Orally administered venlafaxine and DVS are well absorbed from the GI tract and undergo extensive first-pass metabolism in the liver. During venlafaxine therapy, ODV accumulates in higher concentrations (typically about twofold higher) than the parent drug. It thus can be said that ODV accounts for a majority of the therapeutic activity of venlafaxine.

Coadministration with food decreases the rate, but not the extent, of absorption of the IR formulation and does not appreciably alter absorption of venlafaxine XR or ODV. Peak plasma concentrations are achieved within 2 to 3 hours after ingestion of the IR formulation of venlafaxine. During therapy with the XR formulation, peak plasma concentrations are achieved within 5.5 hours for venlafaxine and 9 hours for ODV. When compared to the initial formulation, therapy with venlafaxine XR results in lower peak plasma concentrations and a flatter plasma drug concentration curve when compared to venlafaxine IR and yet virtually identical bioavailability. During therapy with DVS, peak plasma concentrations of ODV are achieved within about 7 to 9 hours. Formulation of ODV as a succinate salt significantly increases the bioavailability of DVS as compared to venlafaxine ER.

Venlafaxine and ODV have linear kinetics over a dose range of 75 to 450 mg/day. Venlafaxine and ODV are primarily eliminated by the kidneys. The elimination half-lives of venlafaxine and its metabolite are short (i.e., 4 and 10 hours, respectively). Neither venlafaxine nor ODV is highly bound to plasma albumin (i.e., 25 to 30 percent protein binding at therapeutic concentrations).

Clearance of venlafaxine and ODV is reduced among patients with cirrhosis and severe renal disease, necessitating use of lower doses for such patients. Without data from formal studies of treatment of patients with severe hepatic or renal disease, a "half-dose–half-speed" approach is clinically reasonable. Adjustments in dosing on the basis of age alone typically are not necessary. However, a low starting dose and slow titration are recommended for treatment of frail or medically compromised older patients.

Therapeutic Indications

Venlafaxine is approved by the FDA for treatment of four therapeutic disorders: major depressive disorder, generalized anxiety disorder, social anxiety disorder, panic disorder, and attention deficit disorder. Major depressive disorder is currently the only FDA-approved indication for DVS.

Depression. The recommended starting dose of both formulations of venlafaxine, 75 mg/day, is the minimum effective dose for treatment of depression. It should be administered with meals, on a two- or three-times-a-day basis for the IR. The XR formulation is available in 37.5-, 75-, and 150-mg capsules. The minimum therapeutic dose of DVS is 50 mg/day and it is available in 50- and 100-mg tablets. Venlafaxine XR and DVS may be taken in the morning or evening, with or without food, as clinically indicated.

In ambulatory clinical trials of venlafaxine using flexible doses, a modal daily dose of 150 mg/day is typically observed, regardless of the

formulation used. When therapy at modest doses is ineffective, further increases up to 375 mg/day can be considered, as tolerated. However, the maximum recommended daily dose of the XR formulation is only 225 mg because of a lack of data on once-daily ingestion of higher dosages. Consistent with this general approach to therapy, higher mean doses are observed in studies of treatment-resistant depression. Despite some concerns that noradrenergic activity may exacerbate anxiety, efficacy has been established in studies of depressed people with significant concomitant symptoms of anxiety.

In placebo-controlled RCTs of DVS, doses ranging from 50 mg/day to 400 mg/day have shown efficacy, with essentially no evidence of greater efficacy at higher doses, although higher regimens were introduced rather abruptly.

Venlafaxine is one of the most extensively studied newer antidepressants. In published studies using active comparators, venlafaxine therapy has been shown to be at least as effective as treatment with the TCAs—imipramine, clomipramine, dothiepin, and amitriptyline (seven studies total). Research also suggests comparable overall efficacy with two other multiaction antidepressants, mirtazapine (Remeron) and bupropion (Wellbutrin), although the former drug was found to have a better effect on sleep and the latter drug was found to have fewer sexual side effects. As described later in the chapter, a pair of RCTs has contrasted venlafaxine XR and duloxetine.

For both conceptual and commercial reasons, comparisons of venlafaxine and various SSRIs have garnered considerable attention. Looking at published fluoxetine (Prozac)-controlled studies, the differences in remission rates have ranged from nil to as much as 30 percent favoring venlafaxine; in aggregate, the difference in effect sizes was statistically significant. Although there are fewer published studies using other SSRIs, venlafaxine therapy similarly has ranged from comparable to more effective than citalopram, fluvoxamine, paroxetine, and sertraline. Only two studies have directly compared escitalopram and venlafaxine: the SNRI showed no efficacy advantage in these trials and tolerability indices favored the SSRI.

As few comparative clinical trials have sufficient statistical power to distinguish between two effective antidepressants, meta-analyses are increasingly used to examine relative efficacy. One such meta-analysis used the entire set of double-blind RCTs comparing venlafaxine IR and XR versus SSRIs conducted by the manufacturer of venlafaxine through 2005, focusing primarily on remission rates after 8 weeks of therapy. In this analysis of more than 7,000 depressed patients, those treated with venlafaxine were about one-third more likely to achieve remission than patients treated with SSRIs (odds ratio = 1.31), with an absolute advantage in remission rates of about 6 percent. Inspection of the results of all studies comparing venlafaxine and SSRIs, including those conducted by other

sponsors, largely confirm this finding, although again the average difference is small (odds ratio = 1.26) and the numeric difference favored the SSRI in approximately 20 percent of the studies (Fig. 34.26–2).

Despite a noteworthy amount of comparative data, venlafaxine has not been studied extensively in bipolar and psychotic subtypes of major depressive disorder. There are only three randomized studies of bipolar depression, including one comparison versus the SSRI paroxetine (bipolar I only), one versus the SSRI sertraline and bupropion (bipolar I and bipolar II), and one versus lithium (bipolar II only). In the first two studies, which required that patients take concomitant mood stabilizers, there were no significant differences in efficacy, although venlafaxine therapy was associated with a higher rate of treatment-emergent affective switches (TEAS) than the comparators. In the third study which compared monotherapies, venlafaxine was significantly more effective than lithium and was not associated with an increased risk of TEAS.

FIGURE 34.26–2. Funnel plot of randomized controlled trials comparing venlafaxine and selective serotonin reuptake inhibitors. CI, confidence interval. (From Nemeroff CB, Entsuah R, Benattia I, Demitrack M, Sloan DM, Thase ME. Comprehensive analysis of remission [COMPARE] with venlafaxine versus SSRIs. *Biol Psychiatry*. 2008;63:424–434.)

Two long-term studies using more methodologically rigorous placebo-controlled discontinuation designs have confirmed efficacy for prevention of relapse (i.e., 6 months after acute-phase treatment) and recurrence (12 and 24 months thereafter).

Generalized Anxiety Disorder. Venlafaxine XR received FDA approval

for treatment of generalized anxiety disorder in 1999. Efficacy and tolerability data for this indication are documented in four published randomized, controlled trials. In the one published study that used an active comparator, venlafaxine was found to be significantly more effective than buspirone (BuSpar) which, in turn, was not significantly more effective than placebo.

To date, higher-dose venlafaxine therapy for generalized anxiety disorder has not been studied systematically, nor have there been any studies using another antidepressant as the active comparator. The regulatory requirements of the first wave of double-blind studies also necessitated exclusion of patients with significant comorbid depression. Nevertheless, efficacy has been established in studies of anxious patients with a primary diagnosis of major depression.

Social Anxiety Disorder. The FDA approved venlafaxine for treatment of social anxiety disorder in early 2003. To date, the results of three double-blind, placebo-controlled studies have been presented at scientific meetings. These trials demonstrated efficacy and tolerability of venlafaxine at doses of 75 to 225 mg/day; both therapeutic effects and tolerability appear to be comparable to those of paroxetine.

Other Psychiatric Disorders. With respect to panic disorder, efficacy has been established in two RCTs, one including a 40 mg/day regimen of the SSRI paroxetine. In the latter study, 225 mg/day of venlafaxine outperformed 75 mg/day and the paroxetine treatment. Despite the obvious parallels with clomipramine, the antiobsessional effects of venlafaxine have not been as extensively studied. Two large RCTs have shown the efficacy of venlafaxine XR in PTSD, but it is an off-label use.

There are studies pertaining to treatment of various other mood and anxiety disorders, ADHD, and other psychiatric disorders. Premenstrual dysphoric disorder may be thought of as a gender-specific form of brief recurrent depression, and it is known to be responsive to SSRIs. A randomized, double-blind, placebo-controlled study evaluated flexible doses of venlafaxine therapy (range from 50 to 200 mg/day) across four menstrual cycles among 157 women with premenstrual dysphoric disorder. There was significantly greater improvement in the venlafaxine group compared to the placebo group across measures of emotion, function, physical symptoms, and pain.

Tolerability

Venlafaxine has a safety and tolerability profile that approaches that of the more widely prescribed SSRI class. For example, in the pooled data set of Michael Thase and colleagues, 9 percent of venlafaxine-treated patients withdrew because of adverse events, as compared to 7 percent of SSRI-

treated patients.

Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine therapy. The mechanism mediating this side effect is thought to be stimulation of central 5-HT type 3 (5-HT_3) receptors. With an incidence of as great as 35 percent in short-term placebo-controlled trials, nausea is approximately one-third more likely than seen with SSRIs. This is presumed to be because low–protein-binding results in relatively high concentrations of free (biologically active) venlafaxine in the CNS shortly after dosing. Nausea reliably diminishes in prevalence and severity during the first few weeks of therapy, presumably because of desensitization of 5-HT_3 receptors. Use of the XR formulation somewhat reduces the incidence and intensity of nausea, as does taking the medication with meals. Initiating therapy at lower dosages (37.5 mg/day) also may help attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT_3 antagonist or mirtazapine.

As with other 5-HT reuptake inhibitors, venlafaxine therapy is associated with sexual side effects, predominantly decreased libido, and a delay to orgasm or ejaculation. The incidence of these side effects is underreported in clinical trials and may exceed 30 to 40 percent when there is direct, detailed assessment of sexual function. Although the exact mechanisms of the sexual side effects are not known, it is thought that 5-HT–mediated inhibition of NE and dopamine effects is implicated.

Other common (reported by >10 percent of subjects in published studies) side effects include headache, insomnia, somnolence, dry mouth, dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, the drug has no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Hypertension

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of blood pressure. Experience with the IR formulation in studies of depressed patients indicated that sustained hypertension was dose related; increasing from 3 to 7 percent at doses of 100 to 300 mg/day and to 13 percent at doses greater than 300 mg/day. In this data set, venlafaxine therapy did not adversely affect blood pressure control of patients taking antihypertensives and actually lowered mean values of patients with elevated blood pressure readings before therapy. In controlled studies of the XR formulation, venlafaxine therapy resulted in only approximately a 1 percent greater risk of high blood pressure when compared to placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies thus greatly attenuated concerns about elevated blood

pressure. When higher doses of the XR formulation are used, however, monitoring of blood pressure is recommended.

Discontinuation Syndrome

Venlafaxine is one of the antidepressants most commonly associated with a discontinuation syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. As the XR formulation does *not* affect the elimination half-life of the compound, it does not decrease the potential for discontinuation symptoms. Patients need to be informed that venlafaxine therapy should not be stopped abruptly and that even missing a few days of therapy may provoke discontinuation symptoms. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped (e.g., reducing the daily dose by no more than 75 mg each week). On occasion, substituting a few doses of fluoxetine may help to bridge this transition, especially at the last step of discontinuation.

Overdose

There were no overdose fatalities in premarketing trials, although ECG changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, 5-HT syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs or alcohol, or both. In an analysis of fatal antidepressant overdoses in the United Kingdom from 1993 to 1999, Nicholas A. Buckley and Peter R. McManus found that venlafaxine had a significantly greater fatal toxicity index (a measure of overdose deaths/million prescriptions) than the SSRIs (13.2 vs. 0.7 to 3.0). These data could raise some concerns about the first-line use of venlafaxine for treatment of suicidal patients. However, it should be noted that the authors did not take into account that psychiatrists wrote most of the venlafaxine prescriptions in the United Kingdom during the time in which these data were collected, whereas the SSRIs were widely prescribed by primary care providers. Thus, the higher fatality index may be describing more the patient profile treated with venlafaxine (i.e., inpatients or those with more chronic, severe, or treatment-resistant mood disorders), rather than the toxicity of the drug.

Drug–Drug Interactions

Venlafaxine is metabolized in the liver primarily by the cytochrome P450 (CYP) 2D6 isoenzyme. Because the parent drug and principal metabolite

are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of CYP 1A2, CYP 2C9, CYP 2C19, and CYP 3A4.

Venlafaxine is contraindicated in patients taking MAOIs because of the risk of a pharmacodynamic interaction (i.e., serotonin syndrome). An MAOI should not be started for at least 7 days after stopping venlafaxine. There are now considerable data from trials of augmentation of inadequate response to antidepressants by atypical antipsychotics with no apparent complications. Regarding the combination of venlafaxine with lithium (Eskalith) and anticonvulsants, clinical judgment should be exercised when combining medications given the paucity of data.

DULOXETINE

Duloxetine hydrochloride is a propanamine compound that was synthesized in the 1980s by the same drug discovery team that identified the SSRI fluoxetine (Fig. 34.26–1). Like fluoxetine, duloxetine is a potent 5-HT uptake inhibitor and lacks affinity for muscarinic, histaminic, and α- and β-adrenergic receptors. Unlike fluoxetine, duloxetine is also a relatively potent inhibitor of NE reuptake and in in vitro studies, duloxetine was found to be a substantially more potent NE reuptake inhibitor than venlafaxine. If these studies predict effects in the brain, duloxetine should be expected to produce dual reuptake inhibition at lower absolute doses than observed with venlafaxine. Duloxetine was approved by the FDA for treatment of major depressive disorder in 2004; other indications include generalized anxiety disorder, fibromyalgia, neuropathic pain associated with diabetic peripheral neuropathy, and chronic musculoskeletal pain.

Pharmacology

Orally administered duloxetine is well absorbed, and peak plasma levels are achieved approximately 3 hours after ingestion. Duloxetine has no active metabolites and exhibits linear pharmacokinetics within a dose range of 20 to 120 mg. Steady-state concentrations are achieved within 3 days of oral dosing, and the drug has an elimination half-life of approximately 12 hours (Fig. 34.26–3).

In the plasma, approximately 90 percent of the drug is protein bound. After hepatic oxidation, metabolites of duloxetine are primarily eliminated by the kidneys. Duloxetine is metabolized by CYP 1A2 and is a moderately potent inhibitor of the CYP 2D6 isoenzyme.

FIGURE 34.26–3. Meta-analytic comparison of duloxetine (40 to 120 mg/day) and two selective serotonin reuptake inhibitors (SSRIs; fluoxetine and paroxetine; 20 mg/day) in six placebo-controlled studies of major depressive disorder. Remission defined as Hamilton Depression (HAMD) Rating Scale Score <7 at end point. Both antidepressants were more effective than placebo overall, with a significant advantage for duloxetine over the SSRIs among the subset of patients scoring 19 or higher on the 17-item HAMD. (From Thase ME, Pritchett YL, Ossanna MJ, Swindle RW, Xu J, Detke MJ. Efficacy of duloxetine and selective serotonin reuptake inhibitors: comparisons as assessed by remission rates in patients with major depressive disorder. *J Clin Psychopharmacol*. 2007;27:672–676.)

Antidepressant Efficacy

Eight phase II and phase III placebo-controlled, randomized, controlled trials were completed to establish efficacy and safety; these studies formed the basis for the FDA's approval of duloxetine therapy of major depressive disorder. No evidence of a dose–response relationship was observed between 60 mg/day and 120 mg/day; somewhat weaker antidepressant effects were observed at 40 mg/day. These clinical results are fully consistent with the observations that 40 mg of duloxetine reached the 80 percent occupancy level of the 5-HT transporter in the brain, achieved with the minimal effective doses of SSRIs and venlafaxine, but that 60 mg once daily was necessary to maintain it. Studies using in vivo methods to assay NE transporter occupancy rates are needed to determine the extent to which NE uptake inhibition contributes to therapeutic efficacy at various doses.

Six of the initial registration studies of duloxetine (40 to 120 mg/day) included an SSRI as an active comparator. A meta-analysis confirmed that both duloxetine and the comparators were effective and, among the subset of patients with moderate-to-severe depressive symptoms, there was a significant advantage favoring the SNRI in remission rates (Fig. 34.26–3). However, none of these studies utilized the 60 mg/day dose of duloxetine and all of these studies used low (20 mg/day) doses of the comparators

(fluoxetine or paroxetine). Three studies subsequently compared duloxetine (60 mg/day) versus escitalopram (10 to 20 mg/day). No advantage in efficacy was observed for the SNRI and tolerability indices favored escitalopram. A pooled analysis of a pair of 6-week double-blind studies contrasting duloxetine (60 mg/day) and venlafaxine XR (150 mg/day) likewise found significant differences in efficacy. Duloxetine therapy was associated with a significantly higher incidence of nausea; venlafaxine therapy was associated with a higher incidence of treatment-emergent high blood pressure and, following withdrawal of study medication, discontinuation emergent symptoms.

Tolerability

The discontinuation rate due to adverse events in the studies summarized by Charles Nemeroff and colleagues was 15 percent in duloxetine-treated patients and 5 percent in placebo-treated patients. Side-effect attrition was slightly higher in the duloxetine groups in the studies that used fluoxetine (10 vs. 6 percent) and paroxetine (14 vs. 10 percent) comparison groups, although these differences were not statistically significant in individual studies. The most commonly reported side effects during duloxetine therapy were nausea (22 percent), dry mouth (16 percent), fatigue (11 percent), dizziness (11 percent), and somnolence (8 percent). Incidence of sexual dysfunction appears to be comparable to that of the SSRIs. Of note, the incidence of nausea was similar for duloxetine (dosed twice daily) to fluoxetine and paroxetine (dosed every day) in head-to-head double-blind trials. Despite the drug's potential usefulness for treatment of urinary incontinence, urinary hesitancy and urinary retention were not common occurrences in studies of depressed patients.

Like other 5-HT uptake inhibitors, duloxetine therapy has been associated with sexual dysfunction and, after abrupt cessation, a characteristic discontinuation syndrome. It is not yet possible to determine the relative risks of these phenomena during duloxetine therapy on a continuum with the other newer antidepressants.

Duloxetine therapy resulted in a small increase in resting pulse rate (approximately two beats per minute) and an average increase in blood pressure of approximately 2 mm Hg in the studies reviewed by Nemeroff and colleagues. Of note, the risk of sustained high blood pressure during duloxetine therapy was approximately 1 percent greater than observed in placebo-treated patients. Curiously, the risk of increased blood pressure does not appear to be dose dependent.

Although the CYP enzyme inhibition profile of the drug looks generally favorable, duloxetine levels are about 30 percent lower in smokers, likely as a result of CYP 1A2 induction, and increased fourfold by potent CYP 1A2 inhibitors, like fluvoxamine and some fluoroquinolone antibiotics. A lethal interaction with MAOIs is expected with duloxetine and the guidelines

suggested previously for venlafaxine therapy must be followed.

MILNACIPRAN AND LEVOMILNACIPRAN

The SNRI, milnacipran is available in Japan and several European countries for the treatment of major depressive disorder, but in the United States only for the treatment of fibromyalgia (Fig. 34.26–1). Milnacipran is distinguished as a dual reuptake inhibitor that on the basis of in vitro and in vivo studies may be viewed as the converse of that of duloxetine and venlafaxine, an NSRI rather than an SNRI. Specifically, milnacipran is several times more potent for inhibition of NE uptake than for 5-HT reuptake inhibition. Milnacipran thus can be thought of as a relatively selective NE uptake inhibitor at the minimum therapeutic dosage (50 mg/day) that exerts progressively greater inhibitory effects on 5-HT reuptake at higher doses (i.e., 200 mg/day, its maximal recommended dose for fibromyalgia). Like the other SNRIs, milnacipran has virtually no affinity for muscarinic, histaminic, or α- and β-noradrenergic receptors.

Pharmacology

Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg/day. Metabolized in the liver, milnacipran has no active metabolites. Milnacipran is primarily excreted by the kidneys. Most orally administered milnacipran is bioavailable, and only 13 percent of milnacipran is bound to plasma protein. Milnacipran is not a potent inhibitor of any of the CYP isoenzymes.

Antidepressant Efficacy

The countries that have approved milnacipran for general use as an antidepressant have not required completion of a large number of placebo-controlled studies, and hence, efficacy is not as well established as is the case for venlafaxine or duloxetine. A meta-analysis of 16 RCTs (including all published and unpublished studies) encompassing 2,277 patients concluded that milnacipran did not have significantly different efficacy, acceptability, and tolerability when compared to other antidepressant agents. However, when compared to TCAs, fewer patients dropped out due to side effects on milnacipran.

Tolerability

In comparative clinical trials, milnacipran therapy was associated with significantly fewer anticholinergic and antihistaminic side effects than the tertiary amine TCAs, and fewer GI side effects than the SSRIs. Noteworthy side effects (i.e., incidence greater than an SSRI) included dizziness, sweating, and urinary hesitancy. Neither prospective data nor any expert opinion on the incidence of sexual dysfunction, especially when contrasted

to the SSRIs, could be located. Likewise, potential for lethality in overdose has not been systematically examined. Like 5-HT reuptake inhibitors, milnacipran should not be prescribed in proximity to an MAOI.

Characteristics of Levomilnacipran

Levomilnacipran is the active enantiomer of the racemic mixture of milnacipran. It is available in an extended release formulation and has a higher maximal plasma concentration (peaks in 6 to 8 hours), a greater area under the curve, and a longer half-life (12 hours) than its much less active dextrorotatory enantiomer. It is only 22 percent bound to plasma proteins and excreted by the kidneys 58 percent unchanged. It is recommended to initiate it at 20 mg/day for 2 days and gradually increase the dose to 40, 80, and 120 mg/day according to tolerability and response. It is effective in the 40 to 120 mg/day based on a data set of five placebo-controlled studies on 2,598 patients aged 18 to 80. Interestingly, it was effective in patients aged 60 and older, a population that is generally resistant to other medications. There are no as yet active comparator studies. In both acute and long-term studies, there was no evidence for weight gain. On average, there was approximately a 7 beats/min increase in hear rate, a thumbprint of NE reuptake inhibition. Only prospective studies using specific sexual function scales, and not merely treatment-emergent adverse events, will determine whether it is less problematic than other more potent 5-HT reuptake inhibiting medications. As for other SNRIs, it is recommended to utilize a gradual taper to discontinue the medication.

The SNRIs venlafaxine, desvenlafaxine, duloxetine, milnacipran, and levomilnacipran are effective antidepressants. There is evidence of an ascending dose–response relationship for venlafaxine and, possibly, milnacipran. A substantial body of research documents that venlafaxine therapy (at higher doses) has stronger antidepressant effects than the SSRIs; some data suggest a similar advantage for duloxetine and, for patients with severe depression, milnacipran. The efficacy of venlafaxine also has clearly been established in controlled studies of generalized anxiety, social anxiety, and panic disorders. Treatment with SNRIs is generally well tolerated. Tolerability and safety profiles are superior to the TCAs and approach that of the SSRIs. A higher initial incidence of nausea and, at higher doses, elevated blood pressure may be distinguishing characteristics of venlafaxine therapy. Apart from duloxetine, the four other medications have a low potential for CYP-mediated drug–drug interactions.

▲ 34.27 Selective Serotonin Reuptake Inhibitors

NORMAN SUSSMAN, M.D.

INTRODUCTION AND OVERVIEW

As a class, the selective serotonin reuptake inhibitors (SSRIs) have been the most widely used psychopharmacological agents for depression worldwide for nearly three decades. They are still extensively prescribed, in part because drugs of this class have been found to be effective in treating a range of disorders and symptoms other than depression. The most important of these are the anxiety disorders. From a historic perspective, the most significant impact of fluoxetine and subsequent SSRIs may have been the attention they generated in the popular press, which helped to reduce the longstanding stigma and fear of taking antidepressants. Patients became more amenable to come forward for treatment.

Clinicians also became less reluctant to prescribe antidepressants, because the side-effect profile of the SSRIs were devoid of side effects associated with the earlier antidepressant drugs—the tricyclics (TCAs) and MAOIs. These included dry mouth, constipation, sedation, orthostatic hypotension, and tachycardia. The ease of SSRI dosing led to clinicians other than psychiatrists prescribing SSRIs. Another very important consideration in the adoption of SSRIs as first-line treatments was their wide therapeutic index. Deaths from antidepressant overdoses plummeted after of SSRIs supplanted TCAs as the mainstays of treatment.

It needs to be kept in mind that the SSRIs have never been shown to be more effective than any other antidepressants. All of the SSRIs, starting with fluoxetine and followed by sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), and escitalopram (Lexapro), have been shown to be equally effective as antidepressants. Neither has the atypical antidepressant vortioxetine been found to produce higher response and remission rates than the SSRIs. There are, however, meaningful differences in pharmacodynamics and pharmacokinetics that might affect clinical responses among individual patients. In fact, some patients respond better to a particular SSRI than another.

SSRIs have proven more problematic in terms of side effects than the

original clinical trials suggested. In clinical practice, quality-of-life-associated adverse effects such as sexual dysfunction, weight gain, and emotional blunting often mitigate the therapeutic benefits of the SSRIs. These side effects were not captured in the short-term pivotal trials of these agents. It should also be noted that some patients report a diminished response or total loss of response to SSRIs with recurrence of depressive symptoms while remaining on a full dose of medication. The exact mechanism of this so-called "poop-out" is unknown, but the phenomenon is commonly seen in clinical practice.

Included in this section is vortioxetine (Brintellix), even though it is not an SSRI. Vortioxetine is classified as an atypical antidepressant, more specifically, a serotonin modulator and stimulator.

THERAPEUTIC INDICATIONS

The extensive use of SSRIs also derives from the fact that they are approved by the FDA for the following indications: Major depression, OCD, PTSD, PMDD, panic disorder, and social phobia (social anxiety disorder). Not all SSRIs have FDA approval for some of these indications, but it is commonly assumed that they in fact have a common spectrum of action.

Major Depression

Thousands of patients have participated in dose-ranging studies and active comparator trials of SSRIs. They may well be the most-studied drugs in the history of psychiatry in terms of the number of patients who have taken them in controlled clinical trials. The majority of studies included outpatients between 18 and 65 years of age with major depressive disorder of at least moderate severity (Hamilton depression [HAMD] Scale >20). These studies show that there is a wide range of doses effective in the treatment of moderate or severe depression.

Meta-analyses of studies that compared the SSRIs have found them to show equal effectiveness as antidepressants. In these analyses, about one-third of patients in short-term (6- to 8-week) placebo-controlled trials achieved full remission as determined by rating scales, about one-third had a partial response and one-third had no response.

One meta-analysis of SSRI showed the drugs had little benefit over placebo in mild and moderate depression but clinically significant benefits over placebo in patients with more severe depression. On the other hand, there have been numerous studies demonstrating the effectiveness of SSRIs in the treatment of dysthymia and other forms of chronic mild depression.

An FDA systematic review of all SSRI maintenance trials submitted to the agency between 1985 and 2012 found that maintenance treatment reduced the risk of relapse by 52 percent compared to patients treated with placebo.

Generalized Anxiety Disorder

Studies of SSRIs in the treatment of GAD have shown the effectiveness of these agents to be greater than the effectiveness of placebo in treating this condition. SSRIs have also been demonstrated to be effective in preventing relapse after the successful treatment of GAD. There may be continuing improvement over a 6-month period in those receiving SSRIs, suggesting the usefulness of ongoing treatment.

Obsessive-Compulsive Disorder

Placebo-controlled studies have demonstrated SSRIs to be efficacious for the treatment of OCD in adults and children. In some but not most cases, doses higher than the maximum recommended for depression are needed. Full response to treatment may take longer than is the case in depressive disorders.

Intravenous administration of citalopram has been studied as a treatment for OCD. Among patients with moderate to severe DSM-IV-diagnosed OCD who had failed at least two adequate treatment trials of SSRIs, excluding citalopram, about 60 percent of patients had a significant decrease in OCD symptoms after 3 weeks of intravenous citalopram.

Panic Disorder

SSRIs decrease the frequency of panic attacks by about 80 percent and decrease associated anticipatory anxiety. Sertraline results in an improvement of quality of life on most parameters. Previous unsuccessful treatment with benzodiazepines does not diminish their efficacy. The response rate may be lower for patients with more severe panic. Patients experience distinct withdrawal, expressed primarily as insomnia and dizziness, and a significant part of the relapse rate among the discontinued patients could possibly be accounted for by the withdrawal syndrome. When stopping SSRIs in patients with panic disorder, gradual discontinuation is recommended.

Social Phobia

SSRIs have been successfully used for the treatment of social phobia. Improvement may be achieved slowly, becoming evident during the second month of treatment and continuing to increase until the third month. The combination of SSRIs and cognitive-behavior therapy is more rapid and more complete than the use of an SSRI alone.

Premenstrual Dysphoric Disorder

SSRIs are effective in alleviating the symptoms of PMDD. Improvement may be seen during the first week of treatment. Mood, irritability, and

anxiety improve. Physical symptoms, such as swelling, bloating, and breast tenderness, are less responsive to treatment.

Posttraumatic Stress Disorder

Placebo-controlled studies have confirmed the efficacy of SSRIs for severe chronic PTSD. Discontinuation of the successful treatment after 6 months might result in the return of the PTSD symptoms in about half of patients.

Other Indications

SSRIs can be used for the treatment of premature ejaculation. In this case, paroxetine may be the most useful of these drugs. However, they require continuous daily treatment to delay ejaculation significantly.

PHARMACODYNAMICS

All SSRIs bind to and inhibit the action of serotonin transporters. This raises serotonin levels in the CNS and throughout the body. The SSRIs act not only on the 5-HT transporter in presynaptic neurons, but also at other sites, some well characterized, others not as clearly delineated. It is not clear whether the degree of SSRI selectivity offers any therapeutic benefit. Studies have failed to demonstrate differential efficacy of any SSRI in the treatment of psychiatric disorders. One must be cautious, however, in extrapolating group effects to those of an individual patient, given that studies have shown that patients who fail to respond to one may respond to another of these drugs.

Medications other than the SSRIs that demonstrate appreciable inhibition of the 5-HT transporter are clomipramine (Anafranil), duloxetine (Cymbalta), milnacipran (Savella available in the United States only for the treatment of fibromyalgia), levomilnacipran (Fetzima), and venlafaxine (Effexor). These agents also act through norepinephrine reuptake inhibition. SSRIs are essentially devoid of any clinically significant degree of receptor antagonistic properties at the muscarinic, cholinergic, H_1, M1-adrenergic, M2-adrenergic, β-adrenergic, 5-HT_1, and 5-HT_2 receptors. Sertraline is approximately 4-fold less potent than paroxetine and 60-fold less potent than amitriptyline at inhibiting [^{3}H]quinuclidinyl benzilate binding, which is a measure of muscarinic cholinergic receptor antagonism. However, paroxetine has the greatest affinity for muscarinic cholinergic receptors of the available SSRIs and therefore produces, in a small percentage of patients, dry mouth, constipation, blurred vision, or urinary hesitancy. However, the affinity of paroxetine for muscarinic receptors as measured by inhibition of [^{3}H]quinuclidinyl benzilate binding is 15-fold less potent than that of amitriptyline, and its anticholinergic properties may underlie its lack of side effects such as diarrhea and loose stools observed with other SSRIs

and its occasional sedating properties.

PET studies of the effect of antidepressants have been used for in vivo confirmation of in vitro and ex vivo derived hypotheses of mechanisms of action as well as for clinical dose finding. For example, one study used PET imaging to measure occupancies of citalopram, fluoxetine, sertraline, paroxetine, or extended-release venlafaxine at minimum therapeutic doses. It investigated the relationship between dose and occupancy. Striatal 5-HTT binding potential was measured before and after 4 weeks of medication administration. Healthy subjects received subtherapeutic doses; subjects with mood and anxiety disorders received therapeutic doses. Percent reduction in 5-HTT binding potential for each medication and dose was calculated. The findings suggested that 80 percent 5-HTT blockade is necessary for an antidepressant effect. A later study looked at a sample of patients in remission from depression, and found 5-HTT occupancy was significantly lower (61 to 74 percent, 95 percent confidence intervals) in the remitted patients.

THERAPEUTIC INDICATIONS

Although not all of the SSRIs have obtained the needed approval for treatment of each of these disorders, the spectrum of action of the SSRIs appears to be a class effect. The current approved indications for the SSRIs are shown in Table 34.27–1.

[a]Available as immediate and controlled release.

[b]Available as immediate- and controlled-release paroxetine HCl as well as immediate-release HCl and mesylate salt.

The SSRIs, as a class, clearly demonstrate superiority in terms of safety when compared to the older antidepressant medications. SSRIs differ from TCAs is that they are devoid of cardiac toxicity. In addition, in contrast to the TCAs, MAOIs, and trazodone (Desyrel), the SSRIs are not antagonists at α-adrenergic receptors and therefore do not produce orthostatic hypotension. In general, with the exception of paroxetine, the SSRIs are relatively devoid of anticholinergic activity and do not demonstrate typical anticholinergic side effects, such as dry mouth, pupillary dilatation, constipation, urinary retention, or confusion. Even though paroxetine has more anticholinergic activity than the other SSRIs, it is only a fraction of that seen with the TCAs.

Each of the SSRIs is structurally unique (Fig. 34.27–1), although escitalopram is the *S*-enantiomer of the racemic mixture that is citalopram, and these differences are seen in the selectivity of reuptake inhibition, drug–drug interactions, and pharmacokinetic profiles. **Studies of the reuptake inhibitory potencies of the SSRIs in vitro have been performed. Although different studies show different values, in general, the K_i values tend to be similar and of the same relative ordering across studies. When interpreting in vitro data and attempting to extrapolate findings regarding relative degrees of reuptake inhibition to in vivo predictions, pharmacokinetic data such as steady-state concentrations, protein binding, molecular weights, and the presence or absence of active metabolites must all be accounted for.**

The combination of fluoxetine and olanzapine (Symbyax) is approved for the treatment of bipolar depression. All of the SSRIs, with the exception of fluvoxamine, were initially approved for the treatment of major depressive disorder. Fluvoxamine is unique in that it is only indicated for the treatment of OCD in the United States. This is a consequence of commercial considerations, not of any significant difference in its clinical profile. It shares the same therapeutic spectrum of activity with the other SSRIs and is widely used as a treatment of major depressive disorder in other countries worldwide.

EFFICACY

As already noted, innumerable clinical trials have failed to produce conclusive evidence that any SSRI is more effective or produces a greater degree or more rapid clinical improvement than any other agent in the class. Moreover, there are no proven differences in effectiveness between

SSRIs and other classes of antidepressants. Ultimately, treatment decisions should be based on considerations of relative patient acceptability, toxicity, and cost. There is also no compelling evidence that any one SSRI possess greater efficacy as an antidepressant or antianxiety treatment than another.

Fluvoxamine

Fluoxetine

Sertraline

Citalopram

Escitalopram

FIGURE 34.27–1. Structures of selective serotonin reuptake inhibitors.

In clinical trials for depression, the number of responders and remitters to the SSRIs are similar across clinical trials. About one-third of patients achieve response, one-third of patients achieve remission, and one-third show no response during an initial treatment period of 6 to 12 weeks. Some patients may demonstrate a better response to one of these agents than to another. The reason for this differential responsiveness is not known, and it is not possible to predict treatment response when initiating treatment.

TOLERABILITY

Both the therapeutic and adverse event profiles of SSRIs are the result of their blockade of serotonin transporter function. They raise serotonin levels in the CNS and throughout the body, with this action being particularly evident in the GI tract. As a group, the SSRIs possess the adverse effects listed in Table 34.27–2.

When reviewing product information for the SSRIs, both the frequency and severity of side effects need to be considered.

Gastrointestinal

Nausea occurs in at least 25 to 40 percent of patients and can range from mild discomfort to, in some patients, vomiting. It is the most common early side effect of SSRI, and most often diminishes during the first weeks of treatment. Nausea at the initiation of treatment is generally dose related. Accordingly, typical starting doses that are used to reduce this side effect are half of the usual starting dose. After 2 to 4 days at the lower doses, or when GI side effects resolve, the dose size is usually doubled. Flatulence may be another SSRI side effect. Unlike nausea, it tends to persist and prove socially embarrassing.

Table 34.27–2.
Selected Treatment-Emergent Adverse Events

Autonomic nervous system disorders
Dry mouth
Increased sweating
Central and peripheral nervous system disorders
Dizziness
Emotional blunting
Mild forgetfulness
Gastrointestinal disorders
Nausea
Diarrhea
Constipation
Indigestion
Abdominal pain

Psychiatric disorders

- Somnolence
- Decreased appetite
- Decreased libido

Respiratory system disorders
- Rhinitis
- Sinusitis

Urogenital
- Ejaculation disorder
- Impotence
- Anorgasmia

General
- Influenza-like symptoms
- Fatigue
- Yawning
- Rash

Sexual Dysfunction

Sexual dysfunction, such as delayed ejaculation in men, delayed orgasm or anorgasmia in women, and diminished libido is a common side effect of 5-HT reuptake inhibition. Antidepressant-associated sexual dysfunction is the most frequent side-effect–associated cause of premature medication treatment discontinuation. Package insert data, almost always derived from phase III clinical trials, have underestimated the true incidence of sexual dysfunction, which is seen in clinical practice in nearly half of all treated patients. Reliable estimates of the incidence and severity of untoward experiences involving sexual desire, performance, and satisfaction are difficult to obtain, however, in part because patients and physicians may be reluctant to discuss them. Accordingly, estimates of the incidence of untoward sexual experience and performance cited in product labeling are likely to underestimate their actual incidence.

In some but not most instances, sexual dysfunction appears to be a dose-related effect, and occasionally decreasing the dose might be helpful. There have been a number of strategies suggested to deal with this important adverse effect, including decreased dose, drug holidays for shorter half-life SSRIs, or addition of buspirone, amantadine, yohimbine, cyproheptadine, stimulants, or bupropion. Anecdotally, selective inhibitors of cGMP-specific phosphodiesterase type 5 (PDE5), such as sildenafil (Viagra), have been reported by some patients to be helpful. One large study that used sildenafil treatment of sexual dysfunction in women taking SRRIs found that its use was associated with a reduction in adverse sexual effects and an improvement in treatment adherence rate. These findings need to be replicated. In fact, none of these approaches appears to be completely successful in reversing sexual side effects.

Sweating

Excessive sweating is not uncommon while being treated with SSRIs. The sweating is unrelated to ambient temperature. Nocturnal sweating may drench bed sheets and require a change of nightclothes. Terazosin, 1 or 2 mg per day, is often dramatically effective in counteracting sweating.

Discontinuation Syndrome

Drugs that have 5-HT reuptake inhibition have the potential to produce a discontinuation syndrome if stopped abruptly. Longer durations of treatment appear, at least in clinical observation, to be associated with a higher probability of discontinuation syndrome than do shorter treatment periods. Similarly, drugs with shorter half-lives are more likely to produce a discontinuation syndrome than those with longer half-lives, although it may also be the factor of discontinuation syndromes being less readily recognized in the latter group. In general, good clinical practice dictates a gradual tapering down of an antidepressant after a successful treatment.

The incidence of this syndrome is inversely proportional to the half-life of the compound. Typical symptoms include asthenia, anxiety, agitation, GI distress, myalgias, sometimes a flu-like syndrome but with the absence of a fever, disequilibrium, and, in extreme cases, an experience described as electrical shocks coursing through the arms and legs. This can often be prevented by advising patients to avoid abrupt discontinuation of the antidepressant (i.e., away for a weekend and neglecting to take the medicine bottle with them or skipping 2 or 3 days of treatment) and, when discontinuing the medication, to do so over the course of weeks rather than days. Drug tapers that become problematic as the last dose is stopped only to see an emergence of the discontinuation syndrome can often be accomplished by prescribing fluoxetine 20 mg per day for 2 weeks and then stopping that medication. Presumably, the longer half-lives of fluoxetine and norfluoxetine counter the discontinuation effects to a significant degree. It is not clear whether there is a discontinuation syndrome that emerges on the discontinuation of fluoxetine. If present, it is most likely delayed compared to that with the other SSRIs.

Although all SSRIs are associated with the possibility of a withdrawal syndrome, the onset is more immediate and more intense with some of the drugs. Decreasing doses every 2 to 3 days by small increments decreases the chances of encountering a discontinuation syndrome. Perhaps one of the more common scenarios in which this is encountered is with the patient who goes away for the weekend and neglects to take his or her prescription. Patient counseling is an important preventative measure in these cases. Occasionally, although rarely, there are patients who find it difficult to complete a taper off shorter–half-life drugs, such as paroxetine, sertraline, citalopram, escitalopram, or fluvoxamine. Anecdotal evidence suggests that a dosing of fluoxetine, 20 mg per day for 2 weeks, which is then stopped, may be helpful for those patients.

Bleeding

Both case reports and epidemiological studies confirm that SSRIs alone may increase bleeding risk in some patients. There have been numerous case reports and case series describing abnormal bruising, bleeding, and heavy menses in patients taking SSRIs. Serotonin is released from platelets following vascular injury. It promotes vasoconstriction and a change in the shape of the platelets that leads to aggregation. Platelets cannot themselves synthesize serotonin, so SSRIs deplete serotonin in the platelets, which may decrease coagulation, leading to excessive bleeding diathesis in some patients. Other physiological mechanisms may also be involved. There is an additive increase in bleeding risk when SSRIs are used concurrently with other drugs that can cause bleeding. SSRIs, for example, increase the incidence of serious bleeding in patients taking warfarin. Risk is also increased with concurrent use of nonsteroidal anti-inflammatory drugs, aspirin, or clopidogrel. A large general practice database search of an analysis data involving nearly 400,000 patients found that the number needed to harm for upper GI bleeding with SSRI treatment in a low-risk population was 3,177; and in a high-risk population it was 881. Thus, this risk associated with SSRI use is modest.

Hyponatremia

There is an increased risk of hyponatremia in patients taking SSRIs. Risk factors include older age, female gender, volume depletion, and use of other medications or medical conditions causing hyponatremia. SSRI-induced hyponatremia typically begins during the first weeks of treatment. In mild cases medication should be stopped (if possible) and water restriction started. The condition should normalize in about 2 weeks. Sodium replacement, if necessary, should not be too aggressive treatment (3 percent saline, with or without furosemide) unless the symptoms are acute or sodium is less than 110 mEq/L. Replacement should be no faster than 0.5 mEq/L per hour correction (to avoid the risk of central pontine myelinolysis). Once sodium reaches 120 mEq/L, there should be water restriction only. This side effect is reversed on discontinuation of the drug. This may be secondary to the syndrome of inappropriate antidiuretic hormone. Groups at risk include elderly patients, patients concomitantly treated with diuretics, and patients who were volume depleted.

Cardiovascular Effects

All SSRIs can lengthen the QT interval in otherwise healthy people and cause drug-induced long QT syndrome, possibly leading to torsade de pointes, especially when taken in overdose. The risk of QTc prolongation increases when an antidepressant and an antipsychotic are used in combination, an increasingly common practice. In 2011, the FDA has

issued a safety warning about high-dose citalopram treatment. It made the following recommendation regarding citalopram use.

- 20 mg/day is the maximum recommended dose for patients with hepatic impairment, who are older than 60 years of age, who are CYP2C19 poor metabolizers, or who are taking concomitant cimetidine.
- No longer prescribe at doses greater than 40 mg/day.
- Do not use in patients with congenital long QT syndrome.
- Correct hypokalemia and hypomagnesemia before administering citalopram.
- Monitor electrolytes monitored as clinically indicated.
- Consider more frequent EKGs in patients with CHF, bradyarrhythmias, or patients on concomitant medications that prolong the QT interval.

This was based on a QT study assessing the effects of 20- and 60-mg doses of citalopram on the QT interval in adults, compared with placebo, found a maximum mean prolongation in the individually corrected QT intervals were 8.5 milliseconds (ms) for 20-mg citalopram and 18.5 ms for 60 mg. For 40 mg, prolongation of the corrected QT interval was estimated to be 12.6 ms.

Comments

A 2013 study done at the Ann Arbor VAMC and the University of Michigan failed to confirm an increased risk for arrhythmias or death associated with daily doses of more than 40 mg. These findings do raise questions about the continued legitimacy of the FDA warning.

The study looked at the records of more than 600,000 VHA patients who received citalopram prescriptions between 2004 and 2009, as well as patient outcomes for more than 300,000 treated with, sertraline, which does not have an FDA warning.

According to study results, citalopram daily doses greater than 40 mg were actually associated with lower risks of ventricular arrhythmia (adjusted hazard ratio = 0.68, 95 percent CI = 0.61 to 0.76), all cause mortality (adjusted hazard ratio = 0.94, 95 percent CI = 0.90 to 0.99) and noncardiac mortality (adjusted hazard ratio = 0.90, 95 percent CI = 0.86 to 0.96) compared with daily doses of 1 to 20 mg. Overall, no increased risks of cardiac mortality were found, according to the researchers.

Physicians should consider whether the benefits of androgen deprivation therapy outweigh the potential risks in SSRI-treated patients with prostate cancer as reductions in androgen levels can cause QTc interval prolongation.

Dextromethorphan/Quinidine (Nuedexta) is available as a treatment for pseudobulbar affect, which is defined by involuntary, sudden, and frequent episodes of laughing and/or crying that are generally out of

proportion or inappropriate to the situation. Quinidine that can prolong the QT interval is a potent inhibitor of CYP2D6. It should not be used with other medications that prolong the QT interval and are metabolized by CYP2D6. This drug should be used with caution with any medications that can prolong the QT interval and inhibit CYP3A4, particularly in patients with cardiac disease.

Antepartum use of SSRIs is sometimes associated with QTc interval prolongation in exposed neonates. In a review of 52 newborns exposed to SSRIs in the immediate antepartum period and 52 matched control subjects, the mean QTc was significantly longer in the group of newborns exposed to antidepressants as compared with control subjects. Five (10 percent) newborns exposed to SSRIs had a markedly prolonged QTc interval (>460 ms) compared with none of the unexposed newborns. The longest QTc interval observed among exposed newborns was 543 ms. All of the drug-associated repolarization abnormalities normalized in subsequent electrocardiographic tracings.

Weight Gain

During early treatment, many patients lose weight. Over time, many patients regain this weight, and it is not uncommon for there to be a significant increase in weight over the following months. In some instances it becomes very difficult for patients to reverse this weight gain, even with rigorous dietary measures and exercise.

Diabetes

Population-based studies have shown that SSRIs may increase the risk of diabetes. An analysis was done based on three large well-known US datasets: the Nurses' Health Studies I and II and the Health Professionals Follow-up Study, a total of 139,000 women and 30,000 men. During over 1.6 million person-years of follow-up the analysis documented a total of 6,641 new cases of type 2 diabetes and found that self-reported antidepressant use was associated with an approximately 10 to 30 percent excess risk of developing diabetes. This association was robust to adjustment for age, ethnicity, marital and living status, smoking habits, alcohol intake, physical activity, family history of diabetes, diet, BMI and major comorbidities (e.g., hypertension and dyslipidemia), and their treatments. There needs to be additional evidence that this increased risk is due to associated factors or SSRI treatment, but these findings suggest that it is prudent to monitor patients periodically for changes in blood glucose levels.

Sleep Disturbances and Daytime Somnolence

Up to one-fourth of persons taking SSRIs note trouble sleeping, excessive

somnolence, or overwhelming fatigue. Bruxism is another side effect. Nocturnal motor activity, including nocturnal myoclonus, may be increased during SSRI treatment. Many persons taking SSRIs report recalling extremely vivid dreams or nightmares. They describe sleep as "busy." Some persons benefit from taking their SSRI dose before going to bed, but other prefer to take it in the morning. SSRI-induced insomnia can be treated with benzodiazepines, trazodone (Desyrel) (clinicians must explain the risk of priapism), or other sedating medicines. Significant SSRI-induced somnolence often requires switching to use of another SSRI or bupropion.

Emotional Blunting

Emotional blunting or indifference are largely overlooked side effects associated with chronic SSRI use. Patients report an inability to cry in response to emotional situations, a feeling of apathy or indifference, or a restriction in the intensity of emotional experiences. This side effect often leads to treatment discontinuation even when the drugs provide relief from depression or anxiety. The frequency of this syndrome is unknown since few empirical studies are available. It has a delayed onset, appears to be related to dosing, and may resolve with a dose reduction or discontinuation of the SSRI.

Yawning

Close clinical observation of patients taking SSRIs reveals excessive yawning as a side effect. This side effect is not well known by practitioners, so it is often overlooked. A 6-week, placebo-controlled, 446 subject trial of citalpram and placebo found 2 percent of participants in the citalopram arm developed yawning, as compared to <1 percent of patients taking placebo. Another study found that 7 percent of patients with OCD, 11 percent of patients with bulimia, and 1 percent of patients with panic disorder receiving fluoxetine experienced yawning as a treatment-emergent side effect of treatment. None of the placebo-treated patients reported this side effect. It should be noted that SSRI-related yawning is not a reflection of fatigue or poor nocturnal sleep but is postulated to be the result of SSRI effects on the hypothalamus. In rare instances, yawning is associated with spontaneous orgasms.

Extrapyramidal Symptoms

The SSRIs may rarely cause akathisia, dystonia, tremor, cogwheel rigidity, torticollis, opisthotonos, gait disorders, and bradykinesia. Rare cases of tardive dyskinesia have been reported. Some people with well-controlled Parkinson disease may experience acute worsening of their motor symptoms when they take SSRIs.

Laboratory Interferences

SSRIs do not interfere with any laboratory measures. Sertraline was found, in premarketing trials, to possess a weak uricosuric effect, with a mean decrease of uric acid by 7 percent.

CHEMISTRY AND PHARMACOKINETICS OF INDIVIDUAL SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The SSRIs as a class exhibit a broad range of chemical structures and serum half-lives ranging from hours to days. There is no evidence that the structure of the drug molecules differentiate the clinical benefits and risks of the drugs in any meaningful way. The wide range of serum half-lives does manifest clinically. This is true not only in terms of time to steady state and the time required for the drug to exit the body after it is stopped, but also in differing potentials for discontinuation syndrome on stopping the SSRI or, more commonly, after missing occasional doses. The SSRIs demonstrate moderate to high protein binding. Table 34.27–3 summarizes the pharmacokinetic properties of the SSRIs. The contribution of protein binding to potential drug–drug interactions is somewhat unclear. The only fraction of drug that is available to exert biological activity is the free drug in the plasma. Protein-bound drug does not equilibrate into the CNS, but neither is it available to be metabolized. The compartment of free drug can enter the CNS but is also subject to being metabolized. SSRIs, such as paroxetine, sertraline, and fluoxetine, are tightly protein bound, and only approximately 1/20 of the drug in the system exists as free drug, the balance being nonspecifically bound to serum proteins. It remains unknown whether clinically significant displacement of protein binding by the SSRIs occurs during concomitant therapy with other medications, such as warfarin (Coumadin). It can be argued that clinicians should actively look for such drug–drug interactions following the addition of one drug with high protein-binding characteristics to another, especially when functional assays (such as with warfarin) are available. Another area that requires exploration is the determination of the level at which protein binding becomes saturated and accumulation of free drug becomes a nonlinear process. This may have important implications for agents that demonstrate different mechanisms of action across low-to-high dosing ranges. The chemical structures of the individual SSRIs are illustrated in Figure 34.27–1, and their pharmacokinetic profiles are shown in Table 34.27–3.

Table 34.27–3.
Pharmacokinetic Profiles of the Selective Serotonin Reuptake Inhibitors

	Time to Peak Plasma	Half-	Half-Life	Time to Steady State	Plasma Protein

Drug	Concentration (hrs)	Life	Metabolite	(days)	Binding (percent)
Citalopram (Celexa)	4	35 hrs	3 hrs	7	80
Escitalopram (Lexapro)	5	27–32 hrs	—	7	56
Fluoxetine (Prozac)	6–8	4–6 days	4–16 days	28–35	95
Fluvoxamine (Luvox)	3–8	15 hrs	—	5–7	80
Fluvoxamine CR (Luvox CR)					
Paroxetine (Paxil)	5–6	21 hrs	—	5–10	95
Paroxetine CR (Paxil CR)	6–10	15–20 hrs	—	<14	95
Paroxetine mesylate (Pexeva)		21 hrs			
Sertraline (Zoloft)	4.5–8.5	26 hrs	62–104 hrs	7	95

CR, controlled release.

FLUOXETINE

Chemistry

Fluoxetine's empirical formula is $C_{17}H_{18}F_3NO \cdot HCl$, and it has a molecular weight of 345.79. Its chemical designation is (±)-*N*-methyl-3-phenyl-3-[(α–α–α-trifluoro-*p*-toylyl)-oxy]-propylamine hydrochloride.

Pharmacological Actions

Absorption. Fluoxetine is well absorbed orally, with 72 to 90 percent systemic availability, reflecting the combination of almost complete absorption and first-pass metabolism by liver hepatocytes. Maximum plasma concentration is achieved within 6 to 8 hours of ingestion after a single 40-mg dose. Peak plasma concentrations are not affected by food, but absorption may be delayed 1 to 2 hours. The delayed-release, enteric-coated preparation of once-weekly fluoxetine also demonstrates peak plasma levels 6 to 8 hours after absorption, although absorption does not begin until entry into the portion of the GI tract where the pH exceeds 5.5. There is more variability of peak and trough levels with the once-weekly preparation compared to once-daily dosing. In addition, the C_{max} after administration of the 90-mg, once-weekly preparation 1 day after 20-mg, once-daily dosing was 1.7 times higher than the C_{max} observed with once-daily dosing. When the transition to once-weekly dosing was delayed by 1 week after the last once-daily dose was given, the observed C_{max} was approximately equal. Fluoxetine is available as pulvules (10, 20, or 40 mg),

tablets (10 mg), an oral concentrate (20 mg/5 mL), and in an enteric-coated, delayed-release, once-weekly form (90 mg).

Distribution. In vitro, fluoxetine is approximately 95 percent bound to serum proteins (albumin and α_1–acid-glycoproteins) at concentrations of 200 to 1,000 ng/mL. The volume of distribution for fluoxetine and norfluoxetine, the biologically active metabolite, ranges from 20 to 45 L/kg. The rate of plasma clearance is 20 and 9 L/hr for fluoxetine and norfluoxetine, respectively. Fluoxetine is widely distributed, including excretion into breast milk.

Metabolism and Elimination. Fluoxetine is a racemic mixture of *R*-fluoxetine and *S*-fluoxetine in equal proportions. Both are approximately equipotent in 5-HT reuptake inhibition activity, although the *S*-fluoxetine enantiomer is more slowly eliminated and is therefore the predominant form in plasma at steady state. Fluoxetine undergoes demethylation in the liver to norfluoxetine and to a number of other unidentified minor metabolites of fluoxetine, although norfluoxetine is the only metabolite identified that possesses biological activity. In animals, the *S*-enantiomer of norfluoxetine is essentially equivalent in activity to that of *R*- or *S*-fluoxetine, but *R*-norfluoxetine has significantly less activity. The kidneys excrete inactive metabolites produced by hepatic metabolism.

The elimination half-life of fluoxetine is 1 to 3 days after acute administration and 4 to 6 days after chronic administration. Norfluoxetine has an elimination half-life of 4 to 16 days, independent of duration of administration. Steady-state levels of fluoxetine are higher than would be predicted based on single-dose administration. This is likely due to saturation of the cytochrome P450 (CYP) 2D6 isozyme and subsequent metabolism by alternate nonsaturable pathways. Steady state is achieved owing to the presence of the nonsaturable pathways. Norfluoxetine, in contrast, demonstrates a linear dose-proportion relationship. The long half-lives of fluoxetine and norfluoxetine indicate the possibility of drug–drug pharmacokinetic interactions for a sustained period of time after the discontinuation of the drug.

Individuals who are deficient in CYP 2D6 activity—so-called poor metabolizers—constitute 6 to 8 percent of the population and metabolize *S*-fluoxetine at a slower-than-expected rate. In contrast, metabolism of *R*-fluoxetine is normal. Owing to the slower metabolism of *S*-fluoxetine, it is present at higher-than-expected concentrations, but *S*-norfluoxetine is found at lower concentrations. The sum total of *S*-fluoxetine and *R*-fluoxetine and *S*-norfluoxetine and *R*-norfluoxetine is approximately equal between poor metabolizers and those with a full complement of CYP 2D6 activity.

Impairment of hepatic function is associated with impaired metabolism

of fluoxetine. In a series of subjects with cirrhosis of the liver, the mean half-life of fluoxetine was increased to 7.6 days, compared to 2 to 3 days for healthy subjects. The half-life of norfluoxetine was similarly increased to a mean of 12 days, compared to 7 to 9 days for healthy subjects. This would indicate the necessity of dose reduction in individuals with significant liver disease.

Renal disease does not appear to impair the metabolism of fluoxetine or norfluoxetine in single-dose studies. One small study (N = 12) of patients on dialysis receiving fluoxetine at 20 mg per day for 2 months found steady-state fluoxetine and norfluoxetine levels close to those observed in patients with intact renal function.

Geriatric patients (60 years of age and older) who were depressed demonstrated fluoxetine levels of 209.3 ± 85.7 ng/mL after dosing of 20 mg per day for 6 weeks. Children with OCD or major depressive disorder (6 to less than 13 years of age; N = 10), compared to adolescents (13 to less than 18 years of age; N = 11), receiving fluoxetine at doses of 20 mg per day showed steady-state (60 days) fluoxetine levels of 171 and 86 ng/mL, respectively. Norfluoxetine levels were also higher in children than in adolescents, 195 and 113 ng/mL, respectively. These differences appear to be primarily related to relative body mass differences, and the levels normalized when this was taken into account.

SERTRALINE

Chemistry

The empirical formula of sertraline is $C_{17}H_{17}NCl_2 \cdot HCl$; it has a molecular weight of 342.7. The structure of sertraline is distinct from that of other 5-HT reuptake inhibitors, and it is a naphthylamine derivative. The chemical designation is (1*S*-*cis*)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1-naphthalenamine hydrochloride.

Pharmacological Actions

Absorption. Sertraline is well absorbed orally, with equivalent absorption observed with tablets and the oral concentrate. Maximum systemic concentration is achieved within 4.5 to 8.4 hours of ingestion after 14 days of dosing in the range of 50 to 200 mg daily. When administered with food, the mean peak plasma concentration is increased by 25 percent with the tablet preparation, and the peak plasma concentration is achieved in 5.5 hours after ingestion, compared to 8 hours when given without food. Whether this food-related increase in sertraline plasma levels is clinically significant in terms of adverse events is unclear, although many clinicians advocate the initial administration of sertraline, like other that of SSRIs, after a meal. Administration of the oral concentrate preparation of sertraline with food is associated with a delay in the time to peak plasma

concentration of from 5.9 to 7.0 hours.

Distribution. In vitro, sertraline is approximately 98 percent bound to serum proteins at concentrations of 20 to 500 ng/mL. The volume of distribution for sertraline is approximately 20 L/kg, and the rate of plasma clearance is 96 L/hr. The extent of distribution of sertraline into breast milk has been studied in detail. The data suggest that sertraline is present in breast milk and in infant serum, albeit in low concentrations.

Metabolism and Elimination. Sertraline undergoes demethylation in the liver to *N*-desmethylsertraline. The half-life of sertraline is 26 hours, and the half-life of *N*-desmethylsertraline is 62 to 104 hours; however, the metabolite is 5 to 10 times less potent in inhibiting 5-HT reuptake than the parent compound. Desmethylsertraline displays a five- to ninefold increase in area under the curve (AUC) and peak and minimum plasma concentrations after 14 days of sertraline administration. In healthy volunteers, sertraline demonstrates linear pharmacokinetics over the range of 50 to 200 mg per day. Based on the use of radiolabeled sertraline in two healthy male subjects, unchanged sertraline was found to constitute less than 5 percent of the plasma radioactivity. After 9 days, 40 to 45 percent of the radioactivity was recovered in urine, but no unchanged sertraline was detected. Another 40 to 45 percent was recovered in feces, of which 12 to 14 percent was unchanged sertraline.

The pharmacokinetics of sertraline in children (6 to 12 years of age) and adolescents (13 to 17 years of age) is similar to that seen in adults when adjustments are made based on body mass. Pediatric patients with major depressive disorder or OCD who were administered sertraline (42 days of sertraline therapy of which at least the final 11 days were at a dose of 200 mg per day) had mean C_{max} (maximal concentrations) and half-lives of 165 ng/mL and 26.2 hours and 123 ng/mL and 27.8 hours for children and adolescents, respectively. In comparison, a separate study involving healthy adults who received sertraline (200 mg per day for 30 days) had a mean C_{max} of 142 ng/mL and a half-life of 27.2 hours. Children and adolescents have a smaller (by approximately 22 percent) AUC with sertraline than adults, suggesting the potential for more rapid metabolism in the younger age group. Even so, initial dosing strategies should typically be adjusted downward for younger patients, who typically have a lower body mass than that of adults.

Liver disease is associated with impaired metabolism of sertraline. In a series of subjects with mild, stable cirrhosis of the liver, the mean half-life of sertraline was increased to 52 hours, compared to 22 hours for normal subjects. This suggests the necessity of dose reduction or increased intervals between dosings in individuals with hepatic impairment.

The presence of renal impairment (mild, moderate, or severe) does not

appear to affect the multiple-dose pharmacokinetics of sertraline. This is perhaps due to renal excretion providing a relatively minor pathway for the elimination of unchanged drug.

Aging is associated with a decrease in sertraline clearance. In 16 elderly patients treated with sertraline (100 mg per day for 14 days), the clearance of sertraline was 40 percent lower than that observed in younger subjects (25 to 32 years of age). The establishment of steady-state drug levels is delayed in this group to a time frame of 14 to 21 days of medication administration. Desmethylsertraline clearance was decreased in older men but not women.

PAROXETINE AND PAROXETINE CR

Chemistry

Paroxetine is the hydrochloride salt of a phenylpiperidine compound and is structurally distinct from other antidepressants. Paroxetine is designated as (–)-trans-4*R*-(4′-fluorophenyl)-3*S*-([3′,4′-methylenedioxyphenoxy]methyl) piperidine hydrochloride hemihydrate. The empirical formula is $C_{19}H_{20}FNO_3 \cdot HCl \cdot \frac{1}{2}H_2O$, and the molecular weight of the free base is 374.8. Paroxetine CR is the same salt as the immediate-release (IR) formulation but is in a degradable polymeric matrix with an enteric coating that delays drug release until the tablet has left the stomach.

Pharmacological Actions

Absorption. Paroxetine is well absorbed orally, and food does not alter absorption. Maximum systemic concentration is achieved approximately 5.2 hours and 6 to 10 hours after ingestion for the IR and CR formulations, respectively. The CR formulation demonstrates a decrease in bioavailability of approximately 25 percent compared to the IR preparation, and thus equivalent doses of paroxetine IR and CR would be 10.0- and 12.5-mg, 20.0- and 25.0-mg, and 30.0- and 37.5-mg tablets, respectively.

Distribution. Paroxetine, like sertraline and fluoxetine, is tightly bound to serum proteins in vitro, with binding of 95 and 93 percent at plasma levels of 100 and 400 ng/mL, respectively. Paroxetine has not been reported to alter the in vitro protein binding of warfarin or phenytoin (Dilantin). The volume of distribution is approximately 15 L/kg, and the rate of plasma clearance is close to 79 L/hr. Most individuals achieve steady-state plasma concentrations within 5 to 10 days of dosing of the IR formulation and within 2 weeks with paroxetine CR.

Metabolism and Elimination. The principal path of metabolism for paroxetine is oxidation and methylation. A number of major metabolites

have been identified, although none appears to be any greater than 1/50 as potent as the parent compound in the in vitro reuptake inhibition of 5-HT. A single test dose of paroxetine (30 mg) was recovered as 64 percent in the urine (2 percent as parent compound and 62 percent as metabolites over 10 days). In the feces, 36 percent was excreted, with less than 1 percent as the parent compound.

Paroxetine saturates the CYP 2D6 isozyme of the CYP system and therefore exhibits nonlinear pharmacokinetics. Steady-state plasma maximal and minimal concentrations were elevated 6 and 14 times, respectively, over single-dose values after reaching steady state. This translates into a 24-hour AUC value close to eightfold higher at steady state than would be predicted from a single dose.

In elderly patients, dosing of paroxetine at 20, 30, or 40 mg per day produced plasma concentrations approximately 70 to 80 percent greater than those observed in younger patients. Patients with a creatinine clearance of less than 30 mL/min demonstrated a fourfold elevation in plasma levels compared to healthy controls. Patients with moderate renal impairment (creatinine clearance of 30 to 60 mL/min), as well as patients with moderate hepatic impairment, had a twofold increase in plasma concentrations. All of the previously mentioned groups should receive reduced starting doses of paroxetine, for example, 10 mg per day of paroxetine or 12.5 mg per day of paroxetine CR.

FLUVOXAMINE AND FLUVOXAMINE CR

Chemistry

Fluvoxamine is a member of the 2-aminoethyloxime ethers of the aralkyl ketone family. The empirical formula of fluvoxamine is $C_{15}H_{21}O_2N_2F_3 \cdot C_4H_4O_4$, and it has a molecular weight of 434.4. The chemical designation is 5-methoxy-4′-(trifluoromethyl)valerophenone-(E)-*O*-(2-aminoethyl)oxime maleate (1:1).

Pharmacological Actions

Absorption. The bioavailability of fluvoxamine maleate is 53 percent by oral administration, and its absorption is essentially unaffected by food. At steady state, maximal plasma concentrations are achieved 3 to 8 hours after dosing.

Distribution. In vitro assays demonstrate protein binding, predominantly albumin, of approximately 80 percent for fluvoxamine at concentrations of 20 to 2,000 ng/mL. The volume of distribution for fluvoxamine is approximately 25 L/kg. The extent of excretion of fluvoxamine into breast milk is unclear.

Metabolism and Elimination. The primary route of metabolism for fluvoxamine is oxidative demethylation and deamination in the liver. The main human metabolite, as determined by radiotracer studies, is fluvoxamine acid, which, along with its *N*-acetylated analog, accounts for approximately 60 percent of urinary products. In this same assay, fluvoxethanol comprised approximately 10 percent. Fluvoxamine acid is 10- to 100-fold less potent in an in vitro assay of 5-HT reuptake inhibition than the parent compound.

