheral chromatin. Eosinophils have distinctive cytoplasmic granules, demonstrated by their staining properties with acidic dyes such as eosin and by their unique electron microscopic appearance. These specific or secondary granules are composed of an electron-dense core and a less electron dense matrix, the core being a crystalline lattice by electron microscopy. In cross section, the eosinophil contains approximately 30 of these membrane-bound, core-containing, secondary granules.[1] Five highly basic proteins are found within the granules: (1) major basic protein (MBP)-1, (2) MBP-2, (3) eosinophil-derived neurotoxin (EDN) also known as ribonuclease (RNase)2, (4) eosinophil cationic protein (ECP) also known as RNase3, and (5) eosinophil peroxidase (EPO). Several other types of proteins are found in secondary granules and include enzymes, cytokines, growth factors, and chemokines. Eosinophils contain three other types of cytoplasmic granules, referred to as (1) primary granules, (2) small granules, and (3) secretory vesicles. Primary granules are of variable size, round, uniformly dense, present in 1–3 per electron microscopic cross section, and more common in immature eosinophilic promyelocytes. These granules may contain Charcot–Leyden crystal protein (also known as galectin-10), which can be found in neutrophils as well[31]; Charcot–Leyden crystals (CLCs) are characteristically found in asthmatic sputum and in feces from patients with helminth infections or eosinophilic gastroenteritis. Small granules contain acid phosphatase and arylsulfatase and are present at 2–8 per electron microscopic cross section. Secretory vesicles, also referred to as tubulovesicular structures or microgranules, are characterized by their small, dumbbell-shaped appearance and their albumin content. They are the most abundant granules in number, with approximately 160 per electron microscopic cross section. Normal eosinophils contain varying numbers of nonmembrane-bound lipid bodies, which are the principal stores of arachidonic acid. Lipid bodies also contain the enzymes, cyclooxygenase, 5- and 15-lipoxygenase, which are required to synthesize prostaglandins, leukotrienes (LTs), and eoxins (vide infra), and are increased in activated eosinophils.[1]

BIOLOGIC FUNCTIONS

MAMMALIAN STUDIES. In mammals, such as the mouse and humans, the eosinophil is released as a mature cell into the circulation from the bone marrow, but is present in the blood only transiently, ranging from 8–18 hours. Eosinophils comprise a small portion, normally 6% or less, of circulating leukocytes. They are primarily tissue dwelling cells, but only in certain tissues in humans, with an average tissue life span of 2–5 days. This may be prolonged by cytokines that increase eosinophil survival for up to 14 days. Under normal circumstances, a balance exists between bone marrow production and release of eosinophils, their time in circulation, and their entrance into tissues. Changes in any one of the compartments causes an increase or decrease in circulating and tissue eosinophils. Eosinophilia in blood or tissue or both is associated with helminthiasis, allergic hypersensitivity, and other pathological conditions. In humans, bone marrow, spleen, lymph node, thymus, and gastrointestinal tract from the stomach through the colon, sparing the esophagus, are the only tissues in which eosinophils normally reside.[38] Furthermore, the gastrointestinal tract is the only organ other than bone marrow in which extracellular eosinophil granule protein deposition is observed even under homeostatic conditions. Eosinophils and their granule proteins are found in the lamina propria in normal gastrointestinal tract and are not found in Peyer's patches or epithelium. Eosinophils may be important for thymocyte deletion based on the localization of eosinophils within the thymus and the timing of their migration during the neonatal period.[39] Murine observations indicate that eosinophils are also important for postnatal mammary gland and uterine development, and their recruitment into the uterus heralds estrus. Although eosinophils, themselves, are not known to participate in human reproduction, eosinophil proMBP-1 is expressed in the uterus by placental X and giant cells during pregnancy, and its production peaks 2–3 weeks before

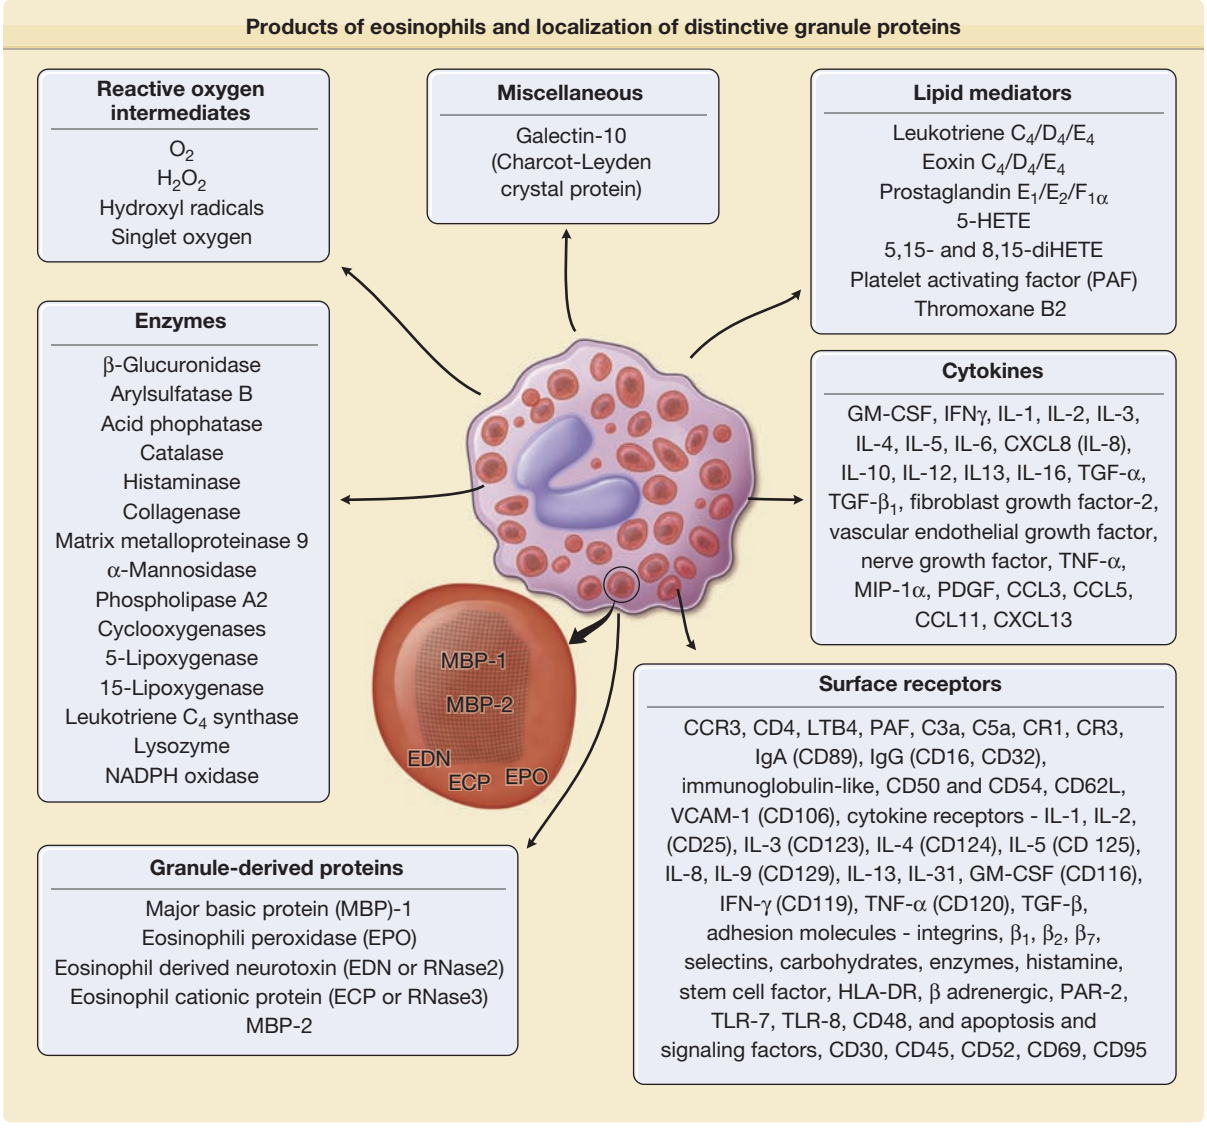

Figure 31-2 Products of eosinophils and localization of distinctive granule proteins. The eosinophil produces myriad products, including toxic granule proteins, which implicate its role in disease pathogenesis. The characteristic eosinophil granules are coarse and, as their name implies, eosinophilic upon staining with eosin. Distinctive granule proteins are localized to core and matrix portions of the specific cytoplasmic granules. **A.** An intact dermal eosinophil with its distinctive granules and typical bilobed nucleus. **B.** Characteristic specific (secondary) eosinophil granule with electron dense crystalline core and radiolucent matrix showing localization of distinctive granule proteins.

parturition.[40,41] The recruitment of eosinophils to the gastrointestinal, thymic, uterine, and mammary tissues is under the control of the CC chemokine, CCL11.[42,43]

Once eosinophils enter tissues, most do not recirculate. Several possible mechanisms exist for removal of tissue eosinophils. These include shedding of the cells across mucosal surfaces into the lumen of the intestinal or respiratory tract, engulfment of apoptotic eosinophils by macrophages, and lysis or degranulation with cellular degeneration. In various inflammatory conditions, including those affecting the skin (Chapter 36), striking numbers of free granules and/or eosinophil granule protein deposition are present in the absence of intact eosinophils.[1] Studies recently have revealed that isolated eosinophil granules express extracellular domains for interferon (IFN)-γ receptor and CCR3 and, upon stimulation, respond independently as organelles by releasing ECP.[44]

ROLE OF EOSINOPHILS IN IMMUNE FUNCTION

Shortly after their discovery by Paul Ehrlich in 1879, eosinophils were observed in association with helminth infections. Theories have been promulgated that eosinophils are important for host defense against parasites spawning numerous studies.[45] For example, in

vitro studies demonstrated that eosinophils are cytotoxic to large nonphagocytosable organisms, such as multicellular helminthic parasites. Eosinophils bind to host-derived immunoglobulins and complement components on the surface of their targets (so-called antibody- or complement-) dependent cytotoxicity. They also bind to carbohydrate ligands expressed on parasites, such as the Lewis^x-related molecules, and cell adhesion molecules similar to selectins. Eosinophils are activated to release their granule products with deposition of these biologically active proteins in and around the parasites causing disruption of the parasite's integument and, ultimately, death of the organism. The granule proteins have different effects. ECP produces fragmentation and disruption whereas MBP-1 produces a distinctive ballooning detachment of the tegumental membrane, and EDN is active only at high concentrations causing crinkling of the tegumental membrane.[46] However, in murine models in which blood, marrow, and tissue eosinophilia is largely abolished by neutralizing IL-5 activity, the intensities of primary or secondary parasitic infection are unchanged indicating that eosinophils have little or no role in parasitic host defense in these models.[1] The results must be interpreted cautiously because mouse and human eosinophils have functional differences, and mice are not natural hosts of many of the parasites tested experimentally.

Eosinophils also release cytotoxic granule proteins onto the surface of fungal organisms and into the extracellular milieu in fungal infections. Eosinophils kill fungi in a contact-dependent manner. Eosinophils adhere to the fungal cell wall component, β-glucan, via a β2-integrin surface molecule, CD11b.[47] Eosinophils do not express other common fungal receptors, such as dectin-1 and lactosylceramide, and, specifically, do not react with chitin. However, chitin, which is a polymer that confers structural rigidity to fungi, helminths, crustaceans, and insects, induces accumulation of eosinophils in tissues through production of LT B4 in mice.[48] Eosinophils also are activated by fungal organisms that release proteases, such as *Alternaria*, through protease-activated receptors (PARs). For example, fungal aspartate protease activates eosinophils through PAR-2 and, thereby, mediates eosinophils' innate responses to certain fungi.[49]

As a granulocyte, the eosinophil is capable of phagocytosing and killing bacteria and other small microbes in vitro, but eosinophils cannot effectively defend against bacterial infections when neutrophil function is deficient. Nevertheless, recent investigations reveal that eosinophils may have a role in innate immunity against bacteria using a unique mechanism, DNA trap.[50] Eosinophils rapidly release mitochondrial DNA when exposed to bacteria, a complement component, C5a, or CCR3 ligands. The traps contain eosinophil granule proteins, ECP and MBP, and have antimicrobial effects. In the extracellular space, the granule proteins and mitochondrial DNA form structures that bind and kill bacteria both in vitro and in vitro. Eosinophils, unlike neutrophils, do not undergo cell death as part of this process. This may be an important innate immune response, particularly in mucosal epithelium.[50]

Another protective function that eosinophils may have is in viral infections. Eosinophils and their granule proteins are increased in the respiratory tracts of patients with respiratory syncytial virus, an RNA-viral infection. EDN (RNase2) and ECP (RNase3), eosinophil granule matrix proteins, are ribonucleases (vide infra). Purified eosinophils, as well as EDN and ECP individually, reduced viral titers when added to respiratory syncytial viral suspensions. In mice, at least 11 eosinophil-associated ribonucleases degrade single stranded RNA containing viruses.[51] Despite divergence of the coding regions, conserved eosinophil ribonuclease activity across species suggests a strong evolutionary pressure to preserve this critical enzymatic activity.[51] In other studies, pretreatment of parainfluenza-infected guinea pigs with anti-IL-5, to reduce numbers of eosinophils, strikingly increased viral load in the airways. Viruses, including parainfluenza virus, respiratory syncytial virus, and rhinovirus, induce the release of another eosinophil granule protein, EPO, when coincubated with antigen-presenting cells and T cells.[52] Paradoxically, eosinophils may be a potential reservoir for the human immunodeficiency virus (HIV)-1.[53]

Eosinophils may have other roles in immune responses as well. Through MHC class II expression and IL-1α production, they can function as antigen-presenting cells for a variety of viral, parasitic, and microbial antigens, including staphylococcal superantigens, and allergens.[54,55] Eosinophils are recruited to secondary lymphoid structures to promote the proliferation of effector T cells although they are unable to affect naïve T cells.[56] Eosinophils, as sources of cytokines, influence T cell-dependent responses.[1] In keeping with the prominence of eosinophils in allergic disorders, eosinophils are involved in T cell polarization favoring Th2 by promoting Th1 apoptosis in addition to their influence via cytokine expression.[54,57–60]

ROLE OF EOSINOPHILS IN DISEASE

The activities of eosinophil-derived products include direct cytotoxic effects on structural cells and microbes, increased vascular permeability, procoagulant effects, innate immune responses to some parasites, viruses, fungi and tumor cells, enhancement of leukocyte migration, amplification of effector T-cell responses and, possibly even mammary gland development. Collectively, these varied biologic actions provide the pathophysiological basis for the signs and symptoms observed in eosinophil-associated diseases.

Eosinophils in lymph nodes and spleen are especially increased after allergen exposures or microbial insults.[61,62] Eosinophils have been found in several cancers, particularly in lymphomas, leukemias, and colon cancer. Clinical studies indicate that certain tumors associated with tissue and/or peripheral eosinophilia have a more favorable prognosis,[63] whereas in other tumors, they are thought to confer a poor prognosis, such as nodular sclerosing Hodgkin disease, Sézary syndrome, and gastric carcinomas. In Sézary syndrome (see Chapter 145), the tumor cells produce IL-5

and, therefore, are responsible for the eosinophilia, which is a reflection of tumor burden.[64] Where eosinophilia is a good prognostic factor, eosinophils are considered to be part of an effective host response to the tumor.[65,66]

EOSINOPHIL CONSTITUENTS AND THEIR ACTIVITIES

The eosinophil contains and produces a myriad of factors that implicate its role in inflammation and tissue destruction and remodeling (see Fig. 31-2).[70] Products released by eosinophils include chemoattractants, colony-stimulating factors, and endothelial-activating cytokines. In addition to toxic cationic proteins from specific granules and oxidative products released into tissues following activation, these factors include arachidonic acid-derived lipids, hydrolytic enzymes, neuropeptides, colony-stimulating factors, and cytokines/chemokines that facilitate further leukocyte recruitment to sites of inflammation (see Fig. 31-2). Surface molecule expression is important in all aspects of eosinophil biology from promoting growth and differentiation to eosinophil trafficking into tissue to activation and/or priming of the cells to senescence. Numerous membrane factors are expressed on eosinophils that further direct eosinophil biological effects. (See eTable 31-0.1 in online edition for designations of various eosinophil factors.)

EOSINOPHIL GRANULE PROTEINS. Among the products of eosinophils that are most damaging to the host are the specific granule's cationic proteins. Furthermore, the granule proteins are markers of eosinophil activity because the eosinophil often loses its characteristic morphology through cytolysis in tissues.[71] Knowledge of their biological actions provides insight into their functions in human disease. Once deposited, the granule proteins persist in tissues for extended times—EPO for 1 week, ECP for 2 weeks, EDN for 2.5 weeks, and MBP-1 for 6 weeks.[72] Each of these proteins have been shown to induce direct tissue damage to both host cells, including myocytes, endothelium, neurons, epithelium, and smooth muscle, and to microbes (vide supra). For example, MBP-1, ECP, or EPO application to airway epithelium in primates produces ciliostasis, desquamation, and hyperreactivity of respiratory smooth muscle mimicking the pathology of asthma.[73,74] Damage to endothelium in eosinophilic endomyocardial disease is thought to be the initiating factor in the cardiomyopathy observed in the hypereosinophilic syndromes (see Chapter 36).[75] All four of the cationic granule proteins [(1) EPO, (2) ECP, (3) EDN, and (4) MBP-1] likely contribute to the edema observed in skin diseases due to their vasodilatory effects with contribution from mast cells and basophil histamine release by MBP-1.[76] Eosinophil granule proteins stimulate various cells in addition to mast cells and basophils, including neutrophils and platelets. Nodules, eosinophilia, rheumatism, dermatitis and swelling (NERDS), episodic angioedema with eosinophilia (Gleich syndrome), urticaria, eosinophilic cellulitis (Wells syndrome), and insect bite reactions demonstrate variable degrees of edema that are probably explained, at least in part, by this mechanism (see Chapter 36). Eosinophil granule proteins injected into skin produce lesions including dose-dependent wheal-and-flare reactions by MBP and ulcerations by ECP and EDN.[77,78] Wound healing is delayed in the presence of eosinophils and eosinophil granule proteins.[79,80] Eosinophils, through activities of granule proteins, have procoagulant activity. Thromboses have developed in the hypereosinophilic syndromes, including several case reports of hepatic vein obstruction (Budd–Chiari syndrome). The thromboses could be the result of direct endothelial damage or due to the ability of MBP and ECP to neutralize heparin. In addition, MBP is a strong platelet agonist, and platelet-activating factor (PAF), which is released by eosinophils, causes platelet aggregation.[1]

MAJOR BASIC PROTEIN

General Characteristics. Major basic protein (MBP) comprises the crystalloid core of the specific eosinophil granule. It was so named because it accounts for a **major** portion, about 55% (in guinea pig), of the eosinophil granule **protein,** and has a high isoelectric point, calculated at greater than pH 11, so strongly **basic** that it cannot be measured accurately. It is now known that MBP is expressed as two homologs, MBP-1 and MBP-2, coded by different genes on chromosome 11.

Tissues Effects of Basic Proteins. MBP-1 directly damages helminths and also lethally damages mammalian cells and tissues, examples of which are its ability to cause exfoliation of bronchial epithelial cells and to kill tumor cells. MBP-1 exerts its effects by increasing cell membrane permeability through surface charge interactions leading to disruption of the cell surface lipid bilayer.[81] MBP-1 and MBP-2, but none of the other eosinophil granule proteins, stimulate histamine and LTC_4 release from human basophils. Further, MBP-1 and MBP-2 stimulate neutrophils, inducing release of superoxide, lysozyme, and IL-8. MBP-1 and EPO are potent platelet agonists causing release of 5-hydroxytryptamine and promoting clotting.

EOSINOPHIL PEROXIDASE. Eosinophil peroxidase (EPO) is highly basic, pI 10.8, localized in the matrix of the specific eosinophil granule and is a key participant in generating reactive oxidants and free radical species in activated eosinophils. EPO consists of a heavy chain and a light chain encoded with a prosequence. The EPO gene is on chromosome 17 and maps closely to myeloperoxidase and lactoperoxidase genes, two other members of the mammalian peroxidase family found in neutrophils and mucosal glands, respectively. Although MBP is present in the highest molar concentration in eosinophil granules, EPO, by weight, is the most abundant protein constituting approximately 25% of the specific eosinophil granule's total protein mass. EPO catalyzes the oxidation of

halides, pseudohalides, and nitric oxide to form highly reactive oxygen species (hypohalous acids), reactive nitrogen metabolites (nitric dioxide), and other oxidants that then oxidize targets on proteins with oxidative stress and subsequent cell death by apoptosis and necrosis. EPO kills numerous microorganisms in the presence of hydrogen peroxide, generated by eosinophils and other phagocytes, and halide. This combination of products also initiates mast cell secretion. As noted, both EPO and MBP induce noncytolytic, dose-dependent 5-hydroxytryptamine release from platelets.[82] Binding of EPO to neutrophils reversibly inhibits EPO peroxidase activity but increases neutrophil aggregation and adhesion to endothelial cells.[83] EPO binding to microbes, including *Staphylococcus aureus*, greatly potentiates their killing by phagocytes. EPO-coated tumor cells are spontaneously lysed by activated macrophages.

EOSINOPHIL CATIONIC PROTEIN AND EOSINOPHIL-DERIVED NEUROTOXIN

General Characteristics. Eosinophil cationic protein (ECP or RNase3) and eosinophil-derived neurotoxin (EDN or RNase2) are homologous proteins with sequence identity in 37 of 55 amino acid residues and are encoded on chromosome 14. ECP also has neurotoxic activity. ECP and EDN play a role in viral host defense to RNA viruses.[51,88,89] New roles for these proteins continue to be identified.[90] EDN induces the migration and maturation of dendritic cells.[91] It also is an endogenous ligand of Toll-like receptor 2 (TLR2) and can activate myeloid dendritic cells by triggering the TLR2-myeloid differentiation factor 88 (Myd88) signaling pathway.[60] Based on its ability to serve as a chemoattractant and activator of dendritic cells along with enhancing antigen-specific Th2-biased immune responses, EDN functions as an alarmin alerting the adaptive immune system to preferentially enhance antigen-specific Th2 responses.[60]

CHARCOT–LEYDEN CRYSTAL PROTEIN

General. Distinctive hexagonal, bipyramidal crystals were initially described in 1853 in a patient with leukemia and later, in 1872, in the sputa of asthmatic patients. Since then, CLCs have been regarded as a hallmark of eosinophilia. CLC protein is an abundant, characteristic, although not unique, protein of eosinophils. It is also found in lesser amounts in basophils. CLC mRNA and EDN mRNA are among the most highly expressed mRNAs in mature peripheral blood eosinophils suggesting de novo synthesis.[1]

CHARCOT–LEYDEN CRYSTALS

REACTIVE OXYGEN METABOLITES. Reactive oxygen species are important mediators of the tissue injury caused by eosinophils. The reactive oxygen intermediates produced by NADPH oxidase during the respiratory burst initiated on eosinophil activation include superoxide, hydroxyl radicals, and hydrogen peroxide. Hydrogen peroxide can generate hypohalous acids through the action of EPO, which are cytotoxic as well. Reactive oxygen species also can augment the inflammatory response by inducing gene expression and T-cell proliferation.[98]

LIPID MEDIATORS

General. Lipid bodies in eosinophils are storage sites for arachidonic acids. Eosinophils produce several arachidonic acid metabolites, including cysteinyl LTs from the 5-lipoxygenase pathway (LTC_4, LTD_4, and LTE_4) and thromboxanes and prostaglandins from the cyclooxygenase pathway [thromboxane B_2, prostaglandin (PG) E_2, and $PGF_1\alpha$].[99,100]

CYTOKINES. Eosinophils are a considerable source of growth factors and regulatory as well as proinflammatory cytokines and chemokines.[1,103] The various growth factors produced by eosinophils include transforming growth factor (TGF)-α, TGF-β, fibroblast growth factor-2, vascular endothelial growth factor, nerve growth factor, and platelet-derived growth factor-β. There is evidence that these growth factors induce stromal fibrosis and basement membrane thickening at sites of chronic eosinophilic inflammation including nasal polyps, asthmatic airways and, likely, in certain skin disorders such as atopic dermatitis.[1] The production and release of nerve growth factor by eosinophils promotes neurites in nerve cells.[104] Another group of cytokines produced by eosinophils modulates other immune cells and includes tumor necrosis factor (TNF)-α, macrophage inflammatory protein (MIP)-1α (CCL3), IL-1α, IL-2, IL-3, IL-4, IL-5, IL-6, CXCL8 (IL-8), IL-10, IL-12, IL-13, IL-16, GM-CSF, and IFN-γ.[103] Additional chemokines produced by eosinophils are CXCL13 (B lymphocyte chemoattractant factor), CCL5 [regulated on activation, normal T cells expressed and secreted (RANTES)], and CCL11, in addition to CCL3 and CXCL8. CCL5 apparently is stored in at least two intracellular compartments, namely, (1) the matrix of specific eosinophil granules and (2) small secretory vesicles. All of these cytokines are constitutively produced in low levels in resting eosinophils and induced in inflammatory conditions with activation of eosinophils by engagement of receptors (vide infra) with immunoglobulins, complement and cytokines, including those produced by eosinophils, themselves, in an autocrine manner. Notably, eosinophils produce the three principal cytokines involved in their own growth and differentiation—(1) IL-3, (2) IL-5, and (3) GM-CSF, as well as chemokines important in their own chemotaxis, CCL5 and CCL11. It is known that eosinophils synthesize and secrete GM-CSF by a peptidyl-prolyl isomerase (PIN1)-dependent mechanism.[105] However, although eosinophils produce quantities of certain cytokines comparable to T cell production,[106] the relative contributions of eosinophil-derived cytokines to inflammation remain to be determined. In summary, the eosinophil-derived cytokines may function in both an autocrine and paracrine fashion and likely have pathophysiological relevance.

SURFACE EXPRESSION. Eosinophils express numerous receptors and other factors on their surface membranes through which they communicate with the extracellular environment, but no single surface protein is uniquely expressed on eosinophils. These receptors have been identified either by flow cytometry or by functional assays, and can be grouped as follows: **chemotactic factor and complement receptors** including chemokine, LT and PAF; **immunoglobulin supergene family member receptors** including immunoglobulins; **cytokine receptors** including those discussed above; **adhesion molecule receptors**; **receptors involved in apoptosis**; and **miscellaneous receptors and surface factors**. Eosinophil membrane proteins are promising targets for therapeutic modulation of eosinophil effects (see section "Pharmacological Manipulation").

CHEMOTACTIC FACTOR AND COMPLEMENT RECEPTORS. Chemotactic factors are important in orchestrating cellular trafficking to sites of inflammation as well as physiologic homing (e.g., eosinophils to gastrointestinal tract). The eosinophil has receptors for many chemotactic agents such as LTB_4, PAF, bacterial products (*N*-formyl-methionyl-leucyl-phenylalanine), complement anaphylatoxins, C3a and C5a. Eosinophils express complement receptor (CR)1 (CD35), a receptor for C1q that also binds C4b, C3b, and iC3b, and CR3 (Mac-1, CD11b/CD18) in addition to receptors for C3a and C5a. These are important receptors in eosinophil effector functions. The binding of chemokines to their respective receptors mediates many biological effects, which, in addition to cell shape change and migration, includes cell activation, receptor internalization, induction of the respiratory burst with generation of toxic oxygen metabolites, and transient activation of integrin adhesiveness. PAF activity on eosinophils is mediated through PAF receptors that have been cloned. PAF is one of the most potent chemoattractants for eosinophils and selectively recruits eosinophils over neutrophils. PAF also induces release of granule proteins, reactive oxygen species, and LTC_4 from eosinophils. LTB_4 through its eosinophil receptor potently stimulates eosinophil chemotaxis and elicits arachidonic acid metabolism and a respiratory burst. It does not induce eosinophil degranulation. Eosinophils also may have LTD_4 receptors.[1] The chemotaxins listed above have potent effects on eosinophils but are nonselective in that they are active on other leukocytes. Because many eosinophil-associated diseases are characterized by tissue eosinophil infiltration with little or no neutrophil infiltration, the identification of the CCR3 receptor and its ligands was an important breakthrough in discovering eosinophil-selective chemotaxins.[107] Specific members of the chemokine family are critical for the cellular trafficking of eosinophils. The major ligands of CCR3, CCL5, CCL11, CCL13 (monocyte chemotactic protein-4), CCL24 (eotaxin-2), CCL26 (eotaxin-3), play a critical role in both the homeostatic and inflammation-induced recruitment of eosinophils to tissue sites.[13,108] Not surprisingly, the most highly expressed chemokine receptor on human eosinophils is CCR3 (40,000–400,000 receptors per cell). CCR3 is a seven-transmembrane spanning G-protein coupled receptor that can deliver both powerful positive and negative signals depending on the interacting ligand.[109]

IMMUNOGLOBULIN SUPERGENE FAMILY MEMBER RECEPTORS. Many of the studies of eosinophil functions, including phagocytosis, antigen-dependent cytotoxicity, oxygen metabolism, LTC_4 production, and eosinophil survival, have been performed using IgG-coated targets. Among eosinophil surface receptors for the immunoglobulin family members, the most highly expressed receptor is FcγRII (CD32), which binds aggregated IgG, particularly of the subclasses IgG_1 and IgG_3. The binding of IgG to this receptor may be important in eosinophil degranulation in parasitic and allergic diseases along with other eosinophil functions.[1] Freshly isolated eosinophils express only FcγRII (CD32) of the IgG receptors, but eosinophils can be stimulated by cytokines, particularly IFN-γ, to express FcγRI (CD64) and FcγRIII (CD16) and augment FcγRII (CD32) expression.

FcαRI (CD89), the IgA receptor, is present on the surface of eosinophils. Eosinophils also possess a binding site for secretory component that may account for the finding that secretory IgA is the most potent immunoglobulin stimulant for eosinophil degranulation. The interaction of eosinophils with IgA is enhanced by Th2 cytokines, IL-4 and IL-5. These observations, coupled with the observation that many eosinophils are found in epithelial tissues such as gastrointestinal tract, suggest that eosinophils and secretory IgA play an important role in mucosal immunity.

Members of the immunoglobulin superfamily are type I transmembrane molecules that share common structural characteristics of the globular domains found in immunoglobulins. Intercellular adhesion molecule (ICAM)-1 (CD54) and ICAM-3 (CD50) are members of this superfamily expressed on eosinophils and are likely important in leukocyte–leukocyte and leukocyte–tissue cell adhesion through leukocyte function-associated antigen (LFA)-1 (αLβ2; CD11a/CD18) as its counterligand (see Fig. 31-1).

CYTOKINE RECEPTORS. Cytokine receptors are present at low levels on the surfaces of eosinophils. Receptors for IL-3 (CD123), IL-5 (CD125), and GM-CSF (CD116) are readily detected and, as noted previously, all share a common β chain (CD132). Eosinophil activation has been observed by a variety of other cytokines through presumed and/or detected receptors. These include: stem cell factor (c-kit receptor; CD117), IFN-γ (CD119), TNF-α (CD120), IL-4 (CD124), IL-9 (CD129 and CD132), IL-13 (gp65), IL-2 (CD25), IL-31, and TGF-β receptors. Many of these receptors are for cytokines that eosinophils produce providing further evidence that they have autocrine functions.

ADHESION MOLECULE RECEPTORS. Adhesion molecule receptors are expressed on the eosinophil cell surface to mediate trafficking to and within tissues, and for general cell–cell interactions.[112] These

receptors fall into three groups: (1) immunoglobulin superfamily (reviewed above), (2) selectins and their glycoprotein counterligands, and (3) integrins. L-selectin (CD62L) and P-SELECTIN glycoprotein ligand-1 (PSGL-1, CD162) are expressed at high levels on eosinophils, whereas E-selectin ligands, as an example, sialyl-Lewis X (CD15s), are expressed at very low levels. P-selectin together with PSGL-1 is the most important selectin pair in eosinophil migration into tissues.

Eosinophils express a variety of integrins (β_1, β_2, and β_7) on their surface, which facilitate their adhesion to extracellular matrix proteins, vascular cellular adhesion molecule (VCAM)-1 (CD106) on activated endothelium, or ICAM-1 present on resting or activated epithelium and activated endothelium. Integrins are composed of two subunits that exist as noncovalently associated heterodimers, with α and β subunits. The β_1 integrins expressed on eosinophils include $\alpha_4\beta_1$ (very late antigen-4 or VLA-4), which binds to VCAM-1 found on activated endothelium and the extracellular matrix protein, fibronectin. Eosinophil adhesion to fibronectin induces the autocrine production of eosinophil-activating survival cytokines, IL-3, IL-5, and GM-CSF. The only other β_1 integrin expressed on eosinophils is $\alpha_6\beta_1$, which mediates the binding to another matrix protein, laminin. Four β_2 integrins are found on eosinophils: (1) $\alpha L\beta_2$ (LFA-1), (2) $\alpha M\beta_2$ (CD11b/CD18 or Mac-1), (3) $\alpha X\beta_2$, and (4) $\alpha D\beta_2$. These integrins bind to ICAM-1, ICAM-2, ICAM-3, VCAM-1, fibrinogen, and the complement fragment, C3bi. Lastly, eosinophils also express $\alpha_4\beta_7$, which is the ligand for the gut mucosal addressin cell adhesion molecule-1 (MAdCAM-1), which is likely important in homing of eosinophils to gastrointestinal mucosa; $\alpha_4\beta_7$ also mediates adhesion to fibronectin and VCAM-1.

RECEPTORS INVOLVED IN APOPTOSIS. Eosinophils express several "death receptors," that are involved in apoptotic pathways, such as Fas receptor (CD95), Siglec-8, CD30, CD45, Campath (CD52), and CD69, along with important intracellular regulators of eosinophil apoptosis such as the members of the B-cell leukemia/lymphoma (Bcl)-2 and inhibitor of apoptosis families.[113] Diseases characterized by eosinophilia likely result, in part, from delayed or defective apoptotic pathways allowing accumulation and persistence of eosinophils in blood and/or tissues.

FACTORS WORKING TOGETHER. The various products elaborated by eosinophils in response to receptor activation do not necessarily function independently but often act in concert to mediate their biological effects. For example, the release of TGF-α, TGF-β, fibroblast growth factor-2, vascular endothelial growth factor, MMP-9, and inhibitors of MMPs from activated eosinophils collectively induce fibroblast proliferation and extracellular matrix protein production. Eosinophils contribute factors of their own and influence factor production from other cells, for example, eosinophil mediators induce platelet release of TGF-β. After intradermal eosinophil infiltration, there is production of extracellular proteins, including tenascin and procollagen 1, as well as myofibroblast formation.[120] Eosinophil-induced fibrosis is observed in the lungs and heart of patients with hypereosinophilic syndrome, in and around organs in other fibrosing/sclerosing disorders and in the skin of patients with eosinophilic fasciitis (Shulman syndrome), eosinophilia–myalgia syndrome, and toxic oil syndrome (see Chapter 36).[121] Eosinophil granule proteins, MBP-1 and EDN, along with other neuroactive mediators produced by eosinophils such as nerve growth factor, vasoactive intestinal peptide, and substance P, likely affect nerve physiology. In fact, eosinophils and eosinophil granule proteins are often observed in close proximity to nerve endings.[122,123] Eosinophil-induced nerve dysfunction is likely an important part of the gastric dysmotility observed in subjects with food allergies, the dysfunction of vagal muscarinic M2 receptors observed in asthmatics, and may also contribute to itch along with other physiological aberrations in atopic dermatitis and other cutaneous diseases.[123,124] Collectively, the eosinophil's response to surface factors determines its role in health and disease.

TISSUE TRAFFICKING

The selective recruitment of eosinophils into sites of inflammation results from interactions among eosinophil-activating cytokines, chemokine-inducing cytokines, and endothelial-activating cytokines (see Fig. 31-1). Similar to other leukocytes, selectin, integrin, and immunoglobulin gene superfamily members contribute to the signaling involved in eosinophil trafficking. In particular, eosinophils constitutively express the integrin, VLA-4, which interacts with its ligand, VCAM-1, induced on endothelial cells by cytokines, especially Th2 cytokines (IL-4 and IL-13).[125] After movement through vessels, eosinophils adhere to extracellular matrix proteins. Here, surface factors, b2 integrins such as CD11b/CD18 (Mac-1), bind to fibrous proteins such as fibronectin, laminin, and collagen, and, not only determine where eosinophils will reside, but likely prolong their survival.[126] In this regard, CD11b/CD18 (Mac-1) integrin is also critical for eosinophil effector functions, including degranulation.[127]

EOSINOPHIL-ACTIVATING CYTOKINES

GENERAL. Eosinophil-activating cytokines can be produced by many cell types in addition to T cells and mast cells, including keratinocytes, endothelial cells, and monocytes, along with eosinophils, themselves. The eosinophil-activating cytokines, IL-3, IL-5, GM-CSF, and others, enhance chemotactic responses, in addition to multiple other effects on eosinophils such as promoting maturation, cell survival, and LT production.[128]

ENDOTHELIAL-ACTIVATING CYTOKINES

(See Chapter 162)

During eosinophil migration, at least three types of endothelial activations occur. The first is the expression of P-selectin, which occurs when Weibel–Palade bodies in endothelial cells are transported to the cell surface rapidly after exposure to histamine, LTs, and a host of other inflammatory mediators. Expression of P-selectin on the endothelial-cell surface initiates leukocyte rolling, via CD162 (PSGL-1), which is the important initial step before firm adhesion and transendothelial migration. A second type of endothelial activation is that induced by nonspecific activators such as IL-1 and TNF-α. These cytokines stimulate endothelial expression of E-selectin, ICAM-1, and VCAM-1, to which eosinophils firmly adhere, or "tether." They also induce production of chemokines by endothelial cells. The third type of endothelial activation is that induced by IL-4 and IL-13. These cytokines selectively induce VCAM-1, which is centrally involved in the recruitment of VLA-4-positive cells, including eosinophils, basophils, and lymphocytes into sites of allergic inflammation.