Fluvoxamine demonstrates nonlinear pharmacokinetics. In 30 normal volunteers receiving fluvoxamine at 100, 200, or 300 mg per day over 10 days, the maximum plasma concentration was 88, 283, and 546 ng/mL, respectively. This represents increases of 160 and 207 percent for the 200- and 300-mg doses, respectively, over what would have been predicted from the lowest dose. The mean plasma half-life at steady state is 15.6 hours in young healthy volunteers receiving 100 mg per day and 13.6 hours in those receiving 50 mg per day. After repeated dosing, the half-life increases to 17 to 22 hours. Steady state is typically achieved in approximately 7 days.

Elderly patients show a prolongation in the half-life of fluvoxamine. Compared to younger patients, in the elderly, the half-life at 50 mg per day goes from 13.6 to 17.4 hours, and it goes from 15.6 to 25.9 hours for dosing of 100 mg per day.

Similar to adults, children (6 to 11 years of age) and adolescents (12 to 17 years of age) display nonlinear, multiple-dose pharmacokinetics with fluvoxamine. Steady-state plasma concentrations of fluvoxamine were two- to threefold higher in children than in adolescents after administration of 100 mg twice a day. The AUC, C_{max}, and minimum drug concentration (C_{min}) were similarly elevated in children compared to adolescents. Female children, in a small sample (N = 3), displayed higher plasma levels than male children. Adolescents are much more similar to adults with regard to the pharmacokinetic profile of fluvoxamine and thus may require higher doses than those necessary for the treatment of children.

Hepatic dysfunction is associated with an approximately 30 percent decrease in fluvoxamine clearance compared to healthy controls. In contrast, renal impairment (creatinine clearance of 5 to 45 mL/min) was not associated with decreased clearance.

CITALOPRAM AND ESCITALOPRAM

Citalopram was a late addition to the US market when it received approval for the treatment of major depressive disorder in 1998. Escitalopram is the *S*-enantiomer of racemic citalopram and is the most recent agent approved for the treatment of major depressive disorder in the United States, having been introduced in 2002.

Chemistry

Citalopram is the hydrobromide salt of a racemic mixture of a bicyclic phthalane derivative designated chemically as (±)–1-(3-dimethylaminopropyl)–1–(4-fluorophenyl)–1,3-dihydroisobenzofuran-5-carbonitrile, HBr. The molecular formula is $C_{20}H_{22}BrFN_2O$, and it has a molecular weight of 405.35.

Escitalopram is the oxalate salt of the *S*-enantiomer of racemic citalopram.

Pharmacological Actions

Absorption. Citalopram is well absorbed orally, and absorption is unaffected by food. The bioavailability of oral citalopram (40 mg, single dose) is approximately 80 percent of that observed after intravenous (IV) administration. Maximum systemic concentration is achieved approximately 4 hours after ingestion. The tablet and oral preparations of citalopram are bioequivalent.

Peak serum levels of escitalopram are seen approximately 5 hours after ingestion. The tablet and oral preparations of escitalopram are bioequivalent.

Distribution. Citalopram has less protein binding than some of the other SSRIs, with citalopram and its two primary metabolites demethylcitalopram (DCT) and didemethylcitalopram (DDCT) displaying in vitro protein binding of 80 percent. The volume of distribution of citalopram is 12 L/kg, and the clearance rate is 19.8 L/hr, of which approximately 20 percent is renal clearance. The half-life of citalopram is approximately 35 hours, and most patients should achieve steady-state concentrations in approximately 1 week.

Escitalopram has protein binding, measured in vitro, of approximately 56 percent. The clearance rate of escitalopram is 36 L/hr, with approximately 7 percent due to renal clearance. The volume of distribution is not well characterized. The mean terminal half-life is approximately 27 to 32 hours, so steady-state concentrations should be achieved after approximately 7 days of dosing.

Metabolism and Elimination. The principal pathway of metabolism for citalopram is by *N*-demethylation to DCT, and the primary CYP isozymes involved are CYP 3A4 and CYP 2C19. Citalopram is the compound found in highest concentrations in humans, with DCT and DDCT present at concentrations of approximately 50 and 10 percent, respectively, of that of citalopram. The metabolites DCT and DDCT possess only approximately one-eighth the potency of inhibition of the 5-HT transporter that citalopram does and so likely contribute little if any to the therapeutic activity. Two other compounds are products of citalopram metabolism in addition to DCT and DDCT; these are citalopram-*N*-oxide and a

deaminated propionic acid derivative. Citalopram displays linear and dose-proportional pharmacokinetics for single and multiple doses in the dose range of 10 to 60 mg per day.

Citalopram pharmacokinetics has been studied in different population subgroups. Normal controls 60 years of age and older in a single-dose study exhibited increases in AUC and half-life by 30 and 50 percent, respectively. The same population after receiving multiple doses had increases of 23 and 30 percent, respectively. Thus, 20 mg is the recommended daily dose in the geriatric population.

Gender differences have been examined in citalopram metabolism as well. In pharmacokinetic studies, citalopram AUC in women was 150 to 200 percent that seen in men. In contrast, however, five other pharmacokinetic studies, as well as the pivotal clinical trials, failed to show differences in steady-state citalopram levels between men and women. There were no differences seen in levels of DCT or DDCT between genders.

Mild to moderate renal impairment is associated with a decreased clearance rate of 17 percent compared to healthy controls. The effect of severe renal impairment on citalopram clearance is not well characterized. Patients with reduced hepatic function have demonstrated a 37 percent decrease in clearance of orally administered citalopram and a doubling of half-life. The recommended dose for patients with hepatic impairment is 20 mg per day.

Escitalopram is metabolized to *S*-demethylcitalopram (*S*-DCT) and *S*-didemethylcitalopram (*S*-DDCT). Similar to the metabolism of citalopram, escitalopram is the predominant compound found in human plasma, with *S*-DCT being present at approximately 30 percent of the concentration of the parent compound. The level of *S*-DDCT is typically below limits of detection. Escitalopram inhibition of the 5-HT transporter in vitro is at least 7 and 27 times more potent than inhibition displayed by *S*-DCT and *S*-DDCT, respectively. The primary CYP isozymes thought to be involved in escitalopram metabolism are CYP 3A4 and CYP 2C19. Escitalopram displays linear and dose-proportional pharmacokinetics for single and multiple doses in the dose range of 10 to 30 mg per day.

Examination of escitalopram clearance in subjects 65 years of age and older in single-dose and multiple-dose studies showed increases of approximately 50 percent in AUC and half-life. Thus, 10 mg is the recommended daily dose in the geriatric population. Similar to citalopram, there have been no gender differences noted in the metabolism of escitalopram. The effect of reduced renal or hepatic function on escitalopram clearance is poorly characterized, but dose adjustments are extrapolated from data available for the racemic compound citalopram.

DRUG INTERACTIONS

SSRIs can produce pharmacodynamic or pharmacokinetic interactions

with other medications. Categories of potential pharmacokinetic interactions between the SSRIs and other agents are enzyme inhibition through the CYP isozyme system and protein binding. Fortunately, the majority of drug–drug interactions are not fatal, but they may insidiously compromise the patient's quality of life or overall tolerability of a therapeutic regimen. Thus, it is not simply an issue of whether drug–drug interactions are seen in a particular area of practice; it is often a question of whether they are recognized, given that they do occur on a regular basis. Ultimately, it is the subsequent pharmacodynamic consequence that dictates the importance of the pharmacokinetic interaction.

Interactions involving SSRIs are particularly relevant clinically because major depressive disorder often requires more than one step of treatment to elicit a remission of symptoms. Frequently, a second medication is added to augment the first. Augmentation of an initial SSRI with an almost endless list of other agents, psychotropic and otherwise, is standard practice. The STAR*D study looked at the "next-step" benefits of switching medications or adding on to an SSRI. The various steps and agents used in this study are shown in Figure 34.27–2. The results found that among patients who do not have a remission during up to 14 weeks of an initial SSRI or who could not tolerate such therapy, switching to another SSRI or augmentation of SSRIs with any agent resulted in similar symptom remission. All strategies used to augment therapy with the SSRI citalopram had similar remission rates. Factors to be considered when selecting augmentation treatments include efficacy, tolerability, burden of side effects, interactions among drugs, dosing convenience, adherence, and cost. These results do not, however, answer the question of whether to use augmentation agents (or other treatment combinations) as first-line treatment in an attempt to achieve greater remission rates sooner in more patients than with SSRIs alone.

Pharmacodynamic Interactions

Symptoms such as autonomic instability, abdominal pain, diarrhea, confusion or delirium, increased motor activity, myoclonus, hyperpyrexia, cardiovascular shock, or death—the serotonin syndrome—are greatest when SSRIs are combined with MAOIs. Accordingly, with the exception of fluoxetine, SSRIs should not be administered within 14 days of discontinuing treatment with an MAOI. At least 14 days should pass before an SSRI (again, with the exception of fluoxetine) is started after treatment with an MAOI is stopped. Because of its long elimination half-life, the prudent washout period for starting fluoxetine after an MAOI would be at least 3 weeks. Five weeks is the minimum recommended interval between stopping fluoxetine and starting an MAOI owing to the long half-life of norfluoxetine. Tryptophan in combination with SSRIs also has the potential to produce the 5-HT syndrome.

FIGURE 34.27–2. Steps in the STAR*D study.

Because SSRIs may reduce dopamine turnover, use in combination with dopamine-receptor antagonists can raise prolactin levels, even causing breast enlargement and galactorrhea and produce extrapyramidal side effects.

A frequent drug combination in clinical practice is the use of a triptan to treat migraine along with an SSRI. Concurrent use of a triptan and an SSRI is normally uneventful, but serotonin toxicity occurs occasionally. There may be additive effects on the serotonin system, as well as inhibition of triptan metabolism by SSRIs. Responding to multiple reports of serious reactions, in 2006 the FDA issued a Public Health Advisory warning of the possibility of serotonin syndrome when triptans and SSRIs are taken together.

According to the FDA advisory, physicians prescribing a triptan and SSRI should weigh the potential risk of serotonin syndrome against the expected benefit of using a triptan with an SSRI and follow patients closely if a triptan and an SSRI are used together, particularly during treatment

initiation, with dose increases, or with the addition of another serotonergic medication. Patients who take a triptan and an SSRI together should be advised to seek medical attention immediately if they experience the symptoms of serotonin syndrome.

Concurrent administration of an SSRI with an MAOI, L-tryptophan, or lithium can result in risk of *serotonin syndrome*. Its symptoms in order of appearance as the condition worsens are (1) diarrhea; (2) restlessness; (3) extreme agitation, hyperreflexia, and autonomic instability with possible rapid fluctuations in vital signs; (4) myoclonus, seizures, hyperthermia, uncontrollable shivering, and rigidity; (5) delirium, coma, status epilepticus, cardiovascular collapse, and death.

Treatment of the serotonin syndrome consists of removing the offending agents and promptly instituting comprehensive support care with nitroglycerine, cyproheptadine, methysergide (Sansert), cooling blankets, chlorpromazine (Thorazine), dantrolene (Dantrium), benzodiazepines, anticonvulsants, mechanical ventilation, and paralyzing agents.

Pharmacokinetic Interactions

The ability of antidepressants to exert a pharmacokinetic effect by enzyme inhibition is dependent on the extent of inhibition that is produced. Typically, classification schemes of antidepressants denote individual drugs as high, medium, or low or minimal potential for isozyme inhibition, as shown in Table 34.27–4.

Predicting the potential clinical relevance of isozyme inhibition requires knowledge of not only the potential inhibitory properties of drugs, but also the clinically relevant substrates for the isozymes. Examples of clinically relevant interactions include fluvoxamine and theophylline (Theo-Dur) through CYP 1A2 inhibition; clozapine (Clozaril) and fluvoxamine through CYP 1A2 inhibition; fluoxetine, sertraline, or paroxetine through CYP 2D6 inhibition; and fluvoxamine with alprazolam (Xanax) or clonazepam (Klonopin) through CYP 3A4 inhibition. Examples of commonly prescribed medications and the isozymes that metabolize them are listed in Table 34.27–4. The combination of a substrate and a potential inhibitor does not contraindicate their simultaneous use.

Fluoxetine may displace other tightly protein-bound drugs, such as warfarin or digitoxin (Digitaline). Good clinical care calls for careful monitoring of potential elevated drug concentrations of agents when tightly protein-bound drugs are coadministered, especially if one agent has a low therapeutic index.

In the CYP isozyme system, fluoxetine is considered to be a relatively potent inhibitor of the CYP 2C and CYP 2D6 isozymes but with no appreciable activity in the CYP 3A4 isozyme system, although norfluoxetine does demonstrate some inhibition of the CYP 3A4 isozyme in vitro. Table

34.27–4 contains a partial listing of substrates at a variety of CYP isozymes.

Fluoxetine, similar to paroxetine, sertraline, and citalopram, inhibits the CYP 2D6 isozyme. Fluoxetine, however, has a significantly longer half-life than the other SSRIs. A study to determine the onset and offset of CYP 2D6 inhibition by fluoxetine (20 mg per day), paroxetine (20 mg per day), or sertraline (50 mg per day for 3 days, then 100 mg per day) found the inhibition half-life for fluoxetine to be longer (7.0 ± 1.5 days) than paroxetine (2.9 ± 1.9 days) or sertraline (3 ± 3 days). There was also a significantly longer period of time required to reverse the CYP 2D6 inhibition after discontinuation of fluoxetine (extrapolated time to baseline of 63.2 ± 5.6 days) compared to paroxetine (20.3 ± 6.4 days) and sertraline (25 ± 11 days). There exists then a potential for drug–drug interactions for an extended period of time after discontinuation.

Fluoxetine may produce hypoglycemia in patients with diabetes who are treated with insulin or oral hypoglycemics. Dose reduction of the hypoglycemic or insulin may be required.

Sertraline, like fluoxetine and paroxetine, is tightly bound to serum proteins, and the manufacturer warns about a potential interaction between sertraline and other tightly protein-bound drugs, such as warfarin and digitoxin. Good clinical practice dictates checking serum levels or activity when an antidepressant with high protein binding is added to a tightly protein-bound drug with a low therapeutic index. Most assays do not differentiate between bound and free drug, so functional assays, such as prothrombin time with warfarin, are a better indicator.

Potential medication interactions with paroxetine include protein-binding interactions or enzymatic inhibition mediated by the CYP isozyme system. Paroxetine, like many of the other SSRIs, is tightly protein bound and may potentially displace other highly protein-bound drugs, such as warfarin or digitoxin. There may be a pharmacokinetic interaction between paroxetine and warfarin that prolongs bleeding, although the prothrombin time is unchanged. The addition of paroxetine, like that of other SSRIs, to a drug regimen in which tightly protein-bound medications are concurrently prescribed warrants careful observation during dose adjustment.

Paroxetine is a relatively potent inhibitor of the CYP 2D6 isozyme system but appears to be without clinically significant effects in the CYP 1A2, CYP 2C, or CYP 3A4 isozyme systems. Coadministration of paroxetine with other medications that are substrates of the CYP 2D6 isozyme should be approached cautiously with an awareness of potential increases in serum concentrations of drugs that primarily use the CYP 2D6 pathway for metabolism. Examples of CYP 2D6 substrates include the type 1C antiarrhythmics—encainide (Enkaid), flecainide (Tambocor), propafenone (Rythmol), and mexiletine (Mexitil)—and β-blockers—labetalol (Normodyne), metoprolol, propranolol, and timolol (Blocadren). Atenolol (Tenormin), a cardioselective β-blocker, is renally excreted and exhibits no

pharmacokinetic interactions. Codeine is inactive as an analgesic and requires metabolism to morphine via the CYP 2D6 isozyme to be effective in reducing pain. Inhibition of the CYP 2D6 pathway can result in loss of analgesic properties. Paroxetine is a substrate and an inhibitor of the CYP 2D6 isozyme system, but there exists an alternative pathway for its metabolism that is not saturated.

Table 34.27–4.
Cytochrome P450 (CYP) Inhibitory Potential of Commonly Prescribed Antidepressants

Relative Rank	CYP 1A2	CYP 2C	CYP 2D6	CYP 3A
Higher	Fluvoxamine (Luvox) Grapefruit	Fluoxetine Fluvoxamine	Bupropion Fluoxetine Paroxetine	Fluvoxamine Grapefruit Nefazodone Tricyclics
Moderate	Tertiary amine tricyclics Fluoxetine (Prozac)	Sertraline	Secondary amine tricyclics Citalopram (Celexa) Escitalopram (Lexapro) Sertraline	Fluoxetine Sertraline
Low or minimal	Bupropion (Wellbutrin) Mirtazapine (Remeron) Nefazodone (Serzone) Paroxetine (Paxil) Sertraline (Zoloft) Venlafaxine	Paroxetine Venlafaxine (Effexor)	Fluvoxamine Mirtazapine Nefazodone Venlafaxine	Citalopram Escitalopram Mirtazapine Paroxetine Venlafaxine

Citalopram enjoys a lower degree of protein binding (80 percent) than many other SSRIs, and escitalopram has an even lower degree of protein binding at approximately 56 percent. Thus, protein-binding interactions would not appear to be a problem with citalopram or escitalopram for the majority of patients, although the clinical trials for these two compounds, as with other antidepressants, are done typically in a relatively healthy population, and the pharmacokinetics of SSRIs when combined with multiple other agents is an underresearched area. The combination of citalopram with a highly protein-bound drug, such as warfarin, resulted in a prolongation of prothrombin time by only 5 percent.

Citalopram and escitalopram are modest inhibitors of the CYP 2D6 isozyme, based on in vivo testing. Coadministration of citalopram (40 mg per day) for 22 days resulted in a doubling of the plasma levels of metoprolol (Lopressor), a β-adrenergic blocker that is a CYP 2D6 substrate. In addition, coadministration of citalopram (40 mg per day) for 10 days along with a single dose of imipramine (Tofranil) (100 mg) did not alter the

plasma concentrations of imipramine but did increase plasma levels of the primary metabolite, desipramine (Norpramin), by 50 percent. Similarly, escitalopram (20 mg per day) for 21 days resulted in increases of C_{max} (50 percent) and AUC (82 percent) of metoprolol given as a single dose of 100 mg. Likewise, escitalopram (20 mg per day) for 21 days resulted in increases of C_{max} (40 percent) and AUC (100 percent) of desipramine given as a single dose of 50 mg.

In vitro enzyme assays suggest that citalopram is not an inhibitor for the CYP 3A4, CYP 2C9, or CYP 2E1 isozymes but is a weak inhibitor for CYP 1A2 and CYP 2C19, in addition to the data presented previously for the CYP 2D6 isozyme. Escitalopram does not appear to have in vitro inhibition of the CYP 3A4, CYP 1A2, CYP 2C9, CYP 2C19, and CYP 2E1 isozymes, although in vivo data are needed to confirm this.

Neither citalopram nor escitalopram, like other SSRIs, should be administered within 14 days of discontinuing treatment with an MAOI. At least 14 days should pass before either is started after treatment with an MAOI is stopped.

Fluvoxamine has moderate protein binding and may be less likely to produce displacement of tightly protein-bound drugs than some of the others in this class. In the CYP system, fluvoxamine is an inhibitor of the CYP 1A2, CYP 2C9, and CYP 3A4 isozyme systems. Theophylline, aminophylline (Phyllocontin), warfarin, propranolol (Inderal), and caffeine metabolism is inhibited through the CYP 1A2 isozyme by fluvoxamine. Warfarin metabolism is also inhibited through the CYP 2C9 isozyme system. Benzodiazepines, including alprazolam, clonazepam, triazolam (Halcion), and midazolam (Versed), are metabolized by hepatic oxidation via the CYP 3A4 isozyme. Approximately twofold elevations in serum concentrations of alprazolam have been observed after coadministration of fluvoxamine. Increased serum levels of carbamazepine (Tegretol), clozapine, methadone (Dolophine), propranolol, amitriptyline, clomipramine, and imipramine have been reported after the addition of fluvoxamine treatment. Thioridazine (Mellaril) should not be combined with fluvoxamine owing to the potential drug–drug interaction and the potential for cardiac QTc interval prolongation secondary to the inhibition of thioridazine metabolism.

The manufacturer warns against the coadministration of fluvoxamine with terfenadine (Seldane), astemizole (Hismanal), cisapride (Propulsid), and pimozide (Orap). All four compounds are inactive prodrugs on ingestion and require CYP 3A4 activity to produce the active metabolite. Inhibition of metabolism produces an accumulation of precursor that may produce cardiac conduction delay and a potentially fatal torsades de pointes type of arrhythmia.

In premarketing trials, smokers demonstrated a 25 percent increase in fluvoxamine metabolism compared to nonsmokers, presumably through

induction of the CYP 1A2 isozyme.

DOSING AND ADMINISTRATION

The therapeutic dose ranges for the SSRIs have been well established. In general, therapeutic effects are not dose related. There are no data that suggest that the presence of therapeutic levels of any SSRI correlates with plasma levels and subsequent clinical response. Nevertheless, patients may vary considerably in the amount of medication they need to derive clinical benefit.

Fluoxetine

Fluoxetine is available in 10- or 20-mg pulvules, as 10-mg tablets, as 90-mg enteric-coated capsules for once-weekly administration, and as an oral concentrate of 20 mg/5 mL. The suggested starting dose of fluoxetine in patients with major depression is 20 mg per day. Effective doses for the treatment of major depression have been reported, ranging from 5 to 80 mg per day in dose-finding trials. Owing to the long half-life, achieving a new steady state after dose adjustment takes longer than that seen with most other antidepressants. Decreasing the dose to treat emerging side effects, particularly if it has been several weeks since initiation of treatment or the last dose adjustment, is a reasonable approach to managing many side effects.

Preclinical trials of fluoxetine in bulimia nervosa showed efficacy greater than placebo at 60 mg per day. Treatment of OCD is also usually at higher doses than those used in major depression, with doses of 20 to 80 mg per day most commonly used. However, SSRIs take longer to reduce OCD symptoms than symptoms of depression, so time for the drug at normal doses should be allowed. The long half-life of fluoxetine and norfluoxetine does make interpretations of what may be the minimal therapeutic dose somewhat complicated. Fortunately, because fluoxetine is generally well tolerated, this becomes less of an issue than it might be with older antidepressants, such as TCAs.

Treatment of panic disorder is often initiated at less than 5 to 10 mg per day with a gradual upward dose titration. Treatment of social anxiety disorder or premenstrual dysphoric disorder is often started at 10 to 20 mg per day. Dose is adjusted upward as needed.

Starting doses of 10 mg per day are often used in treating children, adolescents, or elderly patients. Adjustment upward is based on clinical response and tolerance of side effects.

Paroxetine

Paroxetine HCl is available as 10-, 20-, 30-, and 40-mg-size tablets. The 20-mg-size tablets are scored. Paroxetine CR is available in 12.5-, 25-, and

37.5-mg tablets. Paroxetine is also available in an oral suspension at a concentration of 10 mg/5 mL. Paroxetine mesylate is available as 10-, 20-, 30-, and 40-mg tablets.

The recommended starting dose for paroxetine is 20 mg per day for all approved indications, except in panic disorder, for which an initial dose of 10 mg per day is suggested. Starting paroxetine at 10 mg per day is also suggested for the elderly, medically ill, or those with significant renal or hepatic impairment. Paroxetine CR starting dose recommendations are similar, with 25 mg per day in major depressive disorder and 12.5 mg per day in patients with panic disorder, the elderly, the medically ill, or those with significant renal or hepatic impairment. Many clinicians find starting the more anxious or somatically preoccupied patient at a dose of 10 mg of paroxetine or 12.5 mg of paroxetine CR for a few days to be of benefit.

Taking paroxetine with meals, at least initially, reduces the incidence of nausea, and the majority of patients describe nausea, if present, to be a transient side effect. Patients with major depression who do not respond to 20 mg per day of paroxetine or 25 mg per day of paroxetine CR can have their doses increased by 10-mg (paroxetine) or 12.5-mg (paroxetine CR) intervals to as much as 50 mg per day (paroxetine) or 62.5 mg per day (paroxetine CR). In studies that established paroxetine to have efficacy in maintenance treatment, patients received a mean dose of approximately 30 mg per day.

The target dose of paroxetine in the treatment of OCD is 40 mg per day, with most responders receiving 40 to 60 mg per day. Presumably, doses of paroxetine CR need to be approximately 25 percent higher. The patient's response to treatment of OCD is often slower than what is seen in major depressive disorder.

Patients with panic disorder usually tolerate the side effects of paroxetine, like antidepressants in general, if started at a lower dose than is typically used in treating depression. Most panic disorder patients do better if started at an initial dose of 10 mg per day, with gradual titration to a target dose of 40 mg per day. Dose increases can be made at the rate of 10 mg per week. The maximal dose studied in premarketing clinical trials of paroxetine was 60 mg per day. The dosing strategy with paroxetine CR is similar, starting at 12.5 mg per week, and the maximal dose studied in clinical trials was 75 mg per day.

Dosing for other disorders is usually done with an initial dose of 10 to 20 mg per day (12.5 to 25.0 mg per day for paroxetine CR) and a gradual upward titration.

Among the SSRIs, paroxetine is associated with the most severe withdrawal syndrome and carries the strongest FDA warning about use in pregnancy. It carries a category D rating from the FDA.

Sertraline

Sertraline is available in scored tablets of 25-, 50-, and 100-mg strengths. The oral concentrate is formulated at a concentration of 20 mg/mL with 12 percent alcohol content and must be diluted before use. Owing to the alcohol content in the oral concentrate, it is contraindicated in conjunction with disulfiram (Antabuse). Initial dosing for major depressive disorder and OCD is typically at 50 mg per day, with escalation to 100 mg per day after 4 to 7 days of treatment. Initial treatment of panic disorder, social anxiety disorder, and PTSD is more typically 25 mg per day. Children in OCD studies were started at 25 mg per day, whereas adolescents in OCD studies were started at 50 mg per day. Treatment of premenstrual dysphoric disorder is usually started at 50 mg per day given daily or during the 2 weeks of the luteal phase. Individual patients may demonstrate improved tolerability starting at lower doses. Not uncommonly, patients require an upward titration of the dose.

The dose range in most patients with anxiety or affective disorders is typically 100 to 200 mg a day, although some patients respond to 50 mg per day. Patients with OCD often require higher doses for full therapeutic effect.

Citalopram and Escitalopram

Citalopram is available in 10-, 20-, and 40-mg-size tablets. The 20- and 40-mg-size tablets are scored. Citalopram is also available in an oral solution at a concentration of 10 mg/5 mL. Escitalopram is available in 10- and 20-mg-size tablets, both of which are scored. An oral solution of 5 mg/5 mL is available as well.

The manufacturer recommends a starting dose for citalopram of 20 mg per day, with the expectation of generally increasing the dose to 40 mg per day, which, in clinical practice, is typically done after at least 1 week on the initial dosing. Highly anxious patients or those with increased sensitivities to side effects of medications may benefit from starting with the 10-mg tablet. The recommended starting dose of escitalopram is 10 mg per day. In clinical trials, the 20-mg-per-day dose did not offer any added benefit, but individual patients are often observed to benefit from the higher dose. If the dose is to be increased to 20 mg, this should generally occur no sooner than after 1 week on the initial dose. Because the 10-mg tablet is scored, 5 mg as a starting dose, if required, is available.

Many patients are observed to do well if citalopram or escitalopram is taken after meals for the first few days. After that period, they can take the medication with or without food.

Fluvoxamine

Fluvoxamine is available in 25-, 50-, and 100-mg scored tablets and 100- and 150-mg controlled release capsules. Adults with OCD are often started

at a dose of 50 mg administered at bedtime. The dose may be increased by 50 mg every 4 to 7 days. The effective dosing range in premarketing trials with OCD was 100 to 300 mg per day, although, clearly, some patients do respond to higher doses. The manufacturer suggests dividing the daily dose if it exceeds 100 mg per day, although many patients tolerate doses larger than 100 mg as a single dose. Initial upward titration is often easier with a split-dose regimen.

Treatment of OCD in adolescents and children should start at 25 mg per day with 25-mg-per-day increases every 4 to 7 days. The effective dosing range in premarketing studies was 50 to 200 mg per day. Adolescents often require a dose close to that used in adults, whereas children, perhaps owing to higher plasma fluvoxamine levels, may respond to the lower portion of the dosing range. Due to its short half-life, total daily doses of fluvoxamine greater than 50 mg should be administered as a split dose. Using the controlled release formulation obviates this need for divided doses.

Dosing for disorders other than those for which fluvoxamine is approved in the United States is usually initiated at 25 to 50 mg per day. Patients with a major depressive disorder typically show responses over the range of 100 to 300 mg per day, although response is often seen in the range of 100 to 200 mg per day. Due to possible early activation of anxiety symptoms, treatment of panic disorder is best started at a dose of 25 mg per day for most patients, owing to increased sensitivity of side effects in this population. The typical effective dose is usually 100 to 200 mg per day.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SUICIDALITY

In the early 1990s, a debate arose as to whether fluoxetine treatment was associated with an increase in suicidal ideation and suicide attempts in some patients. A comparison of the emergence of suicidal ideation in patients receiving fluoxetine, TCAs, or placebo suggested that fluoxetine-treated patients had less emergent suicidal ideation than those treated with TCAs. Both antidepressant groups showed less emergent suicidal ideation than the group treated with placebo. At times, fluoxetine produces symptoms, often described as restlessness, that are similar to akathisia in some patients. In the spring of 2004, the FDA asked manufacturers of the SSRIs, along with those of the other newer-generation antidepressants, to include a warning in their labeling recommending close observation of both adult and pediatric patients for signs or symptoms of worsening depression, including suicidal ideation, early on in therapy with these medications or on titration of dosing. This followed earlier recommendations concerning the potential of newer-generation antidepressants to be associated with a higher rate of agitation, suicidal thoughts, or both in clinical trials when these rates were compared to treatment with placebo in studies of children and adolescents with major depressive disorder. Many clinicians believe that the recommendations to

observe patients for worsening of symptoms during the initiation of therapy represent a recommendation for sound clinical care. The issue regarding treatment of children and adolescents remains somewhat unclear. One distinct possibility is that the 2 percent rate of agitation that was generally observed in studies that have been made public may represent pediatric patients who would ultimately go on to develop bipolar affective disorder.

A problem with the FDA advisory is that it was based on short-term trials, and did not include suicidal patients. A study—the Adolescent Depression and Psychotherapy Trial (ADAPT)—actively included suicidal patients, and found that the propensity for depressive relapse and self-reported suicidality in adolescents were reduced with SSRI administration. Furthermore, this study found that the reduction in clinical symptoms with SSRIs appeared to be a long-term effect. The authors of that study concluded that SSRIs are not detrimental to adolescent brain development and that therapeutic benefits outweigh the potential developmental risks.

Since the first press reports appeared, and especially since the new warning about suicidality in children and adolescents, there has been a drop in both SSRI prescriptions for that group and a decrease in the diagnosis of depression. Unfortunately, studies in the United States, Canada, and The Netherlands have shown a dramatic increase starting in 2003 to 2004 in suicide attempts and completed suicides. Analysis involving older adults shows that antidepressants reduce the risk of suicidal thoughts for 25- to 64-year-olds and may reduce the risk of both suicidal thoughts and behavior for people older than 65 years. The obvious conclusion is that although SSRIs might increase suicidality in a small percentage of patients, the use of these drugs is associated with significant decreases in suicide attempts. Health advisories and warnings issued by the FDA may in fact have produced an unintended withholding of appropriate care and caused unexpected harm.

PREGNANCY AND BREAST-FEEDING

SSRIs are the most frequently used class of antidepressant medications among women of childbearing age. It is therefore not surprising that they are the most commonly used psychotropic drugs during pregnancy. With the exception of paroxetine, the SSRIs are considered relatively safe to take during pregnancy when deemed necessary for treatment of the mother. There are adverse effects, in terms of both serotonin toxicity and withdrawal.

Women who are pregnant or planning a pregnancy and are taking SSRIs should consult with their physician about whether to continue taking their medication. As with all medications that treat serious disorders, such as those treated by SSRIs, the potential benefits and risks of SSRI treatment need to be weighed against the potential effect of not treating,

given that pregnancy does not protect against the serious disorders these drugs treat.

A Centers for Disease Control and Prevention (CDC) epidemiological study on the causes of birth defects looked at the use of fluoxetine, sertraline, paroxetine, and citalopram during pregnancy. It found that these drugs did not significantly increase the risk for most birth defects. The study did find an association between SSRI use and a slightly increased risk for three specific birth defects: A defect of the brain, one type of abnormal skull development, and a GI abnormality. These increases in risk were minimal and have not been found before or since.

The CDC study also looked at the risk for congenital heart defects associated with paroxetine use. In 2005, at the FDA's recommendation, paroxetine's pregnancy category was changed from C to D and new data added the Warnings section of paroxetine's prescribing information. The FDA's conclusions and changes in paroxetine's prescribing information were based on preliminary analyses of two unpublished epidemiology studies: In a study using Swedish national registry data, women who received paroxetine in early pregnancy had an approximately twofold increased risk for having an infant with a cardiac defect compared to the entire national registry population (the risk of a cardiac defect was about 2 percent in paroxetine-exposed infants vs. 1 percent among all registry infants). In a separate study using a US insurance claims database, infants of women who received paroxetine in the first trimester had a 1.5-fold increased risk for cardiac malformations and a 1.8-fold increased risk for congenital malformations overall compared to infants of women who received other antidepressants in the first trimester. The risk of a cardiac defect was about 1.5 percent in paroxetine-exposed infants versus 1 percent among infants exposed to other antidepressants.

Most of the cardiac defects observed in these studies were atrial or ventricular septal defects, conditions in which the wall between the right and left sides of the heart is not completely developed. In general, septal defects are among the most common types of congenital malformations. They range from those that are symptomatic and may require surgery to those that are asymptomatic and may resolve on their own. It is of note that the data in these studies were limited to first trimester exposures only, and there are not data to address whether this or any other risk extends to later periods of pregnancy. Based on this labeling, it was recommended that paroxetine should not be initiated in women who are in their first trimester of pregnancy or in women who plan to become pregnant in the near future.

Transient QTc prolongation has been noted in newborns whose mother was being treated with an SSRI during pregnancy.

Another possible pregnancy-related side effect in offspring of SSRI-treated mothers is persistent pulmonary hypertension of the newborn (PPHN), a condition associated with substantial infant mortality and

morbidity. A study has shown that infants with PPHN who were exposed to an SSRI after the completion of the 20th week of gestation, as compared with infants who were not exposed to an SSRI or non-SSRI before the 20th week of gestation or the use of non-SSRI antidepressant drugs at any time during pregnancy, had an increased risk of PPHN. Some neonates exposed to SSRIs late in the third trimester developed complications requiring prolonged hospitalization, respiratory support, and tube feeding. These are listed as precautions in the product information for all SSRIs. Physicians are advised in the labeling to consider tapering SSRIs in the third trimester, but it is not known whether stopping treatment in the last trimester avoids this problem. In addition, the clinical need for treatment of the mother—the risk of nontreatment—needs to be weighed. For example, pregnant women with untreated depression have a greater risk for obstetrical complications, premature delivery, and pre-eclampsia. Newborns of these women are at greater risk to be low birth weight, exhibit lower activity and interactive behaviors, have increased irritability, and demonstrate delayed language and behavioral difficulties.

Excretion of SSRIs in Breast Milk

SSRIs appear in breast milk to varying extents, and data from the literature differ in their findings with regard to the relative dose to the infant. Various reports about drug levels in milk are unreliable because of variations in milk collection procedures and because antidepressants tend to be lipophilic, so that breast milk concentrations for some drugs may vary more than twofold between the watery fore milk and the fattier hind milk, whereas others may show little variation. Accordingly, clinical monitoring of maternal plasma or breast milk is not routinely indicated.

In some studies, concentrations are lowest for fluvoxamine and sertraline. Low levels of both sertraline and its metabolite are found in the sera of infants. Concentration of sertraline and desmethylsertraline in breast milk is highly variable and, on average, is of the same order of magnitude as their concentration in the blood plasma of the mother. As a result, more than half of breast-fed babies receive less than 2 mg/day of sertraline and desmethylsertraline combined, and in most cases these substances are undetectable in their blood. No changes in serotonin uptake by the platelets of breast-fed infants occur, as measured by blood serotonin levels before and after beginning sertraline treatment. Sertraline is more likely to be detected in an infant if the maternal daily dose is 100 mg or higher. Data on paroxetine are mixed, with some studies showing somewhat higher breast milk concentrations and others reporting paroxetine to have the lowest transfer into breast milk. According to a pooled analysis of available data, breast-feeding infants exposed to paroxetine or sertraline are least likely to demonstrate detectable or elevated plasma drug levels, whereas infants exposed to fluoxetine appear

to be at higher risk of developing elevated levels. Most data show that the relative infant dose of citalopram is intermediate between those of paroxetine and fluoxetine. High doses of citalopram should also be used with caution. Escitalopram (Lexapro) and its demethyl metabolite into milk, the absolute and relative infant doses via milk and to assess any unwanted effects in the breast-fed infant.

Because its absolute infant dose is lower than that for an equivalent antidepressant dose of citalopram, it may be preferred over citalopram in treating depression in lactating women.

If treatment with an SSRI is started during the postpartum period, fluoxetine should not be the first alternative. Fluoxetine transfers to a greater extent and its active metabolite, norfluoxetine, has a long half-life of 1 to 2 weeks and may accumulate in a breast-fed infant. When the use of an SSRI is clearly indicated in a breast-feeding woman, the data generally indicate that the positive effects of breast-feeding outweigh the risks for pharmacological effects in the infant. Adverse effects are rarely reported in breast-fed infants. Some short-term adverse effects that have been reported in association with fluoxetine include colic, seizures, irritability, withdrawal symptoms, and cyanosis.

Adverse effects, although rare, may occur, so parents and caretakers should report irritability, poor feeding, or poor sleep or any other worrisome signs or symptoms in the infant. Premature infants or those with impaired hepatic or other metabolite disturbances need to be monitored more closely if the mother is taking SSRIs and breast-feeding.

USE IN CHILDREN

Use of SSRI antidepressants in children and adolescents has been controversial. Few studies have shown clear-cut benefits from the use of these drugs. However, some children and adolescents do exhibit dramatic response to these drugs in terms of depression and anxiety. Fluoxetine has most consistently demonstrated effectiveness in reducing symptoms of depressive disorder in both children and adolescents. This may be a function of the quality of the clinical trials involved. Sertraline has been shown to be effective in treating social anxiety disorder in this population, especially when combined with cognitive-behavioral therapy. Given the potential negative effect of untreated depression and anxiety in a young population and the uncertainty about many aspects of how children and adolescents might react to medication, any use of SSRIs should be undertaken only within the context of comprehensive management of the patient.

VORTIOXETINE

Vortioxetine (Brintellix) is an atypical antidepressant (a serotonin modulator and stimulator) approved by the FDA in 2013 for the treatment

of MDD in adults. Some experts think the drug should be classified as an SSRI because its major pharmacological effect is to inhibit the serotonin transporter. The clinical development program for vortioxetine yielded six positive 6- to 8-week studies, including one study in elderly people, and another positive maintenance study in adults. Vortioxetine was investigated as a treatment for GAD, but was found to be no better than placebo.

Pharmacodynamics

Vortioxetine is classified as a "serotonin modulator and stimulator." Some regard it as a multi-modal 5-HT_3, 5-HT_7, and 5-HT_{1D} receptor antagonist, 5-HT_{1B} receptor partial agonist, 5-HT_{1A} receptor agonist, and inhibitor of the 5-HT transporter. More specifically, it has been shown to possess the following pharmacological actions:

- Serotonin transporter blocker—K_i (binding affinity) = 1.6 nM,IC_{50} = 5.4 nM
- Norepinephrine transporter blocker—K_i = 113 nM
- 5-HT_{1A} receptor high-efficacy partial agonist/near-full agonist—K_i = 15 nM, IA = 80 percent
- 5-HT_{1B} receptor partial agonist—K_i = 33 nM
- 5-HT_{1D} receptor antagonist—K_i = 54 nM
- 5-HT_{3A} receptor antagonist—K_i = 3.7 nM
- 5-HT_7 receptor antagonist—K_i = 19 nM
- β_1-Adrenergic receptor ligand—K_i = 46 nM

Vortioxetine also increases extracellular levels of acetylcholine and histamine in the rat medial prefrontal cortex.

Therapeutic Indications

Being relatively new in clinical practice, most of the data about the efficacy of vortioxetine in treating MDD derives from multiple short-term clinical trials and one long-term relapse prevention trial. Of nine short-term (6- to 8-week) placebo-controlled trials in nonelderly patients, five were considered positive. Two trials were positive for vortioxetine 20 mg/day, but not for 10 or 15 mg/day. One trial failed because the active control did not separate from placebo. Another trial failed because the active control (duloxetine) did separate from placebo. Two other trials failed to demonstrate statistical superiority for vortioxetine over placebo. In the short-term placebo-controlled studies, a statistically significant antidepressant effect was observed at week 2, with additional improvement in subsequent weeks. The full antidepressant effect of vortioxetine was

typically not seen until week 4 or later.

Based on analysis of evaluable trials, the NNT for response with vortioxetine versus placebo is 7 and for remission versus placebo is 11. The most robust NNT for response versus placebo was for the 15-mg/day dose, with an NNT of 6; the most robust NNT for remission versus placebo was for the 5-mg/day dose. In studies with the active controls duloxetine 60 mg/day and venlafaxine 225 mg/day, the control drugs exhibited more robust effect sizes for response and remission compared with vortioxetine at any dose.

An MDD relapse-prevention (maintenance) trial was conducted involving subjects aged 18 to 75 years. Inclusion criteria were a current major depressive episode of at least 4 weeks' duration and at least one prior episode and a MADRS total score of at least 26. Subjects received a 12-week, open-label trial of vortioxetine 5 or 10 mg/day. Subjects who achieved considered full remission were randomized to either continue receiving vortioxetine or to receive placebo in a double-blind fashion. The dose of vortioxetine received at the last assessment in the open-label period was 5 mg/day for 35 percent of the subjects and 10 mg/day for the remaining 65 percent. Of the patients randomized, 75 percent in the vortioxetine group and 66 percent in the placebo group took vortioxetine 10 mg/day at the end of the open-label period. Time to relapse was the primary efficacy outcome and demonstrated superiority for vortioxetine versus placebo.

Pharmacokinetics

The pharmacological activity of vortioxetine is entirely derived from the parent molecule. It has no active metabolites. In normal volunteers, single daily doses of vortioxetine exhibits linear pharmacokinetics for the dose range of 2.5 to 60 mg. It has a mean terminal half-life of about 66 hours. Vortioxetine reaches peak plasma concentration within 7 to 11 hours postadministration. Steady-state plasma concentrations are usually achieved within 2 weeks. In studies, no differences were observed between the fed and fasting states. Accordingly, it may be taken with or without food. The absolute bioavailability of vortioxetine is 75 percent, and it has an extended absorption phase, a medium clearance and a large volume of distribution. C_{max} is reached in 7 to 11 hours. Vortioxetine is extensively metabolized, mainly through the CYP450 isozymes 2D6, 3A4/5, 2C19, 2C9, 2A6, 2C8, and 2B6. After oxidation it undergoes glucuronic acid conjugation. It is converted to a pharmacologically inactive, carboxylic acid metabolite through CYP2D6 oxidation. Poor metabolizers of CYP2D6 have nearly twice the plasma concentration vortioxetine than do extensive metabolizers. No significant impact on plasma protein binding or clearance has been demonstrated by hepatic or renal disease. Insignificant amounts

of unchanged vortioxetine are excreted in the urine. Concurrent use of vortioxetine has no effect on plasma levels of ethinyl estradiol/levonorgestrel or 5′-hydroxyomeprazole or bupropion. However, steady-state AUC and C_{max} of vortioxetine are increased when coadministered with bupropion fluconazole and ketoconazole. These are decreased, when vortioxetine is used with rifampicin.

Precautions and Adverse Reactions

The most common side effects reported with vortioxetine are nausea, diarrhea, xerostomia, constipation, vomiting, flatulence, dizziness, and sexual dysfunction. Based on clinical trial data, the incidence of sexual dysfunction is reportedly higher in patients taking vortioxetine than in patients taking placebos, but lower than in patients taking venlafaxine. Vortioxetine used alone in high dose or in combination with other medications, such as other antidepressants, can produce serotonin syndrome.

There are no published data on the efficacy and safety of vortioxetine use in children and adolescents. It has been studied in elderly patients, with no evidence of unusual adverse events. Vortioxetine is classified as FDA pregnancy category C.

Dosing

Patients typically initiate drug therapy at 10 mg daily, which may be subsequently increased to 20 mg daily. If 10 mg dosing is poorly tolerated, the dose can be lowered to 5 mg per day, though available evidence demonstrating clinical efficacy at this lower dosage is not entirely conclusive and is questionably reliable.

Reported efficacy data across clinical trials failed to indicate any linear correlation to patient dosing. Clinical trial data do not indicate a clinically significant difference response and remission rates at doses above 20 mg/day. In fact, during clinical trials, clinical improvement noted in those patients receiving a higher dose of 20 mg/day, compared to 10 mg/day, was insignificant. Of course, there are always outliers who may benefit from higher doses.

Available Formulations

In the United States vortioxetine is available in 5-, 10-, 15-, and 20-mg tablets.

▲ 34.28 Second-Generation Antipsychotics

STEPHEN R. MARDER, M.D., AND MICHAEL C. DAVIS, M.D., PH.D.*

INTRODUCTION

The second-generation antipsychotics (SGAs) are a group of antipsychotic agents that were introduced into clinical psychiatry during the early 1990s. In the United States and most parts of the world, these agents are the most widely prescribed agents for schizophrenia and other illnesses associated with psychotic symptoms. In prior editions of this text, these agents were referred to as serotonin-dopamine antagonists (SDAs) based on the belief that they could be differentiated from the dopamine receptor antagonists based on their high affinity for serotonin 2A (5-HT_{2A}) as well as dopamine (D_2) receptors. However, as noted below, this explanation for differentiating the effects of these agents remains controversial. As a result, this term has gradually been replaced by the term second-generation antipsychotics or SGAs, which will be used in this section.

The first agent in this group was clozapine (Clozaril), an antipsychotic that was introduced in the United States in 1990, although it had been available in some countries in Europe since the early 1970s. Clozapine was considered an "atypical" antipsychotic because it was an effective agent at doses that caused negligible EPS. Moreover, it had broad effectiveness for a range of mood and anxiety symptoms that were common in schizophrenia. The enthusiasm for its effectiveness was balanced by a number of side effects (described later in this section). Attempts to duplicate clozapine's effectiveness in agents with milder side effects led to the development of a group of agents that included risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), and aripiprazole (Abilify). Since the last edition, iloperidone (Fanapt), asenapine (Saphris), and lurasidone (Latuda) have been introduced in the United States. Cariprazine (Vraylar) and Brexpiprazole (Rexulti) have been introduced now. Unfortunately, none of these drugs duplicated clozapine's effectiveness in patients who are partially responsive to FGAs. However, these drugs are associated with antipsychotic effects at doses less likely to cause EPS. The term *atypical* is probably outdated since these agents are currently the most prescribed group of antipsychotics.

Since the previous edition of this text, new information about the effectiveness and tolerability of SGAs has become available as a result of large trials comparing these drugs and FGAs. New formulations of existing SGAs have been introduced and new indications for these agents have been approved by the FDA. In addition, the prescribing of SGAs for off-label conditions such as anxiety disorders, OCD, insomnia, and agitation in

elderly patients has increased despite very limited data indicating that these agents are both safe and effective for these conditions.

COMPARISONS OF SGAS

The results from meta-analyses have provided important information about the relative effectiveness of the SGAs and how they compare to FGAs. One large meta-analysis included more than 43,000 subjects and compared 13 SGAs and 2 FGAs (haloperidol and chlorpromazine). The study did not find a pattern indicating that there was a difference in efficacy between first- and second-generation agents. Rather, there were small differences in efficacy among the antipsychotics with clozapine, amisulpride (which is not available in the United States), olanzapine, and risperidone having an efficacy advantage. There were substantial differences among the agents in side effects, however, with clozapine, sertindole (which is not available in the United States), olanzapine, and quetiapine showing the least EPS and haloperidol the most. Haloperidol, ziprasidone, and lurasidone resulted in the least weight gain and clozapine and olanzapine caused the most. Paliperidone and risperidone led to the largest increases in prolactin and aripiprazole the least. These effects are consistent with results from a maintenance treatment trial that compared long-acting formulations of paliperidone and haloperidol. The effectiveness of the two agents for preventing relapse was similar. However, paliperidone resulted in greater prolactin elevation and more weight gain whereas haloperidol led to more akathisia. Taken together these results do not indicate a clear advantage for SGAs, except for likely a lower propensity for causing tardive dyskinesia. Instead, clinicians will need to consider a number of factors in selecting an antipsychotic that is suited for an individual patient.

SGAS AND MORTALITY

One study evaluated the risk of sudden cardiac death in a large population of patients in Tennessee. Although the study was unable to explain the cause of these deaths, the authors believe that they were most likely due to ventricular arrhythmias that can occur when drugs block potassium channels and prolong cardiac repolarization. The study found that both FGAs and SGAs were associated with an increased risk and that the newer drugs had a slightly higher risk. The incidence rate ratios for SGAs were 3.67 for clozapine, 2.91 for risperidone, 2.04 for olanzapine, and 1.88 for quetiapine. The study was unable to evaluate the risks of ziprasidone, aripiprazole, and paliperidone. The risk of cardiac death increased with both age and drug dose. Overall, the findings point to a relatively low risk of cardiac death, although the risk is greater than the risk of death from agranulocytosis with clozapine. Clinicians should consider obtaining an ECG before and after treating patients with an FGA or SGA. A prolonged

QT interval would signal that the patient is at risk.

A population-based cohort study from Finland evaluated mortality on different antipsychotics during an 11-year period from 1996 to 2006. Clozapine, an antipsychotic that had been considered a drug associated with high risk, was actually associated with the lowest risk of death and quetiapine was associated with the greatest risk. There was no indicating that the introduction of SGAs during the 1990s resulted in increased mortality. Long-term treatment with an antipsychotic in schizophrenia was associated with lower mortality when compared to not receiving an antipsychotic. These studies support the relative safety of long-term treatment with an antipsychotic.

BLACK BOX WARNINGS

Increased Mortality in Elderly Patients with Dementia

In 2005, the FDA mandated a black box warning for all SGAs for increased mortality in elderly patients with dementia-related psychosis. This was based on meta-analysis of 17 placebo-controlled trials, which demonstrated a risk of death of 1.6 to 1.7 times in the drug-treated patients versus the placebo-treated patients. The causes of death were variable but mostly cardiovascular or infectious in nature. It is noted that it is not clear whether the increased mortality can be directly attributed to the SGA as opposed to other patient characteristics.

Suicidal Thoughts and Behaviors

SGAs that carry therapeutic indications for the treatment of depression (e.g., quetiapine, aripiprazole, lurasidone, olanzapine, and brexpiprazole) carry the black box warning that is associated with all antidepressant medications. This warning is based on pooled analyses of short-term placebo-controlled trials of antidepressants (24 trials, 9 antidepressants, over 4,400 patients). These analyses found that antidepressant treatment was associated with an increased risk of suicidal thinking in behavior in children, adolescents, and young adults up to age 24. There was no increased risk of suicidality associated with antidepressant use in adults older than 24 (295 short-term trials, 11 antidepressants, over 77,000 patients), and there was a reduction in suicidality in adults 65 and older. It is recommended that all patients started on antidepressants be monitored for the emergence of agitation, irritability, unusual behavior, as well as suicidal thoughts and behaviors.

CLOZAPINE

History

Clozapine was the first of the SGAs. It was discovered in 1958 in Bern,

Switzerland, and was first studied in animal experiments in 1960. Soon after clinical trials with clozapine began, the drug appeared to be an effective antipsychotic agent that did not cause extrapyramidal side effects. The first studies showed that patients became calmer in the first 5 days, and psychotic excitement decreased from day 5 onward. Day 20 effects on psychosis were substantial, and negative symptoms improved at 40 days. However, early studies with clozapine in Europe were met with skepticism because this agent was inconsistent with the dogma that effective antipsychotic agents were associated with extrapyramidal effects. This dogma was challenged by a number of European authorities, including Hans Hippius, and, as a result, clozapine was eventually approved in several countries in Europe in 1972.

The enthusiasm about clozapine was dampened when it was discovered that the drug was associated with significant hematological toxicity. In 1975, clozapine was introduced in Finland, where 16 of 1,600 treated patients developed granulocytopenia (1,600 cells or less per mm^3). Eight of the 13 patients in whom granulocytopenia progressed to agranulocytosis died of infectious diseases. After 50 patients around the world had died, clozapine was withdrawn from most European markets, and research with this drug came to a virtual halt. Some patients who were receiving clozapine before its withdrawal from the market continued on the drug because of its clear advantages over prior treatment. Regular monitoring of white blood cell (WBC) counts in these individuals showed that clozapine-induced agranulocytosis was reversible when drug use was stopped. In addition, controlled trials in Europe showed that clozapine was more effective than conventional agents for treating schizophrenic patients who were either severely ill or resistant to other antipsychotic agents.

Discussions with the FDA led to a US multicenter trial to determine whether clozapine was effective for treatment-refractory patients. The effectiveness of clozapine was compared with that of chlorpromazine (Thorazine) in 268 schizophrenia patients with thoroughly documented failure to respond to conventional antipsychotic agents. The study, reported in 1988 by John Kane, Herbert Meltzer, and others, found that clozapine was more effective than chlorpromazine in terms of a number of important outcomes, including psychosis, mood, and anxiety. The results from this study and others led to the approval of clozapine in the United States in 1990 for schizophrenia patients who are resistant to treatment with other antipsychotic drugs or who are unable to tolerate conventional drugs because of extrapyramidal side effects or severe tardive dyskinesia.

Treatment resistance in schizophrenia is a poorly defined concept that has evolved since clozapine's introduction. At that time, treatment resistance referred to a failure to respond to a conventional dopamine receptor antagonist. Because of clozapine's side-effect profile, it was hoped that other SGAs would replace it as the agent of choice for treatment-

resistant patients and, to some extent, this appears to have happened, as clozapine use continues to be restricted to a relatively small proportion of patients with schizophrenia and other psychotic illnesses. As noted below, there is substantial evidence, including the results from phase 2E of Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) as well as meta-analyses, indicating that clozapine is probably the most effective antipsychotic.

Chemistry

Clozapine is a five-membered heterocyclic compound, 8-chloro-11-(4-methyl-1-piperazinyl)-5*H*-dibenzo-[*b,e*][1,4-]diazepine. Its chemical formula is $C_{18}H_{19}N_4Cl$ with a molecular weight of 326.8. Substitutions for the A-ring have led to other clinically effective clozapine-like agents; however, loxapine (Loxitane), an antipsychotic with a clozapine-related molecular structure, has a clinical and side-effect profile similar to other traditional antipsychotic drugs. Other clozapine-derived antipsychotic agents are olanzapine and quetiapine, but being a derivative does not translate to similar efficacy. Chemical structures for clozapine and the other SGAs discussed in this chapter are depicted in Figure 34.28–1.

Pharmacological Actions

Pharmacokinetics. The pharmacokinetic profiles of clozapine and other SGAs in special populations are summarized in Table 34.28–1.

FIGURE 34.28–1. Molecular structures of SGAs discussed in this chapter. Panels a-l by Fuse809, via Wikimedia Commons. Licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license. Panel j in public domain.

ABSORPTION. Clozapine is only available as an oral preparation. As with other antipsychotic agents, peak plasma levels are reached approximately 2 hours after oral administration (range, 1.1 ± 0.5 to 3.0 ± 1.5 hours). The elimination half-life is approximately 12 hours (between 10 and 16 hours; range, 6 to 33 hours). As a result, twice-daily dosing results in steady-state plasma concentrations in less than 1 week. Based on animal studies, coadministration of highly protein-bound drugs may increase free clozapine concentrations, although the total concentration (free plus bound) may be unchanged.

DISTRIBUTION. Clozapine has a large volume of distribution (mean of 2.0 to 5.1 L/kg [range, 1.0 to 10.2 L/kg]), although this is lower than other antipsychotic drugs.

METABOLISM AND ELIMINATION. Clozapine undergoes extensive first-pass

metabolism in liver and gut. Absolute bioavailability (percentage of clozapine reaching the systemic circulation unchanged) after oral administration varies from 27 to 47 percent. The primary metabolic routes are demethylation, *N*-oxidation, oxidation of the aromatic ring, and conjugation. Reportedly 80 percent of administered clozapine appears in the urine or feces as metabolites. Less than 5 percent of the parent compound is found unchanged in the urine.

Table 34.28–1.
Changes in Pharmacokinetics: Special Populations

Drug	Elderly	Renal Impairment	Hepatic Impairment	Genetic Variants of Metabolic Enzymes	Notes
Clozapine (Clozaril)	↓↓ Dosage	No δ dosage	↓ Dosage	Consider ↓ Dosage if CYP2D6 poor metabolizer	
Risperidone (Risperdal)	↓↓ Dosage	Dosage	↓ Dosage	Consider ↓ Dosage if CYP2D6 poor metabolizer	
Olanzapine (Zyprexa)	↓ Dosage (35%)	No δ dosage	No δ dosage		Clearance 30% lower in women and 40% higher in smokers
Quetiapine (Seroquel)	↓↓ Dosage	No δ dosage	Slight ↓ dosage		
Ziprasidone (Geodon)	No δ dosage	No δ dosage	↓ Dosage		
Aripiprazole (Abilify)	No δ dosage	No δ dosage	No δ dosage	↓ Dosage if CYP2D6 poor metabolizer	
Paliperidone (Invega)	No δ dosage	↓ Dosage	No δ dosage		
Iloperidone (Fanapt)	?	No δ dosage	No δ dosage	↓ Dosage if CYP2D6 poor metabolizer	
Asenapine (Saphris)	↓↓ Dosage	No δ dosage	Do not use with severe hepatic impairment		
Lurasidone (Latuda)	No δ dosage	↓ Dosage	↓ Dosage		
Cariprazine	No δ	CrCl <30 mL/min:	Severe impairment		

(Vraylar)	dosage	Use not recommended	(Child-Pugh class C): Use not recommended.	
Brexpiprazole (Rexulti)	No δ dosage	CrCl <60 mL/min: Maximum dose: Major depressive disorder: 2 mg Schizophrenia: 3 mg	Moderate to severe impairment (Child-Pugh class B or C): Maximum dose: Major depressive disorder: 2 mg Schizophrenia: 3 mg	å dose if poor CYP2D6 metabolizer

CYP2D6, cytochrome P450 system 2D6 polymorphism. Poor metabolizers indicated by this genetic polymorphism include ~8% of Caucasians and smaller proportions of Asians and African Americans. PD, pharmacodynamic; PK, pharmacokinetic; δ, change in; ↓,↓↓, decrease;?, uncertain.

Adapted from Ereshefsky L. Pharmacokinetics and drug interactions: Update for new antipsychotics. *J Clin Psychiatry*. 1996;57(Suppl):12 and information provided by manufacturers.

The *N*-desmethylclozapine metabolite represents 40 to 80 percent of the concentration of clozapine. It is a muscarinic type 1 (M_1) receptor agonist, whereas clozapine itself has muscarinic antagonist effects. According to Herbert Meltzer, this metabolite may be a major contributor to clozapine's purported superior effects on cognition and negative symptoms compared to the other agents.

Pharmacodynamics

MECHANISM OF ACTION. The explanation for clozapine's unique clinical profile remains controversial. Preclinical studies in rats have shown that clozapine blocks the conditioned avoidance response, indicating that the drug has potential antipsychotic activity. However, it did not produce catalepsy in animals, suggesting that it is unlikely to produce EPS in humans. This made it different from conventional antipsychotic medications, which all cause extrapyramidal side effects as a direct result of their D_2 receptor blockade in the forebrain.

The relatively low affinity for D_2 receptors may explain clozapine's lack of extrapyramidal side effects. In patients treated with most FGAs and SGAs, PET scan studies have shown that, with doses comparable to 10 mg of haloperidol (Haldol), more than 80 percent of striatal D_2 receptors are occupied. Higher doses do not increase receptor occupancy further. In clinically effective doses, clozapine only occupies 40 to 50 percent of D_2 receptors. This weak effect at the D_2 receptor site may be related to clozapine's unusual biological profile that combines a low D_2 affinity with activity at a number of other receptor sites, including serotonergic (e.g., 5-HT_2 and 5-HT_{1C}), adrenergic, and cholinergic sites.

Several hypotheses address the mechanism of action of clozapine.

Because its D_2 receptor activity is lower than that of traditional antipsychotic agents and its 5-HT_2 receptor blockade is stronger than that of haloperidol, Herbert Meltzer has proposed that the differential antipsychotic effect of clozapine is related to its low D_2 to 5-HT_2 ratio. Clozapine's affinity for the 5-HT_2 receptor is among the highest for antipsychotic agents. An alternative hypothesis proposes that clozapine is effective because it has a selective preference for the mesolimbic dopamine system. D_2 receptor blockade in the striatum caused by conventional agents may interfere with their antipsychotic effects and induce negative symptoms. Others have focused on clozapine's stronger 5-HT_3 blockade and its stronger α_1- and α_2-adrenergic receptor blockade. Other differences include its stronger affinities for histamine type 1 (H_1) receptors and muscarinic receptors but lower affinity for sigma receptors than haloperidol.

As mentioned above, the clozapine metabolite *N*-desmethylclozapine has M_1 agonist activity. Studies suggest that patients who have higher ratios of this metabolite to the parent compound tend to have better clinical outcomes. This suggests that M_1 agonism may contribute to clozapine's unique effectiveness.

Philip Seeman and Shitij Kapur have proposed that the lack of EPS with clozapine and other SGAs is related to their fast dissociation from the D_2 receptor. Conventional dopamine receptor antagonists tend to bind more tightly to dopamine receptors than dopamine itself. Clozapine and nearly all of the other SGAs bind more loosely and tend to come off the receptor more readily in the presence of dopamine. As a result, these newer agents may block these receptors more transiently, coming off the receptor to permit more normal dopamine transmission. Clozapine also has a 10-fold higher affinity for the D_4 receptor than do other antipsychotics. The D_4 receptor is present in the cortex and less so in the striatal areas. However, other agents with high affinity for D_4 receptors have failed to demonstrate that they are effective antipsychotics.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. As with most antipsychotic drugs, patients display considerable variability in their clozapine plasma concentrations among patients receiving the same daily dose. This probably results from differences in both absorption and metabolism. Variability is also observed within patients, which is presumably related to variable absorption rates rather than changes in hepatic metabolism and clearance. Some reports show that women have slightly higher and smokers slightly lower plasma levels (20 to 30 percent). The plasma levels of older adults may be twofold higher than those of young adults.

Several investigators have studied the relationship between plasma

concentrations of clozapine and clinical response. Their findings suggest that monitoring clozapine plasma concentrations may be useful under certain conditions. A wide range of clozapine concentrations appears to be associated with a clinically meaningful response. Plasma concentrations of clozapine average approximately 10 to 80 ng/mL/mg of drug given per kilogram of weight. Thus, a typical daily dosage of 300 to 400 mg (approximately 5 mg/kg) is associated with plasma concentrations ranging from 200 to 400 ng/mL. Studies indicate that patients are more likely to respond when their clozapine plasma concentrations are >350 ng/mL. If patients with a plasma concentration of 250 ng/mL have not responded by 6 weeks, the clinician should consider adjusting the dosage to raise the concentration to approximately 350 ng/mL. The correlations between plasma concentration and clinical improvement or side effects are weak, as is observed with other antipsychotic agents.

Design and Interpretation of Clinical Drug Studies

Clozapine for Acute Schizophrenia. Open-label clinical trials conducted in the early 1970s suggested that clozapine was an effective antipsychotic drug that lacked extrapyramidal side effects. These findings were then reinforced with double-blind trials comparing clozapine with other agents. In 79 percent of the controlled trials that compared clozapine with another antipsychotic drug, clozapine was superior. In reviewing these studies, Ross Baldessarini cautions that the differences between clozapine and the comparator drug were relatively small. Nevertheless, certain patterns emerge. One comparison with chlorpromazine found a small advantage favoring clozapine when a heterogeneous group of patients was studied, but differences favoring clozapine were clearer when the most severely ill subgroup was studied. Another study compared haloperidol with clozapine in more severely ill and treatment-refractory patients and found a clear advantage of clozapine over haloperidol. One study comparing clozapine with risperidone found no differences in clinical response at the end of 6 weeks. Response to risperidone came sooner, but some extrapyramidal effects were observed with risperidone. Few treatment-refractory patients were included. In summary, these studies suggest that clozapine may be particularly effective for a subgroup of patients with schizophrenia who are both severely ill and refractory to treatment with conventional drugs. Whether clozapine is more effective in acutely psychotic patients who are likely to respond to conventional antipsychotics is unclear, although a study suggests that clozapine also has advantages in these patients. In a US multicenter study of patients who had tardive dyskinesia or were sensitive to extrapyramidal side effects, clozapine was superior to chlorpromazine.

Efficacy in Treatment-Refractory Patients. Early clinical experience with clozapine suggested that it was more effective than conventional drugs for

patients who were unresponsive to conventional antipsychotic agents. Moreover, the studies cited in the previous section suggested that the differences between clozapine and other antipsychotics were greater in patients who were severely ill and refractory to treatment with conventional dopamine receptor antagonists. Before marketing clozapine for these patients, the FDA and the manufacturer of clozapine developed a study comparing clozapine with chlorpromazine plus benztropine (Cogentin). The 268 patients who participated in this trial had previously responded poorly in at least three prior antipsychotic trials and a prospective single-blind trial of haloperidol. This study compared the effectiveness of chlorpromazine and clozapine in 248 patients who had thorough documentation of poor responsiveness to conventional antipsychotic agents. During this 6-week trial, the clozapine-treated patients did better on a range of measures of both positive and negative symptoms. Thirty percent of clozapine-treated patients met a priori criteria for significant improvement, in contrast to only 4 percent of chlorpromazine-treated patients. Other studies show that this 6-week trial may have significantly underestimated the proportion of patients who respond to clozapine, and that up to 60 percent of patients may display substantial improvement after a 6-month trial. Clozapine in this trial was superior to chlorpromazine on 14 of 18 Brief Psychiatric Rating Scale (BPRS) items, as well as on the Clinical Global Impression (CGI) and nursing ratings such as social competence, social interest, personal neatness, irritability, manifest psychosis, and motor retardation. When patients were classified as having improved (by prospective criteria) to a clinically significant extent, 30 percent of clozapine patients improved within 6 weeks versus only 4 percent of those receiving chlorpromazine plus benztropine ($p < 0.001$). Based on this trial, the FDA approved clozapine for limited use in the United States.

As noted in another section of this chapter, the NIMH CATIE study compared clozapine (open label) to double-blind risperidone, olanzapine, or quetiapine in patients who had their phase 1 medication changed for lack of efficacy. Patients assigned to clozapine had the best outcome with 56 percent of clozapine patients being discontinued compared to 71 percent on olanzapine, 86 percent on risperidone, and 93 percent on quetiapine. These results were also supported by a study from the UK by Shon Lewis that compared clozapine to an SGA selected prior to the randomization and found an advantage for clozapine.

The effectiveness of clozapine in treatment-refractory schizophrenia has also been compared to the use of SGA polypharmacy, which is a nonrecommended strategy that is often used in this population. In this study, the utilization of emergency department and hospital services, as well as cost outcomes, was compared between Medicaid beneficiaries receiving clozapine monotherapy and those receiving two or more SGAs. It

was found that Medicaid beneficiaries receiving clozapine monotherapy between 2006 and 2009 (N = 479) had a lower risk for emergency department use as well as lower Medicaid payments (both all-cause and mental disorder related) than patients receiving SGA polypharmacy.

Altogether, these studies support the view that patients with schizophrenia who continue to demonstrate psychotic symptoms that are bothersome should not be considered refractory to treatment unless they have had an adequate trial with clozapine. An adequate trial is probably at least 3 months of clozapine at an adequate dose.

Long-Term Effectiveness. Long-term studies have supported the concept of maintaining patients on clozapine. A 29-week study reported in 2001 found that 60 percent of moderately refractory outpatients with schizophrenia treated with clozapine met improvement criteria compared with 12 percent of haloperidol-treated patients. In a study of patients with schizophrenia in Connecticut state hospitals, those who were discharged on clozapine treatment were more likely to remain out of the hospital when compared with individuals discharged on treatment with other agents. A Department of Veterans Affairs Cooperative Study comparing 1 year of treatment with clozapine to that of haloperidol also found that clozapine was associated with a decreased need for hospitalization. Moreover, patients treated with clozapine demonstrated a greater likelihood of participating in psychosocial treatments and rehabilitation programs. As mentioned in an earlier section, there is evidence that patients who are unresponsive to treatment in adequate trials of conventional dopamine receptor antagonists may respond when treated with SGAs other than clozapine. As a result, patients who respond poorly to conventional dopamine receptor antagonists may benefit from a trial of at least one of these agents before receiving a clozapine trial. Clinicians should also consider that prolonged sequential trials with a number of antipsychotics may take months or even years, thus delaying treatment with an agent that may be effective.

Severe Tardive Dyskinesia. Patients with severe tardive dyskinesia should also be considered for a clozapine trial. Most clinical reports indicate that clozapine can suppress abnormal movements in tardive dyskinesia. This is not surprising, as conventional antipsychotic agents are effective for the short-term suppression of tardive dyskinesia. However, clozapine is probably less likely to cause the disorder and, therefore, is promising for the long-term management of patients, particularly those who already have tardive dyskinesia. Although rare cases of tardive dyskinesia have been found in patients who receive clozapine, the risk of developing this disorder is substantially reduced. Studies using animal models indicate that clozapine does not result in the increased sensitivity of

striatal D_2 receptors that is associated with typical antipsychotic agents and has been theorized to result in tardive dyskinesia. It remains to be established whether a positive effect on tardive dyskinesia results from a direct suppressive effect of clozapine on certain transmitter systems or whether clozapine spares the striatal D_2 receptors, allowing spontaneous remission of tardive dyskinesia. The former interpretation is supported by the reports of a return of tardive dyskinetic movements after clozapine withdrawal.

Clozapine in Hostile and Aggressive Patients. Clozapine has also been studied in patients with schizophrenia and other psychotic disorders who display hostile and aggressive behaviors. A study of 157 inpatients by Citrome found that clozapine treatment led to greater reductions in ratings of hostility than other antipsychotics. Similarly, Chengappa found that clozapine led to a reduction in the need for seclusion and restraint. These findings suggest that clozapine may be of particular benefit to refractory patients who demonstrate hostile and aggressive behaviors.

Patients at Risk for Suicide. Clozapine may also be a preferred agent for patients with schizophrenia who are at a higher risk of suicide. Large epidemiological studies found what appeared to be a reduction in death from suicide in patients receiving clozapine. This and other observations led Herbert Meltzer and colleagues to design the International Suicide Prevention trial (or InterSePT). The study compared clozapine and olanzapine in 956 patients with schizophrenia or schizoaffective disorder who were considered at risk for suicide. Clozapine was more effective in delaying the time to recurrent suicidal behavior. In addition, over a 2-year period, 24 percent of clozapine and 32 percent of olanzapine patients were hospitalized for suicidal risk.

Schizophrenia with Substance Abuse. Although the effectiveness of clozapine in patients with comorbid substance abuse has not been demonstrated by randomized controlled trials, there is some supporting evidence from naturalistic studies. A retrospective study by Green and coworkers found that patients treated with clozapine were more likely to abstain from alcohol and cannabis use than patients treated with risperidone. A prospective study by the same investigators found that patients treated with clozapine were better able to reduce their substance abuse.

Treatment-Resistant Mania. Clozapine can be an effective treatment of manic symptoms that are not responsive to other agents. Early clinical case reports indicated that clozapine was effective both as monotherapy and as an adjunct to mood-stabilizing agents in this population. An open-label,

randomized trial in acutely manic patients found that clozapine had a more rapid onset of effect than that of chlorpromazine. In another open-label trial involving patients with schizoaffective disorder or bipolar disorder who were randomized to either clozapine or treatment as usual, clozapine-treated patients demonstrated greater improvements. Although the available data support clozapine's effectiveness in mania, none of these trials have used a double-blind design.

Severe Psychotic Depression. The effectiveness of clozapine in the treatment of patients with major depression with psychotic features is supported by clinical case reports alone.

Neurological Illnesses. Clozapine has also found uses in patients with neurological disorders. It has been used in idiopathic Parkinson disease as a treatment of psychotic symptoms that are secondary to dopaminergic agents that are used to treat the disease. These patients may respond to relatively low dosages of clozapine (doses of 25 to 75 mg). Higher dosages (e.g., 100 to 250 mg a day) may exacerbate the parkinsonian symptoms. The effectiveness of clozapine in patients with idiopathic Parkinson disease is supported by at least two double-blind studies. A report from the American Academy of Neurology recommends clozapine as a preferred agent for psychosis in Parkinson disease. Patients with benign essential tremor or with Huntington disease have also responded positively to clozapine.

Polydipsia–Hyponatremia Syndrome. Case reports suggest that clozapine may have advantages over other antipsychotic agents in patients who tend to intoxicate themselves with water. This syndrome—called *polydipsia–hyponatremia syndrome*—can result in seizures.

Treatment Resistance in Other Disorders. Treatment-resistant patients with a pervasive developmental disorder, autism of childhood, or OCD have responded well to clozapine, either by itself or in addition to their regular treatment.

Effects on Specific Organs and Systems

General. Sedation is the most common adverse effect of clozapine treatment. It occurs early in treatment, and tolerance usually develops after the first few days or weeks. Giving the larger part of the daily dose at bedtime may reduce daytime sedation. However, many individuals are still unable to tolerate the sedative effects and should, therefore, be treated with another antipsychotic. Dizziness or vertigo may be related to orthostatic hypotension.

Disturbances in Temperature Regulation. Benign hyperthermia is occasionally observed during the first 3 weeks of clozapine treatment, with a peak incidence on the tenth day. The increase in temperature is usually not more than 1 to 2°F and resolves over a few days. Occasionally, however, temperature readings above 101°F have been seen, which require temporary interruption of clozapine treatment and frequent hematological monitoring. Differential diagnoses include drug fever, intercurrent infection, infection secondary to agranulocytosis, dehydration, heat stroke, lethal catatonia, and, possibly, NMS. Patients who develop a high temperature can be given the drug again but with a more gradual increase in dosage. If this strategy does not work, clozapine may need to be discontinued. As is also seen with chlorpromazine, mild hypothermia is frequently observed (87 percent) after clozapine treatment. This common effect may indicate the poikilotherm effect of antipsychotic agents, presumably mediated by the hypothalamus.

Cardiovascular. The cardiovascular side effects most frequently observed with clozapine are tachycardia and postural hypotension. The tachycardia is probably a direct effect of the vagolytic properties of the drug. It can be present in the supine position and is thus not the result of orthostatic changes. Increased pulse rates of 20 to 25 beats per minute are encountered when clozapine reaches 300 mg per day or more over a 7-day period (e.g., sinus tachycardia). Tachycardia related to clozapine may be treated with a β-blocker such as atenolol (Tenormin), although patients should then be monitored for hypotension. Propranolol (Inderal) should not be prescribed because it may increase the risk of agranulocytosis.

Reversible nonspecific ST-T wave changes, T-wave flattening, or inversions (repolarization effects) are seen infrequently with clozapine and are usually of no clinical significance. These changes are similar to those seen with other antipsychotic agents and are dose dependent. Clozapine can increase the QT interval, although there are very limited data to determine if these increases are associated with a risk of ventricular arrhythmias. Orthostatic hypotension is more likely to occur during initial titration of clozapine in association with rapid dose escalation but may occur after the first dose. In one report, initial dosages of clozapine as low as 12.5 mg were associated with orthostatic collapse and respiratory arrest. The risk of postural hypotension progressing to orthostatic collapse is substantially greater if the initial dosage of clozapine exceeds 75 mg per day. Tolerance to the hypotensive effects of clozapine often develops over time, and the effects can usually be managed if the initial dosage is low (e.g., 25 mg per day) and is increased gradually. When hypotension occurs, lowering the dosage to the previous level and slowing the rate of upward titration usually limits problems. Support stockings, increased sodium intake, or fludrocortisone (Florinef) may be helpful. Rarely (approximately

1 case per 3,000 or 4,000 patients), orthostatic collapse can be profound, accompanied by respiratory or cardiac arrest.

Paradoxically, hypertension has also been observed with clozapine (less than 4 percent). Clozapine induces significant changes in hemodynamic mechanisms; it should be used with caution in patients with pre-existing cardiovascular disease, such as a history of myocardial infarction or of arrhythmias. The authors recommend careful monitoring of vital signs during the first few weeks of treatment.

Clozapine has been associated with idiopathic myocarditis. The section on warning and precautions below will discuss this further.

Gastrointestinal. Constipation, most probably due to the antimuscarinic effects of clozapine, is the most common gastrointestinal adverse effect and, if left untreated, can progress to intestinal obstruction. Clinicians treating patients with clozapine should monitor the presence of constipation and intervene proactively at the earliest sign that this symptom has developed. Interventions may include modifications in the patient's diet, use of stool softeners, increased fluid intake, and exercise.

Nausea and vomiting may occur during the initial stages of clozapine treatment. Patients who experience the side effects can often, but not always, be managed by dosage reduction.

Urogenital. Urogenital effects include enuresis, frequency and urgency, hesitancy, urinary retention, and impotence. All of these are independent of dose or blood concentrations of clozapine. Urinary incontinence or enuresis can be managed by setting an alarm clock to ring at night or administering intranasal desmopressin (DDAVP) or oxybutynin (Ditropan) (5 to 15 mg per day). So far, a few cases of clozapine treatment-associated priapism have been noted. Because patients may not volunteer these complaints, clinicians should ask about them.

Therapeutic Indications

Treatment-Resistant Schizophrenia. Clozapine is indicated for patients who have failed trials with other antipsychotics. Given the serious side effects associated with clozapine treatment, including seizures and agranulocytosis, most guidelines recommend a trial of a minimum of two other antipsychotics, one of which should be an SGA. Studies have found that clozapine's advantage when compared with other antipsychotics extends from patients who continue to experience severe symptoms to those who have moderate symptoms.

Reduction in the Risk of Recurrent Suicidal Behavior in Schizophrenia or Schizoaffective Disorder. The InterSePT study as well as epidemiological data indicate that clozapine is indicated for those patients who are at risk of

suicidal behaviors. It is the only antipsychotic with this particular indication.

Precautions and Adverse Reactions

The only contraindications to the use of clozapine are history of hypersensitivity to clozapine or tablet components, a WBC count below 3,500 cells per mm^3, a previous bone marrow disorder, a history of agranulocytosis during clozapine treatment, or the concomitant use of another bone marrow suppressant drug such as carbamazepine (Tegretol). History of myocarditis is not a labeled contraindication, but the authors recommend against use of clozapine in these patients. Although the mechanism of action is unknown, there is a slight risk of respiratory depression or collapse if treatment is initiated while patients are taking benzodiazepines.

Black Box Warnings

AGRANULOCYTOSIS. The risk of clozapine-induced agranulocytosis is 0.73 percent during the first year of treatment and 0.07 percent in the second year. Review of the clozapine registry indicates that the incidence may be as low as 0.038 percent. The risk of this adverse effect is greatest during the first 3 months of treatment, but a significant risk remains during the first year of treatment. For neutropenia, the risk is 2.32 percent in the first year and 0.69 percent in the second year.

Increased familiarity of clinicians with agranulocytosis (absolute neutrophil count [ANC] less than 500 cells per mm^3 or WBC less than 1,000 cells per mm^3) decreased the incidence of agranulocytosis by more than 50 percent from before 1995 to after 1997.

Agranulocytosis due to clozapine is a potentially fatal condition that requires immediate medical attention. The risk of agranulocytosis increases with age and is higher in women. Therefore, before treating patients with clozapine, clinicians must register patients with a clozapine monitoring system. The United Kingdom and Australia require, in addition to the 3,500 WBC per mm^3, that granulocyte count (ANC) is 2,000 cells per mm^3 or higher when clozapine is initiated. Patients who are treated with clozapine in the United States must receive the following monitoring protocol:

- WBC is no longer required to be monitored—only ANC.
- Initial ANC must be $\geq 1{,}500/mm^3$, and in patients with benign ethnic neutropenia it must be $\geq 1{,}000/mm^3$.
- Monitoring is weekly for the first 6 months, every 2 weeks for the second 6 months, and monthly after 12 months. The threshold minimum ANC that is not classified as neutropenia is now $1{,}500/mm^3$ rather than

1,000/m3.

The requirement for ANC monitoring is continued for as long as patients receive the drug and for at least 1 month after it is discontinued. Current guidelines specify that any fever or sign of infection (e.g., pharyngitis) is an immediate indication for a WBC count, particularly in the first 18 weeks of treatment. The revised requirements indicate that clozapine treatment should be interrupted for ANC <1,000/mm3. Reports of clozapine re-exposure after hematologic recovery have shown that all such patients again experienced agranulocytosis, but sooner and at lower doses than during initial treatment. As a result, patients who develop agranulocytosis should not receive clozapine again. Although a WBC count below 3,500 cells per mm3 is not a proven risk factor, clozapine should be administered cautiously in patients with such low counts because of the difficulty in early identification of agranulocytosis. Rechallenge is not dictated by WBC any longer, only ANC. Rechallenge is allowed following recovery from moderate neutropenia (500 to 999/mm3) but not after recovery from severe neutropenia (<500/mm3) unless prescriber determines benefits outweigh risks. Clozapine therapy should be discontinued whenever the total WBC count falls below 3,000 cells per mm3 or the granulocyte count falls below 1,500 cells per mm3.

Other hematological changes have been reported with clozapine, including leukocytosis (0.6 percent), eosinophilia (1 percent), and leukopenia, neutropenia, decreased WBC count (3 percent), and, rarely, thrombocytopenia. If the total eosinophil count rises above 4,000, clozapine should be discontinued until the count falls below 3,000.

ORTHOSTATIC HYPOTENSION. On rare occasions clozapine can cause severe episodes with orthostatic hypotension and possible syncope. This has been associated with cardiac or respiratory arrest. These serious events are more likely to occur early in treatment when the dose is being increased. Also, these events have been associated with benzodiazepine use and suggest that combining clozapine and benzodiazepines early in treatment should be done cautiously. Dosage should be increased slowly, with divided doses, and clozapine should be used with caution in patients with cardiovascular or cerebrovascular disease or conditions predisposing them to hypotension.

SEIZURES. Five to 10 percent of patients treated with clozapine will develop seizures. The risk is clearly related to dosage, with an increased risk at dosages greater than 600 mg. Rapid escalation of dosage during the first weeks of clozapine treatment may increase the likelihood of seizures. A pre-existing seizure disorder or head trauma places the patient at even greater risk.

A number of strategies may be effective for managing the risk of seizures. Monitoring clozapine plasma concentrations in patients receiving

higher dosages may ensure that concentrations do not become excessive. Patients with a history of head injury should have baseline electroencephalographs (EEG) performed before the initiation of clozapine. Clinicians may also consider an EEG before increasing clozapine dosages above 600 mg. In addition, when patients receive higher doses or have abnormal EEGs, adding an anticonvulsant such as sodium valproate (Depakene) may be helpful.

The occurrence of seizures in patients treated with clozapine should not be viewed as a clear reason to stop clozapine. Lowering the dosage and adding an anticonvulsant is usually sufficient to prevent further seizures. Sodium valproate, gabapentin (Neurontin), and topiramate (Topamax) have been effective in treating clozapine-induced seizures. Carbamazepine should not be prescribed because it can also cause neutropenia or granulocytopenia. Once patients have begun anticonvulsant therapy, the dosage of clozapine can be retitrated to an optimal level.

MYOCARDITIS AND CARDIOMYOPATHY. Clozapine is associated with an increased risk of myocarditis. Although the incidence of myocarditis is very low (approximately 2.8/100,000 patient-years), it can result in death. Clinicians should consider the possibility of myocarditis when patients receiving clozapine present with unexplained chest pain, tachycardia, palpitations, dyspnea, fever, flu-like symptoms, or hypotension. Unfortunately, some of these symptoms are common in individuals who are in the early stages of clozapine treatment, and 80 percent of clozapine-induced cases of myocarditis occurred during the first 6 weeks of treatment. Because mortality from myocarditis approaches 40 percent, early detection and treatment are important. If this syndrome is suspected, clozapine should be discontinued and evaluations including an ECG, creatine kinase level, and erythrocyte sedimentation rate should be performed.

INCREASED MORTALITY IN ELDERLY PATIENTS WITH DEMENTIA. Clozapine and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

Other Adverse Events

SIALORRHEA. Sialorrhea is an uncomfortable adverse effect that develops early in treatment. Hypersalivation is most profound during sleep, and patients may complain that their pillow is wet in the morning. Placing a towel over the pillow may be of some help. Clonidine (Catapres) (0.1- or 0.2-mg patch once a week) or amitriptyline (Elavil, Endep) at bedtime has been used to treat sialorrhea. Studies suggest that clozapine does not increase saliva flow but decreases swallowing, which becomes more pronounced during sleep.

PERIPHERAL ANTICHOLINERGIC EFFECTS. Dry mouth, blurred vision, constipation, and urinary retention are commonly observed with clozapine. Constipation can be severe, particularly when patients fail to exercise or drink sufficient fluids. Other side effects of the autonomic nervous system, such as increased sweating, have also been reported.

WEIGHT GAIN. Clozapine can be associated with substantial weight gain; a meta-analysis of short-term trials with clozapine found an average weight gain of 4.45 kg over 10 weeks. This exceeded the weight gain observed with all of the other medications evaluated in the trials. Other studies indicate that patients can continue to gain weight over a period of 5 years. The amount of weight that patients gain can be substantial and can result in some patients becoming obese. Younger patients, including adolescents, may be more vulnerable to gaining weight on clozapine.

These observations demonstrate the importance of preventing substantial weight gain for patients receiving clozapine. Physicians should weigh patients frequently during the first months of clozapine treatment and should encourage patients to monitor their own weight. If weight gain is observed, it is important for clinicians to intervene with counseling about nutrition, weight, and exercise. If these interventions are unsuccessful, changing medication to an agent less likely to cause weight gain should be considered.

DIABETES MELLITUS. Clozapine, along with many other SGAs, can increase the risk of type 2 diabetes mellitus. In a naturalistic study by David Henderson that monitored 81 patients over a 5-year period, 36.6 percent developed diabetes. Case reports suggest that new cases of diabetes usually occur during the first 6 months of clozapine treatment. Michael Sernyak and his coworkers examined the records of more than 30,000 veterans and found that the prevalence of diabetes was higher in patients receiving clozapine, olanzapine, or quetiapine. It is also concerning that a number of case reports indicate that patients receiving clozapine developed diabetic ketoacidosis. Although these forms of evidence remain inconclusive, they strongly suggest that clinicians should be aware of the possible association of clozapine with an increased risk of diabetes. This may lead clinicians to monitor patients for diabetes, with fasting blood glucose determinations at regular intervals. It may also be helpful to inquire if patients are experiencing clinical signs of diabetes, such as polydipsia, polyuria, or weight loss.

LIVER FUNCTION DISTURBANCES. Liver function disturbances are generally mild and transient.

EXTRAPYRAMIDAL SIDE EFFECTS. Clozapine has a much lower incidence of extrapyramidal side effects than other antipsychotics. Akathisia (6

percent), tremors (6 percent), and rigidity (3 percent) are considerably less frequent with clozapine than with FGAs. The authors are not aware of reports of acute dystonia with clozapine. Case reports suggest that tardive dyskinesia may improve with clozapine.

NEUROLEPTIC MALIGNANT SYNDROME. Consistent with clozapine's low affinity for D_2 receptors, there have been few reports of NMS developing in patients who were treated solely with clozapine, although case reports of this syndrome developing in patients when concomitantly treated with lithium (Eskalith) exist. Although two patients had experienced NMS with conventional antipsychotics before, one case has been reported of a patient with a history of NMS that was successfully treated with clozapine. The authors recommend, therefore, that lithium should not be used as adjunctive treatment with clozapine in patients who have previously experienced NMS.

Because clozapine treatment is accompanied by side effects that resemble several signs and symptoms of NMS (e.g., hyperthermia, cardiovascular effects, delirium, increased sweating, elevations in creatine phosphokinase, and leukocytosis), clinicians should be alert for the development of a potential NMS during clozapine treatment. Some case reports have described NMS without rigidity in patients treated with clozapine, although the lack of rigidity could preclude the diagnosis of this syndrome.

PREGNANCY AND LACTATION. Clozapine is rated as pregnancy category B. Studies have not revealed evidence that clozapine causes harm to the fetus. However, there are no adequate and well-controlled studies in pregnant women. Studies in animals suggest that clozapine is excreted in breast milk. As a result, women taking clozapine should not breastfeed.

Discontinuing Clozapine

If a decision is made to change a patient to a different antipsychotic, it should not be made abruptly unless patients have developed agranulocytosis. In some individuals, the sudden discontinuation of clozapine has led to a severe exacerbation of their underlying illness. In addition, withdrawal of a potent antimuscarinic agent such as clozapine can lead to cholinergic rebound, with symptoms such as nausea and vomiting. For these reasons, the authors recommend that patients are gradually cross-tapered from clozapine to another antipsychotic agent over 2 to 4 weeks.

Drug Interactions

Because the cytochrome P450 (CYP) mitochondrial system is involved in the metabolism of clozapine, ethnic differences and interactions with drugs

that inhibit or stimulate this system will affect clozapine plasma concentrations. For instance, caffeine *N*-3-demethylation, which is a measure of CYP isoenzyme 1A2 (CYP1A2) activity, accounts for 70 percent of the variance in clozapine clearance. This suggests that administration of fluvoxamine (Luvox), a potent inhibitor of CYP1A2, will elevate clozapine concentrations, whereas fluoxetine (Prozac) administration may only lead to changes in higher dosage ranges. Cimetidine (Tagamet), SSRIs, tricyclic drugs, and valproic acid decrease clearance, presumably through inhibition of CYP1A2 and CYP2D6, whereas phenytoin (Dilantin) and carbamazepine induce CYP2C and CYP3A4 hepatic isoenzymes and may decrease concentrations of clozapine.

Furthermore, when risperidone, which weakly inhibits CYP2D6, is added, clozapine concentrations may increase. Erythromycin (E-Mycin) and ketoconazole (Nizoral) may increase clozapine concentrations.

Laboratory Interference

Clozapine does not appear to interfere with other laboratory tests.

Dosage and Administration

Initiating Treatment. Clozapine treatment should begin with 12.5 to 25 mg per day and increased to 25 or 50 mg per day on the second day. The daily dose, which should be administered at least twice daily initially, can usually be increased by 25 mg every 1 or 2 days until a target dose of 300 to 450 mg per day is reached. The rate of increase is often limited by sedation and orthostatic hypotension. Because the titration phase for clozapine may require several weeks in some individuals, these patients should be continued on their current antipsychotic agent, which should be gradually decreased as the clozapine dosage increases. Patients who fail to respond to respond in the 300 to 450 mg per day range and who do not have serious side effects can be increased gradually to doses as high as 900 mg per day. However, clinicians and patients should be aware of the risk of seizures at higher levels and when doses are escalated more rapidly.

Duration of Treatment. Once the appropriate dosage has been reached and the patient improves, the medication should be continued. There is evidence that patients who receive clozapine will continue to improve over a 3- to 6-month period. If there are concerns that patients are experiencing excessive side effects or an inadequate response, measurement of plasma concentration may be helpful. Levels above 350 ng/mL are an indication that patients are receiving adequate dosages of clozapine.

RISPERIDONE

History

During the early 1980s scientists at Janssen Pharmaceutica were interested in developing an antipsychotic that would have a clinical profile similar to clozapine but without a tendency to cause agranulocytosis. The company developed a number of drugs with 5-HT_2 antagonism with and without D_2 activity. One compound, setoperone, had weak dopamine activity and was a relatively weak antipsychotic. Ritanserin was developed as a 5-HT_2 antagonist (inverse agonist) that could be added to a D_2 antagonist to decrease the amount of extrapyramidal side effects. Although ritanserin had anti-negative symptom effects, improved sleep, and some weak antipsychotic effects, it also had significant effects on QTc interval. The synthesis of risperidone in 1984 led the company to focus on the development of this agent since it combined strong D_2 and 5-HT_2 antagonism. Subsequent safety and efficacy studies with risperidone led to its approval in the United States in 1994.

Risperidone was the first SGA medication to be approved following clozapine. Whereas clozapine was reserved for patients with illnesses that were poorly responsive to available antipsychotic drugs, risperidone was a first-line antipsychotic that could be administered to nearly every patient with a psychotic illness. Following its introduction it was hoped that risperidone would share clozapine's efficacy for a broad range of psychopathology in schizophrenia and that it would be more effective than the FGAs. Although this promise has not been met, risperidone has been widely accepted and is among the most prescribed antipsychotics worldwide.

Chemistry

Risperidone is a benzisoxazole derivative (Fig. 34.28–1). The molecular formula is $C_{23}H_{27}FN_4O_2$ and its molecular weight is 410.49.

Pharmacological Action

Pharmacokinetics

ABSORPTION AND DISTRIBUTION. Risperidone has a bioavailability of 70 percent, and studies show that all oral forms of risperidone are bioequivalent. Risperidone is metabolized in the liver to 9-hydroxyrisperidone (or paliperidone [Invega]), which has generally the same pharmacological profile as the parent compound. After ingestion, peak plasma levels of the parent compound occur within 1 hour and within 3 hours for 9-OH-risperidone. Steady state is expected to be reached by 5 days (with a range of 1 to 5 days, depending on the CYP2D6 activity in the individual patient). Food does not affect the rate or extent of absorption in the gut.

The volume of distribution is 1 to 2 L/kg. Risperidone is 90 percent

plasma protein bound, and its metabolite is 77 percent protein bound. However, there is only a slight increase in the free fraction of risperidone and paliperidone with high therapeutic doses of warfarin (Coumadin) and other highly protein-bound medications.

METABOLISM AND ELIMINATION. Risperidone undergoes extensive metabolism, primarily by CYP2D6 (see section on drug interactions). The major metabolite is 9-OH-risperidone, which has similar pharmacologic activity as risperidone. The half-life of risperidone is 3 hours in rapid metabolizers and 20 hours in poor metabolizers. The half-life of 9-OH-risperidone is 21 hours in rapid metabolizers and 30 hours in poor metabolizers. The combined half-life of risperidone and its metabolites has a mean of 20 hours. Seventy percent of risperidone is excreted in the urine.

Pharmacodynamics

MECHANISM OF ACTION. Risperidone has high affinity for dopamine D_2 receptors (Table 34.28–2) and for serotonin 5-HT_{2A} receptors, and its potent antagonism at these receptors is thought to mediate its therapeutic effects. Risperidone also demonstrates high affinity for adrenergic α_1- and α_2-receptors and histaminergic H_1 receptors. It has moderate affinity for serotonin 5-HT_{1C}, 5-HT_{1D}, and 5-HT_{2A} receptors, and weak affinity for dopamine D_1 receptors. Risperidone has no affinity for cholinergic muscarinic receptors or adrenergic β_1 and β_2 receptors. Although risperidone has high affinity for D_2 receptors, it does not have the rates of EPS that the high-potency FGA medications have. This is most likely due to the dopamine-promoting effects of 5-HT_{2A} antagonism. Risperidone blocks 65 percent of D_2 receptors (the lowest threshold percentage for antipsychotic efficacy) at an average dose of 2 mg per day. At an average of 6 mg per day, 80 percent of D_2 receptors are blocked, and EPS may occur. At the 2-mg dose, 5-HT_{2A} effects may not be optimal.

Table 34.28–2.
Side Effects Associated with Receptor Antagonism

Item	D_2	D_1	5-HT_{2A}	H_1	`1	`2	ACh
Extrapyramidal symptoms (parkinsonism, dystonia, akathisia)	+	0	−	0	0	0	−
Tardive dyskinesia	+	0	0	0	0	0	0
Sedation, somnolence	+	0	0	+	+	+	+
Neuroleptic malignant syndrome	+	0	0	0	0	0	0

Tachycardia	0	0	0	+	+	+	+

Anticholinergic side effects (dry mouth, blurred vision, constipation, difficulty urinating)	0	0	0	+	0	0	+
Prolactin increase	+	0	0	0	0	0	0
Decreased ejaculatory volume	+	0	0	0	0	0	0
Weight gain	0	0	+	+	0	0	0
Sexual dysfunction	+	0	0	0	0	0	+

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY. The clinical activity of risperidone results from the combination of risperidone and 9-OH-risperidone. No clear evidence exists supporting the usefulness of measuring these levels in managing patients on oral or long-acting risperidone. As the ratio of 5-HT_{2A} over D_2 binding is constant across doses for the risperidone molecule, the individual antipsychotic response and side-effect profile may vary among patients based on their own 5-HT_{2A} and D_2 receptor activities (e.g., for some patients 6 mg may provide too much D_2 but not enough 5-HT_{2A} antagonism, while others may respond to only 2 mg or up to 10 mg per day).

Design and Interpretation of Clinical Drug Studies

Design. Since risperidone has become available, there have been numerous studies evaluating its efficacy, safety, and tolerability. In this section, the focus mostly will be on randomized double-blind, placebo- or active-controlled trials.

SCHIZOPHRENIA AND PSYCHOSIS: ACUTE TREATMENT. Multiple studies with brief treatment trials have confirmed risperidone's efficacy in treating the acute phase of psychosis associated with schizophrenia, schizoaffective disorder, schizophreniform disorder, and acute psychotic disorder. Risperidone has consistently been shown to be superior to placebo, superior or equivalent to FGAs such as haloperidol and perphenazine, and equivalent to other SGAs with the exception of clozapine. Early multicenter trials in the United States and Canada compared risperidone 2, 6, 12, or 16 mg, haloperidol 20 mg, or placebo in a combined total of 513 patients with schizophrenia. The results from the US and Canadian studies were very similar. In the Canadian study, risperidone 2 mg per day was not shown to be superior to placebo on measures of efficacy. Risperidone was superior to placebo at all higher doses and superior to haloperidol on a variety of measures, most noticeably the Positive and Negative Syndrome Scale (PANSS). Risperidone 6 mg was as efficacious as the higher doses. In the US sample, there was no significant difference in the rates of EPS between patients on risperidone 6 mg and placebo. There was a linear trend toward more EPS as risperidone doses increased. A factor analysis using the combined results of the Canadian and US placebo-controlled studies examined the effects of

risperidone on the five dimensions of schizophrenia (negative symptoms, positive symptoms, disorganized thought, uncontrolled hostility and excitement, and anxiety and depression). Risperidone (at all dosages studied) produced significantly greater improvements than haloperidol on all dimensions of schizophrenia ($p \leq 0.05$). The difference was most pronounced on three dimensions—hostility and excitement, anxiety and depression, and negative symptoms. Another large multicenter, multinational study of 1,362 patients with schizophrenia compared risperidone 1, 4, 8, and 12 mg per day to haloperidol 10 mg for 8 weeks. At doses of 4 and 8 mg, the response rates were 63 percent and 66 percent, respectively. There was no significant difference between response to haloperidol (response rate 59 percent) and response to risperidone. Risperidone was associated with lower EPS side effects at all doses compared with haloperidol. An 8-week study comparing risperidone (dose range 2 to 6 mg per day) to olanzapine (dose range 5 to 20 mg per day) in 377 patients with schizophrenia found similar improvements in PANSS scores between the two drugs. Risperidone showed a slight advantage in positive symptom and anxiety or depressive symptom reduction. Rates of EPS were similar between the two drugs, and rates of weight gain of over 7 percent of baseline body weight were 12 and 27 percent for risperidone and olanzapine, respectively. A Cochrane review of risperidone versus olanzapine treatment concluded that the two medications have equivalent short-term efficacy, and that more patients gained weight or experienced metabolic side effects on olanzapine than on risperidone. Both medications were associated with EPS side effects; 25 percent of risperidone users required anticholinergic medication versus 18 percent of people on olanzapine. Two studies comparing risperidone to quetiapine found risperidone improved PANSS scores significantly more than did quetiapine at 8 and 12 weeks.

Taken together these studies indicate that risperidone at doses of 4 to 8 mg has similar effectiveness to other SGAs. Using group data, the findings suggest that there is little advantage to increasing the dose above 4 to 6 mg. This observation, and the tendency of risperidone to be associated with dose-dependent EPS, has led many clinicians to target risperidone in the 3 to 5 mg range.

SCHIZOPHRENIA AND PSYCHOSIS: MAINTENANCE TREATMENT. In a randomized, nonblinded study of 184 patients, Bouchard and colleagues compared the long-term (12 months) efficacy of risperidone and conventional neuroleptics for treating patients with schizophrenia. After 12 months' treatment, risperidone (mean dose of 5.5 mg per day) demonstrated significantly greater clinical improvement than did conventional neuroleptics, both in terms of average change in score from baseline on the PANSS ($p = 0.006$) and the proportion of good responders (defined as

those with at least a 20 percent decrease in PANSS total scores, $p = 0.03$). Twice as many risperidone patients responded (30 percent) as patients treated with conventional neuroleptics (15 percent, $p = 0.03$). In a double-blind clinical trial of 555 first-episode schizophrenia patients randomized to haloperidol or risperidone for long-term treatment, patients in both groups showed similar levels of clinical improvement. Time to relapse was significantly longer with risperidone treatment (median = 466 days) versus haloperidol treatment (median = 205 days), and fewer patients relapsed on risperidone than on haloperidol. Marder and colleagues compared the effectiveness and tolerability of risperidone (mean dose 5.7 mg per day) and low-dose haloperidol (mean dose 4.5 mg per day) in 63 patients over 2 years. There were no significant differences between the treatment conditions for the risk of psychotic exacerbation or study discontinuation. Both groups showed improvements on the BPRS over time, although there was a significant advantage to risperidone treatment of the anxiety/depression cluster. Furthermore, risperidone-treated subjects had lower rates of EPS than subjects on low-dose haloperidol.

SCHIZOPHRENIA AND PSYCHOSIS: ADOLESCENTS. Two trials evaluating the efficacy of risperidone in adolescents aged 13 to 17 with schizophrenia compared risperidone at doses ranging from 0.15 to 6 mg per day with placebo. Risperidone treatment significantly improved PANSS total scores. Doses below 0.6 mg per day were less effective than higher doses. Doses above 3 mg per day were not more efficacious and resulted in a greater side-effect burden.

BIPOLAR MANIA: ADULTS. In two 3-week studies comparing risperidone treatment with placebo in patients with acute mania, risperidone treatment was associated with significantly greater improvements on the Young Mania Rating Scale (YMRS) versus placebo. Time to onset of improvement was as brief as 3 days in the first study. A recent meta-analysis by Scherk et al. was conducted on the effects of SGAs in the treatment of mania. It concluded that risperidone was significantly more efficacious than placebo in the treatment of mania, as efficacious as haloperidol, and more effective when used in combination with a mood stabilizer than was a mood stabilizer alone. A small study of 65 patients compared risperidone with haloperidol and lithium and found all medications were similarly efficacious.

BIPOLAR MANIA: CHILDREN AND ADOLESCENTS. An 8-week open-label trial of 30 children and adolescents (aged 6 to 17) found that risperidone monotherapy (mean dose 1.25 mg per day) resulted in clinically significant improvements in the YMRS scores, although at end point there were mild residual symptoms present. A double-blind trial of children and adolescents aged 10 to 17 years compared risperidone 0.5 to 2.5 mg per

day, risperidone 3 to 6 mg per day, and placebo in the treatment of manic or mixed episodes of bipolar I disorder. Risperidone in both dosage groups significantly improved YMRS scores compared to placebo. Doses above 2.5 mg per day were not more efficacious than lower doses.

IRRITABILITY ASSOCIATED WITH AUTISM: CHILDREN AND ADOLESCENTS. A study of 101 children and adolescents aged 5 to 17 years compared risperidone treatment (dose range 0.5 to 3.5 mg per day) with placebo on measures of irritability and global improvement. Sixty-nine percent of risperidone-treated patients versus 12 percent of placebo-treated patients were classified as responders. Hyperactivity and stereotypy scores also improved significantly in the risperidone group. Patients treated with risperidone gained more weight (mean = 2.7 kg) than did patients on placebo (mean = 0.8 kg) in the 8-week trial. EPS rates were similar, although parents reported a higher incidence of tremor in the risperidone group. Of the risperidone responders followed in open-label treatment for the next 6 months, 68 percent maintained those gains. A continuation of the same study followed 63 of the original patient sample for 4 months on open-label risperidone treatment, followed by an 8-week placebo-controlled discontinuation protocol. During the 4-month risperidone continuation phase, 83 percent of the patients maintained the gains in irritability diminution they had achieved during the original 8-week trial. Overall the mean irritability ratings increased from 9.5 to 10.8, an increase the authors concluded was clinically insignificant. Thirty-eight subjects were enrolled in the placebo-controlled discontinuation phase. The relapse rate was 62.5 percent in the placebo group, versus 12.5 percent in the risperidone group. A randomized double-blind, placebo-controlled trial of 40 children with autism (aged 2 to 9 years) found that risperidone 1 mg per day produced improvements of 20 percent or greater on the Childhood Autism Rating Scale and the Children's Global Assessment Scale in 63 and 89 percent, respectively, versus 0 and 10 percent of children treated with placebo. Risperidone was also associated with improvements in social responsiveness, nonverbal communication, hyperactivity, and aggression.

OTHER DIAGNOSES. Risperidone has been used off-label for multiple different symptoms and diagnoses. Approximately a dozen small studies, both open-label and double-blind, initially evaluated the use of risperidone in the treatment of combat- and non-combat-related PTSD. Early studies reported improvements in symptom scores with risperidone treatment, both as adjunctive treatment and as monotherapy. Subsequently, a larger VA Cooperative Study was conducted of a 6-month randomized controlled trial of risperidone (up to 4 mg daily) versus placebo, as adjunctive treatment to ongoing pharmacologic and psychosocial treatments of chronic PTSD. In this study (N = 247), risperidone did not show significant

difference from placebo on the primary outcome measure (Clinician-Administered PTSD Scale) or scales assessing depression, anxiety, and quality of life, but it caused more adverse events.

Risperidone augmentation has demonstrated efficacy in symptom reduction in treatment-refractory patients with major depressive disorder in a few studies. Case reports, open-label trials, and small randomized double-blind trials have shown that risperidone has efficacy as an adjunctive treatment in treatment-refractory OCD. There are a few case reports and a small study demonstrating improvements in various symptoms domains, including aggression and mood, in patients with borderline personality disorder treated with risperidone. Children with severe disruptive behavioral disorders and conduct disorders have been shown to benefit from treatment with risperidone, with important positive effects of risperidone on destructive behaviors such as aggression and self-injury. Additionally, risperidone is efficacious and well-tolerated in children with Tourette syndrome. There is a growing body of data that shows risperidone is useful in children with disruptive behaviors and below average intelligence. In this population, effective doses range from 0.01 to 0.06 mg/kg per day. In smaller studies, risperidone has been used successfully in patients with psychotic disorder secondary to brain trauma (i.e., hemorrhage) and drug-induced psychotic disorder. It has also demonstrated clinical efficacy in those with acquired immunodeficiency syndrome (AIDS)–related dementia and psychosis or with agitation in elderly patients with schizophrenia. It is not effective or well tolerated in the treatment of psychosis in Parkinson disease. Open studies indicate that elderly patients may require lower dosages (0.25 to 3.0 mg per day). Other case reports indicate that behavioral disturbances in Huntington disease and levodopa-induced hallucinations may respond favorably as well.

RISPERIDONE LONG-ACTING INJECTABLE MICROSPHERES. A double-blind, placebo-controlled study of 640 patients compared oral risperidone therapy with risperidone long-acting microspheres for 12 weeks. There was no significant difference in PANSS total score or symptom factor scores. There was no significant difference in adverse events between the two groups. A randomized, controlled, open-label study of 377 patients compared long-acting risperidone microspheres (25 or 50 mg) with olanzapine (5 to 20 mg per day) for 53 weeks. The initial assessment at 13 weeks demonstrated noninferiority of risperidone microspheres (mean dose 40.7 mg per injection) to olanzapine (mean dose 14.6 mg per day). At 12 months, the risperidone group had significantly greater improvement on the disorganized thought factor of the PANSS, while olanzapine showed greater improvement on the anxiety/depression factor. There was a trend toward greater clinical improvement in the risperidone microspheres group at 12 months. There was a greater rate of EPS in the risperidone group; the

olanzapine group had higher rates of weight gain. Another trial of 188 clinically stable patients evaluated clinical improvement on risperidone microspheres after switching from a first-generation depot medication. The authors reported that treatment with risperidone microspheres resulted in clinical improvement, defined by over 20 percent improvement in PANSS total scores, achieved in 51.5 percent of patients switched from first-generation depot medication to risperidone microspheres. There was also an improvement in EPS.

The available data with risperidone microspheres fail to address some of the important issues related to long-term treatment. First, there are no studies available that address whether this new formulation has any advantages in efficacy or tolerability when compared with other available long-acting compounds such as fluphenazine (Prolixin Decanoate) or haloperidol decanoate. In addition, at this time, the longest comparison with oral risperidone was only 12 weeks.

CATIE TRIAL. In CATIE phase I, risperidone, like the other SGAs other than olanzapine, did not significantly lengthen time to treatment discontinuation compared to perphenazine or the other second-generation medications. The mean dose of risperidone was 3.9 mg per day. Risperidone was associated with the lowest rate of discontinuation secondary to intolerable side effects (10 percent). Risperidone and olanzapine were associated with fewer concomitant prescriptions for antianxiety medications than the other antipsychotics. In CATIE phase II, risperidone was associated with gains in psychosocial functioning consistent with the gains made by the other medications in the CATIE trial. In patients who had discontinued perphenazine, risperidone was associated with a significantly shorter time to discontinuation than olanzapine or quetiapine. In patients who had discontinued an SGA, risperidone and olanzapine had significantly longer times to discontinuation than did quetiapine or ziprasidone. Of the patients who discontinued the original second-generation medication due to intolerability, there was a trend toward longer time to discontinuation with risperidone compared to the other second-generation medications.

Effects on Specific Organs and Systems

Cardiovascular System. Tachycardia and palpitations are the most commonly reported cardiovascular side effects, followed by hypotension and postural hypotension. This is most likely related to α-receptor blockade. Palpitations are noted to be dose related. There have been rare reports of atrioventricular and bundle branch block.

Respiratory System. Dyspnea and cough are reported with some frequency. Reports of rhinitis and upper respiratory tract infection are

most common in the pediatric population.

Gastrointestinal System. Abdominal pain and salivary hypersecretion are the most commonly reported gastrointestinal side effects reported in adults taking risperidone. There are also reports of dyspepsia, dry mouth, nausea, and diarrhea. In children, salivary hypersecretion, abdominal pain, nausea, dyspepsia, vomiting, and diarrhea are commonly reported side effects.

Hematological and Lymphatic System. Epistaxis and anemia are rare side effects in the adult population. No hematological effects have been reported in the pediatric population.

Central Nervous System. The majority of common CNS effects are EPS related. These include parkinsonism, dystonia, tremor, akathisia, and dyskinesia. These are also common side effects in the pediatric population, as are automatisms (or compulsive symptoms). Dizziness is also frequently reported. The presence of akathisia probably indicates that not enough 5-HT_{2A} blockade is present.

Genitourinary System. Ejaculatory disorders, priapism, and sexual dysfunction have been reported in men. Nonpuerperal lactation and menstrual irregularities are reported in women and adolescent girls. Sexual side effects may be related to risperidone effect on prolactin levels. There are some reports of urinary tract infections and urinary incontinence with risperidone therapy.

Dermatological System. Rash has been reported with risperidone use. There have been case reports of recurrent giant urticaria and angioedema associated with risperidone use.

Therapeutic Indications

Schizophrenia. Risperidone is effective for both first and later episodes of psychosis in schizophrenia and schizoaffective disorder, as well as other psychoses with prominent positive or negative symptoms. A fast-dissolving tablet (Risperdal M-tab) is available and is especially useful in the treatment of acute psychosis. Risperidone has also been found to be effective for long-term maintenance treatment of schizophrenia.

Bipolar Mania. Risperidone is indicated in adults and children aged 10 to 17 years as monotherapy or adjunctive therapy with lithium or valproate in the treatment of acute manic or mixed episodes associated with bipolar I disorder.

Irritability Associated with Autistic Disorder. Risperidone is indicated for irritability associated with autism in children and adolescents aged 5 to 17 years.

Other Diagnoses. A number of controlled studies have also been conducted in other indications, including schizoaffective disorder and schizotypal personality disorder, bipolar maintenance therapy, PTSD, treatment-resistant depression, borderline personality disorder, and aggression. One patient with Lesch–Nyhan syndrome showed fewer episodes of self-mutilation during treatment with risperidone.

Precautions and Adverse Reactions

Black Box Warning. Risperidone and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

Cerebrovascular Adverse Events. In placebo-controlled trials, elderly patients with dementia-related psychosis treated with risperidone had significantly higher incidences of cerebrovascular accidents and other related adverse events than did patients treated with placebo.

Neuroleptic Malignant Syndrome. Risperidone has been associated with NMS, possibly at rates higher than most other SGA medications. NMS is a serious and potentially life-threatening condition. Patients with suspected cases of NMS should be immediately discontinued from the antipsychotic agent and aggressively treated with supportive measures, symptomatic treatment, and medical monitoring. If the patient requires antipsychotic treatment after recovery from NMS, close monitoring and gradual reintroduction is essential.

Tardive Dyskinesia. All antipsychotic medications (with the possible exceptions of clozapine and quetiapine) carry a risk of tardive dyskinesia. Tardive dyskinesia risk is thought to be related to a combination of factors, the most important of which is unopposed D_2 blockade in the basal ganglia. Risperidone has a high affinity for D_2 receptors, but its action at the 5-HT_{2A} receptors may partially mitigate some of the striatal D_2 blockade. In one trial of risperidone treatment, 5 of 453 patients developed symptoms of tardive dyskinesia, and 14 patients with pre-existing tardive dyskinesia improved. In another study of risperidone microspheres, the rate of tardive dyskinesia emergence in 530 patients after 50 weeks of treatment was 1.19 percent. A review article that considered the second-generation medications together reported a rate of tardive dyskinesia with risperidone, amisulpride (Solian), olanzapine, and quetiapine ranging from 0.5 to 1.5

percent. The rates of tardive dyskinesia emergence are slightly higher in elderly populations, especially among women. Among 133 elderly adults administered risperidone the incidence of persistent tardive dyskinesia was 2.6 percent, and at doses of 0.75 to 1.5 mg per day the incidence dropped to 1 percent.

Hypercholesterolemia, Hyperglycemia, and Diabetes Mellitus. Studies indicate that risperidone has a lower risk of hyperglycemia and diabetes mellitus than some of the other atypical antipsychotic medications, in particular olanzapine. Multiple studies have concluded that risperidone has a risk of developing diabetes comparable to the FGAs. A population-based case-control study evaluating 19,637 patients in the United Kingdom concluded that risperidone use was associated with a nonsignificant increased risk of developing diabetes versus no antipsychotic treatment. Another study analyzing health plan claims for 4,308 patients taking antipsychotic medications concluded that the frequency of new onset diabetes type 2 was not significantly different in patients treated with risperidone versus untreated patients (N = 3,625). Results from the CATIE study indicate that risperidone produced changes in glucose level comparable to perphenazine and quetiapine, with an increase lower than that with olanzapine treatment and higher than that with ziprasidone treatment. Some SGA medications have also been associated with elevations in total cholesterol, low-density lipoprotein (LDL), and triglycerides. Studies examining the rates of lipid elevations with risperidone use have generally concluded that risperidone has a rate of hyperlipidemia similar to that of high-potency FGAs or untreated controls. The CATIE data demonstrate little or no change in lipid parameters with risperidone treatment. However, despite the statistically lower rates of hyperglycemia and hyperlipidemia with risperidone treatment versus some other second-generation agents, regular monitoring of fasting cholesterol and glucose levels is appropriate in all patients on SGA medications.

Changes in Weight. In the CATIE study, patients on risperidone gained an average of 0.8 lb during treatment, and 14 percent gained more than 7 percent of their body weight. There was no significant difference between risperidone, quetiapine, perphenazine, and ziprasidone on measures of body weight change. The percentage of patients gaining over 7 percent of their body weight during the 6- to 8-week trials was 18 percent versus 9 percent for placebo. Other studies indicate that weight gain on risperidone is highest in people with a low baseline body mass index (BMI) and lowest in people with a high baseline BMI.

Movement Side Effects and Disorders. Double-blind trials indicate that risperidone treatment is associated with a dose-dependent increase in

extrapyramidal side effects. Although most adult patients may not experience these effects at the recommended daily dosage of 6 mg, dystonic reactions have occurred with dosages between 4 and 16 mg per day, and akathisia has been described. Many patients require only 2 to 4 mg per day of risperidone.

Orthostatic Hypotension and Syncope. Risperidone has antagonistic activity at α-receptors, which contributes to its risk of orthostatic hypotension, dizziness, and syncope. In phase II and III trials among adult patients with schizophrenia, 0.2 percent of patients reported syncope on risperidone. Limiting the initial dose to 2 mg per day either in a single or divided dose may minimize these side effects in healthy adults. In patients with hepatic or renal insufficiency, or elderly patients, the initial dose should be reduced to 0.5 mg twice a day to reduce the potential for hypotension and syncope. Risperidone should be used with caution in people with known cardiovascular disease or individuals with predispositions to hypotension.

Hyperprolactinemia. Risperidone increases prolactin levels. In the CATIE study, risperidone increased prolactin a mean of 15.4 ng/dL, and it was the only study medication to significantly increase prolactin levels. Hyperprolactinemia suppresses gonadotropin-releasing hormone (GnRH), which reduces gonadotropin release and can impair gonadal steroidogenesis in men and women. This elevation is sometimes but not always associated with inhibited reproductive function and symptoms such as galactorrhea, amenorrhea, gynecomastia, erectile dysfunction, and anorgasmia. Long-term hyperprolactinemia may lead to decreased bone density in both sexes when associated with hypogonadism (although no direct evidence exists that would suggest that risperidone decreases bone density, regardless of prolactin level). Approximately one-third of breast cancers are prolactin dependent. The manufacturer suggests that patients with a history or family history of breast cancer should be monitored for emergent malignancy, especially if they develop hyperprolactinemia while on risperidone.

Pregnancy. Risperidone is considered pregnancy category C. A retrospective and prospective case series of 713 pregnancies with risperidone exposure found that in the prospective data, the percentage of congenital malformations (3.6 percent) and spontaneous abortions (16.9 percent) was consistent with background rates in the general population. In the retrospectively identified cases, the percentages of congenital malformation (7.6 percent) and spontaneous abortion (16.7 percent) were higher, but retrospective reporting is subject to bias. Thirty-seven of 197 pregnancies retrospectively had perinatal syndromes, 21 of which were

behavioral or motor disorders. These syndromes involved symptoms of tremor, jitteriness, irritability, somnolence, and feeding problems, consistent with possible risperidone withdrawal or risperidone-induced movement side effects. All but one of these children recovered completely. Use of risperidone in pregnant women should be considered carefully after weighing the risks of fetal exposure with the risks of untreated mental illness in the mother. If risperidone is used during pregnancy, the medication should be slowly titrated down prior to delivery.

Lactation. Risperidone is excreted in breast milk. Studies of the distribution of risperidone and its metabolite, 9-OH-risperidone, reveal that the milk/plasma concentration ratio for both agents was less than 0.5. Relative infant doses of risperidone ranged from 2.3 to 4.7 percent of the maternal dose. In infants who were breastfed, risperidone and 9-OH-risperidone were not detected in the plasma of the infants. However, the possibility of infant exposure and possible EPS/NMS risk cannot be ruled out. The decision to breastfeed while on risperidone should be made only after careful risk–benefit analysis.

Fertility and Teratogenicity. Risperidone increases prolactin, which can decrease fertility in men and women. Meta-analysis of 15 antipsychotic medications across 212 clinical trials found risperidone and its metabolite paliperidone caused the greatest elevation in prolactin level of the drugs studied.

In rat populations, risperidone doses of 0.16 to 5 mg/kg impaired mating in female rats, but not fertility. Beagles given risperidone showed decreases in testosterone levels and sperm motility, which continued at an attenuated level at least 2 months after drug discontinuation. In animal studies, risperidone was associated with a higher number of rat pup deaths in both the perinatal and neonatal periods. Risperidone doses administered to the rat mothers were between 0.1 and 3 times the maximum recommended human dose. There was no increase in the incidence of malformations in the rat pups compared to pups born to untreated mothers.

Carcinogenesis. Risperidone has been associated with increases in pituitary gland adenomas, endocrine pancreas adenomas, and mammary gland adrenocarcinomas in mice and rats. The no-effect dose for the tumors is less than or equal to the maximum human recommended dose. The increase in the above tumors is considered to be associated with prolonged D_2 antagonism and hyperprolactinemia. The relevance to human populations of these findings in rodents is unknown.

Mutagenesis. There is no evidence of mutagenesis with risperidone.

Special Populations

PEDIATRIC USE. Risperidone has been approved for use in children aged 5 to 16 years old for irritability associated with autism, aged 10 to 17 years for bipolar disorder, manic, or mixed episodes, and aged 13 to 17 years for schizophrenia. Overall, over 1,850 pediatric patients have been treated with risperidone in industry-sponsored clinical trials. The rate of tardive dyskinesia in this population was 0.1 percent, and it resolved with discontinuation of risperidone. In a review of studies lasting more than 11 months, Correll and Kane reported an annual tardive dyskinesia incidence in children and adolescents of 0.3 percent. Weight gain among children and adolescents must be monitored with regard to expected weight gain for the appropriate age group. Risperidone is associated with larger than expected levels of weight gain in these populations. In a study of 103 adolescents with diagnoses of schizophrenia, the average weight gain was 9.0 kg over 8 months. In several studies of children with autistic disorder or other disorders, there was an average weight gain of 7.5 kg over 1 year, compared to the expected gains of 3 to 3.5 kg per year, depending on age. Risperidone increases prolactin in children and adolescents, as it does in adults. Rates of prolactin elevation vary from 49 to 87 percent of pediatric patients taking risperidone compared to 2 to 7 percent of patients on placebo. Galactorrhea was reported in 0.8 percent of pediatric patients on risperidone; and gynecomastia was reported in 2.3 percent of risperidone users in the pediatric population. The long-term effects of risperidone treatment on growth and sexual maturation have not been assessed. Transient somnolence lasting a median of 16 days after treatment initiation was reported frequently in the child and adolescent population.

Risperidone use in the elderly should be initiated cautiously. Elderly patients are more prone to orthostatic hypotension, which can put them at greater risk of falls. Furthermore, elderly patients tend to have reduced pharmacokinetic clearance, higher rates of hepatic or renal insufficiency, and greater likelihood of polypharmacy. Elderly patients started on risperidone should be given a lower initial dose of 0.5 once or twice daily, and titration should be slower than in the adult population. Potential drug interactions should be carefully monitored, and any medications significantly metabolized by CYP2D6 should be coadministered with caution. In particular, two placebo-controlled trials found that concomitant administration of risperidone and furosemide (Lasix) increased mortality in elderly patients with dementia-related psychosis, compared to patients treated with risperidone or furosemide alone. Furosemide should not be combined with risperidone in the elderly.

Drug Interactions

Risperidone is extensively metabolized by the cytochrome P450 2D6

enzyme, where it is converted to its major metabolite 9-OH-risperidone. There are identified genetic polymorphisms for the CYP2D6 enzyme, and some percentage of people (6 to 8 percent in Caucasians; higher in African Americans) have little to no 2D6 activity. These people are poor metabolizers of drugs hydroxylated through the 2D6 pathway. Similarly, some individuals are rapid metabolizers at this enzyme site. Risperidone metabolism can also be affected by drugs that are inhibitors (paroxetine [Paxil], fluoxetine, quinidine [Cardioquin]) or inducers (carbamazepine, phenytoin, rifampin [Rifadin], phenobarbital [Bellatal]) of the 2D6 enzyme. Medications that inhibit the 2D6 enzyme (Table 34.28–3) increase plasma levels of risperidone and decrease the rate of conversion to 9-OH-risperidone. Dosing of 20 mg each of fluoxetine and paroxetine (strong inhibitors of 2D6) raised plasma levels of risperidone by 2.5 times and 3.9 times, respectively. Because risperidone and its major metabolite have similar if not identical pharmacologic effects, the result of 2D6 inhibition may not be clinically meaningful. However, risperidone dosage should be reassessed whenever a medication with 2D6 inhibition is initiated, discontinued, or changed. Medications that induce 2D6 metabolism can substantially decrease the steady-state levels of risperidone and 9-OH-risperidone. Carbamazepine (a strong 2D6 inducer) lowers the steady-state concentrations of risperidone and its metabolite by up to 50 percent. Patients coadministered risperidone and any 2D6 inducer, like carbamazepine, should be closely monitored when the inducing medication is initiated, titrated, or discontinued. In particular, if a 2D6-inducing medication is discontinued, risperidone may need to be decreased to avoid plasma concentration increases to toxic levels.

Other potential drug interactions include up to 20 percent higher levels of valproic acid with risperidone coadministration and the additive effects of medications with the potential to cause orthostatic hypotension.

Dosage and Administration

Schizophrenia. For adults starting oral risperidone (available as tablets, fast-dissolve tablets, or a solution), the initial dose should be no higher than 2 mg daily in a single or divided dose. Higher starting dosages are associated with tachycardia and orthostatic hypotension. Dose increases of 1 to 2 mg per day are acceptable but should not be spaced less than 24 hours apart. Most patients are evaluated on 4 to 6 mg for the first 4 to 6 weeks. Many patients may be optimally treated with an average 4 mg daily dose, but doses ranging from 2 to 16 mg have been found effective. Several studies have concluded that doses above 6 mg per day in divided doses were not more effective than lower doses and were associated with higher rates of EPS and other dose-dependent side effects. However one study assessing once-daily doses concluded that 8 mg per day was more efficacious than 4 mg per day. Given the risk of EPS, tardive dyskinesia,

and prolactin elevation, efforts should be made to maintain patients on the lowest effective dose. Lorazepam (Ativan) may be added during dose titration if the patient shows agitation in the early phases of treatment. Most of the improvement occurs in the first 8 weeks. Risperidone can be given once daily, which is as effective as twice-daily dosing.

Table 34.28–3.
Overview of Potential Cytochrome P450 Interactions with Second-Generation Antipsychotics

SGA	Major P450 Pathway[a]	Drugs that ↑ SGA Levels[b]	Drugs that ↓ SGA Levels[b]	SGA Effect on Other Med Levels[b]	Comments
Clozapine (Clozaril)	1A2, 2D6, 3A4	Fluvoxamine (paroxetine, fluoxetine, bupropion, other 2D6 → modest ↑), cimetidine, caffeine, ciprofloxacin, erythromycin	Nicotine, carbamazepine, modafinil, St. John wort, omeprazole, phenytoin, rifampin	Mild 2D6 inhibitor. Caution advised with other meds metabolized by 2D6. Levels of both may be ↑.	May decrease tobacco use, which can ↑ clozapine leve caution when patients change tobacc use; due to high toxicity and multiple P450 pathway check all coadministere medicines for interactions and monitor clozapine leve with medicine changes.
Risperidone (Risperdal)	2D6	Fluoxetine, paroxetine, bupropion, quinidine	Carbamazepine, phenytoin, phenobarbital, rifampin	Valproate ↑ by 20%	Risperidone and its metabolite are both active
Olanzapine (Zyprexa)	1A2	Fluvoxamine, ciprofloxacin, fluoxetine (small)	Nicotine, carbamazepine, modafinil, omeprazole, rifampin	N/A	
Quetiapine (Seroquel)	3A4	Divalproex (small), cimetidine (small), nefazodone, ketoconazole, clarithromycin, erythromycin, ritonavir	Carbamazepine, thioridazine, phenytoin, modafinil, St. John wort	Slight decrease in lorazepam clearance; Slight decrease in valproic acid exposure	
Ziprasidone	3A4	Nefazodone,	Carbamazepine,	N/A	Concomitant Rx

(Geodon)		ketoconazole, clarithromycin, erythromycin, protease inhibitors	phenytoin, modafinil, St. John wort		of medicines that ↑ QTc is contraindicate or should be used with caution.
Aripiprazole (Abilify)	2D6, 3A4	Fluoxetine, paroxetine, bupropion, quinidine, nefazodone, ketoconazole, clarithromycin, erythromycin, protease inhibitors	Carbamazepine, rifampin, phenytoin, modafinil, St. John wort	N/A	
Paliperidone (Invega)	N/A	Paroxetine (small), divalproex	N/A	N/A	As the metabolit of risperidone, paliperidone undergoes onl limited P450 metabolism.
Iloperidone (Fanapt)	2D6, 3A4	Fluoxetine, paroxetine, ketoconazole, itraconazole	Carbamazepine, rifampin, phenytoin, modafinil, St. John wort	N/A	Recommend not using with other drugs which prolong QTc interval.
Asenapine (Saphris)	1A2	Fluvoxamine, imipramine (small)	Paroxetine (small), carbamazepine (small)	Weak 2D6 inhibitor → double paroxetine exposure	
Lurasidone (Latuda)	3A4	Ketoconazole, clarithromycin, ritonavir, voriconazole, mibefradil, diltiazem, atazanavir, erythromycin, fluconazole, verapamil, grapefruit juice	Rifampin, avasimibe, St. John wort, Phenytoin, carbamazepine	Small increase in midazolam exposure (CYP3A4 substrate)	
Cariprazine (Vraylar)	3A4, 2D6	Ketoconazole, erythromycin	Carbamazepine, phenytoin, modafinil, St. John wort		
Brexpiprazole (Rexulti)	2D6, 3A4	Fluoxetine, paroxetine, bupropion, ketoconazole, quinidine,	Carbamazepine, phenytoin, rifampin, modafinil, St. John wort		

	erythromycin

Rx, prescription; N/A, not available.

[a]Medications primarily metabolized by only one cytochrome system, especially CYP2D6, are subject to more numerous and more significant potential drug–drug interactions than medications with multiple pathways.

[b]This is not a comprehensive list of potential interactions. Clinicians should check for possible drug interactions whenever patients' medication regimens are changed, including by other providers.

Adolescents with schizophrenia should be started on no more than 0.5 mg once daily. Dose increases should be made in increments of 0.5 to 1 mg per day, no less than 24 hours apart. The recommended daily dosage for adolescents with schizophrenia is 3 mg per day. Although a dose range of 1 to 6 mg per day has demonstrated efficacy, doses higher than 3 mg per day did not provide additional benefit and were associated with higher rates of side effects. If side effects are experienced, tolerability may be improved by dividing the dose into twice-daily dosing.

Elderly and Parkinson disease patients should start with 0.5 mg once or twice daily. Doses should be divided into twice-daily dosing to reduce the risk of orthostatic hypotension. Dose increases should be spaced 2 to 3 days apart, and dose increases above 1.5 mg twice a day should be made no sooner than 1 week after the last dosage change. This population may need maintenance doses of 1 mg or less to prevent other side effects.

Bipolar Mania. Adults with acute bipolar mania should be started at a dose of 2 to 3 mg per day with once-daily dosing. Dose increments should not be higher than 1 mg per day or spaced less than 24 hours apart. In this population, doses higher than 6 mg per day have not been fully evaluated.

Children and adolescents with bipolar mania should be started at doses of 0.5 mg once daily and titrated up by 0.5 to 1 mg per day no less than 24 hours apart to a recommended dose of 2.5 mg per day. Doses as high as 6 mg per day have been studied in this population, but efficacy was no greater at doses above 2.5 mg per day. The dose can be divided to reduce side effects, should they emerge. Given the unknown long-term impact of risperidone on the neurological, endocrinological, and sexual maturation of children, clinicians should strive to find the lowest effective dose and regularly re-evaluate risperidone's efficacy and appropriateness for each patient.

Irritability Associated with Autism. Children and adolescents with autistic disorder should be initiated on 0.25 mg per day for patients under 20 kg and 0.5 mg per day for patients over 20 kg. No further dose increase should be initiated for a minimum of 4 days, after which time the dose can be titrated up to 0.5 mg per day for patients under 20 kg, and 1 mg per day for patients over 20 kg. This dose should be maintained for 2 weeks. If

there is no or partial response at that dose, increases of 0.25 mg per day for patients below 20 kg and 0.5 mg per day for patients over 20 kg should occur at intervals no briefer than 2 weeks. In clinical trials of children and adolescents with autistic disorder, 90 percent of the medication responders responded to doses between 0.5 and 2.5 mg per day. In patients over 45 kg, the optimal dose may be slightly higher, approximately 3 mg per day. As in the pediatric bipolar population, given the unknown long-term impact of risperidone on the neurological, endocrinological, and sexual maturation of children, clinicians should strive to find the lowest effective dose and regularly re-evaluate risperidone's efficacy and appropriateness for each patient.