CHEMOKINES

The transition from rolling to firm adherence is substantially increased by CCR3 ligands, the CC chemokines. Induction of the expression of chemokines by activated endothelial cells results in higher levels of chemokines on or near the endothelial surface, which transiently affect β_1 and β_2 integrin avidity, resulting in firm adhesion of the eosinophil to the endothelial cell. However, chemokines produced by structural cells such as fibroblasts, smooth muscle cells, and epithelium probably are more important in directing migration and activation of eosinophils within tissues than those expressed on endothelial cells.[137]

Tissue chemokine expression forms a gradient signal that guides eosinophils into tissue. CCL11 guides eosinophils into tissue locations in which eosinophils are normally present, thymus, uterus, mammary gland, and gastrointestinal tract.[143] In Th2 disorders, Th2 cytokines induce chemokine expression. In lungs affected by asthma and eosinophilic pneumonia, CCL11, CCL24, and CCL26 are increased along with other chemokines,[144] such as LTB_4 and galectin-9.[145,146] In the intestinal tract, CCL26 plays a key role in eosinophilic esophagitis, whereas CCL11 is involved in lower gastrointestinal eosinophil disorders. In skin, IL-4, IL-13, and TNF-α stimulate CCL11, CCL24, and CCL26 production from mast cell and lymphocyte sources as well as from fibroblasts (CCL11 and CCL26) and keratinocytes (CCL26).[147] As in eosinophilic esophagitis, CCL26 may be important in atopic dermatitis in which serum CCL26 levels correlate with disease activity.[148]

Arachidonic acid metabolites, particularly, the cysteinyl LTs, LTC_4, LTD_4 and LTE_4, and PGD_2, are involved in eosinophil trafficking as evidenced by the observations that LT receptor antagonists reduce blood and lung eosinophilia and that mice, depleted of LTB4 receptors, have markedly reduced lung eosinophilia after allergen exposure. Eosinophil, basophil, and Th2 cell recruitment occurs, to some extent, through CRTH2 (CD294), the high affinity PGD_2 type 2 receptor. Other factors that contribute to eosinophil trafficking are being identified. For example, eosinophils express high levels of histamine 4 receptors that mediate chemoattraction and activation.[149] An extracellular matrix protein, periostin, encoded by an IL-13 inducible gene, likely facilitates eosinophil infiltration into tissues by directly affecting eosinophil adhesion; periostin is overexpressed in eosinophilic esophagitis and correlates with eosinophil numbers in biopsies.[150]

ACTIVATION OF EOSINOPHILS

As reviewed previously, various inflammatory mediators activate eosinophils. In addition to cytokines, TNF-α, GM-CSF, IL-3, and IL-5, these include complement components, C3a and C5a, lipid mediators, LTC_4 and PAF, chemokines, as well as engagement of IgA and IgG Fc receptors. CD11b/CD18 (Mac-1)-dependent cellular adhesion is a critical component for degranulation and superoxide production induced by GM-CSF and PAF eosinophil activation and likely is an in vitro mechanism that results from eosinophil contact with stromal cells and/or proteins.[151] Members of the CC chemokine subfamily, CCL5, CCL7 (MCP-3), CCL11, CCL13 (MCP-4), CCL24 that bind to the chemokine receptor, CCR3, also potently activate eosinophils. Activated eosinophils develop a number of phenotypic changes, including a reduction in granules, vacuolization, and an expansion of their cytoplasm, leading to a reduction in cell density and are referred to as *hypodense*. The number of hypodense cells predicts allergic disease severity. A cell surface marker that distinguishes hypodense from normodense eosinophils has not been identified, but there are several surface markers with enhanced expression on in vitro or in vitro activated or hypodense cells: αM integrin (CD11b), αX integrin (CD11c), FcγR111 (CD16), hyaluronic acid receptor (CD44), ICAM-1 (CD54), CD69, and HLA-DR.[152]

Upon recruitment and activation in tissues, eosinophils have various effects as detailed in previous sections. In tissues, eosinophils release granule contents into their extracellular space via three mechanisms: (1) piecemeal degranulation, (2) regulated secretion (also referred to as regulated exocytosis), and (3) cytolytic degranulation. First, in piecemeal degranulation, eosinophils selectively release specific granule components; as an example, IFN-γ activation promotes mobilization of granule-derived CCL5 to the eosinophil's surface without inducing cationic protein release.[153–155] Second, in regulated secretion, a docking complex forms consisting of soluble *N*-ethylmaleimide-sensitive factor attachment protein (SNAP) receptors (SNAREs) located on the vesicle (vSNAREs) and the target membrane (tSNAREs). Two types of SNAREs have been described based on the presence of a conserved amino acid, arginine (R)

or glutamine (Q). Human eosinophils express the R-SNARE, vesicle-associated membrane protein (VAMP)-2 on cytoplasmic secretory vesicles, and the Q-SNAREs, SNAP-23, and syntaxin-4, on the plasma membrane.[156] VAMP-7 also plays a critical role in both eosinophil and neutrophil mediator release.[157] The current understanding is that receptor-induced eosinophil activation leads to rapid mobilization of cytoplasmic vesicles to the plasma membrane, leading to the formation of a SNARE complex (VAMP-2, -7/SNAP-23/syntaxin-4) and mediator release. Third, cytolytic degranulation occurs in many inflammatory diseases including skin disease, such as atopic dermatitis, eosinophilic esophagitis, and lesions found in affected organs with the hypereosinophilic syndromes. It is characterized by organelle rupture, chromatolysis of nuclei with loss of morphologic integrity and identity of eosinophils, and extensive deposition of eosinophil granules and granule products in tissue.[71] Therefore, it seems somewhat paradoxical that eosinophils from atopic dermatitis patients have prolonged eosinophil survival and yet exhibit such marked cytolytic degranulation in skin lesions. Clearly, there is much more to learn about eosinophil biology and its relevance to human diseases.

PHARMACOLOGICAL MANIPULATION.

Eosinophil-associated disease is a term that, strictly speaking, refers to diseases in which eosinophil numbers or eosinophil granule protein levels (or other eosinophil products) are associated with disease activity. This term encompasses multiple heterogeneous disorders, including skin diseases (see Chapter 36), in which targeting eosinophils and/or their products is a therapeutic goal. Many available treatments reduce eosinophils numbers, thereby inhibiting eosinophilic inflammation, including glucocorticoids, calcineurin inhibitors, IFN-α, IFN-γ, LT antagonists, myelosuppressive/cytotoxic drugs, and, possibly, even antihistamines. However, none is specific for eosinophils. It is only in recent years that selective and direct reduction of eosinophils has been achieved, and these therapies have provided new insight into disease pathogenesis.[9]

Among the nonselective drugs for eosinophil reduction, glucocorticoids generally are very effective. The immediate (within 3 hours) reduction in circulating eosinophils observed after systemic administration of glucocorticoids likely occurs as a consequence of sequestration into extramedullary organs (liver, spleen, and lymph node), as has been shown in rodents. Glucocorticoids affect eosinophil infiltration into tissues by four mechanisms: (1) sequestration into lymphoid tissues, (2) induction of eosinophil apoptosis, (3) reduction of eosinophil production by bone marrow, and (4) alterations in the production of the cytokines/chemokines important in eosinophil trafficking.[158–160] Glucocorticoids suppress the production of several cytokines important for the induction of adhesion molecules on endothelial cells, including IL-1, TNF-α, IL-4, and IL-13, and the release of eosinophil-active chemokines, including CCL5, CCL7, and CCL11. Unfortunately, "steroid resistance" develops in some patients, and long-term administration of glucocorticoids is associated with limiting side effects. The mechanism of glucocorticoid resistance is unclear but, in part, may be explained by decreased numbers of glucocorticoid receptors, and polymorphisms and alterations in transcription factor activator protein-1 (AP-1).[161] Patients who have or who develop glucocorticoid resistance require other therapies. Interestingly, lidocaine and sulfonylureas (such as glyburide) also inhibit cytokine-induced eosinophil survival with glucocorticomimetic effects and may have antieosinophilic effects clinically.[162–164]

Calcineurin antagonists, such as cyclosporine, tacrolimus, and pimecrolimus, broadly inhibit T-cell cytokine release including those that specifically induce eosinophilic inflammation (IL-4, IL-5, and GM-CSF). They also decrease the expression of CCL5, CCL11, and IL-5 with associated decreased tissue eosinophilia as has been shown in atopic dermatitis.[165] Mammalian target of rapamycin (mTOR) inhibitors, including rapamycin, have direct effects on eosinophils, decreasing eosinophil granule protein release after IL-5 activation.[166] The use of these therapeutic agents are limited by their side effects including immunosuppression, as well as other metabolic effects that may be in part genetically determined.[167]

Several myelosuppressive drugs, including hydroxyurea, vincristine sulfate, cyclophosphamide, methotrexate, 6-thioguanine, 2-chlorodeoxyadenosine and cytarabine combination therapy, pulsed chlorambucil, and etoposide, may be beneficial in eosinophil-associated disease alone or as steroid-sparing agents. Hydroxyurea has been particularly effective in decreasing circulating eosinophil numbers.

In myeloproliferative hypereosinophilic syndrome (chronic eosinophilic leukemia) with the *FIP1L1-PDGFRA* mutation that codes for a tyrosine kinase, imatinib mesylate, a tyrosine kinase inhibitor, is approved for the treatment of chronic myelogenous leukemia and the hypereosinophilic syndrome and has produced rapid, complete or near complete remissions.[168] Patients who have features of myeloproliferative HES but who lack *FIP1L1-PDGFRA* still may respond to imatinib (see Chapter 36).[169]

Alemtuzumab is a monoclonal antibody to CD52 that is used to deplete CD52+ lymphocytes in the treatment of chronic (B-cell) lymphocytic leukemia and T-cell lymphoma. Eosinophils, but not neutrophils, also express CD52, and alemtuzumab has been useful in treating patients with refractory hypereosinophilic syndrome, including those with abnormal T cells,[170–172] but has serious limiting side effects from cytopenias, infusion reactions and infections.

Interferons, both IFN-α and IFN-γ, may be therapeutically beneficial in eosinophil-associated disease by inhibiting eosinophil degranulation and inflammatory mediator release. IFN-α may be better tolerated than IFN-γ and is used as a steroid-sparing agent predominantly in patients with lymphocytic variant hypereosinophilic syndrome, but also may be useful in myeloproliferative variant hypereosinophilic syndrome (see Chapter 36).[173,174]

Chapter 32 :: Acute Febrile Neutrophilic Dermatosis (Sweet Syndrome)

:: Philip R. Cohen, Herbert Honigsmann, & Razelle Kurzrock

ACUTE FEBRILE NEUTROPHILIC DERMATOSIS (SWEET SYNDROME) AT A GLANCE

- Acute febrile neutrophilic dermatosis (Sweet syndrome) is characterized by a constellation of symptoms and findings: the acute onset of fever, neutrophilia, erythematous, and tender skin lesions that typically show an upper dermal infiltrate of mature neutrophils, and the prompt improvement of both symptoms and lesions after initiation of treatment with systemic corticosteroids.
- Cardiovascular, central nervous system, gastrointestinal, hepatic, musculoskeletal, ocular, oral, otic, pulmonary, renal, and splenic organs can be involved by the extracutaneous manifestations of Sweet syndrome.
- Classical Sweet syndrome may be associated with infection of the upper respiratory tract and/or gastrointestinal tract, inflammatory bowel disease, and pregnancy.
- Malignancy-associated Sweet syndrome occurs in individuals with previously undiagnosed or relapsing hematologic malignancies and solid tumors; in these patients, Sweet syndrome appears as a cutaneous paraneoplastic syndrome.
- Drug-induced Sweet syndrome describes the onset of dermatosis in patients following the initiation of certain medications—most commonly granulocyte-colony stimulating factor.
- Cytokines—directly or indirectly—may have an important etiologic role in the pathogenesis of this dermatosis.
- The first-line oral systemic agents for treating Sweet syndrome are corticosteroids, potassium iodide, and colchicine.
- The second-line oral systemic agents for treating Sweet syndrome are indomethacin, clofazimine, cyclosporine, and dapsone.
- Topical application of high-potency corticosteroids or intralesional corticosteroids may be efficacious for treating localized Sweet syndrome lesions.

HISTORY

Acute febrile neutrophilic dermatosis was originally described by Dr. Robert Douglas Sweet in the August–September 1964 issue of the *British Journal of Dermatology*. The cardinal features of "a distinctive and fairly severe illness" that had been encountered in eight women during the 15-year period from 1949 to 1964 were summarized. Although the condition was originally known as the Gomm–Button disease "in eponymous honor of the first two patients" with the disease in Dr. Sweet's department, "Sweet's syndrome" has become the established eponym for this acute febrile neutrophilic dermatosis.[1–10]

EPIDEMIOLOGY

More than 1,000 cases of Sweet syndrome have been reported since Sweet's original paper.[1–509] The distribution of Sweet syndrome cases is worldwide and there is no racial predilection.[1,2,12,16–20,30,31] The dermatosis presents in three clinical settings.[13,15]

Diagnostic criteria for classical or idiopathic Sweet syndrome were proposed by Su and Liu in 1986 and modified by von den Driesch in 1994 (Table 32-1).[11–14] It may be associated with infection (upper respiratory tract or gastrointestinal tract), inflammatory bowel disease, or pregnancy.[13,15] Two studies have noted a seasonal preference for the onset of Sweet syndrome for either autumn or spring in 70% of 42 patients.[416] or autumn.[496]

Classical Sweet syndrome most commonly occurs in women between the ages of 30 to 60 years. However, classical Sweet syndrome also occurs in younger adults and children.[32–48,405,415,445,447,453] The youngest Sweet syndrome patients are brothers who developed the dermatosis at 10 and 15 days of age.[46]

Several investigators consider it appropriate to distinguish between the classical form and the malignancy-associated form of this disease since the onset or recurrence of many of the cases of Sweet syndrome are temporally associated with the discovery or relapse of cancer.[15,49–60] Recently, the investigators of a comprehensive review of 66 pediatric Sweet syndrome patients observed that 44% of 30 children between 3 and 18 years of age had an associated hematologic malignancy.[405,447] Malignancy-associated Sweet syndrome in adults does not have a female predominance and is most often associated with acute myelogenous leukemia.[61,62] In Sweet syndrome patients with dermatosis-related solid tumors, carcinomas of the genitourinary organs, breast, and gastrointestinal tract are the most frequently occurring cancers.[1,2,63–66]

Criteria for drug-induced Sweet syndrome were established by Walker and Cohen in 1996 (Table 32-1).[13] This variant of the dermatosis is most frequently observed to occur in association with the administration of granulocyte-colony stimulating factor (G-CSF).[1,2,13,67,68] However, several other medications have also been implicated in eliciting drug-induced Sweet syndrome (eTable 32-1.1 in online edition).[11,13,17,39,41,69–124,401,402,422,427–429,436,437,439,446,455,456,463,464,468,469 471,474,476,477,482,487, 489,490,492,493,505,506]

TABLE 32-1
Diagnostic Criteria for Classical Sweet Syndrome Versus Drug-Induced Sweet Syndrome

Classical[a]	Drug Induced[b]
(1) Abrupt onset of painful erythematous plaques or nodules	(A) Abrupt onset of painful erythematous plaques or nodules
(2) Histopathologic evidence of a dense neutrophilic infiltrate without evidence of leukocytoclastic vasculitis	(B) Histopathologic evidence of a dense neutrophilic infiltrate without evidence of leukocytoclastic vasculitis
(3) Pyrexia >38°C	(C) Pyrexia >38°C
(4) Association with an underlying hematologic (most commonly acute myelogenous leukemia) or visceral malignancy (most commonly carcinomas of the genitourinary organs, breast, and gastrointestinal tract), inflammatory disease (Crohn's disease and ulcerative colitis) or pregnancy, or preceded by an upper respiratory (streptococcosis) or gastrointestinal (salmonellosis and yersiniosis) infection or vaccination	(D) Temporal relationship between drug ingestion and clinical presentation or temporally related recurrence after oral challenge
(5) Excellent response to treatment with systemic corticosteroids or potassium iodide	(E) Temporally related resolution of lesions after drug withdrawal or treatment with systemic corticosteroids
(6) Abnormal laboratory values at presentation (three of four): erythrocyte sedimentation rate >20 mm/hour; positive *C*-reactive protein; >8,000 leukocytes; >70% neutrophils	

[a]The presence of both major criteria (1 and 2) and two of the four minor criteria (3, 4, 5, and 6) is required in order to establish the diagnosis of classical Sweet syndrome; the patients with malignancy-associated Sweet syndrome are included with the patients with classical Sweet syndrome in this list of diagnostic criteria.
[b]All five criteria (A, B, C, D, and E) are required for the diagnosis of drug-induced Sweet syndrome.
Adapted with permission from Walker DC, Cohen PR: Trimethoprim-sulfamethoxazole-associated acute febrile neutrophilic dermatosis: Case report and review of drug induced Sweet syndrome. *J Am Acad Dermatol* **34**:918-923, 1996.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of Sweet syndrome may be multifactorial and remains to be definitively determined. A condition, similar to Sweet syndrome, presenting as a sterile neutrophilic dermatosis, has been described in a female standard poodle dog after treatment with the nonsteroidal anti-inflammatory drug firocoxib and in multiple dogs temporally associated with the administration of carprofen.[403]

Sweet syndrome may result from a hypersensitivity reaction to an eliciting bacterial, viral, or tumor antigen.[2,127] A septic process is suggested by the accompanying fever and peripheral leukocytosis. Indeed, a febrile upper respiratory tract bacterial infection or tonsillitis may precede skin lesions by 1–3 weeks in patients with classic Sweet syndrome. Also, patients with *Yersinia enterolitica* intestinal infection-associated Sweet syndrome have improved with systemic antibiotics.[2,77,125–127]

The systemic manifestations of Sweet syndrome resemble those of familial Mediterranean fever. Recently, the simultaneous occurrence of both conditions has been observed.[421] Also, in a patient with chronic myelogenous leukemia-associated Sweet syndrome, the causative gene mutation for familial Mediterranean fever was detected.[448] Hence, the pathogenesis for these conditions may be similar.

Leukotactic mechanisms, dermal dendrocytes, circulating autoantibodies, immune complexes, human leukocyte antigen (HLA) serotypes, and cytokines have all been postulated to contribute to the pathogenesis of Sweet syndrome. Complement does not appear to be essential to the disease process. In some patients antibodies to neutrophilic cytoplasmic antigens (ANCAS) have been demonstrated;[430] however, these are likely to represent an epiphenomenon.[2]

Cytokines—directly and/or indirectly—may have an etiologic role in the development of Sweet syndrome symptoms and lesions.[2,21–23] Elevated serum levels of granulocyte-colony stimulating factor and interleukin-6 were detected in a patient with myelodysplastic syndrome-associated Sweet syndrome who was not receiving a drug.[128] Detectable levels of intra-articular synovial fluid granulocyte macrophage-colony stimulating factor has also been observed in an infant with classical Sweet syndrome.[44] Another study demonstrated that the serum G-CSF level was significantly higher in individuals with active Sweet syndrome than in dermatosis patients with inactive Sweet syndrome.[129] And, a recent study showed that the level of endogenous G-CSF was closely associated with Sweet syndrome disease activity in a patient with acute myelogenous leukemia-associated Sweet syndrome and neutrophilic panniculitis.[461]

Significantly elevated levels of helper T-cell type 1 cytokines (interleukin-2 and interferon-γ) and normal levels of a helper T-cell type 2 cytokine (interleukin-4) have been seen in the sera of Sweet syndrome patients.[130] In a patient with neuro-Sweet disease presenting with recurrent encephalomeningitis, serial measurements of cerebral spinal fluid interleukin-6, interferon-γ, interleukin-8, and IP10 [which is also referred to as the chemokine (C–X–C motif) ligand 10 (CXCL10)] were elevated as compared to levels in control subjects with neurologic disorders and also correlated with total cerebral spinal fluid cell counts; this data suggests an important role of the helper T-cell type 1 cell (whose cytokines include interferon-γ and IP10) and interleukin-8 (a specific neutrophil chemoattractant) in the pathogenesis of neuro-Sweet disease.[478] Other studies showed decreased epidermal staining for interleukin-1 and interleukin-6 and postulated that this was due to the release of these cytokines into the dermis.[131] In summary, G-CSF, granulocyte macrophage colony stimulating factor, interferon-γ, interleukin-1, interleukin-3, interleukin-6, and interleukin-8 are potential cytokine candidates in the pathogenesis of Sweet syndrome.[2,13,21–23,44,128–132]

CLINICAL FINDINGS

HISTORY

Sweet syndrome patients may appear dramatically ill. The skin eruption is usually accompanied by fever and leukocytosis. However, the skin disease can follow the fever by several days to weeks or be concurrently present with the fever for the entire episode of the dermatosis. Arthralgia, general malaise, headache, and myalgia are other Sweet syndrome associated symptoms (Table 32-2).[1,2,23]

CUTANEOUS LESIONS

Skin lesions of Sweet syndrome typically appear as tender, red or purple–red, papules or nodules. The eruption may present as a single lesion or multiple lesions that are often distributed asymmetrically (Fig. 32-1).

Figure 32-1 Unilateral lesions of Sweet syndrome around the eye and upper lip consisting of plaques and pseudovesicular papules suggesting herpes simplex.

TABLE 32-2
Clinical Features in Patients with Sweet Syndrome

Characteristic	Clinical Form			
	Classical[a] (%)	Hematologic Malignancy[a] (%)	Solid Tumor[a] (%)	Drug Induced[b] (%)

[c]Recurrence following oral rechallenge testing in the patients with drug-induced Sweet's syndrome.
[d]Temperature greater than 38°C.
[e]Neutrophil count greater than 6000 cells/uL.
[f]Erythrocyte sedimentation rate greater than 20 mm/hour.
[g]Hemoglobin less than 13 g/dL in men and less than 12 g/dL in women.
[h]Platelet count less than 150,000/uL or greater than 500,000/uL.
[i]This includes hematuria, proteinuria, and renal insufficiency.

The pronounced edema in the upper dermis of the lesions results in their transparent, vesicle-like appearance and has been described as an "illusion of vesiculation" (Fig. 32-2). In later stages, central clearing may lead to annular or arcuate patterns. The lesions may appear bullous, become ulcerated, and/or mimic the morphologic features of pyoderma gangrenosum in patients with malignancy-associated Sweet syndrome.[133,134] The lesions enlarge over a period of days to weeks. Subsequently, they may coalesce and form irregular sharply bordered plaques (Fig. 32-3). They usually resolve, spontaneously or after treatment, without scarring. Lesions associated with recurrent episodes of Sweet syndrome occur in one-third to two-thirds of patients.[1,2,135,136]

Cutaneous pathergy, also referred to as skin hypersensitivity, is a dermatosis-associated feature.[1,2] It occurs when Sweet syndrome skin lesions appear at sites of cutaneous trauma.[458,496] These include the locations where procedures have been performed such as biopsies,[20] injection sites,[431] intravenous catheter placement,[20] and venipuncture.[12,17,20,37,137,138] They also include sites of insect bites and cat scratches,[20] areas that have received radiation therapy,[139–141,138,484] and places that have been contacted by sensitizing antigens.[137,142,420] In addition, in some Sweet syndrome patients, lesions have been photodistributed or localized to the site of a prior phototoxic reaction (sunburn).[13,20,98,143–145] Sweet syndrome lesions have also rarely been located on the arm affected by postmastectomy lymphedema.[100,146,419,505]

Sweet syndrome can present as a pustular dermatosis.[147] The lesions appear as tiny pustules on the tops of the red papules or eythematous-based pustules. Some of the patients previously described as having the

Figure 32-2 Multiple confluent papules and plaques of Sweet syndrome that at first sight give the illusion of vesiculation but are solid on palpation. (From Honigsmann et al: Akute febrile neutrophile Dermatose. *Wien Klin Wochenschr* **91**:842, 1979, with permission.)

"pustular eruption of ulcerative colitis" are perhaps more appropriately included in this clinical variant of Sweet syndrome.[1,148]

"Neutrophilic dermatosis of the dorsal hands" or "pustular vasculitis of the dorsal hands" refers to a localized, pustular variant of Sweet syndrome when the clinical lesions are predominantly restricted to the dorsal aspect of the hands.[3,149–154] The lesions from this latter group of individuals are similar to those of Sweet syndrome in morphology and rapid resolution after systemic corticosteroids and/or dapsone therapy was initiated. In addition, many of the individuals with this form of the disease also had concurrent lesions that were located on their oral mucosa, arm, leg, back, and/or face.[3,155–163,425,435,440,442,457,462,470,495,497]

The cutaneous lesions of subcutaneous Sweet syndrome usually present as erythematous, tender dermal nodules on the extremities.[4,8,12,17,99,119,164–185] When the lesions are located on the legs, they often mimic erythema nodosum.[170] Since Sweet syndrome can present concurrently[21,125,187–189] or sequentially[170] with erythema nodosum,[17,21,187,190,509] tissue evaluation of one or more new dermal nodules may be necessary to establish the correct diagnosis—even in a patient whose Sweet syndrome has previously been biopsy-confirmed.[1,2,4]

RELATED PHYSICAL FINDINGS

EXTRACUTANEOUS MANIFESTATIONS. (eTable 32-2.1 in online edition.) Extracutaneous manifestations of Sweet syndrome may include the bones, central nervous system, ears, eyes, kidneys, intestines, liver, heart, lung, mouth, muscles, and spleen.[12,16,17,20,25,26,32,33,44,73,75,101,117,138,139,165,202,203,205,212–257,407,408,410,433,444,450,452,459,465,468,475,478,481,486,599] The incidence of ocular involvement (such as conjunctivitis) is variable in classical Sweet syndrome and uncommon in the malignancy-associated and drug-induced forms of the dermatosis; however, it may be the presenting feature of the condition. Mucosal ulcers of the mouth occur more frequently in Sweet syndrome patients with hematologic disorders and are uncommon in patients with classical Sweet syndrome[23,26,102,117,203,252]; similar to extracutaneous manifestations of Sweet syndrome occurring at other sites, the oral lesions typically resolve after initiation of treatment with systemic corticosteroids.[1,2] In children, dermatosis-related sterile osteomyelitis has been reported.

ASSOCIATED DISEASES. (eTable 32-2.2 in online edition.) Several conditions have been observed to occur either before, concurrent with, or following the diagnosis of Sweet syndrome. Therefore, the development of Sweet syndrome may be etiologically related to Behcet's disease, cancer, erythema nodosum, infections, inflammatory bowel disease, pregnancy, relapsing polychondritis, rheumatoid arthritis, sarcoidosis, and thyroid

Figure 32-3 Acute febrile neutrophilic dermatosis. Typical lesion consisting of coalescing, plaque-forming papules. **A.** Bright-red lesions on the neck. **B.** Lesion on the dorsum of the right-hand exhibiting the "relief of a mountain range" feature. (From Honigsmann H, Wolff K: Acute febrile neutrophilic dermatosis (Sweet's syndrome). In: *Major Problems in Dermatology, vol 10, Vasculitis*, edited by K Wolff, RK Winkelmann, consulting editor A Rook. London, Lloyd-Luke, 1980, p. 307, with permission.)

disease. The association between Sweet syndrome and the other conditions (eTable 32-2.2 in online edition) remains to be established.[1,2,5,11–20,30,36–43,69–126,158–161,164,166,186–190,195,214,231,236,259–339,400,402,406,410,411,415,417,418,421–424,426–429,434,436–442,445,446,448,449,452–456,459,460,463,464,466–469,471–477,479,480,482,483,487–490,492–494,496,497,500,502–504,508,509]

ASSOCIATED NEUTROPHILIC DERMATOSES.

An inflammatory infiltrate of mature polymorphonuclear leukocytes is the unifying characteristic of neutrophilic dermatoses of the skin and mucosa. Concurrent or sequential occurrence of Sweet syndrome with either erythema elevatum diutinum,[340] neutrophilic eccrine hidradenitis,[6] pyoderma gangrenosum,[9,231,269,341,342,430,483,497] subcorneal pustular dermatosis,[6,9] and/or vasculitis[3,192,231] has been observed. Although these conditions can display similar clinical and pathologic features, the location of the neutrophilic infiltrate helps to differentiate them.[6,120,499]

CONCURRENT LEUKEMIA CUTIS.

In patients with hematologic disorders, Sweet syndrome may present as a paraneoplastic syndrome (signaling the initial discovery of an unsuspected malignancy), a drug-induced dermatosis (following treatment with either all-*trans*-retinoic acid, bortezomib, G-CSF, or imatinib mesylate), or a condition whose skin lesions concurrently demonstrate leukemia cutis.[1] Acute leukemia (myelocytic and promyelocytic) is the most frequent hematologic dyscrasia associated with leukemia cutis (characterized by abnormal neutrophils) and Sweet syndrome (consisting of mature polymorphonuclear leukocytes) being present in the same skin lesion.[1,70,71,93,109,165,205–211,497] Myelodysplastic syndrome and myelogenous leukemia (either chronic or not otherwise specified) are the other associated hematologic disorders that have been associated with concurrent Sweet syndrome and leukemia cutis.[109]

"Secondary" leukemia cutis, in which the circulating immature myeloid precursor cells are innocent bystanders that have been recruited to the skin as the result of an inflammatory oncotactic phenomenon stimulated by the Sweet syndrome lesions has been suggested as one of the hypotheses to explain concurrent Sweet syndrome and leukemia cutis in the same lesion.[165,206,207] Alternatively, "primary" leukemia cutis, in which the leukemic cells within the skin constitutes the bonified incipient presence of a specific leukemic infiltrate is another possibility.[207] Finally, it is possible that the atypical cells of leukemia cutis developed into mature neutrophils of Sweet syndrome as a result of G-CSF therapy-induced differentiation of the sequestered leukemia cells in patients with "primary" leukemia cutis who were being treated with this agent.[205]

LABORATORY TESTS

HISTOPATHOLOGY

Evaluation of a lesional skin biopsy is helpful when the diagnosis of Sweet syndrome is suspected. Lesional tissue should also be submitted for bacterial, fungal, mycobacterial, and possibly viral cultures since the pathologic findings of Sweet syndrome are similar to those observed in cutaneous lesions caused by infectious agents.[1,2]

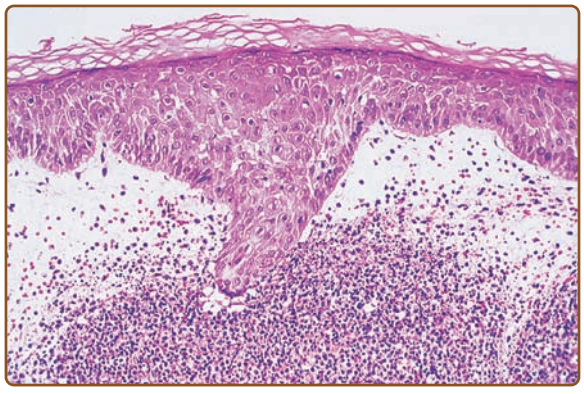

Figure 32-4 Histopathologic presentation of acute febrile neutrophilic dermatosis (Sweet syndrome) demonstrates massive edema of the papillary dermis and a dense diffuse infiltrate of mature neutrophils throughout the upper dermis (hematoxylin and eosin stain). (From Cohen PR et al: Sweet's syndrome in patients with solid tumors. *Cancer* **72**:2723-2731, 1993, with permission.)

A diffuse infiltrate of mature neutrophils is characteristically present in the papillary and upper reticular dermis (Fig. 32-4); however, it can also involve the epidermis or adipose tissue. "Histiocytoid" Sweet syndrome refers to the setting in which the hematoxylin and eosin-stained infiltrate of immature myeloid cells are "histiocytoid-appearing" and are therefore initially misinterpreted as histiocytes.[201,412–414,436,443,445,460,474]

The dermal inflammation is usually dense and diffuse; however, it can also be perivascular or demonstrate "secondary" changes of leukocytoclastic vasculitis believed to be occurring as an epiphenomenon and not representative of a "primary" vasculitis,[3,192,193] Neutrophilic spongiotic vesicles[194] or subcorneal pustules[12,80,167,195,196] result from exocytosis of neutrophils into the epidermis.[12,17,80,167,194,195,197] When the neutrophils are located either entirely or only partially in the subcutaneous fat, the condition is referred to as "subcutaneous Sweet syndrome".[4,8,12,17,99,119,164–184,451,461,493,497]

Edema in the dermis, swollen endothelial cells, dilated small blood vessels, and fragmented neutrophil nuclei (referred to as karyorrhexis or leukocytoclasia) may also be present (Fig. 32-5). Fibrin deposition or neutrophils within the vessel walls (changes of "primary" leukocytoclastic vasculitis) are usually absent and the overlying epidermis is normal.[1,2,23,167,168] However, the spectrum of pathologic changes described in cutaneous lesions of Sweet syndrome has expanded to include concurrent leukemia cutis, vasculitis, and variability of the composition or the location of the inflammatory infiltrate.[3,191,491,496]

Lymphocytes or histiocytes may be present in the inflammatory infiltrate of Sweet syndrome lesi ons.[11,104,167,168,198–200,504] Eosinophils have also been noted in the cutaneous lesions from some patients with either idiopathic[11,167,168,195,202–204,212] or drug-induced[84,107,110,111]

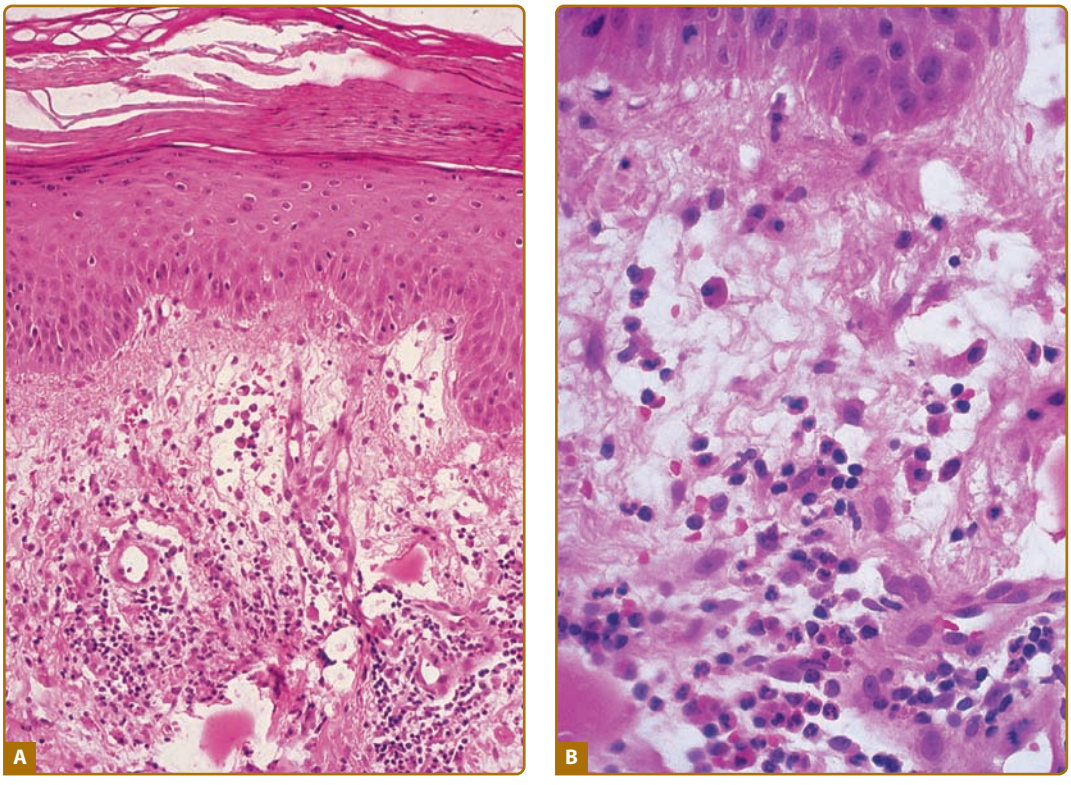

Figure 32-5 Characteristic histopathologic features of Sweet syndrome are observed at low (**A**) and high (**B**) magnification: papillary dermal edema, swollen endothelial cells, and a diffuse infiltrate of predominantly neutrophils with leukocytoclasia, yet no evidence of vasculitis (hematoxylin and eosin stain). (From Cohen PR et al: Concurrent Sweet's syndrome and erythema nodosum: A report, world literature review and mechanism of pathogenesis. *J Rheumatol* **19**:814-820, 1992, with permission.)

Sweet syndrome. Abnormal neutrophils (leukemia cutis)—in addition to mature neutrophils—comprise the dermal infiltrate in occasional Sweet syndrome patients with hematologic disorders.[1,70,71,93,109,165,205–211]

Pathologic findings of Sweet syndrome can also occur in extracutaneous sites. Often, these present as sterile neutrophilic inflammation in the involved organ. These changes have been described in the bones, intestines, liver, aorta, lungs, and muscles of patients with Sweet syndrome.[2]

OTHER LABORATORY TESTS

Peripheral leukocytosis with neutrophilia and an elevated erythrocyte sedimentation rate and are the most consistent laboratory findings in Sweet syndrome.[23] However, leukocytosis is not always present in patients with biopsy-confirmed Sweet syndrome.[26] For example, anemia, neutropenia, and/or abnormal platelet counts may be observed in some of the patients with malignancy-associated Sweet syndrome. Therefore, a complete blood cell count with leukocyte differential and platelet count, evaluation of acute phase reactants (such as the erythrocyte sedimentation rate or *C*-reactive protein), serum chemistries (evaluating hepatic function and renal function), and a urinalysis should be performed. It is also reasonable to perform a serologic evaluation of thyroid function since there appears to be a strong association between thyroid disease and Sweet syndrome.[1,2]

SPECIAL TESTS

EVALUATION FOR EXTRACUTANEOUS MANIFESTATIONS. Extracutaneous manifestations of Sweet syndrome may result in other laboratory abnormalities. Patients with central nervous system involvement may have abnormalities on brain SPECTs (single photon emission computed tomography), computerized axial tomography, electroencephalograms, magnetic resonance imaging, and cerebrospinal fluid analysis. Patients with kidney and liver involvement may demonstrate urinalysis abnormalities (hematuria and proteinuria) and hepatic serum enzyme elevation. And, patients with pulmonary involvement may have pleural effusions and corticosteroid-responsive culture-negative infiltrates on their chest roentgenograms.[2,343]

MALIGNANCY WORKUP. Recommendations for the initial malignancy workup in newly diagnosed Sweet syndrome patients without a prior cancer were proposed by Cohen and Kurzrock in 1993.[15] Their recommendations were based upon the age-related recommendations of the American Cancer Society for

early detection of cancer in asymptomatic persons and the neoplasms that had concurrently been present or subsequently developed in previously cancer-free Sweet syndrome patients. The recommended evaluation included the following:

1. A detailed medical history
2. A complete physical examination, including:
   (a) examination of the thyroid, lymph nodes, oral cavity, and skin;
   (b) digital rectal examination;
   (c) breast, ovary, and pelvic examination in women; and
   (d) prostate and testicle examination in men.
3. Laboratory evaluation:
   (a) carcinoembryonic antigen level;
   (b) complete blood cell count with leukocyte differential and platelet count;
   (c) pap test in women;
   (d) serum chemistries;
   (e) stool guaiac slide test;
   (f) urinalysis; and
   (g) urine culture.
4. Other screening tests:
   (a) chest roentgenograms;
   (b) endometrial tissue sampling in either menopausal women or women with a history of abnormal uterine bleeding, estrogen therapy, failure to ovulate, infertility, or obesity; and
   (c) sigmoidoscopy in patients over 50 years of age.

Since the initial appearance of dermatosis-related skin lesions had been reported to precede the diagnosis of a Sweet syndrome-associated hematologic malignancy by as long as 11 years, they also suggested that it was reasonable to check a complete blood cell count with leukocyte differential and platelet count every 6–12 months.[2,15]

DIFFERENTIAL DIAGNOSIS

CLINICAL DIFFERENTIAL DIAGNOSIS

Sweet syndrome skin and mucosal lesions mimic those of other conditions (Table 32-3.)[2,15,23,148,165,202,220,344,345,409,421,448,498] Therefore, infectious and inflammatory disorders, neoplastic conditions, reactive erythemas, vasculitis, other cutaneous conditions, and other systemic diseases are included in the clinical differential diagnosis of Sweet syndrome.

HISTOLOGIC DIFFERENTIAL DIAGNOSIS

The histologic differential diagnosis of Sweet syndrome includes conditions microscopically characterized by either neutrophilic dermatosis or neutrophilic panniculitis (eTable 32-3.1 in online edition).[2–4,6,12,193,346–353,432,451]

The pathologic changes associated with Sweet syndrome are similar to those observed in an abscess or cellulitis; therefore, culture of lesional tissue for bacteria, fungi, and mycobacteria should be considered to rule out infection.[23] Leukemia cutis not only mimics the dermal changes of Sweet syndrome, but can potentially occur within the same skin lesion as Sweet syndrome; however, in contrast to the mature polymorphonuclear neutrophils found in Sweet syndrome, the dermal infiltrate in leukemia cutis consists of malignant immature leukocytes.[354] The pathologic changes in the adipose tissue of subcutaneous Sweet syndrome lesions can be found in either the lobules, the septae, or both; therefore, conditions characterized by a neutrophilic lobular panniculitis also need to always be considered and ruled out.[2,4]

COMPLICATIONS

Complications in patients with Sweet syndrome can be directly related to the mucocutaneous lesions or indirectly related to the Sweet syndrome-associated conditions. Skin lesions may become secondarily infected and antimicrobial therapy may be necessary. In patients with malignancy-associated Sweet syndrome, reappearance of the dermatosis may herald the unsuspected discovery that the cancer has recurred. Systemic manifestations of Sweet syndrome-related conditions—such as inflammatory bowel disease, sarcoidosis and thyroid diseases—may warrant disease-specific treatment.

PROGNOSIS AND CLINICAL COURSE

The symptoms and lesions of Sweet syndrome eventually resolved without any therapeutic intervention in some patients with classical Sweet syndrome. However, the lesions may persist for weeks to months.[10,23,254,355] In patients with malignancy-associated Sweet syndrome, successful management of the cancer occasionally results in clearing of the related dermatosis.[13,15,23] Similarly, discontinuation of the associated medication in patients with drug-induced Sweet syndrome is typically followed by spontaneous improvement and subsequent resolution of the syndrome.[13,15,23] Surgical intervention has also resulted in the resolution of Sweet syndrome in some of the patients who had associated tonsillitis, solid tumors, or renal failure.[1,2,19,315,356,357,507]

Sweet syndrome may recur following either spontaneous remission or therapy-induced clinical resolution.[10] The duration of remission between recurrent episodes of the dermatosis is variable. Sweet syndrome recurrences are more common in cancer patients; in this patient population, the reappearance of dermatosis-associated symptoms and lesions may represent a paraneoplastic syndrome that is signaling the return of the previously treated malignancy.[1,2,15,135]

TREATMENT

Systemic corticosteroids are the therapeutic mainstay for Sweet syndrome (eTable 32-3.2 in online edition).[7,8–10,12,16,17,19,20,23,36,49,50,70,184,223,233,240,250,284,358–361] Initiation of therapy promptly results in improvement of the symptoms and resolution of the mucocutaneous lesions. Daily pulse methylprednisolone administered intravenously may be necessary in patients with refractory disease. Topical (such as 0.05% clobetasol propionate)[13,19–21,30,234,362–365] or intralesional (such as triamcinolone acetonide at a dose between 3.0 and 10.0 mg/cc)[362,366,367] corticosteroids may be effective for treating localized Sweet syndrome lesions.[1,2,7,9]

Potassium iodide and colchicine are also first-line systemic treatments for Sweet syndrome (eTable 32-3.2 in online edition).[10,12,17,20,23,30,49,70,143,184,198,203,221,223,231,240,245,250,259,261,281,284,294,296,329,359–363,368–384,468,496] Vasculitis and hypothyroidism are potential drug-induced side effects of potassium iodide.[385] Gastrointestinal symptoms such as diarrhea, abdominal pain, nausea, and vomiting are potential adverse effects from colchicine which may improve after lowering the daily dose of the drug.[2]

Second-line systemic agents for Sweet syndrome include indomethacin,[259,261,284,378,490] clofazimine,[12,296,379] cyclosporine,[12,30,231,294,380,381] and dapsone[17,20,30,203,221,245,284,372,382–384,459,460,486] (eTable 32-3.2 in online edition). They have all been used as monotherapy either in the initial management of the patient or after first-line therapies has failed. In addition, cyclosporine and dapsone have been used in combination therapy either as a corticosteroid-sparing agent or with other drugs.[1,2,7,303]

There are certain patients whose Sweet syndrome lesions have improved after receiving systemic antibiotics[7,412]: individuals with *Staphylococcus aureus* secondarily impetiginized lesions treated with an antimicrobial agent to which their bacterial strain is susceptible,[23] patients with inflammatory bowel disease treated with metronidazole,[267,387] and persons with dermatosis-related *Yersinia*[125,126] or *Chlamydia*[306,307] infection treated with either doxycycline,[125,389] minocycline,[30,126] or tetracycline.[306,307,388]

In addition, effective treatment of Sweet syndrome has also been described, predominantly in case reports, with other drugs: cytotoxic chemotherapies and antimetabolites (chlorambucil and cyclophosphamide),[30,39,148,200,251,360,390] danazol,[9] etretinate,[361] hepatitis therapy,[9] immunoglobulin,[303] interferon α,[202,366] and tumor necrosis factor antagonists[444] (adalimumab,[501] etanercept,[392,404] infliximab,[264,265,278,266,501] and thalidomide[5,393]). Anakinra (an interleukin-1 receptor antagonist), in combination with oral prednisone, was promptly effective in resolving the symptoms—and subsequently the clinical lesions—of Sweet syndrome in a patient with long-standing disease that was refractory to other therapies.[399] Pentoxifylline was hypothesized to be beneficial for treating Sweet syndrome[394,395]; however, when used as monotherapy, it was not found to be efficacious.[1,2,7,295,362]

Chapter 33 :: Pyoderma Gangrenosum

:: Frank C. Powell, Bridget C. Hackett, & Daniel Wallach

PYODERMA GANGRENOSUM AT A GLANCE

- Pyoderma gangrenosum (PG) is a rare inflammatory disease of unknown etiology characterized by sterile neutrophilic infiltration of the skin. Similar neutrophilic infiltrations may occur in other organs. It is considered to be one of the groups of neutrophilic dermatoses and clinical and histological overlap with some of these may occur.
- PG is more frequent in female patients and occurs at any age, but usually between 40 and 60 years.
- The majority of patients with PG have other systemic diseases (such as arthritis, inflammatory bowel disease, hematological dyscrasias, malignant disease, etc.), but PG occurs independently of these disorders.
- PG may present as ulcerative, bullous, pustular, or vegetative variants. Clinical features of different variants sometimes overlap in individual patients but usually one variant dominates the clinical picture.
- There is no laboratory test or investigation that establishes the diagnosis of PG with certainty. The histopathological findings are not diagnostic but can be supportive of the diagnosis of PG in the appropriate clinical setting and are essential to rule out alternative diagnoses.
- Specified criteria (see below) suggest the diagnosis of PG, but other conditions (particularly infection, vascular disease, and malignancy) must be excluded.
- The mainstays of management are systemic immunosuppressive agents together with appropriate local and topical therapy.
- Ulcerative PG is a chronic disease. Remission usually requires months of treatment; maintenance therapy is necessary in many and relapses are common. Significant morbidity and mortality are experienced by patients with ulcerative and bullous PG.

EPIDEMIOLOGY

The prevalence of pyoderma gangrenosum (PG) is unknown. Estimates have suggested that approximately three cases of PG per million of the population occur per year, with most large referral centers seeing one to two cases per year.[1] It has been reported in all age groups but mainly affects adults between the ages of 40 and 60 years.[2] Most reported series of patients with PG indicate a moderate preponderance of females. PG often occurs in patients who have other diseases (arthritis, inflammatory bowel disease, hematologic dyscrasias, etc.), but is not a manifestation or complication of these diseases and its clinical course is usually unrelated to their severity or activity.[3]

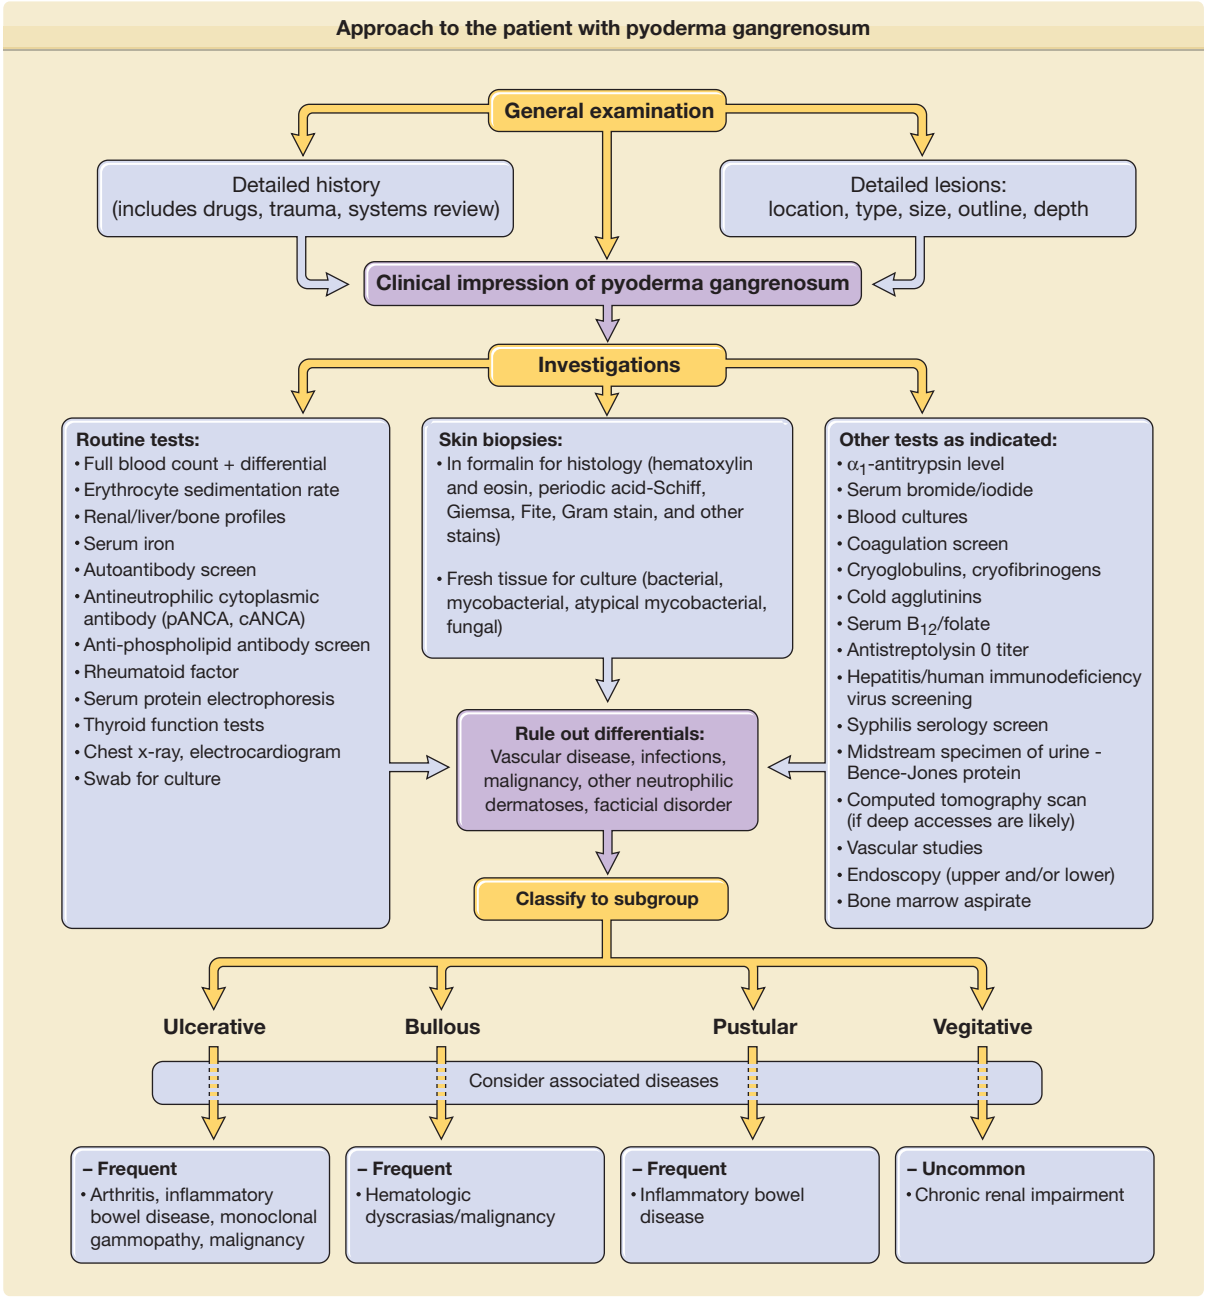

Figure 33-1 Approach to the patient with pyoderma gangrenosum.

ETIOLOGY AND PATHOGENESIS

The etiology of PG is unknown, and its pathogenesis poorly understood. Based on the presence of a lymphocytic infiltrate at the active advancing border of PG lesions, it has been postulated that lymphocytic antigen activation occurs with cytokine release and neutrophil recruitment. This may take place not only in the skin but also in other tissues such as the lung, intestine, and joints. The predominance of the neutrophilic infiltrate in established lesions of PG have led to its classification as one of the neutrophilic dermatoses.[4] Clinical (and to an extent histologic) overlap occurs with the other dermatoses in this category, especially atypical or bullous forms of Sweet syndrome (see Chapter 32). Several of the neutrophilic dermatoses (Sweet syndrome, erythema elevatum diutinum, subcorneal pustular dermatosis, and PG) share an association with immunoglobulin A monoclonal gammopathy, and diseases such as inflammatory bowel disease and hematologic disorders occur more frequently than expected in these patients. The recent description of the PAPA (Pyogenic Arthritis, Pyoderma gangrenosum-Acne) syndrome,[5] a disease considered to be one of the "autoinflammatory"

diseases, raises the possibility that PG may lie within this spectrum.

CLINICAL FINDINGS

The approach to an individual suspected of having PG is outlined in the patient algorithm (Fig. 33-1). The clinical presentation of PG may be diverse and there is neither a diagnostic laboratory test nor pathognomonic histopathologic findings. Therefore, it is important to avoid misdiagnosing other diseases as PG.[6] The most important considerations are the exclusion of infection (bacterial, viral, and deep fungal), vascular disease (stasis, occlusion, and vasculitis), and malignancy in every patient. Close follow-up and reevaluation (with repeated skin biopsies, tissue and swab cultures, and other tests as clinically indicated) is an important part of the ongoing evaluation of patients with suspected PG, particularly those who show a poor response to therapy.

HISTORY

A patient with PG usually complains of severe pain that is out of proportion to the clinical appearance of the lesion. Approximately 25% of patients note the onset of PG at sites of cutaneous trauma (needle stick, inoculation site, insect bites, or surgical procedures). This is called the *pathergic phenomenon* (Fig. 33-2). Lesions progress rapidly (with the exception of vegetative PG) and cutaneous destruction evolves over days rather than weeks. Special inquiry regarding drug intake (especially iodides/bromides, hydroxyurea); exposure to and symptoms of infectious diseases (Box 33-1); symptoms relating to the musculoskeletal system (joint pains, swelling, etc.), the gastrointestinal tract (abdominal pain, diarrhea, constipation, etc.), hematologic disease (tiredness, anemia, bruising, blood clotting disorders, etc.), respiratory disease, and nonspecific but potential malignancy-related symptoms, such as weight loss and fatigue, should be made.

Figure 33-2 Several pathergic pyoderma gangrenosum lesions occurring along a thoracotomy scar site. Note central ulceration, violaceous borders, and peripheral rim of erythema.

CUTANEOUS LESIONS: CLINICAL VARIANTS OF PG

PG is protean in its clinical expression with variable presentation according to the variant and the stage of disease. Lesions can be classified morphologically as being (1) ulcerative (the commonest and originally described variant), (2) bullous, (3) pustular, or (4) vegetative. Although some patients may show more than one variant (e.g., isolated pustular lesions frequently occur in patients with ulcerative PG), usually one variant of PG dominates the clinical picture and the patient should be classified accordingly.

The most common initial clinical lesion in a patient with *ulcerative PG* is an inflammatory pustule or nodular furuncle (these lesions are usually single but may be multiple). They erupt on apparently normal skin (the most common site being the leg), or sometimes at the site of trauma or surgery (Fig. 33-2). The enlarging initial lesion develops a surrounding areola or zone of erythema that extends into the surrounding skin (Fig. 33-3). As it enlarges, the center degenerates, crusts, and erodes, converting it into an eroding ulcer the development of which is accompanied by an alarming increase in the severity of the pain. The ulcer often has a bluish/violaceous edge (due to undermining by the necrotizing inflammatory process) and the base is covered with purulent material. Ulcerative PG may erode deeply with exposure of muscle or tendon in some cases.

Bullous PG (sometimes called atypical PG) presents as a painful, rapidly expanding superficial inflammatory blister that quickly erodes. In the early acute stage, the bullous nature of the lesion is evident, but because the roof of the blister necroses rapidly, close inspection of the border of established lesions is necessary to reveal its bullous nature (Fig. 33-4). Bullous PG is commonly associated with hematologic disease and most

Figure 33-3 Established lesion of ulcerative pyoderma gangrenosum showing well-defined ulceration with surrounding zone of erythema.

BOX 33-1 DIFFERENTIAL DIAGNOSIS OF PYODERMA GANGRENOSUM (PG)

VARIANT SPECIFIC

Ulcerative PG

Most Likely

- Vascular
  - Venous stasis ulceration
  - Occlusive disease/Arteritis
  - Vasculitis
  - Antiphospholipid–antibody syndrome
- Malignancy
  - Primary or secondary
- Infection
  - Bacterial
  - Mycobacterial/Atypical mycobacterial
  - Viral (herpes simplex)
  - Deep fungal infection (*Sporotrichosis*, *Aspergillus*, *Cryptococcus*)
- Other
  - Drugs (halogenoderma/hydroxyurea, etc.)

Consider

- Infection
  - Necrotizing fasciitis
  - Syphilis/Amebiasis/Mucormycosis
  - Histoplasmosis/Rhizopus
- Other
  - Dermatitis artefacta
  - Calciphylaxis/Insect bite (spider)

Bullous PG

Most Likely

- Infection
  - Bacterial (cellulitis/impetigo)
  - Viral (in immunocompromised)
  - Fungal (mucormycosis in diabetics)
- Other
  - Sweet syndrome/Behçet disease

Consider

- Bullous dermatoses
  - Erythema multiforme/Bullous pemphigoid
- Other
  - Insect/Arthropod bite/Malignancy

Pustular PG

Most Likely

- Infection
  - Bacterial/Viral/Fungal
- Vasculitis
  - Pustular vasculitis

Consider

- Other
  - Pustular psoriasis
  - Sneddon–Wilkinson disease
  - Pustular drug eruption
  - Bowel bypass syndrome
  - Pyostomatitis vegetans

SITE SPECIFIC[a]

Parastomal

Most Likely

- Dermatoses (extraintestinal Crohn's)
  - Irritant/Allergic contact dermatitis
  - Other (e.g., psoriasis)
- Infection
  - Bacterial (*Staphylococcus*/*Streptococcus*)/Cellulitis
  - Fungal (*Candida*)
- Other
  - Extraintestinal inflammatory
  - Bowel disease
  - Malignancy

In Wounds

Most Likely

- Infection
  - Bacterial/Cellulitis
  - Fungal (e.g., mucormycosis)
- Breakdown
  - Suture allergy
  - Mechanical

Consider

- Malignancy

Genital

Most Likely

- Infection
  - Bacterial/Viral infection (herpes simplex virus, Epstein–Barr virus, cytomegalovirus)
  - Tuberculosis/Tuberculide
  - Fournier gangrene
- Malignancy
  - Squamous cell/Extramammary
  - Paget disease

Consider

- Infection
  - Syphilis/Lymphogranuloma
  - Venereum/Histoplasmosis
  - Leishmaniasis/Granuloma inguinale
- Other
  - Dermatitis artefacta
  - Behçet disease

Head and Neck

Most Likely

- Infection
  - Bacterial/Viral/Fungal
  - Dissecting cellulitis of the scalp
- Malignancy
  - Squamous cell carcinoma
  - Basal cell carcinoma

Consider

- Vasculitis
  - Granulomatosis with polyangiitis (Wegener's)
  - Malignant pyoderma

Dermatitis artefacta

[a]The differential diagnosis of lower limb PG is essentially that delineated for variant-specific ulcerative PG.

often appears on the upper limbs.[2] This variant of PG may show clinical and histological overlap with Sweet Syndrome (one of the neutrophilic dermatoses which is itself often associated with hematologic disease).

Pustular PG (also called the *pustular eruption of inflammatory bowel disease*) is a generalized eruption that occurs almost exclusively in the setting of an exacerbation of acute inflammatory bowel disease (usually ulcerative colitis). Its onset is dramatic, with the rapid development of multiple, large, circular-to-oval, painful pustules on the trunk and, to a lesser extent, the face and limbs (Fig. 33-5). Control of this eruption is difficult without controlling the bowel disease, which in some cases requires extensive resective surgery.

Vegetative PG (or superficial granulomatous pyoderma) usually presents as a single furunculoid nodule, abscess, plaque, or superficial ulcer, typically on the trunk (Fig. 33-6). In contrast to other variants, it is gradual in its onset, mild in the discomfort it generates, and not usually associated with the presence of systemic disease. This form of PG is usually more responsive to localized or mild forms of systemic therapy than the other variants.[7]

Postoperative and *Peristomal* PG are considered to be examples of ulcerative PG demonstrating the pathergic phenomenon, while the PAPA syndrome has recently been reported as an autosomal dominant condition classified as being one of the group of "autoinflammatory" diseases.

Figure 33-4 Bullous pyoderma gangrenosum lesion showing collapsed roof of blister and superficial erosive quality of the subsequent ulceration.

RELATED PHYSICAL FINDINGS

The clinician should be aware that sterile neutrophilic abscesses of internal organs (lung, bone joints, CNS, CVS, intra-abdominal viscera, eye) can occur in association with or even precede the onset of cutaneous PG.[7] In the patient without cutaneous lesions surgical procedures may be undertaken to establish the

Figure 33-5 Pustular pyoderma gangrenosum lesions of the penis in a patient who also had ulcerative pyoderma gangrenosum.

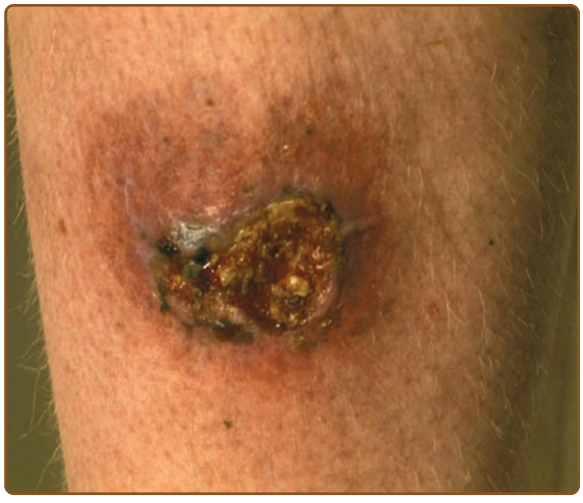

Figure 33-6 Vegetative pyoderma gangrenosum—an indolent area of chronic inflammation and ulceration that was present for months.

diagnosis of the internal neutrophilic infiltration, the wounds of which may subsequently break down and present as postoperative PG. Because many patients with PG also have diseases of other systems (more than 70% of cases), a thorough physical examination is mandatory with particular search for clinical and biological markers of inflammatory bowel disease, arthritis, vasculitis (leukocytoclastic/granulomatous/cryoglobulinemic/Takayasu arteritis), hematologic disease (monoclonal gammopathy and other dyscrasias), and internal malignancy.

LABORATORY TESTS

ROUTINE INVESTIGATIONS

(See Fig. 33-1)

All patients with PG should have the following tests carried out: full blood cell count with differential white cell count and erythrocyte sedimentation rate liver, and bone profiles; autoantibody screen (including anti-Ro/La antibodies, antineutrophilic cytoplasmic antibodies, antiphospholipid antibodies, rheumatoid factor); serum protein electrophoresis; thyroid function studies; chest X-ray (Fig. 33-7), electrocardiogram, and midstream specimen of urine; and swabs from lesions sent for bacterial, fungal, and viral cultures. An incisional, wedge skin biopsy should be taken from the edge of the lesion sampling a portion of normal skin progressing through the border into the area of active inflammation to allow the various histological patterns to be discerned. The excised tissue should then be divided with one section (fresh tissue) sent for bacterial, mycobacterial, and fungal culture, and another portion sent in formalin for histological evaluation requesting hematoxylin and eosin and periodic acid-Schiff, Giemsa, Fite, Gram, and other stains considered relevant. Although immunofluorescent studies may show positive vascular staining in perilesional skin, this is not essential for diagnostic purposes and can be omitted unless vasculitis is suspected in the differential diagnosis.

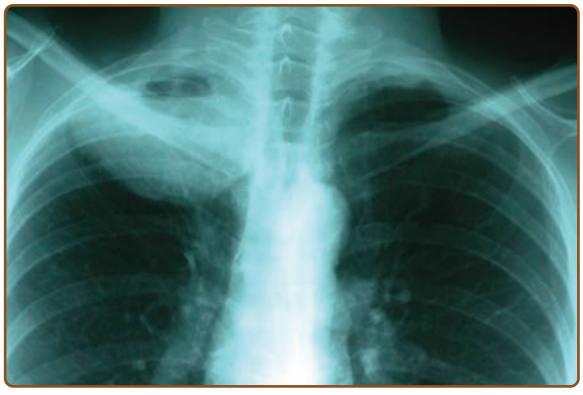

Figure 33-7 Chest X-ray showing neutrophilic abscess in the right upper lung with clear fluid level visible.

HISTOPATHOLOGY

The histopathological changes in the skin are not diagnostic but can be highly suggestive of PG and require experience to interpret. The inflammatory changes that are seen depend on (1) the clinical variant of PG (ulcerative, bullous, pustular, or vegetative), (2) the timing of the biopsy (early lesions show less marked changes than established lesions), and (3) the site of the biopsy relative to the inflammatory process.[8] The site of the biopsy is particularly important because biopsies taken from the center of established ulcerative, bullous, or pustular PG lesions usually show marked neutrophilic infiltration with abscess formation in the mid and deep dermis extending to the panniculus, whereas those taken from peripheral areas (the ulcer edge or inflammatory zone of erythema) show a mixed or predominantly lymphocytic inflammatory infiltrate.

A marked perivascular lymphocytic infiltration is seen in biopsies taken from the "zone" or area of erythema which surrounds active lesions of ulcerative PG. Lymphocytes may be seen to infiltrate vessel walls with intramural and intravascular fibrin deposition indicative of vascular damage (sometimes called lymphocytic vasculitis).[9] Abscess formation with intense dermal neutrophilic infiltration extending to the panniculus and areas of tissue necrosis dominates the histological findings in biopsies taken from central areas of ulcerative PG lesions. Leukocytoclasis is not a prominent finding and although occasionally evidence of leukocytoclastic vasculitis is seen close to the abscess center, this is a minor feature and considered secondary to the intense inflammatory changes rather than the primary event. Histological examination of lesional skin from a patient with bullous PG shows a subepidermal or intraepidermal bulla with overlying epidermal necrosis and marked upper dermal edema with prominence of neutrophils. Biopsy of pustular PG shows a dense dermal neutrophilic infiltration (often centered about a follicle) with subepidermal edema and infiltration of neutrophils into the epidermis with

subcorneal aggregations. Vegetative PG is characterized histologically by the presence of pseudoepitheliomatous hyperplasia, sinus tract formation, and the presence of palisading granulomas in the setting of focal dermal neutrophilic abscesses.

SPECIAL INVESTIGATIONS

In some patients the following additional tests may be warranted: endoscopy (upper and/or lower gastrointestinal); vascular studies; bone marrow aspirate examination; ultrasound of abdomen (including liver/spleen/aorta); computed tomography of the thorax, abdomen, or brain; and other directed investigations as outlined in Fig. 33-1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis to be considered in a patient with PG is extensive.[6] Different variants of PG (ulcerative, bullous, vegetative, pustular) suggest alternative diagnoses and the occurrence of PG at certain cutaneous sites raises further diagnostic issues for the clinician, as shown in Box 33-1.

Because there is no confirmatory diagnostic test for PG, the following major criteria are proposed which make the diagnosis of PG likely:

1. Major criteria are as follows:
   (a) Sudden onset of a painful lesion fitting the morphologic descriptions outlined above (ulcerative, bullous, pustular, or vegetative) in a (usually middle-aged) apyrexial patient without significant toxemia or relevant drug intake
   (b) Histological evidence of marked tissue neutrophilia in the absence of significant leukocytoclastic vasculitis and histopathological exclusion of malignancy and of infective organisms by special studies and negative tissue culture
   (c) Exclusion of vascular stasis/occlusion/vasculitis by appropriate studies
2. Minor criteria that are supportive of the diagnosis are as follows:
   (a) Localization of lesions at characteristic sites (ulcerative PG on the legs, vegetative on the trunk, bullous PG on the upper limb, pustular PG on the trunk or face) or at a site of cutaneous trauma (postoperative ulcerative PG or peristomal PG).
   (b) Rapid progression of the inflammatory lesion with escalating pain severity (except vegetative PG).
   (c) Occurrence in an individual with systemic disease, such as arthritis, inflammatory bowel disease, or hematological dyscrasias (except vegetative PG).
   (d) Rapid reduction of pain and inflammation on initiation of systemic steroid therapy.

COMPLICATIONS

Active or poorly controlled cutaneous PG causes significant morbidity (loss of mobility, pain, exposure to secondary infection, anemia of chronic disease, etc.). Lack of recognition of the neutrophilic infiltration of internal organs in PG may lead to unnecessary surgical procedures. Many of the treatments for PG must be administered for many months and may have significant side effects. Frequent monitoring and follow-up of patients are necessary. Elective surgery should be undertaken with caution because of the possibility of inducing new PG lesions.

PROGNOSIS AND CLINICAL COURSE

The prognosis depends on the PG variant; the age and sex of the patient; presence of other systemic disease; and the type, dosage, and duration of therapy required to bring the disease under control. Patients with vegetative PG generally have a good prognosis and the skin lesions often heal within 6 months of the initiation of relatively mild forms of treatment.[7] Peristomal PG similarly has a good prognosis often responding to topical or intralesional therapy. Patients with pustular PG often have complete remission of their cutaneous lesions if the severe inflammatory bowel disease that usually accompanies this variant is controlled. Ulcerative PG is a chronic recurrent disease with a significant morbidity and mortality.[2,10] Patients with this variant older than 65 years of age and male patients seem to have a worse prognosis. Patients with bullous PG who have an associated hematological disorder also have a poor prognosis. The onset of bullous PG in a patient with stable polycythemia rubra vera appears to herald the onset of leukemic change in some patients.[11]

TREATMENT

GENERAL MEASURES

The age, mobility, social support networks, pain threshold, extent and severity of disease, and ability to comply with therapeutic measures should be evaluated for each patient and the treatment adapted accordingly. The patient should be given realistic expectations of the speed of recovery likely in this disease. Thus, although lesions develop and evolve within days, the healing process usually takes weeks or even months. Adequate bed rest, efficient pain relief, correction of anemia, and appropriate therapy of any associated disease are pivotal in the overall management strategy of a patient with PG.[12] If other systemic illnesses are present, cooperation with an internal medicine specialist is important, and if surgery is anticipated appropriate measures (such as the use of subcuticular sutures and systemic steroid cover) should be adopted to avoid precipitating new postoperative PG lesions.

The location, morphology, size, and outline of each lesion should be recorded (by photography and by using a calibrated transparent plastic sheet placed over lesions on which the outline is traced) on presentation and subsequent review.

WOUND CARE

The cutaneous lesions of PG are usually extremely tender so cleansing should be carried out daily with tepid sterile saline or a mild antiseptic solution. Potassium permanganate solution diluted 1:2,000 is helpful if there is marked exudation. Silver sulphadiazine 1% cream is usually soothing when applied to the ulcerated lesions of PG and may facilitate granulation tissue formation as well as inhibiting bacterial growth. A nonadhesive dressing should be applied over the lesion and held in place with a crêpe elasticized bandage wound firmly, but not tightly, over it. Some patients, particularly those with superficial lesions, obtain significant relief with the use of hydrocolloid dressings, which can be left on for 2–3 days and "melt" into the lesion. Careful instruction to the patient and nurse is important to ensure compliance and to avoid the use of irritants such as chemical desloughing agents, caustics (such as silver nitrate), or dressings (such as gauze impregnated with soft paraffin and/or antibacterial agents which may adhere to the ulcer base) or pressure dressings as are sometimes prescribed for patients with ulcers due to venous insufficiency. A variety of bacteria may be cultured from the wound surface, but these usually represent contaminants and directed antibiotic therapy is not required unless there are clinical signs of incipient cellulitis around the wound.

TOPICAL TREATMENTS

Topical treatments are important adjuncts to the systemic treatment needed for the management of most PG patients, and may be sufficient to bring the condition under control in those who have vegetative or mild ulcerative PG. Potent topical corticosteroids applied to the periphery of an active PG lesion can reduce inflammation and may be sufficient to heal vegetative or peristomal ulcerative PG.[13] Although topical disodium cromoglycate (with or without occlusion), benzoyl peroxide, nicotine cream or patches, hyperbaric oxygen, and radiotherapy have all been reported as being helpful in individual patients with PG, their effectiveness has not been established. Clinical impression suggests that topical tacrolimus (with or without occlusion) is particularly effective for isolated pustular lesions and for the superficial ulcerations of peristomal PG.

INTRALESIONAL TREATMENTS

Intralesional triamcinolone acetonide (5–10 mg/mL) injected twice weekly into the border of a vegetative or peristomal PG lesion may lead to healing and can also be useful in a patient with ulcerative PG if one section of the ulcer is proving recalcitrant to other therapies. Intralesional cyclosporine and tacrolimus have also been reported to be effective in some PG patients.

SYSTEMIC TREATMENTS

Because PG is a rare disease, most systemic treatment recommendations are based on experience gained from small series of patients studied.[14] The main systemic treatments used for PG with their suggested dosages are listed in Box 33-2. As experience with newer agents is gained, it is likely these recommendations will change.[15] The initiation of systemic therapy is based on the variant of PG (ulcerative and bullous PG usually require systemic therapy), the rapidity of its evolution, the extent of cutaneous involvement, and the general medical status of the patient.

Systemic corticosteroid treatment is probably the initial treatment of choice for most patients with PG. It is important to initiate systemic steroids at a sufficiently high dose to control the disease. Rapid diminution of pain is often recorded by the patient after initiation of therapy and steroids should be continued at this dosage until lesions show evidence of healing, after which gradual tapering of the dose can be undertaken. A steroid-sparing agent should be added as soon as possible, as well as bone protective measures to diminish the risk of osteoporosis because prolonged therapy can be anticipated in most patients. Intravenous corticosteroids in pulsed doses have been used to induce PG remission, but serious potential adverse effects limit their use to exceptional circumstances. Dapsone has been traditionally used in the treatment of PG and remains a useful drug, particularly when used in conjunction with systemic corticosteroids. Dapsone is generally well tolerated, but hematological complications (including agranulocytosis, hemolysis, hemolytic anemia, and methemoglobulinemia) as well as other potentially serious side effects may occur. Other antimicrobial agents reported as successful in

BOX 33-2 SYSTEMIC TREATMENTS FOR PYODERMA GANGRENOSUM

MEDICATION	DOSAGE
Prednisone	0.5–1.5 mg/kg/day PO
Methylprednisolone (pulsed dose)	500 mg–1 g IV
Dapsone	50–200 mg/day PO
Clofazimine	200–400 mg/day PO
Minocycline	50–100 mg twice daily PO
Cyclosporine	3 to 5 mgs/kg/day PO
Tacrolimus	0.1–0.3 mg/kg PO
Mycophenolate mofetil	500 mg–1 g bid PO
Infliximab	5 mg/kg IV

the treatment of PG patients include rifampicin, tetracyclines, vancomycin, mezlocillin, clofazimine, and minocycline. These have usually been prescribed in combination with other systemic therapies and seem to work in PG patients by mechanisms other than their antibacterial properties. Most experience has been with clofazimine and minocycline (100–200 mg daily). The latter agent is well tolerated and often allows for a reduction in systemic corticosteroid dosage and appears to prolong remission in some patients.

Cyclosporine is an alternative first-line therapy of PG[16] or may be used in combination with systemic corticosteroids to achieve rapid control of disease. Doses of 3 to 5 mgs/kg/day have shown efficacy and continued treatment is usually required for 3–4 months. Less risk of serious side effects (such as impairment of renal function and hypertension) is seen at these low doses, but careful monitoring of patients is required and attention should paid to the possibility of other drugs interacting with this medication.

Tacrolimus (FK-506) and mycophenolate mofetil have also been used successfully in the treatment of PG either as monotherapies or in combination with systemic corticosteroids or cyclosporine.[17] Both drugs cause significant immunosuppression with resultant susceptibility of the patient to infection and malignant disease and can have other potentially serious side effects. Infliximab, an antitumor necrosis factor antibody, has been used successfully to treat patients with inflammatory bowel disease and has been reported to be effective in some patients with PG.[18] Other similar drugs that have been reported to be efficacious in the treatment of patients with PG include etanercept and adalimumab. The role of these agents in the management of PG has yet to be fully defined and susceptibility to reactivation of tuberculosis infection and other significant side effects remain a concern. Anakinra, an IL-1 receptor antagonist has been reported to be effective in treating PG of the PAPA syndrome and suggests another possible treatment for this condition.[5] The use of thalidomide in the treatment of PG has probably been superseded by the development of these other agents. Other drugs which have been reported to be helpful in the treatment of PG include azathioprine (thiopurine methyl transferase levels should be checked pretreatment), colchicine,[19] cyclophosphamide, chlorambucil, and melphalan. These agents can have toxic effects and evidence of their efficacy is limited.

Other modalities which have been reported to be useful in the management of individual patients or small series of patients with PG include human intravenous immunoglobulin,[20] interferon-α, nicotine,[21] potassium iodide, leukocytapheresis,[22] and plasma exchange. Skin grafting should be avoided if possible because of the risk of inducing new PG lesions at the donor sites, but cultured tissue allografts/autografts and the use of bovine collagen matrix have been reported to be useful in patients in whom the disease is controlled but reepithelialization incomplete.[23]

The unpredictable nature of PG and its variable aggressiveness in individual patients mean that a flexible approach to treatment is required and the use of therapeutic agents have to be adapted to the patient's physiologic state (childhood, pregnancy, old age). By whichever modality control of PG is achieved, maintenance therapy should be continued until there is complete wound healing. In addition, patients with ulcerative PG have a significant risk of relapse, so long-term follow-up is required.

PREVENTION

A patient who has had a history of PG should be advised to avoid trauma to the skin as there is the possibility of precipitating a new lesion (the pathergic phenomenon). If such patients have to undergo surgery, they should have close supervision by a dermatologist of their postoperative course. Patients with a history of aggressive PG may warrant a course of systemic steroids during and for a period (2 weeks or longer) postoperatively to prevent the development of new PG lesions and subcuticular sutures should be used where possible. Patients with a history of PG and Crohn's disease who are to have an ileostomy should be warned about the possible development of peristomal PG lesions.

Chapter 34 :: Granuloma Faciale

:: David A. Mehregan & Darius R. Mehregan

GRANULOMA FACIALE AT A GLANCE

- Granuloma faciale is an uncommon inflammatory dermatosis characterized clinically by reddish brown papules and plaques primarily involving the face.
- The pathology shows changes of a chronic leukocytoclastic vasculitis with a mixed infiltrate containing eosinophils, extensive perivascular fibrin deposition, and dermal fibrosis.
- Etiology is unknown.

EPIDEMIOLOGY

Early cases of granuloma faciale were reported as "eosinophilic granuloma" of the skin. Weidman was the first to separate three cases that had been previously reported in the literature as variants of erythema elevatum diutinum.[1] Lever and Leeper helped to differentiate the lesions from other eosinophil-rich diseases.[2] Cobane, Straith, and Pinkus later stressed the histologic resemblance to erythema elevatum diutinum (EED) and termed the lesions "facial granulomas with eosinophilia" and later granuloma faciale.[3] Granuloma faciale occurs predominantly in adult men and women. There is a slight male predominance, and mean age at presentation is 52 years.[4,5] Granuloma faciale can occur in individuals of any race; however, it is more common in Caucasians. The disease presents most commonly with a single lesion on the face, but extrafacial lesions have been described.[6] Patients with multiple lesions have also been reported.[7] A rare mucosal variant has been described as eosinophilic angiocentric fibrosis, which typically involves the upper respiratory tract.[8]

ETIOLOGY AND PATHOGENESIS

The etiology of granuloma faciale is unknown. The disease can be considered a localized chronic fibrosing vasculitis.[9] Immunofluorescence studies have revealed deposition of immunoglobulins and complement factors in the vessel walls consistent with a type III immunologic response, marked by deposition of circulating immune complexes surrounding superficial and deep blood vessels.[10,11] However, other authors have described negative results with immunofluorescence.[12]

CLINICAL FINDINGS

Granuloma faciale is characterized by solitary papules, plaques, or nodules. The lesions are typically asymptomatic red, brown, or violaceous plaques that are soft, smooth, and well circumscribed, often showing follicular accentuation and telangiectasia (Figs. 34-1 and 34-2). Ulceration is rare. Lesions are most common on the face. Sites of predilection include the nose, preauricular area, cheeks, forehead, eyelids, and ears.[4,12] Rarely, patients may present with multiple lesions or lesions on the trunk or extremities. Extrafacial lesions have been reported both as isolated findings and in conjunction with facial lesions. Lesions may be present for weeks or months and tend to follow a chronic course. Lesions are typically asymptomatic; however, patients may complain of tenderness, burning, or pruritus.[4] Photoexacerbation of lesions has been reported.[13]

LABORATORY FINDINGS

An extensive laboratory evaluation is not required. Peripheral blood eosinophilia is occasionally detected.

The diagnosis may be established by a combination of clinical findings and confirmatory tissue biopsy results. A punch biopsy that includes the full thickness of the dermis is recommended. Histologic examination shows a normal-appearing epidermis, which may be separated from the underlying inflammatory infiltrate by a narrow grenz zone (Fig. 34-3). Within the dermis is a dense and diffuse infiltrate of lymphocytes, plasma cells, eosinophils, and neutrophils with evidence of leukocytoclasis (Fig. 34-4). The inflammatory infiltrate surrounds the blood vessels, which show evidence of fibrin deposition. In later stages, the perivascular fibrin

Figure 34-1 Granuloma faciale. Raised edematous plaques on cheek showing prominent follicular ostia.