Overdose. Reports of overdose up to 360 mg of risperidone are associated with signs and symptoms such as sedation, tachycardia, hypotension, EPS, prolonged QT interval, and convulsions. A study evaluating the symptoms associated with overdose has shown that risperidone is associated with fewer side effects than clozapine and olanzapine (particularly anticholinergic side effects like agitation, confusion, and dysarthria).

Long-Acting Risperidone Microspheres. In 2003, Janssen released a novel long-acting intramuscular (IM) preparation of risperidone (Consta), the first SGA available in long-acting injectable form. Uniquely, among IM formulations, the long-acting preparation of risperidone is an aqueous suspension, with risperidone contained in a matrix of glycolic acid–lactate polymer "microspheres" (25 to 150 μm). This preparation minimizes pain and inflammation at the injection site. Gradual hydrolysis of the copolymer at the site of injection ensures slow, steady, and smooth release of risperidone over several weeks. The administration of risperidone in this long-acting, bimonthly preparation removes the need to remember once-daily dosing.

Multiple-dose pharmacokinetic studies have indicated that patients can be smoothly transitioned from oral to long-acting risperidone while maintaining stable plasma drug levels. Once administered, the main drug release commences 3 weeks after injection, is sustained for 4 to 6 weeks, and subsides by 7 weeks. To maintain steady plasma levels, oral risperidone is coadministered with the injectable risperidone microspheres for the first 3 weeks, after which the oral preparation can be gradually discontinued. Risperidone microspheres achieve steady-state concentrations after about four injections, and therapeutic concentrations are maintained for 4 to 6 weeks after the last injection. Dosing risperidone microspheres every 2 weeks ensures sustained therapeutic concentrations without significant fluctuations in plasma level. Doses range from 12.5, 25, 37.5, and 50 mg per 2 weeks. Studies evaluating doses higher than 50 mg have found no

additional clinical benefit and a higher rate of side effects and adverse events. A recent 48-week randomized, single-blind pharmacokinetic study evaluating switching dose from oral to long-acting risperidone had the following recommendations: For patients on 3 mg or less of oral risperidone, administer a 25-mg dose of the microsphere preparation; for 3 to 5 mg of oral medication, use 37.5 mg of the preparation; above 6 mg of oral risperidone, begin injections at the 50-mg dose. Patients with hepatic or renal impairment should be initiated at a 12.5-mg dose. Risperidone microspheres should be injected into alternating gluteal muscles. Detailed instructions on proper injection procedure are included with the medication. Patients obtaining the medication in advance of the injection should be advised to keep it refrigerated until their appointment. Risperidone microspheres have a lower incidence of side effects such as EPS, insomnia, orthostatic hypotension, sexual dysfunction (less than 2 percent), and weight gain (0.5 kg in the 25-mg dose group and 1.4 kg in the 50-mg group in 12-week trials). If a good symptomatic response is obtained with oral risperidone or other oral SGA agents but side effects are intolerable, switching to risperidone microspheres may be preferable. Because the smooth, continuous pharmacokinetic profile of this formulation is associated with a positive tolerability profile, it is likely to promote enhanced patient compliance and autonomy as well as improved outcomes. Hospitalization rates at 1 year were found to be lower after treatment with long-acting IM risperidone than would normally be anticipated after treatment with oral atypical antipsychotic agents.

OLANZAPINE

Olanzapine is an effective agent for the treatment of psychosis in schizophrenia and bipolar disorder. It has a mildly sedating, calming effect that has led to its acceptance in many acute psychiatric settings. The results from recent large trials, including CATIE, suggest an important dilemma for clinicians and patients. On the one hand, olanzapine may have marginal efficacy advantages when compared with some other antipsychotics. On the other hand, olanzapine is also associated with serious side effects including weight gain, lipid elevation, and an increased risk of diabetes.

History

Eli Lilly and Company formulated olanzapine in Great Britain in 1982. Since olanzapine is similar in structure to clozapine, its early development was encouraged by the hope that it would have similar efficacy with milder side effects. Phase III clinical trials were completed in July 1995, and olanzapine became available on the US and European markets in the fall of 1996.

Chemistry

Olanzapine is a thienobenzodiazepine (Fig. 34.28–1). It can be considered a derivative of clozapine with substitution of a thieno ring for clozapine's carbonyl ring.

Pharmacological Action

Pharmacokinetics

ABSORPTION. Olanzapine is well absorbed when administered orally. Peak plasma concentrations are reached in about 6 hours. Food has relatively little influence on its absorption. Olanzapine's half-life is influenced by smoking, gender, and age with a mean of about 31 hours (range of 21 to 54 hours). This allows for once-daily dosing. Patients reach steady plasma concentrations in about 7 days. IM administration of olanzapine leads to peak plasma concentrations within 15 to 45 minutes.

DISTRIBUTION. Olanzapine is widely distributed throughout the body. The drug is 93 percent protein bound to plasma proteins.

METABOLISM AND ELIMINATION. The primary metabolic pathways for olanzapine are direct glucuronidation and P450-medicated oxidation. None of olanzapine's metabolites are active. Although in vitro studies indicate that CYP1A2 and 2D6 and the flavin-containing mono-oxygenase system are involved in its oxidation, CYP1A2 appears to be the major pathway.

Pharmacodynamics

MECHANISM OF ACTION. Olanzapine is a high affinity antagonist at 5-$HT_{2A/2C}$, 5-HT_6, D_{1-4}, H_1, and adrenergic α_1-receptors and a moderate affinity antagonist at M_{1-5} and 5-HT_3 receptors. It resembles most of the SGAs by having a combination of high 5-HT_2 and D_2 activity. PET studies indicate that typical doses of olanzapine such as 10 to 20 mg result in 68 to 84 percent D_2 occupancy. Its 5-HT_2 activity is approximately eight times as strong as its dopamine receptor blockade. Compared with risperidone, quetiapine, and ziprasidone, olanzapine has greater muscarinic and histaminergic receptor antagonism. This histamine activity may explain its tendency to cause weight gain.

BLOOD CONCENTRATIONS AND CLINICAL ACTIVITY. A study by Perry and coworkers measured plasma concentrations in a large early olanzapine trial. Their findings indicate that patients with plasma concentrations above 23 ng/mL were more likely to have a favorable clinical response.

Design and Interpretation of Clinical Drug Studies

Acute Treatment of Schizophrenia. Double-blind studies have

compared once-daily olanzapine at dosages ranging from 2.5 to 17.5 mg per day, with placebo and haloperidol (10 to 20 mg per day). In one study, olanzapine was found to be superior to placebo and comparable to haloperidol in treatment of overall psychopathology (mean CGI-S score), and positive psychotic symptoms (positive BPRS and PANSS scores) at intermediate (7.5 to 12.5 mg per day) and high (12.5 to 17.5 mg per day) dosages. Olanzapine was also found to be superior to haloperidol in negative psychotic symptom response.

In another 6-week, fixed-dose, double-blind study involving 1,996 patients in North America and Europe, olanzapine showed significantly greater clinical improvement over haloperidol (total BPRS score, $p < 0.02$). Significant improvement was also seen in both positive symptom and negative symptom scores ($p = 0.03$) as well as depression rating ($p = 0.001$).

Two other dose-ranging studies have also shown olanzapine (1 to 15 mg per day) to have significant antipsychotic activity against both positive and negative symptoms of schizophrenia. Acute EPS were less frequent with olanzapine at all doses compared with haloperidol. Olanzapine has also been shown to be superior to haloperidol in treating schizophrenia patients experiencing first-episode psychosis. One study has reported that olanzapine has a significantly better risk–benefit profile than haloperidol in this group of patients.

Double-blind studies have also evaluated the effect of a rapid-acting IM formulation of olanzapine in the treatment of acute agitation in schizophrenia. IM olanzapine was found to be effective against positive symptoms in acutely agitated patients, superior to placebo and similar to IM haloperidol.

Olanzapine in Children and Adolescents. There is relatively few data evaluating the effectiveness of olanzapine for children or adolescents with schizophrenia or bipolar illness. A study in adolescents reported by Kryzhanovskaya and coworkers found that olanzapine was more effective than placebo, but associated with somnolence, liver enzyme elevations, prolactin elevation, and weight gain. An 8-week study that compared olanzapine, risperidone, and haloperidol in 50 patients aged 8 to 19 years with psychosis found that the three conditions were equally effective. However, weight gain and EPS on olanzapine and risperidone appeared to be greater than had been reported in adults. A trial by Linmarie Sikich and coworkers compared risperidone and olanzapine to molindone (Moban) in patients between 8 and 19 years of age. The NIMH Data and Safety Monitoring Board closed randomization to the olanzapine arm due to weight gain. These concerns are mirrored from a study of bipolar adolescents (13 to 17 years) who were randomized in a 3-week comparison of olanzapine or placebo. Although olanzapine was effective in reducing

symptoms, it was also associated with increases in weight, liver enzymes, fasting cholesterol, prolactin, and fasting glucose.

Taken together, all of these studies support very serious safety concerns related to treatment with olanzapine in children and adolescents. In the opinion of the authors, olanzapine should be considered for this population only when other antipsychotics have failed.

Olanzapine in First-Episode Schizophrenia. A study of 263 patients with first-episode schizophrenia reported by Jeffrey Lieberman found that olanzapine had advantages over haloperidol in total PANSS scores and depression. An interesting finding from this study indicated that first-episode patients who received haloperidol experienced losses in gray matter, which did not occur in patients who received olanzapine. An analysis of data over 2 years found that fewer patients discontinued olanzapine. However, olanzapine was associated with greater weight gain and elevations in liver enzymes. A 1-year double-blind study reported by Joseph McEvoy randomized 400 recent-onset patients to olanzapine, quetiapine, or risperidone. Discontinuation rates were similar on the three drugs. However, there were advantages for olanzapine on positive symptoms. As in other studies, weight gain was highest with olanzapine.

Comparisons with Clozapine. One published study has compared olanzapine with clozapine. In the double-blind study, 180 patients with chronic and resistant schizophrenia randomly received olanzapine (15 to 25 mg per day) or clozapine (200 to 600 mg per day) for 18 weeks. Both drugs were equally effective in reducing overall psychopathology. A significantly greater number of patients discontinued treatment with clozapine compared with olanzapine ($p = 0.022$). However, other studies have not supported this claim of superior efficacy.

Efficacy in Prodromal Schizophrenia. Thomas McGlashan and a group of North American investigators evaluated the effectiveness of olanzapine versus placebo for delaying the onset of psychosis in individuals who had prodromal symptoms. During a year of double-blind treatment 16.1 percent of olanzapine and 37.9 percent of placebo patients converted to psychosis. There was also an advantage of olanzapine for decreasing the severity of prodromal positive symptoms. However, olanzapine patients experienced a mean weight gain of 8.79 kg compared to 0.30 kg on placebo. This finding mirrors other studies in which the advantages of olanzapine are balanced by its tendency to cause substantial weight gain, particularly in younger patients.

Efficacy in Treatment-Refractory Patients. Olanzapine is potentially of interest for treatment-refractory patients because it has a biochemical

profile similar to that of clozapine and is more effective at treating negative symptoms than haloperidol. One study reported that olanzapine was as effective as clozapine in treatment-resistant patients. Alan Breier and his colleagues demonstrated that olanzapine provided a significantly greater mean improvement than haloperidol for key symptom domains (PANSS negative symptoms, comorbid depressive symptoms) and side effects (EPS, akathisia) in treatment-resistant patients.

Long-Term Effectiveness. A year-long maintenance study found fewer relapses with olanzapine than with placebo or haloperidol. At higher dosages of olanzapine, fewer patients dropped out of the study than with haloperidol.

Efficacy for Mania and Mixed States in Bipolar Disorder. Two studies found that olanzapine monotherapy at doses between 5 and 20 mg was superior to placebo at reducing manic symptoms as measured by the YMRS. A third study failed to find this advantage for olanzapine. These studies support the use of olanzapine in bipolar patients with mania or in mixed states. A study by Perlis and coworkers compared olanzapine and risperidone and found that the two SGAs had similar effectiveness in reducing manic symptoms. Two trials evaluated the effectiveness of adding olanzapine or placebo to either lithium or valproate when patients had symptoms that were inadequately controlled on the first drug. In both trials, the addition of olanzapine was more effective than the addition of placebo in reducing manic symptoms.

Agitation in Schizophrenia and Bipolar Disorder. Studies of IM olanzapine focused on the short-term reduction in agitation in patients with schizophrenia or bipolar disorder. They were double-blind and consisted of patients being assigned to receive up to three injections in the first 24 hours. Two studies compared IM olanzapine to placebo in patients with schizophrenia who demonstrated symptoms of excitement. Olanzapine at doses of 2.5, 5, 7.5, and 10 mg was more effective than placebo at decreasing levels of excitement. The higher olanzapine doses resulted in greater reductions in excitement. The advantage of olanzapine was apparent for all doses at 2 hours and for 5 to 10 mg at 30 minutes. These improvements were similar to those with IM haloperidol or IM lorazepam in separate studies. Another study found that 10 mg of IM olanzapine was more effective than placebo and oral olanzapine for reducing excitement in bipolar patients with mania or mixed states.

Effects on Specific Organs and Systems

CARDIOVASCULAR. Olanzapine is associated with orthostatic hypotension,

tachycardia, and possible syncope. This probably results from its α_1-adrenergic antagonistic properties. IM olanzapine has been associated with a syndrome that includes hypotension with bradycardia.

GASTROINTESTINAL. The anticholinergic effects of olanzapine can lead to constipation in some patients.

CENTRAL NERVOUS SYSTEM. Olanzapine is somewhat sedating and may affect motor skills.

Therapeutic Indications

Schizophrenia. Olanzapine is an effective agent for treating acute psychotic symptoms in schizophrenia. Since it is mildly sedating, psychiatrists in acute settings often favor olanzapine for patients who will benefit from a calming agent.

Olanzapine is also effective for maintaining an antipsychotic response in stabilized patients. In large studies such as CATIE, olanzapine patients tended to have lower discontinuation rates when compared with other first- and second-generation drugs. However, weight gain, lipid elevations, and insulin resistance can be serious problems in some patients. As a result, patients who continue in long-term treatment should be carefully monitored for these metabolic effects.

Bipolar Disorder. Olanzapine is effective for the acute treatment of mania and mixed states, both as monotherapy and as adjunctive therapy to lithium or valproate. It is notable that olanzapine is effective for both psychotic and nonpsychotic patients.

Olanzapine is also effective as monotherapy for maintaining response in patients who have been treated for mania or mixed states. As with schizophrenia, patients receiving long-term treatment with olanzapine should be carefully monitored for its metabolic adverse effects.

Agitation Associated with Schizophrenia and Bipolar I Mania. IM olanzapine is indicated for agitation that can be associated with schizophrenia or mania. The olanzapine product information defines psychomotor agitation as "excessive motor activity associated with a feeling of inner tension." It should be noted that oral olanzapine in its different formulations as well as other antipsychotics are also effective for agitation. The important advantage of the IM route is a more rapid onset of action.

Other Possible Indications. In double-blind studies, olanzapine has been effective in patients with schizoaffective disorder, Tourette syndrome, and for psychosis in dementia. However, there are serious concerns about increased mortality in dementia patients treated with olanzapine. In open-

label studies, olanzapine has been found to be effective in autism and in producing weight gain in patients with anorexia nervosa. Olanzapine is also used in combination with fluoxetine (Symbyax), which is indicated for depressive episodes associated with bipolar I disorder as well as treatment-resistant depression.

Precautions and Adverse Reactions

Black Box Warning

INCREASED MORTALITY IN ELDERLY PATIENTS WITH DEMENTIA. Olanzapine and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

Weight Gain. A large number of studies indicate that olanzapine is associated with greater weight gain than other SGAs with the possible exception of clozapine. In the NIMH CATIE study, olanzapine patients gained approximately 2 lb per week. Studies during long-term therapy with olanzapine found that 56 percent of patients gained greater than 7 percent of baseline weight. Weight gain occurred across all BMI levels indicating that low, normal, overweight, and obese patients were vulnerable to weight gain. As mentioned earlier, children and adolescents are more vulnerable to weight increase with olanzapine treatment.

Hyperlipidemia. Patients treated with olanzapine may experience serious increases in total cholesterol, LDL cholesterol, and triglycerides. Triglycerides are most likely to be elevated, sometimes to levels above 500 mg/dL. In the NIMH CATIE study, the mean increase in triglycerides in patients taking olanzapine was 40.5 mg/dL. For comparison, quetiapine was associated with an increase of 21.2, risperidone with a decrease of 2.4, perphenazine with an increase of 9.2, and ziprasidone with a decrease of 16.5. Since some patients were receiving olanzapine at the start of the trial and may have already experience increases, this may be an underestimate of triglyceride elevation on olanzapine. Patients with no prior history of hyperlipidemia were particularly vulnerable to increases during olanzapine treatment. These concerns about hyperlipidemia suggest that patients who are treated with olanzapine should have lipid levels monitored before and after olanzapine treatment is initiated and at regular intervals.

Hyperglycemia, Insulin Resistance, Diabetes Mellitus. Several studies suggest that hyperglycemia and diabetes mellitus are potential side effects that follow treatment with olanzapine. A number of studies, including CATIE, found greater elevations in blood glucose on olanzapine than on other antipsychotics. These effects were apparent in individuals with normal glucose regulation as indicated by normal fasting blood glucose as

well as in individuals with diabetes mellitus or other evidence of glucose dysregulation. Other studies have found that olanzapine is associated with an increase in insulin resistance in both obese and nonobese patients. This suggests that the effects of olanzapine are not just secondary to weight gain.

There is also substantial evidence indicating that olanzapine treatment is associated with an increased risk of the development of type 2 diabetes mellitus. Using the United Kingdom General Practice Research Database, Koro and coworkers found that olanzapine was associated with a significantly increased risk of diabetes when compared with patients who were not on antipsychotics (odds ratio 5.8) or taking FGAs. This finding has been supported by other large epidemiological studies. The increased risk could be related to weight gain, which is highly associated with the development of diabetes. However, there are descriptions of normal weight patients on olanzapine who develop diabetes.

There is also evidence that olanzapine can result in elevations in blood glucose that are life-threatening. In a retrospective epidemiological survey of spontaneously reported adverse events related to olanzapine therapy, 237 patients with olanzapine-associated diabetes or hyperglycemia were identified. Seventy-three percent of all cases of hyperglycemia appeared within 6 months of initiating olanzapine therapy. Eighty patients had metabolic acidosis or ketosis, 41 had glucose levels of 1,000 mg/dL or greater, and 15 patients died. When olanzapine was discontinued or the dosage was decreased, 78 percent of patients had improved glycemic control. Hyperglycemia recurred in eight of ten cases with rechallenge.

These concerns regarding glycemic control with olanzapine indicate that other antipsychotics may be preferred for patients who already have diabetes as well as those with risk factors for diabetes such as obesity or a family history of diabetes. In addition, the American Psychiatric Association and Mount Sinai Guidelines recommend that clinicians evaluate fasting blood glucose before and after initiating treatment with olanzapine.

Neuroleptic Malignant Syndrome and Tardive Dyskinesia. The product information for olanzapine has the same warnings regarding tardive dyskinesia and NMS as other FGAs and SGAs. However, most studies of tardive dyskinesia indicate a reduced risk with olanzapine compared to FGAs. In addition, there are few reports of NMS with olanzapine.

Elevated Hepatic Enzymes. Placebo-controlled trials of olanzapine found a small incidence of elevated liver enzymes. For example, 2 percent of olanzapine-treated patients had clinically significant alanine aminotransferase (ALT) elevations, which were defined as three times the upper level of normal. Patients with these elevations did not develop jaundice.

Pregnancy. Olanzapine is considered pregnancy category C. In a study that compared exposure to all SGAs to no exposure during pregnancy, the authors reported no increased risk of malformation or neonatal complications, except for lower birth weight in the exposed group. Although patients on SGAs had a higher risk of excessive weight gain during pregnancy, olanzapine was not associated with an increased risk among the SGAs. A 2000 article by the manufacturer reported on 37 prospective and 11 retrospective pregnancies with exposure to olanzapine. The rate of spontaneous abortion and malformation was at population norms. Of the prospective pregnancies, 84 percent had normal delivery and postnatal course. The remaining 16 percent had a number of problems, including prematurity, postmaturity, and low and high birth weight. Data on the metabolic status of the mothers were not reported; however, at least two of the mothers were noted to have gestational diabetes. Another study measured placental passage of medication from mother to fetus and documented neonatal outcomes in 54 women followed through pregnancy. Newport and colleagues concluded that olanzapine has the highest rate of placental passage, compared with haloperidol, risperidone, and quetiapine. Furthermore, neonates exposed to olanzapine showed trends toward lower birth weights and more neonatal intensive care unit admissions than neonates exposed to other antipsychotic medication. Case reports have indicated increased risk of gestational diabetes among pregnant women treated with olanzapine. Concerns of excessive weight gain during pregnancy and its concomitant risks to mother and fetus must be considered. The benefits of olanzapine treatment should be weighed against the potential risks to the fetus.

Nursing Mothers. Olanzapine is excreted in breast milk, but the concentration of olanzapine in breast milk appears to be low. A study was conducted by Gardiner and colleague that measured transfer of olanzapine to breast milk and then infant plasma in seven mother–infant pairs. The measured concentration of olanzapine in breast milk was approximately 1 percent of maternal dose. Olanzapine was undetectable in the plasma of exposed infants, and all infants were healthy without observable side effects. As with any medication use during breastfeeding, mothers should be advised of the risks and benefits of breastfeeding while on medication and the potential consequences of olanzapine exposure to their infant.

Drug Interactions

Agents that induce CYP1A2 such as omeprazole (Prilosec) and rifampin may decrease olanzapine plasma concentrations. Smoking also induces CYP1A2 and may have similar effects. Carbamazepine can increase the clearance of olanzapine and may also decrease plasma concentrations. Fluvoxamine, an inhibitor of CYP1A2, can cause increases in olanzapine

levels.

Laboratory Interference

Olanzapine does not interfere with common laboratory tests.

Dosage and Administration

Olanzapine is available as 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets; as 5-, 10-, 15-, and 20-mg orally disintegrating tablets (Zydis); as vials with 10 mg of olanzapine for IM injection; and as vials with 150-, 210-, 300-, or 450-mg olanzapine pamoate extended release for IM injection (Relprevv).

Treatment of Schizophrenia. Olanzapine is effective at dosages between 7.5 and 20.0 mg per day administered once daily without regard to meals. A single starting dose of 5 to 10 mg is well tolerated in most adult patients. The recommended initial dose is then adjusted as necessary within the range of 5 to 20 mg per day. Although clinical studies suggest that there is not an advantage for prescribing doses above 10 mg daily, the impression of many clinicians is that doses of 15 to 25 mg or more are optimal for acute schizophrenia. This is reflected in the CATIE study where the mean modal daily dose of olanzapine was 20.1 mg daily. In other words, the mean dose was above the maximum dose of 20 mg that is recommended in the product information. In adolescents, the dose range of 2.5 to 20 mg/day demonstrated efficacy, with the mean dose being 11.1 mg/day.

Maintenance in Schizophrenia. Long-term studies indicate that doses of 10 to 20 mg daily of olanzapine are sufficient to prevent psychotic relapse in stabilized patients.

Treatment of Bipolar Disorder. Patients with mania or mixed states can usually be started on 10 to 15 mg daily of oral olanzapine. Doses can be increased to 20 or 25 mg daily. Similar doses can be prescribed when olanzapine is added to lithium or valproate. Patients with bipolar disorder who have been stabilized can usually be maintained on 5 to 10 mg of olanzapine daily.

Special Populations. Patients who are debilitated or vulnerable to hypotension should be started on 5 mg or less. Doses of 5 to 10 mg orally may effective for schizophrenia or bipolar disorder in these individuals.

IM Olanzapine in Agitation Associated with Schizophrenia or Bipolar Disorder. IM doses of 2.5 to 10 mg have been effective in reducing agitation. In most cases, 10 mg IM is an appropriate initial dose. Lower doses may be appropriate for some patients. Doses of 10 mg may be repeated after 2 hours if the patient remains agitated. As noted earlier, the

advantage of IM administration is a more rapid onset of calming. Therefore, cooperative patients may be changed to oral administration with rapid dissolve or regular tablets.

Olanzapine Pamoate Long-Acting Injectable. In 2009, the FDA-approved olanzapine pamoate as a long-acting IM injectable agent indicated for the treatment of schizophrenia. Its efficacy was demonstrated in an 8-week randomized controlled trial (*N* = 404), in which patients with schizophrenia were discontinued from their prior oral antipsychotics and underwent a 2 to 7 day washout, followed by initiation of olanzapine long-acting injectable 210 mg every 2 weeks, 405 mg every 4 weeks, 300 mg every 2 weeks, or placebo. The primary outcome measure was the change in PANSS total score from baseline to end point. Olanzapine long-acting injectable showed statistically significant improvement over placebo at all three dosages. A subsequent longer-term trial enrolled 1065 adults with schizophrenia who were stable for 4 to 8 weeks on oral olanzapine. They were randomized to either continue their current oral olanzapine or switch to olanzapine in long-acting injectable form. The primary outcome measure was the time to exacerbation of schizophrenia, which was defined by prespecified increases in BPRS positive symptom score or hospitalization. In this study, olanzapine long-acting injectable at dosages of 150 mg every 2 weeks, 405 mg every 4 weeks, and 300 mg every 2 weeks were superior to the lower dose of 45 mg every 4 weeks.

Of particular importance, this medication has a black box warning for post-injection/sedation syndrome, which can present with signs and symptoms similar to overdose of olanzapine (e.g., may include sedation, delirium, EPS, dysarthria, ataxia, aggression, dizziness, weakness, hypertension, and convulsions). In its most extreme presentation, it can lead to coma and require intubation. This syndrome generally occurs within the first 3 hours after injection, but can also occur after this period. The frequency of this syndrome is reported to be <0.1 percent of injections and in roughly 2 percent of patients who received injections for up to 46 months.

The FDA mandates that this medication be administered at registered facilities with access to emergency services if needed. After injection, patients must be under observation for at least 3 hours before leaving the site. If this medication is used, the prescriber, health care facility, patient, and pharmacy must be enrolled in a patient care program to facilitate medication distribution.

Patients being prescribed olanzapine long-acting injection should already be taking olanzapine orally to ensure medication tolerability. This medication is recommended to be administered every 2 to 4 weeks by deep IM gluteal injection. The dosage schedules specify initial dose during the first 8 weeks, followed by maintenance dosing thereafter. To achieve levels

roughly equivalent to a 10 mg/day oral dose, patients should be initially administered 210 mg every 2 weeks or 405 mg every 4 weeks, followed by maintenance dosing of 150 mg every 2 weeks or 300 mg every 4 weeks. To achieve levels roughly equivalent to a 15 mg/day oral dose, patients should be initially administered 300 mg every 2 weeks, following by maintenance dosing of 210 mg every 2 weeks or 405 mg every 4 weeks. To achieve levels roughly equivalent to a 20 mg/day oral dose, patients should be initially administered 300 mg every 2 weeks, following by maintenance dosing of 300 mg every 2 weeks. Patients who are debilitated or more sensitive to olanzapine should be started at 150 mg every 4 weeks.

QUETIAPINE

Since its release in 1998, quetiapine has become a first-line SGA medication. In clinical trials, efficacy in schizophrenia has been demonstrated at a dosage range of 150 to 800 mg per day. The efficacy of quetiapine is superior to placebo and generally equivalent to other antipsychotic medications. Quetiapine can be distinguished by a lower incidence of extrapyramidal side effects than any of the other SGAs, with the possible exception of clozapine. Other side effects include drowsiness, orthostatic hypotension, increased heart rate, dry mouth, constipation, weight gain, hyperlipidemia, and hyperglycemia. No blood dyscrasias or effects on prolactin concentrations have been observed in long-term trials. In addition to its indication for treatment of schizophrenia, quetiapine is FDA approved for the treatment of depressive episodes in bipolar I and II and manic episodes in bipolar I. An extended release formulation is also available, which allows once-daily dosing rather than the recommended twice-daily dosing for the original formulation.

History

Quetiapine was developed by Zeneca Laboratories. Its new drug application was filed with the FDA in 1996 and approved in 1998.

Chemistry

Quetiapine is a dibenzothiazepine with more potent 5-HT_2 than D_2 receptor-blocking properties. Its molecular formula is $C_{42}H_{50}N_6O_4S_2 \cdot C_4H_4O_4$. Quetiapine is related to the clozapine, olanzapine (Fig. 34.28–1), and fluperlapine molecules.

Pharmacological Action

Pharmacokinetics

ABSORPTION. The time to maximum concentration (T_{max}) after oral intake is 1.5 hours, with an estimated half-life of 6 hours. No difference was

found between twice- and three-times-daily dosing, in spite of a steady-state half-life of 6.9 hours.

DISTRIBUTION. Steady-state levels are reached in 48 hours. Quetiapine has a wide volume of distribution, approximately 10 L/kg.

METABOLISM AND ELIMINATION. Quetiapine is extensively metabolized by the liver. It has many metabolites, although only a small percentage of these are active. The primary metabolic pathway is through CYP3A4. Ninety-five percent of [^{3}H] quetiapine is recovered as metabolites in urine and feces, but only 1 percent is recovered as quetiapine itself.

Pharmacodynamics

MECHANISM OF ACTION. Quetiapine is a multitransmitter antipsychotic agent: It has a high affinity for 5-HT_2, histamine H_1, α_1, and α_2 receptors; a moderate affinity for 5-HT_{1A} receptors; a moderate affinity for D_2 and a low affinity for D_1 receptors. Quetiapine has a very low affinity for cholinergic M_1 and D_4 receptors (despite its low affinity for cholinergic receptors, quetiapine is associated with several typically anticholinergic side effects, such as dry mouth and constipation).

Quetiapine's low incidence of EPS may be explained by its relatively high 5-HT_{2A} binding compared to its activity at D_2 receptors, according to Meltzer. An early PET study demonstrated that 2 hours after a single clinical dose, quetiapine occupies 44 percent of D_2 receptors and 72 percent of 5-HT_2 receptors. Other PET studies demonstrate rapid dissociation of quetiapine from the D_2 receptor. In one study, D_2 receptor occupancy 2 hours post dose ranged from 58 to 64 percent, and fell to 20 to 0 percent 12 to 24 hours post dose for single doses of 400 and 450 mg, respectively. This supports the hypothesis of Kapur and colleagues who propose that quetiapine's "fast dissociation" (i.e., a high D_2 occupancy which decreases to low levels by the end of the dosing interval) may be sufficient to induce antipsychotic response while minimizing EPS.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Schizophrenia: Acute Treatment. The earliest clinical trials demonstrated that quetiapine is significantly superior to placebo at reducing positive, negative, and depressive symptoms of schizophrenia. A post-hoc analysis of early placebo-controlled trials found that quetiapine separated from placebo on multiple clinical measures by the end of the first week of treatment. Later trials compared quetiapine to other FGAs and SGAs. Some of the early comparison trials suffered from quetiapine underdosing, with some study doses as low as 150 to 300 mg per day.

These studies generally found quetiapine to have comparable efficacy to haloperidol in reducing positive symptoms, but slightly less efficacy in reducing negative symptoms. Later studies began assessing quetiapine treatment at higher doses, up to 800 mg per day. Such studied mostly found comparable efficacy between quetiapine and haloperidol on positive and negative symptoms, and virtually no EPS or persistent prolactin elevation with quetiapine. In two separate 6- to 8-week, double-blind comparative studies, quetiapine (300 to 600 mg per day) had comparable efficacy to haloperidol in reducing psychotic symptoms. Both quetiapine and haloperidol produced clear reductions in mean PANSS scores, with more quetiapine-treated patients showing a clinical response (greater than 20 percent reduction in total PANSS score, $p = 0.043$). In addition, patients treated with quetiapine had a greater reduction in EPS ($p = 0.005$) and fewer treatment-emergent extrapyramidal-related adverse events ($p < 0.001$) compared with haloperidol-treated patients. In another study comparing multiple fixed doses of quetiapine to haloperidol and placebo, a dose range of 150 to 750 mg per day of quetiapine was comparable to haloperidol 12 mg per day in reducing positive symptoms, and doses of quetiapine above 300 mg per day were comparable in reducing negative symptoms. A post-hoc analysis of this data concluded that patients treated with quetiapine had significantly greater reductions of hostility and agitation compared to both placebo- and haloperidol-treated patients that were independent of the improvements in psychotic symptoms. An 8-week double-blind trial of 673 patients comparing quetiapine (mean dose 525 mg per day) and risperidone treatment (mean dose 5.2 mg per day) found that overall treatment efficacy did not differ between the two drugs, although there were some data to support greater positive symptom reduction with risperidone. Quetiapine had significantly lower rates of EPS and prolactin elevation but higher rates of somnolence. Another 6-week, double-blind trial in recently hospitalized patients with schizophrenia found that treatment with risperidone, but not quetiapine, was associated with a statistically significant separation from placebo by week 2 of treatment. Patients on quetiapine required higher rates of antipsychotic polypharmacy to control symptom exacerbation.

Schizophrenia: Maintenance Treatment. Quetiapine does not have FDA approval for the maintenance treatment of schizophrenia. However, quetiapine is frequently used off-label for maintenance treatment. Studies of quetiapine treatment in schizophrenia have followed patients for up to 18 months and found continued symptomatic improvement of positive, negative, and affective symptoms on par with improvements seen in acute treatment with quetiapine and the maintenance effects of other FGAs and SGAs. A small open-label study of 25 patients compared treatment with oral quetiapine (mean dose 493 mg per day) to treatment with haloperidol

decanoate (mean dose 170 mg per injection). Quetiapine treatment was associated with comparable prevention of symptom exacerbation over 48 weeks, less rigidity and akathisia, and greater improvement in negative symptoms over haloperidol decanoate treatment. There have been few direct comparisons between quetiapine and the other SGA medications. A large multinational naturalistic prospective study of 5,883 participants compared the efficacy of haloperidol, olanzapine, risperidone, and quetiapine at 6 months of treatment. Quetiapine was found to have comparable efficacy to haloperidol but was less efficacious than olanzapine and risperidone. However, quetiapine was likely underdosed, with a mean study dose of 200 mg per day at baseline and 300 mg per day by 6 months.

An open-label study of 728 patients with schizophrenia compared quetiapine to risperidone treatment for 4 months. Quetiapine- and risperidone-treated patients showed similar improvements on positive and negative symptoms scales, and quetiapine-treated patients had greater improvements on depressive symptom scales. Quetiapine was not associated with any extrapyramidal side effects but had higher rates of dry mouth, somnolence, and dizziness. A 6-month study comparing treatment with quetiapine or olanzapine in 346 patients found that both medications demonstrated similar efficacy in the treatment of negative symptoms, but that olanzapine therapy was associated with significantly greater positive symptom reduction, improvements in measures of functional outcome, and reduced rates of medication discontinuation. Finally, a 1-year study comparing olanzapine, risperidone, and quetiapine in the treatment of 400 patients with early onset psychosis found no differences in the all-cause discontinuation rate among the drugs. However, positive symptoms reductions were greater in the olanzapine and risperidone groups at some (but not all) time points.

These studies suggest that when appropriately dosed, quetiapine has equivalent or near equivalent efficacy compared with FGAs or other SGAs. Quetiapine appears to demonstrate a tendency toward slightly weaker symptom control but a better movement disorder profile than most other antipsychotic medications.

CATIE Trial. Quetiapine did not separate from fluphenazine, risperidone, or ziprasidone on the primary measure of time to discontinuation in the first phase of CATIE. Treatment with quetiapine (mean dose 543.4 mg per day) was associated with higher rates of side effects like dry mouth and constipation. In phase II, patients who had discontinued an SGA due to lack of efficacy had a significantly longer time to discontinuation on olanzapine and risperidone than on quetiapine or ziprasidone. However, in patients who had discontinued the first-generation medication due to lack of efficacy, time to discontinuation was longer in the quetiapine and olanzapine groups than the risperidone group.

This latter finding suggests that quetiapine, because of its low incidence of EPS, may have advantages for patients who have difficulty tolerating FGAs.

Bipolar Depression. Two 8-week, placebo-controlled trials of identical design evaluated treatment response to quetiapine at 300 mg per day and 600 mg per day fixed doses in 542 and 509 outpatients with bipolar I or bipolar II depression. The results of both studies were similar. Both fixed doses demonstrated significant improvements in depressive symptoms, which separated from placebo by the first week of treatment. There were no statistically significant differences between the dosage groups. There was no difference between quetiapine- and placebo-treated patients in terms of manic switch rate. A subanalysis of one of the studies examined patients with rapid-cycling course and concluded that quetiapine 300 or 600 mg per day was significantly more efficacious than placebo at reducing symptoms of depression, anxiety, and related symptoms in this patient population.

Bipolar Mania. Two identical studies comparing adjunctive quetiapine treatment versus adjunctive placebo treatment in 191 and 402 bipolar manic patients on lithium or valproate found that adjunctive quetiapine treatment (mean dose 584 mg per day and 492 mg per day, respectively) was associated with significantly greater reductions in manic symptoms and significantly higher rates of remission than adjunctive treatment with placebo. In the second study, a statistically greater degree of improvement in manic symptoms was evident in the adjunctive quetiapine group by the end of the first week of treatment. A study of 302 patients randomized to quetiapine, lithium, or placebo monotherapy treatment concluded that quetiapine was significantly more effective at reducing manic symptoms than placebo. Although the study was not powered to detect differences between lithium and quetiapine treatment, post-hoc analyses found no significant differences in symptom reduction between patients treated with quetiapine versus lithium. Another placebo-controlled study using haloperidol as the active control found that quetiapine was slightly less effective at reducing symptoms and achieving remission than haloperidol. The comparative analysis was post-hoc and some differences between the medications were not statistically significant. A placebo-controlled trial of 403 patients with mania concluded that quetiapine was associated with higher rates of symptom remission than was placebo at both 3 and 12 weeks.

Other Diagnoses. Quetiapine is used off-label for a number of other diagnoses and symptoms, despite limited controlled data. Three small open-label studies have evaluated the effects of treatment with quetiapine for chronic PTSD. In all three studies, quetiapine significantly reduced the

severity of PTSD symptoms in patients with and without psychotic features.

There are several small trials of quetiapine treatment of OCD. A small single-blind, placebo-controlled study found that adjunctive treatment with quetiapine and an SSRI was more efficacious at reducing symptoms of OCD than placebo and SSRI.

There are a few case reports and small open-label trials of quetiapine in the treatment of borderline personality disorder. The dose ranges in these studies varied from about 200 to 800 mg per day. Overall, the studies reported that treatment with quetiapine improved multiple symptom clusters, most notably mood, impulsivity, and aggression. There have been no randomized, double-blind, controlled trials in this population, to date.

Several studies have assessed quetiapine's effect on reducing aggression associated with psychiatric illness. A small study of adolescents with both bipolar disorder and disruptive behavior disorders found that quetiapine and divalproex had equivalent efficacy in reducing impulsivity and reactive aggression.

Anecdotally, quetiapine is considered the antipsychotic drug of choice to treat psychosis in Parkinson disease. Although quetiapine does not appear to worsen parkinsonism, in two placebo-controlled trials it failed to show efficacy in treating the psychotic symptoms associated with dopaminergic treatment of Parkinson disease. One study comparing quetiapine to clozapine (the only antipsychotic medication with proven efficacy and tolerability in Parkinson psychosis) found comparable levels of efficacy between the two drugs. Because of the high 5-HT_{2A} blockade and relatively low D_2 binding, quetiapine has been used off-label as first-line treatment psychosis in Parkinson disease. Quetiapine is more easily administered than clozapine in patients with Parkinson disease, but treatment efficacy has not been sufficiently established. The sedating effects and potential EPS are treatment limiting in this population.

Quetiapine Extended Release Formulation. A study comparing quetiapine XR (once daily dosing) to quetiapine immediate release (twice daily dosing) and placebo found comparable improvements with both forms of quetiapine preparation compared to placebo. There were no adverse events specific to the XR formulation.

Effects on Specific Organs and Systems

Cardiovascular System. Postural hypotension, likely due to quetiapine's high affinity for adrenergic α_1 receptors, is the most common cardiovascular effect. Tachycardia also occurs at rates above placebo; whether the tachycardia is secondary to postural hypotension or a separate effect is not clear. Quetiapine is not associated with clinically important increases in the QTc interval.

Respiratory and Ear, Nose, and Throat System. Dyspnea, cough, pharyngitis, rhinitis, and nasal congestion have been reported with rates slightly above placebo, which is observed with all SGAs.

Gastrointestinal System. Dry mouth, constipation, and dyspepsia are commonly reported side effects of quetiapine, with dry mouth being an especially frequent side effect. Abdominal pain is less common, but it (along with dyspepsia) is a dose-related effect.

Hematological and Lymphatic System. Leukopenia and neutropenia in conjunction with quetiapine therapy have been observed. Very rare cases of agranulocytosis, including fatal cases, have also been described.

Central Nervous System. Sedation, somnolence, and dizziness are frequently reported effects, with lethargy slightly less so. Headache and to a lesser degree asthenia are also commonly reported.

Metabolic and Nutritional System. Peripheral edema has been described with quetiapine and other antipsychotics. Hyperlipidemia, hypertriglyceridemia, and hyperglycemia are common effects of quetiapine. These have been attributed to the H_1 and 5-HT_{2C} binding as in other multireceptor antipsychotics.

Therapeutic Indications

Schizophrenia. Quetiapine is indicated for the acute treatment of schizophrenia, although in clinical practice it is used both acutely and for maintenance treatment.

Bipolar Disorder. Quetiapine is indicated for the acute treatment of manic episodes in bipolar I disorder, either as monotherapy or as adjunctive treatment with lithium or valproate. It is also indicated for monotherapy for the acute treatment of depressive episodes associated with bipolar I or II disorder. Quetiapine is indicated for the maintenance treatment of bipolar I disorder, as an adjunct to lithium or divalproex.

Off-Label Uses. Quetiapine is used in clinical practice to treat a number of symptoms. Typically in these cases clinicians are taking advantage of quetiapine's sedative and somnolent properties to treat insomnia, anxiety, and agitation. Usually the doses used for such symptomatic indications are between 12.5 and 100 mg per day, and insomnia will often respond to a dose range of 25 to 50 mg at bedtime. Sleep induction may be mediated by H_1 blockade, while improvement in sleep maintenance insomnia (i.e., decreased slow wave sleep) may be caused by 5-HT_{2A} antagonism. This mechanism in insomnia is similar to

the effects of low-dose doxepin (Sinequan). Although quetiapine benefits from having limited abuse potential, the possible metabolic risks of quetiapine use must be weighed against the benefits of a nonaddictive medication. Having lower doses for these indications means that the metabolic risks are also lower, but still require regular assessment.

Quetiapine is used to treat nonpsychotic disorders such as major depressive disorder, OCD, and borderline personality disorder.

Anecdotally, quetiapine is considered the antipsychotic drug of choice to treat psychosis in Parkinson disease, although efficacy failed to be established in two placebo-controlled trials.

Precautions and Adverse Reactions

Black Box Warnings

INCREASED MORTALITY IN ELDERLY PATIENTS WITH DEMENTIA-RELATED PSYCHOSIS. Quetiapine and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

SUICIDAL THOUGHTS AND BEHAVIORS. After quetiapine received an indication for the treatment of depression in bipolar disorder, it received the same black box warning as other antidepressant medications. In 2004, the FDA issued a warning about suicidal ideation and antidepressant therapy in the pediatric and young adult population. Although quetiapine was not one of the agents included in the 24 trials that led to the FDA black box warning, the impact of quetiapine on suicidal ideation in patients with depression or anxiety has not been assessed. Any patient, especially patients younger than 24 years, treated with medication for depression or severe anxiety should be monitored for the emergence or worsening of suicidal ideation. Emergent or worsening symptoms of anxiety, panic attacks, agitation, irritability, hostility, aggressiveness, impulsivity, akathisia, insomnia, hypomania, and mania may precede the onset of suicidal ideation and should be evaluated carefully at each visit. Patients started on treatment of depression or severe anxiety should be monitored frequently for the first 2 to 3 months of treatment or until remission occurs.

Neuroleptic Malignant Syndrome. Despite quetiapine's very low rate of EPS, rare cases of NMS have been reported with quetiapine use. Physicians should remain aware that even medications with low to nonexistent EPS risk can still occasionally cause NMS. Furthermore, several cases of high creatine kinase levels in the absence of clear NMS have been reported with quetiapine.

Tardive Dyskinesia. Quetiapine has a very low rate of tardive

dyskinesia. Although there are some reported cases of presumed quetiapine-induced tardive dyskinesia, there are many more reports of quetiapine being an effective treatment of tardive dyskinesia, much like clozapine. However, the data supporting quetiapine as a treatment of tardive dyskinesia are equivocal.

Movement Side Effects and Disorders. Since its release in 1998, most studies suggest that quetiapine, along with clozapine, has the lowest rate of extrapyramidal side effects of all the SGAs. This is thought to be the result of quetiapine's low and transient D_2 occupancy and its relatively high 5-$HT_{2A/2C}$ binding.

Hypercholesterolemia and Hypertriglyceridemia. In the industry-sponsored efficacy and safety trials of quetiapine, 16 percent of patients with schizophrenia and 9 percent of patients with bipolar disorder developed hypercholesterolemia, compared with 7 and 6 percent of placebo-treated patients. The rates of hypertriglyceridemia were higher; 23 percent of people with schizophrenia and 14 percent of people with bipolar disorder, versus placebo rates of 16 and 9 percent. In phase I of the CATIE trial, quetiapine-treated patients experienced exposure-adjusted mean increases in cholesterol and triglycerides of 6.6 and 21.2 mg/dL, respectively. These increases were second only to olanzapine, and clinically significantly higher than those seen with risperidone or perphenazine. Severe cases of hypertriglyceridemia, with levels above 400 mg/dL, are not uncommon with quetiapine therapy. Patients on quetiapine should be monitored regularly (at baseline and every 6 months) for changes in lipid parameters.

Hyperglycemia and Diabetes Mellitus. Quetiapine is associated with increases in plasma glucose and an increased risk of diabetes, but the degree of glucose increase is less dramatic than that of lipid and triglyceride increases with quetiapine. In two long-term treatment studies, 10.7 percent of patients on quetiapine developed fasting glucose measurements greater than 126 mg/dL, versus 4.6 percent of placebo-treated patients. During phase I of the CATIE trial, patients treated with quetiapine had exposure-adjusted mean increases in blood glucose of 7.5 mg/dL, an increase that was not significantly larger than that seen with risperidone or perphenazine. Patients treated with quetiapine should be monitored regularly for increases in fasting glucose above 100 mg/dL.

Changes in Weight. Quetiapine is associated with significant increases in weight, likely related in part to its high affinity for histaminergic H_1 receptors. In four 3- to 6-week trials of patients with schizophrenia, 23 percent of quetiapine-treated patients and 6 percent of placebo-treated

patients gained more than 7 percent of their body weight. Similar rates were seen in patients with bipolar disorder treated with either quetiapine or placebo. However, the increases are not as extreme as those seen with olanzapine or clozapine. In phase I of the CATIE study, 16 percent of patients treated with quetiapine gained over 7 percent of their body weight. The mean weight gain for quetiapine-treated patients was 1.1 lb from baseline to last observation.

Orthostatic Hypotension and Syncope. Quetiapine is a potent antagonist at the α_1 adrenergic receptor, contributing to its risk of orthostatic hypotension and syncope. Other related effects include dizziness and tachycardia. These symptoms are most pronounced during the initial dose titration and are minimized by starting doses of 25 mg twice a day or less. In the elderly, even lower initial doses may be indicated. Patients with known cardiovascular disease, cerebrovascular disease, or conditions that increase the risk of hypotension should be initiated on quetiapine with caution and frequent monitoring.

Cataracts. Studies on dogs at quetiapine doses four times the maximum human dose found associations between long-term (6- or 12-month) quetiapine use and cataracts. Studies in humans have failed to find similar associations between cataracts and quetiapine use. The product insert for quetiapine recommends slit lamp examinations at treatment initiation and every 6 months thereafter; it is unclear if these recommendations are followed regularly in clinical care or whether the health care costs of such frequent assessment are justified by the hypothetical human risk of cataracts.

Thyroid Hormone Changes. Quetiapine affects total and free thyroxine (T_4) levels in a dose-dependent manner. At the high therapeutic dose range of quetiapine, T_4 levels may be decreased by as much as 20 percent. These changes are generally not clinically significant, nor do they typically result in changes to TSH or thyroid-binding globulin (TBG). Less than 1 percent of patients had changes in TSH while on quetiapine. T_4 levels generally return to baseline with discontinuation of quetiapine. Patients on lithium therapy who are started on adjunctive treatment with quetiapine are likely at greater risk of thyroid hormone fluctuation than those not started on quetiapine adjunctively.

Elevated Transaminases. Quetiapine has been associated with transient and asymptomatic elevations in serum transaminases, especially ALT. In 3- to 6-week trials of patients with schizophrenia, 6 percent of people on quetiapine had elevations in transaminases of over three times the normal limit, compared with 1 percent of people on placebo. The transaminase

elevations typically occurred by the third week of treatment, and levels returned to baseline with continued quetiapine administration.

Somnolence and Sedation. Quetiapine can cause significant sedation and somnolence, especially during initial dose titration. In industry-sponsored studies, the rates of somnolence in the schizophrenia, bipolar mania, and bipolar depressed groups ranged from 18 to 34 percent of patients treated with quetiapine, versus 7 to 9 percent of patients treated with placebo. The percentage of patients on quetiapine reporting somnolence in the CATIE trial was 31 percent, but this was not significantly different from the other antipsychotic treatment groups. The sedation and somnolence are likely secondary to quetiapine's high affinity for histaminergic H_1 receptors.

Pregnancy. Quetiapine is rated pregnancy category C. Three cases studies of pregnant women treated with quetiapine throughout all or part of their pregnancies reported no noticeable effects of quetiapine treatment on the neonates. A study that compared the pregnancy outcomes of 151 women on all SGA medications found no increased risk of malformation or spontaneous abortion, but a small but statistically significant risk of low birth weight in neonates prenatally exposed to SGAs. In a study measuring the degree of placental passage of SGAs, the authors concluded that quetiapine had the lowest placental passage, as compared to haloperidol, olanzapine, and risperidone. The majority of the evidence available suggests that quetiapine is safe to use during pregnancy. However, the data are limited to case studies and small trials, and infant outcomes have not been assessed beyond the 3- to 6-month mark. Physicians should carefully discuss and document the risks and benefits to antipsychotic therapy during pregnancy with their patients, and pregnant patients treated with antipsychotic medication should be frequently monitored by both a psychiatrist and obstetrician throughout the pregnancy.

Lactation. A single case study of quetiapine excretion in human breast milk concluded that by 2 hours post dose, the level of quetiapine in breast milk was almost at the pre dose level. The calculated infant dose based on the levels collected pre dose and again at 1, 2, 4, and 6 hours post dose ranged from 0.09 to 0.43 percent of the weight-adjusted maternal dose. The infant breastfed by this mother showed no signs of adverse effects from the mother's continued quetiapine treatment. Another case study on a breastfed infant found the weight-adjusted infant dose was .1 percent of the maternal dose, and no adverse effects on the infant were noted with continued breastfeeding. The available data on the excretion of quetiapine in human breast milk and the consequent effects on infant development are sparse and limited to case studies. Patients should be advised about the

potential risks of breastfeeding while on psychotropic medications.

Dosage and Administration

Schizophrenia. Quetiapine dosages should be titrated to avoid excessive somnolence, postural hypotension, and syncope. The manufacturer's recommended dosing schedule is as follows: 25 mg twice daily on day 1, 75 to 100 mg in divided doses by day 2 or 3, for a total dose of 300 to 400 mg in divided doses by day 4. Dose increments above day 4 should occur no more rapidly than every 2 days (however, other studies have shown that a more aggressive titration is well tolerated and associated with a good response). The target dose range is 150 to 800 mg per day. All efficacy studies occurred with twice or three times a day dose schedules, but in the community quetiapine is frequently administered once daily at bedtime. Dosages above 800 mg have not been systematically evaluated, but doses up to 1,200 mg per day have been used clinically.

Mania. In acute mania, the manufacturer recommends an initial dose of 100 mg in a divided dose, with a rapid titration of up to 100 mg increases per day in divided doses, to a total dose of 400 mg by day 4. The dose can be escalated by up to 200 mg increases on day 5 and 6, for a total dose of 800 mg by day 6. Children and adolescents (10 to 17 years) should start with 25 mg twice daily and should reach a total dose of 400 mg by day 5. Patients should be monitored for orthostatic hypotension and syncope. The effective dose range for mania is 400 to 800 mg per day (400 to 600 mg per day in children and adolescents). Inpatients may benefit from the daytime sedative effects of twice-daily dosing, and as an outpatient, community practice is once a day at bedtime dosing.

Depression. The recommended titration schedule for bipolar depression is as follows: Day 1, 50 mg at bedtime; day 2, 100 mg at bedtime; day 3, 200 mg at bedtime; day 4, 300 mg at bedtime. Patients being titrated beyond 300 mg can receive 400 mg by day 5 and 600 mg by day 8. In efficacy trials no additional antidepressant benefit was noted above doses of 300 mg. The efficacy trials for bipolar depression dosed quetiapine once daily at night.

The manufacturer's recommended titration schedules should be modified for people who demonstrate significant orthostatic hypotension, somnolence, or have episodes of syncope.

Quetiapine Extended Release. The extended release formulation of quetiapine is intended for once-daily dosing at bedtime. The recommended initial dose is 300 mg. The dose can be titrated up to 800 mg as rapidly as by day 3. The tablets should not be crushed or cut. It is recommended that quetiapine extended release be taken without food or with no more than

300 calories at time of administration, as high calorie or fat meals cause increased plasma concentrations.

Dosing in Special Populations

ELDERLY. Elderly patients are generally more sensitive to quetiapine's effect on blood pressure. In this population orthostatic hypotension or syncope can increase the risk of falls. Furthermore, metabolism of all drugs is slowed in geriatric populations. The titration schedule in the elderly should be slowed and the target doses lower. Initial doses should be 12.5 to 25 mg per day, and increments of no more than 25 mg should occur every 1 to 3 days, depending on tolerability. Quetiapine is not indicated for patients with psychosis due to dementia.

HEPATIC IMPAIRMENT. Patients with hepatic impairment should be initiated at doses no higher than 25 mg per day. The dose can be increased daily by 25 to 50 mg to an effective dose.

Drug Interactions

Quetiapine is metabolized by the cytochrome P450 system. CYP 3A4 is the major metabolic pathway, and CYP 2D6 is a minor pathway. Quetiapine is neither an inhibitor nor an inducer of any CYP enzyme system. Cimetidine (a nonspecific enzyme inhibitor) did not inhibit quetiapine metabolism. Phenytoin, a strong inducer of CYP3A4, caused a fivefold increase in quetiapine clearance. Similarly, ketoconazole, a strong CYP3A4 inhibitor, increased quetiapine levels by 335 percent. Valproic acid increased quetiapine plasma levels by a clinically insignificant amount. Lithium, lorazepam (or other benzodiazepines), risperidone, haloperidol, fluoxetine, and imipramine (Tofranil) had no effects on the pharmacokinetics of quetiapine and vice versa (i.e., did not require dose adjustments). Concomitant administration of thioridazine (Mellaril), however, increased oral clearance of quetiapine by 65 percent.

Overdose

Quetiapine is relatively safe in overdose. Acute nonfatal overdoses up to 30 g have been described. One fatal overdose involved ingestion of over 13 g of quetiapine. The effects of overdose are exaggerations of the medication's side-effect profile: Sedation and somnolence, hypotension, and tachycardia.

ZIPRASIDONE

History

Ziprasidone was the fifth SGA approved in the United States. It was

synthesized in 1987 by Harry Howard of Pfizer Pharmaceuticals. Tom Seeger screened the compound and identified the activity at D_2 and 5-HT_2 receptors. Early on it was noted that ziprasidone differed from the other agents in this class by not being associated with weight gain and having relatively little sedative side effect. Its approval in the United States was delayed due to concerns regarding its tendency to prolong the QT interval on the ECG. The FDA required Pfizer to document the extent of the problem in a large trial that evaluated the effects of several antipsychotics on the QT interval. The results of this study led to ziprasidone's approval in the United States in 2001.

Concerns about weight gain, diabetes, and lipid elevations led to an increase in the use of ziprasidone. For example, in the NIMH CATIE trial, patients randomized to ziprasidone showed negligible changes in weight, glucose, or lipids. Moreover, patients who gained weight on other antipsychotics were likely to show substantial weight loss when they were switched to ziprasidone.

Chemistry

Ziprasidone is a benzisothiazolyl piperazine (Fig. 34.28–1) with a structure unlike any of the other SGAs.

Pharmacological Action

Pharmacokinetics of Oral Ziprasidone

ABSORPTION. Ziprasidone is well absorbed when orally administered. Bioavailability doubles when ziprasidone is administered with food. Therefore, patients should be instructed to take ziprasidone with a meal. After administration of multiple doses of ziprasidone under fed conditions, peak serum concentrations occur at 6 to 8 hours.

DISTRIBUTION. Ziprasidone has a mean volume of distribution of 1.5 L/kg. It is more than 99 percent protein bound.

METABOLISM AND ELIMINATION. Ziprasidone is extensively metabolized, with less than 1 percent excreted unchanged in the urine and less than 4 percent in feces. In vitro studies indicate that the formation of the major metabolites is mediated by CYP3A4, although there is a small contribution from CYP1A2. Ziprasidone's metabolites are for the most part inactive, representing less than 1 percent of the binding affinity of the parent compound for D_2 and 5-HT_{2A} receptors. Unmetabolized ziprasidone represents 44 percent of the circulating drug-related material.

Steady state is attained after 1 to 3 days of dosing. Overall exposure at steady state is relative to the dose over the range of 20 to 80 mg twice a day. The mean terminal plasma half-life for ziprasidone at steady state

ranges from 5 to 10 hours in volunteers and in schizophrenia patients. The 0.5- to 1-hour lag in reaching peak plasma concentrations has been attributed to delayed gastric emptying. Age, gender, or mild to moderate renal or hepatic impairment have no significant effect on the pharmacokinetics of ziprasidone, making dosage adjustments unnecessary.

Pharmacokinetics of IM Ziprasidone

ABSORPTION AND DISTRIBUTION. Intramuscularly administered ziprasidone, as with all parenterally administered drugs, is 100 percent bioavailable. Serum concentrations of ziprasidone reach their peak approximately 1 hour after IM administration, with a half-life from 2 to 5 hours.

METABOLISM AND ELIMINATION. After IM administration, metabolism and elimination are anticipated to occur via the same pathways as with oral administration.

Pharmacodynamics

MECHANISM OF ACTION. In vitro studies show that while ziprasidone is strong D_2 antagonist, it is an even more potent antagonist at the 5-HT_{2A} receptor, with a very high 5-HT_{2A} to D_2 ratio of 11. PET studies in healthy volunteers confirm that 5-HT_2 occupancy substantially exceeds D_2 occupancy. Ziprasidone also has potent affinity for the D_3 receptor and moderate affinity for the D_4 receptor, similar to haloperidol; the affinity for the D_1 receptor is 100-fold lower than for other dopamine receptors. Ziprasidone is an agonist at the 5-HT_{1A} receptor and a potent antagonist at 5-HT_{2C} (five times greater than clozapine and 19 times greater than risperidone) and 5-HT_{1D} receptors. It also moderately affects norepinephrine and serotonin (and dopamine) uptake sites. Ziprasidone has only moderate affinity for the α_1 receptor and low affinity for the H_1 receptor. Ziprasidone is the only agent providing uptake inhibition of norepinephrine and serotonin. Stimulation of 5-HT_{1A} receptors is shared with clozapine.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. With twice-daily administration of oral ziprasidone, estimates based on systemic exposure and PET scan data predict that 5-HT_2 and D_2 receptor occupancy ranges from 80 to 90 percent and 45 to 75 percent, respectively. Ziprasidone at serum concentrations of 30 to 40 ng/mL is likely to be associated with approximately 75 percent 5-HT_2 and more than 65 percent D_2 receptor occupancy, as determined from PET scan data.

Early Clinical Trials in Schizophrenia. Results from 4- to 6-week, fixed-dosage, double-blind clinical trials indicate that oral ziprasidone is effective in the treatment of positive, negative, and affective symptoms in patients with schizophrenia and schizoaffective disorder. In two separate 4- to 6-week clinical trials in patients with acute psychotic exacerbation of schizophrenia, oral ziprasidone (80 to 160 mg per day) was significantly superior to placebo, and, in a 4-week trial, oral ziprasidone (160 mg per day) was comparable to haloperidol (15 mg per day) in reducing psychotic symptoms. Statistically significant, dose-dependent improvements in negative symptoms, as measured by the PANSS, have been observed with oral ziprasidone (80 and 160 mg per day) compared with placebo in a 6-week trial. Oral ziprasidone (160 mg per day) also significantly improved depressive symptoms in patients with clinically significant symptoms at baseline (Montgomery–Asberg Depression Rating Scale [MADRS] 14 or more; baseline mean, 23.5) compared with placebo at 6 weeks. The statistically significant improvement has also been observed in affective symptoms at 4 weeks in patients with a BPRS anxiety-depression cluster baseline score greater than or equal to 18. Further evidence for efficacy in negative symptoms comes from a 4-week, placebo-controlled trial in which a significant improvement in the BPRS anergia factor was observed with ziprasidone at 120 mg per day. A dose-dependent effect was not observed, which suggests that the negative symptom reduction effect may be related to its lack of extrapyramidal side effects.

A careful look at these short-term trials provides valuable information about the dosing of ziprasidone. In most of the fixed dose studies, less than 40 mg twice daily was not superior to placebo; results for 40 mg twice daily were mixed. This suggests that for most patients, dosing of ziprasidone should be targeted at above 40 mg twice daily.

CATIE Trial and Ziprasidone. In phase I of CATIE, discontinuation rates on ziprasidone were similar to those for patients treated with the other SGAs and perphenazine. Ziprasidone had the best metabolic profile among the phase I agents. Ziprasidone-treated patients showed slight weight loss, as well as small reductions in cholesterol and triglycerides and trivial increases in glucose levels. Among patients who gained more than 7 percent of their baseline body weight during phase I, 42 percent of those assigned to ziprasidone during phase II lost 7 percent of their new weight.

Long-Term Effectiveness in Schizophrenia. Oral ziprasidone appears to be effective in the long-term treatment of stable patients with chronic schizophrenia according to double-blind, randomized studies. Results from a 28-week, fixed-dose comparative study indicate that ziprasidone is comparable to haloperidol in reducing overall psychopathology during long-term treatment of schizophrenia. Ziprasidone, however, demonstrated

superior tolerability and control of negative symptoms.

Results from a prospective, 1-year double-blind, fixed-dose ziprasidone study in patients with chronic or subchronic schizophrenia showed that oral ziprasidone (40 to 160 mg per day) is associated with significantly lower relapse rates compared with placebo. This group of stable patients experienced a significant reduction in negative symptoms from baseline compared with placebo, as measured with the negative symptom subscale of the PANSS. This improvement in negative symptoms was maintained throughout 12 months of treatment, with a tendency for continuing improvement in those patients completing the study.

Bipolar Mania. A study reported by Paul Keck and coworkers randomized 210 patients with mania or mixed states to a 3-week trial of ziprasidone or placebo. Dosing was flexible. From day 8 to 14 the mean ziprasidone dose was 139 mg; between days 15 to 21, it was 130.1. Ziprasidone-treated patients demonstrated significant improvements compared to placebo-treated patients on a Mania Rating Scale and the CGI. Improvements on ziprasidone emerged by day 2. Advantages on the same instruments were found in a second 3-week controlled study.

Agitation in Schizophrenia. Two double-blind studies evaluated the efficacy of IM ziprasidone for reducing agitation in schizophrenia during a 24-hour period. Patients could receive up to four injections 4 hours apart. Both studies used the Behavioral Activation Scales (BARS) to evaluate outcome. One study found that 20 mg was more effective than the 2-mg dose and the other found that 10 mg was superior to 2 mg. Two other studies were open-label and compared 3 days of IM ziprasidone or haloperidol followed by 4 days on the same drug. A 6-week study administered IM ziprasidone or haloperidol for 3 days followed by oral treatment. Each of these studies found that IM ziprasidone had similar or better efficacy against agitation than haloperidol and caused fewer extrapyramidal side effects.

Effects on Specific Organs and Systems

General. Ziprasidone causes drowsiness in a relatively small proportion of patients.

Dermatological System. In premarketing trials 5 percent of patients treated with ziprasidone developed a rash or urticaria.

Cardiovascular System. Ziprasidone has substantial α_1-adrenergic antagonist effects, which may explain a tendency to cause orthostatic hypotension, tachycardia, and dizziness in some individuals. Ziprasidone can cause prolongation of the QTc interval (see Precautions and Adverse

Reactions).

Gastrointestinal System. Occasionally, patients experience anorexia and nausea.

Endocrine. Ziprasidone can increase prolactin in some patients. However, the effects are less prominent than FGAs or risperidone.

Therapeutic Indications

Schizophrenia. Ziprasidone is effective for the treatment of schizophrenia. The evidence supporting its efficacy is from 4- to 6-week trials indicating greater efficacy than placebo. A large 52-week double-blind trial also found that ziprasidone was more effective than placebo for preventing relapse in stabilized patients with schizophrenia.

Bipolar I Disorder. Ziprasidone is also indicated as monotherapy for the acute treatment of manic or mixed episodes in bipolar I disorder. It is also indicated for the maintenance treatment of bipolar I disorder, as an adjunct to lithium or valproate. The efficacy of ziprasidone as monotherapy for maintenance therapy has not been systematically evaluated.

Acute Treatment of Agitation in Schizophrenia. IM ziprasidone is effective for managing agitation in patients with schizophrenia. The advantage of IM medication is a more rapid onset of effects. The product information for ziprasidone has the following description of the type of individual where ziprasidone may be useful: "Schizophrenic patients experiencing agitation often manifest behaviors that interfere with their diagnosis and care, for example, threatening behaviors, escalating or urgently distressing behavior, or self-exhausting behavior, leading clinicians to the use of IM antipsychotic medications to achieve immediate control of the agitation."

Precautions and Adverse Reactions

Black Box Warning. Ziprasidone and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

QT Prolongation. Ziprasidone is associated with a dose-related prolongation of the QT interval on the ECG. This is a concern since a prolonged QT interval can lead to the development of a characteristic ventricular tachycardia known as torsade de pointes. This arrhythmia can result in hypotension, or more seriously, ventricular fibrillation and death. There is a concern that if ziprasidone was administered in combination with other agents associated with QTc prolongation, the effects could be

additive. As a result, the product information for ziprasidone warns against combining it with other drugs that may increase the QT interval including dofetilide (Tikosyn), sotalol (Betapace), quinidine, other class Ia and III antiarrhythmics, mesoridazine (Serentil), thioridazine, chlorpromazine, droperidol (Inapsine), pimozide (Orap), sparfloxacin (Zagam), gatifloxacin (Tequin), moxifloxacin (Avelox), halofantrine (Halfan), mefloquine (Lariam), pentamidine (Nebupent), arsenic trioxide (Trisenox), levomethadyl acetate (Orlaam), dolasetron mesylate (Anzemet), probucol (Lorelco), or tacrolimus (Prograf). Ziprasidone should also not be prescribed for patients with existing QT prolongation. In addition, it should not be prescribed in patients who have conditions such as hypokalemia and hypocalcemia, which can prolong the QT interval.

An interesting study that was required prior to the approval of ziprasidone by FDA gives a perspective on the amount of QT prolongation associated with ziprasidone and other antipsychotics. Patients receiving six antipsychotics had their QT interval measured at their maximal plasma concentration. This was done in the presence and absence of a metabolic inhibitor of the antipsychotic in question (in the presence of an inhibitor, the plasma concentration of the antipsychotic drug increases). Ziprasidone administration resulted in a mean increase in the QTc (that is the QT interval corrected for heart rate) of 9 to 14 ms greater than four of the comparator drugs (risperidone, olanzapine, quetiapine, and haloperidol) but 14 ms less than thioridazine. This finding was sufficiently reassuring to lead to the approval of ziprasidone.

Use in Pregnancy and during Lactation. Ziprasidone is considered category C for pregnancy. Although there are no well-controlled studies on the risk of ziprasidone to the fetus, animal studies suggest that there is a potential for teratogenic effects from ziprasidone. Unlike the other older SGAs, little is published on the effects of ziprasidone during pregnancy and lactation. Therefore, ziprasidone should only be taken during pregnancy if the clinical benefits justify the risk to the fetus.

Other Side Effects. Double-blind comparisons of ziprasidone and placebo have not found a statistically significant difference in EPS or akathisia. However, case reports suggest that some patients experience an increase in restlessness that may be mild akathisia.

Drug Interactions

Ziprasidone should not be combined with drugs that prolong the QT interval. Otherwise, ziprasidone has low potential for clinically significant drug interactions. In vitro studies indicate that ziprasidone is not a substrate for CYP2D6, CYP2C9, CYP2C19, or CYP1A2 and has low potential to inhibit CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. The lack of

clinically relevant CYP2D6 inhibition has been confirmed in healthy volunteers, in whom ziprasidone did not inhibit metabolism of dextromethorphan (Benylin) (a CYP2D6 model substrate) to its major metabolite, dextrorphan. Although ziprasidone is a substrate for CYP3A4, cimetidine (a CYP3A4 inhibitor) does not inhibit its metabolism, suggesting that significant metabolism occurs by an alternative pathway. Carbamazepine induces CYP3A4 and lowers ziprasidone plasma concentrations. In healthy subjects, clinically significant interactions have not been reported with lithium, cimetidine, antacids (aluminum and magnesium hydroxides), ketoconazole, or oral contraceptives. Ziprasidone did not affect steady-state lithium concentrations.

Laboratory Interference

Ziprasidone does not affect common laboratory tests.

Dosage and Administration

Schizophrenia. For most adult patients, ziprasidone should be initiated at 20 mg twice a day with food. Dosage may be increased every 2 days. As mentioned earlier, trials in schizophrenia indicate that patients receiving a total daily dose of 100 mg or greater are more likely to respond. Daily dosage can be adjusted on the basis of clinical status up to a maximum of 80 mg twice a day.

Duration of Treatment. The benefits of ziprasidone in schizophrenia have been found to be maintained for periods of up to 1 year when given at dosages ranging from 20 to 80 mg twice a day, although in these studies no additional benefits were seen at dosages higher than 20 mg twice a day. Ziprasidone has been administered safely for up to 2 years.

Bipolar I Disorder. For the acute treatment of manic or mixed episodes, ziprasidone should be given at an initial dose of 40 mg twice daily with food. It may be increased to 60 mg or 80 mg twice daily on day 2, and titrated according to efficacy and tolerance. In flexible-dose trials, the mean daily dose used was around 120 mg. For maintenance treatment as an adjunct to lithium or valproate, patients should be continued at the same dose as initial stabilization, within the range of 40 to 80 mg twice daily with food.

Acute Treatment of Agitation in Schizophrenia (IM Formulation). The recommended IM dosage is 10 to 20 mg administered every 2 hours for the 10-mg dose and every 4 hours for the 20-mg dose, up to a maximum dosage of 40 mg per day. IM administration has not been studied for longer than 3 consecutive days, and it is recommended that oral therapy be initiated if longer-term treatment is necessary.

ARIPIPRAZOLE

Aripiprazole differs from other SGAs due to its partial agonist activity at D_2 and 5-HT_{1A} receptors. It is similar to other SGAs in having a relatively high affinity for both 5-HT_{2A} and D_2 receptors. However, in contrast to other agents that are full antagonists at D_2 receptors, aripiprazole has substantial intrinsic activity. The development of this drug was based on the hope that its partial agonist activity would result in decreased dopamine activity in limbic brain areas and increased activity in frontal areas. This pattern of dopamine activation, it was hypothesized, would lead to an effective antipsychotic that could improve negative symptoms and improved cognition. The clinical importance of this different mechanism of action is as yet unclear. The available data indicate that aripiprazole is an effective agent with minimal sedation and metabolic effects. It has a relatively long half-life that allows once-daily dosing.

Aripiprazole has become a common alternative when patients and clinicians are concerned about metabolic effects. Although the introduction of a short-acting IM formulation has increased the usefulness of aripiprazole in acute settings, its lack of ability to sedate and its tendency to cause psychomotor restlessness in some individuals have led to some reluctance to prescribe aripiprazole for the most seriously ill psychotic patients.

History

The Nobel laureate Arvid Carlsson, most responsible for identifying the importance of dopamine in antipsychotic therapeutics, suggested that a dopamine partial agonist that acted at dopamine autoreceptors may be effective in treating psychosis. This led to a search by Tetsuro Kikuchi and Yasuo Oshiro at the Otsuka Pharmaceuticals laboratory in Tokushima, Japan, for partial dopamine agonists. Aripiprazole was synthesized in 1988 and entered phase I and early phase II studies in Japan in 1990, with later phase II trials in the United States beginning in 1993. In 1999, a collaborative arrangement was developed between Otsuka Pharmaceuticals and Bristol-Meyers Squibb for the worldwide development of aripiprazole.

Chemistry

Aripiprazole is a highly lipid-soluble quinolinone derivative. Its chemical structure does not resemble any of the available antipsychotics (Fig. 34.28–1).

Pharmacological Action

Pharmacokinetics

ABSORPTION. Aripiprazole is well absorbed after oral administration. Peak plasma concentrations are reached within 3 to 5 hours after administration. The bioavailability of aripiprazole after oral administration is 87 percent. Aripiprazole's absorption is not affected by administration with food.

IM administration of aripiprazole (short acting form) leads to peak plasma concentrations at 1 to 3 hours. The bioavailability is 100 percent.

DISTRIBUTION. Aripiprazole is more than 99 percent bound to serum proteins. Studies of its steady-state volume of distribution indicate that aripiprazole has extensive extravascular distribution.

METABOLISM AND ELIMINATION. The activity of aripiprazole is primarily due to the parent compound, although some activity is related to dehydroaripiprazole metabolite. The mean elimination half-life of aripiprazole is approximately 75 hours, and the mean half-life for dehydroaripiprazole is 96 hours. These relatively long half-lives support once-daily dosing for aripiprazole and indicate that patients should attain a steady-state plasma concentration within 14 days. Aripiprazole is extensively metabolized in the liver by dehydrogenation, hydroxylation, and *N*-alkylation. Metabolism is primarily by CYP 3A4 and CYP 2D6 enzymes.

Pharmacodynamics

MECHANISM OF ACTION. A partial agonist is an agent that binds to a receptor and induces a signal that is somewhat reduced compared with the endogenous ligand; this differs from an antagonist that occupies a receptor and completely blocks the signal from the endogenous ligand. The putative advantage of a partial agonist is that it may stabilize a neurotransmitter system by decreasing the amount of signaling when there is excessive ligand (by occupying receptors and transmitting a reduced signal compared to the endogenous ligand) and by increasing the signal when there is reduced activity (by acting as an agonist). For aripiprazole, D_2 partial agonism could translate into an agent that acts as a functional antagonist under hyperdopaminergic conditions and as an agonist under hypodopaminergic conditions. An advantage of this mechanism is that it could address concerns that schizophrenia may be an illness that is associated with excessive dopamine activity at sites in limbic areas and decreased dopamine activity in frontal and prefrontal areas. In addition, a partial D_2 agonist may not result in the severe hypodopaminergic state in striatal areas that results in extrapyramidal side effects.

The evidence that aripiprazole acts as a partial agonist at D_2 receptors is substantial. In vivo binding studies have found that aripiprazole binds with

high affinity to D_2 receptors. Studies in human volunteers have found that, at its clinically effective doses, aripiprazole occupies a similar proportion of D_2 receptors to that of other antipsychotic agents. Aripiprazole blocks stereotypy induced by apomorphine in rodents, as do other antipsychotics. Agonist effects of aripiprazole were identified in a study in which its administration resulted in a release of prolactin from rat pituitary slices. This property was supported in a model of dopamine hypoactivity in which aripiprazole decreased the reserpine-induced DOPA accumulation that results from stimulation of presynaptic D_2 receptors.

Aripiprazole also appears to be a partial agonist at 5-HT_{1A} receptors. The importance of this activity in schizophrenia is unclear. Because buspirone (BuSpar), also a 5-HT_{1A} partial agonist, is an effective anxiolytic, it is conceivable that aripiprazole may also decrease anxiety. Aripiprazole also binds with high affinity to D_3, 5-HT_{2A}, 5-HT_{2C}, and H_1 receptors.

Design and Interpretation of Clinical Drug Studies

Efficacy for Acute Schizophrenia. Double-blind trials have compared aripiprazole with placebo, risperidone, and haloperidol. The earliest published study evaluated 15 and 30 mg of aripiprazole, 10 mg of haloperidol, and placebo in 414 patients with acute schizophrenia and schizoaffective disorder. Over the 4 weeks of the trial, all three active groups were significantly superior to placebo and similar to one another on PANSS total and PANSS positive symptoms. For PANSS negative symptoms, 15 mg of aripiprazole and 10 mg of haloperidol resulted in significantly greater improvements compared with placebo. A subsequent study compared 20 and 30 mg of aripiprazole to placebo and 6 mg of risperidone in 406 patients with schizophrenia or schizoaffective disorder. All of the active conditions were superior to placebo for both positive and negative symptoms on the PANSS. Another study that evaluated 10, 15, and 20 mg of aripiprazole and placebo in 420 patients also found that all three active doses were more effective than placebo. Moreover, there were no significant differences among the three doses. The findings from these acute studies indicate that doses of 10, 15, 20, and 30 mg of aripiprazole are more effective than placebo. There is also no indication that 30 mg is more effective than the lower doses. These results are consistent with a study indicating that 10 mg of aripiprazole results in 85 percent D_2 occupancy.

A study reported by John Kane and collaborators evaluated aripiprazole in patients who were treatment resistant. Treatment resistance was confirmed in an open-label trial of risperidone or olanzapine. After 6 weeks of double-blind treatment with aripiprazole or perphenazine, there were no significant differences in the number of patients who met improvement criteria. However, in both groups, a substantial proportion of patients, 27 percent of aripiprazole and 25 percent of perphenazine patients, met these

criteria. This suggests that either strategy may be useful for patients who fail to respond well to risperidone or olanzapine.

Efficacy for Acute Mania. Aripiprazole at 30 mg daily was compared to placebo in two studies of bipolar disorder patients in an acute manic or mixed episode. Aripiprazole was superior to placebo in both improvement on the YMRS and in the proportion of patients who demonstrated substantial improvement during the trial.

Long-Term Effectiveness in Schizophrenia. Two trials have evaluated the long-term effectiveness of aripiprazole in schizophrenia. In one study, stabilized patients (N = 310) were randomly assigned to either 15 mg of aripiprazole or placebo and observed for relapse over a 6-month period. Sixty-four percent of aripiprazole-treated patients survived the 6-month period without relapsing ($p < 0.01$) compared with 43 percent of placebo-treated patients. This study indicates that aripiprazole is an effective agent for preventing relapse in stabilized patients with schizophrenia.

The second study evaluated 1,294 patients who had experienced a psychotic relapse. Patients were randomly assigned to 30 mg of aripiprazole or 10 mg of haloperidol and followed for 1 year to evaluate their recovery from acute psychosis and the subsequent maintenance of the response. Aripiprazole-treated patients were more likely to remain on their medication for the full 52 weeks. Moreover, aripiprazole treatment was associated with greater improvements over the course of the study in both positive and negative symptoms, as well as depression as measured by the MADRS.

Long-Term Effectiveness in Bipolar Disorder. Patients with bipolar disorder who were stabilized on aripiprazole following a recent episode of acute or mixed mania were randomly assigned to continue on aripiprazole or change to a placebo. Aripiprazole was superior to placebo in delaying manic and depressed episodes.

Agitation in Schizophrenia or Bipolar Disorder. Clinicians often prescribe sedating antipsychotics for patients who appear agitated. This common practice as well as the tendency of aripiprazole to cause restlessness in some individuals has led some to avoid prescribing this agent in agitated patients. A recent meta-analysis combining the data from several trials indicated that aripiprazole was effective in patients with relatively high and low levels of agitation.

A short-acting IM formulation of aripiprazole was evaluated in two studies of agitated patients with schizophrenia or schizoaffective disorder. In one study, patients (N = 357) were randomly assigned 1.0, 5.25, 9.75, or 15 mg of aripiprazole, 7.5 of haloperidol, or placebo. Although all of the

treatment groups except 1 mg of aripiprazole were more effective than placebo, the 9.75 mg had the best response. Patients in this group demonstrated improvement by 45 minutes following their injection. A second study (*N* = 448) compared 9.75 mg of aripiprazole, 6.5 mg of haloperidol, and placebo. Both aripiprazole and haloperidol were superior to placebo.

Adjunctive Treatment in Major Depression. Two double-blind, placebo-controlled trials evaluated adjunctive aripiprazole (2 to 15 mg per day) in patients with major depressive disorder who had inadequate responses to escitalopram (Lexapro), fluoxetine, paroxetine controlled-release, sertraline (Zoloft), or venlafaxine extended release (Effexor XR). Improvement on the MADRS was greater in the group that received aripiprazole. However, rates of akathisia and restlessness were higher in the aripiprazole group. The average doses in the two trials were 10.7 and 11.4 mg daily.

Other Studies of Aripiprazole. Aripiprazole is the only antipsychotic that may reduce levels of prolactin. A study from South Korea found that elevated levels of prolactin in patients receiving haloperidol could be reduced by adding 30 mg daily of aripiprazole. This suggests an interesting possible use of aripiprazole for patients who show their best antipsychotic responses to drugs that elevated prolactin and who have prolactin-related side effects.

Effects on Specific Organs and Systems

General. Aripiprazole is among the least sedating of available antipsychotics. Aripiprazole is also associated with only minimal weight gain; in the comparison with haloperidol and placebo and risperidone and placebo, there were no significant differences in weight change among the treatment groups. It also appears to have minimal effects on lipids and glucose. This suggests that aripiprazole may have an important advantage for patients in whom there is concern about weight gain. Since aripiprazole was not included in the CATIE study, there is insufficient information to compare its weight gain and lipid liabilities with other antipsychotics.

Neurological. Aripiprazole appears to be associated with only minimal amounts of extrapyramidal side effects. In the comparison of aripiprazole (15 or 30 mg), 10 mg of haloperidol, and placebo, only haloperidol resulted in a significantly greater increase in EPS as measured by the Simpson-Angus Scale compared with placebo. Patients treated with haloperidol were more likely to receive treatment of extrapyramidal side effects than were patients in the other groups. Thirty percent of patients receiving haloperidol, 12 percent on placebo, 8 percent on 15 mg of aripiprazole, and

15 percent on 30 mg of aripiprazole received benztropine. However, there are a number of reports suggesting that aripiprazole-treated patients may experience restlessness. It is unclear if this experience is related to stimulating effects of aripiprazole or to akathisia.

Cardiac. Aripiprazole is not associated with prolongation of the QT interval as assessed by ECG.

Therapeutic Indications

Schizophrenia. Aripiprazole is effective for the treatment of acute psychosis in schizophrenia. It is also effective for preventing relapse in stabilized patients with schizophrenia. This is supported by a 26-week trial that found higher relapse rates on placebo compared to aripiprazole. The 52-week comparison with haloperidol also provides evidence that patients tend to remain stable once they have responded to aripiprazole. Its effectiveness appears to be similar to that of haloperidol and risperidone. Aripiprazole is also indicated for adolescents aged 13 to 17 with schizophrenia.

Bipolar I Disorder. Aripiprazole is effective for treating acute manic and mixed episodes, as monotherapy or as adjunctive therapy with lithium or valproate. It is also indicated for children and adolescents (age 10 to 17 years).

Adjunctive Treatment of Depression. Aripiprazole is indicated as an adjunctive treatment of patients who have inadequate responses to antidepressants.

Irritability Associated with Autistic Disorder. Aripiprazole is indicated in the treatment of irritability associated with autistic disorder. Trials demonstrating efficacy were conducted in patients 6 to 17 years of age.

Tourette Disorder. Aripiprazole is indicated in the treatment of Tourette disorder. Studies evaluating efficacy were conducted in pediatric patients aged 6 to 18 years of age.

Agitation Associated with Schizophrenia or Bipolar Mania. Short-acting IM aripiprazole has been approved for acute agitation. A dose of 10 mg of aripiprazole was effective after 45 minutes versus 7.5 mg IM haloperidol at 100 minutes.

Precautions and Adverse Reactions

Black Box Warning

INCREASED MORTALITY IN ELDERLY PATIENTS WITH DEMENTIA-RELATED PSYCHOSIS. Aripiprazole and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

SUICIDAL THOUGHTS AND BEHAVIORS. As with other SGAs with indications for depression (and all other antidepressants), aripiprazole has a black box warning indicating antidepressants may be associated with an increased risk of suicidal thinking and behavior in children, adolescents, and young adults.

Pregnancy and Lactation. Aripiprazole is designated pregnancy category C. There have been limited reports documenting neonatal and maternal outcomes to aripiprazole exposure during pregnancy. In one report, mother and neonate had no pregnancy or labor-related complications, and the infant seemed to be developing normally at a 6-month follow-up. However, the mother was unable to lactate, raising concerns about potential hypoprolactinemia. Aripiprazole has been associated with teratogenicity in animal studies at three to ten times the maximum recommended dose for humans. Given the paucity of published data on the effect of aripiprazole on fetal and neonatal development, this medication should be prescribed during pregnancy only after a careful risk–benefit analysis. Currently there is no published information on the effects of aripiprazole use in nursing mothers.

Drug Interactions

Aripiprazole is metabolized by CYP3A4 and CYP2D6. Because carbamazepine induces CYP3A4, coadministration with this agent reduces aripiprazole concentrations. Agents that inhibit CYP3A4, such as ketoconazole, may reduce the metabolism of aripiprazole, leading to an increase in concentrations. Similarly, agents that inhibit CYP2D6, such as quinidine, may raise aripiprazole concentrations (Table 34.28–4).

Laboratory Interference

There is no evidence that aripiprazole interferes with laboratory tests.

Dosage and Administration

Aripiprazole can be administered orally as a conventional tablet, an orally disintegrating tablet, or as an oral solution. It is also available as a short-acting IM formulation in single dose vials containing 9.75 mg of aripiprazole and in a long-acting IM formulation (Maintena) in both single dose vials and prefilled syringes containing 300 mg or 400 mg of lyophilized aripiprazole.

Schizophrenia. Aripiprazole is administered at dosages between 10 and 30 mg daily. Two studies compared 10 mg of aripiprazole with placebo; in one study, aripiprazole was more effective than placebo, whereas, in the other, it was not. This suggests that 15 mg administered once a day is a reasonable dosage for initiating treatment. There is no evidence that higher dosages are associated with a greater likelihood of improvement. As a result, patients should probably be treated with 15 mg per day for a sufficient amount of time (e.g., 2 to 4 weeks) before increasing the dosage. Oral aripiprazole can be administered once daily without regard to meals.

Studies in adolescents found that aripiprazole was well tolerated when patients were started at 2 mg and raised to 5 mg in 2 days and to the target dose of 10 mg in 2 additional days.

Bipolar Disorder. Aripiprazole is effective at doses of 15 to 30 mg for patients with mania and mixed states. The recommended starting dose in adults is 15 mg daily if given as monotherapy or 10 to 15 mg daily if given as adjunctive therapy with lithium or valproate. In pediatric patients aged 10 to 17 years, it should be started at 2 mg/day, titrated to 5 mg/day after 2 days, and titrated to the target dose of 10 mg/day after 2 additional days. Further dose increases can be made by increments of 5 mg/day.

Adjunctive Treatment of Major Depressive Disorder. The recommended starting dose of aripiprazole in adults with inadequate responses to antidepressants is 2 to 5 mg daily. The effective dose appears to be between 10 and 15 mg.

Irritability Associated with Autistic Disorder. In patients aged 6 to 17 years, aripiprazole should be started at 2 mg/day, then increased to 5 mg/day, and subsequently increasing to 10 or 15 mg/day based on efficacy and tolerability.

Tourette Disorder. For pediatric patients (age 6 to 18 years) weighing less than 50 kg, aripiprazole can be started at 2 mg/day, increased to 5 mg/day after 2 days, and subsequently increased to 10 mg/day based on efficacy and tolerability. For patients weighing more than 50 kg, aripiprazole should be titrated to a target dose of 10 mg/day on day 8, and the dose can be increased up to 20 mg/day if needed for control of tics.

Agitation Associated with Schizophrenia or Bipolar Mania (IM Formulation). The recommended IM dose for treating agitation in schizophrenia or bipolar mania is 9.75 mg. There is no indication that higher doses are more effective. As with other IM antipsychotics, if repeated injections are required, patients should be treated with an oral formulation.

There is no indication that adjustments in dosage are required for age, gender, race, or smoking.

Long-Acting Injectable. In 2013, a long-acting form of aripiprazole was approved for IM injection, with indication for the treatment of schizophrenia. As with all long-acting injectables, it is recommended to first assess medication tolerability with the oral formulation. The recommended starting and maintenance dose is 400 mg IM monthly. If this dose is not tolerated, it can be reduced to 300 mg IM monthly. The median T_{max} of this formulation is 5 to 7 days and the terminal half-life of a 400 mg IM dose is 46.5 days. Thus, it is recommended that when starting this medication, oral antipsychotic should be continued for 14 days before discontinuation, given the gradual increase in plasma levels after initial injection.

Table 34.28–4.
Comparison of Usual Dosing[a] for the Currently Available Second-Generation Antipsychotics in Schizophrenia

Antipsychotic	Typical Starting Dosage	Maintenance Therapy Dose Range	Titration/Notes	Maximum Recommended Dosage
Clozapine (tablets) (Clozaril)	12.5 mg once or twice a day	150–450 mg per day in divided doses or as a single bedtime dose	The dosage should be increased to 25–50 mg on the second day. Further increases may be made in daily increments of 25–50 mg to a target dose of 300–450 mg per day. Subsequent dosage increases should be made no more than once or twice weekly in increments of no more than 100 mg.	900 mg per day
Risperidone (tablets, orally disintegrating tablets, and oral solution) (Risperdal)	1 mg twice a day or 2 mg at night	2–8 mg per day, in divided doses or as a single bedtime dose	Increase by increments of 1–2 mg per day. In some patients (elderly, hepatic or renal impairment), a slower titration may be appropriate.	16 mg per day
Risperidone IM long acting (Consta)	25 mg every 2 wks	25–50 mg every 2 wks	Continue oral antipsychotic for 3 wks. Titrate by 12.5 mg every 4 wks.	50 mg every 2 wks
Olanzapine (tablets and orally disintegrating tablets) (Zyprexa)	5–10 mg per day	10–20 mg per day	Dosage increments of 5 mg, at change intervals of not less than 1 wk.	20 mg per day

Olanzapine IM long acting (Relprevv)	210 mg/2 wks or 405 mg/4 wks (for target10 mg/day); 300 mg/2 wks (for target 15–20 mg/day)	150 mg/2 wks or 300 mg/4 wks (for target 10 mg/day); 210 mg/2 wks or 405 mg/4 wks (for target 15 mg/day); 300 mg/2 wks (for target 20 mg/day) Requires a 3 hour observation period after injections.	Adjust dosage at intervals of 2 or 4 wks, depending on dosing schedule and maintenance therapy target dose.	300 mg IM every 2 wks
Quetiapine (tablets) (Seroquel)	25 mg twice a day	400–800 mg per day	Increase by 25–50 mg in divided doses for first several days, to target of 300–400 mg per day by day 4. Adjustments can be made by 25–50 mg twice daily, every 2 days	800 mg per day
Quetiapine extended release (Seroquel XR)	300 mg nightly	400–800 mg per day	Can increase by up to 300 mg per day at intervals as short as 1 day	800 mg per day
Ziprasidone (capsules) (Geodon)	20 mg twice a day with food	20–80 mg twice a day with food	Adjust at intervals not less than 2 days	80 mg twice a day
Ziprasidone (intramuscular)	For acute agitation: 10–20 mg, as required, up to a maximum of 40 mg per day	N/A	For acute agitation: Dosages of 10 mg may be administered every 2 hrs and dosages of 20 mg may be administered every 4 hrs up to a maximum of 40 mg per day.	For acute agitation: 40 mg per day, for not more than 3 consecutive days
Aripiprazole (tablets) (Abilify)	10–15 mg once per day	10–30 mg per day	Dosage increases should not be made at intervals less than every 2 wks	30 mg per day
Aripiprazole IM long acting (Maintena)	400 mg IM monthly	300–400 mg IM monthly	Continue oral antipsychotic for 14 days before discontinuing.	400 mg IM monthly
Paliperidone (tablets) (Invega)	6 mg once per day	3–12 mg per day	Efficacy beyond 6 mg per day has not been shown. Dose increases of 3 mg should occur at intervals no less than 5 days.	12 mg per day
Paliperidone palmitate (Invega Sustenna)	234 mg IM on day 1, then 156 mg IM 1	39–234 mg IM monthly (117 mg recommended)	Make adjustments no more frequently than monthly	234 mg IM monthly

	wk later			
Iloperidone (Fanapt)	1 mg twice daily	6–12 mg twice daily	Can make dose increases no more frequently than by 2 mg twice daily every day	12 mg twice daily
Asenapine (Saphris)	5 mg twice daily	5–10 mg twice daily	Can increase to 10 mg twice daily after 1 wk	10 mg twice daily
Lurasidone (Latuda)	40 mg daily with food	40–160 mg daily with food	Not specified; tablets are available in 20, 40, 60, 80, and 120 mg strengths	160 mg daily
Cariprazine (Vraylar)	1.5 mg once per day	1.5–6 mg once daily	Start with 1.5 mg for 1 day with increases in 1.5 mg increments; due to the long half-life of cariprazine and its active metabolites, changes in dose will not be fully reflected in plasma for several weeks	6 mg
Brexpiprazole (Rexulti)	1 mg once per day	2–4 mg daily for schizophrenia; 2–3 mg daily for adjunctive treatment of depression	For schizophrenia start 1 mg qd for 4 days, then 2 mg for 3 days, then 4 mg qd. For adjunctive treatment of depression, start 0.5–1 mg qd, then increase dose to 2 mg qd after 1 wk.	4 mg for schizophrenia; 3 mg for adjunctive treatment of depression

Information taken from U.S. Prescribing Information for individual agents.

[a]Dosage adjustments may be required in special populations.

The clinical efficacy of aripiprazole long-acting injectable was established in two clinical trials. The first trial (N = 339) was a 12-week randomized controlled trial in adults with schizophrenia who were having an acute relapse. The primary outcome measure used was the change in PANSS total score from baseline to week 10. Participants were randomized to receive aripiprazole long-acting injectable 400 mg or placebo on day 0, 28, and 56, with the dose of aripiprazole being allowed to be adjusted to 300 mg if clinically indicated. Aripiprazole showed statistically significant improvement on the primary outcome measure as compared to placebo. A second trial assessed longer-term efficacy. In this study, adults with schizophrenia were converted and stabilized on oral aripiprazole (10-30 mg daily). Next, participants were stabilized on aripiprazole long-acting injection (400 mg or 300 mg monthly) for at least 12 weeks, discontinuing oral aripiprazole after the first 2 weeks. In the final double-blind placebo-controlled randomized withdrawal phase, patients (N = 403) were randomized to either continue aripiprazole long-acting injection or switch to placebo injection. The primary outcome measure was the time to relapse, defined as worsening on prespecified CGI scales, prespecified PANSS items, hospitalization, or violent behavior. Participants randomized to continue aripiprazole long-acting injectable had a longer time to relapse than those randomized to placebo.

PALIPERIDONE

Paliperidone is the major active metabolite of risperidone and shares risperidone's receptor profile. Paliperidone extended release tablets use a pressure-based osmotic release oral system (OROS) delivery system to provide continual drug delivery for over 24 hours (see below). Because paliperidone extended release is gradually released into the plasma without peaks in concentration, it permits treatment initiation without titration. As the primary metabolite of risperidone, paliperidone does not undergo further significant hepatic metabolism. Therefore, it suffers from fewer potential drug–drug interactions.

OROS Delivery

The OROS delivery system is capsule shaped and consists of an osmotically active trilayer core surrounded by a subcoat and semipermeable membrane. The trilayer core has two drug layers and a push layer containing osmotically active components. In the gastrointestinal tract, the color overcoat of the capsule dissolves quickly and water enters the semipermeable membrane. The semipermeable membrane controls the rate at which water enters the tablet core and so determines the rate of drug delivery. The hydrophilic polymers in the core hydrate and swell and create a gel that contains paliperidone, which is pushed out of two laser-drilled orifices in the tablet shell. The osmotic delivery system reduces or eliminates plasma concentration fluctuations, allowing for once-daily dosing without fluctuating plasma levels.

Chemistry

Paliperidone belongs to the class of benzisoxazole derivatives (Fig. 34.28-1). The chemical name of paliperidone is (±)-3-[2-[4-(6-fluoro-1,2-benzisoxazol-3-yl)-1-piperidinyl]ethyl]-6,7,8,9-tetrahydro-9-hydroxy-2-methyl-4H-pyrido[1,2-a]pyrimidin-4-one. Its molecular formula is $C_{23}H_{27}FN_4O_3$ and its molecular weight is 426.49. Paliperidone contains a racemic mixture of (+) and (–) paliperidone.

Pharmacological Action

Pharmacokinetics

ABSORPTION. Peak plasma concentration of paliperidone extended release is reached approximately 24 hours after a single dose. The half-life of paliperidone is about 23 hours, which allows for once a day dosing. Absorption is increased by approximately 60 percent when paliperidone extended release is taken with food.

DISTRIBUTION. Steady-state concentrations are reached after 4 to 5 days of daily dosing. Paliperidone has a volume of distribution of 487 L and is 74 percent plasma protein bound.

METABOLISM AND ELIMINATION. In vitro studies demonstrate that paliperidone is a substrate at CYP2D6 and CYP3A4, but in vivo studies do not support a clinically significant role for the P450 system in the metabolism of paliperidone. For instance, there was no difference in the exposure or clearance rates of subjects who are rapid or poor metabolizers of CYP2D6 substrates. Fifty-nine percent of paliperidone is excreted unchanged in the urine, and clearance is decreased in patients with moderate-to-severe renal impairment. The tablet shell is excreted whole in the stool and patients should be advised not to worry if they see what looks like an undissolved tablet in their stool.

Pharmacodynamics

MECHANISM OF ACTION. As mentioned above, paliperidone is the major active metabolite of risperidone. Both drugs, therefore, share the same receptor affinities and putative mechanism of action. Paliperidone is an antagonist at dopamine D_2 and serotonin 5-HT_{2A} receptors. In a small sample pharmacokinetics study, PET imagery demonstrated a median D_2 receptor occupancy of 64 percent 22 hours after a single dose of 6 mg paliperidone extended release. The 5-HT_{2A} receptor occupancy was 65 percent at 4.5 hours after a dose. Paliperidone also has antagonist activity at α_1, α_2, and H_1 receptors.

Design and Interpretation of Clinical Drug Studies

Acute Treatment Trials. Three 6-week randomized double-blind, placebo-controlled efficacy and safety studies were conducted using fixed doses of paliperidone extended release. Kane and colleagues administered placebo, 6, 9, or 12 mg of paliperidone extended release to 628 patients with schizophrenia. Davidson and colleagues treated 618 subjects with schizophrenia with placebo or 3, 9, or 15 mg of paliperidone extended release. Marder and colleagues evaluated 444 patients administered placebo, 6, or 12 mg of paliperidone extended release. In each of the three studies a 10-mg olanzapine group was also included for trial validity assessment only. In all three studies, the PANSS total score decreased significantly in all paliperidone arms compared with placebo. In the study by Kane et al., there was a trend toward greater improvement with the 12-mg paliperidone group. Davidson's group reported that as early as day 4 the three paliperidone arms had separated significantly from placebo on PANSS total score. The study by Marder and colleagues found significant improvement by day 4 for the 6-mg arm and by day 15 for the 12-mg arm.

In all three studies, the three paliperidone arms showed significant or trend improvement from baseline compared with placebo on positive, negative, disorganized, hostility or agitation, and anxiety or depression factor scores. The paliperidone groups also improved compared with placebo on measures of personal and social functioning, although whether this change was more reflective of improving psychosis is unclear. Paliperidone was associated with some metabolic and movement-related adverse events, especially in the 9-, 12-, and 15-mg groups.

Maintenance Treatment Trials. Kramer and colleagues treated 205 patients in a study with an 8-week open-label run-in phase, followed by a 6-week open-label stabilization period before entering a variable duration double-blind treatment phase where patients were randomized to either placebo or paliperidone 3 to 15 mg daily. The primary efficacy variable was time to first recurrence of schizophrenia symptoms (e.g., hospitalization, changes in symptom scores, aggressive, self-injurious, or suicidal behavior). Time to recurrence was significantly longer in the paliperidone group; at the final analysis 52 percent of patients on placebo had a recurrence versus 22 percent on paliperidone. Twenty-five percent of patients on placebo had a recurrence event by day 23, whereas 25 percent of paliperidone-treated patients had a recurrence event by day 83.

Effect on Sleep Architecture. In a randomized double-blind, placebo-controlled trial, Luthringer and his colleagues evaluated the effect of paliperidone extended release on sleep architecture in 36 patients with schizophrenia and insomnia. Using a significance level of 0.1 percent, they found that 9 mg of paliperidone extended release significantly increased overall sleep duration, and stage 2 and rapid eye movement (REM) sleep duration over treatment with placebo. Paliperidone treatment was associated with an 11 percent increase in sleep efficiency index. In this study, paliperidone was not associated with daytime somnolence.

Effects on Specific Organs and Systems

General. None of the randomized control studies reported statistically significant changes in glucose, insulin, or lipid levels in the paliperidone arms versus placebo. However, there were isolated cases of hyperglycemia reported. Across the studies, approximately 7 to 12 percent more patients in the higher dose paliperidone arms versus the placebo arms experienced a weight gain over 7 percent of their body weight during the course of the medication trial. This suggests that paliperidone has a weight gain profile similar to that of risperidone.

Cardiovascular System. Tachycardia and palpitations are relatively frequent side effects of paliperidone, as they are with risperidone.

Tachycardia does not appear to be dose related. Less frequently reported is a risk of bradycardia. Paliperidone has a modest effect on the QT interval. Vascular ischemia and venous thrombosis occurred rarely.

Respiratory System. Dyspnea not associated with further adverse outcome occurred with some frequency during the phase II and III clinical trials of paliperidone. Pulmonary emboli occurred in less than 0.001 percent of patients on paliperidone.

Gastrointestinal System. Abdominal pain and salivary hypersecretion were noted to occur with paliperidone administration during early trials. Salivary hypersecretion appeared to be dose related, with most cases occurring at the 12-mg dose.

Hematological and Lymphatic System. Thrombocytopenia was a rare occurrence, occurring in less than 1 of 1,000 patients. Edema was noted in less than 1 percent of patients.

Central Nervous System. Headache and insomnia were frequent side effects of paliperidone treatment in the randomized clinical trials. Confusion, abnormal gait, and impaired coordination were noted infrequently in patients taking therapeutic doses of paliperidone.

Immunologic System. Anaphylactic reactions occurred in less than 1 of 1,000 people who took paliperidone.

Endocrine. Paliperidone increases prolactin levels. In the randomized clinical trials, prolactin levels were highest in those on the greatest doses of paliperidone extended release. In the study by Kane and colleagues, mean plasma prolactin levels rose 27 ng/mL in men and 86 ng/mL in women. In Davidson's group, male patients on 15 mg of paliperidone experienced mean plasma prolactin level increases of 35.3 ng/mL, and female patients had mean increases of 106.9 ng/mL. In all studies, 4 percent or less of patients on paliperidone reported prolactin-related side effects, such as galactorrhea, gynecomastia, amenorrhea, anorgasmia, and abnormal sexual function. However, spontaneous reports of side effects may underestimate the number of patients experiencing these effects.

Therapeutic Indications

Schizophrenia. Paliperidone extended release is indicated for the acute and maintenance treatment of schizophrenia. Efficacy was also established in adolescent subjects aged 12 to 17.

Schizoaffective Disorder. Paliperidone extended release is also

indicated for the treatment of schizoaffective disorder, both as monotherapy or as adjunct therapy to mood stabilizers and/or antidepressants.

Precautions and Adverse Reactions

Black Box Warning. Paliperidone and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

QT Prolongation. Paliperidone immediate release has been shown to have a modest effect on the QT interval; with a mean increase of 12.3 ms at the 8-mg dose (which has a mean steady-state peak plasma concentration over twice the exposure of a 12-mg dose of paliperidone extended release). In the QT study and the three fixed-dose studies, only one patient had a change exceeding 60 ms at one time point. No patient on paliperidone had a QTc exceeding 500 ms at any time in the studies. Paliperidone use should be avoided or initiated with care in patients on class IA or class III antiarrhythmic medications, on other medications that increase the QT interval, or with other cardiac arrhythmias including congenital QT prolongation.

Neuroleptic Malignant Syndrome. One patient in the five clinical trials investigating the safety and efficacy of paliperidone extended release had symptoms of NMS after 19 days on paliperidone extended release treatment.

Tardive Dyskinesia. All antipsychotic medications (with the possible exception of clozapine and quetiapine) carry a risk of tardive dyskinesia. Risk of tardive dyskinesia is difficult to assess in the course of 6-week trials. However, acute dyskinesias occurred in 7.7 percent and 8.7 percent of patients in the 9- and 12-mg paliperidone extended-release groups versus 3.4 percent in the placebo group.

Hypercholesterolemia, Hyperglycemia, and Diabetes Mellitus. In the early clinical trials, paliperidone extended release was not associated with statistically significant changes in cholesterol, glucose, or insulin levels compared to placebo. Given that paliperidone is the metabolite of risperidone, it is reasonable to predict the two medications will have similar metabolic profiles. However, many of the SGA medications have been associated with increases in fasting serum glucose levels and rates of diabetes mellitus type 2. Some SGA medications have also been associated with elevations in total cholesterol, LDL, and triglycerides. Regular monitoring of fasting cholesterol and glucose levels is appropriate in all patients on SGA medications.

Gastrointestinal. The paliperidone extended release tablet does not deform or change shape in the gastrointestinal tract. Therefore, there is a potential risk of obstruction in patients with pre-existing and severe gastrointestinal tract narrowing. Patients with such conditions should not be administered paliperidone extended release.

Cerebrovascular. Trials of other SGA medications, such as risperidone, aripiprazole, and olanzapine, have demonstrated higher incidences of strokes and transient ischemic attacks in elderly patients with dementia compared to patients on placebo. No data exist on paliperidone in this population, but SGAs are not indicated in elderly patients with dementia.

Movement Side Effects and Disorders. In all studies, paliperidone extended release was noted to be associated with higher rates of movement side effects in dosages above 9 mg. Reported symptoms include hypertonia, dystonia, tremor, hyperkinesia, and oculogyric crisis. Serious movement side effects were rare, although one study reported a possible case of NMS after 19 days of paliperidone extended release treatment. Generally, across the studies, patients on paliperidone doses above 6 mg required more doses of anticholinergic medication than did patients on placebo.

Orthostatic Hypertension and Syncope. Like risperidone, paliperidone has antagonistic activity at the α receptors, contributing to its risk of orthostatic hypotension and syncope. Paliperidone extended release should be used with caution in people with known cardiovascular disease or individuals with predispositions to hypotension.

Hyperprolactinemia. Paliperidone increases prolactin levels through D_2 antagonism (see above section on metabolic effects). Hyperprolactinemia suppresses GnRH, which reduces gonadotropin release and can impair gonadal steroidogenesis in men and women. The result can be inhibited reproductive function and symptoms such as galactorrhea, amenorrhea, gynecomastia, impotence, and anorgasmia. Long-term hyperprolactinemia may lead to decreased bone density in both sexes when associated with hypogonadism. Approximately one-third of breast cancers are prolactin dependent, and patients with a personal or family history of breast cancer should be monitored closely, especially if they develop hyperprolactinemia while on paliperidone extended release.

Pregnancy. Paliperidone is rated pregnancy category C. In rats and rabbits given paliperidone up to eight times the maximum recommended human dose (MRHD), there were no increases in fetal abnormalities. However, reproduction studies with risperidone have demonstrated increases in pup deaths at oral doses less than the maximum recommended

doses in humans. Use of FGAs during the third trimester has been associated with self-limited EPS in the neonate. Whether paliperidone will produce similar symptoms in the neonate is still unknown. Given the limited information available on the effects of paliperidone on pregnant women and neonates, it should be used only after careful consideration of the risks and benefits.

Lactation. Paliperidone is excreted in breast milk. Studies of the distribution of risperidone and its metabolite, paliperidone, reveal that the milk/plasma concentration ratio for both agents was less than .5. Relative infant doses of risperidone ranged from 2.3 to 4.7 percent of the maternal dose. In infants who were breastfed, risperidone and paliperidone were not detected in the plasma of the infants. However, the possibility of infant exposure and possible EPS or NMS risk cannot be ruled out. The decision to breastfeed while on paliperidone should be made only after careful risk–benefit analysis.

Fertility. In female rats on doses up to 2.5 mg/kg per day the percentage of pregnancies was not affected, but pre- and postimplantation loss was increased and the number of live embryos was decreased. In male rats given doses of paliperidone up to 2.5 mg/kg per day fertility was not affected, but sperm analysis was not conducted. Beagles given risperidone showed decreases in testosterone levels and sperm motility, which continued at an attenuated level at least 2 months after drug discontinuation.

Carcinogenesis. Carcinogenesis studies of paliperidone have not yet been performed. Risperidone was associated with increases in pituitary gland adenomas, endocrine pancreas adenomas, and mammary gland adrenocarcinomas in mice and rats. The no-effect dose for the tumors was less than or equal to the maximum human recommended dose. The increase in the above tumors is considered to be associated with prolonged D_2 antagonism and hyperprolactinemia. The relevance to human populations of these findings in rodents is unknown.

Mutagenesis. There is no evidence of mutagenesis with paliperidone.

Geriatric Use. Paliperidone use in geriatric populations was assessed in the 6-week placebo-controlled studies that included 125 elderly subjects over age 65 with schizophrenia. No overall differences in safety and effectiveness were observed between elderly and younger subjects when renal function was not impaired. SGA medications are associated with greater risk of death compared with placebo in elderly patients with dementia-related psychosis.

Overdose. There are limited data on overdose with paliperidone. The highest estimated ingestion was 405 mg, which resulted in signs of gait unsteadiness and EPS. As paliperidone is the active metabolite of risperidone, overdosage effects are likely to be similar.

Drug Interactions

Although in vitro studies demonstrate that paliperidone is a substrate of both CYP3A4 and CYP2D6, in vivo studies do not demonstrate clinically significant metabolism by 2D6 or 3A4 isozymes. Therefore, paliperidone is unlikely to be affected by drugs metabolized by the P450 system. Similarly, paliperidone is not an inhibitor or inducer of any of the P450 isozymes and is not expected to inhibit or induce drug clearance of any P450 substrates.

As with risperidone, paliperidone's effects on α_1 and α_2 receptors can lead to orthostatic hypotension. Other drugs with this side effect should be used with caution given potential additive effects.

Dosage and Administration

Paliperidone extended release comes in 3-, 6-, and 9-mg tablets. The recommended dosage range for paliperidone extended release is 3 to 12 mg, although some clinical trials included a 15-mg paliperidone group. The recommended starting dose is 6 mg and no titration is needed. The existing clinical trials found no significant difference in antipsychotic response between the 6-mg dose and higher dosages; however, there was a trend toward better response at higher dosages. Beyond the 6-mg starting dose, upward titration by 3 mg every 5 days is recommended. In adolescents aged 12 to 17, paliperidone should be started at 3 mg daily. If dose increases are necessary, they should occur by no more than 3 mg/day every 5 days.

Dosing in Special Populations. No dosage adjustments are needed for those with hepatic impairment. People with mild renal impairment should not be prescribed more than 6 mg of paliperidone a day. People with moderate-to-severe renal impairment should not take more than 3 mg per day. No adjustments are necessary for elderly populations beyond the above recommendations regarding renal status. Paliperidone has not yet been evaluated in pediatric populations.

Long-Acting Injectable. Paliperidone also comes in a long-acting injectable formulation (Sustenna), with kits containing needles prefilled syringes containing 39-, 78-, 117-, 156-, or 234-mg paliperidone palmitate.

In 2009, the FDA approved this medication as a long-acting injectable formulation of paliperidone. Its indications are for the treatment of schizophrenia and for the treatment of schizoaffective disorder, both as monotherapy and as an adjunct to mood stabilizers or antidepressants.

This medication can be administered by gluteal or deltoid IM injection.

As with all long-acting injectable medications, it is recommended that tolerability is established by taking oral paliperidone (or risperidone due to its metabolism into paliperidone) prior to switching to the injectable formulation. The oral antipsychotic can then be discontinued immediately after the first injection. The dosage recommendations consist of an initiation phase (injections on day 1 and day 8), followed by a monthly maintenance phase. The recommended dosage is 234 mg IM on day 1, followed by 156 mg IM on day 8, followed by 39 to 234 mg (for schizophrenia) or 78 to 234 mg (for schizoaffective disorder) 4 weeks later, then monthly. The recommended initial maintenance dose for the treatment of schizophrenia is 117 mg IM monthly and this can be adjusted within specified ranges according to tolerability and effectiveness. In patients with mild renal impairment (creatinine clearance 50 to 79 mL/min), the day 1 injection should be 156 mg, followed by 117 mg on day 8, and then using 78 mg monthly maintenance doses. Paliperidone palmitate should not be used in patients with creatinine clearance <50 mL/min.

Efficacy was established for the acute treatment of schizophrenia in one 9-week and three 13-week trials of relapsed adult inpatients. The primary outcome measures were the change in PANSS total score from baseline to end point. Dosages tested in the trials included 39, 78, 156, 234 mg, and all dosages were found to be statistically superior to placebo in one or more trials. Efficacy for maintenance monotherapy treatment of schizophrenia was established in a double-blind placebo-controlled randomized withdrawal study. In this study, adults with schizophrenia who were stabilized on paliperidone palmitate (N = 410) were randomized to continue paliperidone long-acting injection or switch to placebo injections. They were then monitored until they experienced a schizophrenia exacerbation, which was defined as either psychiatric hospitalization or prespecified increase in PANSS score. The primary outcome measure was time to relapse. In this study, paliperidone palmitate was statistically superior to placebo in increasing time to relapse.

Efficacy for the maintenance treatment of schizoaffective disorder (either as monotherapy or as adjunct to mood stabilizer or antidepressant) was established in one long-term randomized withdrawal study. In this study, adults with DSM-IV schizoaffective disorder (bipolar or depressive types) were first stabilized on open-label flexible-dose paliperidone palmitate in a 13-week lead-in. Participants could be taking concomitant mood stabilizers or antidepressants. Subjects (N = 334) who met stabilization criteria for at least 12 weeks (by prespecified PANSS, YMRS, and HAM-D scores) were randomized (double-blind) to continue paliperidone palmitate or switch to placebo injections, then monitored for 15 months. The primary outcome measure was time to relapse, as defined

by either psychiatric hospitalization, intervention used to avert hospitalization, self-injury, suicidal or homicidal ideation, violent behavior, prespecified increase on certain PANSS items, or increase in CGI-S-SCA overall score. Paliperidone palmitate was statistically superior to placebo in increasing time to relapse.

ILOPERIDONE

Iloperidone is an antipsychotic with high affinity for 5-HT_{2A} and D_2 receptors. Important clinical properties include a low liability to cause EPS, but a risk of orthostatic hypotension requiring a titration period of several days.

History

Initial research and development of iloperidone occurred in the early to middle 1990s. FDA approval for the treatment of schizophrenia was finally granted in 2009, after an initial new drug application submitted in 2007 was denied due to need for additional clinical trial support.

Chemistry

Iloperidone belongs to the class of piperidinyl-benzisoxazole derivatives (Fig. 34.28–1). The chemical name of iloperidone is 4′-[3-[4-(6-Fluoro-1,2-benzisoxazol-3-yl)piperidino]propoxy]-3′-methoxyacetophenone. Its molecular formula is $C_{24}H_{27}FN_2O_4$ and its molecular weight is 426.48.

Pharmacological Action

Pharmacokinetics. According to the product label, the mean elimination half-lives for iloperidone and its two major metabolites (P88 and P95) are 18, 26, and 23 hours, respectively, in CYP2D6 extensive metabolizers. In poor metabolizers, the half-lives are 33, 37, and 31 hours. Steady-state concentrations in plasma are reached after 3 to 4 days of dosing.

ABSORPTION. Iloperidone is well-absorbed with oral administration, with peak plasma levels occurring 2 to 4 hours after ingestion. Administration with a high-fat meal delayed T_{max} for iloperidone by 1 hour and its major metabolites, P88 and P95, by 2 and 6 hours, respectively. As a high-fat meal does not significantly affect the maximum concentration or area under the curve of iloperidone or its major metabolites, product labeling indicates it can be administered without regard to meals.

DISTRIBUTION. Iloperidone has an apparent volume of distribution of 1,340 to 2,800 L and it, as well as its major metabolites, is approximately 95 percent serum protein-bound.

METABOLISM AND ELIMINATION. Iloperidone is metabolized by three pathways: CYP2D6-mediated hydroxylation, CYP3A4-mediated O-demethylation, and carbonyl reduction. There are two major metabolites of iloperidone, P95 and P88, with P95 exposure being greater in CYP2D6 extensive metabolizers and P88 being greater in CYP2D6 poor metabolizers. Elimination of metabolites is primarily through the urine, with feces accounting for a lesser proportion.

Pharmacodynamics

MECHANISM OF ACTION. Iloperidone functions as an antagonist with high affinity at 5-HT_{2A}, D_2, D_3, α_1, and α_{2c} adrenergic receptors; intermediate affinity at D_4, 5-HT_6, and 5-HT_7 receptors; and low affinity for 5-HT_{1A}, D_1, and H_1 receptors. Iloperidone possesses negligible affinity for muscarinic receptors. Its metabolite P88 has receptor affinities "generally equal or less than that of the parent compound" according to product labeling. Its metabolite P95 possesses high affinity for 5-HT_{2A}, α_{1A}, α_{1B}, α_{1D}, and α_{2C} receptors only.

Design and Interpretation of Clinical Drug Studies

Acute Treatment Trials. The efficacy of iloperidone was supported by two large trials—one 4 weeks and one 6 weeks in duration. In the 4-week trial, 604 participants with DSM-IV schizophrenia were randomized to receive iloperidone 24 mg daily (titrated over course of 1 week, with twice-daily dosing), ziprasidone (160 mg daily), or placebo. The primary end point was the change in PANSS total score from baseline to end of treatment (day 28). In this study, both iloperidone and ziprasidone were statistically superior to placebo in improving PANSS scores. Iloperidone was noted to have a different adverse event profile than ziprasidone, with iloperidone having less sedation, somnolence, EPS, akathisia, agitation, and restlessness and causing more weight gain, tachycardia, orthostatic hypotension, dizziness, and nasal congestion. In the 6-week trial, 706 participants with DSM-IV schizophrenia were randomized to receive either one of 2 flexible dose ranges of iloperidone (12 to 16 mg/day or 20 to 24 mg/day), risperidone (6 to 8 mg/day), or placebo. The primary end point was the change in BPRS total score from baseline to end of treatment (day 42). Both dose ranges were superior to placebo in improving BPRS scores. While the efficacy of risperidone appeared greater than iloperidone within the first 2 weeks of treatment, the efficacy between treatments was similar in patients who remained on treatment of at least 2 weeks. This differential efficacy in the first 2 weeks was attributed to the slower dose titration schedule necessary for iloperidone.

Two additional large short-term studies were performed to assess the

efficacy of iloperidone for the treatment of schizophrenia or schizoaffective disorder. In the first study (6 weeks), iloperidone 12 mg/day (but not 4 mg or 8 mg/day) statistically improved the PANSS and BPRS total scores as compared to placebo. In the second 6-week study, both iloperidone 4 to 8 and 10 to 16 mg/day outperformed placebo for improving the BPRS total score. For the PANSS, the 4 to 8 mg/day group outperformed placebo only on the positive symptom subscale, while the 10 to 16 mg/day group outperformed placebo on the PANSS total as well as positive and negative symptom subscales.

Maintenance Treatment Trials. While iloperidone is currently only indicated "for the treatment of adults with schizophrenia," based on two large short-term studies, limited long-term maintenance studies have been performed. Kane et al. reported the data from three trials. Subjects from three short-term studies (N = 1,644), who had experienced at least a 20 percent reduction in PANSS total score in the initial 6-week study, were randomized to receive iloperidone 4 to 16 mg/day or haloperidol 5 to 20 mg/day for 46 weeks. The primary outcome measure was the time to relapse, defined as a ≥25 percent increase in PANSS total score, discontinuation due to lack of efficacy, aggravated psychosis with hospitalization, or 2-point increase on the CGI-C after week 6. Iloperidone was found to be statistically equivalent to haloperidol for relapse prevention.

A second long-term extension study was published by Cutler et al., in which participants with a CGI-C score of at least 4 (indicating improvement) in the acute efficacy trial could continue in a 25-week open-label extension study. In this study, participants were all treated with iloperidone 12 mg twice daily, with the dose permitted to be decreased to 12 mg nightly by investigator discretion. There was no significant worsening in PANSS total score at 25 weeks (using last observation carried forward analyses), though only 72 out of 173 patients completed the entire 25-week study.

Therapeutic Indications

Schizophrenia. Iloperidone is indicated for the treatment of schizophrenia, with efficacy established based on two short-term studies.

Precautions and Adverse Reactions

Black Box Warning. Iloperidone and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

QT Prolongation. Iloperidone, at the dose of 12 mg twice daily, was

found to increase the QTc interval by 9 ms in an open-label study of 160 individuals. This QTc prolongation was increased to 19 ms in the presence of CYP2D6 inhibitor (paroxetine) or CYP3A4 inhibitor (ketoconazole). It is recommended that iloperidone be avoided in combination with other medications known to increase the QTc interval, in individuals with congenital long QT syndrome, history of cardiac arrhythmias, or histories of significant cardiovascular illness. It is also recommended that individuals at risk of electrolyte disturbances have potassium and magnesium levels monitored periodically, as low levels can increase the risk of QTc prolongation and arrhythmia. Iloperidone should be discontinued if QTc is found to be greater than 500 ms.

Neuroleptic Malignant Syndrome. NMS has been associated with the use of antipsychotic medications, including iloperidone. If NMS is suspected, iloperidone and other antipsychotic medications should be discontinued immediately and the patient should undergo intensive supportive care and medical monitoring.

Extrapyramidal Symptoms. Iloperidone is associated with a low risk of EPS, including akathisia, bradykinesia, dyskinesia, dystonia, parkinsonism, and tremor. When considering all EPS events in four short-term trials, 15.1 percent of subjects taking iloperidone 20 to 24 mg/day (N = 391), 13.5 percent of subjects taking 10 to 16 mg/day (N = 483), and 11.6 percent of subjects taking placebo (N = 587) reported any type of EPS. Parkinsonism was reported in 0.3 percent of subjects taking iloperidone 20 to 24 mg/day as compared to 0 percent in subjects taking placebo.

Tardive Dyskinesia. Tardive dyskinesia can develop in all patients treated with antipsychotic drugs. Its prevalence is highest among the elderly. The propensity of iloperidone to cause tardive dyskinesia is not known, but expected to be low due to the minimal extrapyramidal side effects of this medication. In general, SGAs have a lower tardive dyskinesia risk than FGAs.

Metabolic Changes. Iloperidone has been associated with hyperglycemia, dyslipidemia, and weight gain, and patients should be monitored accordingly. In a pooled analysis of longer term trials, iloperidone 10 to 16 mg/day was associated with a 1.8 mg/dL glucose increase at 3 to 6 months (N = 773) and a 5.4 mg/dL glucose increase at >12 months (N = 425). Iloperidone 10 to 16 mg/day was associated with a –3.9 mg/dL change in total cholesterol and –8.9 mg/dL change in triglycerides at 3 to 6 months (N = 783) and –7.7 mg/dL change in total cholesterol and –17.7 mg/dL change in triglycerides at >12 months (N = 428). Of note, the observed decrease in lipid parameters could be a

consequence of the participants switching to iloperidone from another antipsychotic with higher propensity for dyslipidemia. Iloperidone has also been associated with weight gain in a dose-dependent manner, with 18 percent of subjects taking iloperidone 20 to 24 mg/day and 12 percent of those taking 10 to 16 mg/day gaining ≥7 percent of bodyweight at 4 to 6 weeks.

Seizures. In 4 to 6 weeks placebo controlled trials, iloperidone was associated with seizure in 1 of 1,344 patients treated with iloperidone (0.1 percent) and 2 of 587 patients treated with placebo (0.3 percent).

Orthostatic Hypotension and Syncope. Iloperidone has been associated with orthostatic hypotension with dizziness, tachycardia, and syncope, and this is thought to be related to its property as an α1-antagonist. In short-term studies where the dose was increased slowly, as per label recommendations, orthostatic hypotension occurred in 5 percent of patients taking iloperidone 20 to 24 mg/day, 3 percent taking iloperidone 10 to 16 mg/day, and 1 percent of patients taking placebo. It is noted that more rapid increases in iloperidone dose would be expected to increase the risk of orthostatic hypotension and syncope.

Hyperprolactinemia. In a 4-week placebo-controlled trial of iloperidone, prolactin increased 2.6 ng/mL in the group taking iloperidone 24 mg/day, as compared to a decrease of 6.3 ng/mL in the placebo group. In longer-term trials (N = 3,210), 0.1 percent of males taking iloperidone developed gynecomastia as compared to 0 percent in the placebo group, and 0.2 percent of females taking iloperidone developed galactorrhea as compared to 0.5 percent in the placebo group.

Priapism. Three cases of priapism were observed in the drug development process, according to manufacturer's prescribing information. This is thought to be related to the α-antagonist properties of iloperidone.

Potential for Cognitive and Motor Impairment. Iloperidone can cause somnolence and sedation, which could impair cognitive and motor skills. In short-term trials, iloperidone at dosages 10 mg/day or greater was associated with somnolence in 11.9 percent of patients as compared to 5.3 percent in the placebo group.

Pregnancy. Iloperidone is currently designated "Category C" for use in pregnant women, meaning that animal studies have shown an adverse effect on the fetus, there are no adequate and well-controlled studies in humans, and potential benefits may warrant use despite potential risks. In pregnant rat studies, a dose of iloperidone 26 times the MRHD (in

mg/kg/day) caused increased intrauterine deaths, decreased fetal weight and length, decreased fetal skeletal ossification, and increased incidence of minor fetal skeletal anomalies. In pregnant rabbits, a dose of iloperidone 20 times the MRHD increased early intrauterine deaths and decreased fetal viability at term. In pregnant rats, doses of 1.6 to 4.8 times the MRHD caused no adverse effects to the pups except for an increase in stillbirth rates at the dose of 1.6 times MRHD. The iloperidone metabolite P95 as given to pregnant rats at 20, 80, and 200 mg/kg/day during the period of organogenesis, and no teratogenic effects were seen; however, delayed skeletal ossification occurred.

Nursing Mothers. While iloperidone has been found to be excreted in milk of lactating rats, it is not known if this occurs in humans. It is currently recommended that women taking iloperidone should not breast-feed.

Dose-Related Adverse Reactions in Clinical Trials. Based on the pooled data from four short-term trials, adverse reactions that occurred in >2 percent of iloperidone patients and which at least doubled in the 20 to 24 mg/day group as compared to the 10 to 16 mg/day group included: abdominal discomfort, dizziness, hypotension, musculoskeletal stiffness, tachycardia, and weight gain.

Common and Drug-Related Adverse Reactions in Clinical Trials. Based on the pooled data from four short-term trials, adverse reactions that occurred in ≥5 percent of iloperidone patients at one dose and at least twice the placebo rate included: dizziness, dry mouth, fatigue, nasal congestion, somnolence, tachycardia, orthostatic hypotension, and weight gain.

Drug Interactions

Iloperidone dose should be reduced by ½ when administered along with strong CYP2D6 inhibitors (e.g., fluoxetine and paroxetine), CYP3A4 inhibitors (e.g., ketoconazole and clarithromycin), or poor CYP2D6 metabolizers. If CYP2D6 or CYP3A4 inhibitors are discontinued, the iloperidone dose can be increased accordingly.

Dosage and Administration

Iloperidone is available in tablets of 1, 2, 4, 6, 8, 10, and 12 mg. Iloperidone should be up-titrated slowly to minimize orthostatic hypotension side effects, given its α-adrenergic antagonist properties. It is recommended to start at 1 mg twice daily, increasing the dose (by no more than 4 mg total/day) to a target dose of 6 to 12 mg twice daily (12 to 24 mg total/day). Efficacy in pivotal trials as demonstrated in the range of 6 to 12 mg twice daily. Iloperidone does not need to be administered with meals. As with all

antipsychotics, it is recommended that patients with initial positive response to the drug be continued beyond the acute response. If have discontinued iloperidone for more than 3 days, it is recommended that the initiation titration schedule be followed.

Dosing in Special Populations

PEDIATRIC USE. Safety and efficacy data supporting the use of iloperidone in child and adolescent patients has not been established.

GERIATRIC USE. Safety and efficacy data supporting the use of iloperidone in geriatric populations has not been established. Only 25 of 3,210 participants of iloperidone premarketing trials were 65 years old or greater.

RENAL IMPAIRMENT. Iloperidone undergoes almost total hepatic metabolism, with <1 percent excreted unchanged. Creatinine clearance <30 mL/min had minimal effect on C_{max} of iloperidone or its P88 and P95 metabolites. However, the area under the curve (AUC) of iloperidone increased by 24 percent, P88 decreased by 6 percent, and P95 increased by 52 percent, so prescribers should monitor patients with renal impairment with greater vigilance.

HEPATIC IMPAIRMENT. No dosing adjustments to iloperidone are needed for patients with mild hepatic impairment. It is recommended that prescribers exercise caution when administering iloperidone to patients to moderate hepatic impairment, and not prescribe iloperidone to patients with severe hepatic impairment. Specifically, in patients with mild hepatic impairment, there were no significant differences in pharmacokinetics of iloperidone or its major metabolites as compared to healthy controls. With moderate hepatic impairment, a twofold higher exposure to the P88 metabolite was observed as compared to healthy controls. Adequate data is not available for patients with severe hepatic impairment.

SMOKERS. Iloperidone is not a substrate for CYP1A2, and it is noted that smoking should not have an effect on iloperidone pharmacokinetics.

ASENAPINE

Asenapine is an antipsychotic with high affinity for 5-HT_{2A} and D_2 receptors, as well as several other serotonergic, dopaminergic, and adrenergic receptors. Important clinical properties include sublingual administration (with temporary oral hypoesthesia as a possible side effect) and minimal anticholinergic side effects. It is associated with mild to moderate sedation (roughly equivalent to olanzapine and haloperidol) and mild changes in body weight.

History

Asenapine was initially developed by Organon. It was approved by the FDA in 2009, with indications for the acute treatment of both schizophrenia and bipolar I disorder (manic or mixed episodes). In 2010, the approval indications were expanded to include maintenance treatment of schizophrenia as well as use as adjunctive therapy (to lithium or valproate) for the acute treatment of manic or mixed episodes in bipolar I disorder.

Chemistry

Asenapine belongs to the class of dibenzo-oxepino pyrroles (Fig. 34.28–1). It was derived chemically by modifying the structure of the tetracyclic antidepressant, mianserin. The chemical name of asenapine is (3aRS,12bRS)-5-Chloro-2-methyl-2,3,3a,12b-tetrahydro-1Hdibenzo[2,3:6,7]oxepino[4,5-c]pyrrole (2Z)-2-butenedioate (1:1). Its molecular formula is $C_{17}H_{16}ClNO{\cdot}C_4H_4O_4$ and its molecular weight is 401.84.

Pharmacological Action

Pharmacokinetics

ABSORPTION. Asenapine is absorbed sublingually and is 35 percent bioavailable by this route. The bioavailability if swallowed is less than 2 percent. Drinking water 2 to 5 minutes after asenapine administration decreases absorption, so it is recommended that eating and drinking are avoided for 10 minutes after administration. Consumption of food immediately prior to sublingual administration decreases asenapine exposure by 20 percent and consumption of food 4 hours after administration decreases exposure by 10 percent; this is due to increased hepatic blood flow.

DISTRIBUTION. Asenapine is rapidly distributed, has a volume of distribution approximately 20 to 25 L/kg, and is highly protein-bound in plasma. Asenapine reaches maximal plasma concentration approximately 1 hour after administration and with twice-daily dosing, reaches steady-state within 3 days.

METABOLISM AND ELIMINATION. The primary metabolic pathways for asenapine are glucuronidation by UGT1A4 and oxidative metabolism by cytochrome P450 isozymes (primarily CYP1A2; CYP3A4 and CYP2D6 to a lesser extent). Asenapine is a weak inhibitor of CYP2D6. Though tobacco smoking induces CYP1A2, the clearance of asenapine in smokers has not been found to be altered. After single-dose administration, 50 percent of labeled asenapine metabolites were recovered in urine and 40 percent in stool. The mean terminal half-life of asenapine is approximately 24 hours.