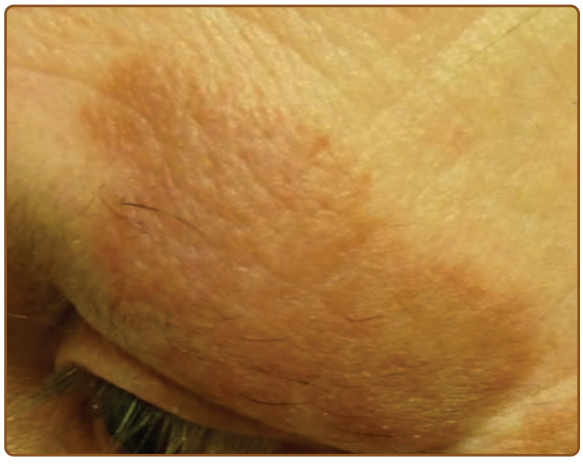

Figure 34-2 Granuloma faciale. Single plaque on the temple showing prominent follicular ostia and central dell.

deposition becomes extensive and dominates the histologic picture. Deposition of hemosiderin may contribute to the brown color seen clinically. Electron microscopic studies confirm the presence of an extensive eosinophilic infiltrate with Charcot–Leyden crystals and numerous histiocytes filled with lysosomal vesicles; however, cases with few eosinophils in the infiltrate have also been described.[14] Immunoglobulins, fibrin, and complement can be found deposited along the dermal–epidermal junction in a granular pattern and around blood vessels by direct immunofluorescence.[10]

DIFFERENTIAL DIAGNOSIS

The clinical differential diagnosis for granuloma faciale includes discoid lupus erythematosus, polymorphous light eruption, fixed drug eruption, benign lymphocytic infiltrate of Jessner, lymphoma cutis, pseudolymphoma, sarcoidosis, granuloma annulare, tinea faciei, insect bite reaction, xanthogranuloma, mastocytoma, basal cell

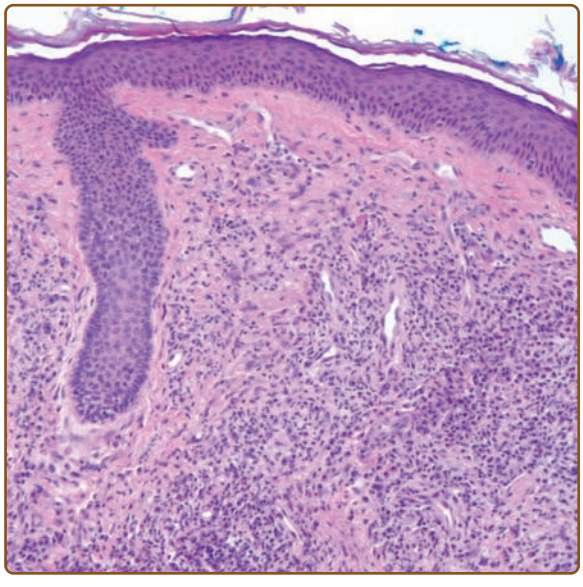

Figure 34-3 Granuloma faciale. This low-power histologic section shows a mixed infiltrate of lymphocytes, histiocytes, neutrophils, plasma cells, and eosinophils. There is sparing of a narrow grenz zone between the inflammatory infiltrate and the overlying epidermis.

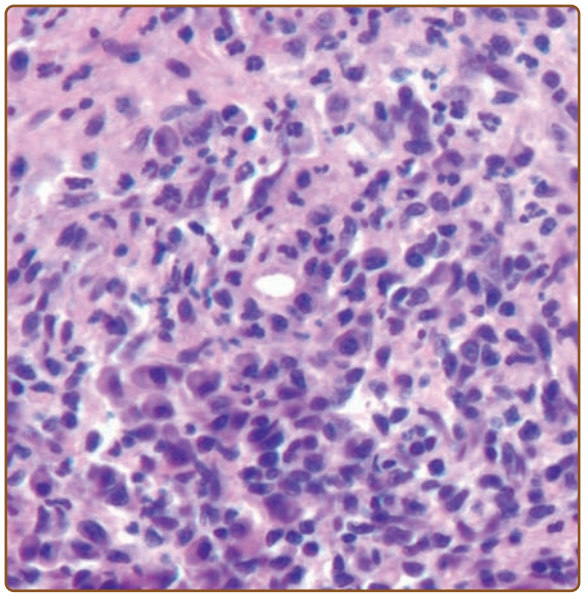

Figure 34-4 Granuloma faciale. This histologic section shows perivascular deposition of fibrin and a mixed infiltrate of lymphocytes, neutrophils, and eosinophils.

BOX 34-1 DIFFERENTIAL DIAGNOSIS OF GRANULOMA FACIALE

Most Likely

- Face
  - Sarcoidosis
  - Benign lymphocytic infiltrate of Jessner
  - Rosacea
- Extrafacial
  - Erythema elevatum diutinum

Consider

- Face
  - Discoid lupus erythematosus
  - Lymphoma cutis
  - Angiolymphoid hyperplasia with eosinophilia
  - Tinea faciei
  - Basal cell carcinoma
  - Xanthogranuloma
  - Mastocytoma
- Extrafacial
  - Granuloma annulare
  - Benign lymphocytic infiltrate of Jessner
  - Fixed drug eruption

Always Rule Out

- Face
  - Discoid lupus erythematosus
- Trunk
  - Erythema elevatum diutinum

BOX 34-2 TREATMENTS FOR GRANULOMA FACIALE

	TOPICAL	PHYSICAL	SYSTEMIC
First-line therapy	Topical corticosteroids	Cryotherapy Intralesional steroids Pulsed dye laser	Dapsone, 50–100 mg/day
Second-line therapy	Topical tacrolimus ointment	Surgical excision	

carcinoma, Langerhans cell histiocytosis, and rosacea (Box 34-1). The diagnosis can be reliably made by histologic examination. Absence of serologic evidence of lupus erythematosus helps to differentiate these lesions from the lesions of discoid lupus erythematosus.

The primary histologic differential diagnosis is EED. Both diseases represent chronic forms of fibrosing small vessel vasculitis and may be related. However, there are several clinical and histologic differences. EED is characterized by multiple lesions, primarily located on extensor surfaces of the extremities in a symmetric acral distribution. The trunk and face are typically spared in EED. Histologically, both show a chronic fibrosing vasculitis.[15] However, a grenz zone of normal collagen beneath the epidermis is not typical of EED. Eosinophils and plasma cells are more prominent in granuloma faciale while neutrophils are more frequently found in EED. EED may be associated with systemic conditions, primarily monoclonal gammopathies, and shows an excellent response to dapsone.[16,17] The histologic and clinical differential may also include angiolymphoid hyperplasia with eosinophilia. However, the lesions of angiolymphoid hyperplasia with eosinophilia contain blood vessels with prominent "hobnail" endothelial cells that protrude into the vascular lumina rather than perivascular fibrin deposition. One case of tinea faciei caused by *Trichophyton rubrum* has been described with clinical and histologic changes consistent with granuloma faciale.[18]

COMPLICATIONS

Granuloma faciale is rarely associated with systemic disease.[19]

PROGNOSIS AND CLINICAL COURSE

Lesions tend to be chronic and resistant to treatment.

TREATMENT

A variety of medical and surgical therapies have been used in the treatment of granuloma faciale (Box 34-2). Because of the small number of patients involved, randomized trials to evaluate these treatments are lacking. Resistance to therapy and cosmetic complications should be discussed with the patient before initiation of therapy. Topical and intralesional steroids have been administered with modest improvement.[4,20] Cryosurgery has been applied with effective results.[21,22] Because the disease is known to be a variant of chronic leukocytoclastic vasculitis, dapsone 25 to 100 mg/day has been used with benefit in a number of patients.[23,24] Topical tacrolimus ointment 0.1% also has been used with success.[25]

Surgical excision may be an option for small lesions. Lesions of granuloma faciale have been treated with a variety of medical lasers. In multiple studies utilizing pulsed dye lasers at 585–595 nm, clinical improvement has been demonstrated.[26–30] A carbon dioxide laser has also been applied with varying success.[31] The use of an argon laser resulted in total resolution of the granuloma faciale with subsequent scarring. The lesions in two patients were reported to respond to the potassium-titanyl-phosphate 532-nm laser in combination with tacrolimus ointment 0.1%.[32] Case studies have suggested a beneficial effect of tacrolimus ointment,[33,34] as well as pimecrolimus cream 1%.[34]

Chapter 35 :: Subcorneal Pustular Dermatosis (Sneddon–Wilkinson Disease)

:: Franz Trautinger & Herbert Hönigsmann

SUBCORNEAL PUSTULAR DERMATOSIS AT A GLANCE

- A rare condition with worldwide occurrence.
- A chronic recurrent disorder with a benign course frequently associated with various forms of immune dysfunction [most commonly immunoglobulin (Ig) A monoclonal gammopathy]. Occurrence of intraepidermal deposits of IgA indicates a relationship with IgA pemphigus.
- Crops of flaccid, coalescing pustules; often in annular or serpiginous patterns.
- Usually distributed symmetrically in the axillae, groins, submammary, the flexor aspects of the limbs, and on the abdomen.
- Pathology: subcorneal pustules filled with polymorphonuclear leukocytes.

Subcorneal pustular dermatosis (SPD) is a rare, chronic, recurrent, pustular eruption characterized histopathologically by subcorneal pustules that contain abundant neutrophils. The condition was originally described in 1956 by Sneddon and Wilkinson,[1] who separated SPD from other previously unclassified pustular eruptions. Until 1966, when the first comprehensive review appeared, more than 130 cases had been reported, but not all fulfilled the clinical and histopathologic criteria required for this diagnosis.[2] A considerable number of additional cases have since appeared in the literature, and a subtype with intraepidermal deposits of immunoglobulin (Ig) A directed against desmocollin 1 has been recognized.[3] Today, these cases are usually classified as SPD-type IgA pemphigus and it is a matter of debate whether the finding of epidermal IgA deposits define a subset of SPD or a new pemphigus variant that is otherwise indistinguishable from "classic" SPD.

EPIDEMIOLOGY

There is no racial predilection. Most of the reported cases have been in whites, but the disease has also been observed in Africans, Japanese, and Chinese. The condition is more common in women and in persons older than 40 years of age, but SPD may occur at any age.[2] A pustular eruption that is clinically and histologically similar to the human disease, which also responds to dapsone treatment, has been observed in dogs.[4]

ETIOLOGY AND PATHOGENESIS

The cause of SPD is unknown. Cultures of the pustules consistently do not reveal bacterial growth. The role of trigger mechanisms such as preceding or concomitant infections, though repeatedly discussed, has remained speculative. Immunologic mechanisms have been implicated in the pathogenesis and in a subset of patients, whose disease clinically resembled SPD, intraepidermal IgA deposits have been detected. Some of these patients also had circulating IgA antibodies against the same sites within the epidermis. Desmocollin 1 and in a single case also desmocollins 2 and 3 have been described as autoantigens in these cases and the disease has been classified as a rare pemphigus variant (SPD-type IgA pemphigus).[3,5–7] The pathogenetic role of these antibodies is still to be demonstrated.[8]

The occasional association of SPD with certain other diseases may represent more than a mere coincidence. Increased serum IgA has been detected in a number of patients, and the disease has been reported to occur in cases of IgA-paraproteinemia and IgA multiple myeloma.[9–12] In addition, SPD is associated with pyoderma gangrenosum,[13,14] ulcerative colitis,[15] and Crohn disease.[16] On the other hand, pyoderma gangrenosum is not uncommon in patients with inflammatory bowel disease, paraproteinemia, and myeloma (see Chapter 33). Whether or not the coexistence of these conditions reflects common pathogenetic mechanisms remains to be clarified, but an additional common denominator linking these disorders is their response to sulfone and sulfonamide therapy.

Further associations reported to date include IgG paraproteinemia,[17,18] $CD30^+$ anaplastic large-cell lymphoma,[19] marginal zone lymphoma,[20] nonsmall cell lung cancer,[21] apudoma,[22] rheumatoid arthritis,[23,24] systemic lupus erythematodes,[25] hyperthyroidism[26] and mycoplasma pneumoniae infection.[27]

CLINICAL FINDINGS

The primary lesions are small, discrete, flaccid pustules, or vesicles that rapidly turn pustular and usually arise in crops within a few hours on clinically normal or slightly erythematous skin (Fig. 35-1). In dependent regions, pus characteristically accumulates in the lower half of the pustule (see Fig. 35-1B); as the pustules usually have the tendency to coalesce, they often, but not always, form annular, circinate, or bizarre serpiginous patterns. After a few days, the pustules rupture and dry up to form thin, superficial scales and crusts, closely resembling impetigo. Peripheral spreading and central healing leave polycyclic, erythematous areas in which new pustules arise as others disappear (see Fig. 35-1A).

Figure 35-1 Subcorneal pustular dermatosis. **A.** Typical distribution. Note accentuated involvement of groin and abdomen. Hyperpigmented macules mark previously affected areas. **B.** Close-up showing coalescence of pustules, which form annular and circinate patterns. Lesions of different developmental stages are seen side by side. At the lower right, newly formed pustule with characteristic hypopyon formation.

There is no atrophy or scarring, but an occasional brownish hyperpigmentation may mark previously affected sites. Variable intervals of quiescence, lasting from a few days to several weeks, may be followed by the sudden development of new lesions. The eruptions tend to occur symmetrically, affecting mainly the axillae, groin, abdomen, submammary areas, and the flexor aspects of the limbs. In rare cases, the face,[28] palms, and soles[29] may be involved. Scalp and mucous membranes invariably remain free of lesions. Episodic itching and burning represent subjective symptoms in a small number of patients, but there are no systemic symptoms or abnormalities in routine laboratory parameters.

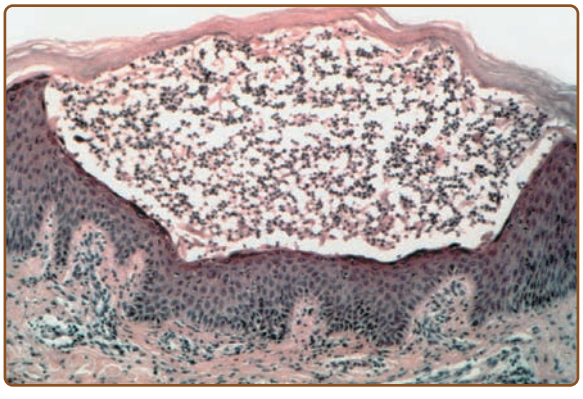

Figure 35-2 Subcorneal pustular dermatosis. Strictly subcorneal pustule filled with polymorphonuclear leukocytes, with the underlying epidermal layers exhibiting only slight edema and some migrating leukocytes. There is a mild inflammatory infiltrate around dermal blood vessels.

HISTOPATHOLOGY

The hallmark of the disease is a strictly subcorneal pustule filled with polymorphonuclear leukocytes,[1] with only an occasional eosinophils.[2] Acantholysis is not involved in pustule formation, but a few acantholytic cells may be found in older lesions (secondary acantholysis). Surprisingly, the epidermal layers underlying the pustule exhibit little pathology, and, apart from a variable number of migrating leukocytes, there is little evidence of spongiosis or cytolytic damage to the epidermal cells. The dermis contains a perivascular infiltrate composed of neutrophils and rarely mononuclear cells and eosinophils (Fig. 35-2).

BOX 35-1 DIFFERENTIAL DIAGNOSIS OF SUBCORNEAL PUSTULAR DERMATOSIS

- Bacterial impetigo
- Dermatitis herpetiformis
- Pemphigus foliaceus
- IgA pemphigus/intraepidermal IgA pustulosis
- Pustular psoriasis
- Necrolytic migratory erythema
- Acute generalized exanthematous pustulosis

BOX 35-2 TREATMENTS FOR SUBCORNEAL PUSTULAR DERMATOSIS

First line	Dapsone Corticosteroids	50–150 mg/day As required
Second line (anecdotally reported beneficial responses)	Retinoids, photochemotherapy, ultraviolet B, colchicine, cyclosporine, infliximab, etanercept	

In a subset of patients, direct immunofluorescence reveals intraepidermal IgA deposits.[17] In these cases, IgA is usually present in a pemphigus-like intercellular pattern, either in the entire epidermis or confined to its upper layers. By indirect immunofluorescence, circulating IgA antibodies directed against the intercellular substance of the epidermis were detected in single cases. Today these cases are usually diagnosed as SPD-type IgA pemphigus (see Chapter 54).

Ultrastructural examination of paralesional skin has shown cytolysis of keratinocytes confined to the granular layer[30]; the formation of pustules has been regarded as a secondary event caused by invasion and subcorneal accumulation of leukocytes.

DIFFERENTIAL DIAGNOSIS

(Box 35-1)

An early localized eruption of SPD may be clinically and histologically indistinguishable from impetigo, but the distribution pattern of the lesions, the absence of bacteria in the pustules, and the ineffectiveness of antibiotic therapy suggest the correct diagnosis. Dermatitis herpetiformis is highly pruritic, affects primarily the extensor surfaces, and has subepidermal vesicles with granular IgA deposits in the dermal papillary tips. Pemphigus foliaceus has acantholysis and a typical immunofluorescence pattern. Generalized pustular psoriasis (von Zumbusch's type) presents with systemic symptoms (fever, malaise, leukocytosis), and spongiform pustules within the epidermis. The necrolytic migratory eruption of glucagonoma syndrome can be differentiated by its distribution, lack of actual pustule formation, erosions of the lips and oral mucosa, and, histologically, necrobiosis of the upper epidermis. Biochemically, hyperglycemia and excess levels of glucagon are diagnostic. Acute generalized exanthematous pustulosis (AGEP) is widespread with an acute febrile onset and histologically exhibits spongiform subcorneal and intraepidermal pustules sometimes with leukocytoclastic vasculitis.

PROGNOSIS AND CLINICAL COURSE

SPD is a benign condition. Without treatment, attacks recur over many years and remissions are variable, lasting from a few days to several weeks. Despite the protracted course the general health of the patient is usually not impaired. However, one of our own cases who had SPD, pyoderma gangrenosum, and IgA paraproteinemia of more than 20 years' duration died of septicemia with staphylococcal abscesses in the lungs, liver, and spleen.

TREATMENT

The drug of choice is dapsone (Box 35-2) in a dose of 50 to 150 mg daily. The response is slower and less dramatic than in dermatitis herpetiformis, but complete remission is most often obtained. In some patients, the treatment may be withdrawn after several months, although in others it may have to be continued for years; the minimal effective dose to suppress disease should be determined in these patients. Systemic corticosteroids are less effective, although they can suppress generalized flares when given in high doses. Responses to retinoids, photochemotherapy, ultraviolet B, colchicine, cyclosporine, and topical tacalcitol (1α-24R-dihydroxyvitamin D_3) have been anecdotally reported.[31–34] More recently antitumor necrosis factor α therapy has been successfully used in single cases. Infliximab was described to induce rapid responses in three recalcitrant cases, with one patient relapsing despite continuing treatment.[25,35,36] In two patients etanercept was able to induce almost complete continuing remissions for 22 and 7 months, in one case combined with acitretin.[37]

EOSINOPHILS IN CUTANEOUS DISEASES AT A GLANCE

- Eosinophils may be seen in skin biopsy specimens from a broad range of cutaneous diseases but are not pathognomonic for any dermatosis.
- Eosinophils are an important component of the characteristic histologic pattern in a limited number of diseases, including the following:
  - Angiolymphoid hyperplasia with eosinophilia
  - Eosinophilic, polymorphic, and pruritic eruption associated with radiotherapy
  - Eosinophilic pustular folliculitis
  - Erythema toxicum neonatorum
  - Eosinophilic ulcer of the oral mucosa
  - Eosinophilic vasculitis
  - Granuloma faciale
  - Hypereosinophilic syndromes
  - Incontinentia pigmenti
  - Kimura disease
  - Pachydermatous eosinophilic dermatitis
  - Wells syndrome (eosinophilic cellulitis)
- Clinical reaction patterns with eosinophil involvement include diseases in which eosinophils probably play a pathogenic role and are a component of the histological pattern, but are not essential for diagnosis.
- Evidence for involvement of eosinophils in cutaneous diseases is provided by observation of intact eosinophils in lesional tissue sections and/or by immunostains for their toxic granule proteins, which are deposited in tissues.

Eosinophils have myriad phlogistic activities that implicate them in disease.[1–3] (See Chapter 31.) Peripheral blood eosinophilia and/or tissue infiltration by eosinophils occur in a variety of common and unusual diseases, including those of infectious, immunologic, and neoplastic etiologies. Organ-specific eosinophil disorders occur in the skin, lung, and gastrointestinal tract.[4–6] Eosinophils are conspicuous in tissue sections stained with hematoxylin and eosin because of their intense avidity for eosin dye. Common dermatoses associated with eosinophils in lesional tissues include arthropod bites and drug eruptions. Parasitic infections, especially those due to ectoparasites and helminthes, typically have a marked host response with eosinophilia.[7,8] Autoimmune blistering diseases, such as bullous pemphigoid and the various forms of pemphigus, often have prominent eosinophil infiltration, including histologic presentation as eosinophilic spongiosis.[9,10] Infiltration of eosinophils in the subcutaneous tissues, so-called eosinophilic panniculitis, is not a specific diagnosis but rather is seen to a variable degree in diverse entities.[11,12] Eosinophils may be found in Langerhans cell histiocytosis,[13] cutaneous epithelial neoplasms,[14] and lymphoproliferative disorders.[15] Although eosinophils constitute one of the histologic features in numerous cutaneous diseases, eosinophil infiltration represents a criterion for histologic diagnosis in relatively few entities (Table 36-1). The absence, presence or number of eosinophils in skin biopsy specimens is often of limited value in reliably choosing among differential diagnoses with different and potentially important implications for clinical management, such as drug reaction versus acute graft-versus-host disease.[16,17] Eosinophils play a role in certain categories of clinical reactions, particularly those characterized by edema.[18] The degree of tissue eosinophil granule protein deposition in such diseases, that exhibit relatively few or no intact eosinophils, suggests that the pathogenic influence of eosinophils may be unrelated to their numbers in tissues. The degree of cutaneous eosinophil infiltration should be taken in the context of other clinical features, other histological features, and knowledge that its diagnostic power has limitations.[19] However, eosinophils do have potent biological activities, particularly imparted by their distinctive granules, and eosinophils may play a pathogenic role in the absence of identifiable cells in tissues.

TABLE 36-1
Eosinophils in Cutaneous Diseases

- Diseases characterized by tissue eosinophils
  - Angiolymphoid hyperplasia with eosinophilia
  - Eosinophilic, polymorphic, and pruritic eruption associated with radiotherapy
  - Eosinophilic pustular folliculitis
    - Classical (Ofugi disease)
    - Infantile/neonatal
    - Human immunodeficiency virus-associated
  - Erythema toxicum neonatorum
  - Eosinophilic ulcer of oral mucosa
  - Granuloma faciale
  - Hypereosinophilic syndromes
  - Kimura disease
  - Pachydermatous eosinophilic dermatitis
  - Wells syndrome (eosinophilic cellulitis)
- Diseases typically associated with tissue eosinophils
  - Arthropod bites and sting reactions
  - Bullous dermatoses
    - Pemphigoid
    - Pemphigus
    - Incontinentia pigmenti
  - Dermatoses of pregnancy
  - Drug reactions
    - DRESS (drug rash with eosinophilia and systemic symptoms)/drug hypersensitivity syndrome
    - Interstitial granulomatous drug reaction
  - Histiocytic diseases
    - Langerhans cell histiocytosis
    - Juvenile xanthogranuloma
  - Parasitic diseases/infestations
  - Urticaria and angioedema
  - Vasculitis
    - Churg-Strauss syndrome
    - Eosinophilic vasculitis
- Histological patterns defined by eosinophils
  - Eosinophilic spongiosis
    - Acute dermatitis
      - Allergic contact dermatitis
    - Arthropod bite
    - Immunobullous diseases
      - Pemphigoid
      - Pemphigus
    - Incontinentia pigmenti
  - Eosinophilic panniculitis
    - Arthropod bite
    - Erythema nodosum
    - Gnathostomiasis
    - Injection granuloma
    - Vasculitis
    - Wells syndrome
- Eosinophils of doubtful, limited or no value in histological diagnosis
  - Drug reaction versus graft-versus-host disease
  - Granuloma annulare
  - Interstitial granulomatous dermatitis
  - Neoplasms
    - Lymphoproliferative disorders (except HES types)
    - Keratoacanthoma

HYPEREOSINOPHILIC SYNDROMES

HYPEREOSINOPHILIC SYNDROMES AT A GLANCE

- Spectrum of entities defined by criteria (Table 36-2).
- Cutaneous lesions are common and may be the presenting sign.
- Two major hypereosinophilic syndromes (HES) subtypes and several variants.
  - Lymphocytic HES characterized by T-cell clones that produce interleukin 5.
    - Variant HES subtypes may evolve into lymphocytic HES.
      - Organ-restricted.
      - Associated with specific disorders such as Churg–Strauss syndrome.
      - Undefined with benign, complex, and episodic presentations.
    - Myeloproliferative HES associated with a deletion on chromosome 4 that produces a tyrosine kinase fusion gene *Fip1-like 1*/platelet-derived growth factor receptor-α or other mutation associated with eosinophil clonality.
      - Responsive to imatinib.
      - Severely debilitating mucosal ulcers portend a grim prognosis unless HES is treated.
      - Overlap with mastocytosis.
  - Familial HES variant, family history of documented persistent eosinophilia of unknown cause.
- Associated embolic events constitute a medical emergency.
- Eosinophilic endomyocardial disease occurs in HES and in patients with prolonged peripheral blood eosinophilia from any cause.

EPIDEMIOLOGY

The hypereosinophilic syndromes (HES) consist of a spectrum of disorders that occur worldwide and span all age groups. Over 90% of patients with myeloproliferative HES and the mutant gene are men, but lymphocytic HES shows equal gender distribution. The relative frequencies of these subtypes are unknown, although up to 25% of HES patients may have lymphocytic HES. Rare familial cases have been reported. A miniepidemic of eosinophilic esophagitis, a subtype of overlap HES with organ-restricted disease, emerged over the last decade with prevalence estimates as high as 1:2,500 among children and 1:4,000 among adults.[31,32]

ETIOLOGY

Eosinophils are implicated as the cause of most end-organ damage in all HES subtypes.[2,33] Clinical improvement usually parallels a decrease in eosinophil count. Patients with lymphocytic HES have abnormal T-cell clones with unusual surface phenotypes, including $CD3^+CD4^-CD8^-$ and $CD3^-CD4^+$. These T cells display activation markers, such as CD25, and secrete T helper 2 cytokines, including high levels of interleukin 5 (IL-5).[23,34] An 800-kilobase deletion on chromosome band 4q12 that codes for a tyrosine kinase has been found in myeloproliferative HES.[26] Patients with this *FIP1L1-PDGFRA* gene mutation form a distinct subset of HES, with cardiomyopathy and endomyocardial fibrosis, that responds to imatinib. Patients in this HES subset have elevated serum tryptase levels and increased atypical spindle-shaped mast cells in bone marrow.[27,28,35] Although they do not have clinical manifestations of systemic mastocytosis or exhibit all its immunological markers, these patients satisfy criteria for mastocytosis.[36] The *FIP1L1-PDGFRA* gene is detected in mast cells,[37] eosinophils, neutrophils, and mononuclear cells. Many HES patients also have marked neutrophilia, likely due to the aberrant gene in the neutrophil lineage. Thus, alteration of several cell lines probably contributes to the pathogenesis of myeloproliferative HES.[38,39] Multiple other chromosomal abnormalities have been identified in myeloproliferative HES, including translocations, partial and complete chromosomal deletions, and trisomies 8, 15, and 21. Myeloproliferative HES with documented mutations also is known as chronic eosinophilic leukemia. The World Health Organization has an updated 2008 classification scheme for myeloid disorders and eosinophilia.[40,41] The etiology of the other HES variants is not well understood, although patients in several HES subtypes, including with episodic angioedema and eosinophilia [Gleich syndrome[42]; see section "Episodic Angioedema Associated with Eosinophilia (Gleich Syndrome)"] and the nodules, eosinophilia, rheumatism, dermatitis, and swelling (NERDS) syndrome,[43] have developed T-cell clones.[30]

TABLE 36-2
Revised Diagnostic Criteria for Hypereosinophilic Syndromes[30]

1. Blood eosinophilia greater than 1500 eosinophils/mm^3 on at least two separate determinations or evidence of prominent tissue eosinophilia associated with symptoms and marked blood eosinophilia
2. Exclusion of secondary causes of eosinophilia, such as parasitic or viral infections, allergic diseases, drug- or chemical-induced eosinophilia, hypoandrenalism, and neoplasms

Original Criteria[21]

- Peripheral blood eosinophilia of at least 1,500 eosinophils/mm^3
  - Longer than 6 months; or
  - Less than 6 months with evidence of organ damage.
- Signs and symptoms of multiorgan involvement.
- No evidence of parasitic or allergic disease or other known causes of peripheral blood eosinophilia.

CLINICAL FINDINGS AND COURSE

Patients satisfying HES diagnostic criteria (Table 36-2) present with signs and symptoms related to the organ systems infiltrated by eosinophils.[44–46] HES often present with skin lesions[47,48] that may be the only manifestations of HES.[49–51] Pruritic erythematous macules, papules, plaques, wheals, or nodules are present in over 50% of patients.[52] Lesions may involve the head, trunk, and extremities. Urticaria and angioedema occur in all HES subtypes and are characteristic of certain variant subtypes. Erythema annulare centrifugum,[53–55] bullous pemphigoid,[56] lymphomatoid papulosis,[57] livedo reticularis, purpura and/or other signs of vasculitis,[58–61] Wells syndrome (eosinophilic cellulitis),[62,63] and multiple other mucocutaneous manifestations[48] may be found in patients with HES (Table 36-3).

In myeloproliferative HES, the usual presenting complex includes fever, weight loss, fatigue, malaise, skin lesions, and hepatosplenomegaly.[29,46,64,65] Mucosal ulcers of the oropharynx or anogenital region (Fig. 36-1) portend an aggressive clinical course; death is likely within 2 years of presentation if the disorder is untreated.[64,66] Cardiac disease occurs frequently.[67] Eosinophils adhere to endocardium and release granule proteins onto endothelial cells, thrombus formation follows, and, finally, subendocardial fibrosis with restrictive cardiomyopathy occurs. Mitral or tricuspid valvular insufficiency results from tethering of chordae tendineae.[67] Cardiac abnormalities that are essentially identical to those of HES but are confined to the intramural regions can occur without appreciable peripheral blood eosinophilia.[68,69] Splinter hemorrhages and/or nail fold infarcts may herald the onset of thromboembolic disease. The central and peripheral nervous system, lungs, and, rarely, kidneys may be affected.[46] Patients with myeloproliferative HES frequently present with clinical features resembling those of chronic myelogenous leukemia and, depending on

(Modified from Leiferman KM, Gleich GJ, Peters MS: Dermatologic manifestations of the hypereosinophilic syndromes. *Immunol Allergy Clin North Am* **27**(3):415-441, 2007 and Stetson CL., Leiferman, KM: Chapter 26, Eosinophilic dermatoses. In: *Dermatology*, 2nd edition, edited by JL Bolognia, J Jorizzo, RP Rapini, TD Horn, AJ Mancini, JM Mascaro, SJ Salasche, J-H Saurat, G Stingl. Mosby, St. Louis 2008. pp. 369-378).

the classification, are regarded as having chronic eosinophilic leukemia. Although chromosomal abnormalities characterize this subtype and the disease may evolve into definite leukemia, the relatively mature nature of the eosinophils and lack of evidence for clonal expansion may preclude such classification.

Lymphocytic HES commonly is associated with severe pruritus, eczema, erythroderma, urticaria, and angioedema, as well as lymphadenopathy and, rarely, endomyocardial fibrosis.[34] In contrast to myeloproliferative HES, lymphocytic HES generally follows a benign course, and T-cell clones can remain stable for years. Patients should be observed closely and regarded as having premalignant or malignant T-cell proliferation, because the disease may evolve into lymphoma.

Churg–Strauss syndrome (see Chapter 164) is a variant HES subtype. Other variant HES subtypes include Gleich syndrome[42] [see section "Episodic Angioedema Associated with Eosinophilia (Gleich Syndrome)"], in which eosinophil counts fluctuate with extreme angioedema.

During the decade or more after diagnosis, HES may evolve into acute leukemia and, less commonly, has been associated with B-cell lymphomas. The overall 5-year survival rate for HES patients is 80%; congestive heart failure from the restrictive cardiomyopathy of eosinophilic endomyocardial disease is a major cause of death, followed by sepsis.

LABORATORY TESTS

A key criterion for diagnosis is marked peripheral blood eosinophilia (see Table 36-2).[44,70–72] Other causes of eosinophilia, including allergic and parasitic diseases, should be excluded. Tests to detect organ involvement, particularly measurement of liver enzyme levels, are important. Because eosinophilic endomyocardial disease can develop in any patient with prolonged peripheral blood eosinophilia, patients should undergo periodic echocardiography along with close observation for signs of thromboembolism. Increased serum levels of immunoglobulin E (IgE) are often present in lymphocytic HES, and levels of vitamin B_{12} and tryptase may be increased in myeloproliferative HES. The Chic2 fluorescent in situ hybridization assay detects the deletion that produces the *FIP1L1-PDGFRA* gene product and should be performed, because patients with this mutation respond to treatment with imatinib.[35,37] Alternatively, the mutant gene can be detected by a polymerase chain reaction assay. Both tests are available commercially. In patients who lack the fusion gene, testing for other clonal

Figure 36-1 Hypereosinophilic syndrome. Mucosal erosions and ulcers of the mouth (**A**) and glans penis (**B**); conjunctival irritation (**C**).

cytogenetic abnormalities or abnormal clonal T-cell populations is warranted.[27] Cytoflow of peripheral blood lymphocytes and immunophenotyping of tissue lymphocytes should be performed for the diagnosis of lymphocytic HES and repeated periodically to detect transformation from a variant HES type to lymphocytic HES or to T-cell lymphoma.[34] An HES evaluation assessment scheme for patients with eosinophilia is presented in Table 36-4.

The cutaneous histopathological features of HES vary with the type of lesion. Skin biopsy specimens from urticarial lesions resemble idiopathic urticaria, with generally mild, nonspecific perivascular and interstitial infiltration of lymphocytes, eosinophils, and, occasionally, neutrophils. Immunostaining reveals extensive deposition of eosinophil granule proteins, in the absence of intact eosinophils, in episodic angioedema with eosinophilia,[42] HES with mucosal ulcers,[73] and in synovial tissues in NERDS.[43] Other than in Churg–Strauss syndrome, vasculitis only rarely has been associated with HES.[58–60]

DIFFERENTIAL DIAGNOSIS

(Box 36-1)

Clinically, parasitic infections and infestations may closely resemble HES.[74] A history of travel to endemic areas or certain dietary exposure implicates helminthiasis. Along with eosinophilia, total serum IgE levels higher than 500 IU/mL commonly are found in helminthic infections. Examination of stool samples for ova and parasites and serologic testing for *Strongyloides* antibodies should be performed. In patients with isolated urticarial plaques with or without angioedema, the differential diagnosis includes common and persistent urticaria,[75,76] but demonstration of multiorgan involvement supports HES. HES with episodic angioedema may resemble hereditary angioedema clinically, although patients with hereditary angioedema often have a family history of the disease rarely have the markedly elevated eosinophil counts that characterize HES, and may be distinguished by complement abnormalities. Pruritic eczematoid lesions of lymphocytic HES may resemble those of atopic dermatitis, contact dermatitis, drug reaction, fungal infection, and T-cell lymphoma. There are multiple diseases in the differential diagnosis of patients with orogenital ulcers,[64] including those associated with thrombosis, such as Behçet syndrome, Crohn disease, ulcerative colitis, and Reiter syndrome. Others considerations are recurrent aphthous stomatitis, immunobullous diseases, erythema multiforme, lichen planus, herpes simplex infection, and syphilis.

TREATMENT

The goal of treatment is to relieve symptoms and improve organ function while keeping peripheral blood eosinophils at 1,000 to 2,000/mm^3 and

TABLE 36-4
Evaluation of Patients with Eosinophilia

- History
  - Attention to travel (parasite exposure)
  - Ingestants (drugs, health foods, food supplements, and food allergy)
  - Close contacts with itch (ectoparasites)
- Physical examination
  - Cutaneous features (see Table 36-3)
  - Cardiovascular signs
    - Murmur of mitral insufficiency
    - Nails for splinter hemorrhage (medical emergency)
  - Hepatosplenomegaly
  - Lymphadenopathy
- Laboratory studies
  - Repeated complete blood counts with differentials
  - Cytogenetics for chromosomal abnormalities to include
    - *FIP1L1-PDGFRA* (*CHIC2* gene) deletional mutation
    - T cell subsets for clonality by cytoflow/T cell receptor gene rearrangement
  - B cell clonality analyses
  - Inflammatory and immunological markers
    - Erythrocyte sedimentation rate
    - C-reactive protein
    - Rheumatoid factor
    - Antiproteinase 3 and antimyeloperoxidase (c-ANCA and p-ANCA)
    - IgE level
    - Strongyloides IgG antibody
    - Interleukin-5 serum level
  - Metabolic parameters
    - Liver function tests to include aspartate aminotransferase and alanine aminotransferase
    - Renal function tests to include creatinine, blood urea nitrogen and urinanalysis for protein and sediment
    - Muscle enzymes to include creatine phosphokinase and aldolase
    - B12 serum level
    - Mast cell/basophil tryptase (protryptase) level
    - Coagulation factors
  - Troponin (before initiation of imatinib treatment)
  - Serum protein analyses
    - Serum protein electrophoresis
    - Quantitative immunoglobulins
    - Immunofixation electrophoresis for monoclonal proteins
- Imaging tests
  - Echocardiography
  - Computerized axiotomography of chest, abdomen, and pelvis
- Gastrointestinal endoscopy, as indicated
- Pulmonary function tests, as indicated
- Bone marrow aspirate and biopsy with staining for tryptase and reticulum (myelofibrosis)
- Tissue biopsy of skin and/or other accessible affected organs
  - Histological examination
  - Direct immunofluorescence for immunobullous disease
  - Immunostaining for eosinophil granule proteins

Modified from Gleich GJ, Leiferman KM: The hypereosinophilic syndromes: Current concepts and treatments. *Br J Haematol* **145**(3):271-285, 2009.

minimizing treatment side effects (Fig. 36-2). Recent reviews have delineated evaluation and management of HES.[29,70–72,77] Myeloproliferative HES is responsive to imatinib.[78] In patients with the mutant gene *FIP1L1-PDGFRA*, administration of imatinib mesylate is indicated and usually induces hematologic remission, but endomyocardial disease may worsen during the first several days of treatment. Troponin levels should be monitored before and during imatinib therapy.[79,80] To improve cardiac function, glucocorticoids should be given before and with initiation of imatinib therapy. Imatinib resistance can develop.[81–83] In the absence of the gene mutation, after *Strongyloides* infection has been excluded,[84] first-line therapy is prednisone. Approximately 70% of patients will respond, with peripheral eosinophil counts returning to normal. Patients for whom glucocorticoid monotherapy fails have a worse prognosis generally; in such cases or when long-term side effects become problematic, other treatments should be used. Effective treatment of HES in imatinib-responsive patients results in improvement of associated conditions including cardiac involvement with endocarditis[85] and myelofibrosis[86] and skin disease with bullous pemphigoid.[56] Patients who have features of myeloproliferative HES but who lack *FIP1L1-PDGFRA* still may respond to imatinib.[25] Interferon (IFN)-α has been beneficial in treating myeloid and lymphocytic HES.[87,88] In one patient, loss of the *FIP1L1-PDGFRA* mutation after several years of IFN-α therapy was associated with complete remission.[89] Extracorporeal photopheresis alone or in combination with IFN-α or other therapies represent additional therapeutic options. Other treatments for HES with reported benefit include hydroxyurea, dapsone, vincristine sulfate, cyclophosphamide, methotrexate, 6-thioguanine, 2-chlorodeoxyadenosine and cytarabine combination therapy, pulsed chlorambucil, etoposide, cyclosporine, intravenous immunoglobulin, and psoralen plus ultraviolet A (UVA) phototherapy.[90] Refractory disease may respond to infliximab (antitumor necrosis factor-α)[91] or alemtuzumab (anti-CD52),[92–94] as well as to bone marrow and peripheral blood stem cell allogeneic transplantation.[95,96] Two monoclonal antibodies against human IL-5 have been associated with clinical improvement and reductions in peripheral blood and dermal eosinophils, particularly in patients with lymphocytic HES.[97–101] Treatments targeting IL-5 have provided new insights into understanding eosinophil-associated disease.[33]

WELLS SYNDROME

WELLS SYNDROME (EOSINOPHILIC CELLULITIS) AT A GLANCE

- Single or multiple lesions commonly located on the extremities or trunk.
- Lesions may be painful or pruritic.
- Associated with general malaise but uncommonly with fever.
- Edematous and erythematous lesions evolve into plaques with violaceous borders.
- Blisters may be a prominent feature.
- Individual lesions persist for weeks and gradually change from red to blue–gray or greenish gray, resembling morphea.
- Multiple recurrences.
- Peripheral blood eosinophilia common.
- Histological pattern characterized by dermal infiltration with eosinophils, and flame figures surrounded by histiocytes.
- Systemic glucocorticoids usually therapeutic.

CLINICAL FINDINGS AND COURSE

Cutaneous edema was the common clinical thread in the first four cases reported by Wells.[102] After prodromal burning or itching, lesions begin with erythema and edema (Fig. 36-3A), sometimes in the form of annular or arcuate plaques or nodules. Over a period of days, they evolve into large edematous plaques with violaceous borders. Bullae may develop.[108,109,120,139] Individual lesions gradually change from bright red to brown–red and then to blue–gray or greenish gray, resembling morphea (Fig. 36-3B). Less common clinical presentations include papules, vesicles (Fig. 36-4), and hemorrhagic bullae. The cutaneous lesions may be single or multiple and may be located at any site, but typically involve the extremities and, less often, the trunk.[137] The most frequent systemic complaint in patients with Wells syndrome is malaise; fever occurs in a minority of cases. Lesions resolve without scarring, usually within weeks to months, but multiple recurrences are common.

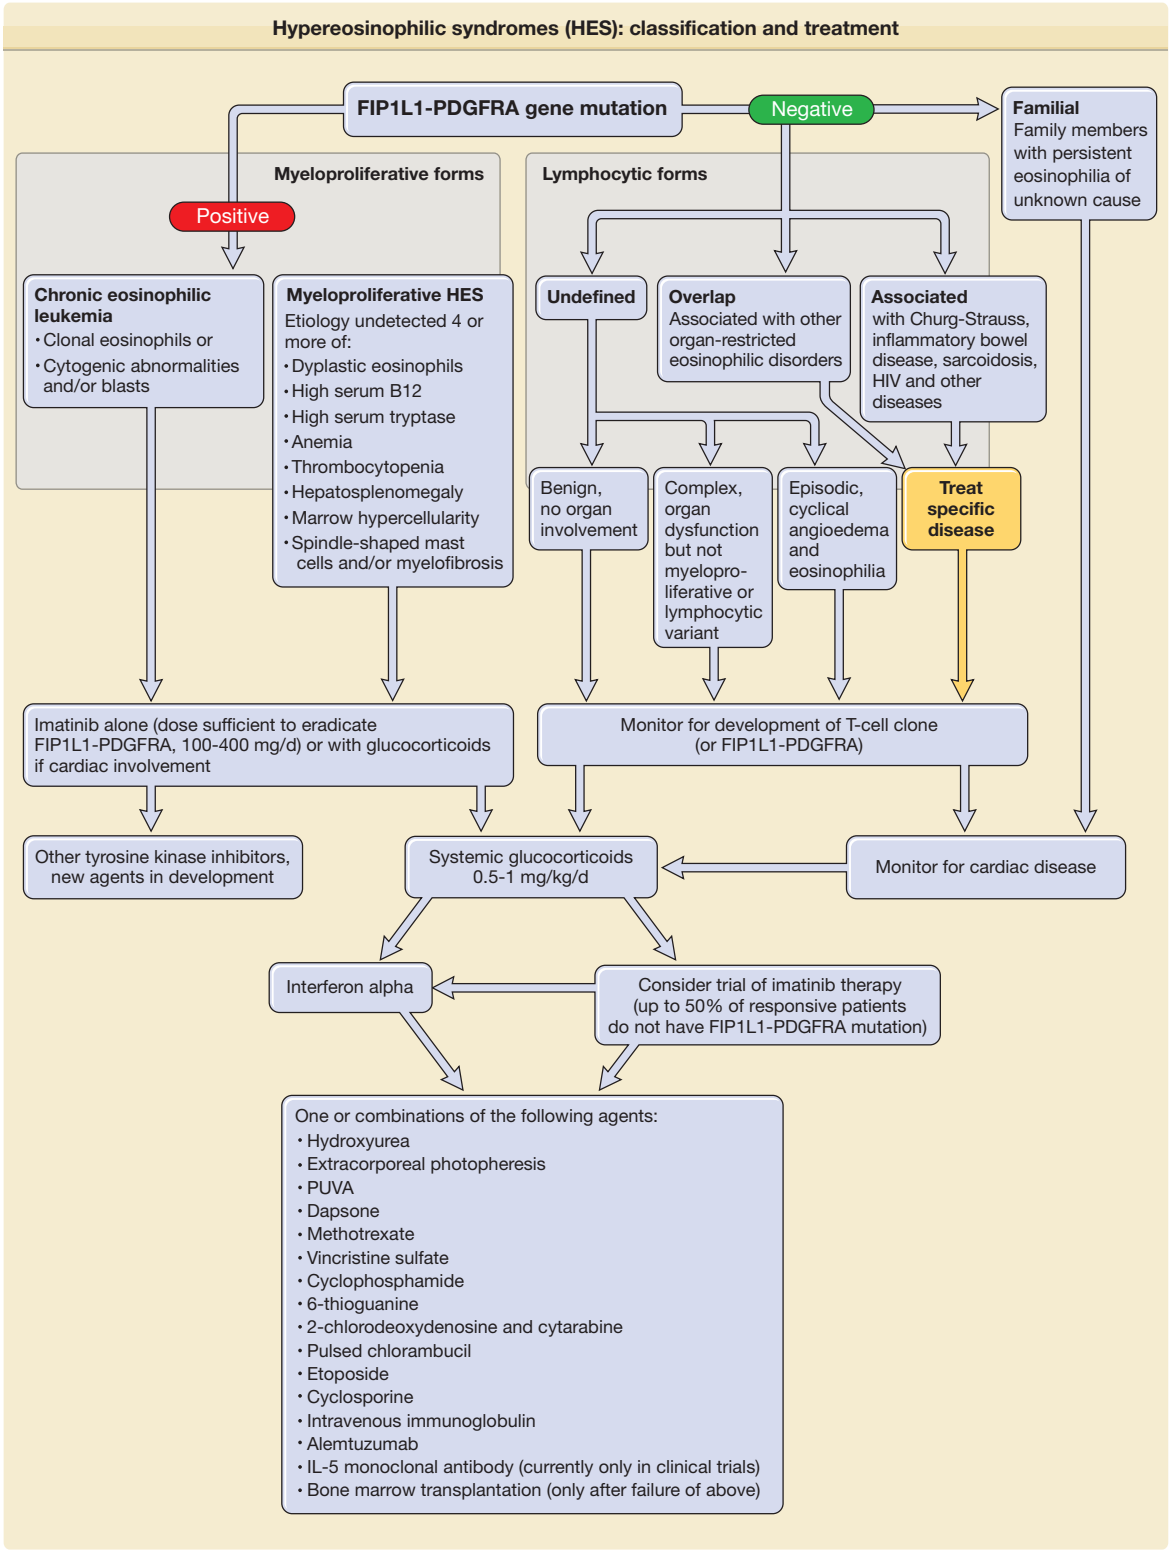

Figure 36-2 Hypereosinophilic syndromes (HES): classification and treatment. Provisional classification consists of myeloproliferative, lymphocytic and familial forms of HES. Chronic eosinophilic leukemia with clonal eosinophilia and myeloproliferative HES with features of the disease but without proof of clonality are included in the myeloproliferative forms of HES; HES with eosinophil hematopoietin-producing T-cells with or without a documented T-cell clone constitute the lymphocytic forms of HES. Further HES classification refinement expected in near future from a multidisciplinary consensus compendium in preparation. *FIP1L1-PDGFRA*, Fip1-like 1/platelet-derived growth factor receptor-α; HIV, human immunodeficiency virus; IL-5, interleukin 5; PUVA, psoralen plus ultraviolet A phototherapy. Further classification revisions likely in near future. (Information from Roufosse F, Weller PF: Practical approach to the patient with hypereosinophilia. *J Allergy Clin Immunol* **126**(1):39-44, 2010; Klion AD: Approach to the therapy of hypereosinophilic syndromes. *Immunol Allergy Clin North Am* **27**(3):551-560, 2007; and Stetson CL, Leiferman KM: Chapter 26: Eosinophilic dermatoses. Figure 36-3 Wells syndrome. **A.** Early lesion with erythema and edema. **B.** Late lesion resembling morphea.

LABORATORY TESTS AND HISTOPATHOLOGY

Peripheral blood eosinophilia is observed in approximately 50% of patients. Skin lesions histologically are characterized by diffuse dermal infiltration with eosinophils, histiocytes, and foci of amorphous and/or granular material associated with connective tissue fibers, which Wells termed *flame figures*.[102] In the early stages, there also is dermal edema. Later, histiocytes palisade around flame figures. In addition to eight patients with the syndrome, the 1979 report of Wells and Smith includes nine patients with the typical histologic features of eosinophilic cellulitis but in association with a variety of clinical diagnoses, including pemphigoid, eczema, and tinea.[103] This and subsequent reports of flame figures in lesions from patients with a wide spectrum of diseases (see Table 36-5 and referenced above) indicate that the flame figure is characteristic for, but not diagnostic of, Wells syndrome.[105] When examined for eosinophil granule major basic protein by immunofluorescence, flame figures show bright extracellular staining (Fig. 36-5), indicating that extensive eosinophil degranulation has occurred.[113]

Figure 36-4 Familial Wells syndrome. Plaques with erythema, edema, vesicles, and bullae resembling acute dermatitis or pemphigoid. (From Davis MD et al: Familial eosinophilic cellulitis, dysmorphic habitus, and mental retardation. *J Am Acad Dermatol* **38**:919, 1998, with permission.)

DIFFERENTIAL DIAGNOSIS

(Box 36-2)

Urticaria, erysipelas, and acute cellulitis should be considered in the differential diagnosis of the early stages of Wells syndrome (see Fig. 36-3A). Later, plaques may resemble morphea (see Fig. 36-3B). The presence of blisters may suggest pemphigoid (see Fig. 36-4). Flame figures are the hallmark of Wells syndrome, but, because they have been identified in biopsy specimens from other dermatoses (Table 36-5), they are not alone sufficient for the diagnosis. However, a diagnosis of Wells syndrome in the absence of flame figures should be met with skepticism, even in the presence of dermal infiltration with eosinophils and histiocytes.[105]

TREATMENT

Wells syndrome usually improves dramatically after administration of systemic glucocorticoids, and tapering of steroid dose over 1 month is well tolerated in most patients. Recurrences may be treated with additional courses of systemic glucocorticoids. For patients who fail to respond, or who experience relapse often enough to raise concerns about the long-term side effects of systemic glucocorticoid therapy, other options such as minocycline, dapsone, griseofulvin, and antihistamines may be beneficial. Cyclosporine and IFN-α also have been used with success. For treatment of mild disease, topical glucocorticoids may be sufficient.

ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA (EPITHELIOID HEMANGIOMA)

EPIDEMIOLOGY

Angiolymphoid hyperplasia with eosinophilia (ALHE) occurs in both males and females, but there is a slight female predominance. Patients are generally in the third to fifth decade of life. In contrast to Kimura disease (KD), which develops mainly in patients from Asia, ALHE has no racial predilection.

ETIOLOGY

The pathogenesis of ALHE is unknown, but it has been considered a vascular proliferation arising in response to or in association with underlying vascular malformation. There is a history of trauma in some cases. ALHE has been reported to occur in pregnancy, which implies that sex hormones may be a factor in its development.[145] ALHE also has developed in patients with T-cell clonality, which suggests that it may be an early or low-grade T-cell lymphoma and further highlights a relationship between T-cells and eosinophils, particularly T-cells with the TH2 phenotype.[146,147]

CLINICAL FINDINGS AND COURSE

ALHE shows a predilection for the head and neck area, including the ears,[148] and is characterized by solitary, few, or multiple, sometimes grouped, erythematous, violaceous or brown papules, plaques, or nodules of the dermis and/or subcutaneous tissues (see Chapter 146). Lesions may be associated with pruritus or pain, or may pulsate. Although they are confined to the skin in most patients, mucosal involvement may occur.[149] ALHE tends to be chronic and nonremitting over months to years.

ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA (EPITHELIOID HEMANGIOMA) AND KIMURA DISEASE AT A GLANCE

- Kimura disease (KD) occurs mainly in Asian males; angiolymphoid hyperplasia with eosinophilia (ALHE) occurs in all races, with a female predominance.
- KD is found in a younger age group than ALHE.
- Characterized by recurrent dermal and/or subcutaneous lesions, primarily of the head and neck area.
  - ALHE lesions tend to be smaller, more superficial, and more numerous than those of KD.
  - KD tends to involve subcutaneous tissues, regional lymph nodes, and salivary glands.
- ALHE may be painful, pruritic, or pulsatile, whereas KD is generally asymptomatic.
- Peripheral blood eosinophilia present in both diseases.
- Increased immunoglobulin E levels are found only in KD.
- Renal disease is associated only with KD (reported incidence of 10% to 20%).
- Histopathological features:
  - Dominant feature of KD is lymphoid proliferation, often with germinal centers, whereas ALHE is characterized by vascular proliferation with numerous large epithelioid or histiocytoid endothelial cells.
  - Fibrosis is characteristic of KD and is limited or absent in ALHE.
  - Inconspicuous to numerous eosinophils in ALHE.
  - Eosinophil abscesses may occur in KD.

LABORATORY TESTS AND HISTOPATHOLOGY

Approximately 20% of patients have peripheral blood eosinophilia; IgE levels are unremarkable. There is no association with renal disease. The dominant histological feature is a well-defined area, in the dermis and/or subcutis, of prominent vascular proliferation with large epithelioid or histiocytoid endothelial cells that contain abundant eosinophilic cytoplasm, often with cytoplasmic vacuoles (see Chapter 147). There are variable numbers of eosinophils and lymphocytes,[150] with an occasional finding of lymphoid nodules. In their report of 116 patients with ALHE, Olsen and Helwig found 53 cases in which "an arterial structure" appeared to be associated with venules or "was the area of endothelial proliferation," which provided evidence that these lesions may represent a form of arteriovenous shunt.[151] The stroma typically is myxoid, and fibrosis is minimal or absent. Mast cells may be a component of the histologic picture.

BOX 36-3 DIFFERENTIAL DIAGNOSIS ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA

Kimura disease
Pyogenic granuloma
Epithelioid hemangioendothelioma
Epithelioid angiosarcoma
Kaposi sarcoma

DIFFERENTIAL DIAGNOSIS

(Box 36-3)

Lesions of ALHE generally are smaller, more superficial, and more numerous than those of KD, and often are symptomatic. Although lymphoid follicles may occur in ALHE, they represent the dominant characteristic of KD (Table 36-6), and although KD may exhibit some vascularity, it lacks the large epithelioid endothelial cells that are a key feature of ALHE (see Table 36-6). ALHE should be distinguished from a variety of benign and malignant vascular proliferations, including pyogenic granuloma, epithelioid hemangioendothelioma, and Kaposi sarcoma—all of which lack a noticeable eosinophil infiltrate.

TREATMENT

Intervention is dictated in part by the number, location, size of lesions, and the patient's general health.[152] Patients with solitary or a few small lesions may benefit from excision or Mohs surgery, [153] but there may be recurrence at the surgical site (see Fig. 36-6). A variety of other treatment modalities have been used with success, including systemic and intralesional glucocorticoid administration, INF-α therapy,[154] cryotherapy,[155] laser therapy,[156] and topical application of tacrolimus.[157]

BOX 36-4 DIFFERENTIAL DIAGNOSIS KIMURA DISEASE

Angiolymphoid hyperplasia with eosinophilia
Lymphoma

KIMURA DISEASE

(Box 36-4)

TREATMENT

Surgical excision is the treatment of choice when feasible in patients with a single or a limited number of nodules, but lesions may recur.[167,168] Other therapeutic options include systemic glucocorticoids, cyclosporine, and radiation therapy.[169,170] The presence of renal disease may influence or dictate the therapeutic regimen. The finding of platelet-derived growth factor-α and c-kit in tissues from KD patients suggests that imatinib or another tyrosine kinase inhibitor may be effective in the disease.[171]

EOSINOPHILIC PUSTULAR FOLLICULITIS

CLINICAL FINDINGS AND COURSE

Classical EPF presents as recurrent crops or clusters of follicular papules and pustules, which may form an

TABLE 36-6
Comparison of Angiolymphoid Hyperplasia with Eosinophilia (ALHE) and Kimura Disease (KD)

	ALHE	KD
Gender	Typically middle-aged females	Predominantly young adult males
Symptoms	Pruritus, pain, pulsation	Asymptomatic
Lesion type and location	Small and superficial, with overlying erythema; head and neck region	Large, mainly subcutaneous; overlying skin normal; head and neck region; may involve regional lymph nodes and salivary glands
Lymphoid follicles	Uncommon	Prominent lymphoid follicles with germinal centers
Vascular proliferation	Prominent vascular proliferation with large epithelioid/histiocytoid endothelial cells; evidence of underlying vascular malformation may be evident	Some stromal vascularity with unremarkable endothelial cells
Fibrosis	Absent or limited	Prominent
Serum immunoglobulin E level	Normal	Increased
Nephropathy	Absent	Present in up to 20% of patients

EOSINOPHILIC PUSTULAR FOLLICULITIS AT A GLANCE

- Three clinical types, characterized by follicular papules and pustules that may involve the head, trunk, and extremities
  - Classic eosinophilic pustular folliculitis (Ofuji disease)
    - Typically occurs in Japanese patients, who have chronic, recurrent follicular pustules, with a tendency to form circinate plaques, in a seborrheic distribution
  - Eosinophilic pustular folliculitis associated with immunosuppression
    - Most often occurs in patients with human immunodeficiency virus infection, who have severely pruritic papules of the face and upper trunk
  - Eosinophilic pustular folliculitis of infancy/neonatal period
    - Follicular pustules of the scalp
- Tendency for recurrences and chronicity (except eosinophilic pustular folliculitis of infancy)
- Characterized by follicular and perifollicular eosinophil infiltration
- Associated with peripheral blood eosinophilia

annular pattern and usually resolve in 7 to 10 days. Lesions predominantly involve the face and trunk but also may affect the extremities, with involvement of the palms and soles in approximately 20% of patients.[177] In EPF of infancy, lesions typically are located on the scalp but also may be found on the face and extremities. In some neonates who have pustular eruptions that clinically resemble EPF and typically have peripheral blood eosinophilia, the disorder may be classified more appropriately under the term *eosinophilic pustulosis* because the cutaneous infiltrates are not folliculocentric (see Chapter 107).[202] In contrast, HIV-associated EPF tends to manifest as extremely pruritic discrete follicular papules, typically involving the head and neck and often the proximal extremities (see Fig. 198-3, Chapter 198). Rosenthal et al emphasized the urticarial quality of such lesions.[178] EPF of infancy has a good prognosis, whereas classical and HIV-associated EPF are characterized by recurrences. Postinflammatory pigmentation may be seen as lesions resolve, but scarring does not occur.

LABORATORY TESTS AND HISTOPATHOLOGY

Patients suspected of having EPF should be evaluated for underlying immune deficiency, particularly HIV infection. Peripheral blood eosinophilia is a component of all three types of EPF. Although patients with classical EPF usually have eosinophilia with leukocytosis, HIV-positive patients often exhibit eosinophilia with lymphopenia. Low CD4 cell counts and high IgE levels are typical of HIV-associated EPF.[178] Histologically, the most striking feature is the infiltration of eosinophils into hair follicles and perifollicular areas (see eFig. 36-6.2 in online edition), sometimes with follicular damage. The infiltrates also may contain lymphocytes and neutrophils, and may be perivascular as well as follicular.[203] Follicular mucinosis (see Chapter 145) has been noted in association with EPF[204]; however, T-cell clonality is not observed in EPF-associated follicular mucinosis.[205]

DIFFERENTIAL DIAGNOSIS

(Box 36-5)

Folliculitis secondary to bacterial or fungal infection must be kept in mind, particularly in immunosuppressed patients. Based on the distribution of lesions, seborrheic dermatitis should be considered, when there is head and neck involvement, and palmar–plantar pustular psoriasis may also be included in the differential diagnosis when there is hand and foot involvement. Acneiform eruptions may resemble EPF. Erythema toxicum neonatorum, acropustulosis, and acne neonatorum also should be considered in infants. Follicular mucinosis usually is clinically and histologically distinguishable from EPF.

TREATMENT

Topical glucocorticoids and topical calcineurin inhibitors generally are the first approach to the treatment of all types of EPF. Topical tacrolimus is helpful for facial lesions.[206] Nonsteroidal anti-inflammatory drugs, particularly indomethacin, also are recommended as first-line therapy; clinical improvement may be observed within 2 weeks and is associated with a decrease in peripheral blood eosinophil counts.[207–209] A mechanism

BOX 36-5 DIFFERENTIAL DIAGNOSIS EOSINOPHILIC PUSTULAR FOLLICULITIS

Folliculitis, bacterial or fungal

Acropustulosis
Follicular mucinosis

for this has been proposed based on the observation that indomethacin, not only inhibits cyclooxygenases and subsequent prostaglandin D2 synthesis, but also is associated with reduction in the prostaglandin D2 receptor (chemoattractant receptor homologous molecule expressed on TH2 cells, CRTH2) on eosinophils and lymphocytes.[210] UV light therapy (UVB or psoralen and UVA) may be beneficial. Topical permethrin, systemic retinoids, systemic glucocorticoids, cyclosporine, itraconazole, metronidazole, cetirizine, minocycline, dapsone, and IFNs have been tried with success.[207,208] Antiretroviral treatment that results in increased CD4 cell counts often is associated with improvement in HIV-associated EPF.

CLINICAL REACTION PATTERNS WITH EOSINOPHIL INVOLVEMENT

There are a variety of diseases in which eosinophils may be present in cutaneous lesions, with or without associated peripheral blood eosinophilia, but either the histologic pattern is unremarkable or eosinophils are not critical for the histological diagnosis of the given entity (see Table 36-1). In many of these dermatoses, the eosinophil loses its morphologic integrity after disruption through cytolysis and is not identifiable histologically.[216] However, toxic granule proteins and other phlogistic eosinophil products are deposited in skin, persist for extended periods of time, and cause tissue effects.[73,217]

EDEMA

Prominent among the eosinophil-associated skin reactions are those manifesting edema, including urticarias.[218–221] In addition to the presence of distinctive, toxic eosinophil cationic granule proteins in lesions, the ability of eosinophils to elaborate vasoactive mediators, induce histamine release from mast cells and basophils, and elicit a cutaneous wheal-and-flare reaction supports a role for the eosinophil as a primary participant in the edema associated with certain cutaneous diseases (see Chapter 31).[2,18]

EPISODIC ANGIOEDEMA ASSOCIATED WITH EOSINOPHILIA (GLEICH SYNDROME).

Episodic angioedema associated with eosinophilia is characterized by recurrent angioedema (with up to 30% increase in body weight), urticaria, fever, increased serum IgM levels, and leukocytosis as high as 100,000 cells/mm^3 with up to 90% eosinophils; disease activity fluctuates with the peripheral eosinophil count.[42,222] Skin biopsy specimens from this disorder[42] and its localized variant, recurrent facial edema with eosinophilia,[223] show few eosinophils, but immunofluorescence staining reveals extracellular deposition of eosinophil granule proteins around collagen bundles and blood vessels. The syndrome is associated with a number of immunologic abnormalities, including increased activated T cells[224,225] and increased serum IL-5 levels.[226,227] Capillary leak syndromes, due to administration of IL-2[228] and granulocyte-macrophage colony-stimulating factor,[229] also are associated with peripheral blood eosinophilia, increased serum IL-5 levels, and eosinophil degranulation.

CHRONIC DERMATITIS/PRURITUS

Although infestations typically are associated with eosinophils, the histologic pattern is nondiagnostic unless a specific organism is identified in tissue sections.[8,230] Infection with *Onchocerca volvulus* causes a pruritic dermatitis with lichenification, associated with slight cutaneous eosinophil infiltration but extensive deposition of eosinophil granule proteins throughout the dermis[231]; after treatment, extracellular deposition of eosinophil granule proteins is located around degenerating microfilaria.[230,232] Although eosinophils are rarely a prominent histological feature of atopic dermatitis, extensive dermal deposition of eosinophil granule proteins is seen in lesions (Fig. 36-7) but not in normal-appearing skin.[231,233] A link between

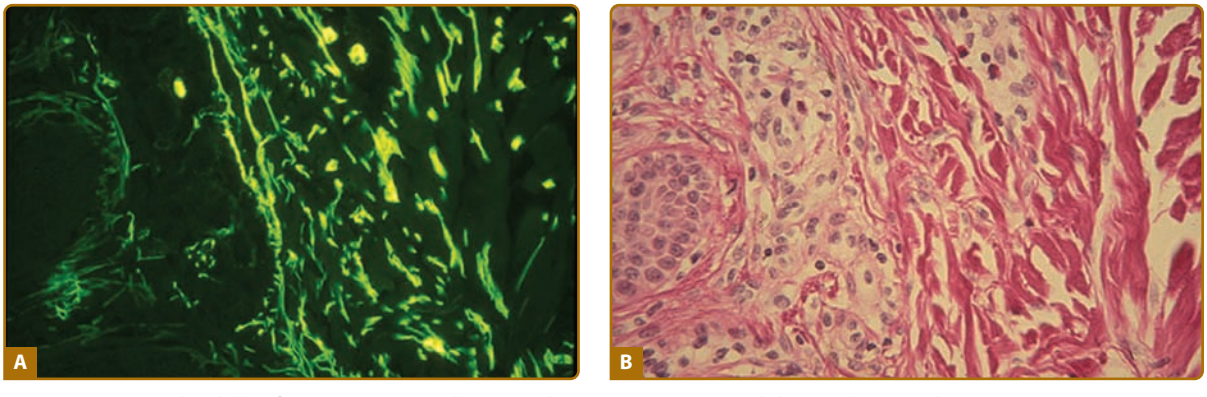

Figure 36-7 Involved skin from a patient with atopic dermatitis. **A.** Eosinophil granule major basic protein immunostain shows extensive extracellular granule protein deposition in the presence of only three intact eosinophils (brightly fluorescent ovals). **B.** Hematoxylin and eosin counterstain of **A** shows minimal nonspecific chronic inflammation. (**A** and **B** ×400, original magnification) (From Leiferman KM et al: Dermal deposition of eosinophil-granule major basic protein in atopic dermatitis. keratinocytes and eosinophils in atopic dermatitis was reported through activity of a novel TH2 cytokine, IL-31.[234] Prurigo nodularis[235] and pachydermatous eosinophilic dermatitis[236] exhibit a pattern of dermal extracellular eosinophil granule protein deposition similar to that seen in atopic dermatitis and onchocercal dermatitis. In both atopic dermatitis and prurigo nodularis, eosinophil granule products are deposited around cutaneous nerves,[235,237] and there is evidence that eosinophils play a role in itch provocation.[238–242] A particularly difficult clinical presentation is the patient with intractable itching and peripheral blood eosinophilia. Such patients may satisfy criteria for the hypereosinophilic syndromes, but their itch is refractory to most therapies. Understanding the eosinophil's role in the pathogenesis of this disorder may help with identifying effective therapies.

DRUG REACTIONS

Eosinophils are found in all types of drug reactions. There is evidence that, when eosinophils are part of the histologic pattern in leukocytoclastic vasculitis, the eruption is probably drug-induced[243] (see Chapter 41). The drug reaction with eosinophilia and systemic symptoms syndrome, so-called DRESS and also known as drug hypersensitivity syndrome, is a serious multiorgan disorder. Many drugs induce DRESS, and a spectrum of skin lesions may present with DRESS. Eosinophils and other inflammatory cells infiltrate skin, lymph nodes, and organs, including the liver. Fulminant hepatitis is associated with a mortality rate of 10%, and transplanted livers may also be affected. Eosinophil infiltration with and without granulomas with hepatocyte necrosis and cholestasis are prominent in liver failure that occurs with DRESS.[244–246]

BLISTERS

Autoimmune blistering diseases (see Chapters 54 and 56) often are associated with prominent infiltration of eosinophils, including presentation as eosinophilic spongiosis (Fig 36-8), and extracellular deposition of eosinophil granule proteins. IL-5 and eotaxin are present in pemphigoid blister fluid, and eosinophil-derived matrix metalloproteinase 9 that likely cleaves basement membrane zone.[247,248, 249]

In addition to pemphigoid gestationis (which may exhibit eosinophilic spongiosis),[250] other pruritic dermatoses of pregnancy (see Chapter 108) may demonstrate tissue eosinophilia.[251–253]

FIBROSIS

Eosinophils are found in association with fibrotic reactions, including those resulting from parasitic infections, pulmonary and hepatic drug sensitivity reactions, and HES.[254] Eosinophils elaborate mediators (see Chapter 31) that degrade collagen and stimulate dermal fibroblast DNA synthesis and matrix production.[255]

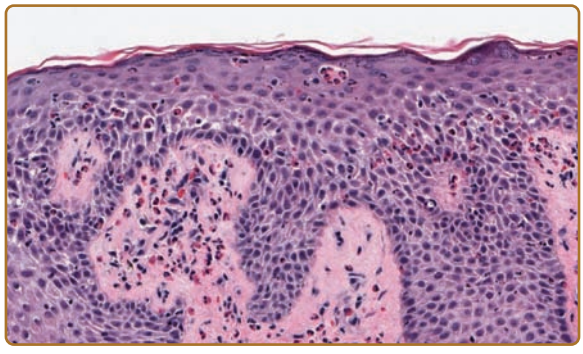

Figure 36-8 Eosinophilic spongiosis. There are eosinophils and intercellular edema within the epidermis. (Hematoxylin and eosin ×400, original magnification)

EOSINOPHILIC FASCIITIS. Eosinophilic fasciitis usually presents with pain, erythema, edema, and induration of the extremities, as well as peripheral blood eosinophilia and hypergammaglobulinemia.[256] Contractures and rippling of the skin may develop (Fig. 36-9). There is infiltration of lymphocytes, plasma cells, mast cells, and eosinophils, as well as increased thickness of the fascia.

EOSINOPHILIA–MYALGIA SYNDROME. Eosinophilia–myalgia syndrome (EMS), historically related to ingestion of certain lots of L-tryptophan,[257] is characterized by marked peripheral eosinophilia, disabling generalized myalgias, pneumonitis, myocarditis, neuropathy, encephalopathy, and fibrosis,[258] a constellation of features that are similar to but distinguishable from eosinophilic fasciitis.[259,260] Cutaneous abnormalities of EMS include edema, pruritus, a faint erythematous rash, hair loss, and *peau d'orange* or morphea-like skin lesions.[261] Lungs, heart, and nervous system may be affected.[262] There

Figure 36-9 Eosinophilic fasciitis. Puckered skin of the thighs.

is a prominent inflammatory infiltrate in the perimysium and fascia, and striking evidence of eosinophil granule protein deposition in skin and around muscle bundles.[257]

TOXIC OIL SYNDROME. Toxic oil syndrome (TOS), which resembles EMS, was linked to consumption of adulterated rapeseed oil distributed in the industrial belt around Madrid.[263] Patients experienced acute respiratory symptoms followed by intense myalgias, thromboembolism, weight loss, and sicca syndrome, followed by a chronic phase characterized by eosinophilic fasciitis-like lesions, peripheral neuropathy, muscle atrophy, and pulmonary hypertension. The cutaneous manifestations of TOS were nonspecific pruritic, erythematous skin lesions that persisted up to 4 weeks, followed over the next 2 months by subcutaneous edema, mainly of the extremities, accompanied by myalgias, arthralgias, contractures, and peripheral blood eosinophilia. Over many years, patients developed indurated plaques of the pretibial areas, and, occasionally, the forearms and abdomen,[263] with marked fibrosis extending into subcutaneous fat. Eosinophil infiltration and degranulation were especially prominent in the acute phase of TOS, and serum eosinophil granule protein levels were elevated during all phases.[264] Potential pathogenic links between TOS and EMS and also eosinophilic fasciitis have been identified.[265,266]

VASCULITIS

In 1951, Churg and Strauss described the complex of systemic vasculitis, asthma, and eosinophilia as *allergic granulomatosis*.[267] Cutaneous lesions develop in approximately two-thirds of cases and are variable consisting of nodules, urticaria, livedo reticularis, purpura, digital gangrene, and blisters. Histologically, the lesions are characterized by eosinophil infiltration, necrotizing vasculitis, and extravascular granulomas with prominent extracellular eosinophil granule protein deposition[268–270] (see Chapter 164). Granuloma faciale is characterized clinically by brown–red infiltrative plaques of the face and represents a localized type of necrotizing vasculitis that contains infiltration of eosinophils as well as neutrophils, lymphocytes, and histiocytes (see Chapter 34). Eosinophilic vasculitis (EV) is associated with peripheral blood eosinophilia and is characterized by chronic, recurrent, widespread pruritic, erythematous, purpuric papules as well as angioedema of face and hands; skin biopsies show necrotizing small vessel vasculitis with prominent infiltration of eosinophils.[271,272] EV may be idiopathic or associated with connective tissue disease,[273] Raynaud phenomenon, or HES.[58]

MALIGNANCY

Eosinophils may be observed in a variety of cutaneous and extracutaneous neoplasms. Their presence in tumors appears to be independent of immune surveillance and likely is part of an early inflammatory reaction at the site of tumorigenesis.[274] Various types of peripheral T-cell lymphomas are eosinophil-rich, including follicular mycosis fungoides and cutaneous anaplastic large cell lymphoma[275–277]; the prognostic significance of tissue eosinophilia in such lesions is not established. Underlying malignancy may prompt lesions associated with eosinophil infiltration, such as the exaggerated arthropod-bite reactions seen in patients with chronic lymphocytic leukemia.[278]

Eosinophilic, polymorphic and pruritic eruption associated with radiotherapy (EPPER) is an uncommon idiopathic disorder that appears in patients undergoing radiation treatment for malignancy. Women are affected more often than men. Onset of the eruption is typically during radiation treatment, but delays up to 7 months are reported.[279,280] Cutaneous findings are not localized to irradiated areas and may include local and generalized pruritus, erythematous papules, wheals, and vesicles and bullae. Eosinophils are prominent in affected skin, but not characteristically in the tumors.

SECTION 6

Inflammatory Diseases Based on Abnormal Humoral Reactivity and Other Inflammatory Diseases

Chapter 37 :: Humoral Immunity and Complement

:: Lela A. Lee

HUMORAL IMMUNITY AND ANTIBODY STRUCTURE AT A GLANCE

- Humoral immunity, mediated by antibodies produced by B lymphocytes, is a form of specific immunity directed primarily toward extracellular antigens.
- Antibody molecules consist of two identical light chains covalently linked to two identical heavy chains. The variable region of the antibody molecule is responsible for antibody binding, and the constant region mediates most effector functions.
- The five antibody classes serve distinct functions. Immunoglobulin (Ig) M is involved in primary antibody responses, IgD is an antigen receptor on naive B cells, IgA is critical for mucosal immunity, IgG is the major Ig in the circulation and is important in secondary antibody responses, and IgE mediates immunity to parasites.
- An individual is capable of generating millions of distinct antibodies in millions of distinct B-cell clones through the processes of gene rearrangement and junctional diversity.

B LYMPHOCYTES

During evolution, jawed vertebrates developed the capacity to respond with exquisite specificity to foreign organisms.[1] Specific immunity is characterized by an enormous diversity of possible responses and by refinement in the immune response with successive exposures to the organism.[2] The cells that can discriminate with fine specificity through their vast repertoire of receptors are lymphocytes. Specific immunity, also called *adaptive immunity* because it develops as an adaptation to infection, can be segregated into humoral immunity, mediated by antibodies produced by B lymphocytes, and cellular immunity, mediated by T lymphocytes. These two forms of specific immunity developed to serve different functions. Humoral immunity is directed primarily toward extracellular antigens such as circulating bacteria and toxins. Cellular immunity is directed primarily toward antigens that infect or inhabit cells (see Chapter 10). To combat extracellular pathogens, the defending agent needs to be abundant and widely distributed in the body, particularly at its interfaces with the environment. Antibodies fulfill these characteristics by being capable of being secreted in great quantity from the cells that produce them and by being distributed in blood, mucosa, and interstitial fluid. In addition, antibodies can attach through Fc receptors (FcRs) to the surface of certain other cells of the immune system, such as mast cells, conferring antigen specificity to cells that do not have their own endogenously produced antigen-specific receptors. In addition to their major function in humoral immunity as antibody producers, B lymphocytes have a role in antigen presentation, regulation of T-cell subsets and dendritic cells, organization of lymphoid tissues, and cytokine and chemokine production.[3,4]

ANTIBODY STRUCTURE

Antibodies, or immunoglobulins (Ig), are a family of glycoproteins that share a common structure.[2,5,6] The antibody molecule has a symmetric Y-shape consisting of two identical light chains, each about 24 kDa, that are covalently linked to two identical heavy chains, each about 55 or 70 kDa, that are covalently linked to one another (Fig. 37-1). Within the light and heavy chains are variable and constant regions. The major function of the variable region is to recognize antigen, whereas the constant region mediates effector functions. The light and heavy chains contain a series of repeating, homologous units of about 110 amino acids that assume a globular structure and are called *Ig domains*. The Ig domain motif is found not only in antibody molecules but also in a variety of other molecules of the Ig "superfamily," including the T-cell receptor, the major histocompatibility complex (MHC), CD4, CD8, intercellular adhesion molecule 1, among other molecules. The light chain has two major domains, (1) a variable (V_L) and (2) a constant (C_L) domain. The heavy chains have four or five domains, a variable (V_H) and three (in IgA, IgD, and IgG) or four (in IgM and IgE) constant (C_H1–4) domains. In IgA, IgD, and IgG, there is a hinge region

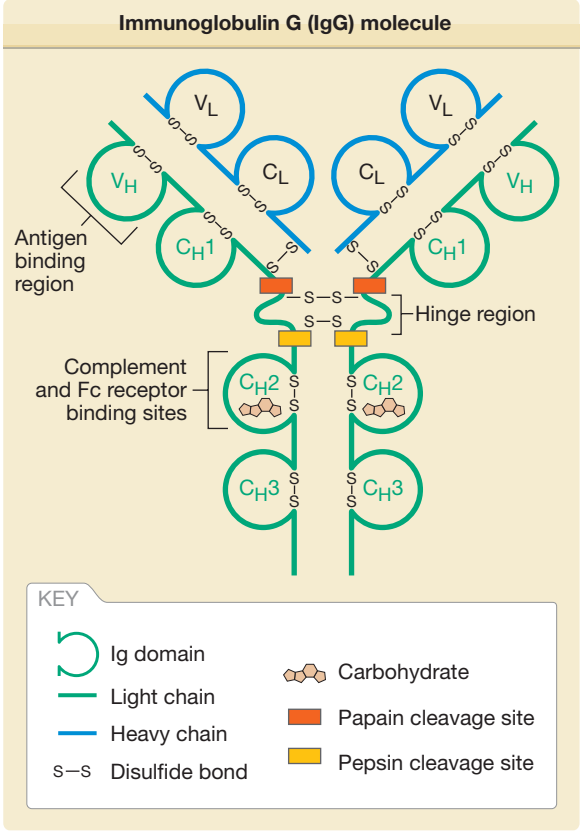

Figure 37-1 Schematic representation of an immunoglobulin G (IgG) molecule.

between C_H1 and C_H2 that confers additional flexibility to the molecule. The variable domains are at the *N*-terminus. At the *C*-terminus are the constant domains and, in the heavy chains of membrane-bound antibodies, the transmembrane and cytoplasmic domains.