Pharmacodynamics

MECHANISM OF ACTION. Asenapine has high affinity for: serotonin 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2A}, 5-HT_{2B}, 5-HT_{2C}, 5-HT_{5A}, 5-HT_6, and 5-HT_7 receptors; dopamine D_{2A}, D_{2B}, D_3, D_4, and D_1 receptors; adrenergic α_{1A}, α_{2A}, α_{2B}, and α_{2C} receptors, and histamine H1 receptors, acting as an antagonist at all of these receptors. It has moderate affinity for histamine H2 receptors and minimal affinity for muscarinic receptors. Its activity is mostly due to parent asenapine rather than metabolites.

Design and Interpretation of Clinical Drug Studies

Schizophrenia. The efficacy of asenapine for acute treatment of schizophrenia was supported by two of three 6-week randomized controlled trials of adults with DSM-IV schizophrenia who were having an illness exacerbation. The primary outcome measure on all three studies was the change in PANSS total score. In the first study (N = 174), asenapine 5 mg twice daily showed statistically significant improvement on the primary outcome measure, as well as the PANSS positive, negative, and general psychopathology subscales, as compared to placebo. The active comparator risperidone did not separate from placebo. In the second study (N = 448), asenapine 5 mg but not 10 mg, was statistically superior to placebo on the primary outcome measure. In the third study (N = 386), which was considered negative, neither 5- or 10-mg asenapine were superior to placebo, as compared to olanzapine 15 mg which was superior to placebo.

The efficacy of asenapine for maintenance treatment of schizophrenia was demonstrated in a randomized withdrawal design trial. Seven hundred patients with schizophrenia entered open-label asenapine treatment for 26 weeks. Three hundred-eighty-six patients who met stability criteria were randomized to either continue asenapine or withdraw to placebo. The primary outcome measure was time to relapse. Asenapine was statistically superior to placebo in increasing time to relapse as well as impending relapse (defined by prespecified changes in PANSS and CGI-S scores).

Bipolar Disorder. The efficacy for asenapine in treating acute mania was established in two trials in adults with DSM-IV bipolar I disorder who were having acute manic or mixed episodes. After a 7-day placebo washout period, patients were randomized to receive asenapine 5 or 10 mg twice daily, olanzapine 5 to 20 mg/day, or placebo. The primary outcome measure was the change in YMRS from baseline to day 21. Both asenapine and olanzapine were statistically superior to placebo on the primary outcome measure as well as the CGI-BP Severity of Illness score.

The efficacy of asenapine as an adjunctive therapy in treating acute mania was established in a 12-week placebo-controlled trial. Patients

experiencing manic or mixed episodes of bipolar I disorder with only partial response to lithium or valproic acid monotherapy were randomized to receive asenapine (5 to 10 mg twice daily, *N* = 154) or placebo (*N* = 162). Adjunctive asenapine was statistically superior to placebo at week 3 on the primary outcome measure (change in YMRS score).

Therapeutic Indications

Schizophrenia. The efficacy of asenapine for the treatment of schizophrenia was established from the results of two 6-week trials and one maintenance trial.

Bipolar Disorder

MONOTHERAPY. Asenapine is indicated for the acute treatment of manic or mixed episodes associated with bipolar I disorder. Efficacy was established in two 3-week monotherapy trials.

ADJUNCTIVE THERAPY. Asenapine is indicated as adjunctive therapy with either lithium or valproate for the acute treatment of manic or mixed episodes associated with bipolar I disorder. Efficacy was established in one 3-week trial.

Precautions and Adverse Reactions

Black Box Warning. Asenapine and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

QT Prolongation. Asenapine has been specifically assessed for its effect on QT interval, at doses of 5, 10, 15, and 20 mg twice daily versus placebo (*N* = 151). Asenapine was associated with an increase in QTc of 2 to 5 ms as compared to placebo and no patients showed greater than 60 ms increase or reached QTc ≥500 ms. In other asenapine premarketing clinical trials, there were no differences in QTc ≥500 ms between asenapine and placebo-treated patients, and there were no reports of Torsade de Pointes or other related events. It is recommended, however, that asenapine should not be combined with other medications known to increase the QTc interval.

Neuroleptic Malignant Syndrome. NMS has been associated with the use of antipsychotic medications, including asenapine. If NMS is suspected, asenapine and other antipsychotic medications should be discontinued immediately and the patient should undergo intensive supportive care and medical monitoring.

Tardive Dyskinesia. Tardive dyskinesia can develop in all patients

treated with antipsychotic drugs. Its prevalence is highest among the elderly. The propensity of asenapine to cause tardive dyskinesia is not known. In general, SGAs have a lower tardive dyskinesia risk than FGAs.

Metabolic Changes. The precise risk with asenapine of hyperglycemia-related adverse reactions, such as ketoacidosis or hyperosmolar coma, is not known. However, hyperglycemia-related adverse reactions have been associated with other SGAs.

In pooled 6-week trials, 5 to 10 mg asenapine twice daily (*N* = 377) was associated with a 3.2 mg/dL increase in glucose, as compared to –0.2 mg/dL in the placebo group (*N* = 232). In a 52-week trial of asenapine, with comparator control, the mean increase of fasting blood glucose was 2.4 mg/dL.

Dyslipidemia has also been associated with asenapine use. In pooled 6-week trials, 5- to 10-mg asenapine twice daily was associated with a 0.4 mg/dL increase in total cholesterol (*N* = 539), 1.3 mg/dL increase in LDL (*N* = 465), 0.5 mg/dL increase in high-density lipoprotein (HDL) (*N* = 480), and 3.8 mg/dL increase in triglycerides (*N* = 380). In the same group of pooled trials, the placebo group showed a 2.2 mg/dL decrease in total cholesterol (*N* = 351), 0.1 mg/dL increase in LDL (*N* = 285), 0.5 mg/dL increase in HDL (*N* = 290), and 7.6 mg/dL decrease in triglycerides (*N* = 233). In a 52-week trial of asenapine, with comparator control, asenapine was associated a 6 mg/dL decrease in total cholesterol and 9.8 mg/dL decrease in triglycerides. Of note, these observed decreases in lipid parameters over 52 weeks could be a consequence of the study participants switching to asenapine from another antipsychotic with higher propensity for dyslipidemia.

Asenapine may also affect body weight. In pooled 6-week studies, asenapine 5 to 10 mg twice daily (*N* = 532) was associated with a 1.1 kg increase in body weight as compared to a mean change of 0 kg in the placebo group (*N* = 348). In a comparator-controlled 52-week trial (*N* = 887), asenapine was associated with a 0.9 kg increase in body weight, with 14.7 percent of participants increasing ≥7 percent of their baseline body weight. The weight gain was most pronounced in participants with baseline BMI <23.

Seizures. In premarketing clinical trials, seizures were reported in 0 percent of patients taking asenapine 5 mg twice daily (*N* = 572), 0.3 percent of patients taking asenapine 10 mg twice daily (*N* = 379), as compared to 0 percent of patients taking placebo (*N* = 503 in short-term schizophrenia trial and *N* = 203 in short-term bipolar mania trial).

Orthostatic Hypotension and Syncope. Asenapine possesses α1-adrenergic antagonist properties and has been reported to cause orthostatic

hypotension and syncope in some patients, particularly early in treatment. In 6-week schizophrenia trials, 1/527 patients taking asenapine experienced syncope, as compared to 1/378 of patients taking placebo. In 3-week bipolar disorder trials, 1/379 patients taking asenapine experienced syncope, as compared to no patients taking placebo. When including all participants in premarketing clinical trials (including 52-week treatment), syncope was reported in 11/1,953 (0.6 percent) of patients taking asenapine.

Hyperprolactinemia. As with most antipsychotic medications, asenapine can increase prolactin levels. In premarketing clinical trials for schizophrenia and bipolar disorder, adverse events related to hyperprolactinemia were found in 0.4 percent of subjects in the asenapine group, as compared to 0 percent in the placebo group.

Leukopenia/Neutropenia. Leukopenia and neutropenia events have been infrequently reported to be temporally associated with asenapine use. It is recommended that patients with low WBC or history of drug-induced leukopenia or neutropenia have their blood counts monitored frequently during the first few months of treatment and that asenapine be discontinued if a WBC decrease is observed that cannot be explained by other factors. Patients with ANC <1,000/mm^3 should discontinue asenapine until it has recovered.

Potential for Cognitive and Motor Impairment. In short-term premarketing schizophrenia trials, somnolence occurred in 15 percent of patients taking asenapine 5 mg twice daily (N = 274) and 13 percent of patients taking 10 mg twice daily (N = 208), as compared to 7 percent of patients taking placebo (N = 389). Somnolence was noted to be most significant during the first week of treatment and led to discontinuation in 0.6 percent of all patients in short-term placebo-controlled trials (N = 1,953).

Body Temperature Regulation. In premarketing short-term trials of asenapine for schizophrenia and bipolar disorder, adverse events suggesting elevated body temperature were uncommon (≤1 percent) and comparable to placebo.

Dysphagia. Dysphagia was reported in 0.2 percent of patients with schizophrenia who were taking asenapine (N = 572), as compared to 0 percent of patients taking placebo (N = 378). There were no reported incidents of dysphagia in premarketing trials for bipolar mania.

Pregnancy. Asenapine is currently designated category C, indicating

that there are no adequate and well-controlled studies of asenapine in pregnant women. In animal studies, asenapine increased postimplantation loss and decreased rodent pup weight and survival though was not found to cause other structural abnormalities. It was found to be nonteratogenic in rat and rabbit studies. It is recommended to be only used during pregnancy if the potential benefit justifies the potential risk to the fetus.

Lactation. Asenapine is excreted in the milk of rats during lactation. It is unknown if this also occurs in humans. It is recommended that women receiving asenapine not breast feed.

Common and Drug-Related Adverse Reactions in Clinical Trials. Adverse reactions that occurred in ≥5 percent of short-term premarketing trial patients receiving asenapine (in either schizophrenia or bipolar disorder trials) and at ≥2 times the rate in the placebo groups included: EPS (both *akathisia* and *other than akathisia* types), oral hypoesthesia, somnolence, dizziness, and weight gain. In short-term premarketing schizophrenia trials (N = 572 receiving asenapine and N = 378 receiving placebo), the only adverse reaction that was dose-related was akathisia.

Oral hypoesthesia is an adverse reaction associated with asenapine but no other SGAs. This can occur immediately after sublingual administration and usually resolves within 1 hour. Oral hypoesthesia was associated with asenapine discontinuation in short-term premarketing trials for bipolar mania, occurring in 1.1 percent of the asenapine group patients (N = 379) and 0 percent of the placebo group (N = 203). In postmarketing monitoring of asenapine use, other oral reactions have been reported to have occurred with asenapine sublingual administration, including oral ulcers, blisters, peeling/sloughing, and inflammation.

Drug Interactions

Asenapine is primarily metabolized by UGT1A4 (direct glucuronidation) and by several cytochrome P450 isozymes (mostly CYP1A2). As such, administration of asenapine 5 mg with the CYP1A2 inhibitor fluvoxamine (25 mg twice daily) for 8 days increased the asenapine AUC by 29 percent; caution is indicated for coadministration of asenapine and fluvoxamine. Coadministration with the CYP2D6 inhibitor paroxetine was associated with a 9 percent decrease in the asenapine AUC. As asenapine is a weak inhibitor of CYP2D6 itself, it is recommended to be used with caution with drugs that are both substrates and inhibitors of CYP2D6 (such as paroxetine). Though valproic acid is an inhibitor of UGT1A4, coadministration of asenapine with valproic acid 500 mg twice daily did not significantly change asenapine levels.

Dosage and Administration

Asenapine is available as sublingual tablets of 5 or 10 mg. Patients should place the tablet under the tongue and allow it to completely dissolve, which occurs within seconds. Product labeling indicates asenapine tablets should not be split, crushed, chewed, or swallowed, and patients should not eat or drink for 10 minutes after administration.

For the treatment of acute schizophrenia, the recommended starting and target dose of asenapine is 5 mg twice daily. Based on clinical response, the dose can be increased to 10 mg twice daily if tolerated. For maintenance treatment of schizophrenia, the starting dose is recommended to be 5 mg twice daily, and in 1 week it can be increased up to 10 mg twice daily if tolerated.

For the acute treatment of manic or mixed episodes associated with bipolar I disorder, the recommended starting dose is 10 mg twice daily. If not tolerated, the dose can be decreased to 5 mg twice daily. For adjunctive therapy with either lithium or valproate, the starting dose of asenapine is recommended to be 5 mg twice daily, and based on clinical response, the dose can be increased to 10 mg twice daily if tolerated. Asenapine is not currently indicated for the maintenance treatment of bipolar disorder.

Asenapine administration is contraindicated in patients with a known hypersensitivity to the medication. Hypersensitivity reactions in clinical trials have included anaphylaxis, angioedema, hypotension, tachycardia, swollen tongue, dyspnea, wheezing, and rash, and some of these cases occurred after the first dose.

Dosing in Special Populations

GERIATRIC USE. Only 25 of 2,250 (1.1 percent) premarketing trial patients receiving asenapine were 65 years or older. In elderly patients, the asenapine AUC was on average 40 percent higher than younger than adults, so elderly patients taking asenapine should be monitored carefully.

HEPATIC IMPAIRMENT. Hepatic impairment has been found to increase the exposure to asenapine, according to the extent of hepatic impairment. Severe hepatic impairment (Child-Pugh C) was associated with a sevenfold increase in asenapine concentrations. Dosage adjustments are not required for mild (Child-Pugh A) or moderate (Child-Pugh B) hepatic impairment, but asenapine is not recommended to patients with severe hepatic impairment.

RENAL IMPAIRMENT. Renal impairment (mild, moderate, or severe, but not on dialysis) was not found to affect exposure to asenapine, so dosage adjustment is not required.

LURASIDONE

Lurasidone is an antipsychotic that is a potent antagonist at 5-HT_{2A}, D_2,

and 5-HT_7 receptors and a partial agonist at the 5-HT_{1A} receptor. It is among the SGAs (along with aripiprazole and ziprasidone) that have a relatively low liability for metabolic side effects. Patients should be cautioned to take lurasidone with food. Its most common side effects include sedation, extrapyramidal side effects (including akathisia), and nausea.

History

Lurasidone was developed by Dainippon Sumitomo Pharma and marketed by Sunovion in the United States. It was approved by the FDA for the treatment of schizophrenia in adults in 2010. Subsequently approval was granted in 2013 for the treatment of adults with bipolar depression (as both monotherapy and as an adjunct to lithium or valproate therapy).

Chemistry

Lurasidone belongs to the class of benzisothiazol derivatives, with the full chemical name of (3aR,4S,7R,7aS)-2-[((1R,2R)-2-{[4-(1,2-benzisothiazol-3-yl)-piperazin-1-yl]methyl}cyclohexyl)methyl]hexahydro-1H-4,7-methanisoindol-1,3-dione. Its molecular formula is $C_{28}H_{36}N_4O_2S$ and its molecular weight is 492.676 (free base). It is currently used in the form of its hydrochloride salt.

Pharmacological Action

Pharmacokinetics

ABSORPTION. Lurasidone has the relatively low oral bioavailability of 9 to 19 percent and its absorption is affected by food intake. Administration of lurasidone with a meal of at least 350 calories increases drug exposure approximately.

DISTRIBUTION. Peak serum concentrations are reached in 1 to 3 hours. The volume of distribution is 6,173 L and lurasidone is highly bound to serum proteins.

METABOLISM AND ELIMINATION. Lurasidone is metabolized mostly by CYP3A4 and is not a substrate for CYP1A1, CYP1A2, CYP2A6, CYP4A11, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, or CYP2E1. Its major biotransformation pathways are oxidative *N*-dealkylation, hydroxylation of its norbornane ring, and S-oxidation. It has two major active and two major inactive metabolites. Lurasidone is eliminated primarily in the feces (80 percent), with 9 percent of labeled metabolites recovered in urine. The mean elimination half-life was found to be 18 hours.

Pharmacodynamics

MECHANISM OF ACTION. Lurasidone is an antagonist with high affinity for the dopamine D_2 receptor as well as serotonin 5-HT_{2A} and 5-HT_7 receptors. It has been found to occupy 60 to 70 percent of D_2 receptors at a 40-mg dose. In addition, it is an antagonist with moderate affinity for α_{2A} and α_{2C} adrenergic receptors and is a partial agonist at the 5-HT_{1A} receptor. It has low affinity for the serotonin 5-HT_{2C} receptor and negligible affinity for histamine H_1 and muscarinic M_1 receptors.

Design and Interpretation of Clinical Drug Studies

Schizophrenia. Efficacy was established for the treatment of schizophrenia by five 6-week randomized controlled trials, with two including active comparators. The studies were conducted in adult patients with DSM-IV schizophrenia. Two of these studies (*N* = 145 and B = 180) used the change in Brief Psychiatric Rating Scale derived (BPRSd) as the primary outcome measure, and lurasidone significantly outperformed placebo at 40, 80, and 120 mg/day dosages. A third study (*N* = 489) used the change in PANSS total score as the primary outcome measure, and lurasidone 80 mg/day was found significantly superior to placebo, but the 40 and 80 mg/day dosages did not separate from placebo. A fourth study (*N* = 473) used olanzapine 15 mg/day as an active comparator. Lurasidone 40 and 120 mg/day, as well as olanzapine 15 mg/day, were significantly more effective than placebo on the primary outcome measure of change in PANSS total score. In the fifth study (*N* = 482), patients were randomized to receive lurasidone 80 mg/day, lurasidone 160 mg/day, quetiapine extended-release 600 mg/day, or placebo. The primary outcome measure was the change in PANSS total score. Both doses of lurasidone, as well as quetiapine extended-release, were associated with significant improvement in the primary outcome measure as compared to placebo. A sixth study (*N* = 353) involved random assignment to lurasidone 20, 40, and 80 mg/day or haloperidol 10 mg/day as an active comparator. This study was considered failed, because lurasidone at all dosages, as well as haloperidol, did not separate from placebo on the primary outcome measure (BPRSd).

Long-term effectiveness of lurasidone has been assessed in a 52-week controlled trial in which 639 stable outpatients with schizophrenia were randomized to receive lurasidone 40 to 120 mg/day or risperidone 2 to 6 mg/day. The two groups did not statistically differ in relapse rate (defined as a 30 percent increase in PANSS total score compared to baseline). Both groups also showed statistically equivalent improvement on PANSS total score over the 12 months.

Depressive Episodes Associated with Bipolar I Disorder

MONOTHERAPY. Efficacy was established in a 6-week randomized

controlled trial (*N* = 485) of adults with DSM-IV bipolar I disorder in a major depressive episode, with or without rapid cycling, and without psychotic features. Participants were randomized to receive flexible-dose lurasidone 20 to 60, 80 to 120 mg/day, or placebo. The primary outcome measure was the change in MADRS score from baseline to week 6. Both dose ranges of lurasidone were superior to placebo, and the effectiveness of the lower- versus higher-range dosing of lurasidone were not statistically different.

ADJUNCTIVE THERAPY. Efficacy was established in a 6-week randomized controlled trial (*N* = 340) of adults with DSM-IV bipolar I disorder in a major depressive episode, with or without rapid cycling, and without psychotic features. Patients who were still symptomatic despite lithium or valproic acid treatment were randomized to receive flexible-dose lurasidone 20 to 120 mg/day or placebo. The primary outcome measure was the change in MADRS from baseline to week 6. Lurasidone, as an adjunct to valproic acid or lithium, was statistically superior to placebo in the reduction of MADRS score.

Therapeutic Indications

Schizophrenia. Lurasidone is indicated for the treatment of patients with schizophrenia. Its efficacy was established in five short-term studies of adults with schizophrenia. Lurasidone is not indicated at the time of writing for longer-term use (greater than 6 weeks).

Depressive Episodes Associated with Bipolar I Disorder

MONOTHERAPY. Lurasidone is indicated as monotherapy for the treatment of patients with major depressive episodes associated with bipolar I disorder. Its efficacy for this indication was established in a 6-week monotherapy study of adults with bipolar depression.

ADJUNCTIVE THERAPY WITH LITHIUM OR VALPROATE. Lurasidone is indicated as adjunctive therapy (with either lithium or valproate) for the treatment of patients with major depressive episodes associated with bipolar I disorder. Its efficacy for this indication was established in a 6-week study of adults with bipolar depression who were being treated with lithium or valproate.

Lurasidone is not indicated at time of writing for longer-term (greater than 6 weeks) treatment of bipolar depression. Lurasidone is also not indicated at time of writing for the treatment of mania associated with bipolar I disorder.

Precautions and Adverse Reactions

Lurasidone is contraindicated in individuals with hypersensitivity to

lurasidone or any components in the tablets. Lurasidone is also contraindicated in patients using strong CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, ritonavir, voriconazole, and mibefradil) or CYP3A4 inducers (e.g., rifampin, avasimibe, St. John wort, phenytoin, and carbamazepine).

Black Box Warnings

INCREASED MORTALITY IN ELDERLY PATIENTS WITH DEMENTIA. Lurasidone and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis compared with placebo.

SUICIDAL THOUGHTS AND BEHAVIORS. Lurasidone also carries a black box warning for suicidal thoughts and behavior in children, adolescents, and young adults. This warning is associated with all antidepressant medications, including SGAs with indications for the treatment of depression.

Neuroleptic Malignant Syndrome. NMS has been associated with the use of antipsychotic medications, including lurasidone. If NMS is suspected, lurasidone and other antipsychotic medications should be discontinued immediately and the patient should undergo intensive supportive care and medical monitoring.

Tardive Dyskinesia. Tardive dyskinesia can develop in all patients treated with antipsychotic drugs. Its prevalence is highest among the elderly. The propensity of lurasidone to cause tardive dyskinesia is not known. In general, SGAs have a lower tardive dyskinesia risk than FGAs.

Metabolic Changes. SGAs have been associated with hyperglycemia, including severe cases with ketoacidosis, hyperosmolar coma, and death. Insufficient data is available to assess whether lurasidone is associated with these risks. When interpreting changes of metabolic parameters in antipsychotic clinical trials, it is important to consider that observed improvements in parameters could be a consequence of participants switching to lurasidone from other antipsychotics with higher propensities for adverse metabolic effects.

FASTING PLASMA GLUCOSE. In pooled short-term schizophrenia studies, changes of fasting serum glucose with placebo (N = 680) and lurasidone 20 (N = 71), 40 (N = 478), 80 (N = 508), 120 (N = 283), and 160 mg/day (N = 113) were 0, −0.6, +2.6, −0.4, +2.5, and +2.5 mg/dL, respectively. In uncontrolled longer-term schizophrenia studies, lurasidone was associated with a change in fasting glucose of +2.3 mg/dL at week 52 (N = 307). In the short-term bipolar depression monotherapy study, changes of fasting

serum glucose with placebo (*N* = 148) and lurasidone 20 to 60 (*N* = 140) and 80 to 120 mg/day (*N* = 143) were +1.8, -0.8, and +1.8 mg/dL, respectively. In the uncontrolled longer-term bipolar depression monotherapy study, lurasidone was associated with a +1.2 mg/dL change in fasting glucose at week 24 (*N* = 129). In the pooled short-term bipolar depression adjunctive therapy study, changes of fasting serum glucose with placebo (*N* = 302) and lurasidone 20 to 120 mg/day (*N* = 319) were −0.9 and 1.2 mg/dL, respectively. In the uncontrolled longer-term bipolar depression adjunctive therapy study, lurasidone was associated with a +1.7 mg/dL change in glucose at week 24 (*N* = 88).

FASTING LIPIDS. In pooled short-term schizophrenia studies, changes of fasting total cholesterol with placebo (*N* = 660) and lurasidone 20 (*N* = 71), 40 (*N* = 466), 80 (*N* = 499), 120 (*N* = 268), and 160 mg/day (*N* = 115) were −5.8, −12.3, −5.7, −6.2, −3.8, and −6.9 mg/dL, respectively. In uncontrolled longer-term schizophrenia studies, lurasidone was associated with a change in fasting total cholesterol of −6.9 mg/dL at week 52 (*N* = 307). In the short-term bipolar depression monotherapy study, changes of fasting total cholesterol with placebo (*N* = 147) and lurasidone 20 to 60 (*N* = 140) and 80 to 120 mg/day (*N* = 144) were −3.2, +1.2, and −4.6 mg/dL, respectively. In the uncontrolled longer-term bipolar depression monotherapy study, lurasidone was associated with a −0.5 mg/dL change in fasting glucose at week 24 (*N* = 130). In the short-term bipolar depression adjunctive therapy study, changes of fasting serum total cholesterol with placebo (*N* = 303) and lurasidone 20 to 120 mg/day (*N* = 321) were −2.9 and -3.1 mg/dL, respectively. In the uncontrolled longer-term bipolar depression adjunctive therapy study, lurasidone was associated with a -0.9 mg/dL change in fasting total cholesterol at week 24 (*N* = 88).

WEIGHT CHANGE. In pooled short-term schizophrenia studies, changes of body weight with placebo (*N* = 696) and lurasidone 20 (*N* = 71), 40 (*N* = 484), 80 (*N* = 526), 120 (*N* = 291), and 160 mg/day (*N* = 114) were −0.02, −0.15, +0.22, +0.54, +0.68, and +0.60 kg, respectively. In uncontrolled longer-term schizophrenia studies, lurasidone was associated with a change in body weight of −0.73 kg at week 52 (*N* = 377). In the short-term bipolar depression monotherapy study, changes of body weight with placebo (*N* = 151) and lurasidone 20 to 60 (*N* = 143) and 80 to 120 mg/day (*N* = 147) were −0.04, +0.56, and +0.02 kg, respectively. In the uncontrolled longer-term bipolar depression monotherapy study, lurasidone was associated with a −0.02 kg change in body weight week 24 (*N* = 130). In the short-term bipolar depression adjunctive therapy study, changes of body weight with placebo (*N* = 307) and lurasidone 20 to 120 mg/day (*N* = 327) were +0.16 and +0.11 kg, respectively. In the uncontrolled longer-term bipolar

depression adjunctive therapy study, lurasidone was associated with a +1.28 kg change in body weight at week 24 (*N* = 86).

QT Prolongation. Lurasidone was evaluated in a randomized controlled thorough QT study in 43 patients with schizophrenia or schizoaffective disorder. Participants were administered lurasidone 120 or 600 mg and ECGs were assessed 2 to 4 hours after dosing. Patients who received the 120-mg dose experienced a 7.5 ms increase in QTc, and those who received the 600 mg experienced a 4.6 ms increase. There was no observed dose–response relationship. In short-term schizophrenia and bipolar depression clinical trials, no study participants experienced QTc prolongation to greater than 500 ms.

Seizures. In short-term premarketing schizophrenia studies, seizures occurred in 0.1 percent (2/1,508) of patients treated with lurasidone as compared to 0.1 percent (1/708) patients treated with placebo. In short-term premarketing bipolar depression studies, no patients experienced seizures.

Orthostatic Hypotension and Syncope. Lurasidone may cause orthostatic hypotension and syncope. In pooled premarketing short-term schizophrenia studies, orthostatic hypotension was reported in 0.3 percent of lurasidone and 0.1 percent of placebo patients; syncope was reported in 0.1 percent of lurasidone and no placebo patients. In the premarketing short-term bipolar depression study, there were no reported adverse events of orthostatic hypotension and syncope. However, orthostatic hypotension, as assessed by vital signs, occurred in 0.6 percent of lurasidone patients as compared to 0 percent receiving placebo. In the premarketing short-term adjunctive therapy bipolar depression study, there were no reported adverse events of hypotension and syncope. Orthostatic hypotension, as assessed by vital signs, occurred in 1.1 percent of lurasidone patients and 0.9 percent of placebo patients.

Hyperprolactinemia. As with most antipsychotic medications, lurasidone can increase prolactin levels. In pooled short-term schizophrenia studies, changes in prolactin level with placebo (*N* = 672) and lurasidone 20 (*N* = 70), 40 (*N* = 476), 80 (*N* = 495), 120 (*N* = 284), and 160 mg/day (*N* = 115) were −1.9, −1.1, −1.4, −0.2, +3.3, and +3.3 ng/mL, respectively. In uncontrolled longer-term schizophrenia studies, lurasidone was associated with a change in prolactin level of −2.2 ng/mL at week 52 (*N* = 307). In the short-term bipolar depression monotherapy study, changes in prolactin level with placebo (*N* = 147) and lurasidone 20 to 60 (*N* = 140) and 80 to 120 mg/day (*N* = 144) were +0.3, +1.7, and +3.5 ng/mL, respectively. In the uncontrolled longer-term bipolar depression

monotherapy study, lurasidone was associated with a –1.15 ng/mL change in prolactin level week 24 (*N* = 130). In the short-term bipolar depression adjunctive therapy study, changes in prolactin level with placebo (*N* = 301) and lurasidone 20 to 120 mg/day (*N* = 321) were 0 and +2.8 ng/mL, respectively. In the uncontrolled longer-term bipolar depression adjunctive therapy study, lurasidone was associated with a –2.9 ng/mL change in prolactin level at week 24 (*N* = 88).

Potential for Cognitive and Motor Impairment. Lurasidone can cause somnolence, which can impair judgment, thinking, and motor skills. In short-term premarketing schizophrenia studies, somnolence was reported by 17 percent of patients receiving lurasidone (*N* = 1,508) and 7.1 percent of patients receiving placebo (*N* = 708). In the premarketing bipolar depression monotherapy study, 6.5 percent of the placebo group (*N* = 168), 7.3 percent of the lurasidone 20 to 60 mg/day group (*N* = 164), and 13.8 percent of the lurasidone 80 to 120 mg/day group (*N* = 167) reported somnolence. In the premarketing bipolar depression adjunctive therapy study, somnolence was reported by 11.4 percent of the lurasidone 20 to 120 mg/day group (*N* = 360) as compared to 5.1 percent of the placebo group (*N* = 334).

Suicide. In short-term premarketing schizophrenia studies, the incidence of suicidal ideation was 0.4 percent (6/1,508) in lurasidone-treated patients as compared to 0.8 percent (6/708) in placebo-treated patients. There were no suicide attempts or completed suicides in these studies. In the short-term bipolar depression monotherapy study, there were no reported events of suicidal ideation, attempts, or completed suicides in either group. In the short-term bipolar depression adjunctive therapy study, the incidence of suicidal ideation was 1.1 percent (4/360) in lurasidone-treated patients and 0.3 percent (1/334) in placebo-treated patients. There were no suicide attempts or completed suicides in this study.

Serum Creatinine. In short-term schizophrenia trials, serum creatinine levels increased 0.05 mg/dL in lurasidone-treated participants as compared to 0.02 mg/dL in placebo-treated participants. Changes in creatinine levels appeared to be dose-dependent, with 7 percent of patients receiving lurasidone 160 mg/day (*N* = 121) shifting from normal to abnormally high creatinine levels as compared to 2 percent of those receiving placebo (*N* = 708).

Extrapyramidal Symptoms. In premarketing schizophrenia studies, EPS (excluding akathisia) was reported in 13.5 percent of patients receiving lurasidone as compared to 5.8 percent of patients receiving placebo.

Akathisia was reported in 12.9 percent of patients receiving lurasidone as compared to 3 percent of patients receiving placebo. These effects were dose-dependent, with the highest percentage of events occurring in the group receiving lurasidone 120 mg/day. EPS were also reported in short-term bipolar depression studies with similar frequencies. Dystonic symptoms occurred in 4.2 percent of patients in premarketing schizophrenia trials versus 0.8 percent of those receiving placebo, and 7/1,508 participants (0.5 percent) discontinued the clinical trial due to dystonic events, which occurred during the first few days of treatment. Dystonia occurred less frequently with lurasidone in bipolar depression studies though still occurred more often than the placebo groups. No participants in bipolar depression studies discontinued participation due to dystonic symptoms.

Pregnancy. Lurasidone is classified as pregnancy category B, which indicates that animal reproductive studies did not identify a specific risk to the fetus, but there are no adequate and well-controlled studies in pregnant women. Lurasidone should only be used in pregnancy if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Rat studies demonstrated excretion of lurasidone in milk during lactation. It is unknown whether this also occurs in humans. Mothers should consider discontinuation of nursing due to the potential for adverse reactions in infants.

Common and Drug-Related Adverse Reactions in Clinical Trials. In short-term premarketing schizophrenia studies, the most common adverse reactions associated with lurasidone (defined as incidence ≥5 percent and at least twice the rate of placebo) were somnolence, akathisia, EPS, and nausea. In the bipolar depression monotherapy study, the most common adverse reactions associated with lurasidone were akathisia, EPS, somnolence, nausea, vomiting, diarrhea, and anxiety. In the bipolar depression adjunctive therapy study, the most common adverse reactions associated with lurasidone were akathisia and somnolence. In premarketing studies for both schizophrenia and bipolar disorder, there were no adverse reactions associated with lurasidone discontinuation (defined as ≥2 percent occurrence and at least twice the rate of placebo).

Drug Interactions

It is recommended that lurasidone not be used in conjunction with strong CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, ritonavir, voriconazole, and mibefradil). If lurasidone is used with moderate CYP3A4 inhibitors (e.g., diltiazem, atazanavir, erythromycin, fluconazole, and verapamil), the lurasidone dose should be reduced by ½. Grapefruit and

grapefruit juice should be avoided in conjunction with lurasidone use.

Lurasidone is contraindicated for use with strong CYP3A4 inducers (e.g., rifampin, avasimibe, St. John wort, phenytoin, and carbamazepine). If lurasidone is used in conjunction with a moderate CYP3A4 inducer, it may be necessary to increase lurasidone dosage after at least 7 days of treatment with the CYP3A4 inducer.

Lithium and valproic acid dosages do not need to be adjusted if used concomitantly with lurasidone. Dosages of P-glycoprotein substrates (i.e., digoxin) and other CYP3A4 substrates (e.g., midazolam or oral contraceptives) also do not need to be adjusted if used with lurasidone.

Dosage and Administration

Lurasidone is available in 20-, 40-, 60-, 80-, and 120-mg tablets. It is recommended that lurasidone is taken with at least 350 calories of food to improve absorption.

For the treatment of schizophrenia, it is recommended to start lurasidone at 40 mg once daily. Lurasidone has been found effective for schizophrenia in the dose range of 40 to 160 mg daily, and the maximum recommended dose is 160 mg daily.

For the treatment of bipolar I depression, the recommended starting dose is 20 mg once daily, given as either monotherapy or as an adjunct to lithium or valproate. Lurasidone has been found effective for bipolar I depression in the dose range of 20 to 120 mg daily, and the maximum recommended dose for both monotherapy and adjunct therapy is 120 mg daily.

Dosing in Special Populations

GERIATRIC USE. There were insufficient numbers of patients aged 65 and older in lurasidone trials to determine whether they respond differently to the medication than younger adults. In a limited sample of elderly patients with psychosis (65 to 85 years of age), plasma concentrations of lurasidone after 20 mg/day administration were similar to those in younger adults.

HEPATIC IMPAIRMENT. In patients with moderate (Child-Pugh Score of 7 to 9) or severe hepatic impairment (Child-Pugh score of 10 to 15), dose reduction in lurasidone is recommended. The recommended starting dose is 20 mg daily and the maximum recommended dose in moderate or severe hepatic impairment is 80 and 40 mg/day, respectively.

RENAL IMPAIRMENT. In patients with moderate or severe renal impairment (creatinine clearance less than 50 mL/min), dose reduction in lurasidone is recommended. In this population, the recommended starting dose is 20 mg daily, and the maximum recommended dose is 80 mg daily.

OTHER NOVEL ANTIPSYCHOTIC AGENTS

Two new antipsychotics have been approved by the FDA in 2015. Cariprazine is an antipsychotic that is a partial agonist at D_2 and D_3 receptors with substantially greater affinity for D_3R. It is unclear how its clinical properties will differ from those of aripiprazole, the only available dopamine receptor partial agonist. Brexpiprazole is a partial agonist at D_2 and 5-HT_{1A} receptors as well as an antagonist at 5-HT_{2A} receptors. There is also an interest in developing new long-acting formulations of current antipsychotics that could be administered at longer intervals.

Although there is an interest in developing antipsychotic agents that are not dopamine receptor antagonists, there has been only limited progress in finding effective agents. Pomaglumetad, an agonist for metabotropic glutamate receptors 2 and 3, appeared to be effective as an antipsychotic in an initial trial, but failed in subsequent phase II trials. Sarcosine, an agent that inhibits the glycine transporter (GlyT-1), has been reported to be effective as an antipsychotic. The results from initial studies will need to be replicated. Another GlyT-1 inhibitor, bitopertin did not appear to be an effective antipsychotic. Pimavanserin, an inverse agonist at the 5-HT_{2A} receptor, is being studied as a possible adjunctive agent that could be added to a subtherapeutic dose of an antipsychotic. Phosphodiesterase inhibitors are being studied as agents that may be effective when added to antipsychotic. A number of these agents are in early trials.

CARIPRAZINE

Cariprazine is a partial agonist at dopamine D_3 and D_2 receptors and serotonin 5-HT_{1A} receptors. The binding affinity for D_3 is an order of magnitude higher than the affinity for D_2. It is plausible that the preference for D_3 might result in improvements in cognition, mood, and negative symptoms.

History

Cariprazine was developed by Gedeon Richter, a pharmaceutical company located in Budapest, Hungary. It was subsequently licensed to Allergan (which was previously known as Actavis) for the United States and Canada. Cariprazine was initially approved for the treatment of schizophrenia and bipolar disorder in September, 2015, under the trade name Vraylar.

Pharmacokinetics

ABSORPTION. Cariprazine is well absorbed following oral administration, reaching peak concentrations between 3 and 6 hours after dosing. Absorption is not substantially affected by food.

Pharmacokinetics. The activity of orally administered cariprazine is mediated by the parent drug and its two major active metabolites, desmethyl cariprazine (DCAR) and didesmethyl cariprazine (DDCAR). The metabolites appear to be equipotent to cariprazine at target therapeutic receptors. After multiple dose administrations, mean cariprazine and DCAR concentrations reached steady state between 1 and 2 weeks; mean DDCAR concentrations reach steady state in 4 to 8 weeks. The mean half-life of cariprazine is 2 to 5 days, whereas the half-life of DDCAR is considerably longer and results in substantial plasma accumulation. This very long half-life of the active metabolite indicates that patients who are started on cariprazine are likely to have a gradual increase in active drug over several weeks. Moreover, when the drug is discontinued, the active moiety is likely to remain in plasma for weeks.

METABOLISM AND ELIMINATION. Cariprazine is extensively metabolized by CYP3A4 and CYP2D6 to DCAR and DDCAR. Approximately 21 percent of the daily dose is found in urine. The excretion half-life is 2 to 4 days for the parent drug and 1 to 3 weeks for the active metabolite.

PHARMACODYNAMICS AND MECHANISM OF ACTION. In vitro studies indicated that cariprazine has greater affinity for D_3 compared with D_2 receptors. A recent PET study found that subjects treated with 1 mg/day of cariprazine had mean D_3 and D_2 receptor occupancies of 76 and 45 percent, respectively, indicating selectivity for D_3 over D_2 receptors at low doses.

Cariprazine is unique among available antipsychotics in having much greater affinity for D_3 as compared to D_2 receptors. In addition, it has greater affinity for D_3 receptors than dopamine itself. It is unclear whether this activity is related to its antipsychotic properties since studies in rodents indicate that D_3 antagonists are not effective in preclinical models of schizophrenia. It is possible that the combination of D_3 and D_2 activity of cariprazine results in antipsychotic activity, and potentially confers additional activity for other domains of psychopathology.

Design and Interpretation of Clinical Drug Studies

The efficacy of cariprazine in acute exacerbations of schizophrenia was demonstrated in three positive clinical trials. In a Phase II trial, patients treated with 1.5, 3, or 4.5 mg daily of cariprazine or 4 mg of risperidone showed significantly greater improvement in total PANSS compared with placebo. Another trial with a similar population found that 3 and 6 mg of cariprazine as well as 10 mg of aripiprazole resulted in greater improvement than placebo. A third trial in acute schizophrenia found that patients dosed from 3 to 6 mg and 6 to 9 mg demonstrated greater improvements than placebo-treated patients.

A separate trial in schizophrenia randomized patients with predominant negative symptoms to 26 weeks of double-blind treatment with cariprazine (mean dose, 4.2 mg/day) or risperidone (mean dose 3.8 mg/day). Patients assigned to cariprazine demonstrated significantly greater improvement in negative symptoms than patients assigned to risperidone, as measured by the PANSS negative symptoms factor score.

Cariprazine was also evaluated in 3-week trials for bipolar I disorder patients with manic or mixed states. In each of the trials, improvement was evaluated with the Young Mania Rating Scale (YMRS). In two flexible dose studies (cariprazine doses of 3 to 12 mg/day), cariprazine was more effective than placebo. A third study compared cariprazine at 3 to 6 and 6 to 12 mg/day with placebo. Both dose ranges of cariprazine were superior to placebo and there was no efficacy advantage for the higher-dose range.

A study of patients with major depressive disorder (MDD) and an inadequate response to an antidepressant randomized subjects to 8 weeks of treatment with adjunctive cariprazine 1 to 2 mg/day, 2 to 4.5 mg/day, or placebo. Patients in the 2 to 4.5 mg group demonstrated greater improvement on the Montgomery-Asberg Depression Rating Scale (MADRS).

Finally, a study in patients with bipolar I depression randomized subjects to treatment with cariprazine 0.75, 1.5, or 3.0 mg/day or placebo. The 1.5- and 3-mg/day doses were associated with greater improvement on the MADRS, but the 0.75-mg/day dose was not more effective than placebo.

Therapeutic Indications. Cariprazine is FDA approved in the United States for the treatment of adult patients with schizophrenia (1.5 to 6.0 mg/day) and acute manic or mixed episodes associated with bipolar I disorder (3.0 to 6.0 mg/day).

Precautions and Adverse Reactions

Cariprazine is contraindicated in individuals with hypersensitivity to the drug or components in the tablets. If cariprazine is prescribed with a strong CYP3A4 inhibitor, the dosage should be reduced.

Cariprazine and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis. Other precautions for all antipsychotic medications include: neuroleptic malignant syndrome; tardive dyskinesia, metabolic changes including hyperglycemia/diabetes mellitus, dyslipidemia, and weight gain. Due to cariprazine's long half-life (related to its active metabolites), patients should be monitored for adverse reactions and patient response for several weeks after starting this drug.

Metabolic Changes. In 3- and 6-week trials for acute psychosis and

mania, shifts in fasting glucose were similar for cariprazine and placebo. In long-term open-label trials, 4 percent of patients with normal hemoglobin A1c baseline values developed elevated levels. In acute studies, the shifts in fasting total cholesterol, LDL, HDL, and triglycerides were also similar in patients treated with cariprazine and placebo. There was a small amount of weight gain associated with cariprazine treatment in acute studies. For long-term, studies in schizophrenia, the mean changes in bodyweight from baseline at 12, 24, and 48 weeks were 1.2 kg, 1.7 kg, and 2.5 kg, respectively.

Extrapyramidal Symptoms and Akathisia. In clinical trials, extrapyramidal symptoms and akathisia were reported at rates ≥5 percent and at least twice the rate of placebo. Both of these effects were more common at higher doses of cariprazine.

Pregnancy. As with other antipsychotic drugs, neonates exposed to cariprazine during the third trimester of pregnancy are at risk for extrapyramidal and/or withdrawal symptoms following delivery. There are insufficient data on cariprazine to determine if it is associated with a risk for birth defects or miscarriage. There are animal data suggesting that cariprazine may cause fetal harm.

Nursing Mothers. There is insufficient information about the presence of cariprazine in human milk, the effects on the breastfed infant, or the effects on milk production.

Dosage and Administration. Cariprazine is available as 1.5-, 3-, 4.5-, and 6-mg capsules. It can be administered as a single daily dose.

For treating schizophrenia, it is recommended that patients be started on 1.5 mg for the first day. The dose can be increased in 1.5-mg increments. The recommended dose range is 1.5 to 6 mg/day. There is no indication that doses above 6 mg/day are associated with greater benefit.

For treating bipolar I mania and mixed states, it is also recommended that patients be started on 1.5 mg the first day, followed by an increase to 3 mg. The recommended dose range is 3 to 6 mg/day.

Dosing in Special Populations. The safety and effectiveness of cariprazine in pediatric populations have not been assessed. There are inadequate data regarding the safety of cariprazine in elderly patients. No dosage adjustment is recommended for patients with mild to moderate renal or hepatic disease.

BREXPIPRAZOLE

Brexpiprazole was developed as a 5-HT_{1A} and dopamine D_2 partial agonist that would have similar efficacy to its predecessor, aripiprazole and a

reduced tendency to cause akathisia, restlessness, and insomnia.

History

Brexpiprazole was discovered by Otsuka Pharmaceutical and was co-developed with Lundbeck. It received FDA approval in July, 2015 for the treatment of schizophrenia and as an adjunctive treatment for depression. In September, 2016, brexpiprazole was approved for the maintenance treatment of schizophrenia.

Pharmacological Action

Pharmacokinetics

ABSORPTION. After a single dose of brexpiprazole, peak plasma concentrations are reached within 4 hours. Steady-state concentrations are achieved within 10 to 12 days of multiple-dose administration. Levels are not affected by the ingestion of food.

METABOLISM AND ELIMINATION. Brexpiprazole is largely metabolized by CYP3A4 and CYP2D6 enzymes. Its main metabolite does not contribute to its clinical activity. After a single oral dose of brexpiprazole, approximately 25 percent of the dose is recovered in the urine and 46 percent in feces.

PHARMACODYNAMICS AND MECHANISM OF ACTION Brexpiprazole is a partial agonist at serotonin 5-HT_{1A} and dopamine D_2 receptors, and an antagonist at serotonin 5-HT_{2A} and adrenergic $\alpha_{1B/2C}$ receptors. The intrinsic activity of brexpiprazole at D_2 receptors is higher than that of pure antagonists but lower than that of aripiprazole. This limited intrinsic activity has the potential for reducing adverse reactions associated with other D_2 antagonists, such as extrapyramidal side effects and prolactin elevation. At the same time, brexpiprazole's lower intrinsic activity compared to aripiprazole may result in fewer adverse reactions related to D_2 receptor agonism such as akathisia, insomnia, restlessness, and nausea.

Design and Interpretation of Clinical Drug Studies

The efficacy of brexpiprazole in the treatment of acute exacerbations of schizophrenia was demonstrated in two pivotal 6-week, fixed-dose studies and a 6-week, flexible-dose trial with an active control, quetiapine XR.

In the fixed-dose studies, patients were randomized to brexpiprazole 2 or 4 mg once per day or placebo. One of the studies included a dose of 0.25 mg and the other 1 mg. The low doses were predicted to be ineffective and were not included in the analyses. Patients who were assigned to brexpiprazole were started on 1 mg for the first 4 days, increased to 2 mg on days 5 to 7, and then treated with 2 or 4 mg for the 5 remaining weeks.

In both of the studies, 4 mg of brexpiprazole resulted in a statistically significantly greater improvement in PANSS total score than placebo. In one of the studies, 2 mg of brexpiprazole also demonstrated a greater improvement than placebo.

In the flexible-dose study, patients were randomized to flexible doses of 2- to 4-mg brexpiprazole, 400- to 800-mg quetiapine XR, or placebo. The mean doses of brexpiprazole and quetiapine at the last study visit were 3.5 mg/day and 674.4 mg/day, respectively. Quetiapine resulted in greater improvement compared to placebo while brexpiprazole came very close to separating from placebo ($p = 0.056$).

The efficacy and tolerability of brexpiprazole as a maintenance treatment for schizophrenia were also demonstrated in a 52-week maintenance study. Patients who had been stabilized on brexpiprazole for at least 12 weeks were randomly assigned to receive brexpiprazole or placebo for 52 weeks. The primary efficacy endpoint was the time from randomization to the exacerbation of psychotic symptoms or an impending relapse. This study was terminated at an interim analysis when brexpiprazole demonstrated a significantly longer time to relapse.

The efficacy of brexpiprazole as an adjunctive treatment of MDD was evaluated in two 6-week, double-blind, placebo-controlled, fixed-dose trials. Subjects for both studies met criteria for MDD and had an inadequate response to prior antidepressant therapy and an inadequate response to 8 weeks of prospective antidepressant treatment (with escitalopram, fluoxetine, paroxetine controlled-release, sertraline, duloxetine delayed release, or venlafaxine extended-release). In one study, patients were randomly assigned to 2 mg once a day or placebo, and in the other to 1 mg, 3 mg, or placebo (added to their antidepressant). For both studies, patients received 0.5 mg once daily during week 1, 1 mg during week 2, and the assigned dose for the 4 remaining weeks. After 6 weeks of treatment, adjunctive brexpiprazole 2 or 3 mg/day provided significantly greater improvements from baseline in mean MADRS total scores.

Therapeutic Indications. Brexpiprazole is FDA approved for the treatment of schizophrenia (2 to 4 mg/day) and as an adjunctive treatment for MDD (2 mg/day).

Precautions and Adverse Reactions

Brexpiprazole is contraindicated in patients with a known hypersensitivity to brexpiprazole or any of its components.

Brexpiprazole and the other SGAs carry a black box warning for increased mortality in elderly patients with dementia-related psychosis. Other precautions for all antipsychotic medications include: neuroleptic malignant syndrome; tardive dyskinesia, metabolic changes including hyperglycemia/diabetes mellitus, dyslipidemia, and weight gain. It also

carries the same warning as other antidepressant medications for an increased suicidal risk in children, adolescents, and young adults with major depressive or other psychiatric disorders.

Metabolic Changes. In the 6-week trials for acute psychosis and depression, shifts in fasting glucose were similar for brexpiprazole and placebo. In the long-term open-label trials, 9 percent of subjects with depression and 10 percent of schizophrenia subjects experienced shifts to high fasting glucose from normal or borderline. The shifts to elevated levels of fasting total cholesterol, LDL, HDL, and triglycerides were also similar to placebo in the acute studies of schizophrenia and depression. In the 6-week trials in schizophrenia, 11 percent of patients who received 2 mg of brexpiprazole and 10 percent of those who received 4 mg had a weight gain equal to or greater than 7 percent compared to 4 percent on placebo. For the acute depression studies, 5 percent of 1 mg patients, 5 percent of 2 mg patients, and 2 percent of patients on 3 mg had a weight gain equal to or greater than 7 percent compared to 2 percent on placebo. This suggests a relatively modest risk for metabolic changes compared to other antipsychotics.

Extrapyramidal Symptoms and Akathisia. Both objective ratings and reported events suggest that brexpiprazole is associated with a small risk for extrapyramidal symptoms (EPS) and akathisia. For example, in depression trials the incidence of reported EPS, excluding akathisia, was 6 percent for brexpiprazole patients and 3 percent for placebo patients. The incidence of akathisia events for brexpiprazole patients was 9 percent versus 2 percent for placebo patients. In schizophrenia trials, the incidences of reported EPS and akathisia were similar for brexpiprazole and placebo.

Other Side Effects. Other notable adverse effects which occurred in ≥1 percent of subjects and at greater frequency than placebo included blurry vision, nausea, prolactin elevation, myalgia, somnolence, and insomnia.

Pregnancy. Neonates exposed to brexpiprazole during the third trimester of pregnancy are at risk for extrapyramidal and/or withdrawal symptoms following delivery. There are insufficient data on brexpiprazole to determine if it is associated with a risk for birth defects or miscarriage.

Nursing Mothers. There is insufficient information about the presence of brexpiprazole in human milk, the effects on the breastfed infant, or the effects on milk production.

Drug Interactions. The dosage of brexpiprazole should be reduced

when it is coadministered with strong CYP3A4 inhibitors or CYP2D6 inhibitors.

Dosage and Administration. Brexpiprazole is available as 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets.

The recommended dose range for schizophrenia is 2 to 4 mg administered as a single daily dose. Patients should be started on 1 mg daily for 4 days, increased to 2 mg for 3 days and then increased to 4 mg if necessary.

The recommended dose for the adjunctive treatment of depression is 2 mg daily. Patients should be started on 0.5 to 1 mg and then increased if necessary.

For both indications, the dose should be decreased 50 percent in CYP2D6 poor metabolizers.

Dosing in Special Populations. The safety and effectiveness of brexpiprazole in pediatric populations have not been assessed. There are inadequate data regarding the safety of brexpiprazole in elderly patients. Patients with moderate to severe hepatic impairment (Child-Pugh score ≥7) should be prescribed a maximum dose of 2 mg once daily for patients with MDD, and 3 mg once daily for patients with schizophrenia. For patients with moderate, severe, or end-stage renal impairment (creatinine clearance CrCl <60 mL/min), the maximum recommended dosage is 2 mg once daily for patients with MDD and 3 mg once daily for patients with schizophrenia.

FUTURE DIRECTIONS

To date, all of the available antipsychotics (except the recently approved 5-HT2A antagonist pimavanserin) target D2 receptors. It is possible that other drugs targeting this mechanism can only be marginal improvements. Drug development has also focused on agents that are effective for other domains of psychopathology in schizophrenia such as cognition or negative symptoms. These agents could be added to an antipsychotic if the drug is not effective for psychotic symptoms. Most of the focus has been on drugs that can enhance cognition. At the time of this writing, a number of drugs are in development with a number of molecular targets.

▲ 34.29 Central Nervous System Sympathomimetic Compounds

MANPREET KAUR SINGH, M.D., AND YURIY DOBRY, M.D.

INTRODUCTION

Sympathomimetic amines are compounds that activate the sympathetic central nervous system (CNS). Endogenous catecholamines, such as norepinephrine and dopamine, are direct sympathomimetic amines and exert their effects by binding to dopamine (DA) and norepinephrine (NE) receptors. Psychostimulants are indirect sympathomimetic amines with both central and peripheral effects. Psychostimulants enhance motivation, attention, concentration, wakefulness, and stimulate the cardiovascular system. They also suppress appetite and interfere with sleep. Psychostimulants achieve these effects by inhibiting the release or slowing the uptake of catecholamines, which leads to build up of DA and NE in the extracellular space.

Amphetamine (AMPH) was the first formulation of stimulants to be synthesized in 1927. Stimulants have been historically used for the treatment of "hyperkinetic" behavior in children, parkinsonism, epilepsy, and for some time, barbiturate poisoning. The second formulation of stimulants, methylphenidate (MPH), was synthesized in 1944, but was not identified as a stimulant until 1954. It was first used to treat barbiturate-induced coma and memory deficits in the elderly. Beginning in the 1960s, methylphenidate was used to treat children with ADHD, known at the time as "hyperactivity or minimal brain dysfunction (MBD)." Together, the AMPH- and MPH-based formulations constitute the psychostimulant medication class, which is currently approved by the United States Food and Drug Administration (US FDA) for the treatment of ADHD and narcolepsy for all age groups. Despite their clear therapeutic benefit, psychostimulants may be highly addictive, and are classified as, schedule II medications by the Drug Enforcement Agency (DEA). Although the immediate-release AMPH and MPH are prototypic psychostimulants, intermediate and long-acting formulations are more frequently prescribed due to the convenience of increased adherence and improved pharmacological coverage. See Table 34.29–1 for a complete list of available psychostimulants, strengths, and dosing recommendations for ADHD.

ETIOLOGY AND PATHOGENESIS OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Research in the pathogenesis and etiology of ADHD may inform the pharmacological properties of psychostimulants. ADHD is a heritable,

chronic, neurobehavioral disorder that is commonly characterized by hyperactivity, impulsivity, and inattention. Clinical characteristics of ADHD correspond with aberrant catecholamine neurotransmission in the prefrontal cortex (PFC) and functionally associated cortical and subcortical areas. To sustain attention, regulate impulse control, facilitate working memory and cognitive flexibility, the PFC exerts a "top-down" control of the temporal cortex, parietal cortex, basal ganglia, amygdala, cerebellum, and corpus callosum. Dysfunction of catecholamine neurotransmission in the PFC compromises these cognitive functions, and can lead to clinical manifestations of ADHD.

AMPH and MPH change the dynamics of catecholamine transport system, which allows for an increase of NE and DA levels in the PFC area, and improves cognitive deficits associated with ADHD. Using animal models, and microdialysis techniques, Volkow and colleagues (2011) demonstrated that psychostimulants work by correcting the catecholamine dysfunction in the PFC, and a related "attention" network. They have shown that MPH can increase DA levels in the ventral striatum, the PFC, and temporal cortex; dysfunction which is implicated in ADHD. Further, MPH increases catecholamine levels in the fronto-striatal-thalamo-cerebellar circuit implicated in executive functions (EFs), and is positively associated with improvement in working memory, reaction time, and focus.

Table 34.29–1.
Clinical Indications of Psychostimulants

Medication	Dosing	Supplied	Average Therapeutic Dose	Maximum Daily Dose	US I Indi
Generic name: Mixed amphetamine and dextro-amphetamine salts **Brand name:** Adderall **Formulation:** Immediate release tablet	**Adults** *ADHD:* Initial: 5 mg once or twice daily Increase daily dose by 5 mg weekly intervals Narcolepsy: Initial: 10 mg daily Increase daily dose in 10 mg weekly intervals **Pediatric** Not FDA approved for children ≤3 years of age *ADHD:* **3–5 yo** Initial 2.5 mg once every morning Increase daily dose	5, 7.5, 10, 20, or 40 mg	**Narcolepsy:** 5–60 mg/day in 1–3 divided doses 2.5–20 mg b.i.d., daily	**Adults** *ADHD* 40 mg *Narcolepsy:* 60 mg **Pediatric** **3–17 yo** *ADHD* 40 mg *Narcolepsy* 60 mg **Not FDA approved for children Ä3 years of age**	Mor fo N

	in 2.5 mg weekly intervals **6–12 yo** Initial: 5 mg once or twice daily Increase daily dose in 5 mg weekly intervals **Adolescents 13–17 yo** Initial: 5 mg once or twice daily Increase daily dose in 5 mg weekly intervals *Narcolepsy:* **6–12 years:** Initial: 5 mg daily Increase daily dose in 5 mg weekly intervals **Children >12 years: Refer to adult dosing.** **Children: <3 years not recommended**				
Generic name: Dextroamphetamine sulfate **Brand name:** Dexedrine, ProCentra, Zenzedi **Formulation: immediate release tablet or extended release capsule**	**Immediate release** **Adults** **Narcolepsy:** Initial: 10 mg once daily Increase in increments of 10 mg at weekly intervals until optimal response is obtained **Pediatric** ADHD: **Children 3 to 5 years:** **Initial:** 2.5 once daily **Increase** daily 2.5 mg dose at weekly intervals *(Current AAP guidelines do not recommend use in children ≤5 years due to insufficient evidence)	5-, 10-, 15-mg capsules	**Adults, children 12 and older:** Narcolepsy: 5 to 60 mg in divided doses	**Immediate Release** **Adults** **ADHD:** 40 mg **Narcolepsy:** 60 mg **Pediatric** **ADHD:** 40 mg **Narcolepsy:** 60 mg **Extended Release** **Pediatric** **ADHD:**40 mg (60 mg in divided doses can be tried in children >50 kg)	Mor A N

	Children ≥6 years and adolescents: Initial: 5 mg once or twice daily; may increase in increments of 5 mg at weekly intervals **Narcolepsy** Children 6 to 12 years: Initial: 5 mg once daily Increase in increments of 5 mg at weekly intervals **Children >12 years and adolescents** Refer to adult dosing. **Extended-release capsules:** Initial: 5 mg once or twice daily Increase in increments of 5 mg weekly				
Generic name: Mixed amphetamine and dextro-amphetamine salts **Brand name:** Adderall XR **Formulation:** Extended-release capsule	**Adults-** *ADHD:* Initial: 20 mg once daily in the morning Not FDA approved for children ≤6 years of age **Pediatric** *ADHD:* Initial: 5–10 mg once daily in the morning Increase daily dose in 5–10 mg increments at weekly intervals	5-, 10-, 15-, 20-, 25- or 30-mg capsule	20–30 mg	30 mg **Children: <6 years not recommended**	Mor A
Generic name: Lisdexamfetamine **Brand name:** Vyvanse **Formulation:** Capsule with inactive pro-drug compound	**Adults** **ADHD:** Initial: 30 mg once daily in the morning Increase in increments of 10 or 20 mg daily at weekly intervals	20-, 30-, 40-, 50-, 70-mg capsule	**ADHD:** 20–70 mg daily **Binge Eating Disorder:** 50–70 mg daily	**Adults** *ADHD* and *BED* 70 mg **Pediatric** *ADHD* 60 mg **Not FDA approved for children Ä6**	Mor A B

	Binge eating disorder (BED)**:** **Pediatric** *ADHD:* Children 6–12 years: Initial: 20 to 30 mg once daily in the morning Increasing: weekly increases of 10 mg daily up to a maximum of 60 mg daily Adolescents: Refer to adult dosing			**years of age**	
Generic: Methylphenidate hydrochloride **Brand Name:** Ritalin **Formulation:** Immediate release tablet	**Adults** **ADHD:** Initial: 5 mg twice daily Increase by 5–10 mg daily at weekly intervals Narcolepsy: Initial: 5 mg twice daily Increase by 5–10 mg daily at weekly intervals Pediatric Not FDA approved for children ≤6 years of age Children ≥6 years and Adolescents: Initial: 5 mg twice daily Increase by 5–10 mg daily at weekly intervals **Off-label use:** Depression in medically ill older adults, adult patients with terminal illness, receiving palliative care: 2.5–5 mg once daily or twice daily Increase by 2.5–5 mg daily every 1–3 days in divided doses	5, 10, 20 mg	20–30 mg Some patients might require 40–60 mg	**Adults** **ADHD** and **Narcolepsy** 60 mg daily (in 2–3 divided doses) **Depression in medically ill older adults, adult patients with terminal illness, receiving palliative care:** 20–40 mg daily **Pediatric** ADHD: 60 mg daily (in 2–3 divided doses)	Mor A N

Generic: Methylphenidate hydrochloride **Brand Name:** Methylin **Formulation:** Immediate release oral solution	Adults Children (6 years and over) Initial: 5 mg twice daily Increase by 5 mg daily at weekly intervals	Methylin Oral Solution 5 mg/5 mL Methylin Oral Solution 10 mg/5 mL	20–30 mg daily	60 mg Not FDA approved for children ≤6 years of age	Mor A N
Generic Methylphenidate hydrochloride **Brand Name:** Ritalin SR **Formulation:** Immediate release tablet or extended release capsule	**Adults and Pediatric** ADHD and Narcolepsy: Equivalent to Ritalin immediate release	20 mg	20–60 mg	60 mg	Mor A N
Generic: Methylphenidate hydrochloride **Brand Name:** Concerta **Formulation:** Extended-release tablet	**Children 6–12 yo, adolescents 12–17 yo, Adults** ADHD: Initial: 18 mg daily (18–36 mg adults) Increased by 18 mg/day at weekly intervals	18, 27, 45, 54 mg	**Adults** 18–72 mg daily **Pediatric** 18–54 mg daily	54 mg (6–12 yo) 72 mg (adolescents and adults) **Not FDA approved for children Ä6 years of age or elderly**	Mor A
Generic: Methylphenidate hydrochloride **Brand Name:** Daytrana **Formulation:** Extended-release transdermal system	**6–12 yo, adolescents-** ADHD: **week 1:** 10 mg/9 hours (1.1 mg/hour) **week 2:** (1.6 mg/hour), 15 mg/9 hours **week 3:** (2.2 mg/hour), 20 mg/9 hours **week 4–7:**30 mg/9 hours (3.3 mg/hour)	Transdermal patch: 10 mg/9 hours (1.1 mg/hour) 15 mg/9 hours (1.6 mg/hour) 20 mg/9 hours (2.2 mg/hour) 30 mg/9 hours (3.3 mg/hour)	1.1–3.3 mg/hour	3.3 mg/hour **Not FDA approved for children Ä6 years of age or elderly** **No indication in adults**	Mor A
Generic: Methylphenidate hydrochloride **Brand name:** Metadate CD **Formulation:** Expended-release capsule	Children 6–12 yo, adolescents 12–17 yo, adults- ADHD: Initial: 20 mg daily; Increase in 10–20 mg increments at weekly intervals	10, 20, 30, 50, mg	60 mg	**Children >6, adolescents, adults** **ADHD: 60 mg**	Mor A N
Generic: Methylphenidate hydrochloride **Brand name:** Metadate ER	**Adults and Pediatric** ***ADHD and Narcolepsy:*** Equivalent to	20 mg	10–60 mg	60 mg	Mor A N

Formulation: Extended-release tablets	Ritalin immediate release				
Generic: Methylphenidate hydrochloride **Brand Name:** Quillivant XR **Formulation:** Extended-release powder for suspension	Not approved by FDA for children <6 years of age Children 6–12 years, adolescents, and adults: ADHD: Initial: 20 mg daily; Increase in 10–20 mg increments at weekly intervals	Bottles of 300-, 600-, 750-, 900-mg powder (5 mg/mL)	60 mg	60	Mor A N
Generic: Dexmethylphenidate **Brand Names:** Focalin and Focalin XR **Formulation:** Immediate release tablet and extended release capsule	Adults: ADHD: Immediate release: Initial: 2.5 mg twice daily Increase in increments of 2.5–5 mg at weekly intervals Extended release: Initial: 10 mg once daily Increase in increments of 10 mg/day at weekly intervals (maximum dose: 40 mg/day) Pediatric ADHD: Children ≥6 years: Initial: 2.5 mg twice daily Increased in increments of 2.5–5 mg at weekly intervals Initial: 5 mg once daily; dosage may be adjusted in increments of 5 mg/day at weekly intervals	Focalin: 2.5, 5, 10 mg Focalin XR: 5, 10, 15, 20, 30, 35, 40 mg	Focalin: 2.5 to 10 mg twice a day (doses should be taken at least 4 hours apart) Focalin XR 20–40 mg daily (adults) and 10–30 mg daily (pediatric)	**Focalin immediate release** 20 mg/day **Focalin extended release** 30 (pediatric) and 40 (adults)	Mor A
Generic: Atomoxetine HCl **Brand name:** Strattera **Formulation:** Immediate release capsules	Adults ADHD Initial: 40 mg/day Increase to ~80 mg/day after minimum of 3 days. May	10, 18, 25, 40, 60, 80, 100 mg	Children and adolescents ≥70 kg: 100 mg Children and adolescents ≤70 kg: 1.2	1.4 mg/kg or 100 mg	Mor A

	increase to 100 mg/day in 2–4 additional weeks to achieve optimal response. Pediatric ADHD: *Children ≥6 years and ≤70 kg* Initial 0.5 mg/kg/day Increase to ~1.2 mg/kg/day after a minimum of 3 days		mg/kg	
Generic Modafinil **Brand name:** Provigil **Formulation:** Immediate release tablet	**Narcolepsy, obstructive sleep apnea/hypopnea syndrome (OSAHS):** Initial: 200 mg daily in 2 divided doses Increase: in 100-mg increments as needed and tolerated **Shift work sleep disorder (SWSD):** Initial: 200 mg as a single dose taken ~1 hour prior to start of work shift	Supplied: 100-, 200-mg tabs	Narcolepsy 200–300 mg/day **SWSD: 200** mg/day	400 mg

Neurobiology of ADHD

Neuroimaging studies have now demonstrated aberrant brain structural and functional characteristics associated with key cognitive deficits in ADHD. Compared to healthy controls, individuals with ADHD across the lifespan have decreased volumes in frontal, parietal, and temporal cortices, as well as in the basal ganglia, limbic system, hypothalamus, cerebellum, and corpus callosum. Impairments in these frontal-striatal-cerebellar networks that are known to regulate attention, impulse control, and other key EFs may lead to deficits in these cognitive functions in ADHD. Importantly, more granular findings have been demonstrated in key functional subregions of the PFC, including the orbitofrontal cortex (OFC; control and processing of emotion and motivation), the inferior frontal cortex (IFC; regulates inhibition impulsive thoughts or feelings, and maintains cognitive flexibility essential for decision making), dorsolateral prefrontal cortex (DLPFC; key for sustained attention, planning and

working memory), dorsal anterior cingulate cortex (dACC; integrates information and controls executive and inhibitory functions; dACC facilitates sensory target detection, proper response selection, error detection, and action monitoring), and the anterior PFC (controls impulsivity of the motor behavior). Collectively, these regions function to filter irrelevant information or "noise" and amplify relevant signal needed to execute a specific task.