Within the variable regions of the light and heavy chains are three areas of intense variability called *hypervariable regions*. These three regions, which are in proximity to one another in the three-dimensional structure of the antibody, are the areas most responsible for binding antigen. Because the hypervariable regions form a shape complementary to that of the antigen, the hypervariable regions are also called the *complementarity-determining regions*. The unique areas formed by the hypervariable regions are present in too low an amount in the individual to generate self-tolerance. Thus, the immune system may not distinguish the unique portion of the antibody as self and may produce antibodies to that region of the antibody. The area of the antibody capable of generating an immune response is called an *idiotope*, and antibody responses to idiotopes result in a network of idiotypic–anti-idiotypic interactions that may help regulate the humoral immune response.[7]

There are two types of light chains, κ and λ, each encoded on different chromosomes. Each antibody molecule has either two κ or two λ chains, never one of each. The functional differences, if any, between κ and λ are not known. There are five types of heavy chains, (1) α, (2) δ, (3) ε, (4) γ, and (5) μ, corresponding to the antibody classes IgA, IgD, IgE, IgG, and IgM, respectively. The different heavy chain classes have significantly different functions, as discussed in Section "Antibody Classes". The IgA and IgG classes contain closely related subclasses, consisting of IgA1 and IgA2, and IgG1, IgG2, IgG3, and IgG4 (Table 37-1).

Enzymatic digestion of IgG molecules by papain results in three cleavage products, two identical Fab fragments consisting of a light chain bound to the V–C_H1 region of the heavy chain and an Fc portion consisting of two C_H2–C_H3 heavy chains bound to each other. *Fab* was so named for its property of antigen binding, and *Fc* was so named for its property of crystallizing. When IgG is digested by pepsin, the *C*-terminal region is digested into small fragments. The remaining product consists of the Fab region along with the hinge region. Fab fragments containing the hinge region are termed Fab'. When the two Fab' fragments in an antibody molecule remain associated, the fragment is called $F(ab')_2$.

ANTIBODY CLASSES

(See Table 37-1)

IMMUNOGLOBULIN M

IgM is evolutionarily the most ancient antibody class and is the first Ig molecule to be expressed during B-cell development.[1] Its secretory form exists mainly as a pentamer consisting of five IgM molecules joined at their *C*-termini by tail pieces and stabilized by a molecule called a *joining (J) chain*. The engagement of membrane-bound IgM by antigen results in the activation of naive B cells. Secreted IgM recognizes antigen, usually through low-affinity interactions, and it can activate complement. IgM is the major effector of the primary antibody response. Although IgM interactions are typically low affinity, IgM can be very effective in responding to a polyvalent antigen (such as a polysaccharide with repeating epitopes) because its pentameric structure allows for multiple low-affinity interactions, resulting in a high-avidity interaction. (*Avidity* refers to the overall strength of attachment, whereas *affinity* refers to the strength of attachment at a single antigen-binding site.)

IMMUNOGLOBULIN D

The IgD molecule exists primarily in a membrane-bound form and is the second antibody class to be expressed during B-cell development. Its function is not completely understood, but in its membrane-bound form it can serve as an antigen receptor for naive B cells.[8] Secreted IgD has been found on the surface of basophils, where it induces production of antimicrobial, opsonizing, inflammatory, and B-cell–stimulating factors.[9]

IMMUNOGLOBULIN A

IgA is the most abundant Ig in the body, being present in large quantity at mucosal sites. It is responsible

TABLE 37-1
Immunoglobulin Classes and Their Functions

A	Subtypes	Secreted Form	Approximate Molecular Weight of Secreted Form (kDa)	Serum Concentration (mg/mL)	Serum Half-Life (Days)	Functions
IgM	None	Pentamer, hexamer	970	1.5	5	Primary antibody response; antigen receptor on naive B cells; complement activation
IgD	None	Monomer	180	Trace	3	Antigen receptor on naive B cells
IgA	IgA1	Monomer, polymer (usually dimer)	160 (monomer), 390 (secretory IgA)	3	6	Mucosal immunity; neonatal immunity

IgE	None	Monomer	190	0.05	2	Immediate hypersensitivity; defense against parasites

Ig = immunoglobulin.

for mucosal immunity and is secreted in breast milk, thus contributing to neonatal immunity. In its secreted form, it exists as a monomer, dimer, or trimer, with the multimers being formed by interactions between tail pieces and stabilized by the J chain. For transport across epithelial surfaces, IgA dimers attach to a type of FcR called the *polymeric Ig receptor*.[10] Once the transport process is complete, the IgA dimers remain attached to the extracellular portion of the receptor, called the *secretory component*, which protects the IgA from proteolysis. Cells of the immune system that have receptors for IgA include neutrophils, eosinophils, and monocytes.

IMMUNOGLOBULIN G

IgG is the most abundant Ig in the circulation. Its secreted form is a monomer. IgG plays an important role in secondary antibody responses, and its interactions with antigen tend to be high affinity, particularly as the immune response matures. A number of cells have FcRs for IgG, including monocytes, neutrophils, eosinophils, natural killer (NK) cells, and B cells. IgG opsonizes (coats) antigen, allowing phagocytosis of the antigen, and activates complement. An exception is IgG4, which does not activate complement. IgG is important in neonatal immunity, as it is the only Ig class to cross the placenta, and it is secreted in breast milk. The interaction of IgG with the MHC class I-related receptor FcRn is involved in the delivery of IgG across the placenta as well as in prolonging its level in the circulation.[11] The serum half-life of IgG is 23 days, considerably longer than that of the other Ig classes.

IMMUNOGLOBULIN E

IgE is found in very small amounts in the circulation. High-affinity receptors for the Fc portion of IgE are present on mast cells, basophils, and eosinophils, and low-affinity receptors are present on B cells and Langerhans cells. In mast cells and basophils, IgE engagement with antigen activates the cells. IgE mediates immediate hypersensitivity, but its principal protective role may be to combat parasites.

MECHANISMS FOR THE GENERATION OF ANTIBODY DIVERSITY

The information encoded by an individual's DNA is limited by the need for the DNA to fit into a package of

the size of a cell. This space is far too small for sufficient DNA to encode billions of different lymphocyte receptors if the genes were encoded separately. Lymphocytes have adapted to this limitation by special mechanisms that increase by orders of magnitude the number of different possible antigen receptors.[12] Each clone of B cells produces identical antigen receptors (i.e., antibodies) with unique specificity. It is estimated that an individual has approximately 10^7 different B-cell clones, resulting in 10^7 distinct antibodies. A major mechanism for generating this enormous diversity is gene rearrangement, whereby segments of DNA within a lymphocyte undergo somatic recombinations.[13] Light chain genes contain three regions, (1) V (variable), (2) J (joining), and (3) C (constant), and heavy chain genes contain four regions, (1) V, (2) D (diversity), (3) J, and (4) C. Within each region are many gene segments from which to select for the final antibody product, which is comprised of one gene segment randomly selected from each region. The initial event in antibody formation is the joining of one D and one J segment from a heavy chain gene, with subsequent deletion of the DNA between the two segments. Next, a V segment is selected to join to the DJ segment, and any remaining D segments are deleted. The VDJ complex has attached 3′ to it any remaining J segments plus the C region. The unused J segments are removed during RNA processing. A similar process occurs in light chain loci; because there are no D segments in light chain loci, a VJ rather than a VDJ complex is formed. (Particularly in the k locus, VJ recombination may occur through a somewhat different mechanism involving inversion of the DNA without deletion of intervening sequences, but the functional result is the same.)

The ability to select one segment each from the many segments available in the V, D, and J regions leads to a vast increase in the repertoire of possible antibodies. Additional diversity is generated by the juxtaposition of a rearranged light chain to a rearranged heavy chain; by the addition, deletion, or transposition of nucleotides at the junctions between V and D, D and J, and V and J segments, a phenomenon called *junctional diversity*; and by somatic hypermutation after antigen stimulation (see below).

B-CELL MATURATION

Cells destined to become mature B cells undergo an orderly progression of events during development, resulting in the formation sequentially of heavy chains, light chains, and whole antibody molecules, with checkpoints to select against cells making unproductive gene rearrangements or autoreactive antibodies, and survival signals to select for cells making potentially useful antibodies. The process of B-cell development occurs in distinct stages, characterized by specific events and identifiable by specific cell surface markers and Ig gene expression.

Bone marrow and fetal liver stem cells that give rise to B cells are initially pluripotent.[2,14] Stem cells developing in the lymphocytic pathway initially become *common lymphoid progenitors*, which can give rise to B, T, or NK cells. B cells originating from fetal liver are mainly B1 cells (see Section "B-Cell Activation and Antibody Function"), whereas B cells originating in the bone marrow are primarily follicular B cells. Cells and extracellular molecules in the stromal microenvironment provide signals required for differentiation of lymphocytes. Induction of the transcriptional regulators EBF, E2A, and Pax-5 leads to the expression of proteins critical to B-cell development. Posttranscriptional regulation of mRNA by RNA-binding proteins and microRNAs provides further control over the process of B-cell differentiation.[15]

The earliest cell committed to the B-cell lineage is called a *pro-B cell*. At the pro-B cell stage, the cell expresses recombination activating gene (RAG) and terminal deoxyribonucleotidyl transferase (TdT) proteins, which will be needed subsequently for somatic recombination and nucleoside transfers involved in junctional diversity, respectively. At the pro-B-cell stage, limited somatic recombination has taken place, and Ig is not yet expressed.

The next stage of B-cell maturation is represented by the *pre-B cell* and is marked by the synthesis of a cytoplasmic μ heavy chain. Because light chains are not yet expressed at this stage, surface Ig is not present. Some of the μ heavy chains associate with invariant molecules called *surrogate light chains* and with the signal transducing proteins Ig α and Ig β to form complexes called *pre-B cell receptors*. Cells that have synthesized heavy chains that are capable of forming part of a pre-B cell receptor are selected for at this stage, as pre-B cell receptors provide important signals for survival, proliferation, and maturation.

The formation of light chains marks the next stage in B-cell maturation, the *immature B-cell* stage. When

B-CELL MATURATION AT A GLANCE

- The pro-B cell expresses enzymes needed for gene rearrangement and junctional diversity, but neither heavy nor light chains are expressed.
- The pre-B cell expresses μ heavy chains in the cytoplasm. On the cell surface, the heavy chains associate with surrogate light chains to form pre-B cell receptors.
- The immature B cell produces light chains and can therefore express antibody molecules on the cell surface. If antigen exposure occurs at this stage, negative selection may take place.
- During the transitional stage, B cells gradually lose sensitivity to negative selection and acquire immune competence.
- The mature B cell expresses both IgM and IgD and is competent to respond to antigen.

light chains join with the μ heavy chains, an IgM molecule results and can be expressed on the cell surface in association with Ig α and Ig β. Although the presence of a B-cell receptor complex confers the ability to recognize specific antigens, at this stage such recognition does not result in proliferation or differentiation. Rather, the cells may undergo negative selection when antigen is encountered. Immature B cells recognizing self-antigen may be negatively selected through deletion,[16] anergy, or receptor editing, a process of secondary gene rearrangement by which a new, nonself specificity is acquired.[17]

The exit of immature B cells from the bone marrow to the spleen marks the beginning of the next stage, the *transitional B-cell* stage.[18] Transitional cells gradually acquire surface IgD, CD21, and CD23 expression and become more immune competent. Alternative splicing of RNA allows the simultaneous expression of IgM and IgD. At the beginning of the stage, cross-linking of the B-cell receptor leads to negative selection. With further maturation, transitional cells become responsive to T-cell help and lose sensitivity to negative selection.

The *mature B cell* expresses IgM and IgD and is competent to respond to antigen. The cell is considered naive because it has not been activated by antigen. The majority of mature B cells circulate through peripheral lymphoid tissues (spleen, lymph nodes, mucosal lymphoid tissue) and are called *follicular B cells*, or recirculating B cells. B cells are recruited to the follicle by the chemokine CXCL13, secreted by follicular dendritic cells, and survive in the follicle with the assistance of a cytokine called BAFF (B-cell activating factor), also known as BLyS (B lymphocyte stimulator). A small percentage of mature B cells home to the marginal zone of the spleen and remain resident there.

The encounter of antigen by mature naive B cells leads to B-cell activation, proliferation, and differentiation (see Section "B Cell Activation and Antibody Function"). A subset of B cells become *memory B cells*, which can persist for long periods apparently without stimulation by antigen, and which respond rapidly if the antigen is encountered subsequently.[19] Another subset of B cells differentiates into cells that make progressively less membrane-bound Ig and more secreted Ig. The terminally differentiated B cells committed to the production of secreted Ig are *plasma cells* and have abundant rough endoplasmic reticulum, consistent with the function of the cells as antibody factories.[20]

ANTIGENS BOUND BY B CELLS

B cells recognize a variety of macromolecules, including proteins, lipids, carbohydrates, and nucleic acids. The portion of the molecule recognized by the antibody is called an *epitope* or *determinant*. B cells recognize both linear epitopes (epitopes formed by several adjacent amino acids) and, quite commonly, conformational epitopes (epitopes present as a result of folding of the macromolecule).[21] In contrast to B cells, T-cell responses are almost entirely restricted to linear epitopes of peptides.

Macromolecules, particularly large proteins, may contain several different epitopes, and a humoral response to a macromolecule typically is comprised of multiple different antibodies. Although each different antibody is specific for a given epitopic configuration, similarities in epitopes may exist such that an antibody to a given epitope on a given macromolecule also may be able to bind a different epitope on a different macromolecule. This phenomenon is called *cross-reactivity*, and may be important in the genesis of autoimmune antibody responses.

Macromolecules that have multiple identical epitopes are classified as being polyvalent or multivalent. Antibodies to these macromolecules or aggregates of macromolecules may form complexes called *immune complexes* with the antigen. At a particular concentration of antibody and antigen, called the zone of equivalence, a large network of linked antigens and antibodies forms. At lower or higher concentrations of antibody or antigen, the complexes are much smaller. Immune complexes, formed in the circulation or in tissue, may be responsible for disease through the initiation of an inflammatory response.

B-CELL ACTIVATION AND ANTIBODY FUNCTION

B-CELL ACTIVATION AND ANTIBODY FUNCTION AT A GLANCE

- When the B-cell receptor (surface antibody) binds antigen, a second signal provided by C3d engagement with complement receptor 2 significantly augments B-cell activation.
- B-cell responses to protein antigens typically involve T-cell help, with resultant antibody class switching and affinity maturation. Activated B cells may become short-lived plasma cells, memory B cells, or long-lived plasma cells. Long-lived plasma cells migrate to the bone marrow, where they may persist indefinitely and are a major source of antigen-specific antibodies in the circulation.
- Effector functions of antibodies include neutralization of antigen, complement activation, cell activation, phagocytosis, and antibody-dependent, cell-mediated cytotoxicity. Most of these are mediated through the binding of Ig to Fc receptors containing an immunoreceptor tyrosine-based activation motif.
- Negative signaling to B cells is provided by binding of IgG to a B-cell Fc receptor that contains an immunoreceptor tyrosine-based inhibition motif. The availability of excess IgG to bind this receptor is an indication that antigen is being successfully eliminated and the immune response is no longer required.

On cross-linking of the mature B-cell receptor by antigen, clustering of receptors initiates signaling transduced by Igα and Igβ. The complex signaling cascade involving the phosphorylation of tyrosine kinases, including Lyn, Fyn, Btk, and Syk, eventuates in the expression of genes involved in B-cell activation.[22] B-cell activation is facilitated by second signals, one of which is provided by the complement protein C3d.[23] Complement fragment C3d is formed as a result of complement activation through any of the complement activation pathways (see Section "Complement"). The B-cell surface contains a coreceptor complex consisting of complement receptor 2 (CR2), CD19, and CD81 (also called TAPA-1, or target for antiproliferative antigen-1). Simultaneous binding of antigen by antibody on the B-cell surface and of C3d by CR2 leads to markedly increased B-cell activation. B-cell activation may also occur through Toll-like receptors that recognize specific microbial products.[24]

The subsequent response to an antigen often involves a complex interaction between B cells and T cells, leading to a fine-tuning of the immune response.[25] Recognition of antigen by both B cells and T cells leads to increased expression of cell surface proteins and cytokines that render these cells increasingly capable of migrating toward and productively interacting with each other. T cells recognizing peptide-class II MHC complexes on dendritic cells receive a primary signal from the complex and a secondary signal from costimulatory interactions involving the binding of B7–1 and B7–2 on dendritic cells to CD28 on T cells.[26] These activated T cells express CXCR5, the ligand for CXCL13, which results in T-cell migration toward the follicle and therefore increasingly toward B cells. In response to a protein antigen, B cells take up the antigen, process it, and present processed antigen on the cell surface in complex with class II MHC. Activated B cells express less CXCR5, which allows them to migrate from the follicle toward the T-cell zone. At the boundary between follicles and T-cell zones, activated T cells interact with B cells and provide signals to the B cells through the binding of CD40 on B cells to CD40 ligand (CD154) on T cells and through the action of cytokines, notably interleukin 2 (IL-2), IL-4, IL-21, BAFF, and APRIL (*a pro*liferation-*i*nducing *l*igand).[2] These signals will be necessary for subsequent class (heavy chain isotype) switching, affinity maturation, and memory B-cell generation. The overall effects on B cells are stimulation of proliferation and differentiation.

At this phase, some of the activated B cells become short-lived plasma cells, which provide a prompt initial response to an antigen, while others migrate back from the periphery of the follicle to proliferate rapidly and form germinal centers. It is primarily in the germinal centers that class switching, affinity maturation, and generation of memory B cells occur. Class switching from IgM to IgA, IgE, or IgG occurs as a result of T cell–B cell interactions.[27,28] The determination of the antibody class selected is based on the site where the antigen is encountered and the cytokine milieu. For example, B-cell responses to antigens encountered on mucosal surfaces characteristically result in class switching to IgA, and transforming growth factor-β is an important contributing cytokine. IL-4 is an important signal for class switching to IgE.

T-cell interaction with B cells also results in affinity maturation, whereby the affinity of antibodies for the antigen progressively increases. During affinity maturation, somatic hypermutations in antibody genes result in antibodies with both greater and lesser affinity for the antigen.[29,30] Those antibodies with greater affinity confer a survival advantage on the B cells that produce them. Progressively, the population of B cells evolves in favor of those producing higher affinity antibodies for the antigen. Both class switching and affinity maturation require the expression of an enzyme called *activation-induced cytosine deaminase* (AID).[31]

The culmination of germinal center activity is the formation of memory B cells and long-lived plasma cells.[32] A number of transcriptional regulators are involved in late B-cell development, including BLIMP1 (B-lymphocyte maturation protein 1), IRF4 (interferon-regulatory factor 4), and XBP1 (X-box-binding protein 1). Plasma cells may arise from and be replenished by memory B cells or may arise from an intermediate cell, the plasmablast. Long-lived plasma cells migrate to and have a survival niche in the bone marrow, where they can persist indefinitely. These bone marrow long-lived plasma cells are the major source of antigen-specific antibody in the circulation.

As noted in Section "Antigens Bound by B Cells," T-cell responses are limited almost entirely to peptides. Thus, B-cell responses to nonprotein antigens may not result in T-cell help through the mechanisms described earlier.[33] In selected cases, T-cell independent nonprotein antigens can induce class switching, but in general, T-cell independent responses are characterized by IgM antibodies of lower affinity. One type of T-cell-independent B-cell response produces so-called *natural antibodies*—IgM antibodies that are largely anticarbohydrate antibodies produced without apparent antigen exposure.[34] These natural antibodies are characterized by a limited repertoire and are produced primarily by B1 peritoneal cells either spontaneously or in response to bacteria that colonize the gut. Marginal zone B cells, located near the marginal sinus in the spleen, may also produce natural antibodies.

Antigen occupation of antibody-binding sites on B cells leads to functional results, called *effector functions*. With the exception of direct neutralization of antigen by antibody binding, effector functions are typically mediated through the binding of Ig to FcRs.[35,36] FcRs can be categorized as those that trigger cell activation and those that do not. Those that can trigger activation contain one or more motifs called *immunoreceptor tyrosine-based activation motifs*. Of those that do not trigger activation, some can inhibit cell activation and contain a motif called *immunoreceptor tyrosine-based inhibition motif*. FcRs that neither activate nor inhibit cell activation are involved in the transport of Ig through epithelia and the prolongation of the half-life of IgG.

The effector functions of antibodies serve to eliminate the antigen that initiated the immune response and also to downregulate the immune response when activation is not required. Effector functions of

antibodies include neutralization of antigen, complement activation, cell activation (of monocytes, neutrophils, eosinophils, and B cells), phagocytosis (by monocytes and neutrophils), and antibody-dependent cell-mediated cytotoxicity (mediated by NK cells and eosinophils). In addition, engagement of IgG by antigen provides a negative signal to B cells, mediated through the binding of the antigen-antibody complex to an immunoreceptor tyrosine-based inhibition motif-containing Fcγ receptor, FcγIIB, on the B cell.[37]

B CELLS AND ANTIBODIES IN DISEASE

Disorders of B cells or antibodies cause or contribute to many diseases of dermatologic relevance. Immunodeficiency diseases may result from abnormalities of B-cell development or activation, or from abnormalities in effector function pathways.[38] B-cell lymphomas may result from failure to regulate proliferation, differentiation, or programed cell death.[39] Ectopic lymphoid aggregates can arise as a result of aberrant chemokine-mediated lymphocyte homing.[40] Antibodies may initiate an inflammatory response that results in injury, as in IgE-mediated allergic reactions or immune-complex diseases.[41,42] In some cases, the antigen may not be obviously harmful, but the response to the antigen is. In other cases, the antigen may be pathogenic, but the character or magnitude of the immune response is inappropriate or inadequately controlled. The regulatory systems that protect an organism from attack by its own immune system occasionally go awry.[43,44] Failure to eliminate autoreactive cells may be a major underlying abnormality in many patients with autoimmunity. In some cases, autoimmunity may be initiated as a result of an immune response to a pathogen.[45] The pathogen may act as a nonspecific activator of the immune system, or may activate the immune response specifically (e.g., by containing an epitope or epitopes that are cross-reactive with an autoepitope). These responses may be particularly difficult to control because the major stimulus for the immune response, the antigen, is a normal component of "self" and cannot be eliminated. As mentioned earlier, B cells have important roles beyond antibody production. Abnormalities or imbalance of immune regulatory functions by B cells may lead to autoimmunity. Thus, through many mechanisms, the normal protective B-cell response, which developed as an elegant means to discriminate very finely among various potential pathogens, can be subverted to result in harm to the organism.

COMPLEMENT

The complement system was discovered through its ability to contribute to, or "complement," bacterial cell lysis by antibodies.[46,47] At physiologic temperatures, serum containing antibacterial antibodies lysed bacteria effectively, whereas serum heated to 56°C (133°F) lost its ability to lyse bacteria. Because antibodies are quite stable at 56°C (133°F), it was postulated that the loss of lytic ability was due to the degradation of heat-labile nonantibody molecules.

Although the complement system was first identified through its role in humoral immunity, a primitive complement system emerged more than 1.3 billion years ago as a component of innate immunity (see Chapter 10).[48] The complement system is constituted in part by a set of plasma proteins that are normally inactive or minimally active. The initial steps of activation involve the cleavage of an inactive protein into a smaller and a larger fragment. The larger fragment, then, is itself able to cleave other proteins in the cascade. Because an activated molecule in one step is capable of generating many activated molecules in the following step, the sequential cleavage and activation of complement proteins result in amplification of the cascade.

COMPLEMENT SYSTEM AND ACTIVATION PATHWAYS AT A GLANCE

- The complement system functions to kill microbes via lysis or phagocytosis, to clear immune complexes and apoptotic debris from the circulation, to promote inflammation, and to stimulate humoral immunity.
- The three pathways of complement activation are the alternative, classical, and lectin pathways.
- The early steps in complement activation are triggered enzyme cascades in which cleavage of an inactive protein into fragments results in cleavage of subsequent proteins in the cascade.
- The alternative and lectin pathways are primarily pathways of innate immunity; the classical pathway is a pathway characteristically initiated by humoral immunity.
- The complement pathways converge at the cleavage of C3 and subsequent cleavage of C5. The final steps of activation consist of the addition of C6–8 to C5b, and polymerization of C9 to form the membrane attack complex.

PATHWAYS OF COMPLEMENT ACTIVATION

The early stages of the activation of complement ultimately result in cleavage of the complement protein C3. This is followed by the cleavage of C5 and initiation of the final steps of complement activation. There are three distinct pathways that lead to the cleavage of C3, the classical, the alternative, and the lectin pathways. Although the classical pathway was the first to be described, the alternative pathway is evolutionarily older.[49]

ALTERNATIVE PATHWAY

(Fig. 37-2)

The first step in the activation of the alternative pathway is the binding of C3b to a cell surface such as a bacterial cell surface. Intact C3 is an inactive molecule, but there is a low-level spontaneous cleavage of C3, called *tickover*, which results in the continuous availability of the C3b fragment. C3b can bind stably to a cell surface through an interaction between a thioester group of C3b and a hydroxyl group of the cell surface. In intact C3, the thioester domain is covered by hydrophobic residues that prevent hydrolysis of the thioester bond. The anaphylatoxin (ANA) domain of C3 stabilizes this inactive conformation. When the ANA domain is cleaved to release C3a, the thioester group is exposed, and conformational change results in its ability to bond to the cell surface.[50,51] If this chemical bonding does not occur, the thioester group is hydrolyzed and C3b is inactivated.

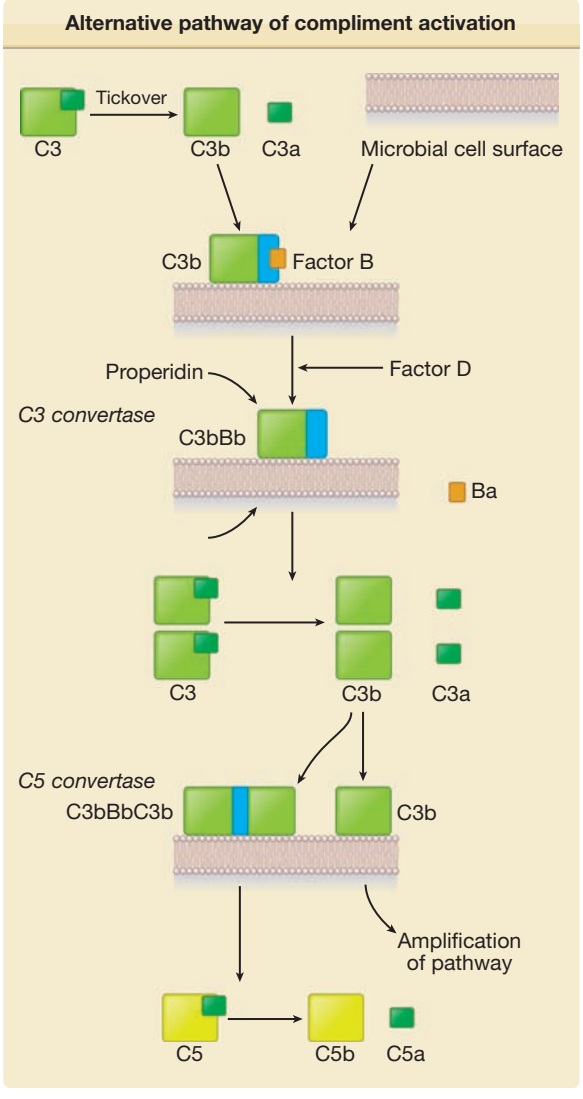

Figure 37-2 The alternative pathway of complement activation. Shown are the steps from the initial attachment of C3b to a microbial cell surface through the cleavage of C5 into C5a and C5b. The final steps of complement activation are shown in Fig. 37-4. See Section "Alternative Pathway" for details.

Once stable attachment of C3b to the cell surface takes place, a plasma protein called *Factor B* binds to C3b. Factor B is in turn cleaved by factor D, generating Bb and Ba. The complex of C3b and Bb, stabilized by the plasma protein properidin, is the alternative pathway C3 convertase (i.e., it cleaves C3 into C3a and C3b). The result of the activity of the C3 convertase is an amplification of the pathway by two or three orders of magnitude. The addition of further C3b to the complex results in C3bBbC3b, which constitutes the alternative pathway to C5 convertase. The late steps of complement activation, after the cleavage of C5, are common to the three pathways and are described in Final Steps of Complement Activation.

Thus, the low level of C3b in the plasma acts as a sentinel for microbes. Once C3b is bound to the cell surface, subsequent molecular interactions result in a substantial amplification of the alternative pathway and cleavage of C5. The requirement for binding of C3b to a structural element serves to limit the effect of complement activation to the area where complement activation is needed. The alternative pathway of complement activation does not require finely specific recognition of antigen and so is considered a component of innate immunity. It follows that if specific recognition is not required, C3b can bind to human cells as well as microbes. However, activation on human cells is generally prevented by the intervention of regulatory proteins present on the surface of human cells, protecting these cells from inappropriate and harmful attack.[52]

CLASSICAL PATHWAY

(Fig. 37-3)

The initial step in the activation of the classical pathway is characteristically the binding of the portion of the C1 complex called *C1q* to IgG or IgM antibodies.[46] The C1q molecule consists of six identical arms attached to a central trunk. The globular ends of the arms attach to the complement-binding regions of the heavy chains of certain Ig classes. In order for C1q to be activated, it must bind simultaneously to at least two Ig heavy chains. This means, in effect, that the Ig must have bound antigen. In the case of IgG, binding of multiple epitopes by antibodies results in close proximity of the antibodies and thus the proper configuration for C1q activation. (As mentioned in Section "Immunoglobulin G," IgG4 is an exception, in that it does not bind C1q or activate complement.) Because IgM exists as a pentamer, theoretically IgM without bound antigen could activate complement. However, when IgM is not bound by antigen, the C1q binding site is not accessible. When antigen is bound, a conformational change results in exposure of the C1q binding site.

The complement component C1 is a complex of C1q, C1r, and C1s. Binding of two or more of the globular heads of C1q results in activation of C1r. Activated C1r is a protease that cleaves and activates C1s, and activated C1s, in turn, cleaves C4 into C4a and C4b.

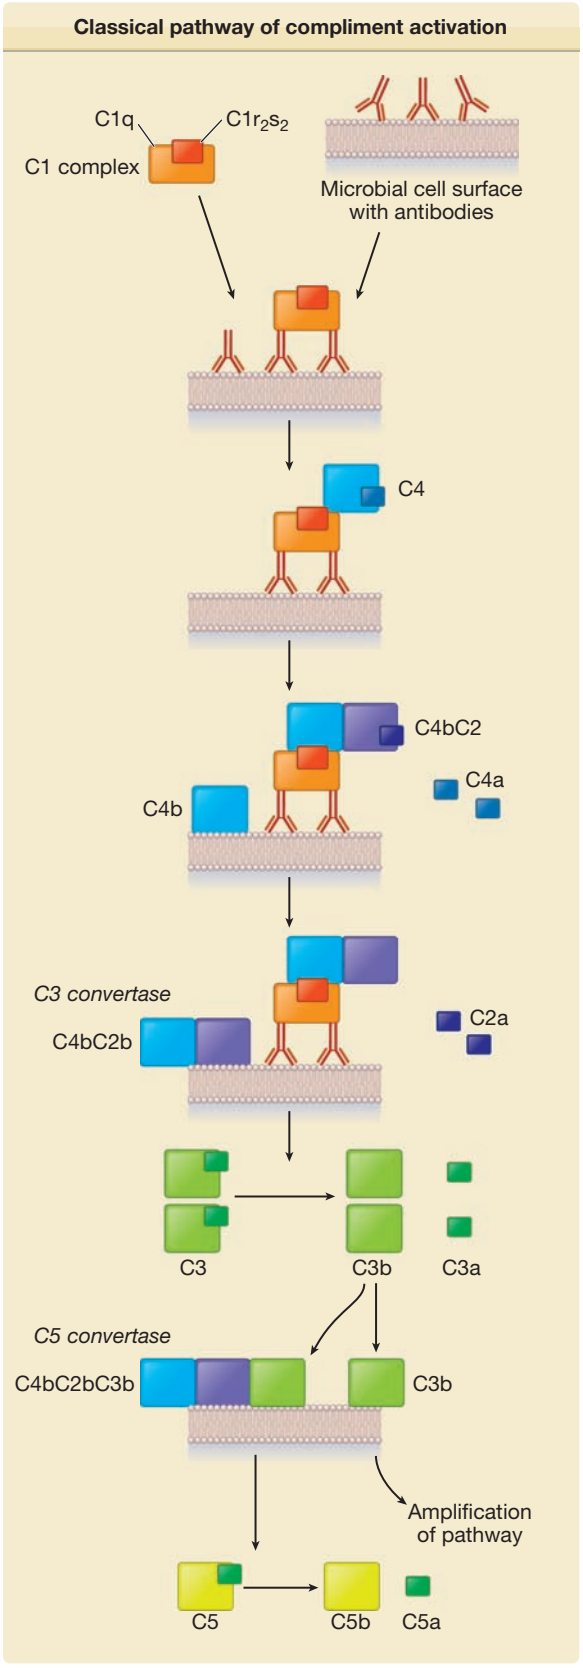

Figure 37-3 The classical pathway of complement activation. Shown are the steps from the initial binding of C1q to antibody–antigen complex through the cleavage of C5 into C5a and C5b. The final steps of complement activation are shown in Fig. 37-4. See Section "Classical Pathway" for details.

(The numbering of the complement proteins differs from their positions in the activation sequence, as components were discovered before the elucidation of their positions in the pathway.) C4b, like C3b, contains a thioester group that can form stable bonds with hydroxyl groups on a particular structure. Bound C4b is then bound by C2, which is cleaved into C2a and C2b. The C4bC2b complex is the classical pathway C3 convertase. (Note: Typically, suffix "a" denotes the smaller and "b" the larger complement fragment. Historically, the exception was C2, where C2a represented the larger and C2b the smaller fragment. Some recent textbooks now identify the smaller fragment as C2a and the larger as C2b, to maintain consistency with the nomenclature of the other complement proteins. However, many recent publications continue to adhere to the historic nomenclature.)

The cleavage of C3 results in C3a and C3b. The C3b fragment may then go on to activate complement by the alternative pathway, or act in concert with C4bC2b to form C4bC2bC3b, the classical pathway C5 convertase.

The major characteristics of the classical pathway are much the same as those of the alternative pathway. Activation of the pathway requires attachment of a complement protein to a structure such as a cell surface or immune complex, so that the effects of complement activation are spatially limited. Initial activation steps result in the formation of a C3 convertase that cleaves C3. Cleavage of C3 leads to the formation of a C5 convertase that cleaves C5 into C5a and C5b. A major difference is the initiation of the classical pathway by specific recognition of antigen by antibodies, in contrast to the less specific binding that occurs to initiate the alternative pathway.

LECTIN PATHWAY

The lectin pathway is very similar to the classical pathway, with the exception of the initiating steps. The first step is the binding of a plasma lectin, mannose-binding protein (MBP), to polysaccharides on microbial cell surfaces.[53] MBP, a member of the collectin (collagenous lectin) family, is structurally similar to C1q and can associate with C1r and C1s. MBP attachment to a microbe can begin the cascade through the activation of C1r and C1s. MBP also interacts with MBP-associated serine proteases (MASPs), which are analogous to C1r and C1s. Binding of MBP to microbial cell surfaces results in cleavage of MBP-associated serine protease and thence cleavage of C4.[54] In either event, the effect is the formation of C4b and its stable binding to a cell surface. As is the case for the alternative pathway, the lectin pathway is a component of innate immunity.

FINAL STEPS OF COMPLEMENT ACTIVATION

(Fig. 37-4)

The alternative, classical, and lectin pathways converge at the cleavage of C5. The C5b fragment remains

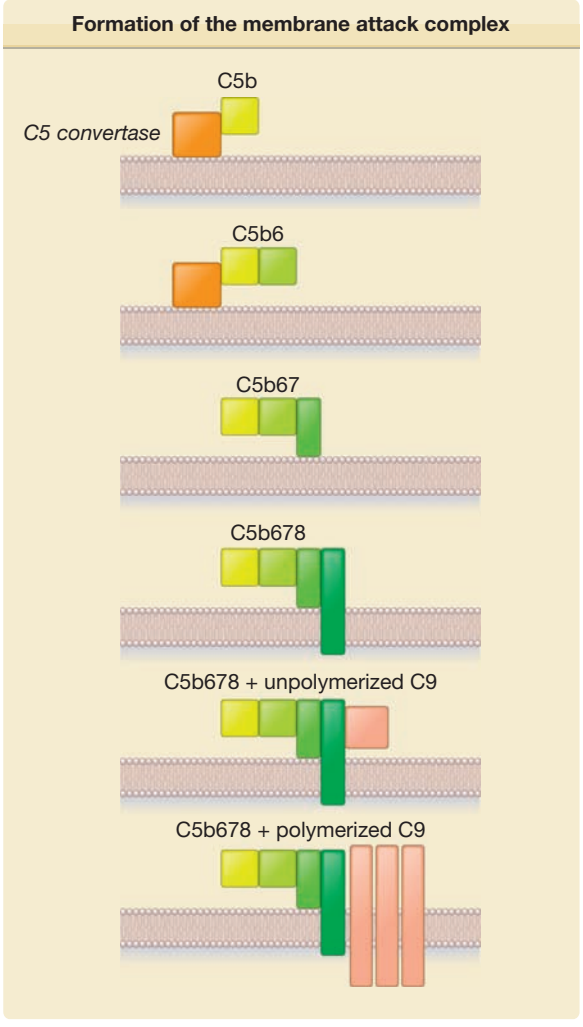

Figure 37-4 Formation of the membrane attack complex. The alternative, classical, and lectin pathways converge at the formation of C5b and its sequential attachment to C6, C7, C8, and C9. The polymerization of C9 results in tubular structures on the cell membrane.

surface bound. The next steps do not involve enzymatic cleavage, but rather the sequential binding of C6, C7, and C8 to C5b. The C5b-8 complex stably bound to a cell membrane becomes an active membrane attack complex (MAC) through the addition of C9. C9 polymerizes around the complex and forms pores in cell membranes. These pores may result in cell death through osmotic rupture, particularly in nonnucleated erythrocytes.

Nucleated cells are more resistant to lysis, but may still exhibit effects attributable to MAC binding.[55] It is quite possible that the nonlytic changes induced by MAC are of more functional and pathologic significance overall than is MAC-induced cell lysis.[56] These nonlytic effects may differ depending on cell type and milieu, and similar effects may lead to different outcomes. For example, MAC insertion into phagocyte cell membranes can lead to the production of inflammatory mediators such as reactive oxygen species and prostaglandins, resulting in phagocyte activation.[57] Glomerular epithelial cells may also exhibit inflammatory mediator production, but, in that setting, the inflammatory mediators may lead to tissue injury.[58] MAC has also been reported to cause proliferation of certain cells, and MAC has been reported to have both apoptotic and antiapoptotic properties.[55]

ADDITIONAL INITIATORS OF COMPLEMENT ACTIVATION

In addition to the characteristic initiators of the three pathways, certain additional structures can trigger complement activation.[59] These include, among others, the following: in the alternative pathway, IgA immune complexes and endotoxin; in the classical pathway, *C*-reactive protein, apoptotic bodies, and serum amyloid P; and in the lectin pathway, serum ficolins (lectins which bind *N*-acetylglucosamine).[53,60]

FUNCTIONS OF COMPLEMENT PROTEINS

As mentioned earlier, the earliest function of the complement system to be discovered was the lysis of bacteria. Killing of microbes through direct lysis is mediated by the MAC, C5b-9. Microbes may also be destroyed through coating, or opsonization, by complement and phagocytosis of the opsonized particles by phagocytic cells. The processes of opsonization and phagocytosis are also mechanisms for another important function of complement—the clearance of immune complexes and apoptotic debris from the circulation.

An ancillary function of complement activation is the induction of inflammation. Inflammation, characterized by vascular changes and ingress and activation of leukocytes and inflammatory proteins, serves to augment the localized immune response in tissue. Three mediators of inflammation initiated by complement activation are the complement fragments C3a, C4a, and C5a. These are called *anaphylatoxins* because of their ability to induce degranulation of mast cells.[61] The most potent of these ANAs is C5a. Receptors for C5a are expressed on endothelial cells, mast cells, eosinophils, basophils, monocytes, neutrophils, smooth muscle cells, and epithelial cells. Binding of C5a to endothelial cells results in increased vascular permeability and expression of P-selectin, both of which promote leukocyte accumulation in tissue. Binding to neutrophils results in increased neutrophil motility, adhesion to endothelial cells, and production of reactive oxygen species. The overall result is the accumulation of inflammatory cells at local sites in tissue where they can phagocytose and efficiently kill microbes.

The activation of complement also results in stimulation of the humoral immune system through the generation of C3d. B cells whose cell surface antibodies recognize complement-bound antigen are upregulated by the concurrent binding of C3d to CR2 on the B-cell surface. Opsonization by complement also facilitates antigen presentation to B cells by follicular dendritic cells.

COMPLEMENT RECEPTORS

COMPLEMENT RECEPTORS AND REGULATORY PROTEINS AT A GLANCE

- Some of the important effects of complement are mediated through binding of complement proteins to complement receptors. CR1 functions in phagocytosis, immune complex clearance, and downregulation. CR2 is important in stimulation of humoral immunity. CR3 and -4 promote phagocytosis.
- Regulation of complement activation is provided by certain serum and cell surface proteins. Many of the regulatory cell surface proteins are expressed on human cells but not microbes, thus protecting human cells from complement damage.
- Some of the regulatory proteins downregulate complement activation by displacing components of the early steps of the cascade. These include C1 inhibitor, factor H, C4 binding inhibitor, decay accelerating factor, membrane cofactor protein, and CR1.

There are several proteins that interact with complement and serve to mediate or regulate its functions. The C5a receptor, which is a member of the seven-transmembrane α-helical G-protein-coupled receptor family, was mentioned in the previous section. Some of the best described of the complement receptors are CR1–CR4.

The type 1 complement receptor, CR1 (CD35), is a member of a family of proteins called *regulators of complement activation* (RCA), which share a common structure consisting of multiple short consensus repeats, also known as *complement control protein repeats*.[52] CR1 binds C3b or C4b and is expressed on peripheral blood cells, including monocytes, B and T lymphocytes, neutrophils, eosinophils, and erythrocytes; on follicular dendritic cells; and on keratinocytes.[62] On phagocytic cells, binding of CR1 to C3b or C4b results in phagocytosis of particles opsonized by complement fragments, as well as activation of microbicidal mechanisms in the phagocytic cells. On erythrocytes, binding of CR1 to C3b- or C4b-coated immune complexes results in transport of the complexes to the spleen and liver, where they are cleared from the circulation by phagocytes. Thus, CR1 serves as an important mediator of complement function. It can also serve as a downregulator of complement activation, as it is involved in the dissociation of C3 convertase complexes.

The type 2 complement receptor, CR2 (CD21), is also a member of the RCA family.[59] CR2 binds C3 fragments iC3b ("i" stands for inactive), C3dg, and C3d, as well as Epstein–Barr virus, interferon-α, and the immunoregulatory protein CD23. CR2 is expressed on subsets of B and T lymphocytes, basophils, mast cells, follicular dendritic cells, and some epithelial cells, including keratinocytes. On B cells, CR2 serves as a coreceptor for B-cell activation. When CR2 is bound by C3d, the level of B-cell activation is increased by orders of magnitude.[63] On dendritic cells, CR2 engagement results in a trapping of immune complexes in germinal centers. CR2 also appears to play a role in antigen presentation to T cells.

The type 3 complement receptor, CR3 (CD11b/CD18, Mac-1), is an integrin cell surface molecule expressed on monocytes, neutrophils, NK cells, and mast cells.[64] It functions to promote phagocytosis of microbes through binding to iC3b and through direct binding to microbes. It interacts with intercellular adhesion molecule 1 expressed endogenously on endothelial cells to stabilize the adhesion of leukocytes to endothelium, facilitating the recruitment of leukocytes from the circulation into tissue.

The type 4 complement receptor, CR4 (CD11c/CD18), is also an integrin cell surface molecule. It is expressed on monocytes, neutrophils, NK cells, and dendritic cells, and probably functions similarly to CR3.

Among the recently described complement receptors are SIGN-R1,[65] which binds C1q and is expressed on splenic marginal zone macrophages, and CRIg (complement receptor of the immunoglobulin family),[66] which binds C3b and iC3b and is expressed on a subset of tissue-resident macrophages.

REGULATION OF COMPLEMENT ACTIVATION

Molecules involved in the regulation of complement activation serve to downregulate the immune response once an immune response is no longer needed and to limit the immune response to the sites required, specifically protecting self from complement attack.

The C1 inhibitor (C1 INH) is a protease inhibitor that inhibits certain plasma serine proteases, including C1, kallikrein, and factor XII.[46] C1 exists as a complex of C1q and a tetramer of two C1r and two C1s fragments. When C1q binds antibody, C1 INH can act to limit complement activation by binding to the C1rC1s tetramer, dissociating it from C1q and preventing downstream activation of the pathway.

Another major point of interaction of regulatory proteins is with bound C3b or C4b.[52] As mentioned earlier, the thioester group of unbound C3b or C4b is rapidly hydrolyzed, rendering these molecules inactive. For surface-bound C3b or C4b, inactivation occurs through the displacement of components of the alternative or classical pathway C3 convertase from C3b or C4b or through proteolysis of C3b or C4b. In the alternative pathway, inactivation of the C3 convertase complex, C3bBb, can take place through the displacement of Bb from C3b by the plasma protein factor H or the cell surface proteins decay accelerating factor (DAF, CD55), membrane cofactor protein (MCP, CD46), and CR1. These three cell surface proteins, all members of the RCA family, are expressed on human cells but not

microbes, thereby allowing complement activation to proceed on microbes while protecting human cells from injury. Factor H preferentially binds cell surfaces with high levels of sialic acid, and the relative abundance of sialic acid on human cells but not microbes further focuses the downregulation of complement activation on human cells. In the classical and lectin pathways, the C3 convertase is C4bC2b. DAF, MCP, and CR1 can displace C2b from C4b, as can the plasma protein C4-binding protein (C4BP). Thus, the cell surface proteins DAF, MCP, and CR1 can dissociate the C3 convertases of both the alternative and the classical/lectin pathways, whereas the plasma proteins factor H and C4BP are specific for alternative or classical/lectin, respectively. Proteolysis of C3b or C4b is mediated by factor I, a plasma protein that requires cofactors for its activity. MCP, CR1, factor H, and C4BP can all serve as cofactors for factor I.

Regulation of complement at the late steps is mediated in part by CD59, a cell surface protein expressed on human cells but not microbes. It binds the C5b-8 complex and inhibits addition of C9, blocking formation of the MAC. Plasma S protein binds the C5b-7 complex and blocks its insertion into the cell membrane and also inhibits C9 polymerization.[67] Intact MACs may be removed from cells through shedding on membrane vesicles or by internalization and degradation.[55]

Carboxypeptidase N can remove the terminal arginine of C3a, C4a, and C5a and has been referred to as *ANA inactivator*.[68] Carboxypeptidase R has also been shown to remove the terminal arginine of C3a and C5a.[69]

COMPLEMENT AND DISEASE

GENETIC ABNORMALITIES OF THE COMPLEMENT SYSTEM

Deficiencies of complement cascade proteins, complement receptors, or complement regulatory proteins can lead to a variety of diseases.[70] Genetic deficiencies of complement have been associated primarily with increased risk for infection or autoimmunity. As examples, deficiencies of many complement components, particularly the early complement components C1–C4, have been associated with early-onset systemic lupus erythematosus (SLE), C3 deficiency has been associated with life-threatening pyogenic infections, and C5–C9 deficiencies have been associated with Neisserial infections (reviewed in Chapter 143). Genetic deficiency of mannose-binding lectin is relatively common, with significantly low levels occurring in about 10% of Caucasians, and is associated with increased risk for infection and autoimmunity, including SLE.[71,72]

Altered expression of CR3 (CD11b/CD18) and CR4 (CD11c/CD18) occurs in leukocyte adhesion deficiency-1, a congenital disorder resulting from mutations in the gene encoding CD18. Mutation in CD18 also affects expression of CD11a/CD18 (leukocyte function-associated antigen-1). Patients with leukocyte adhesion deficiency-1 exhibit significant abnormalities of leukocyte adhesion and have recurrent infections (see Chapter 143).

COMPLEMENT AND DISEASE AT A GLANCE

- Genetic deficiencies of complement components have been associated primarily with susceptibility to infection or autoimmunity. Genetic deficiencies of regulatory complement proteins may result in inappropriately prolonged complement activation, such as occurs with C1 inhibitor deficiency.
- Complement is associated with systemic lupus erythematosus through several possible mechanisms. These include increased risk of autoimmunity conferred by certain complement deficiencies, tissue damage resulting from autoantibody-induced complement activation, ineffective clearance of autoimmunity-promoting apoptotic debris, and failure to eliminate self-reactive B cells.
- Complement activation has been implicated in the pathogenesis of atherosclerosis, reperfusion injury after myocardial ischemia, diabetic microvascular disease, and cerebral infarct in ischemic stroke.
- Certain infectious agents have evolved mechanisms for evasion of destruction by complement, and some use complement receptors or regulatory proteins to gain entry into the cell.

Deficiency of the complement regulatory protein C1 INH causes angioneurotic edema as a result both of poorly regulated classical pathway activation and of excess bradykinin due to the actions of kallikrein and factor XII. Angioedema may also occur if one has markedly reduced levels of the ANA inactivator, carboxypeptidase N[73] (see Chapter 38).

Deficiency of a protein required for the proper expression of DAF and CD59 on the cell surface is associated with paroxysmal nocturnal hemoglobinuria, a disease characterized by complement-mediated erythrocyte lysis.[74] Hemolytic-uremic syndrome has been associated with mutations in MCP, factor H, and factor I.[75] Factor H deficiency has also been associated with membranoproliferative glomerulonephritis.

The risk for developing age-related macular degeneration is affected significantly by the presence of certain polymorphisms in genes of the complement system, particularly complement factor H but also factor B and C2.[76]

COMPLEMENT, SYSTEMIC LUPUS ERYTHEMATOSUS, AND AUTOANTIBODIES

Complement has been closely associated with SLE (see also Chapter 155), albeit in seemingly paradoxical

ways.[77,78] Genetic deficiencies of complement components are associated with SLE, but some of the tissue injury seen in SLE appears to be mediated in part by complement activation. Thus, complement seems to be simultaneously protective and deleterious. These observations underscore the protean roles of complement in the immune system. Complement activation has the potential for causing tissue injury, but complement components may be important in clearance of immune complexes and apoptotic debris. Apoptotic bodies that are not cleared effectively may be able to trigger autoimmunity through presentation of normally sequestered autoantigens to the immune system. It has also been suggested that complement participates in eliminating self-reactive immature B cells, a further mechanism for a protective effect of complement in SLE.[78]

Altered expression of both CR1 and CR2 has been observed in patients with SLE.[79] In murine models of lupus, knockout mice lacking expression of CR1 and CR2 (located on the same gene in mice and produced through alternative splicing) have accelerated autoimmunity if the mice otherwise have the optimal genetic background. These findings indicate that the interaction of CR2 and C3d, important in B-cell response to antigen, is another factor that determines susceptibility to SLE.

Autoantibodies to complement components can result in or exacerbate disease.[80] Autoantibodies to C1q are relatively common in SLE and have been associated with more severe renal disease, possibly through an adverse affect on the clearance of immune complexes or apoptotic bodies.[81] C3 nephritic factor is an autoantibody to the C3 convertase, C3bBb, which acts to stabilize the complex. Its clinical significance is its association with membranoproliferative glomerulonephritis type II and partial lipodystrophy.

COMPLEMENT AND VASCULAR DISEASE

Complement activation has been implicated in the pathogenesis of atherosclerosis, reperfusion injury after myocardial ischemia, and cerebral infarct in ischemic stroke.[82,83] In the microvascular proliferative disease associated with diabetes, glycation, and thereby inactivation of CD59, may result in cellular proliferation due to nonlytic proliferative effects of MAC.[84] Complement activation has also been implicated in hyperacute rejection of xenotransplants due to the presence of natural antibodies to components of the endothelial cells of the transplanted organ, with resultant complement activation, endothelial cell injury, and intravascular coagulation.

EVASION OR SUBVERSION OF COMPLEMENT BY MICROBES

The observation that individuals with deficiencies of components of the late stages of complement activation are at increased risk for only a limited set of infections illustrates that infectious agents have evolved means of evading destruction by complement.[85] Gram-positive bacteria have thick cell walls that are difficult to penetrate by MAC.[46] Group A streptococcus M protein binds factor H, which downregulates complement activation, and many pathogens have evolved mechanisms to attract factor H through the expression of sialic acids on their surfaces. *Staphylococcus aureus* expresses several proteins that inhibit C3 activation. A protein of vaccinia virus (VCP-1, vaccinia virus complement control protein-1) acts as a cofactor for factor I, leading to proteolysis of C3b and C4b. In human immunodeficiency virus (HIV) infection, the inclusion of downregulatory molecules of the complement system into the viral or host cell membrane allows HIV to evade complement-mediated destruction.[86] DAF and CD59 can be subsumed into the HIV virus membrane upon budding from infected human cells, and factor H can bind to HIV surface glycoproteins on infected human cells.

The complement system has been subverted by certain infectious agents for entry into the cell. Epstein–Barr virus penetrates B cells via binding to CR2 on the B-cell surface.[46] Measles virus binds to cells via MCP. *Mycobacteria* make C4-like molecules that bind C2b and then cleave C3. The deposition of C3b on the mycobacterial cell membrane leads to its uptake into macrophages, where it exists as an intracellular parasite. Knowledge of these evasive and subversive strategies of pathogens may be useful in designing vaccines and targeted therapies.[85]

Chapter 38 :: Urticaria and Angioedema

:: Allen P. Kaplan

URTICARIA AND ANGIOEDEMA AT A GLANCE

- Occurs acutely at some time in 20% of the population; incidence of chronic urticaria/angioedema is approximately 0.5%.
- Acute urticaria/angioedema is caused by drugs, foods, occasionally infection in association with immunoglobulin E-dependent mechanisms (allergy), or metabolic factors.
- Chronic urticaria/angioedema is an autoimmune disorder in 45% of patients.
- In the absence of urticaria, angioedema can be due to overproduction or impaired breakdown of bradykinin.
- Treatment of acute urticaria/angioedema relies on antihistamines and short courses of corticosteroids, and identification and elimination of endogenous and exogenous causes.
- Treatment of C1 inhibitor deficiency includes androgenic agents, antifibrinolytic agents, and C1 inhibitor (C1 INH) concentrates, a kallikrein inhibitor, and bradykinin receptor antagonist.
- Treatment of physical urticaria/angioedema includes high-dose antihistamine prophylaxis, except for delayed pressure urticaria.
- Treatment of chronic idiopathic or autoimmune urticaria/angioedema includes antihistamines (nonsedating preparations primarily), low-dose daily or alternate day corticosteroids, or cyclosporine.

Urticaria is defined as a skin lesion consisting of a wheal-and-flare reaction in which localized intracutaneous edema (wheal) is surrounded by an area of redness (erythema) that is typically pruritic. Individual hives can last as briefly as 30 minutes to as long as 36 hours. They can be as small as a millimeter or 6–8 inches in diameter (giant urticaria). They blanch with pressure as the dilated blood vessels are compressed, which also accounts for the central pallor of the wheal. The dilated blood vessels and increased permeability that characterize urticaria are present in the superficial dermis and involves the venular plexus in that location. Angioedema can be caused by the same pathogenic mechanisms as urticaria but the pathology is in the deep dermis and subcutaneous tissue and swelling is the major manifestation. The overlying skin may be erythematous or normal. There is less pruritus (fewer type C nerve endings at the deeper cutaneous levels) but there may be pain or burning.

EPIDEMIOLOGY

Urticaria and angioedema are common. Age, race, sex, occupation, geographic location, and season of the year may be implicated in urticaria and angioedema only insofar as they may contribute to exposure to an eliciting agent. Of a group of college students, 15%–20% reported having experienced urticaria, while 1%–3% of the patients referred to hospital dermatology clinics in the United Kingdom noted urticaria and angioedema. In the National Ambulatory Medical Care Survey data from 1990 to 1997 in the United States, women accounted for 69% of patient visits. There was a bimodal age distribution in patients aged birth to 9 years and 30–40 years.[1]

Urticaria/angioedema is considered to be acute if it lasts less than 6 weeks. Most acute episodes are due to adverse reactions to medications or foods and in children, to viral illnesses. Episodes of urticaria/angioedema persisting beyond 6 weeks are considered chronic and are divided into two major subgroups: (1) chronic autoimmune urticaria (45%) and (2) chronic idiopathic urticaria (55%) with a combined incidence in the general population of 0.5%.[2] Physically induced urticaria/angioedema is not included in the definition. Various types of physical urticaria/angioedema may last for years, but the individual lesions last fewer than 2 hours (except delayed pressure urticaria) and are intermittent. Whereas 85% of children experience urticaria in the absence of angioedema, 40% of adult patients with urticaria also experience angioedema.

Approximately 50% of patients with chronic urticaria (with or without angioedema) are free of lesions within 1 year, 65% within 3 years, and 85% within 5 years; fewer than 5% have lesions that last for more than 10 years. Angioedema alters the natural history, and only 25% of patients experience resolution of lesions within 1 year. There are no data regarding the remission rate in patients with only angioedema. The hereditary group is considered to be life long once the diagnosis becomes clinically manifest.

PATHOGENESIS

MAST CELL AND HISTAMINE RELEASE

The mast cell is the major effector cell in most forms of urticaria and angioedema, although other cell types undoubtedly contribute. Cutaneous mast cells adhere

to fibronectin and laminin through the very late activation (VLA) β_1 integrins VLA-3, VLA-4, and VLA-5 and to vitronectin through the $\alpha_v\beta_3$ integrin. Cutaneous mast cells, but not those from other sites, release histamine in response to compound 48/80, C5a, morphine, and codeine. The neuropeptides substance P (SP), vasoactive intestinal peptide (VIP), and somatostatin, (but not neurotensin, neurokinins A and B, bradykinin, or calcitonin gene-related peptide), activate mast cells for histamine secretion. Dermal microdialysis studies of the application of SP on skin indicate that it induces histamine release only at 10^{-6} M, which suggests that after physiologic nociceptor activation, SP does not contribute significantly to histamine release.[3] Yet it is a major contributor to the flare reaction induced by histamine stimulation of afferent type C fibers (mediating pruritus) with release of SP from adjacent nerve endings by antidromic conduction. Histamine is found associated with the wheal.[4] Recently, the spinal cord afferent fibers mediating pruritis have, for the first time, been distinguished from pain fibers in the lateral spinothalamic tracts.[5]

Not all potential biologic products are produced when cutaneous mast cells are stimulated. For example, SP releases histamine from cutaneous mast cells above 10^{-6} M but does not generate prostaglandin D_2 (PGD_2). Vascular permeability in skin is produced predominantly by H_1 histamine receptors (85%); H_2 histamine receptors account for the remaining 15%.

The current hypothesis regarding cellular infiltration that follows mast cell degranulation suggests that the release of mast cell products (histamine, leucotrienes, cytokines, chemokines) leads to alterations in vasopermeability, upregulation of adhesion molecules on endothelial cells, and rolling and attachment of blood leukocytes, followed by chemotaxis and transendothelial cell migration.

Various forms of physical urticaria/angioedema have provided experimental models for the study of urticaria/angioedema by allowing the observation of the elicited clinical response, examination of lesional and normal skin biopsy specimens, assay of chemical mediators released into the blood or tissues, and characterization of peripheral leukocyte responses.[6,7] The intracutaneous injection of specific antigen in sensitized individuals has provided an experimental model for analysis of the role of immunoglobulin (Ig) E and its interaction with the mast cell. In many subjects, the challenged cutaneous sites demonstrate a biphasic response, with a transient, pruritic, erythematous wheal-and-flare reaction followed by a tender, deep, erythematous, poorly demarcated area of swelling that persists for up to 24 hours. This is the late-phase response with recruitment of variable numbers of neutrophils, prominent eosinophils, monocytes, small numbers of basophils, and CD_4^+ T-lymphocytes of the TH_2 subclass.[8] Chemokines (chemotactic cytokines) strongly associated with Th2 lymphocyte predominance include those reactive with chemokine receptors CCR3, CCR4, and CCR8 on T lymphocytes. Characteristic cytokines produced by Th2 lymphocytes include interleukins (ILs) 4, 5, 9, 13, 25, 31 and 33. The cellular infiltrate seen in biopsy specimens of delayed pressure urticaria is a variant of a late-phase reaction while mast cell degranulation in most other physical urticarias has no associated late phase. These include typical acquired cold urticaria, cholinergic urticaria, dermatographism, and type I solar urticaria.

AUTOIMMUNITY AND CHRONIC URTICARIA

The first suggestion that patients with chronic urticaria and angioedema might have an autoimmune diathesis was the observation that there is an increased incidence of antithyroid antibodies in such patients relative to the incidence in the population at large.[9] These include antimicrosomal (perioxidase) and antithyroglobulin antibodies, as seen in patients with Hashimoto's thyroiditis.[10] Patients may have clinical hypothyroidism, but a small number might be hyperthyroid if inflammation is at an early stage when thyroid hormone is released into the circulation. This atypical presentation should be distinguished from the occasional patient with Grave's disease. Nevertheless, most patients are euthyroid. The incidence of antithyroid antibodies in chronic urticaria, as reported in the literature, varies between 15% and 24%,[11,12] but the most recent data are closer to the latter figure[12] and demonstrate segregation of antithyroid antibodies with chronic autoimmune urticaria rather than chronic idiopathic urticaria. However, the association is not absolute. The incidence in the autoimmune subgroup was 27%, in the chronic idiopathic urticaria subgroup 11%, while in the population at large it is 7%–8%. Gruber et al (1988)[13] considered the possibility that patients might have circulating and anti-IgE antibodies that are functional and did indeed find these in about 5%–10% of patients. Gratten et al[14,15] sought antibodies reactive with skin mast cells by performing an autologous skin test and found a 30% incidence of positive reactions in patients with chronic urticaria. There were only rare positive reactions in healthy control subjects or patients with other forms of urticaria. Subsequently, this level of positivity was shown by Hide et al[16] to be due to an IgG antibody reactive with the α subunit of the IgE receptor; in addition a 5%–10% incidence of functional anti-IgE antibodies was confirmed (eFig. 38-1.1 in online edition).[17]

CELLULAR INFILTRATE

Mast cell degranulation certainly initiates the inflammatory process in autoimmune chronic urticaria and is assumed to also do so in idiopathic chronic urticaria. Evidence for an increased number of mast cells in chronic urticaria has been presented,[36,37] but there are also publications indicating no significant differences from normal;[38] these studies did not discriminate the autoimmune from the idiopathic groups. However, no alternative mechanisms for mast cell degranulation in the idiopathic groups have been suggested to date. Yet the histology of the two groups differs only in minor ways. Common to all biopsy specimens is a perivascular

infiltrate that surrounds small venules within the superficial and deep venular plexus, with a prominence of $CD4^+$ T lymphocytes and monocytes and virtually no B cells.[36,39] Granulocytes are quite variable but are plentiful if the lesion undergoes biopsy early in its development. Neutrophils and eosinophils are both present,[40,41] although the degree of eosinophils accumulation varies greatly.[39] Even when eosinophils are not evident, major basic protein can be identified within lesions (in at least two-thirds of patients), which most likely represents evidence of prior eosinophil degranulation.[42] The presence of basophils has also been recently demonstrated by using an antibody (BB1) that is specific for this cell type.[41] Thus, the infiltrate resembles that of an allergic late-phase reaction, as suggested previously,[43] although the percentage of each cell types differs, with neutrophils and monocytes being relatively more prominent in urticaria. Endothelial cell activation is suggested by the presence of intercellular adhesion molecule 1 and E-selectin in biopsy specimens of urticarial lesions.[44] Sources of chemokines include the mast cell and the activated endothelial cell; the latter cells are stimulated not only by cytokines or monokines, such as IL-4, IL-1, and tumor necrosis factor-α (TNF-α), but also by the vasoactive factors, for example, histamine and leukotrienes released from activated mast cells.[45] Complement activation and the release of C5a results not only in augmented mast cell (and basophil) histamine release, but C5a is also chemotactic for neutrophils, eosinophils, and monocytes. The presence of C5a is one of the factors that would distinguish this lesion from a typical allergen-induced cutaneous late-phase reaction. The particular chemokines released in chronic urticaria have not been studied. The presence of increased plasma IL-4 levels[25] in patients with chronic urticaria provides indirect evidence of lymphocyte activation, basophil activation, or both, and isolated $CD4^+$ lymphocytes of patients were shown to secrete greater amounts of both IL-4 and IFN-γ compared with that seen in healthy control subjects on stimulation with phorbol myristate acetate.

A direct comparison between cutaneous late-phase reactions and the histology of chronic urticaria revealed that infiltrating cells had characteristics of both T_H1 and T_H2 cells, with production of IFN-γ by the former cells and IL-4 and IL-5 by the latter.[46] Alternatively, this might represent activated T_H0 cells (i.e., activated $CD4^+$ lymphocytes that are not differentiated to T_H1 or T_H2 cells). When the histology of autoimmune and idiopathic chronic urticarias was compared,[41] the autoimmune subgroup had greater prominence of granulocytes within the infiltrate, whereas other infiltrating cells were quite similar, with a small increment in cytokine levels in the autoimmune group and greater tryptase positivity (? less degranulation) in the autoantibody-negative group. The patients with autoimmune chronic urticaria generally had more severe symptoms than those with idiopathic chronic urticaria.[47]

BASOPHIL RELEASIBILITY

(Figs. 38-1 and 38-2)

The basophils of patients with chronic urticaria have been shown to be hyporesponsive to anti-IgE, an observation made by Kern and Lichtenstein[48] long before there were any clues to the pathogenesis of this disorder. These findings were confirmed[49] and

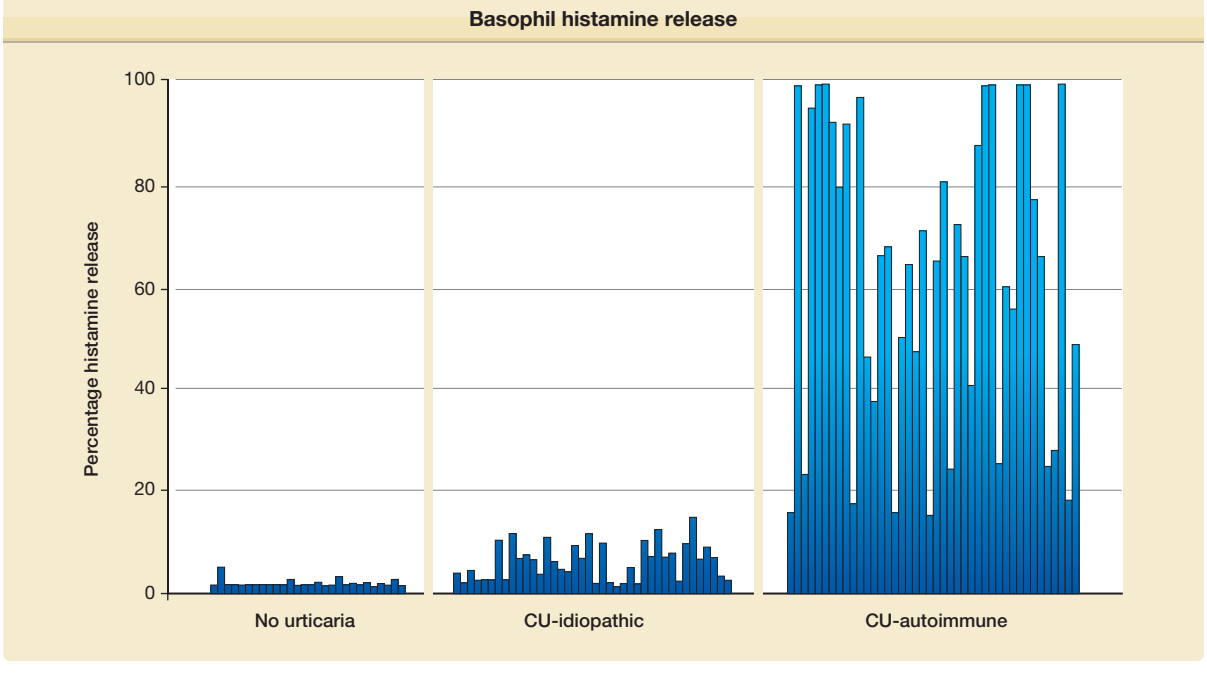

Figure 38-1 Basophil histamine release comparing normal sera (N = 35) with sera from patients with chronic urticaria (N = 104). Those designated as having chronic autoimmune urticaria are shown on the right.

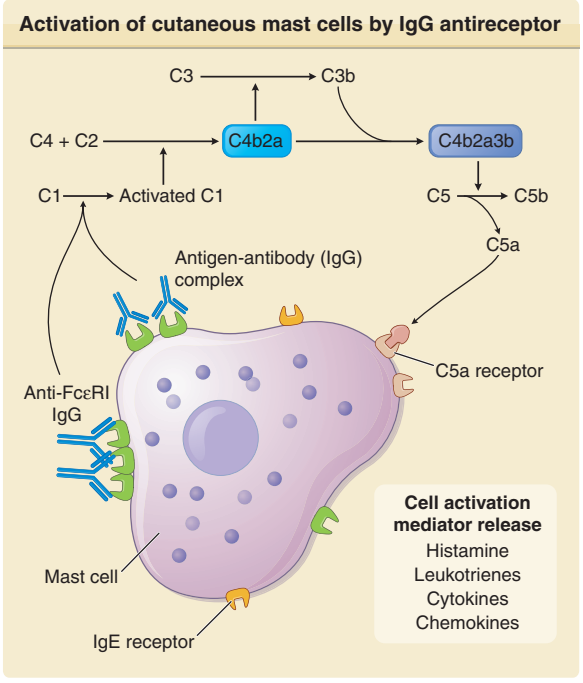

Figure 38-2 Schematic diagram of the activation of cutaneous mast cells by IgG antireceptor antibody, followed by activation of complement, release of C5a, and augmentation of mast cell release.

appeared to be associated with basopenia[50] and to segregate with the autoimmune subgroup. One obvious interpretation is that there is in vivo desensitization of basophils in the presence of circulating anti-IgE receptor. Vonakis et al have demonstrated that patients' basophil hyporesponsiveness to anti-IgE is due to augmented levels of SHIP phosphatase[51] that limits phosphorylation reactions critical for histamine secretion. Although manifest in about half the patients with chronic urticaria (and not segregated with either the autoimmune or idiopathic subgroups), the abnormality appears to reverse when patients remit. Thus, it may be a marker of disease activity. We have found a paradoxical result when the isolated basophils of patients with chronic urticaria were activated and compared with the basophils of healthy control subjects. Although the basophils of the patients with urticaria were clearly less responsive to anti-IgE, they demonstrated augmented histamine release when incubated with serum and it did not matter whether the sera were taken from normal subjects, other patients with chronic urticaria, or was their own.[52]

ROLE OF THE EXTRINSIC COAGULATION CASCADE

Studies of the plasma of patient with chronic urticaria demonstrate the presence of D-dimer and prothrombin 1 and 2 fragments indicating activation of prothrombin to thrombin as well as digestion of fibrinogen by thrombin.[53] The reaction is not specific for chronic urticaria as similar observations have been noted in multiple nonsteroidal hypersensitivity syndrome.[54] Nevertheless, the data are of considerable interest and activation of the coagulation cascade is dependent on tissue factor rather than factor XII, i.e., the extrinsic coagulation cascade. Although activated endothelial cells are a well-known source of the tissue factor, histologic studies suggest that eosinophils are a prominent source.[55] The relationship of these observations to histamine release by basophils or mast cells is not clear. Whereas thrombin activation of mast cells has been reported, the amounts required are large and the observations thus far are confined to rodent mast cells. One publication relating to eosinophil to histamine release found IgG antibody to Fc_eRII in the serum of patients with chronic urticaria which activates eosinophils to release cationic proteins.[56] They propose basophil activation by these eosinophil cationic proteins but do not demonstrate it; however, they offer an additional mechanism for basophil and possibly mast cell histamine release.

BRADYKININ: ROLE IN ANGIOEDEMA

Kinins are low-molecular-weight peptides that participate in inflammatory processes by virtue of their ability to activate endothelial cells and, as a consequence, lead to vasodilatation, increased vascular permeability, production of nitric oxide, and mobilization of arachidonic acid. Kinins also stimulate sensory nerve endings to cause a burning dysesthesia. Thus, the classical parameters of inflammation (i.e., redness, heat, swelling, and pain) can all result from kinin formation. Bradykinin is the best characterized of this group of vasoactive substances.

There are two general pathways by which bradykinin is generated. The simpler of the two has only two components: (1) an enzyme tissue kallikrein[57] and (2) a plasma substrate, low-molecular-weight kininogen.[58,59] Tissue kallikrein is secreted by many cells throughout the body; however, certain tissues produce particularly large quantities. These include glandular tissues (salivary and sweat glands and pancreatic exocrine gland) and the lung, kidney, intestine, and brain.

The second pathway for bradykinin formation is far more complex and is part of the initiating mechanism by which the intrinsic coagulation pathway is activated (eFig. 38-1.2 in online edition).[60] Factor XII is the initiating protein that binds to certain negatively charged macromolecular surfaces and autoactivates (autodigests) to form factor XIIa.[61,62] This is synonymous with Hageman factor as designated in the figure. There are two plasma substrates of factor XIIa, namely (1) prekallikrein[63] and (2) factor XI,[64,65] and each of these circulates as a complex with high-molecular-weight kininogen (HK).[66,67] These complexes also attach to initiating surfaces, and the major attachment sites are on two of the domains of HK, which thereby places both prekallikrein and factor XI in optimal conformation for cleavage to kallikrein (plasma kallikrein) and factor XIa, respectively. It is important to note that plasma kallikrein and tissue kallikrein are

separate gene products and have little amino acid sequence homology, although they have related functions (i.e., cleavage of kininogens). Tissue kallikrein prefers low-molecular-weight kininogen but is capable of cleaving HK, whereas plasma kallikrein cleaves HK exclusively. The two kininogens have an identical amino acid sequence starting at the *N*-terminus and continuing to 12 amino acids beyond the bradykinin moiety[59] but differ in *C*-terminal domains because of alternative splicing at the transcription level.[68,69] Both factor XII and HK bind to endothelial cells (which may function as the "natural" surface in the presence of physiologic zinc ion), thus activation may occur at the cell surface.[70,71]

A scheme for both production and degradation of kinins is shown in eFig. 38-1.2 in online edition. The enzymes that destroy bradykinin consist of kininases I and II. Kininase I is also known as plasma carboxypeptidase N,[72] which removes the *C*-terminal arg from bradykinin or kallidin to yield des-arg[73] bradykinin or des-arg[74] kallidin, respectively.[75] It is the same enzyme that cleaves the *C*-terminal arg from the complement anaphylatoxins C3a and C5a. Kininase II is identical to angiotensin-converting enzyme (ACE).[76] Kininase II is a dipeptidase that cleaves the *C*-terminal phe-arg from bradykinin to yield a heptapeptide, which is cleaved once again to remove ser-pro and to leave the pentapeptide arg-pro-pro-gly-phe.[75] If the *C*-terminal arg of bradykinin is first removed with kininase I, then ACE functions as a tripeptidase to remove ser-pro-phe and to leave the above pentapeptide.[77] Bradykinin and kallidin stimulate constitutively produced B2 receptors,[78] whereas des-arg[73]-BK or des-arg[74] lys-BK both stimulate B1 receptors,[79] which are induced as a result of inflammation. Stimuli for B1 receptor transcription include IL-1 and TNF-α.[80,81]

CLINICAL FINDINGS

Circumscribed, raised, erythematous, usually pruritic, evanescent areas of edema that involve the superficial portion of the dermis are known as *urticaria* (Fig. 38-3); when the edematous process extends into the deep dermis and/or subcutaneous and submucosal layers, it is known as *angioedema*. Urticaria and angioedema may occur in any location together or individually. Angioedema commonly affects the face or a portion of an extremity, may be painful but not pruritic, and may last several days. Involvement of the lips, cheeks, and periorbital areas is common, but angioedema also may affect the tongue, pharynx, or larynx. The individual lesions of urticaria arise suddenly, rarely persist longer than 24–36 hours, and may continue to recur for indefinite periods. They are highly pruritic.

IMMUNOLOGIC: IMMUNOGLOBULIN E- AND IMMUNOGLOBULIN E RECEPTOR-DEPENDENT URTICARIA/ANGIOEDEMA

ATOPIC DIATHESIS. Episodes of acute urticaria/angioedema that occur in individuals with a personal or family history of asthma, rhinitis, or eczema are presumed to be IgE dependent. However, in clinical practice, urticaria/angioedema infrequently accompanies an exacerbation of asthma, rhinitis, or eczema. The prevalence of chronic urticaria/angioedema is not increased in atopic individuals.

Figure 38-3 Urticaria and angioedema. This patient has urticaria occurring on the face, neck, and upper trunk with angioedema about the eyes.

SPECIFIC ANTIGEN SENSITIVITY. Common examples of specific antigens that provoke urticaria/angioedema include foods such as shellfish, nuts, and chocolate; drugs and therapeutic agents notably penicillin; aeroallergens; and Hymenoptera venom (see Fig. 38-3). Urticaria in patients with helminthic infestations has been attributed to IgE-dependent processes; however, proof of this relationship is often lacking. Specific allergens and nonspecific stimuli may activate local reactions termed *recall urticaria* at sites previously injected with allergen immunotherapy.

PHYSICAL URTICARIA/ANGIOEDEMA[5,6]

DERMOGRAPHISM. Dermographism is the most common form of physical urticaria and is the one most likely to be confused with chronic urticaria. A lesion appears as a linear wheal with a flare at a site in which the skin is briskly stroked with a firm object (Fig. 38-4). A transient wheal appears rapidly and usually fades within 30 minutes; however, the patient's normal skin is typically pruritic so that an itch–scratch sequence may appear. The prevalence of dermographism in the general population was reported as 1.5% and 4.2%, respectively, in two studies, and its prevalence in patients with chronic urticaria is 22%. It is not associated with atopy. The peak prevalence occurs in the second and third decades. In one study, the duration of dermographism was greater than 5 years in 22% of individuals and greater than 10 years in 10%.

Figure 38-4 Topical dermatographic response to scratching the skin.

Elevations in blood histamine levels have been documented in some patients after experimental scratching, and increased levels of histamine,[82] tryptase, SP, and VIP, but not calcitonin gene-related peptide, have been detected in experimental suction-blister aspirates. The dermographic response has been passively transferred to the skin of normal subjects with serum or IgE.[83]

In delayed dermographism, lesions develop 3–6 hours after stimulation, either with or without an immediate reaction, and last 24–48 hours. The eruption is composed of linear red indurated wheals. This condition may be associated with delayed pressure urticaria and these two may, in fact, represent the same entity. Cold-dependent dermographism is a condition characterized by marked augmentation of the dermatographic response when the skin is chilled.[84]

PRESSURE URTICARIA. Delayed pressure urticaria appears as erythematous, deep, local swellings, often painful, that arise from 3 to 6 hours after sustained pressure has been applied to the skin.[85,86] Spontaneous episodes are elicited on areas of contact after sitting on a hard chair, under shoulder straps and belts, on the feet after running, and on the hands after manual labor. The peak prevalence occurs in the third decade. Delayed pressure urticaria may occasionally be associated with fever, chills, arthralgias, and myalgias, as well as with an elevated erythrocyte sedimentation rate and leukocytosis. In one study, it accompanied chronic urticaria in 37% of patients. This is far more commonly seen than patients with pressure urticaria and no spontaneously occurring hives. An IgE-mediated mechanism has not been demonstrated; however, histamine and IL-6 have been detected in lesional experimental suction-blister aspirates and in fluid from skin chambers, respectively.[87–89]

VIBRATORY ANGIOEDEMA. Vibratory angioedema may occur as an acquired idiopathic disorder, in association with cholinergic urticaria, or after several years of occupational exposure to vibration.[90] It has been described in families with an autosomal dominant pattern of inheritance.[91] The heritable form often is accompanied by facial flushing. An increase in the level of plasma histamine was detected during an experimental attack in patients with the hereditary form and in patients with acquired disease.[91,92] A typical symptom is hives across the back when toweling off after a shower (in the absence of dermatographism).