Biochemistry of Catecholamine Neurotransmission

ADHD-related dysfunction may be related to disruption of PFC fibers that project catecholamines to cortical and subcortical regions. This model of ADHD has also been supported by animal and human lesion and neuroimaging (diffusion tensor imaging) studies that show that disruption of key PFC projections result in attention, emotion, and locomotor dysregulation. Further, mutating genes that encode for the dopamine transporter protein (DAT) and enzymes that metabolize DA and NE, have conferred behavioral traits in animals that mimic ADHD-like traits. Indeed, both DA and NE play an important role in the pathophysiology of ADHD, and are candidate targets for treatment with psychostimulants. DA enhances working memory through its interaction with D1 receptors. NE functions to increase arousal, excitability, and memory storage and retrieval, and to modulate executive function, including cognitive organization and problem solving through its interactions of the postsynaptic α2A-adrenoceptors. Thus, deficits in this catecholamine system within the PFC have been associated with decreased control over irrelevant information, leading to inattention, impulsivity, and hyperactivity associated with ADHD. As above, psychostimulants are thought to inhibit or reverse the direction of the NE/DA membrane transporter proteins (NET/DAT), which increase catecholamines in the synaptic space, leading to enhanced function in the PFC to restore attention.

Genetics

Family, adoption, and twin studies suggest that the mean heritability estimate of ADHD is ~76 percent in children and adolescents, and ~30 percent in adults. Gene variants associated with the ADHD phenotype include mutations of genes that encode for the proteins involved in the catecholamine neurotransmission system. Unfortunately, the strength of the association between ADHD and likelihood of carrying mutations of most candidate genes that have been identified so far has not been adequately validated.

MECHANISMS OF ACTION OF PSYCHOSTIMULANTS

As above, psychostimulants exert clinical effects by raising extracellular catecholamine levels in the context of catecholamine deficit. The chemical compositions of psychostimulants AMPH and MPH are different. AMPH belongs to the phenethylamine chemical class. The asymmetric α-carbon atom gives rise to two AMPH enantiomers, the L-stereoisomer and the D-stereoisomer. MPH has four isomers but only L-MPH and D-MPH are part of the currently available MPH preparations, and only D threomethylphenidate exhibits clinically useful pharmacological activity.

Just as chemical compositions vary, the mechanisms of action of various psychostimulants also differ significantly. Whereas MPH blocks the DAT and NET, and increases DA and NE from the synaptic vesicle pool by inhibiting endocytosis, AMPH compounds use DAT and NET, along with several other transporters, to actively unload vesicular catecholamine stores. Using PET and radioligands specific to the DAT, NAT, and DA and NE receptors, D-methylphenidate has been shown to rapidly cross the blood–brain barrier (BBB), and bind to the DAT and NET. To reach efficacy threshold, MPH needs to occupy approximately 70 to 80 percent of NET and 60 to 70 percent of DAT, in order to increase synaptic DA in the PFC leading to increased attention. The rate of extracellular DA rise is proportional to the rate at which methylphenidate crosses the BBB.

In contrast to these MPH mechanisms, AMPH functions as a potent full agonist of trace amine-associated receptor 1 (TAAR1), which inhibits vesicular monoamine transporter function (VMAT), DAT (especially D1, the predominant receptor type in the PFC), and NET. AMPH also functions by reducing the DA and NE vesicular pH gradient, leading to reversal of catecholamine transport and inhibition of the monoamine oxidase (MAO) and catechol-o-methyltransferase (COMT) enzymes that degrade catecholamines. This confers more potency in AMPH compared to MPH, which translates to more rapid extracellular increases in DA and NE concentrations compared to MPH. Indeed, microdialysis studies in rat brains have demonstrated that AMPH induces three times greater behavioral effects and greater synaptic DA and NE boost compared to the catecholamine rise caused by much higher doses of MPH. Thus, AMPH may be a more effective indirect sympathomimetic agent than MPH, and may require lower effective doses to induce MPH-equivalent physiological effects.

CLINICAL PHARMACOLOGY OF PSYCHOSTIMULANTS

Psychostimulants, amphetamine and methylphenidate compounds, are the most commonly used psychotropic medications nationwide, and have US FDA–indicated treatment for ADHD and narcolepsy in children, adolescents, and adults. Please refer to Table 34.29–1 for a list of clinical indications of psychostimulants. This section will review the pharmacokinetics (see Table 34.29–2), pharmacodynamics, interactions,

efficacy, and tolerability (including adverse effects, contraindications, and precautions) of psychostimulants, and then conclude with an overview on these characteristics for nonstimulant medications, modafinil and atomoxetine (ATM).

Pharmacokinetics

Immediate-Release Formulations. Due to their high degree of lipophilicity, psychostimulants rapidly cross the gastrointestinal tract and the BBB. The absorption phase parallels the rate of release of the catecholamine neurotransmitters into the CNS synaptic clefts.

AMPH-related compounds typically reach peak blood levels in 2 to 3 hours, with a variable effect of several hours after oral administration. Amphetamine is metabolized by deamination, oxidation, and hydroxylation. Deamination produces an inactive metabolite, phenylacetone, which is further oxidized and then excreted in urine as hippuric acid and glucuronide conjugates. Amphetamine is also converted to norephedrine by oxidation and then this metabolite and the parent compound are p-hydroxylated. Several metabolites, including norephedrine, its hydroxymetabolite, and hydroxyamphetamine, are all pharmacologically active. The excretion of amphetamine depends on urinary pH, which provides a basis for using ammonium chloride to acidify the urine to manage an amphetamine overdose, which markedly increases excretion. Approximately 70 percent of the dose is excreted in a 24-hour urine collection with 30 percent excreted as unchanged drug. This increases to 74 percent under acidic conditions and decreases to 1 percent in alkaline urine.

The MPH tablet releases equal amounts of D-MPH and L-MPH, at a nearly identical, linear rate. The behavioral effects of MPH are exerted by its d-MPH enantiomer whereas L-MPH has little or no behavioral effect. MPH and related compounds reach peak blood concentration in 2 hours and have a short half-life of 1 to 2 hours. Concentrations of MPH in the brain exceed concentrations in the blood. Metabolism of MPH is highly enantio-specific, favoring L-MPH over D-MPH. Plasma half-life (t1/2) of D-MPH is markedly longer than that of L-MPH, and oral bioavailability is 22 percent for D-MPH and 2 to 8 percent for L-MPH. MPH undergoes hydrolysis an deesterification by a liver and stomach enzyme, CES-1. Another route of metabolism is hepatic deesterification and oxidation. Ritalinic acid is the major metabolite of MPH that is renally excreted.

Long-Acting Formulations. Methylphenidate and amphetamine long-acting products extend the apparent plasma half-life of methylphenidate and amphetamine by altering the absorption kinetics. Methylphenidate sustained release (Ritalin SR) was the first available long-acting formulation of methylphenidate. It delivers a single, prolonged pulse of

MPH via a wax-matrix–based technology. This formulation has a problematic delay in release rate, onset of behavioral effects, significant intrasubject variability and has been shown to have inferior clinical properties compared to MPH administered several times per day. Due to the availability of new multiple long-lasting release formulations of MPH, Ritalin-SR is rarely used. Controlled-release formulations of methylphenidate include Metadate CD, Focalin XR, and Ritalin LA. Metadate CD is the first extended-release formulation to use beaded technology. The MPH compound is stored in porous beads, with pore diameter controlling its release. The porous beads produce a bimodal MPH distribution, with an immediate burst of a D- and L-methylphenidate mixture, and an extended release of the remaining MPH approximately 5 hours later. The Focalin XR formulation also demonstrates similar bimodal kinetics. It provides 8-hour coverage without significant troughs. Focalin XR releases D-threo-methylphenidate, which is approximately twice as potent as L-threo-methylphenidate.

Mixed salts of a single-entity amphetamine product (Adderall XR) contain two types of beads in a 50:50 ratio. The immediate-release beads create an almost immediate burst of AMPH, and the delayed-release beads provide the second burst approximately 4 hours after oral ingestion. Extended-release methylphenidate, Ritalin LA, uses a spheroidal oral drug absorption system (SODAS) technology to evenly distribute MPH over approximately 8 hours. It has a bimodal distribution of a mixture of D- and L-threo-methylphenidate. Extended-release methylphenidate (Concerta) uses an oral osmotic release system (OROS), which relies on an osmotic gradient to provide extended coverage. The capsule is composed of a medication layer next to a layer of inactive matrix material. A third layer contains active osmotic components, which regulate the rate of release. In an aqueous environment such as gastrointestinal tract, the matrix layer dissolves within 1 hour, providing an initial dose of methylphenidate. Water expands the osmotic layer, and then the remaining amount of MPH is released, controlled by the diameter of the osmotic layer orifices.

Table 34.29–2.
Pharmacological Properties of Psychostimulants

Medication	T_{max} (h)	Half-life (hours)	Duration of Action (hours)	C_{max} (ng/mL)
Mixed (R,S)-amphetamine salts, short acting (Adderall) Racemic mixture of D:L-amphetamine isomers in a 3:1 ratio Each Adderall XR capsule	2	For D-Isomer ~11–13 L-Isomer ~15–17 (if urine is acidic-> both	6	110

contains a 1:1 ratio of immediate- to delayed-release mixed amphetamine salts beads.		isomers' half-lives are reduced to 7 hours)		
Mixed (R,S)-amphetamine salts, extended release (Adderall XR) Racemic mixture: D:L amphetamine isomers in a 3:1 ratio Each Adderall XR capsule contains a 1:1 ratio of immediate- to delayed-release mixed amphetamine salts beads.	Children 6–12 years: D-amphetamine: 9 hours L-amphetamine: 11 hours Adolescents 13–17 years: D-amphetamine: 11 hours L-amphetamine: 13–14 hours Adults D-amphetamine: 10 hours L-amphetamine: 13 hours An acidic diet: 8–11 hours An alkaline diet 16–31 hours	Mean 11.5	10–12	40.10
Dextroamphetamine sulfate extended release (Dexedrine)	First peak: 1.6 hours Second peak: 6.5 hours	9.4–13	10	36.6
Dextroamphetamine sulfate **immediate release**	1–2	9.4–13	10	36.6
Lisdexamfetamine dimesylate(Vyvanse)	3.8–4.7	1	10–12	58.2 +/– 28.1 ng/mL
Methylphenidate hydrochloride (Ritalin)	2	2–3	4	3.5 +/– 0.4 ng/mL
Methylphenidate sustained release (Ritalin SR)	3–8	Unknown	~8	4.84
Methylphenidate Extended-Release Oral Suspension (MEROS) Long-acting liquid preparation with MEROS delivery system. MEROS consists of drug–polymer complexes 80% of drug–polymer complexes are coated with an extended-release coating of varying thicknesses, which allows for release of methylphenidate throughout the day 20% of drug–polymer complexes are uncoated and	First peak ~2 Second peak 5	5–6	10–12	3.6 (± 5.8) ng/mL

act as immediate-release methylphenidate				
Methylphenidate hydrochloride oral solution (Methylene)	2	2–3	4	3.5 +/– 0.4 ng/mL
Extended-release methylphenidate hydrochloride (Metadate CD) Contains two types of coated beads, one type with immediate-release *methylphenidate* and second with extended-release *methylphenidate*. 30% of beads deliver d-threo- and l-threo-methylphenidate immediately The remaining 70% of beads are extended release, delivering the mixture of L-threo-methylphenidate content and D-threo-methylphenidate content several hours after the beads with methylphenidate have been released.	First peak ~2 Second peak 4–6	6.8	8–9	24.7–40.9 ng/mL
D-Threo-Methylphenidate (Focalin)	2	2–3	4	3.5 +/– 0.4 ng/mL
Dextra-methylphenidate extended release (Focalin XR) Formulation provides coverage of up to 12 hours. d- Focalin XR contains only the *d*-MPH which is twice as potent as Focalin immediate release. It delivers 50% of its d-threo-MPH initially, and 3 to 4 hours later. This creates an approximate 8–10 coverage without significant troughs. Thus, the closest concentration curve can be recreated by methylphenidate twice daily (50% of the dose).	First peak 1–2 Second peak 5–6	3.5	8–10	14–16
Methylphenidate transdermal system (Daytrana) Delivers methylphenidate into the systemic circulation directly through the skin,	10 hours after single application 8 hours after repeat patch	3–4	9	5.7 ± 9.39:12.5 CM^2– 542.9 ± 22.4:37.5

reducing first-pass metabolism by the liver.	applications			
Extended-release methylphenidate (Ritalin LA) Delivers MPH via spheroidal oral drug absorption system (SODAS) technology to produce a bimodal distribution of 1:1 racemic mixture of d-and l-threo-MPH enantiomers. 50% is released initially and another 50% approximately 3–4 hours later	First peak 1–2 Second peak 5–6	3.5	6–8	16.4
Extended-release methylphenidate (Concerta) It delivers methylphenidate via oral osmotic release system (OROS), which is composed of two drug layers containing the drug and excipients, and a push layer with active osmotic components. It delivers 1:1 racemic mixture of l:d-threo-methylphenidate. In the gastrointestinal tract, the drug overcoat dissolves within 1 hour, providing an initial dose or 22% of the medication. Water then permeates the tablet core, osmotically active polymer, releasing the remaining 78% of the mediation through the orifice	8–12	3.5	9–11	3.3–7.8
Extended-delivery methylphenidate (MEROS or Quillivant XR) is a powder that, after reconstitution with water, forms an extended-release oral suspension formulation of methylphenidate intended for once daily oral administration. It contains approximately 20% immediate-release and 80% extended-release methylphenidate	5.0	5.2		13.6 (± 5.8) ng/mL
Modafinil (Provigil)	2–3	D-modafinil: 4–5 hours	6–14	6.4 µg/mL

C_{max}, maximum plasma methylphenidate concentration
T_{max}, time to maximum plasma methylphenidate concentration

The methylphenidate transdermal system (Daytrana) delivers methylphenidate through a transdermal matrix. It does not undergo first-pass metabolism by CES-1 in the liver and stomach, and has a relatively constant release of both D- and L-methylphenidate throughout the entire patch over time, resulting in constant plasma methylphenidate levels. Daytrana may be useful for patients who have problems tolerating oral medications. In addition, extended-delivery methylphenidate (MEROS or Quillivant XR) is a powder formulation of MPH that forms an extended-release oral suspension for once per day oral administration. It contains approximately 20 percent immediate-release and 80 percent extended-release methylphenidate. This formulation might be advantageous for patients who cannot tolerate pill and prefer a liquid form. Finally, lisdexamfetamine dimesylate (LDX; Vyvanse) is the first known inactive pro-drug psychostimulant that is activated by a chemical modification in erythrocytes. LDX has high aqueous solubility, partially due to low lipophilicity. It is likely that in the small intestines LDX is transported by peptide transport proteins such as PEPT1 and PEPT2. Unlike other amphetamines, it consistently increases the extracellular concentration of serotonin in the PFC and striatum.

Pharmacodynamics

Traditional stimulants are all considered indirect-acting sympathomimetics because they do not act directly on receptors, as do natural catecholamines. Stimulant action occurs through simultaneous neurotransmitter release at the synapse and block of reuptake, thereby slowing metabolic breakdown of active neurotransmitters. Dextroamphetamine is the most potent by virtue of its ability to release both DA and NE and its capacity to release newly formed soluble pools and granule-stored pools of catecholamines in nerve endings. MPH acts on DA (but not NE) through release of DA from granular pools and blockage of DA reuptake. This may explain why

amphetamine is a more powerful stimulant and is more likely to activate latent hypertension than is methylphenidate. See Table 34.29–3 for important psychostimulant drug–drug interactions.

Table 34.29–3.
Important Psychostimulant Drug–Drug Interactions

Methylphenidate	**Inhibits metabolism of:**
	Anticoagulants (e.g., Coumadin)
	Tricyclic drugs (e.g., imipramine, clomipramine, desipramine)
	Anticonvulsants (e.g., phenobarbital, phenytoin, primidone)
	CYP2D6 substrates (e.g., flecainide, haloperidol, metoprolol, propafenone, risperidone, thioridazine SSRIs, SNRIs)
	Cyclosporine
	Glipizide
	Induces metabolism of:
	Methylphenidate
	Metabolism is inhibited by:
	Bupropion
	CYP2D6 inhibitors (e.g., chlorpromazine, delaviridine, fluoxetine, miconazole, paroxetine, pergolide, quinidine, quinine, ritonavir, and ropinirole)
	Metabolism is induced by: Carbamazepine
Amphetamines	**Acetazolamide**
	Acetazolamide decreases clearance of amphetamine
	Chlorpromazine
	Decreased amphetamine effectiveness
	Donepezil
	Increased norepinephrine availability lowers seizure threshold
	Guanethidine
	Decreases guanethidine effectiveness
	Opipramol, **Pargyline**, **Phenelzine**, **Procarbazine**, **Protriptyline**, **Tranylcypromine, Doxepin, Trimipramine, Toloxatone, Rasagiline**, **Selegiline**, **Sibutramine, Amitriptyline:** Increased norepinephrine availability can result in a hypertensive crisis (headache, hyperpyrexia, hypertension)
	The concurrent use of amphetamine and monoamine oxidase inhibitors (MAOIs) is contraindicated. At least 14 days should elapse following the discontinuation of MAOIs before amphetamine therapy is instituted
	Desvenlafaxine, Dolasetron, Lofepramine, Lorcaserin, Hydroxytryptophan, Imipramine, Iproniazid, Almotriptan, Clorgyline, Desipramine, Isocarboxazid, Meperidine, Moclobemide, Nialamide, Nortriptyline Tramadol,Trazodone, Vilazodone, Vortioxetine, Ziprasidone, Fentanyl, Fluoxetine, Furazolidone, Mirtazapine, Granisetron, Levomilnacipran, Palonosetron: increased risk of serotonin syndrome from additive serotonergic effects

Efficacy and Tolerability of Stimulants in the Treatment of ADHD and Other Conditions

Several randomized controlled trials (RCTs) have characterized the efficacy, tolerability, and adverse effects of stimulants for ADHD and for

other psychiatric disorders. In total, approximately 5,899 children, adolescents, and adults have been involved in RCTs examining the efficacy and safety of stimulants in treatment of ADHD. Outcomes of these studies pooled together have demonstrated that 65 to 75 percent of individuals in the treatment arm improved in core ADHD symptoms (inattentiveness, hyperactivity, impulsivity), compared to 5 to 30 percent of individuals who improved when assigned to the placebo arm, with large effect sizes (Cohen's d = 0.7 to 1.5). Psychostimulants are considered highly effective and relatively safe for the treatment of ADHD in all age groups. Based on such robust evidence, the American Academy of Pediatrics and the American Academy of Child and Adolescent Psychiatry (AACAP) have adopted guidelines that regard stimulant medications as a cornerstone treatment for ADHD.

Data in Children and Adolescents with ADHD. The Collaborative Multisite Multimodal Treatment Study of Children with ADHD (MTA) is the first major RCT that demonstrated long-term efficacy and safety of methylphenidate in the treatment of children diagnosed with ADHD, combined type. MTA investigators followed 579 children, 7 to 9.9 years of age. Participants were randomized to three carefully designed treatment groups and a control group that received treatment in the community. Treatment groups included one group of participants who were treated with immediate-release methylphenidate (MPH-IR) monotherapy, a second group treated with MPH-IR in combination with behavioral and community interventions, and a third group treated with behavioral and community interventions only. Participants were assessed using parent- and teacher-reported ADHD rating scales at baseline and after 14 months of treatment. Adverse effects were also assessed and reported. MPH-IR was administered 3 times/day, with a mean total daily dose was 32.1 ± 15.4 mg. Subjects treated with MPH-IR with or without behavioral or community interventions showed significant improvement in core ADHD symptoms such as inattention, impulsivity, and hyperactivity. In addition, children randomized to the two groups with methylphenidate treatment demonstrated significant improvement in family, social, and academic functioning, as well as in externalizing symptoms. The symptomatic and functional improvements persisted for the duration of the treatment.

A 93 percent retention rate was reported 24 months after the initiation of the MTA trial when ADHD symptoms and level of social, academic, and family functioning were reassessed. Most subjects continued to benefit from methylphenidate or from the combination of methylphenidate and behavioral interventions. The difference in ADHD symptoms and functioning among subjects treated with methylphenidate, subjects receiving behavioral intervention alone, or subjects treated in a community setting decreased significantly over time. Improvement seen in the two

groups treated with methylphenidate remained, but the effect size decreased by 50 percent. Twenty-four months after initiation of treatment, 21.8 percent of youth in the combination methylphenidate and behavioral treatment group stopped treatment versus 25.8 percent of subjects in the methylphenidate-only group. In the behavioral therapy-only group, at 24-month assessment, 68.2 percent of subjects added methylphenidate to their treatment regimen.

At the end of 14 months, 77 percent children in the methylphenidate monotherapy treatment group maintained their original dose of methylphenidate. In 23 percent of subjects who did not maintain the original dose, initial titration did not lead to an adequate response, and 12 percent did not maintain satisfactory long-term therapeutic gains. For the roughly 5 percent of youth who did not respond to initial titration of methylphenidate, switching to dextroamphetamine was effective. Methylphenidate was later found to be effective in a minority of children who did not respond to the initial methylphenidate titration, reflecting a false-negative titration outcome. Thus, some proportion of ADHD patients do not respond to initial stimulant treatment. However, a significant percentage of these patients will likely respond to another stimulant. Ninety percent of all MTA subjects assigned to methylphenidate treatment (with or without behavioral intervention) responded well to either the first stimulant trial with methylphenidate (79 percent) or a second stimulant trial with dextroamphetamine (11 percent).

The Preschool ADHD Treatment Study (PATS) is a double-blind, placebo-controlled, crossover trial that examined the effects of immediate-release methylphenidate in 165 children, ages 3 to 5.5 years, diagnosed with severe ADHD. Subjects were randomly assigned to four treatment arms, each at a different methylphenidate dose (1.25, 2.5, 5, or 7.5 mg, three times daily), or placebo. Significant improvements in ADHD symptoms were found with an average methylphenidate dose of 14.2 ± 8 mg/day. This average effective dose was considerably lower than the effective dose reported in the MTA study of older children (30.5 ± 14.2 mg/day). Twenty-one percent of the total subjects in the trial were reported to be “excellent responders.” During the 10-month maintenance phase of the PATS, 95 of the 140 children demonstrated continued improvement in global functioning, including improvement in social skills. However, parent and teacher symptom rating scales declined over the same time period for about one-third of these children. PATS had a relatively lower effect size range (Cohen’s d = 0.22 to 0.87) compared to the MTA study (Cohen’s d = 0.8 to 1.2).

Several adverse effects were reported in the PATS. Approximately 30 percent of PATS subjects developed moderate to severe side effects, and up to 11 percent of the subjects discontinued treatment due to medication intolerability. Side effects included insomnia, appetite loss, emotional

outbursts, repetitive thoughts/behaviors, and irritability. Thus, based on findings from the MTA and PATS studies, it appears that compared to school-aged children, psychostimulants have lower short-term efficacy and lower tolerability in preschoolers. One-third of preschool-aged subjects discontinued stimulants due to adverse events such as worsening behaviors, while others discontinued to switch to a long-acting stimulant or discontinued due to inadequate benefit.

Data in Adults with ADHD. A Cochrane review of 7 RCTs, with 1,091 subjects combined examined the efficacy and tolerability of three different amphetamine agents (dextroamphetamine, lisdexamfetamine, and mixed amphetamine salts [MAS]) in adults with ADHD. While dexamphetamine, lisdexamfetamine, and MAS all improved core ADHD symptoms, MAS was associated with lowest incidence of adverse effects and highest retention in treatment. In other pooled analyses of 19 trials in adults, effect sizes varied based on whether the psychostimulants were long-acting (pooled Cohen's d = 0.73) or immediate-release (pooled Cohen's d = 0.96) formulations. LDX had a significantly higher pooled effect size (Cohen's d = 1.5) based on several RCTs compared to other psychostimulants.

Other Clinical Indications of Psychostimulants

Beyond their use for the treatment of ADHD, psychostimulants have been used in several conditions including oppositional defiant disorder (ODD), conduct disorder (CD), symptoms of inattention and hyperactivity associated with autism, cognitive deficits associated with traumatic brain injury (TBI), apathy, depression, and cognitive deficits associated with seizure disorder and epilepsy. Stimulant use in these other disorders has been less extensively studied compared to ADHD, and the general recommendation to providers is to administer stimulants at lower doses than typically prescribed for treatment of ADHD. The following sections consider use of psychostimulants in each of these disorders.

Oppositional Defiant Disorder and Conduct Disorder Comorbid with ADHD

Up to 70 percent of ADHD patients also carry a diagnosis of ODD or CD. In a 4-week, multicenter, randomized, double-blind, parallel-group, forced dose-escalation study, 308 children and adolescents diagnosed with ODD with and without ADHD were treated daily with 30 or 40 mg daily of MAS XR (Adderall XR). Independent of the ADHD diagnosis, treatment with Adderall XR led to a reduction of ODD symptoms measured with the SNAP-IV parent rating subscale. Subjects who received both 30-mg/day (Cohen's d = 0.52) and 40-mg/day (Cohen's d = 0.56) MAS XR showed efficacy in the medium effect size range. Adverse effects were mild to moderate in severity and included anorexia/decreased appetite (25.3

percent), insomnia (19.5 percent), headache (18.5 percent), and abdominal pain (10.7 percent).

In a similar trial of 84 children between the ages of 6 and 15 years with cooccurring CD in two-thirds of children with ADHD, participants were randomized to methylphenidate hydrochloride (average methylphenidate hydrochloride dose was 41.3 mg/day) or placebo for 5 weeks. Behavior was evaluated by parent, teacher, and clinician reports and by direct classroom observations. Compared with the placebo group, methylphenidate showed significant benefit for ADHD symptoms, and CD symptoms including cheating and stealing, obscene language, attacks on others, vandalism of property, and deliberate cruelty.

Treatment of Neurodevelopmental Disorders with ADHD Symptoms. ADHD symptoms occur in 41 to 78 percent of children with autism spectrum disorders (ASDs). These symptoms often affect quality of life, interfering with learning or interventions that target primary ASD symptoms. Children who have developmental disabilities (including ASD, intellectual disabilities, Fragile X syndrome), have lower effect sizes with these medications and are more sensitive to adverse effects, including agitation and emotional lability, compared with typically developing children with ADHD. One large RCT of methylphenidate in children with ASD found that only 49 percent of children responded to stimulants compared to the 69 percent response rate in the MTA study. In addition, 18 percent of the children with ADHD and ASD discontinued participation due to adverse events (prominently irritability) compared to 1.4 percent in children with ADHD only.

NEUROPSYCHIATRIC DEFICITS SECONDARY TO TRAUMATIC BRAIN INJURY. The overall risk of TBI in the general population has been estimated at 2 to 5 percent. In the United States, approximately 230/100,000 of children under 15 years of age, and 294/100, 000 adolescents between 15 and 19 years of age experience a TBI each year. A significant proportion of patients who sustained a TBI will experience disturbance in academic, emotional, and social functioning. In a research setting, the most common psychiatric complication of TBI was a cluster of symptoms consistent with ADHD. A double-blind, placebo-controlled, crossover-study design used to investigate the efficacy of methylphenidate in children with ADHD symptoms secondary to a TBI, has demonstrated that methylphenidate was superior to placebo to benefit attention and concentration. This finding is in line with other RCTs that have demonstrated benefit of other stimulants, including pemoline and dextroamphetamine, for symptoms of ADHD secondary to TBI.

APATHY. Apathy is a common symptom of neurodegenerative diseases such as Alzheimer disease (AD), Parkinson disease (PD), as well as an

adverse effect of the sedative effects of pain medications, or toxic effects of chemotherapy. Unfortunately, few studies have investigated the benefit of psychostimulants in treating apathy secondary to these conditions. One RCT examining the efficacy of methylphenidate for the treatment of apathy associated with AD demonstrated greater reduction of apathy with methylphenidate 10 mg twice daily compared with placebo on Apathy Evaluation Scale change scores. Thus, efficacy studies of psychostimulants for the treatment of secondary neuropsychiatric complications are all limited by a small sample size, and necessitate larger trials to guide evidence-based practice.

DEPRESSION. Antidepressants are first-line treatment for moderate or severe depression, but depression resistant to antidepressants presents a therapeutic challenge. A Cochrane review article assessed evidence from RCTs on the effectiveness and safety of stimulants, such as methylphenidate and methylamphetamine, and modafinil and compared them to placebo in the treatment of major depressive disorder, either as monotherapy or as adjuncts to antidepressants. Several placebo-controlled parallel design studies have demonstrated benefit-adjunctive psychostimulants to reduce depressed mood in the short term. Further examination and pooling of longer-term outcomes for other symptoms of depression suggest that psychostimulants reduce fatigue associated with depression, but do not effectively target other neurovegetative symptoms. Other smaller short-term trials of psychostimulants used adjunctively versus placebo have not found significant differences in overall depression scores. In addition, modafinil is no more effective than placebo in targeting symptoms of depression including fatigue or hypersomnia. The overall quality of the extant data was suboptimal due to small sample sizes, selection bias due to inadequate randomization, attrition, and performance bias.

Treatment of Comorbid ADHD and Seizure Disorder. A retrospective study of youth with comorbid epilepsy and ADHD found that being seizure-free did not predict response to stimulant treatment. An MPH preparation had a 5.57-fold greater chance of treatment response compared to an AMPH preparation. Importantly, cognitive level may play a role in treatment response, but age, type of seizure, and success of previous stimulant trials were not associated with response to stimulants in this population. Stimulant discontinuation rates were comparable in seizure-free group (35 percent) and not-seizure-free groups (53 percent). In the not-seizure-free group, 3 out of the 19 patients had a worsening of seizures while on a stimulant.

Tolerability of Psychostimulants: Adverse Effects, Contraindications, and

Precautions

Psychostimulants are generally well tolerated. Different formulations of methylphenidate and amphetamine have similar side-effect profiles that present similarly in pediatric and adult populations, with some exceptions that will be noted below. Common side effects associated with stimulants include insomnia, decreased appetite, weight loss, headache, stomachache, and mild increases in heart rate and blood pressure (see Table 34.29–4 for a comprehensive list of adverse effects). Short-term or acute stimulant side effects are more likely to be related to higher doses, and careful dose titration mitigates these acute adverse effects.

Certain patient groups appear to be more sensitive to stimulants at doses lower than the general population, including preschool children with ADHD, children with developmental delays, and the elderly. It is recommended that stimulants be used with caution in the following populations: children under 5 years of age with IQ ≤5 years old, severe tics, or in children with histories of severe anxiety, mood, or psychotic symptoms. Further consideration of lower doses should be given in the elderly population. Nevertheless, stimulants may be first-line treatments for ADHD symptoms in these populations, despite a relatively small number of RCTs, response rates of 50 percent, and higher rates of side effects. Absolute and relative contraindications for stimulant use are listed in Table 34.29–5. Specific adverse reactions to stimulants will now be discussed in more detail.

Table 34.29–4.
Comprehensive List of Adverse Events

Adverse Effects	
Common:	***Uncommon:***
MPH/AMPH	Psychosis
Anorexia, weight loss (13–20%)	Euphoria/mania Sadness/isolation
Insomnia (11–30%)	Major depressive episodes Cognitive impairment Growth retardation
Headaches (12–15%)	Tic disorders (i.e., Tourette syndrome) Increased heart rate (clinically significant)
Abdominal pain (6–12%)	Impaired liver functioning (pemoline only) Increased blood pressure
Emotional lability (2–10%)	Dizziness, lethargy, fatigue Nausea, constipation Rash/hives
Slight increase in HR, BP	Hyperacusis

***Severe side effects occur in 4–10% of children treated with stimulants**	Formication Necrotizing angitis brain (IV amphetamine) Neuroleptic malignant syndrome?

Specific Adverse Events

Tics. Significant concerns regarding the development of tics and Tourette disorder due to use of psychostimulants in children and adolescents were initially raised in the 1980s. For many years, stimulants had been thought to induce or worsen tics in youth and presence of tics constituted a contraindication to psychostimulant use. In the last decade, several studies have suggested that stimulants do not worsen or reactivate tics, and might even improve pre-existing tics in many patients.

Table 34.29–5.
Contraindications to Psychostimulants

Absolute Contraindications	Relative Contraindications
1. Known hypersensitivity to stimulants 2. Structural cardiac defects 3. Narrow-angle glaucoma 4. Moderate to severe substance abuse disorder 5. Current use of MAOI or within 14 days after an MAOI has been discontinued	1. Presence of psychotic disorders like Schizophrenia, because of stimulants' potential to worsen or even precipitate psychotic symptoms 2. A severe tic or Tourette syndrome is a relative contraindication. This contraindication does not apply to mild tics in patients with severe ADHD symptoms 3. Unstable hypertension is a relative contraindication. Blood pleasure should be normalized and well controlled before administering stimulant medications

A Cochrane review analyzed eight RCTs for a potential relation between psychostimulant use and the development of tic disorders. One RCT in children with cooccurring ADHD and Tourette syndrome found a positive treatment effect with methylphenidate compared to placebo and with clonidine plus methylphenidate on measures of ADHD and tic severity. In the methylphenidate group only, 20 percent of participants reported worsening of tics as an adverse event compared to 22 percent receiving placebo. In a small placebo-controlled crossover study of dextroamphetamine that randomized 20 children to 3 dosage titrations of dextroamphetamine (target doses of 7.5, 15, or 22.5 mg twice daily) for 3 weeks, dextroamphetamine decreased hyperactivity but there was no significant interaction between drug and dose, indicating that additional improvements in hyperactivity were not observed for higher doses. Tic severity was significantly greater during the second (15 mg twice daily) and third weeks (22.5 mg twice daily) of dextroamphetamine treatment compared to weeks on placebo. Drug dose did not worsen tics, however. Larger studies are needed to definitively determine whether psychostimulants worsen tics or reduce pre-existing tics in youth with

comorbid ADHD and a tic disorder.

The increased sensitivity of dopaminergic brain systems has been widely implicated in the pathophysiology of tics. To date, no clear genetic relation between tics and ADHD on the emergence of tics during stimulant trials has been established. Moreover, there is commonly a delay between stimulant exposure and tic onset making it difficult to establish a causal association between stimulant exposure and tic outcome. In individuals with a personal or family history of tics or Tourette disorder and ADHD, stimulant medications may exacerbate motor and vocal tics. However, the data are not conclusive and in most cases, the benefit of treating ADHD outweighs the risk of stimulants triggering tics.

Cardiovascular Effects. A risk of sudden cardiac death from psychostimulant use emerged around the time they became a mainstay treatment for ADHD. The US FDA identified 11 sudden deaths in pediatric patients taking methylphenidate from 1992 to 2005. However, the rate of sudden cardiac death among patients with ADHD is equivalent to that of the general population and comparable to mortality due to motor vehicle accidents in children. In large community samples of children and adolescents, stimulants have not been shown to increase risk of cardiovascular complication, including risk of sudden death. Risk for stimulant-induced adverse cardiovascular events appears to be elevated in children with ADHD and a family history significant for early cardiac death, arrhythmia, cardiogenic syncope, or a personal history of structural cardiac abnormalities, exercise-induced syncope, chest pain, or palpitations. According to the AACAP practice guidelines, in such cases an assessment by a pediatric cardiologist prior to stimulant treatment is recommended. Finally, authors of the large prospective MTA study investigated stimulant-related changes in vital signs in youth treated for ADHD for up to 10 years. Treatment was associated with increases in heart rate at 14-month, 3-year, and 8-year follow-ups suggesting chronic induction of the sympathomimetic system by stimulant treatment. Stimulants were not associated with elevations in systolic or diastolic blood pressure.

Growth Velocity. Long-term stimulant use has been associated with interfering with typical growth trajectories in children and adolescents with ADHD. Specifically, MTA subjects reported significant decreases in height velocity with long-term stimulant treatment. Maximal reduction in annual growth rate occurred in the first year, decreased in the second year, and then subsided completely by the third year of treatment. Matched subjects with history of treatment before entry into the MTA study did not show differences in height velocity compared to treatment-naive youth over 3 years of follow-up. Treatment-naive youth had small growth acceleration at

2-year follow-up that was equivalent to the untreated group, and the treatment-naive group on stimulants did not compensate for the slowdown of growth observed initially. Compared to typically developing healthy comparison youth without a diagnosis of ADHD, ADHD youth not treated with stimulants were taller and heavier and grew at a faster rate. It is hypothesized that stimulant-related reductions in growth may be related to DA-induced decrease of prolactin secretion by the pituitary gland or suppression of growth hormone (GH) and insulin-like growth factors (IGFs).

The PATS study reported significant growth velocity suppression in preschoolers treated with stimulants for at least 1 year, with a 20 percent less than expected height gain (−1.38 cm/year) and 55 percent less than expected weight gain (−1.32 kg/year). Children under 6 years of age (mean age = 4.4 years) with ADHD were measured up to 29 times for at least 10 months in study follow-up. The height and weight of 140 stimulant-naive preschool-age children with a diagnosis of ADHD were much larger (an average of 2.04 cm taller and 1.78 kg heavier) than expected than referenced Centers for Disease Control (CDC) norms. After initiation of stimulant medication, the height and weight velocity slowed, and for the children who remained on medication, this resulted in annual gain that was 20 percent less for height and 55 percent less for weight than expected by CDC standards. These findings are consistent with the growth velocity findings reported in the MTA study. Moreover, greater stimulant-related reductions in height velocity have been observed with longer exposure to psychostimulants, in younger children compared to older adolescents, and for taller and heavier children. The magnitude of weight and height deficits does not appear to differ between MPH and AMPH.

In the long term, growth deficits normalize so that final height is not affected. In some children with ADHD, deficits in physical growth constitute a developmental delay much like core behavioral and cognitive signs of the disorder. Indeed, stimulant-associated growth deficits in children with ADHD may represent early temporary manifestations of ADHD itself. In addition, a failure to gain weight may impact height velocity although no studies have directly examined this possibility in youth with ADHD or have followed patients into adulthood to investigate a complete height trajectory. Stimulant effects on child growth should be part of a risk/benefit discussion with the child and family as part of the informed consent, and clinicians should monitor growth parameters in all patients taking stimulants. Change in weight or height crossing two percentile lines on a standardized growth curve suggest a deficit in growth that should prompt a clinical response. Possible responses might include stimulant drug holiday, nutritional supplementation, dose reduction, or change to a nonstimulant ADHD medication.

Abuse and Dependence. Risk of substance use, abuse or dependence in individuals diagnosed with ADHD complicates the diagnosis and is of great interest to clinicians and researchers. In a 10-year follow-up study, children and adolescents diagnosed with ADHD had an increased risk of a substance use disorder (SUD) compared to matched controls. Factors such as ADHD severity and duration, comorbid mood disorders, and CD are independently associated with a higher risk for SUD compared to controls. Presence or absence of treatment did not appear to change the risk of substance use, abuse, or dependence. In the MTA group, there were no protective or predisposing factors associated with SUD at 3-year follow-up. At the 6-year follow-up (mean age = 15 years), 35 percent of the ADHD struggled with an SUD versus 20 percent of controls. Thus, according to the MTA study, stimulants neither protect from, nor increase risk for, SUD. Finally, in a prospective study, a risk of SUD increased with age at initiation of methylphenidate, suggesting that delays in treatment of ADHD may be associated with the development of SUD.

Misuse and Diversion. When taken as indicated, stimulants are generally safe and highly effective for the treatment of ADHD symptoms. However, stimulant-induced elevations in DA in key brain regions appear to be integral to both efficacy in ADHD and potential for abuse. The nonmedical use of stimulants has received increasing attention, and has prompted consideration of nonstimulant options for the treatment of ADHD. Data from the National Survey on Drug Use and Health (NSDUH) database tracks the diversion and misuse of stimulants. In 2002 to 2003, the NSDUH found that approximately 6 percent of 16 to 25 year olds reported lifetime nonmedical misuse. Between 2003 and 2009, the lifetime prevalence of nonmedical misuse of methylphenidate was stable at lower rates ranging between 1.8 and 2.1 percent. Among 18 to 25-year-old youths, over the same time period, prevalence rates were around 5 percent.

Benson and colleagues (2015) published a meta-analysis on the misuse and diversion in the college student population. They found that a substantial number of college students are involved in nonmedical misuse and diversion of stimulants. Diversion is defined as giving away, selling, or otherwise distributing one's own medication. In 2014, 36 percent of stimulant prescription holders diverted their stimulant, and Adderall was the most frequently diverted stimulant. Fifty-six percent of prescription holders had been approached to divert their medication in the last 6 months. Factors associated with misuse of stimulants were male gender, being a member of a social college organization, having a diagnosis of CD and/or SUD, using immediate-release formulations, or using alcohol or illicit substances.

Thus, stimulant diversion and misuse among student populations is growing and is higher than that among general population samples.

However, misuse appears to be most prevalent and problematic among adults with ADHD and illicit drug users. Based on these data, the AACAP practice parameters recommend that clinicians obtain a careful personal and family history of substance abuse or dependence prior to prescribing a stimulant, and should educate populations most vulnerable to diversion, including high school or college students.

MODAFINIL (PROVIGIL)

Modafinil is a wakefulness-promoting agent with behavioral actions similar to psychostimulants, but is different pharmacologically not to be classified as a psychostimulant. Physiologically, modafinil can increase energy, concentration, and induce wake-promoting effects. Modafinil is approved for treatment of excessive sleepiness associated with narcolepsy, obstructive sleep apnea/hypopnea syndrome (OSAHS) or shift work sleep disorder (SWSD). In addition, multiple studies have investigated the efficacy and safety of modafinil in the treatment of ADHD, mood disorders, schizophrenia, and SUD.

MECHANISM OF ACTION

Modafinil is a racemic compound. The chemical name for modafinil is diphenylmethyl sulfinyl acetamide and its molecular formula is C15H15NO2S. Modafinil and its R-enantiomer, armodafinil, exert clinical effects by enhancing catecholamine neurotransmission. Modafinil has been found to activate lateral hypothalamus orexin (hypocretin) neurons that send axons to numerous brain regions, including major nuclei that have been implicated in sleep regulation. However, because its pharmacological profile is unique from stimulants, it is not classified as such. In addition to the wake-promoting effects, modafinil increases motor activity, euphoria, and alterations in perception, emotions, and cognition typical of CNS stimulants. Its optical enantiomer, armodafinil, has similar pharmacological actions in animals.

Modafinil, like other psychostimulants, increases the release of monoamines, but also elevates histamine, epinephrine, γ-aminobutyric acid, and glutamate levels. As a result, some researchers consider modafinil a “wakefulness-promoting agent” rather than a classic amphetamine-like psychostimulant. For example, mice lacking dopamine transporters (DATs) do not respond to the wake-promoting effects of modafinil, and this is also true for mice lacking D1 and D2 receptors. Further, microdialysis studies have reported that modafinil increases extracellular DA. PET with a D2/D3 radioligand (sensitive to changes in endogenous DA) and [11C] cocaine (DA transporter radioligand) was used to measure the effects of modafinil on extracellular DA and on DAT in 10 healthy males. A significant correlation between the percentage DA transporter occupancy and plasma modafinil

concentration in the caudate was demonstrated. Other studies have demonstrated that in mice engineered without DAT, modafinil failed to induce wake-promoting activity, suggesting that DAT was essential for its ability to exert its effects. Unlike those of amphetamine, however, the function of modafinil was not inhibited by a DA receptor antagonist. These studies suggest that despite some functional mimicry, modafinil acts through different cellular mechanisms than through stimulants.

Studies have also demonstrated that modafinil has moderate interaction with NE and serotonin receptors. However, unlike stimulants, modafinil does not release NE at a high rate. It has been hypothesized that this difference in effect on the catecholamine system might be responsible for lower efficacy in reducing of ADHD symptoms, compared to psychostimulants.

Pharmacological Properties of Modafinil

Modafinil is rapidly absorbed, and the absorption of the medication is not affected at steady state; a peak plasma concentration of 6.4 mg/mL was reached in 2.7 hours with modafinil 200 mg once daily. Approximately 90 percent of a modafinil dose is metabolized hepatically, primarily to two inactive metabolites. Less than 10 percent of an administered dose is excreted as the parent compound. The pharmacokinetics of modafinil may be altered in older males and in patients with chronic hepatic impairment. In vitro, modafinil has been shown to inhibit the cytochrome P450 (CYP) isoenzyme CYP2C19 (moderately potent, reversible inhibition), modestly induce CYP1A2, CYP3A4/5, and CYP2B6 and suppress CYP2C9.

US FDA–Approved Uses of Modafinil

Narcolepsy. Narcolepsy is a common, disabling sleep disorder characterized by excessive daytime sleepiness (EDS) and rapid eye movement (REM) sleep manifestations that intrude into wakefulness, including cataplexy (sudden loss of muscle tone triggered by strong emotions), sleep paralysis, hypnagogic/hypnopompic hallucinations (sensory events that occur at the transition from wakefulness to sleep), and sleep-onset REM periods. Narcolepsy affects approximately 0.02 percent of the population worldwide and causes disability in 24 percent of the affected subjects.

Currently, modafinil is considered a first-line therapy for EDS in narcolepsy. Four randomized, double-blind, placebo-controlled trials have assessed the usefulness of modafinil in treatment of EDS in narcolepsy and have demonstrated that treatment with modafinil 200 to 400 mg/day had significant positive impact on improved EDS. Modafinil does not appear to benefit cataplexy. Abrupt discontinuation may cause rebound sleepiness but does not appear to be associated with any amphetamine-like

withdrawal symptoms.

Obstructive Sleep Apnea. Efficacy and safety of modafinil treatment for obstructive sleep apnea (OSA) in patients who are not benefiting from CPAP has been demonstrated in a meta-analysis of 3 RCTs in this population. Modafinil is also effective in improving intentional or unintentional sleep in SWSD, which translated into fewer accidents and near accidents on the commute home but not during the night shifts.

Non-US FDA–Indicated Use of Modafinil

ADHD. Although sympathomimetic stimulants are the most common treatment for ADHD, a sizable minority of children and adolescents with ADHD do not respond adequately to psychostimulants or have intolerable side effects. Thus, additional treatment options are needed. Given the attention and wakefulness-enhancing properties of modafinil, it has been considered a candidate medication for ADHD. By 2007, multiple trials had examined the clinical utility of modafinil for ADHD. More than 900 children and adolescents were examined, and demonstrated the efficacy and tolerability of modafinil for the treatment of ADHD.

In 2005, 250 6- to 17-year-old youth, normalized for demographic factors, were involved in a 9-week, multicenter, randomized, double-blind, placebo-controlled, flexible-dose study of the film-coated tablet formulation of modafinil for treatment of ADHD symptoms. Modafinil was titrated to an optimal dose based on efficacy and tolerability (range: 170 to 425 mg once daily). Efficacy was assessed by clinicians (who completed the Attention-Deficit/Hyperactivity Disorder Rating Scale-IV (ADHD-RS-IV), interviews with teachers (who completed School Version of the ADHD-RS-IV) and parents (who completed Home Version of the ADHD-RS-IV) and the Clinical Global Impression of Improvement scale. Safety assessment was based on adverse events reported, laboratory tests, and vital signs. The effect size for improvement of core ADHD symptoms was moderate to large (Cohen's d = 0.69). Thus, once-daily modafinil was effective on the core symptoms of inattention, hyperactivity, and impulsivity, both at school and at home. Among the most common adverse events reported were insomnia and decreased appetite, and were mild to moderate in severity.

Cocaine Addiction. Several small RCTs have examined the use of modafinil to prevent cravings in patients with cocaine addiction. In a parallel group study, 62 treatment-seeking cocaine-dependent subjects without significant medical or psychiatric problems were randomized to receive modafinil 200 to 400 mg/day or placebo for 8 weeks. All subjects also received cognitive behavioral therapy twice a week. The efficacy measures were clean urine toxicology, subjective craving, and withdrawal reporting. Even though there were significantly more negative urine results

in patients taking modafinil, the subjective reporting of cocaine use, dollars spent, and cocaine craving remained unchanged. At present, there is no consistent evidence that modafinil is beneficial for treatment of cocaine craving.

Cognitive Enhancement. A number of neurodevelopmental and neuropsychiatric disorders are associated with cognitive impairment. Impaired cognition can lead to poor functional outcome and may limit the benefit gained by psychosocial interventions. Modafinil has recently emerged as a possible medication to improve cognition for certain patients. It has been shown to improve cognitive function including memory, planning and attention in animal studies, as well as reaction time, logical reasoning and short-term working memory, planning and mental flexibility in nonsleep-deprived and sleep-deprived humans. Modafinil may offer advantages over compounds such as amphetamine and L-dopa particularly if repeated administration is needed, as it is associated with low risk of abuse and has a relatively mild side-effect profile.

Adverse Effects. Modafinil is generally well tolerated in patients with excessive sleepiness associated with OSAHS or SWSD. Adverse events are generally of mild to moderate severity, and include headache, nausea, and nervousness.

ATOMOXETINE (STRATTERA)

ATM was the first US FDA medication approved for ADHD in children older than 6 years of age, adolescents, and adults. Similar to psychostimulants, ATM shows potent and very selective NE transporter binding. It selectively blocks NE reuptake at the noradrenergic neuron and is classified as a selective norepinephrine reuptake inhibitor (SNRI). However, it is not classified as a psychostimulant, and is not a controlled substance.

Mechanism of Action

ATM has been shown to increase extracellular availability of both NE and DA in the rat PFC. ATM improves measures of PFC cognitive function in rats, monkeys, and humans. In order to improve executive function in primates, ATM has to produce an optimal dose of catecholamines in the synaptic space; higher than optimal doses may impair executive function. The enhancing effects are blocked by coadministration of either an NE alpha-2 or DA D1 antagonist, suggesting that the NE and DA neurotransmission complement are essential for ATM function. Interestingly, optimal doses vary widely, which may explain variability of drug response in ATM compared to psychostimulants.

Pharmacological Properties and Drug Interactions of Atomoxetine

ATM has high aqueous solubility and lipophilicity that facilitates its rapid and complete GI absorption after oral administration. In the serum, 98 percent of the medication is bound primarily to albumin. Three oxidative metabolic pathways are involved in the hepatic metabolism of ATM: aromatic ring hydroxylation, benzylic hydroxylation and *N*-demethylation. Aromatic ring hydroxylation results in the formation of the primary oxidative metabolite of ATM, 4-hydroxyatomoxetine, which is subsequently excreted in urine. The formation of 4-hydroxyatomoxetine is primarily mediated by P450 (CYP) 2D6. This results in two distinct populations of individuals: those exhibiting active metabolic capabilities (CYP2D6 extensive metabolizers) and those exhibiting poor metabolic capabilities (CYP2D6 poor metabolizers) for ATM.

The oral bioavailability and clearance of ATM are influenced by the activity of CYP2D6. In extensive metabolizers, ATM has a plasma half-life of 5.2 hours. Poor metabolizers, ATM has a plasma half-life of 21.6 hours. As a result, the average steady-state plasma concentrations are approximately 10-fold higher in poor metabolizers compared with extensive metabolizers. ATM accumulates in plasma of poor metabolizers, but very little accumulation in extensive metabolizers. The volume of distribution in ATM suggests that it is distributed in total-body water, in both extensive and poor metabolizers. ATM is highly bound to plasma albumin (~99 percent bound in plasma). ATM does not inhibit or induce the clearance of other medications metabolized by the CYP system. In extensive metabolizers, potent and selective CYP2D6 inhibitors reduce ATM clearance; however, administration of CYP inhibitors to poor metabolizers has no effect on the steady-state plasma concentrations of ATM.

Albuterol used concomitantly with ATM may increase heart rate and blood pressure. ATM is contraindicated in patients currently receiving or having recently received (i.e., within 2 weeks) MAO inhibitor therapy. The starting dose of ATM should be reduced when potent CYP2D6 inhibitors including fluoxetine, paroxetine, or quinidine are administered concomitantly with ATM.

▲ 34.30 Dopamine Receptor Agonists

CARLOS A. ZARATE, JR., M.D., AND LAWRENCE T. PARK, M.D.

INTRODUCTION AND HISTORY

Since Carlsson's discovery of the physiological functions of dopamine (3-hydroxytyramine) in 1957, the dopaminergic system has been extensively studied and is among the best understood of all neurotransmitter systems. In humans, four major dopaminergic pathways have been identified: nigrostriatal (A9), mesolimbic (A10), mesocortical (A10), and tuberoinfundibular (A8). These pathways have been implicated in motor activity, affect, reward mediation, attention, cognitive functioning, appetite, and sleep. Five subtypes of dopamine (D) receptors have been identified (D1, D2, D3, D4, D5). They are all G protein–coupled receptors and are classified into D1 class (D1 and D5) which increases cAMP production via positive coupling to adenylyl cyclase and D2 class (D2, D3, D4) which is associated with inhibition of adenylyl cyclase and decreases cAMP production.

Dopamine receptor agonists (DA) bind to and activate dopamine receptors to reproduce the activity of the endogenous neurotransmitter. Classic DAs were initially developed during the 1970s to treat advanced Parkinson disease (PD). They are typically classified into nonergot and ergot derivatives. Nonergot DAs include apomorphine (Apokyn), pramipexole (Mirapex), and ropinirole (Requip). Though successfully used as monotherapy for new-onset PD, they are more commonly used as adjunctive treatment with levodopa (a dopamine precursor); as a result, smaller doses of levodopa are required and complications are delayed or reduced. Apomorphine has D1 and D2 agonist effects, and though it has demonstrated efficacy in PD, it is not used in the United States due to its short half-life. However, it is used in Europe for PD via subcutaneous and intravenous pump administration. Pramipexole and ropinirole are FDA approved for use in PD and restless legs syndrome (RLS), and have been studied as an adjunctive treatment for unipolar and bipolar depression. Amantadine (Symmetrel), an adamantane derivative, is FDA approved to treat PD, drug-induced extrapyramidal symptoms (EPS), and influenza A infection. It is also used off-label to treat neuroleptic malignant syndrome (NMS) and Cotard syndrome, a psychiatric condition that involves a delusional belief that one is dead. The ergot class includes bromocriptine (Parlodel), cabergoline (Dostinex, Caberlin), and pergolide (Permax). Bromocriptine is FDA approved for use in PD, galactorrhea (due to hyperprolactin conditions), and acromegaly, and is used off-label to treat RLS and NMS. Cabergoline is FDA approved for the treatment of

hyperprolactinemic disorders, either idiopathic or due to pituitary adenomas. In addition, a number of studies have suggested that cabergoline may be effective in treating PD or preventing ovarian hyperstimulation syndrome. Pergolide, an ergot D1/2 agonist was FDA approved for PD and studied as an adjunctive treatment of treatment-resistant depression (TRD). It is important to note that the entire class of ergot derivatives has been associated with cardiac fibrosis. As a result, the FDA issued a warning for the risk of cardiac valvulopathy for cabergoline in 2011 and pergolide was withdrawn from the US market in 2007 because of an increased risk of valvular heart disease.

Other classes of drugs may also exert agonist effects at the dopamine receptor. The wakefulness-promoting agents, modafinil (Provigil) and armodafinil (Nuvigil), have complex prodopaminergic activity, including dopamine transporter inhibition. They may also have dopamine (D2) receptor partial agonist effects. These drugs have been FDA approved to improve wakefulness in adult patients with excessive sleepiness associated with narcolepsy, obstructive sleep apnea (OSA), or shift work disorder (SWD). They have been studied as an adjunctive treatment for unipolar and bipolar depression, and attention-deficit/hyperactivity disorder (ADHD). These drugs have been used in nonpathological settings to optimize normal performance.

Finally, certain drugs have demonstrated partial agonist/antagonist properties at the dopamine receptor. For instance, aripiprazole (Abilify), a second-generation antipsychotic drug approved for the treatment of schizophrenia, acute manic/mixed episodes of bipolar I disorder, and irritability associated with autistic disorder in children and adolescents, is also approved as an adjunctive treatment for major depressive disorder (MDD). Cariprazine, a partial D2/3 agonist (with D3 selectivity), has a pending New Drug Application (NDA) with the FDA for schizophrenia and bipolar I disorder and is being investigated as an adjunctive treatment for MDD.

This chapter describes the key therapeutic DAs with significant psychiatric applications: pramipexole, ropinirole, amantadine, bromocriptine, modafinil, armodafinil, and aripiprazole.

CHEMISTRY

Pramipexole is a nonergot synthetic aminothiazole derivative. The chemical name is (S)-2-amino-4,5,6,7-tetrahydro-6-(propylamino)benzothiazole dihydrochloride monohydrate (IUPAC nomenclature). The molecular formula is $C_{10}H_{17}N_3S.2HCl.H_2O$ and the molecular weight is 302.27. It is a white to off-white crystalline powder, freely soluble in water, soluble in methanol, sparingly soluble to slightly soluble in ethanol, and practically insoluble in methylene chloride. The molecular structure is shown in Figure 34.30–1.

Ropinirole is a nonergot hydrochloride salt. The chemical name is 4-[2-(dipropylamino)ethyl]-1,3-dihydro-2*H*-indol-2-one. The molecular formula is C16H24N2O.HCl and the molecular weight is 296.84. It is a pale cream to yellow powder, soluble in water and methanol, and very slightly soluble in ethyl alcohol. The molecular structure is shown in Figure 34.30–2.

Amantadine is a nonergot adamantane derivative. The chemical name is adamantan-1-amine. The molecular formula is C10H17N and the molecular weight is 151.24868. It is a stable white or nearly white crystalline powder, freely soluble in water and soluble in alcohol and chloroform. The molecular structure is shown in Figure 34.30–3.

FIGURE 34.30–1. Molecular structure of pramipexole. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 119570. http://pubchem.ncbi.nlm.nih.gov/compound/119570. Accessed May 13, 2015.)

Bromocriptine is a semisynthetic ergotamine alkaloid. The chemical name is (5′α)-2-bromo-12′-hydroxy-5′-(2-methylpropyl)-2′-(propan-2-yl)-3′,6′,18-trioxoergotaman.The molecular formula is C32H40BrN5O5 and the molecular weight is 654.5945. It is a white or slightly colored fine crystalline powder, soluble in methyl alcohol, and practically insoluble in water, chloroform, and benzene. The molecular structure is shown in Figure 34.30–4.

Modafinil is an oxazolidinone compound, which is a racemic compound consisting of a 1:1 mixture of R- and S-isomers (enantiomers). Armodafinil is the R-isomer of the racemic mixture. The chemical name of modafinil is 2-[(diphenylmethyl)sulfinyl]acetamide and armodafinil is (–)-2-[(*R*)-(diphenylmethyl)sulfinyl]acetamide. For both, the molecular formula is C15H15NO2S and the molecular weight is 273.35. Modafinil (and armodafinil) is a white to off-white crystalline powder that is sparingly to slightly soluble in methanol and acetone, and practically insoluble in water and cyclohexane. The molecular structure is shown in Figure 34.30–5.

Aripiprazole is a second-generation antipsychotic benzisoxazole derivative. The chemical name is 7-[4-[4-(2,3-dichlorophenyl) piperazin-1-yl]butoxy]-3,4-dihydro-1H-quinolin-2-one. The molecular formula is C23H27Cl2N3O2 and the molecular weight is 448.38538. Aripiprazole is a white to off-white crystalline powder. It is freely soluble in methylene chloride; sparingly soluble in toluene; insoluble in methanol and in water. The molecular structure is shown in Figure 34.30–6.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

After oral administration, pramipexole is rapidly absorbed with >90 percent bioavailability. Absorption is not significantly affected by food. It undergoes little first pass metabolism. The time to maximum concentration (T_{max}) is approximately 2 hours and the half-life ($T_{1/2}$) is approximately 8 hours (12 hours in elderly patients). It undergoes minimal metabolism with 90 percent of the drug being excreted unchanged in the urine.

FIGURE 34.30–2. Molecular structure of ropinirole. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 5095. http://pubchem.ncbi.nlm.nih.gov/compound/5095. Accessed May 13, 2015.)

FIGURE 34.30–3. Molecular structure of amantadine. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 2130. http://pubchem.ncbi.nlm.nih.gov/compound/2130. Accessed May 13, 2015.)

FIGURE 34.30–4. Molecular structure of bromocriptine. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 31101, http://pubchem.ncbi.nlm.nih.gov/compound/31101. Accessed May 13, 2015.)

FIGURE 34.30–5. Molecular structure of modafinil (armodafinil). (From National Center for Biotechnology Information. PubChem Compound Database; CID = 4236, http://pubchem.ncbi.nlm.nih.gov/compound/4236. Accessed May 13, 2015.)

FIGURE 34.30–6. Molecular structure of aripiprazole. (From National Center for Biotechnology Information. PubChem Compound Database; CID = 60795, http://pubchem.ncbi.nlm.nih.gov/compound/60795. Accessed May 13, 2015.)

Ropinirole is rapidly absorbed after oral administration. Absorption is not significantly affected by food. Absolute bioavailability is 55 percent indicating significant first pass metabolism. The time to maximum concentration (T_{max}) is approximately 1 to 1.5 hours and half-life ($T_{1/2}$) is approximately 6 hours. Steady-state concentrations are expected within 2 days of dosing. It is primarily metabolized by CYP1A2 to inactive metabolites and excreted in the urine. Clearance is reduced by approximately 30 percent in patients above 65 years of age.

Amantadine is well absorbed after oral administration. The time to maximum concentration (T_{max}) is on average 3.3 hours and the half-life ($T_{1/2}$) is approximately 17 hours. It is primarily excreted unchanged in the urine. Clearance of amantadine is significantly reduced in patients with renal insufficiency.

The oral absorption rate of bromocriptine is approximately 28 percent. Absorption is not significantly affected by food though it is recommended that the drug be administered with food to reduce possible nausea/vomiting. Absolute bioavailability is 6 percent indicating a significant first pass effect. The time to maximum concentration (T_{max}) is approximately 1 to 2 hours and half-life ($T_{1/2}$) is 2.5 to 5 hours. It is primarily metabolized by CYP3A4 and excreted in the feces via biliary secretion; 6 percent is eliminated in the urine.

Modafinil is a racemic compound whose isomers have different kinetics. Armodafinil is the R-isomer of modafinil. Both isomers are rapidly absorbed after oral administration. The time to maximum concentration (T_{max}) is 2 to 4 hours for modafinil and 2 hours for armodafinil. Absorption is not significantly affected by food. The half-life of the R-isomer is approximately three times that of the S-isomer, so that exposure to the R-isomer is about three times that of the S-isomer. While the effective half-life ($T_{1/2}$) of both modafinil and armodafinil is approximately 11 to 15 hours after multiple doses, maximum plasma drug concentrations of armodafinil

remain higher for a longer period of time because the S-isomer is cleared more quickly than the R-isomer. Modafinil is predominantly metabolized by the liver via glucuronide conjugation (also CYP3A4/5 metabolism) and is excreted in the urine.

Aripiprazole is well absorbed after oral administration with a bioavailability of 87 percent. It can be administered with or without food. The time to maximum concentration (T_{max}) is 3 to 5 hours and the half-life ($T_{1/2}$) is 75 hours for extensive metabolizers and 146 hours for poor metabolizers. It is extensively metabolized by CYP2D6 and 3A4 isoenzymes and is primarily excreted in the urine.

Pharmacodynamics

Pramipexole and ropinirole are nonergot DAs with high specificity and full intrinsic activity at the D2 subtype receptors, with higher affinity binding at D3 (compared to D2 and D4) receptor subtypes. Both have been shown to stimulate dopamine receptors in the striatum. Pramipexole may also exert robust neurotropic effects. Ropinirole demonstrates moderate in vitro affinity for opioid receptors.

Amantadine is a nonergot adamantane derivative that may have direct and indirect effects on the dopamine neuron, including dopamine receptor agonist, serotonergic antagonist, and glutamatergic (*N*-methyl-D-aspartate [NMDA]) antagonist properties. The antiviral effects are thought to be mediated by interfering with the viral M2 protein. The mechanism of action for the treatment of PD and EPS is unknown, but may involve effects on the dopamine and/or NMDA system.

Bromocriptine is a semisynthetic ergotamine alkaloid with D2 and D3 receptor agonist activity. It is thought that postsynaptic D2 stimulation is primarily responsible for the antiparkinsonian effect while presynaptic D2 stimulation is associated with a neuroprotective effect. It also exhibits agonist activity at 5-HT1D, 5-HT1A, 5-HT2A, 5-HT1B, and 5-HT2C receptors and antagonist activity at α2A, α2C, α2B, and D1 receptors. It demonstrates partial agonist activity at 5-HT2B receptors and inactivated D4 and 5-HT7 receptors. In the tuberoinfundibular pathway, bromocriptine inhibits prolactin secretion by pituitary lactotrophs. Hallucinations caused by bromocriptine are thought to arise due to 5-HT2A agonism while pulmonary fibrosis may be associated with 5-HT1B and 5-HT2B activities.