COLD URTICARIA. There are both acquired and inherited forms of cold urticaria/angioedema; however, the familial form is rare. Idiopathic or primary acquired cold urticaria may be associated with headache, hypotension, syncope, wheezing, shortness of breath, palpitations, nausea, vomiting, and diarrhea. Attacks occur within minutes after exposures that include changes in ambient temperature and direct contact with cold objects. The elicitation of a wheal after the application of ice has been called a diagnostic cold contact test (Fig. 38-5). This can be performed with thermoelectric elements with graded temperatures so that the temperature threshold for producing a wheal can be determined and a dose-response (sensitivity) in terms of stimulus duration can be readily obtained.[92] If the entire body is cooled (as in swimming), hypotension and syncope, which are potentially lethal events (by drowning), may occur. In rare instances, acquired cold urticaria has been associated with circulating cryoglobulins, cryofibrinogens, cold agglutinins, and cold hemolysins, especially in children with infectious mononucleosis.[93–95]

Passive transfer of cold urticaria by intracutaneous injection of serum or IgE to the skin of normal recipients has been documented.[96,97] Histamine, chemotactic

Figure 38-5 Positive ice cube test in a patient with cold urticaria.

factors for eosinophils and neutrophils, PGD_2, cysteinyl leukotrienes, platelet-activating factor, and TNF-α have been released into the circulation after experimental challenge.[98–104] Histamine, SP, and VIP, but not calcitonin gene-related peptide, have been detected in experimental suction-blister aspirates. Histamine has been released in vitro from chilled skin biopsy specimens that have been rewarmed.[105] Neutrophils harvested from the blood of an experimentally cold-challenged arm manifested an impaired chemotactic response suggesting in vivo desensitization. Whereas complement has no role in primary acquired cold urticaria, cold challenge of patients with cold urticaria who have circulating immune complexes (such as cryoglobulins) can provoke a cutaneous necrotizing venulitis with complement activation.[106–109]

Rare forms of acquired cold urticaria have been described mainly in case reports include systemic cold urticaria,[84] localized cold urticaria,[110] cold-induced cholinergic urticaria, cold-dependent dermographism,[84] and localized cold reflex urticaria.[111,112] Three forms of dominantly inherited cold urticaria have been described. Familial cold urticaria which has been termed *familial cold autoinflammatory syndrome* and is considered a type of periodic fever.[113] It is a disorder showing an autosomal dominant pattern of inheritance with a genetic linkage to chromosomes 1q44. The responsible gene has been identified as *CIASI*, which codes for a protein involved in regulation of inflammation and apoptosis.[114] The eruption occurs as erythematous macules and infrequent wheals and is associated with burning or pruritus. Fever, headaches, conjunctivitis, arthralgias, and a neutrophilic leukocytosis are features of attacks. The delay between cold exposure and onset of symptoms is 2.5 hours, and the average duration of an episode is 12 hours. Renal disease with amyloidosis occurs infrequently. Skin biopsy specimens show mast cell degranulation and an infiltrate of neutrophils. Results of the cold contact test and passive transfer with serum have been negative. Serum levels of IL-6 and granulocyte colony stimulating factor were elevated in one patient. Other studies suggest a pathogenic role for IL-1. Delayed cold urticaria occurs as erythematous, edematous, deep swellings that appear 9–18 hours after cold challenge. Lesional biopsy specimens show edema with minimal numbers of mononuclear cells; mast cells are not degranulated; and neither complement proteins nor immunoglobulins are detected. Cold immersion does not release histamine, and the condition cannot be passively transferred. Recently, a new form of familial cold urticaria with dominant inheritance has been reported with pruritus, erythema, and urticaria with cold exposure that can progress to syncope. The ice cube test is negative and it lacks the fever, and flu-like symptoms associated with familial cold autoinflammatory syndrome.[115]

CHOLINERGIC URTICARIA. Cholinergic urticaria develops after an increase in core body temperature, such as during a warm bath, prolonged exercise, or episodes of fever.[116] The highest prevalence is observed in individuals aged 23–28 years. The eruption appears as distinctive, pruritic, small, 1- to 2-mm wheals that are surrounded by large areas of erythema (Fig. 38-6). Occasionally, the lesions may become confluent, or angioedema may develop. Systemic features include dizziness, headache, syncope, flushing, wheezing, shortness of breath, nausea, vomiting, and diarrhea. An increased prevalence of atopy has been reported. The intracutaneous injection of cholinergic agents, such as methacholine chloride, produces a wheal with satellite lesions in approximately one-third of patients.[117,118] Alterations in pulmonary function have been documented during experimental exercise challenge[119] or after the inhalation of acetylcholine, but most are asymptomatic.

Figure 38-6 Lesions of cholinergic urticaria observed in a patient after 15 minutes of exercise in a warm room.

A major subpopulation of patients with cholinergic urticaria have a positive skin test result and in vitro histamine release in response to autologous sweat.[120] It is not clear whether this is IgE mediated and any antigen present in sweat is unidentified. This is the same subpopulation with a positive methacholine skin test with satellite lesions and a nonfollicular distribution of the wheals. The remaining patients had negative results on autologous sweat skin tests or in vitro histamine release. Results of the methacholine skin test are negative for satellite lesions and the hives tend to be follicular in distribution.

Familial cases have been reported only in men in four families.[121] This observation suggests an autosomal dominant pattern of inheritance. One of these individuals had coexisting dermographism and aquagenic urticaria.

After exercise challenge, histamine and factors chemotactic for eosinophils and neutrophils have been released into the circulation.[99,119] Tryptase has been detected in lesional suction-blister aspirates. The urticarial response has been passively transferred on one occasion; however, most other attempts to do so have been unsuccessful.

Cold urticaria and cholinergic urticaria are not uncommonly seen together[122,123] and cold-induced cholinergic urticaria represents an unusual variant

in which typical "cholinergic" appearing lesions occur with exercise, but only if the person is chilled, for example, with exercise outside on a winter's day. The ice cube test and methacholine skin test are both negative.[124]

LOCAL HEAT URTICARIA. Local heat urticaria is a rare form of urticaria in which wheals develop within minutes after exposure to locally applied heat. An increased incidence of atopy has been reported. Passive transfer has been negative. Histamine, neutrophil chemotactic activity, and PGD_2 have been detected in the circulation after experimental challenge.[125] A familial delayed form of local heat urticaria in which the urticaria occurred in 1–2 hours after challenge and lasted up to 10 hours has been described.

SOLAR URTICARIA. Solar urticaria occurs as pruritus, erythema, wheals, and occasionally angioedema that develop within minutes after exposure to sun or artificial light sources. Headache, syncope, dizziness, wheezing, and nausea are systemic features. Most commonly, solar urticaria appears during the third decade.[126] In one study, 48% of patients had a history of atopy. Although solar urticaria may be associated with systemic lupus erythematosus and polymorphous light eruption, it is usually idiopathic. The development of skin lesions under experimental conditions in response to specific wavelengths has allowed classification into six subtypes; however, individuals may respond to more than one portion of the light spectrum. In type I, elicited by wavelengths of 285–320 nm, and in type IV, elicited by wavelengths of 400–500 nm, the responses have been passively transferred with serum, suggesting a role for IgE antibody. In type I, the wavelengths are blocked by window glass.[127,128] Type VI, which is identical to erythropoietic protoporphyria, is due to ferrochelatase (hemesynthetase) deficiency (see Chapter 132).[74] There is evidence that an antigen on skin may become evident once irradiated with the appropriate wave length of light followed by complement activation and release of C5a.[129–131]

Histamine and chemotactic factors for eosinophils and neutrophils have been identified in blood after exposure of the individuals to ultraviolet A, ultraviolet B, and visible light.[132,133] In some individuals, uncharacterized serum factors with molecular weights ranging from 25 to 1,000 kDa, which elicit cutaneous wheal-and-erythema reactions after intracutaneous injection, have been implicated in the development of lesions.

EXERCISE-INDUCED ANAPHYLAXIS. Exercise-induced anaphylaxis is a clinical symptom complex consisting of pruritus, urticaria, angioedema respiratory distress, and syncope that is distinct from cholinergic urticaria.[134–137] In most patients, the wheals are not punctate and resemble the hives seen in acute or chronic urticaria. The symptom complex is not readily reproduced by exercise challenges as is cholinergic urticaria. There is a high prevalence of an atopic diathesis. Some cases are food dependent, i.e., exercise will lead to an anaphylaxis-like episode only if food was ingested within 5 hours of the exercise. The food dependency is subdivided into two groups: in the first the nature of the food eaten is not relevant, whereas in the second a specific food to which there is IgE-mediated hypersensitivity must be eaten for hives to appear.[138–141] Yet in these cases, eating the food without exercise does not result in urticaria. The food-dependent group is easier to treat because avoidance of food (or a specific food) for 5–6 hours before exercise prevents episodes. Cases not related to food require therapy for acute episodes and attempts to prevent episodes with high-dose antihistaminics or avoidance of exercise. Results of a questionnaire study of individuals who had had exercise-induced anaphylaxis for more than a decade[142] disclosed that the frequency of attacks had decreased in 47% and had stabilized in 46%. Forty-one percent had been free of attacks for 1 year. Rare familial forms have been described. In exercise-induced anaphylaxis, baseline pulmonary function tests are normal. Biopsy specimens show mast cell degranulation, and histamine and tryptase are released into the circulation when symptoms appear.

ADRENERGIC URTICARIA. Adrenergic urticaria occurs as wheals surrounded by a white halo that develop during emotional stress. The lesions can be elicited by the intracutaneous injection of norepinephrine.

AQUAGENIC URTICARIA AND AQUAGENIC PRURITIS. Contact of the skin with water of any temperature may result in pruritus alone or, more rarely, urticaria. The eruption consists of small wheals that are reminiscent of cholinergic urticaria. Aquagenic urticaria has been reported in more than one member in five families.[143] Aquagenic pruritus without urticaria is usually idiopathic but also occurs in elderly persons with dry skin and in patients with polycythemia vera, Hodgkin's disease, the myelodysplastic syndrome, and the hypereosinophilic syndrome. Patients with aquagenic pruritus should be evaluated for the emergence of a hematologic disorder. After experimental challenge, blood histamine levels were elevated in subjects with aquagenic pruritus and with aquagenic urticaria. Mast cell degranulation was present in lesional tissues. Passive transfer was negative.

CONTACT URTICARIA

Urticaria may occur after direct contact with a variety of substances. It may be IgE mediated or nonimmunologic. The transient eruption appears within minutes, and when it is IgE mediated, it may be associated with systemic manifestations. Passive transfer has been documented in some instances. Proteins from latex products are a prominent cause of IgE-mediated contact urticaria.[144] Latex proteins also may become airborne allergens, as demonstrated by allergen-loaded airborne glove powder used in inhalation challenge tests. These patients may manifest cross-reactivity to fruits, such

as bananas, avocado, and kiwi.[145] Associated manifestations include rhinitis, conjunctivitis, dyspnea, and shock. The risk group is dominated by biomedical workers and individuals with frequent contact with latex, such as children with spina bifida. Agents such as stinging nettles, arthropod hairs, and chemicals may release histamine directly from mast cells.

PAPULAR URTICARIA

Papular urticari occurs as episodic, symmetrically distributed, pruritic, 3- to 10-mm urticarial papules that result from a hypersensitivity reaction to the bites of insects such as mosquitoes, fleas, and bedbugs. This condition appears mainly in children. The lesions tend to appear in groups on exposed areas such as the extensor aspects of the extremities.[146]

URTICARIA/ANGIOEDEMA MEDIATED BY BRADYKININ, THE COMPLEMENT SYSTEM OR OTHER EFFECTOR MECHANISMS

KININS AND C1 INHIBITOR DEFICIENCY.

C1 inhibitor (C1 INH) is the sole plasma inhibitor of factor XIIa and factor XIIf,[147,148] and it is one of the major inhibitors of kallikrein[149] as well as factor XIa.[150] Thus, in the absence of C1 INH, stimuli that activate the kinin-forming pathway will do so in a markedly augmented fashion; the amount of active enzyme and the duration of action of the enzymes are prolonged. C1 INH deficiency can be familial, in which there is a mutant *C1 INH* gene, or it can be acquired. Both the hereditary and acquired disorders have two subtypes. For the hereditary disorder, type I hereditary angioedema (HAE) (85%) is an autosomal dominant disorder with a mutant gene (often with duplication, deletions, or frame shifts) leading to markedly suppressed C1 INH protein levels as a result of abnormal secretion or intracellular degradation.[151] Type 2 HAE (15%) is also a dominantly inherited disorder, typically with a point (missense) mutation leading to synthesis of a dysfunctional protein.[152] The C1 INH protein level may be normal or even elevated, and a functional assay is needed to assess activity. The acquired disorder has been portrayed as having two forms, but they clearly overlap and have in common B cell activation that is often clonal. One group is associated with B-cell lymphoma[153–155] or connective tissue disease,[156] in which there is consumption of C1 INH. Examples are systemic lupus erythematosus and cryoglobulinemia, in which complement activation is prominent, and B-cell lymphomas, in which immune complexes are formed by anti-idiotypic antibodies to monoclonal immunoglobulin expressed by the transformed B lymphocytes.[157] A second group has a prominence of a circulating IgG antibody to INH itself,[158–160] but this may be seen with lymphoma or systemic lupus erythematosus as well. Acquired types have depressed C1q levels, whereas hereditary types do not, and depressed C4 levels characterize all forms of C1 INH deficiency. The acquired autoimmune subgroup has a circulating 95-kDa cleavage product of C1 INH because the antibody depresses C1 INH function yet allows cleavage by enzymes with which it usually interacts.[159–162]

It is now clear that depletion of C4 and C2 during episodes of swelling[163,164] is a marker of complement activation but does not lead to release of a vasoactive peptide responsible for the swelling. Bradykinin is, in fact, the mediator of the swelling[165–167]and the evidence in support of this conclusion is summarized below. Patients with HAE are hyperresponsive to cutaneous injection of kallikrein.[168] They have elevated bradykinin levels, and low prekallikrein and HK levels during attacks of swelling.[169–171] The augmentation in complement activation seen at those times may be due to activation of C1r and C1s by factor XIIf.[172] The presence of kallikrein-like activity in induced blisters of patients with HAE also supports this notion,[173] as does the progressive generation of bradykinin on incubation of HAE plasma in plastic (noncontact-activated) tubes[165,166] as well as the presence of activated factor XII and cleaved HK levels seen during attacks.[174] One unique family has been described in which there is a point mutation in the *C1 INH* (A1a 443 → Val) leading to an inability to inhibit complement but normal inhibition of factor XIIa and kallikrein.[175,176] No family member of this type 2 mutation has had angioedema,[175] although complement activation is present. In recent studies plasma bradykinin levels have been shown to be elevated during attacks of swelling in both hereditary and acquired C1 inhibitor deficiency,[169] and local bradykinin generation has been documented at the sites of swelling.[177] It is not known whether bradykinin generation is predominantly seen in the fluid phase, occurs along cell (endothelial) surfaces, or both. A rodent model of HAE demonstrated that angioedema can be prevented by "knockout" of the B-2 receptor.[178] Figure 38-7 depicts a patient with facial swelling due to HAE. Figure 38-8 is a diagram depicting the steps in the bradykinin-forming cascade that are inhibitable by C1 INH.

An estrogen-dependent form of hereditary angioedema has been recognized that is now designated type 3 HAE. One of the first reports involved a single family with seven affected individuals in three generations, which suggests a hereditary (autosomal dominant) pattern.[73] Clinical features include angioedema without urticaria, laryngeal edema, and abdominal pain with vomiting. Attacks occur during pregnancy and with the administration of exogenous estrogen. Numerous subsequent reports support these observations.[179] In one subgroup, there is a mutation in factor XII such that the activated form (factor XIIa) is more potent than normal.[180] These patients all have normal C4 and normal C1 INH protein and function. Bradykinin is the likely mediator; for those with a factor XII mutation, the active enzyme may be less readily inhibited. Although uncommon, a male with the disorder has been described[181] and a bradykinin receptor antagonist (Icatibanit) has provided effective therapy for acute episodes.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS.

Angioedema has been associated with the administration of ACE inhibitors.[182] The frequency of

Figure 38-7 Hereditary angioedema. Extensive involvement (**A**) is to be contrasted with the patient's normal facies (**B**).

angioedema occurring after ACE inhibitor therapy is 0.1%–0.7%. There is a predilection to ACE inhibitor reactions in the African-American population that may relate to polymorphisms in the genes encoding other enzymes that catabolize bradykinin such as aminopeptidase P or neutral endopeptidase. Low levels of these would predispose to bradykinin accumulation. Angioedema develops during the first week of therapy in up to 72% of affected individuals and usually involves the head and neck, including the mouth, tongue, pharynx, and larynx. Urticaria occurs only rarely. Cough and angioedema of the gastrointestinal tract are associated features. It has been suggested that therapy with ACE inhibitors is contraindicated in patients with a prior history of idiopathic angioedema, HAE, and acquired C1 INH deficiency.[183] It

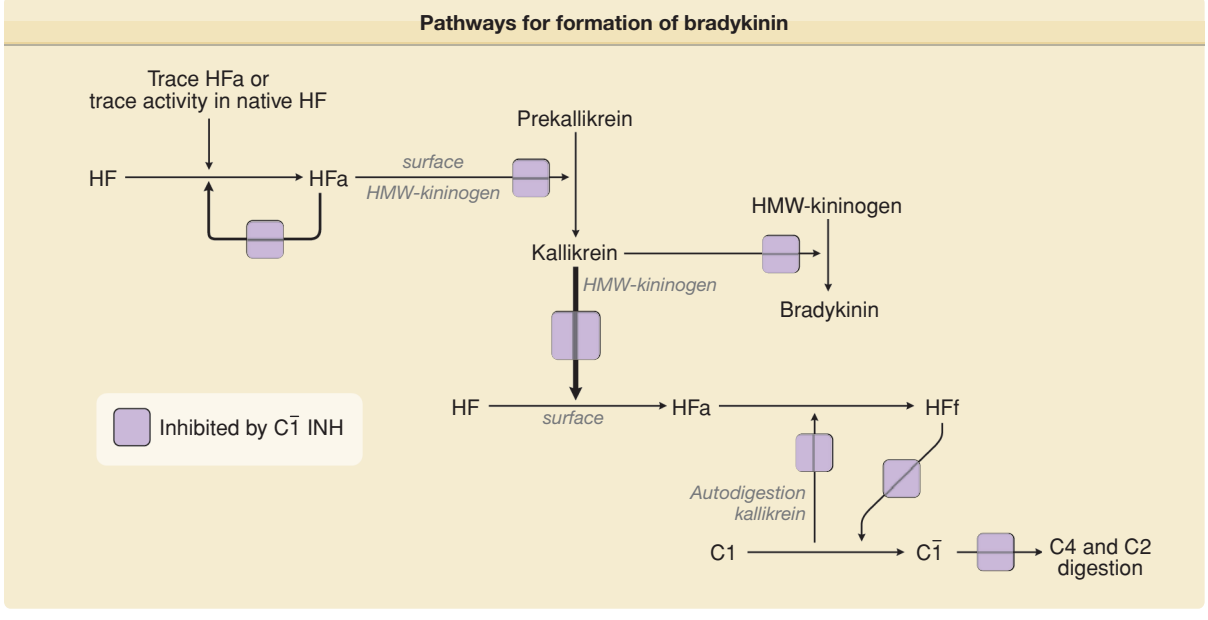

Figure 38-8 Pathways for formation of bradykinin, indicating all steps inhibitable by C1 inhibitor as well as complement activation by means of factor XIIf.

appears that this swelling is also a consequence of elevated levels of bradykinin;[169] however, the accumulation of bradykinin is due to a defect in degradation rather than an excessive production. ACE, being identical to kininase II, is the major enzyme responsible for bradykinin degradation (See eFig. 38-1.2 in online edition) and although it is present in plasma, the vascular endothelium of the lung appears to be its major site of action.[184] The action of ACE always leads to the formation of degradation products with no activity, whereas kininase I alone yields the des-arg products, which are capable of stimulating B1 receptors.

The excessive accumulation of bradykinin implies that production is ongoing, with activation of the plasma cascade or release of tissue kallikrein faulty inactivation of bradykinin then leads to swelling. Continuous turnover of the plasma cascade is implied by data demonstrating activation along the surface of cells and cellular expression or secretion of a prekallikrein activator other than factor XIIa.[185,186]

URTICARIAL VENULITIS

Chronic urticaria and angioedema may be manifestations of cutaneous necrotizing venulitis, which is known as *urticarial venulitis* (See Chapter 163).[187,188] Associated features include fever, malaise, arthralgia, abdominal pain, and less commonly conjunctivitis, uveitis, diffuse glomerulonephritis, obstructive and restrictive pulmonary disease, and benign intracranial hypertension. The term hypocomplementemic urticarial vasculitis syndrome is used in patients with more severe clinical manifestations of urticarial venulitis with hypocomplementemia and a low-molecular-weight C1q-precipitin that has been identified as an IgG autoantibody directed against the collagen-like region of C1q.

SERUM SICKNESS

Serum sickness, which was defined originally as an adverse reaction that resulted from the administration of heterologous serum to humans, but may similarly occur after the administration of drugs. Serum sickness occurs 7–21 days after the administration of the offending agent and is manifested by fever, urticaria, lymphadenopathy, myalgia, arthralgia, and arthritis. Symptoms are usually self-limited and last 4–5 days. More than 70% of patients with serum sickness experience urticaria that may be pruritic or painful. The initial manifestation of urticaria may appear at the site of injection.[189–197]

REACTIONS TO THE ADMINISTRATION OF BLOOD PRODUCTS

Urticaria/angioedema may develop after the administration of blood products. It usually is the result of immune complex formation and complement activation that leads to direct vascular and smooth muscle alterations and indirectly, via anaphylatoxins, to mast cell mediator release. Aggregated IgG may also be responsible for human reactions to immunoglobulins as evidenced by the fact that the administration of IgG from which aggregates have been removed is not associated with urticaria or anaphylaxis.

An uncommon mechanism for the development of urticaria after the administration of blood products is the transfusion of IgE of donor origin directed toward an antigen to which the recipient is subsequently exposed. Another mechanism may be the transfusion of a soluble antigen present in the donor preparation into a previously sensitized recipient.

INFECTIONS

Episodes of acute urticaria can be associated with upper respiratory tract viral infections, most commonly in children.[198] The acute urticaria resolves within 3 weeks. Hepatitis B virus infection has been associated with episodes of urticaria lasting up to 1 week that are accompanied by fever and arthralgias as part of the prodrome. The mechanism is analogous to that seen in serum sickness-like reactions with virus–antibody immune complexes. The mechanism for urticaria occasionally associated with infectious mononucleosis may be analogous.

URTICARIA/ANGIOEDEMA AFTER DIRECT MAST CELL DEGRANULATION

Various therapeutic and diagnostic agents have been associated with urticaria/angioedema. Up to 8% of patients receiving radiographic contrast media experience such reactions, which occur most commonly after intravenous administration. Decreased serum alternative pathway complement protein levels and increased serum histamine levels have been detected in patients receiving radiocontrast media. Opiate analgesics, polymyxin B, curare, and D-tubocurarine induce release of histamine from mast cells and basophils.

URTICARIA/ANGIOEDEMA RELATING TO ABNORMALITIES OF ARACHIDONIC ACID METABOLISM

Intolerance to aspirin manifested as urticaria/angioedema occurs in otherwise normal individuals or in patients with allergic rhinitis and/or bronchial asthma. Urticaria/angioedema in response to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) occurred in approximately 10%–20% of individuals referred to a hospital dermatology clinic in the United Kingdom. Patients intolerant of aspirin also may react to indomethacin and to other NSAIDs.

Reactions to aspirin are shared with other NSAIDs because they reflect inhibition of prostaglandin endoperoxide synthase 1 (PGHS-1, cyclooxygenase I)[199] as

well as inhibition of the inducible PGHS-2 (cyclooxygenase 2). Sodium salicylate and choline salicylate generally are well tolerated because of their weak activity against PGHS-1. PGHS-2 inhibitors are generally well tolerated in those with NSAID-induced urticaria.[200,201] Reactions to NSAIDs increase the levels of cysteinyl leukotrienes,[202] which may relate to the appearance of urticaria, although their role in NSAID-induced asthma is better characterized. Prick skin tests are of no diagnostic value, passive transfer reactions are negative, and neither IgG nor IgE antibodies have been associated with clinical disease. The clinical manifestations elicited by aspirin challenge of aspirin-intolerant patients are blocked when such patients are protected with a cysteinyl leucotriene receptor blocker or biosynthetic inhibitor; this finding confirms a pathobiologic role for the cysteinyl leukotrienes.

CHRONIC IDIOPATHIC URTICARIA AND IDIOPATHIC ANGIOEDEMA

Because the clinical entities of chronic idiopathic urticaria (with or without angioedema) and idiopathic angioedema are frequently encountered, have a capricious course, and are recognized easily, they are frequently associated with concomitant events. Such attributions must be interpreted with caution. Although infections, food allergies, adverse reactions to food additives, metabolic and hormonal abnormalities, malignant conditions, and emotional factors have been claimed as causes, proof of their etiologic relationship often is lacking. Among the recent considerations is chronic urticaria as a consequence of infection with *Helicobacter pylori*. Articles both supporting[203–205] and denying[206–209] a relationship are numerous and a definite answer is not available. However, the *H. pylori* infection rate in the population at large is far greater than the incidence of chronic urticaria and in the opinion of this author, the association is spurious. The controversy has been put in perspective by M. Greaves.[210] Idiopathic angioedema is diagnosed when angioedema is recurrent, when urticaria is absent, and when no exogenous agent or underlying abnormality is identifiable. An extensive review of angioedema has been recently published.[184]

Cyclic episodic angioedema has been associated with fever, weight gain, absence of internal organ damage, a benign course, and peripheral blood eosinophilia.[211] Biopsy specimens of tissues show eosinophils, eosinophil granule proteins, and CD4 lymphocytes exhibiting HLA-OR. Blood levels of IL-1, soluble IL-2 receptor, and IL-5 are elevated.

Idiopathic angioedema is characterized by recurrent episodes of angioedema in the absence of any urticaria, which may include the face (lips, tongue, periorbital region, pharynx), extremities, and genitalia, but is not associated with laryngeal edema or massive tongue/pharyngeal swelling that yield airway obstruction. It may not be a continuum with chronic urticaria with or without concomitant angioedema, as is often considered, because the incidence in men and women is about the same and the presence of antithyroid antibodies or anti-IgE receptor antibodies is far less. Extreme cases, particularly if associated with laryngeal edema, could represent type 3 HAE in a patient with a new mutation (i.e., no family history) or a variant of idiopathic anaphylaxis.

MISCELLANEOUS

Muckle–Wells syndrome consists of urticaria, amyloidosis, and nerve deafness and is due to the same gene defect as is seen in familial cold urticaria.[114] Schnitzler syndrome is a chronic urticaria with histology resembling an urticarial vasculitis associated with fever, joint pain, an IgM monoclonal protein, and osteosclerosis. An antibody to IL-1α has been shown to be present.[212]

APPROACH TO THE PATIENT

The evaluation of patients with urticaria/angioedema (Fig. 38-9) begins with a comprehensive history, with particular emphasis on the recognized causes, and a physical examination. Some varieties of urticaria may be identified by their characteristic appearance, such as the small wheals with a large erythematous flare of cholinergic urticaria, the linear wheals in dermographism, and the localization of lesions to exposed areas in light- or cold-induced urticaria. If suggested by the history, the physical examination in all patients with urticaria should include tests for physical urticaria, such as a brisk stroke to elicit dermographism, the use of a weight to elicit delayed pressure urticaria, and application of a cold or warm stimulus for cold-induced urticaria and localized heat urticaria, respectively. Exercise, such as running in place, may elicit cholinergic urticaria and, in some instances, exercise-induced anaphylaxis. Phototests to elicit solar urticaria usually are performed in referral centers, as are challenges for exercise-induced anaphylaxis.

When urticaria has been present for days or weeks at a time (but less than 6 weeks) or occurs recurrently for similar intervals, the main considerations are allergic reactions (IgE mediated) to food or drugs. A careful history regarding possibilities is essential. Skin testing can corroborate IgE-mediated hypersensitivity to foods or can provide suspects when the history is unrevealing. Double-blind placebo-controlled food challenge can demonstrate clinical relevance in cases in which the role of a food is uncertain. Non-IgE-mediated causes of urticaria include adverse reactions to NSAIDs and opiates. Any of these can be associated with concomitant angioedema or, less commonly, present as angioedema in the absence of urticaria. Children may have acute urticaria in association with viral illnesses; it is unclear whether infection with bacteria such as *Streptococcus* can induce urticaria as well, but neither form occurs in adults with the exception of urticaria in association with infectious mononucleosis (Epstein–Barr virus) or as a prodrome to hepatitis B

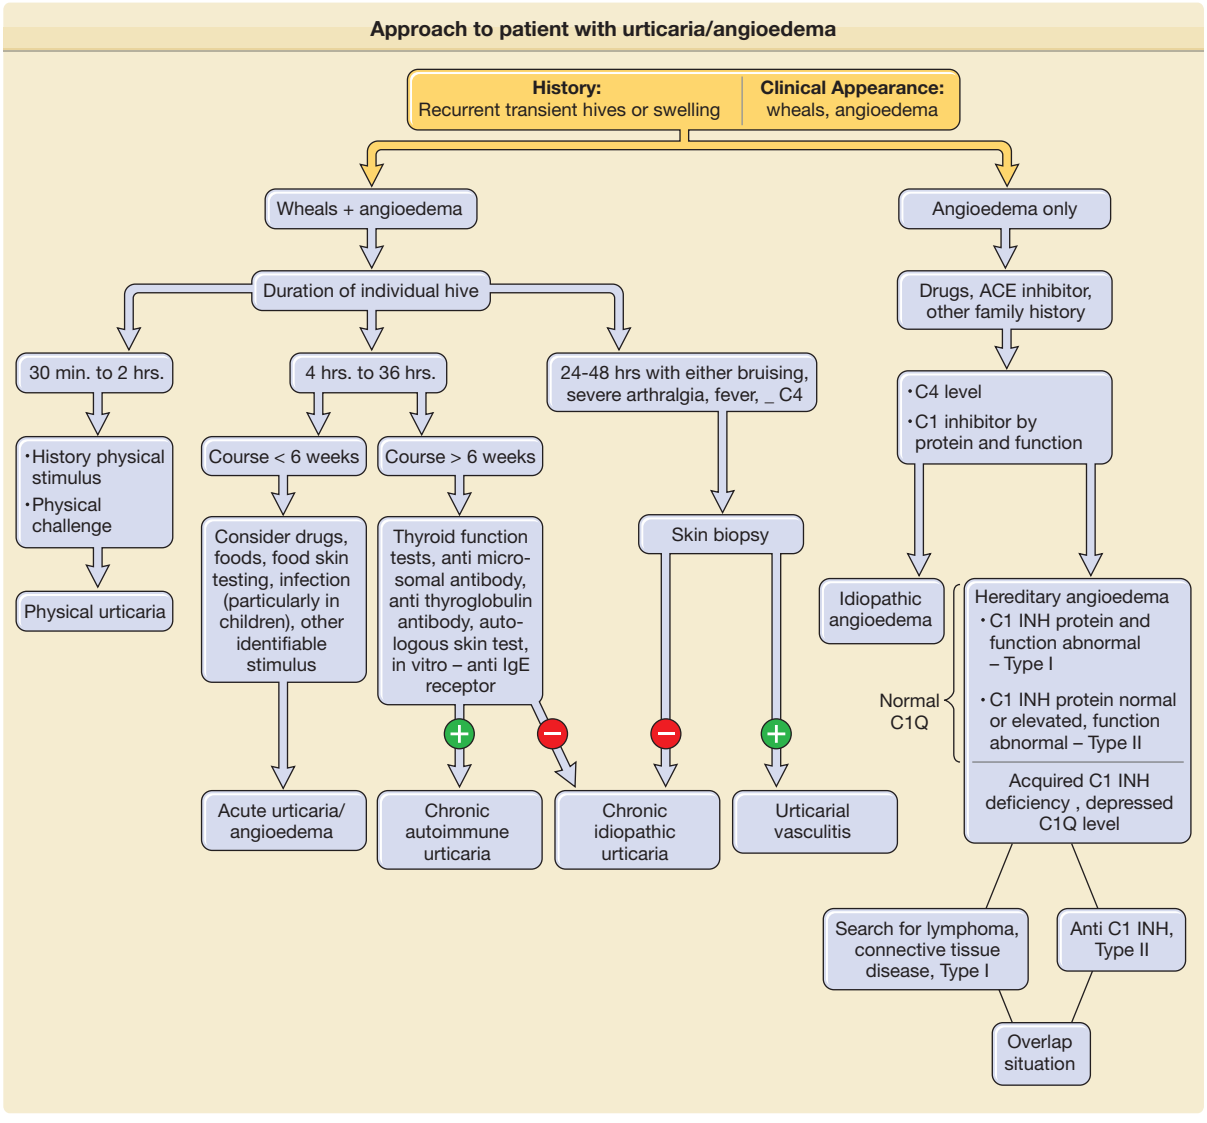

Figure 38-9 Approach to the patient with urticaria/angioedema. ACE = angiotensin-converting enzyme; IgE, immunoglobulin E; INH = inhibitor; ↓ = decreased.

infection. In each of these circumstances, individual lesions last anywhere from 4 hours to 24 hours and fade without associated purpura. If hives last less than 2 hours, the cause is usually physical urticaria, the most common being dermatographism, cholinergic urticaria, and cold urticaria. The main exception is delayed pressure urticaria, in which lesions typically last 12–36 hours and first appear 3–6 hours after the initiating stimuli. Once urticaria continues for longer than 6 weeks (particularly if present for many months or years) chronic urticaria is present. The term chronic spontaneous urticaria has been employed recently to eliminate confusion with physical urticarias. Chronic urticaria is now divided into chronic idiopathic urticaria for which a cause has not yet been found and chronic autoimmune urticaria. Angioedema accompanies chronic urticaria in 40% of cases and is more problematic in the autoimmune subgroup. Swelling in association with chronic urticaria can affect hands, feet, eyes, cheeks, lips, tongue, and pharynx, but not the larynx. When angioedema is present in the absence of an identifiable antigen or exogenous stimulus, the main entities to consider are C1 INH deficiency (hereditary or acquired) and idiopathic angioedema. Approximately 0.5% of patients have an urticarial vasculitis with palpable purpura or other stigmata of a possible vasculitis, such as fever, elevated sedimentation rate, petechiae or purpura, elevated white blood cell count, or lesions of unusual duration (36–72 hours). The differential diagnosis of acute, chronic, and physical urticaria/angioedema is summarized in Box 38-1.

LABORATORY FINDINGS

In most patients with chronic urticaria/angioedema, no underlying disorders or causes can be discerned.

BOX 38-1 DIFFERENTIAL DIAGNOSIS OF URTICARIA/ANGIOEDEMA

ACUTE (<6 WEEK)

- Drug reaction
  - Immunoglobulin E (IgE) mediated
  - Metabolic—idiosyncratic
  - Cellular immunity
- Food reactions
  - IgE mediated
  - Non-IgE mediated (e.g., scombroid poisoning)
- Intravenous administration
  - Blood products
  - Contrast agents
  - Intravenous γ globulin
- Infection
  - Viral in children
  - Infectious mononucleosis or hepatitis B prodrome
  - ? Bacterial in children

PHYSICAL

- Individual lesions last <2 hours
  - Cold urticaria
  - Cholinergic urticaria
  - Dermatographism
  - Local heat urticaria
  - Aquagenic urticaria
  - Cold-induced cholinergic urticaria
  - Cold-dependent dermatographism
- Lesions last >2 hours
  - Delayed pressure urticaria
  - Vibratory angioedema
  - Familial cold-induced syndromes, usually with fever

CHRONIC (>6 WEEK)

- Autoimmune, often with antithyroid antibodies
- Idiopathic
- Urticarial vasculitis
  - Idiopathic—skin only
  - Associated with other connective tissue disease
- Familial febrile syndromes with urticaria-like rash
- Schnitzler's syndrome

Diagnostic studies should be based on findings elicited by the history and physical examination. Evaluation of chronic urticaria/angioedema should include thyroid function tests, assays for antimicrosomal and antithyroglobulin antibodies, and the autologous skin test can be done, even in an office setting.[213] Routine screening laboratory tests are of little value. The histamine release assay for anti-IgE receptor or anti-IgE antibodies are now available in specialized laboratories. Serum hypocomplementemia is not present in chronic idiopathic urticaria or chronic autoimmune urticaria and mean levels of serum IgE in these patients are not different from the general population in which the incidence of atopy is 20%.

Cryoproteins should be sought in patients with acquired cold urticaria. An antinuclear antibody test should be obtained in patients with solar urticaria. Assessment of serum complement proteins may be helpful in identifying patients with urticarial venulitis or serum sickness (C4-, C3-, C1q-binding assay for circulatory immune complexes), as well as those with hereditary and acquired forms of C1 INH deficiency (C4, C1 INH by protein and function, C1q level).

Skin biopsy of chronic urticarial lesions should be undertaken to identify urticarial venulitis or to assess rashes where the urticarial nature is not clear.

There is little role for routine prick skin testing or the radioallergosorbent test in the diagnosis of specific IgE-mediated antigen sensitivity in chronic urticaria/angioedema. Inhalant materials are uncommon causes of urticaria/angioedema, and food skin tests may be difficult to interpret. The tests for drugs are limited to penicillin but cannot be performed in patients with dermographism. The radioallergosorbent test should be reserved for those in whom skin testing is contraindicated, unavailable, or unrevealing despite a highly suspected history.

A finding of the release of histamine from peripheral basophilic leukocytes has supported the diagnosis of anaphylactic sensitivity to a variety of antigens, which include pollens and insect venom.

HISTOPATHOLOGY

Edema involving the superficial portion of the dermis is characteristic of urticaria, whereas angioedema involves the deeper dermis and subcutaneous tissue. Both disorders are associated with dilatation of the venules.

In chronic urticaria, the dermal infiltrating inflammatory cells may be sparse or dense and include more CD4 than CD8 T lymphocytes, neutrophils, eosinophils, and basophils[46,214] without B lymphocytes or natural killer (NK) cells. NKT cells have not been assessed. Increased expression of TNF-α and IL-3 on endothelial cells and perivascular cells was detected in the upper dermis of patients with acute urticaria, chronic idiopathic urticaria, and delayed-pressure urticaria and in one patient with cold urticaria.[215] TNF-α also was detected on epidermal keratinocytes in lesional and nonlesional biopsy specimens. In chronic idiopathic urticaria, CD11b and CD18 cells were detected about the blood vessels in the superficial and deep dermis. Direct immunofluorescence tests for immunoglobulins and complement proteins were negative.

Major basic protein and eosinophil cationic protein, which are derived from the eosinophils granule, are present around blood vessels and are dispersed in the dermis in lesions of acute urticaria, chronic

idiopathic urticaria, delayed-pressure urticaria, cholinergic urticaria, and solar urticaria. In chronic idiopathic urticaria, free eosinophil granules in the dermis were increased in wheals of greater than 24 hours' duration as compared with wheals lasting fewer than 24 hours. The secreted form of eosinophil cationic protein and eosinophil-derived neurotoxin were detected on cells in greater amounts in biopsy specimens from patients with chronic urticaria without autoantibodies than in those with autoantibodies. P-selectin, E-selectin, intercellular adhesion molecules 1, and vascular cellular adhesion molecule 1 have been demonstrated on the vascular endothelium of patients with chronic idiopathic urticaria and dermographism. Major histocompatability complex class II antigen also is upregulated on the endothelial cells of patients with chronic urticaria, and the peripheral blood lymphocytes have increased CD40 ligand expression and higher Bcl-2 expression; these observations suggest an augmentation of autoimmune phenomena.[216]

In papular urticaria, the epidermis is thick with intercellular edema and lymphocytes. In the dermis, there is edema with an infiltrate containing T lymphocytes, macrophages, eosinophils, and neutrophils without B lymphocytes or the deposition of immunoglobulins, fibrin and C3.

TREATMENT

Therapy of acute urticaria uses antihistamines as described in Fig. 38-10; however, the rash can be severe and generalized, and angioedema may be present as well. Thus, if relief provided by nonsedating antihistamines appears insufficient, one can try hydroxyzine or diphenhydramine at 25–50 mg qid.[217] Alternatively nonsedating antihistamines can be tried employing up to 4–6 tablets/day as has been reported for treatment of cold urticaria.[92] A course of corticosteroid can be used, for example, 40–60 mg/day for 3 days and taper by 5–10 mg/day. Epinephrine can relieve severe symptoms of urticaria or angioedema (generalized urticaria, severe pruritus, accelerating angioedema) and is indicated if laryngeal edema is present. Edema of the posterior tongue and/or pharyngeal edema can be confused with it.