Modafinil and its corresponding R-isomer, armodafinil, are oxazolidinone compounds that have complex neurotransmitter effects, including dopamine transporter blockade, dopamine reuptake inhibition, and possibly dopamine receptor agonist properties (including in the nucleus accumbens). Modafinil has been found to activate orexin (hypocretin)-containing neurons, which are located exclusively in the

lateral hypothalamus and send axons to numerous brain regions, including major nuclei implicated in sleep regulation. Animal studies have found that modafinil increases extracellular glutamate levels in the medial preoptic area and posterior hypothalamus, as well as decreasing γ-aminobutyric acid (GABA) levels in these areas. Evidence suggests that modafinil acts robustly on catecholamines, glutamate, GABA, serotonin, orexin, and histamine systems in the brain.

Aripiprazole is a second-generation antipsychotic benzisoxazole derivative that has high affinity for D2 and 5HT2 receptors. It demonstrates partial agonist properties at the D2 receptor with antagonist effects in the mesolimbic pathway and partial agonist activity in D2 mesocortical pathway. It is thought that antipsychotic effects are primarily mediated via D2 partial agonist effects. It also demonstrates partial agonist effects at the 5-HT1A receptor and antagonist effects at 5-HT2A. It also has moderate affinity for alpha-adrenergic and H1 histaminic receptors.

CLINICAL DRUG STUDIES

Major Depressive Disorder

Several lines of evidence suggest that the dopaminergic system may be an effective target for the treatment of depression. Depressed patients demonstrated decreased levels of dopamine metabolites (homovanillic acid —HVA) in cerebrospinal fluid and blood. Though results have been mixed, some SPECT studies have indicated higher in vivo availability of D2 receptor binding in depressed subjects compared to controls. In postmortem brains, lower levels of dopamine transporter binding were found in basal and central amygdaloid nuclei, whereas increased D2/3 receptor binding was found in basal, central, and lateral amygdaloid nuclei in major depression compared with controls. This finding supports the theory that a deficiency in mesolimbic dopamine may result in certain associated symptoms of depression (particularly anhedonia and loss of motivation). Finally, certain prodopaminergic agents such as bupropion (a dopamine reuptake inhibitor) have demonstrated efficacy and been approved for the treatment of MDD.

Pramipexole has been the most studied DA for the treatment of MDD. Several open-label studies have reported the efficacy of pramipexole in augmenting tricyclic antidepressants and SSRIs in TRD. One small open-label trial of 10 patients with treatment-resistant MDD (who had failed at least 2 prior antidepressant trials) demonstrated that pramipexole augmentation lead to significant improvement in depressive symptoms from baseline to posttreatment, with 6 subjects meeting criteria for treatment response (i.e., ≥50 percent reduction in Montgomery-Asberg Depression Rating Scale [MADRS] score). A randomized double-blind placebo-controlled trial of pramipexole augmentation in 60 treatment-

resistant MDD outpatients demonstrated modest but statistically significant benefit (p = 0.038). In another double-blind, comparative study, 39 subjects who had failed a standard antidepressant trial were randomized to receive pramipexole, escitalopram, or the combination. After 6 weeks of treatment, subjects receiving pramipexole monotherapy demonstrated significantly lower MADRS scores than the combination group (p = 0.01). In the combination group, however, only 15 percent of subjects tolerated regularly scheduled increases in pramipexole. This study demonstrated that concurrent initiation and titration of SSRI and pramipexole resulted in side effects often leading to cessation of treatment. Adjunctive use of pramipexole appeared to be better tolerated when it was added to ongoing SSRI treatment.

Ropinirole has also been studied as an augmentation strategy for standard antidepressants. An open-label trial of 10 subjects (7 with treatment-resistant MDD) demonstrated a statistically significant 4.5-point decrease in MADRS score from baseline to after 16 weeks of treatment. Another study demonstrated the effectiveness of ropinirole for antidepressant-induced sexual dysfunction.

Modafinil augmentation for MDD has also been extensively studied. A meta-analysis of six randomized controlled trials (four MDD trials) demonstrated that modafinil augmentation was effective for acute MDD, including for symptoms of fatigue, and was well tolerated.

Aripiprazole has an FDA-approved indication for the adjunctive treatment of MDD. Approval for this indication was based on two positive 6-week placebo-controlled trials (n = 381, n = 362) of treatment-resistant MDD (in the current episode) that demonstrated the drug was superior to placebo in reducing MADRS scores. In a meta-analysis of atypical antipsychotic treatment for MDD, aripiprazole demonstrated a statistically significant increased likelihood of achieving remission (OR, 2.01) compared to placebo, but was also associated with adverse events (akathisia, sedation, and weight gain) Table 34.30–1.

Bipolar Depression

There is growing support for the use of pramipexole in bipolar depression. Several case reports, case series, and open-label trials have reported the efficacy of pramipexole in augmenting tricyclic antidepressants and SSRIs in treatment-resistant depression; approximately half of the reported patients were diagnosed with bipolar disorder. One randomized controlled trial found that pramipexole was associated with superior response compared with placebo (60 percent vs. 9 percent) for bipolar II depression when added to therapeutic levels of lithium or valproate. Overall, pramipexole was found to have a large effect size (0.6 to 1.1) in the treatment of both MDD and bipolar depression, and was associated with a low switch rate (1 percent mania, 5 percent hypomania). In a functional

neuroimaging study of 15 bipolar II depressed subjects treated with 6 weeks of pramipexole augmentation of mood stabilizers versus placebo, pramipexole treatment was associated with reductions in normalized metabolism in bilateral orbitofrontal cortex, left ventrolateral prefrontal cortex, and right anteromedial prefrontal cortex. Voxel-wise analyses additionally showed decreased normalized metabolism in the left inferior parietal cortex and medial frontopolar cortical (BA 10P) area of the anteromedial prefrontal cortex.

Ropinirole has also been reported to be effective in the augmentation of standard antidepressants. Limited evidence supports its off-label efficacy for augmenting antidepressant response in patients with treatment-resistant bipolar depression or for alleviating antidepressant-induced sexual dysfunction. In one open-label trial, ropinirole was used in combination with lithium for acutely depressed bipolar patients and demonstrated a significant treatment effect. No switching into hypomania or mania was observed.

Table 34.30–1.
Management of Adverse Events of Sympathomimetic Drugs

Adverse Event	Management
For all adverse events	Unless severe, allow 7–10 days for tolerance to develop
	Evaluate dose–response relationships
	Evaluate time–action effects and then adjust dosing intervals or switch to sustained-release preparation
	Evaluate for concurrent conditions, including comorbidities and environment stressors
	Consider alternative treatments
Abuse/Dependence	Strict medication supervision
	Consider switching to lisdexamfetamine, atomoxetine, or other drug
	Abuse/dependence evaluation and treatment
	Discontinue stimulant treatment
Cardiovascular	Monitor blood pressure and pulse
Including: hypertension, tachycardia, arrhythmias, myocardial ischemia/infarction	Cardiac evaluation, including 12-lead ECG
	Lower dose
	Consider switch to other stimulant, atomoxetine
Anorexia or dyspepsia	Administer before, during, or after meals
Weight loss	Give drug after breakfast and after lunch
	Implement calorie-enhancement strategies
	Give brief drug holidays
Slowed growth	Apply weight loss remedies
	Give weekend and vacation (longer) drug holidays
	Consider another stimulant or nonstimulant drug
Dizziness	Monitor blood pressure and pulse
	Encourage adequate hydration
	If associated with only T_{max}, change to sustained release

	preparation
Insomnia or nightmares	Administer earlier in day
	Omit or reduce last dose
	If giving sustained preparation, switch to tablet drug
	Consider adjunctive antihistamine or clonidine
Dysphoric mood or emotional constriction	Reduce dose or switch to long-acting preparation
	Switch stimulants
	Consider comorbidity requiring alternative or adjunctive treatment
Rebound	Switch to sustained-release preparation
	Combine long- and short-acting preparations
Tics	Firmly establish correlation between tics and pharmacotherapy by examining dose–response relationship, including no-medication condition
	If tics are mild and abate after 7–10 days with medications, reconsider risks and benefits of continued stimulant treatment and renew informed consent
	Switch stimulants
	Consider nonstimulant treatment (e.g., clonidine or tricyclic antidepressant)
	If tic disorder and attention-deficit/hyperactivity disorder are severe, consider combining stimulant with high-potency neuroleptic drug
Psychosis	Discontinue stimulant treatment
	Assess for comorbid thought disorder
	Consider alternative treatments

T_{max}, time of maximal concentration.

Adapted from Creenhill LL, Halperini M, March JS. Psychostimulants. In: Tasman A, Kay J, Lieberman JA, eds. *Psychiatry*. Philadelphia, PA: WB Saunders; 1997.

Modafinil and armodafinil have been studied in the treatment of bipolar depression. A meta-analysis of six randomized controlled trials (two bipolar depression trials) demonstrated that modafinil augmentation was effective for acute bipolar depression, including for symptoms of fatigue, and was well tolerated. One placebo-controlled trial found that modafinil was effective as monotherapy for bipolar depression. A randomized, double-blind, placebo-controlled, multicenter trial found that armodafinil is a safe and effective adjunctive treatment for bipolar depression.

While aripiprazole has an FDA-approved indication for the adjunctive treatment of MDD, it has been widely studied for the treatment of bipolar depression as well. Despite fairly common use as an adjunctive strategy for acute bipolar depression and two initial positive uncontrolled open-label reports, two placebo-controlled trials were negative. Other analyses suggest that aripiprazole has not demonstrated efficacy in acute monotherapy or adjunctive therapy, but may be effective for maintenance treatment of bipolar depression.

Mood and Fatigue Related to PD (and Other Medical Conditions)

According to some estimates, depressive symptoms may occur in up to 45 percent of patients with PD. Depressive symptoms are an important factor affecting the quality of life of PD patients. Given the dysfunction of the dopaminergic nigrostriatal pathways in PD, it has been thought that dopaminergic mesolimbic reward pathways may be similarly affected, resulting in depressive symptoms such as anhedonia or lack of motivation. Several studies have supported the efficacy of DAs in treating depressive symptoms associated with PD. In a large open-label trial of 657 patients with depressive symptoms associated with PD, anhedonia and depression were reduced with adjunctive treatment of L-dopa and pramipexole. In addition, in a study comparing pramipexole and sertraline, pramipexole demonstrated superior benefit in the treatment of depression associated with PD, and was also reported to reduce anhedonia in PD patients. Another randomized double-blind placebo-controlled 12-week trial of 323 mild–moderate PD patients demonstrated that pramipexole was associated with greater decrease in depression scores (on Beck Depression Inventory) compared to placebo ($p = 0.01$). A meta-analysis of the effect of pramipexole on mood and motivation symptoms in PD concluded from seven randomized controlled trials that the drug had a beneficial effect on mood and motivational symptoms in PD patients who did not have MDD. However, a systematic review of the literature (by the same authors) concluded that given the quality of the data, further studies are required to determine if DAs are effective to treat depressive symptoms in PD.

DA agonists have also been used in an attempt to improve cognitive recovery and rehabilitation in traumatic brain injury patients. In a systematic review of methylphenidate, amantadine, and bromocriptine, however, no positive trend could be established for any of the drugs.

Armodafinil has been studied as a treatment for sleepiness and fatigue related to PD and HIV. In one study, armodafinil effectively treated 10 PD patients with excessive daytime sleepiness and was noted to increase tolerance for higher doses of dopamine agonists, which may cause sleepiness as a side effect. Also, a placebo-controlled, randomized, double-blind trial of 70 HIV-positive subjects found that armodafinil successfully reduced HIV-related fatigue. Although armodafinil did not improve depressive symptoms in the absence of fatigue improvement, it did improve depressive symptoms in those with an axis I depressive disorder who experienced an increase in energy.

Restless Leg Syndrome

Pramipexole and ropinirole have been FDA-approved for use in treating moderate-to-severe primary RLS. Pramipexole demonstrated effectiveness in four randomized controlled trials (two fixed dose studies, one flexible

dose study, and one treatment withdrawal with survival analysis) across approximately 1,000 subjects. Ropinirole demonstrated effectiveness in three randomized, double-blind placebo-controlled studies involving over 500 subjects.

Extrapyramidal Symptoms

Amantadine (Symmetrel) is FDA-approved for the treatment of drug-induced EPS. The mechanism of action of this effect is unclear. A double-blind study of amantadine compared to benztropine for drug-induced EPS; amantadine was found to be comparable in effect to benztropine, but with fewer side effects.

Neuroleptic Malignant Syndrome

There are no currently approved drug treatments for NMS. Treatment generally consists of immediate removal of the presumed offending agent as well as any other dopamine antagonists, and supportive care. Though data are limited, pharmacological considerations may include benzodiazepines (for milder cases), DAs, dantrolene, and electroconvulsive therapy. Bromocriptine (starting at 2.5 mg b.i.d.–t.i.d., maximum total daily dose 45 mg) and amantadine (200 to 400 mg/day in divided doses) are DAs that may enhance presynaptic release of dopamine to treat the presumed underlying cause of NMS. They may be particularly helpful if NMS was caused by withdrawal of medication to treat PD. However, bromocriptine may induce or exacerbate serotonin syndrome so this diagnosis should be clearly ruled out.

Excessive Daytime Sleepiness

Modafinil has been approved for use in excessive daytime sleepiness secondary to narcolepsy, shift work sleep disorder, and OSA. Two large placebo-controlled, randomized, double-blind parallel group studies found modafinil to be effective and well tolerated in the treatment of excessive daytime sleepiness secondary to narcolepsy, with effects being maintained for at least 40 weeks. Modafinil was also effective in 10 patients with excessive daytime sleepiness secondary to head injury and two patients with excessive somnolence due to sedating drugs at doses of 400 mg; no side effects or evidence of loss of effect or tolerance were noted over 5 to 13 months of continued use. Another open-label study of 72 patients with fatigue associated with multiple sclerosis found that 200 mg per day of modafinil was well tolerated and significantly improved fatigue.

Armodafinil has also been approved to treat excessive daytime sleepiness secondary to narcolepsy, shift work sleep disorder, and OSA/hypopnea syndrome. One large, placebo-controlled, multicenter trial found that armodafinil significantly improved ability to remain awake

compared to placebo in individuals with narcolepsy and shift work sleep disorder. In addition, two large, placebo-controlled trials showed that armodafinil significantly improved ability to remain awake compared to placebo in subjects with OSA/hypopnea syndrome.

Performance Enhancement

In schizophrenia, modafinil and armodafinil have been studied as an augmentation strategy targeting negative symptoms, fatigue/sleepiness, and cognition. A systematic review and meta-analysis concluded that both agents were well tolerated and reduced negative symptoms, though the effect size was small. Their effects on fatigue/sleepiness and cognition have been less clear. Various studies have investigated the ability of these agents to enhance certain aspects of cognition (i.e., alertness, attention, executive functioning, memory) in conditions such as substance abuse/dependence, neurological conditions (e.g., multiple sclerosis, dementia, brain tumors, stroke), and cancer.

While the traditional goal of medicine has been to ameliorate pathological conditions, modafinil and armodafinil have increasingly been used to enhance normal human functioning. From initial use to increase alertness and physical performance in military personnel (sometimes taking the place of psychostimulants), off-label use of these agents is expanding to enhance performance in a variety of settings; reports have noted their use by military/rescue personnel, athletes, academicians, university students, and video-game participants. The development and use of these agents as performance enhancers in nonpathological conditions has prompted a public discussion of ethical questions such as: who should control access to these agents, what risks accompany their use, how does the absence of disease affect the benefit risk assessment, what are the appropriate parameters of their use, is use fair in competitive settings, what are the limits to the enhancement effects, and how may enhancement effects influence human experience.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Central Nervous System

DAs display prominent central nervous system effects. From their initial development as treatment for PD, the prodopaminergic activity of the classic DAs underlies their effectiveness for RLS, mood disorders, EPS, and NMS. Central prodopaminergic activity also mediates many of the adverse events, including depression, irritability, confusion, hallucinations, dyskinesias, and impulsive/compulsive behavior. Interestingly, while administration of aripiprazole may be associated with akathisia, tardive dyskinesia, and NMS, full DAs may be used to treat NMS, and abrupt discontinuation of certain DAs may induce parkinsonian/extrapyramidal

and NMS-like symptoms. The increased wakefulness, energy, initiative, self-confidence, positive mood, and enhanced physical and mental performance associated with the wakefulness-promoting agents, modafinil and armodafinil, can often be dramatic and of rapid onset. As a result, the potential for abuse and the danger of dependence or addiction must be kept in mind. Finally, the partial dopamine agonist/antagonist properties of aripiprazole and cariprazine are powerful mechanisms for the treatment of mood and psychotic disorders. With aripiprazole, elderly patients may be at increased risk of cerebrovascular events.

Cardiovascular System

The entire class of ergot DA agonists has been associated with cardiac fibrosis. As a result, pergolide was withdrawn from the US market in 2007 because of an increased risk of valvular heart disease. Cabergoline remains on the market, but the FDA issued a warning in 2011 for the risk of cardiac valvulopathy. Bromocriptine has been associated with pericardial and pulmonary fibrosis particularly with long-term high-dose treatment, and increased risk of myocardial infarction in postpartum women. Congestive heart failure in conjunction with amantadine administration has also been reported. In general, most DAs can produce hypotension.

Modafinil and armodafinil are less commonly associated with cardiovascular adverse events.

Immunological Effects

Modafinil and armodafinil have been associated with certain hypersensitivity reactions, particularly in pediatric patients. 0.8 percent of pediatric subjects in premarket studies developed a rash resulting in drug discontinuation; one case proceeded to Stevens–Johnson syndrome while another developed multiorgan hypersensitivity reaction. There have also been one case of angioedema reported with modafinil, and one case of hypersensitivity, and one case of angioedema reported with armodafinil. Based on the possibility of hypersensitivity reactions, modafinil did not receive FDA approval for the treatment of ADHD, despite good effectiveness data.

Endocrine Effects

Aripiprazole may be associated with hyperglycemia and diabetes mellitus. It is recommended that blood glucose should be monitored during the time of administration.

Hematological Effects

On rare occasions, aripiprazole, as well as other second-generation antipsychotic drugs, may be associated with leukopenia, neutropenia, and

agranulocytosis. It is recommended that blood counts be closely monitored, especially during the first few months of administration.

THERAPEUTIC IMPLICATIONS

Pramipexole and ropinirole are FDA-approved for use in PD and RLS, and have been studied as an adjunctive treatment for unipolar and bipolar depression. Amantadine is FDA approved to treat PD, drug-induced EPS, and influenza A infection. It is also used off-label to treat NMS and Cotard syndrome, a psychiatric condition that involves a delusional belief that one is dead. Bromocriptine is FDA approved for use in PD, galactorrhea (due to hyperprolactin conditions) and acromegaly, and is used off-label to treat RLS and NMS. Cabergoline is FDA approved for the treatment of hyperprolactinemic disorders, either idiopathic or due to pituitary adenomas. In addition, a number of studies have suggested that cabergoline may be effective in treating PD or preventing ovarian hyperstimulation syndrome. Modafinil and armodafinil have been FDA approved to improve wakefulness in adult patients with excessive sleepiness associated with narcolepsy, OSA, or SWD. They have been studied as an adjunctive treatment for unipolar and bipolar depression, ADHD, and treatment of fatigue and cognitive dysfunction associated with medical conditions. They also have been used in nonpathological settings to optimize normal performance. Aripiprazole is FDA approved for the treatment of schizophrenia, acute manic/mixed episodes of bipolar I disorder, and irritability associated with autistic disorder in children and adolescents, and as an adjunctive treatment for MDD. Cariprazine, a partial D2/3 agonist (with D3 selectivity), was approved in 2015 by the FDA for the acute treatment of manic and mixed episodes associated with bipolar I disorder and the treatment of schizophrenia. It is also under investigation as an adjunctive treatment for MDD.

PRECAUTIONS AND ADVERSE REACTIONS

Each class of DAs has characteristic side effects that should be considered and discussed with patients before they are prescribed. Table 34.30–2 lists common and potentially serious adverse events associated with each drug.

Common side effects of the nonergot drugs, pramipexole and ropinirole, include somnolence, orthostatic hypotension, dyskinesias, and hallucinations. Use of these drugs has been associated with the possibility of sudden onset of sleep in the midst of daily activities, including driving. In addition, rare cases of impulsive/compulsive behavior (i.e., pathological gambling, hypersexuality, compulsive eating [including binge eating] and increased spending) have been reported. Some of these side effects may be dose related, while some may be related to individual susceptibility. One meta-analysis of nonergot dopamine agonists in PD found increased incidence of nausea and other symptoms compared to placebo. In addition,

a greater incidence of side effects such as dizziness, somnolence, constipation, vomiting, and insomnia were only found in early PD, while higher risks of dyskinesia and hallucination were only found in advanced PD. Pramipexole and ropinirole are classified as pregnancy risk C.

Common side effects of amantadine include nausea, dizziness, and insomnia. Psychiatric side effects such as depression, anxiety, irritability, hallucinations, and confusion have also been reported. Care should be taken in patients with seizure disorders as amantadine may increase seizure activity. Several cases of congestive heart failure in conjunction with amantadine administration have also been reported. Deaths from overdose using amantadine have also occurred with the lowest reported acute lethal dose of 1 g. When the drug is tapered or discontinued, care should be taken to decrease the dose gradually. Abrupt discontinuation may precipitate a parkinsonian crisis. In addition, sporadic cases of possible NMS have been reported. Amantadine is classified as pregnancy risk C.

Common side effects of bromocriptine include nausea, headache, dizziness, fatigue, light-headedness, vomiting, abdominal cramps, nasal congestion, constipation, diarrhea, drowsiness. Somnolence and symptomatic hypotension may occur especially in PD populations. Episodes of sudden sleep onset may occur and PD patients taking or prescribed bromocriptine should be cautioned not to drive or operate machinery. Bromocriptine use in pregnancy is contraindicated because the safety to mother and fetus has not been established. In addition, rare instances of myocardial infarction, seizures (including status epilepticus), and strokes have been reported in postpartum women receiving bromocriptine. Like other ergot derivatives, bromocriptine increases the risk of fibrotic complications. Pleural and pericardial effusions, as well as pleural and pulmonary fibrosis and constrictive pericarditis, and retroperitoneal fibrosis have been reported, especially with long-term, high-dose treatment. In PD patients, there is an increased risk of psychiatric complications such as confusion, mental disturbance, hallucinations, impulse control (with intense urges to gamble, increased sexual urges, intense urges to spend money uncontrollably and other intense urges). Hallucinations typically resolve with dose reduction. Caution should be taken in PD patients with a history of myocardial infarction who have residual, atrial, nodal, or ventricular arrhythmia. In acromegalic patients, there have been reports of cold-sensitive digital vasospasm, possible tumor expansion, and severe GI bleeding from peptic ulcers (with some fatalities). Bromocriptine is classified as pregnancy risk B.

Table 34.30–2.

Adverse Events of Dopamine Receptor Agonist Drugs

Drug	Common Adverse Events	Other Potential Serious Adverse Events
Pramipexole Pregnancy risk: C Ropinirole Pregnancy risk: C	Dizziness, somnolence, orthostatic hypotension, dyskinesias and hallucinations, constipation, vomiting, and insomnia	Episodes of sudden sleep onset, impulsive/compulsive behavior (i.e., pathological gambling, hypersexuality, compulsive eating (including binge eating) and increased spending)
Amantadine Pregnancy risk: C	Nausea, dizziness, and insomnia, depression, anxiety, irritability, hallucinations, and confusion	Congestive heart failure, increase in seizure activity Abrupt discontinuation may result in parkinsonian crisis, NMS
Bromocriptine (ergot) Pregnancy risk: B	Nausea, headache, dizziness, fatigue, light-headedness, vomiting, abdominal cramps, nasal congestion, constipation, diarrhea, drowsiness, confusion, mental disturbance, hallucinations, impulse control (intense urges to gamble, increased sexual urges, intense urges to spend money uncontrollably and other intense urges) Somnolence, hypotension (in PD)	Pleural/pericardial effusion, pleural/pulmonary fibrosis, constrictive pericarditis, retroperitoneal fibrosis Episodes of sudden sleep onset (PD) Cold sensitive digital vasospasm, tumor expansion, GI bleed from peptic ulcer (acromegaly)
Modafinil Pregnancy risk: C Armodafinil Pregnancy risk: C	Headache, nausea, nervousness, rhinitis, diarrhea, back pain, anxiety, insomnia, dizziness, and dyspepsia, mania, delusions, hallucinations, suicidal ideation, and aggression	Stevens–Johnson syndrome, multiorgan hypersensitivity reaction, angioedema Substance abuse
Aripiprazole Pregnancy risk: C	Nausea, vomiting, constipation, headache, dizziness, akathisia, anxiety, insomnia, and restlessness Somnolence, extrapyramidal symptoms, increased appetite, nasopharyngitis, and weight increase (pediatric patients)	Increased mortality (dementia-related psychosis in elderly patients) Increased risk of suicidal thinking/behavior (children, adolescents, and young adults) Cerebrovascular events (elderly) NMS, tardive dyskinesia, hyperglycemia, diabetes mellitus, orthostatic hypotension, seizures, cognitive and motor impairment, dysphagia, body temperature dysregulation, leukopenia, neutropenia, agranulocytosis

Modafinil and armodafinil are generally well-tolerated drugs. Common side effects include headache, nausea, nervousness, rhinitis, diarrhea, back pain, anxiety, insomnia, dizziness, and dyspepsia. Psychiatric

complications of mania, delusions, hallucinations, suicidal ideation, and aggression have been reported. There have also been some reports of abuse, however, the abuse potential of this class of drugs is significantly lower than with psychostimulants. In pediatric patients, a rash resulting in drug discontinuation occurred in 0.8 percent of patients (i.e., 13 of 1,585 subjects). Of these cases, one proceeded to Stevens–Johnson syndrome and there was also one report of multiorgan hypersensitivity reaction. The median time to rash was 13 days. No rashes or Stevens–Johnson syndrome have been observed in adults. In postmarket surveillance, modafinil has been associated with one case of angioedema and armodafinil has been associated with one case of hypersensitivity and one case of angioedema. Modafinil and armodafinil are classified as pregnancy risk C.

Aripiprazole has two black box warnings associated with its use. The first black box warning states that it is not approved for dementia-related psychosis in elderly patients due to an increased risk of mortality. The second black box warning states that use in children, adolescents, and young adults with depression may increase the risk of suicidal thinking and behavior. In adult patients, common side effects of aripiprazole include nausea, vomiting, constipation, headache, dizziness, akathisia, anxiety, insomnia, and restlessness. Pediatric patients may also experience somnolence, EPS, increased appetite, nasopharyngitis, and weight increase. Elderly patients may be at increased risk of cerebrovascular events. NMS has been reported with aripiprazole use; if this should occur, the drug should be immediately discontinued and the patient should be closely monitored. Tardive dyskinesia, hyperglycemia (and diabetes mellitus), orthostatic hypotension, seizures, cognitive and motor impairment, dysphagia, and body temperature dysregulation have also been reported. There is also a potential for the development of leukopenia, neutropenia, and agranulocytosis with the use of aripiprazole. Blood counts should be monitored, especially in the first few months of use. Aripiprazole is classified as pregnancy risk C.

DRUG INTERACTIONS

Pramipexole is not significantly metabolized by CYP enzymes and does not have significant effects on the CYP enzymes. It is renally cleared. Coadministration of cimetidine, an inhibitor of renal tubular secretion, may increase pramipexole C_{max} by 40 percent and half-life ($T_{1/2}$) 40 percent.

Ropinirole is an inhibitor of CYP1A2, therefore coadministration with CYP1A2 substrates may result in higher concentrations of the substrate drug. For instance, in one study, coadministration with L-dopa increased C_{max} by 20 percent.

Bromocriptine is a CYP3A4 substrate. Therefore, CYP3A4 inducers such

as macrolide antibiotics, azole antimycotics, and HIV protease inhibitors may increase serum levels. In one study, coadministration of bromocriptine and erythromycin increased bromocriptine levels by a factor of four. For all DA's coadministration with dopamine antagonists may result in decreased levels and decreased effect.

Amantadine is primarily excreted unchanged in the urine, therefore, clearance is significantly reduced in patients with renal insufficiency. Coadministration of amantadine with quinine or quinidine may reduce renal clearance of amantadine by up to 30 percent. When amantadine is administered with anticholinergics, anticholinergic-like side effects of amantadine may be potentiated. Coadministration of thioridazine with amantadine may worsen tremor in elderly patients with PD. Use of amantadine may potentially interfere with intranasal live attenuated influenza vaccine (though this has not been evaluated). However, there is no interaction between amantadine and trivalent inactivated influenza vaccine.

Modafinil and armodafinil are reversible moderate inhibitors of cytochrome P450 (CYP) 2C19, a drug-metabolizing enzyme, and may increase blood levels of diazepam (Valium), phenytoin, propranolol (Inderal), omeprazole, and clomipramine. In individuals deficient in the enzyme CYP2D6 (~7 to 10 percent of the Caucasian population and similar or lower for other populations), drugs such as tricyclic antidepressants, SSRIs, and bupropion may be increased. Chronic administration of modafinil may lead to a modest induction of CYP3A4 (armodafinil is associated with moderate enzyme induction), which may reduce levels of steroid contraceptives, triazolam, cyclosporine (Neoral), and theophylline (Bronkodyl), and dose adjustments of these medications may be required. Neither modafinil nor armodafinil have been studied in combination with MAOI medications; caution should thus be used when concomitantly administering MAOIs and these drugs. Because modafinil and armodafinil are partially cleared by CYP3A enzymes, coadministration of potent CYP3A4/5 inducers (e.g., carbamazepine, phenobarbital, and rifampin) or inhibitors (e.g., ketoconazole, erythromycin) may significantly alter drug plasma levels.

Table 34.30–3.
Dosing of Dopamine Receptor Agonist Drugs for Neuropsychiatric Indications

Drug	Indication	Dose
Pramipexole	PD	0.125–1.5 mg t.i.d. (0.375–4.5 mg total daily dose)
	RLS	0.125–0.5 mg (2–3 hours before bedtime)
	Depression (investigational)	0.375–3 mg (total daily dose)
Ropinirole	PD	0.25–1 mg t.i.d. (0.75–3 mg total daily dose)
	RLS	0.25–4 mg at bedtime

	Depression (investigational)	Up to 200 mg total daily dose
Amantadine	PD	100–400 mg total daily dose
	EPS	100–300 mg total daily dose
	NMS (off-label)	200–400 mg total daily dose
Bromocriptine	PD	1.25–100 mg total daily dose
	NMS (off-label)	2.5 mg b.i.d.–15 mg t.i.d. (5–45 mg total daily dose)
Modafinil	All indications	200–400 mg total daily dose
Armodafinil	All indications	150–250 mg total daily dose
Aripiprazole	Adult indications	10–30 mg total daily dose
	Pediatric/adolescent indications	2–30 mg total daily dose

Aripiprazole is metabolized by CYP3A4 and CYP2D6. Strong 3A4 inhibitors (e.g., ketoconazole) and 2D6 inhibitors (e.g., fluoxetine, quinidine) may reduce aripiprazole levels by up to 50 percent. Strong 3A4 inducers (e.g., carbamazepine) will decrease aripiprazole levels and higher doses of aripiprazole may be considered in these situations (e.g., use double the usual dose). Aripiprazole is unlikely to affect levels of other coadministered drugs.

LABORATORY INTERFERENCE

No significant laboratory interference has been reported.

DOSAGE AND ADMINISTRATION

Typical doses of medications for given indications are presented in Table 34.30–3.

For pramipexole, the recommended dose range for PD is 0.125 mg t.i.d. (total daily dose 0.375 mg) to 1.5 mg t.i.d. (total daily dose 4.5 mg). The recommended dose range for RLS is 0.125 mg daily (2 to 3 hours before bedtime) to 0.5 mg daily. For adjunctive treatment of depression, studies have used 0.375 to 3 mg (total daily dose).

For ropinirole, the recommended dose range for PD is 0.25 t.i.d. (total daily dose 0.75 mg) to 1 mg t.i.d. (total daily dose 3 mg). The recommended dose range for RLS is 0.25 mg to 4 mg at bedtime. For adjunctive treatment of depression, studies have investigated doses up to 200 mg total daily dose.

For amantadine, the recommended dose range for PD 100 to 400 mg total daily dose. For EPS, the recommended dose range is 100 to 300 mg total daily dose. For influenza A, the recommended adult dose range is 100 to 200 mg total daily dose. For pediatric patients (1 to 9 years of age), the total daily dose should be calculated on the basis of 2 to 4 mg/lb/day (4.4 to 8.8 mg/kg/day), not to exceed 150 mg total daily dose. For NMS, off-label use has typically administered 200 to 400 mg total daily dose.

For bromocriptine, the recommended dose range for hyperprolactinemia is 1.25 to 15 mg total daily dose. For acromegaly, the recommended dose range is 1.25 to 100 mg total daily dose. For PD, the

recommended dose range is 1.25 to 100 mg total daily dose. For NMS, off-label use has typically administered 5 mg (2.5 mg b.i.d./t.i.d.) to 45 mg total daily dose.

Dose ranges for modafinil are 200 to 400 mg total daily dose and armodafinil are 150 to 250 mg total daily dose.

For aripiprazole, recommended adult dose ranges are 10 to 30 mg total daily dose, and 2 to 30 mg total daily dose for pediatric/adolescent patients.

▲ 34.31 Thyroid Hormones

RUSSELL T. JOFFE, M.D.

INTRODUCTION

Various hormonal systems have been implicated in the biology of the stress response and in the pathophysiology of mood disorders. The adrenal axis has been the focus of most attention, but the thyroid axis has also been established as an important endocrine system.

Thyroid hormones have long been of interest to those who study and treat mood disorders, both unipolar major depression and bipolar disorder. There have been two major areas of research study. The first is whether thyroid hormones are implicated in the etiology of mood disorders and whether there is a specific abnormality of the thyroid axis in primary mood disorders. The second, following on the first, is whether thyroid hormones may be useful in the treatment of unipolar or bipolar mood disorders.

For more than a century, depressive symptoms have been known to be one of the most prominent features of clinical thyroid disease, particularly hypothyroidism. Beginning in the late part of the 19th century, depression was seen as a prominent clinical component of clinical hypothyroidism,

although other psychiatric symptoms were often present. Clinical hyperthyroidism has been observed to have a much more heterogeneous presentation with a wider variety of psychiatric symptoms reported. Earlier studies and clinical observations also noted that when the particular thyroid deficiency or excess was corrected, depressive or other psychiatric symptoms frequently, but not invariably, resolved. As a result of the strong inverse relationship between thyroid function and depression observed in endocrine patients, it was hoped that thyroid hormones—particularly thyroid hormone deficiency—might be a biological factor in the etiology of unipolar and bipolar mood disorders.

Although thyroid hormone deficiency has been excluded as a major contributor to the biological basis of primary mood disorders, particularly depression, its potential role in the cascade of biological events that leads to depressive and bipolar disorders remains to be clarified. Thyroid hormones have extensive effects on various cellular mechanisms and may still be implicated in the biology of these disorders.

The early link established between abnormal mood symptomatology and thyroid deficiency in endocrine patients prompted the investigation of the use of thyroid hormones to treat depression. Earlier studies produced ambiguous findings, which may have been contributed to by methodological limitations in the studies done, especially lack of controlled designs and heterogeneous groups of patients. In the 1960s, levothyroxine (Synthroid), synthetic forms of thyroxine (T_4) and liothyronine (Cytomel), the synthetic levorotatory isomer of triiodothyronine (T_3), were developed and replaced desiccated thyroid as a primary replacement therapy for thyroid disease. This allowed a more refined approach to examining the efficacy of thyroid hormones in the treatment of mood disorders, and the therapeutic use of thyroid hormones in the treatment of depression became the subject of study. Although thyroid hormones have been used to treat a range of psychiatric illnesses, systematic research data have been collected primarily on unipolar mood disorders and to a lesser extent, on bipolar mood disorders.

CHEMISTRY

The source of thyroid hormones in the body is the thyroid gland. Several thyroid hormones are produced by the thyroid gland. The two main circulating hormones are thyroxine (T_4) and triiodothyronine (T_3). T_4 is derived mainly from the process of iodination of tyrosine in the thyroid gland, whereas the main source of T_3, approximately 80 percent, is by monodeiodination of T_4 in extrathyroidal tissue by deiodinase enzymes. Only a limited amount of T_3 is produced in the thyroid gland. Other thyroid hormones produced include reverse T_3, 3-diiodothyronines, 3-monoiodothyronines, and the acetate metabolites of T_4 and T_3—tetrac and

triac, respectively. These other thyroid hormone products are produced in very small amounts and have unknown physiological significance.

The secretion of thyroid hormones by the thyroid gland is regulated by the hypothalamic–pituitary–thyroid axis. This involves the classic negative feedback regulatory mechanism, which applies to most of the major endocrine systems.

The cells of the hypothalamus secrete TRH, which regulates the secretion of thyrotropin (thyroid-stimulating hormone [TSH]) from the cells of the anterior pituitary via the portal venous blood system, which connects the hypothalamus and the pituitary gland. The TSH released from the pituitary then acts on the thyroid gland to stimulate the production of thyroid hormones, including T_4 and T_3. A negative feedback system operates at both the levels of the pituitary and the hypothalamus to modulate circulating levels of T_4 and T_3 and thereby regulates the activity of the thyroid axis.

The physiological action of T_4 is largely dependent on its extrathyroidal conversion to T_3, which then acts at the T_3 receptor in various tissues to initiate the physiological actions of thyroid hormones. For the most part, the conversion of T_4 to T_3 occurs in the circulation so that the thyroid hormone available to peripheral tissues is largely T_3. In the brain to a greater extent and pituitary to a lesser extent, the main source of thyroid hormone for action at the receptor is T_4, which gets converted locally within the neuron or cell to T_3 before exerting its hormonal action.

PHARMACOLOGICAL ACTION

Pharmacokinetics

Levothyroxine and liothyronine are both relatively small molecules that are easily absorbed across the gastrointestinal tract. Both hormones are strongly protein bound and are widely distributed in tissues. There is an active transport mechanism for the uptake of thyroid hormones across the blood–brain barrier. There is also a transport mechanism at the choroid plexus to ensure the wide distribution of thyroid hormones within the CNS. Several deiodinase enzymes, particularly the type III deiodinase enzyme, convert T_3 to smaller molecules including reverse T_3, which are then excreted in both urine and feces. Levothyroxine has a long half-life of approximately 7 days, whereas liothyronine has a half-life of approximately 8 to 12 hours.

Pharmacodynamics

Thyroid hormones have widespread metabolic effects in numerous organs and tissues. In the mature adult, they play key roles in both protein synthesis and calorigenesis and they also have an important role in the

development of the maturing infant.

Until the mid-1970s, it was unclear whether thyroid hormones had a substantial role in mature brain function. Studies since then have indicated that thyroid hormones play an active role in the mature brain and that they are very highly regulated to ensure that brain thyroid hormone levels remain within very narrow limits.

CLINICAL HORMONE STUDIES

The vast majority of patients with primary major depression are euthyroid. A large number of studies evaluating baseline thyroid function tests have produced inconsistent findings. The most consistent findings to emerge are higher measures of T_4 or free T_4 in the depressed state as compared with recovery or to healthy controls with much more inconsistent findings for measures of circulating T_3 or free T_3. Up to one-third of depressed patients may have a blunted TSH response to TRH which often normalizes with treatment. However, due to low sensitivity and moderate specificity for major depression the TRH test is not diagnostic for depression. Although a specific abnormality of thyroid function within the normal range has not been identified, there is some limited data on baseline thyroid function and the relationship to antidepressant response. In some studies, higher mean T_4 levels and in other studies higher mean TSH levels have been associated with antidepressant response. A reduced TSH response to TRH has also been associated with treatment response. There are preliminary data that polymorphisms of the deiodinase enzymes, which are responsible for the extrathyroidal conversion of T_4 to T_3 (type I and type II deiodinase) and for the inactivation of T_3 by conversion to reverse T_3 (type III deiodinase), may be associated with antidepressant response in euthyroid-depressed patients.

Subclinical hypothyroidism (SCH), defined as elevated TSH levels with normal circulating T_4 and T_3 levels, occurs in a minority of patients, at most 10 to 15 percent, with primary mood disorders. SCH is more common with advanced age and in women. SCH is associated with a lower response rate to antidepressants and there is recent evidence that even the presence of thyroid autoimmunity as measured by positive anti-thyroperoxidase antibodies with normal TSH may be associated with lower rates of antidepressant response. There are no data to guide clinical decision making about whether thyroid replacement would enhance antidepressant response so the decision on thyroid replacement should be consistent with current guidelines for the treatment of SCH.

All peptides and hormones of the hypothalamic–pituitary–thyroid axis have been studied for the treatment of mood disorders. These include TRH and TSH, as well as the peripheral hormones T_4 and T_3. The best evidence for therapeutic efficacy is the use of liothyronine in unipolar major

depression, although there are less data on the role of levothyroxine in the treatment of depression. Preliminary data suggest that levothyroxine may have a role as a mood stabilizer in bipolar disorder.

In major depression, thyroid hormones have been used in several ways. First, in very early studies, they have been used as monotherapy for treatment of depression with uncertain benefit. Second, they have been used at the outset of an antidepressant trial, primarily with tricyclic antidepressants, to accelerate the response to antidepressant treatment. Third, they have been added to antidepressants in patients who have failed to have a satisfactory response to an antidepressant trial—that is, for augmentation therapy. Fourth, they have been used at the initiation of an antidepressant trial to determine whether they would accelerate and enhance antidepressant response in depressed subjects requiring antidepressant therapy. Finally, they have been used as mood stabilizers in bipolar disorders, especially rapid-cycling forms.

Thyrotropin-Releasing Hormone

TRH is a peptide released from the hypothalamus that regulates thyroid hormone secretion by the thyroid gland through its effects on pituitary TSH release. In addition, TRH is a peptide that circulates in the brain and has behavioral effects. These include reversal of drug-induced sedation or anesthesia and stimulation of locomotor activity in the rat. In addition, TRH also has effects on cardiorespiratory, gastrointestinal, and other neurological functions. Because of the widespread effects of TRH on basic physiological functions in the CNS and elsewhere, as well as its effects on the thyroid axis, it has been tested as an antidepressant. Most studies have involved monotherapy, but there have also been studies of the use of TRH together with electroconvulsive therapy (ECT). TRH has been administered to patients by both intravenous and oral routes for depression. TRH has been administered intravenously either as a single dose or as several doses over a period of 3 to 4 days, and transient antidepressant effects have been demonstrated. These studies are summarized in Table 34.31–1. However, at least half of these studies have reported no effect or very minimal therapeutic response to administration of either intravenous or oral TRH administered as monotherapy with duration of treatment ranging from a single dose up to 30 days. Although a positive effect on depressed mood cannot be definitively excluded, it is very difficult to determine whether TRH has a significant and specific therapeutic role in the treatment of depression. Moreover, the transient effects noted may have little to do with the thyroid axis and may be a nonspecific activating effect of the peptide.

Table 34.31–1.
Antidepressant Response to Thyrotropin-Releasing Hormone

Number of Studies	Total N	Route of Administration	Duration	Response
3	36	Intravenous	Single dose	1 of 3 responded to TRH > placebo
6	86	Intravenous	3–4 days	1 of 6 showed transient response
3	52	Oral	7–30 days	1 of 3 responded to TRH = amitriptyline

The effect of TRH on mood and cognitive side effects of electroconvulsive therapy (ECT) have also been studied. In a small, randomized, double-blind, placebo-controlled crossover study in which 500 μg of TRH was administered to eight depressed patients who also received ECT for their depression, TRH administered intravenously before the ECT yielded greater arousal and improved cognitive functioning when compared with placebo. TRH did not have any substantial effect on any seizure variables. This is a small study that requires replication before one can assess whether there is any clinical applicability of these findings.

Thyrotropin

TSH has also received limited attention as an antidepressant. The rationale for its use is based on its stimulation of the thyroid gland and, thus, would achieve an effect similar to the administration of peripheral thyroid hormones for the treatment of depression. One study to date has examined the antidepressant effect of TSH by administering 10 IU of TSH intravenously to 20 depressed women 1 day before beginning an antidepressant trial with the tricyclic imipramine (Tofranil). When compared to a placebo control group, the TSH-treated patients had a rapid antidepressant response. These data, while of interest, require replication with larger samples, current methodology for clinical trials, and the use of SSRIs. Such study designs would allow a more appropriate evaluation of the efficacy of TSH in accelerating the response to antidepressants.

Liothyronine

Liothyronine is the most broadly studied thyroid hormone for the treatment of depression. In early studies, it was used as monotherapy for the treatment of depressed patients. The data from these studies were largely inconclusive, as they involved small patient samples, inadequate clinical trial designs by current standards, and the use of heterogeneous patient groups who, by today's diagnostic criteria, would not necessarily be diagnosed with major depression. There have been no well-designed studies of liothyronine monotherapy to date, and, therefore, its use as a single treatment for depression has not gained any clinical use.

Liothyronine has been used in earlier studies to accelerate the response to tricyclic antidepressants. Liothyronine was administered at the outset of

a tricyclic antidepressant trial and a shorter lag in onset of therapeutic effect as compared with placebo was noted in some but not all studies. This acceleration effect was observed particularly in women as compared with men. All of these studies had major methodological flaws, including small numbers of patients, poorly defined patient groups, and relatively brief duration of treatment, as well as the fact that these earlier studies involved tricyclic antidepressants, as SSRIs were not available, usually at suboptimal doses by current standards. Nonetheless, a recent meta-analysis of these earlier studies showed a significant acceleration of antidepressant response during the initial 4 weeks of tricyclic treatment, for liothyronine over placebo.

The third approach to the use of liothyronine in depressive disorders has been to augment response to antidepressants in those who failed to respond to a tricyclic antidepressant trial. These studies are reviewed in Table 34.31–2. Open and controlled studies show that approximately 50 to 60 percent of patients who do not respond to an antidepressant trial with tricyclics will respond within 2 to 3 weeks after the addition of liothyronine. Liothyronine augmentation has also been found to be comparable to lithium augmentation of both tricyclics and SSRIs. In view of the limitations of the studies of liothyronine augmentation to date, a meta-analysis of these studies concluded that liothyronine may increase response rates and decrease severity of depression scores in patients who are refractory to tricyclic antidepressant treatment. Patients with liothyronine augmentation were approximately twice as likely to respond as were controls.

In the past few years there have been emerging data on the use of liothyronine to augment SSRIs in antidepressant nonresponders. The findings with the SSRIs are consistent with those for the tricyclics and are included in Table 34.31–3. Both open and controlled studies are generally positive and indicate that liothyronine may be an effective augmentation agent for SSRI nonresponders. In recent data from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, liothyronine augmentation had comparable remission rates to other augmentation options and a more favorable adverse event dropout rate.

There are also preliminary data that if liothyronine is administered at the outset of a course of ECT, a reduced number of treatments are required to achieve therapeutic response, and there may be a greater sparing of cognitive difficulties.

In recent studies, there has been another use of liothyronine, that is, it has been studied at the outset of an SSRI trial to determine whether it would reduce delay in therapeutic onset and increase rates of treatment response in patients not necessarily refractory to antidepressant treatment. The studies to date have generally shown no benefit of liothyronine addition to the SSRI.

There is preliminary evidence suggesting that liothyronine may be effective in treatment-resistant patients. Larger studies are required to address several issues. First, further studies of liothyronine augmentation with SSRIs with large-scale, well-controlled designs are needed. Second, issues such as dosing and duration of treatment need to be addressed to provide solid data to guide the use of liothyronine in a broad-based safe clinical approach to treatment-resistant depression.

Table 34.31–2.
Liothyronine Augmentation of Antidepressants

Study	N	T_3 Dose (lg/day)	Design	Result
Earle, 1970	25	25	Open	14 of 25 responded
Ogura et al., 1974	44	20–30	Open	29 of 44 responded

SSRI, selective serotonin reuptake inhibitor; STAR*D, sequenced treatment alternatives to relieve

depression; T_3, triiodothyronine.

Levothyroxine

This thyroid hormone has been used in two ways in the treatment of mood disorders. First, it has been used as an augmentation agent for the treatment of tricyclic-refractory depression and, second, as a mood stabilizer for rapid-cycling bipolar disorder.

Levothyroxine has received less attention as an augmentation agent, as most of the initial studies were carried out using liothyronine. However, there is a database on the use of levothyroxine in refractory depression. These studies are summarized in Table 34.31–3. These studies generally involve open designs using various diagnoses, including both unipolar and bipolar subjects in one study and chronic depression or dysthymic patients in another study. All involve small sample designs. In each of these studies, levothyroxine showed augmentation effect in antidepressant nonresponders.

Levothyroxine has also been used in high doses as a mood stabilizer. There are now five case studies or case series, four involving rapid-cycling bipolar patients and one involving nonrapid-cycling bipolar patients. The total patient sample in the five studies consists of 30 patients. These studies are reviewed in Table 34.31–4. Doses of levothyroxine ranged from 150 to 500 μg/day. Of the 30 patients, 27 were reported to respond to levothyroxine or augmentation of mood stabilizers. Clearly, these data are of considerable interest, especially because rapid-cycling bipolar patients represent a substantial therapeutic challenge. A large-scale systematic control trial would clarify the efficacy of levothyroxine in bipolar disorder and its role relative to other mood-stabilizing interventions.

Liothyronine has been preferably used in psychiatric disorders whereas thyroxine is the standard thyroid hormone used for replacement for hypothyroidism. Liothyronine has a lower therapeutic index and a much shorter half-life, making thyroid axis suppression—a goal of replacement therapy—unreliable. In the last 20 years, there has been greater appreciation of substantial dissatisfaction on a minority of patients who receive thyroxine replacement. Many of them complain of symptoms in the psychiatric domain including fatigue, lethargy, depression, and anxiety. Several meta-analyses have failed to demonstrate a significant advantage for combined thyroxine and liothyronine over thyroxine replacement, which remains the standard treatment. However, there is now increasing recognition that a selected group of patients may benefit from the combination and these are likely identified by various polymorphisms of the deiodinase enzymes which would shift the ratio of circulating T_4 and T_3.

Table 34.31–3.
Antidepressant Augmentation with Levothyroxine

Study	N	Patients	T_4 Dose (lg/day)	Design	Response
Joffe and Singer, 1990	38	Unipolar major depression	150	Double-blind vs. T_3	4 of 21 responded to T_4, $T_4 < T_3$
Bauer et al., 1998	17	Unipolar (or?) bipolar depression	300–500	Open	10 of 17 showed full or partial response
Spoov and Lahdelma, 1998	22	Major depression	200	Crossover vs. lithium	T_4 > lithium
Rudas et al., 1999	9	Chronic depression and dysthymia	150–300	Open	6 of 9 full or partial response
Lojko and Rybakowski, 2007	17	Unipolar and bipolar depression	100	Open, on SSRI	11 remission and 16 response

T_3, triiodothyronine; T_4, thyroxine; SSRI, selective serotonin reuptake inhibitor.

Table 34.31–4.
Levothyroxine as Adjunctive Mood Stabilizer in Bipolar Disorder

Study	N	T_4 Dose (lg/day)	Type	Design	Response
Stancer and Persad, 1982	10	240–500	Rapid cycling	Open	8 of 10
Leibow, 1983	1	400	Rapid cycling	Open	1 of 1
Bauer and Whybrow, 1990	11	150–400	Rapid cycling	Open	10 of 11
Horowitz and Leibowitz, 1993	2	200–350	Rapid cycling	Open	2 of 2
Baumgartner et al., 1998	6	250–500	Nonrapid cycling	Open	6 of 6

T_4, thyroxine.

Therapeutic Indications

None of the peptides or hormones of the hypothalamic–pituitary–thyroid axis have received formal approval by regulatory authorities in North America or worldwide for use in the treatment of depression. Preliminary evidence suggests that these hormones may have clinical use in the treatment of different types of mood disorders. Liothyronine may be useful as an augmentation agent in refractory depression and may also have some use in accelerating antidepressant response. The use of levothyroxine in refractory depression requires further study, and levothyroxine may be an adjunct to mood-stabilizer treatment, particularly in rapid-cycling patients. For thyroid hormones to have broad clinical application, empirical data are required to clarify their efficacy and to determine their role relative to other options for these various types of mood disorders. Until such data are obtained, liothyronine remains one of many possibilities to consider for use in patients who do not respond to their first or subsequent antidepressant

trial. Moreover, levothyroxine may be considered as an option for the refractory bipolar patient, especially when conventional mood stabilizers have proven to be ineffective or only partially effective.

Precautions and Adverse Reactions

Liothyronine administered in the usual doses for augmentation treatment should not lead to symptoms of thyrotoxicosis. A dosage of 25 μg/day is below the replacement dosage for this hormone; thus, symptoms of thyroid toxicity are extremely rare. A dose of 50 μg/day is closer to the daily T_3 production range; thus, symptoms of thyroid excess could occur. It should be noted that there are no well-demonstrated dose–response studies for liothyronine; therefore, doses in excess of 25 μg should be used with caution and are not generally recommended.

Liothyronine is generally well tolerated when administered to depressed patients. A transient headache is the most commonly reported adverse effect, and it usually subsides after 1 or 2 days, either spontaneously or with the administration of mild analgesics. Allergic reactions are extremely uncommon. Liothyronine should be used with great caution in patients, particularly the elderly and those with various medical disorders, including endocrine and cardiovascular disease, and should be avoided in pregnancy.

The same precautions as noted for liothyronine apply to levothyroxine, especially since this compound is commonly used in supraphysiological doses. A recent study has demonstrated that depressed patients are able to tolerate supraphysiological doses of levothyroxine much better than are healthy controls. Long-term thyroid hormone treatment may be associated with bone demineralization, resulting in osteoporosis in women. Although this association is still controversial, one should approach the long-term use of thyroid hormones with caution.

Dosage and Administration

Liothyronine is generally administered as a single dose in the morning to avoid insomnia. There is a good rationale for divided administration of liothyronine because of its short half-life, but a single daily dose is commonly used to improve compliance. Levothyroxine has been administered in dosages that produce a circulating levothyroxine concentration, which exceeds or is at the upper range of normal for patients with bipolar mood disorder. These dosage recommendations apply to healthy adults and should be modified for older patients or those with significant medical illnesses. There are no data to support the efficacy of thyroid hormone treatment of depression in children.

▲ 34.32 Trazodone

HISTORY

Developed in Italy in 1966, trazodone (Desyrel) is considered the first of the SGAs, possessing a novel triazolopyridine chemical structure that distinguished it from the TCAs that preceded it. This structural uniqueness was associated with pharmacological properties that also differentiated it from the TCAs in its performance on animal antidepressant screens, proposed mechanism of action, and adverse effect profile. Trazodone was first marketed in Europe in the 1970s and received FDA approval in 1981 for the treatment of major depression in the United States. Its improved safety and tolerability compared to TCAs was most likely responsible for trazodone's rapid rise in clinical use after its introduction. However, with the increased popularity of SSRI antidepressants, trazodone has fallen out of favor as a first-line treatment for depression in the United States. A once-a-day formulation of trazodone (Oleptro—trazodone/Contramid) was introduced by Labopharm Inc. in 2010 and approved by the FDA for the treatment of major depressive disorder.

FIGURE 34.32–1. Molecular structure of trazodone (Desyrel).

CHEMISTRY

Trazodone is a triazolopyridine derivative, designated as 2-[3-[4-(3-chlorophenyl)-1-piperazinyl] propyl]-1,2,4-triazolo[4,3-a]pyridin-3(2H)-one hydrochloride. Its empirical formula is $C_{19}H_{22}ClN_5O.HCl$, and its molecular structure is depicted in Figure 34.32–1. Trazodone's molecular weight is 408.3. It is soluble in water, possessing a pKa of 6.7.

PHARMACOLOGY

Pharmacokinetics

Trazodone is absorbed efficiently by the human digestive tract after oral administration, reaching peak plasma concentration in about 1 hour. When consumed with food, the total amount of drug absorption is increased, maximum plasma concentration is decreased, and time to peak

concentration is doubled. Since some adverse effects such as dizziness are related to peak plasma levels, this strategy has been shown to increase tolerability. Trazodone exhibits a linear pharmacokinetic profile in the dosage range of 50 to 150 mg twice daily. When administered twice daily, initial steady-state concentrations are achieved in approximately 36 hours, with restabilization at new levels in 12 hours after dosage adjustment. There may be up to a fourfold difference in steady-state plasma levels between individuals maintained on identical dosages. Steady-state AUC of trazodone IR 100 mg three times daily and Oleptro 300 mg daily were similar, although steady-state C_{max} and C_{min} after 1 week were not found to be equivalent.

Trazodone is approximately 90 percent bound to plasma proteins and distributes without selective localization in any tissue. Trazodone and its major metabolite, meta-chlorophenylpiperazine (mCPP), both cross the blood–brain barrier. Trazodone is also excreted into breast milk, with one study reporting that the concentration is about 14 percent of the maternal plasma concentration.

Trazodone is primarily metabolized via hydroxylation and oxidation by the hepatic cytochrome P450 (CYP) system. Several studies implicate the CYP 3A4 microsomal enzyme in the production of its major, active metabolite, mCPP, while reports on the role of CYP 2D6 are conflicting. The elimination of trazodone is biphasic, with half-lives of 3 to 6 hours and 5 to 9 hours, respectively. It is eliminated primarily via the kidneys as metabolites, with only about 1 percent excreted as the parent compound. The half-life of mCPP is about 14 hours. The half-life of Oleptro is reported at 10 hours.

Pharmacodynamics

Trazodone's main pharmacological effects are believed to be mediated through its actions at postsynaptic serotonin (5-hydroxytryptamine [5-HT]) 5-HT_2 receptors. Although it exhibits weak in vitro effects at the presynaptic serotonin transporter, which is responsible for the main therapeutic effects of the SSRIs, in vivo studies suggest that this is of negligible significance in humans. Trazodone is a potent 5-HT_{2A} receptor antagonist, with a 100-fold selectivity for the 5-HT_2 relative to the 5-HT_1 binding site. Chronic administration causes a downregulation of 5-HT_2 as well as β-adrenergic receptors, similar to the actions of some other antidepressant compounds.

Trazodone's major metabolite, mCPP, is also active at serotonin receptors. It is an agonist at 5-HT_{1B} and 5-HT_{1C}, and possibly, 5-HT_{1A} and 5-HT_{1D} receptors. Research suggests that the parent compound, and not its metabolite, is responsible for the antidepressant effects. In fact, mCPP has been shown to be behaviorally activating and anxiogenic in experimental

animals and human subjects.

Trazodone is an antagonist at peripheral α-adrenergic receptors, which is most likely responsible for its adverse effects of orthostatic hypotension and dizziness, dry mouth, and priapism. It has no significant activity at noradrenergic or dopaminergic receptors. Antagonism at acetylcholine and histamine type-1 (H_1) receptors is negligible. One in vitro study suggests that inhibition of T-type calcium channels may contribute to trazodone's psychiatric and neurological effects.

There is no established consensus regarding the relationship between steady-state blood levels of trazodone and therapeutic response. One study in elderly subjects reported that a threshold concentration of 650 ng/mL predicts clinical efficacy, but studies in other populations produced conflicting results. An open-label, 3-week treatment study in a Japanese population of 26 adult patients with major depression reported a linear relationship between trazodone (but not mCPP) steady-state plasma concentration and both the final Montgomery Asberg Depression Rating Scale (MADRS) score and the percentage improvement at study completion. Also, the proportion of responders was significantly higher in the patients whose plasma concentration exceeded 714 ng/mL, consistent with the above study. No relationship between adverse effects and either trazodone or mCPP levels was seen. This finding suggests that, although not common in clinical practice, measuring trazodone levels to ensure that they exceed a threshold of 650 to 700 ng/mL may help improve outcome in patients with inadequate response to the usual dosage regimen.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Major Depressive Disorder

The majority of clinical research on trazodone has focused on its use in the treatment of major depressive disorder. After a series of open trials suggesting the efficacy of trazodone in depressive syndromes, double-blind comparison trials of trazodone were carried out first in Europe and then in the United States. Some, but not all, of the studies included a placebo comparison arm, as some investigators considered it unethical to withhold active medication from seriously depressed patients. Comparator drugs included amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), mianserin (Tolvon), dothiepin (Prothiaden), and diazepam (Valium). The studies were conducted in inpatient, outpatient, and general practice settings. Most, but not all, of these studies found trazodone to possess efficacy that is comparable to the TCAs. Several reviews and meta-analyses that attempted to overcome the limitations of the individual studies concluded that trazodone was indeed as efficacious as TCAs for the acute treatment of major depression. One such meta-analysis calculated the pooled odds ratio for response to trazodone compared to imipramine as

0.93 (95 percent confidence interval: 0.64 to 1.36), supporting the hypothesis of near-equivalent efficacy of the two medications. In addition, a 12-month, double-blind maintenance study found trazodone to be superior to imipramine on end-point efficacy measures.

Later studies have compared trazodone to other newer antidepressants. Two double-blind, randomized, 6-week comparisons between trazodone and fluoxetine (Prozac) in 43 and 126 patients, respectively, reported equivalent response rates for the two medications, although trazodone demonstrated better HAM-D sleep subscale scores in the first study. One double-blind, placebo-controlled multicenter trial compared trazodone (50 to 300 mg) and venlafaxine (Effexor) (25 to 150 mg) in 225 patients in a 6-week acute treatment phase followed by a 1-year continuation phase for responders. Subjects in the venlafaxine group were more likely to respond sufficiently to enter the continuation phase and more likely to remain in the continuation phase. Trazodone proved more effective on measures of sleep and venlafaxine proved more effective on measures of cognition and psychomotor slowing. Another 6-week, parallel, double-blind, randomized trial compared trazodone 50 to 300 mg to bupropion (Wellbutrin) 225 to 450 mg in 126 moderately to severely depressed outpatients, finding no significant differences in efficacy measures between the two treatments at end point but greater improvement with trazodone at 7 days based on sleep measures. However, a 6-week, double-blind comparison of trazodone (150 to 450 mg per day) and mirtazapine (Remeron) (24 to 72 mg per day) in 200 inpatients with a *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) diagnosis of moderate to severe major depressive episode found mirtazapine to be superior to trazodone on most efficacy measures. Since the introduction of controlled-release trazodone in 2000, two small, 6-week, double-blind studies reported equal efficacy in response and remission rates between this and both paroxetine (Paxil) and sertraline (Zoloft). A more recent once-a-day formulation of trazodone (Oleptro) was studied in a randomized double-blind, placebo-controlled multicenter trial in 2009 indicating statistically significant improvement in HAM-D 17 score versus placebo. Additionally, the antidepressant efficacy was shown to be independent of insomnia presence at baseline and independent of the overall reduction of insomnia. A 2007-published meta-analysis detected no significant differences between trazodone and its sister 5-HT_2 receptor antagonist, nefazodone (Serzone), compared with SSRIs for the treatment of major depression.

Trazodone has been systematically studied in elderly depressed patients, as its low potential for anticholinergic and cardiovascular side effects suggested greater tolerability compared with tricyclics in this population. Trials comparing trazodone with various tricyclic and heterocyclic antidepressants found comparable efficacy and a generally lower side-effect burden for trazodone. The most frequently reported side

effect in the elderly was dizziness, which may have been the result of orthostatic hypotension, expected from trazodone's pharmacological profile. This symptom can be significant in the elderly for its potential to produce falls and, therefore, may limit the use of trazodone in those most sensitive to it, particularly if exacerbated by physical illness or concomitant medications such as antihypertensives. In addition, studies have compared antidepressants for their effects on cognitive performance in the elderly. One review of such studies found evidence of impaired ability to concentrate or sustain attention for sedating antidepressants including trazodone, but little or no effects on memory with trazodone compared with tricyclics. In comparison, that review reported no cognitive adverse effects for MAOIs or SSRIs, suggesting that trazodone may not be the best choice for geriatric depression since the introduction of the SSRIs. Regarding the treatment of symptoms of depression in children, it should also be noted that a 2003 survey of 1,273 child and adolescent psychiatrists indicated that trazodone was the most frequently prescribed medication for insomnia for children with sleep disturbance associated with mood disorders despite very limited evidence for the efficacy and safety of trazodone for use in children.

During clinical studies of trazodone's antidepressant properties, several double-blind trials compared the efficacy of single bedtime dosing and divided daily dosing. One smaller study compared single bedtime dosing with thrice-daily dosing in a 4-week trial of 56 patients with major depression. That study reported equivalent therapeutic efficacy and tolerability for the two dosing regimens; a trend for greater improvement in onset and duration of sleep was noted for the bedtime dose group, as well as more side-effect complaints in the thrice-daily dosing group. In a larger trial of 146 depressed patients, twice-daily dosing was the comparison with single bedtime dosing over a period of 6 weeks. That study similarly reported equivalent antidepressant efficacy for both regimens as well as improvements in sleep for both overall. During the early weeks of the study, the single bedtime dosing group reported significantly superior sleep, while the twice-daily dosing group reported significantly greater daytime fatigue.

Overall, trazodone is an effective treatment for major depression. There is no clear indication that its effectiveness differs from that of the TCAs or SSRIs. Some studies suggest that its tolerability, and perhaps its overall effectiveness, is maximized by limiting doses to the more moderate ranges (300 mg per day or less). Adverse effects of sedation can be minimized via bedtime dosing, which also utilizes its beneficial effects for early relief of depression-related insomnia.

Anxiety Disorders

Although most clinical trials with trazodone have been undertaken for

major depression, many of those studies gave early indication that trazodone possesses antianxiety as well as antidepressant effects as evidenced by significant reductions in anxiety-related symptom scales. In addition, small, uncontrolled studies in patients with prominent anxiety symptoms or anxiety neurosis suggested its potential as an anxiolytic. However, few controlled trials of trazodone in samples meeting diagnostic criteria for anxiety disorders exist.

Generalized Anxiety Disorder. Two hundred and thirty patients with DSM-III GAD, in whom major depression and panic disorder were excluded, were treated with trazodone, imipramine, or diazepam in a randomized, double-blind, placebo-controlled 8-week trial. Although diazepam produced the greatest improvement in anxiety ratings during the first 2 weeks, both trazodone and imipramine attained comparable efficacy to diazepam in weeks 3 through 8, but only imipramine was significantly better than placebo at end point. Among completers, 73, 69, and 66 percent of imipramine-, trazodone-, and diazepam-treated patients reported moderate to marked improvement, respectively, compared to only 47 percent of patients treated with placebo. The antidepressants tended to provide greater improvement in the psychic symptoms of worry, tension, and apprehension compared to diazepam.

Panic Disorder. Data regarding the efficacy of trazodone for panic disorder is limited and conflicting. A small, uncontrolled, single-blind 8-week trial of trazodone in 11 patients with DSM-III diagnoses of panic disorder or agoraphobia with panic attacks reported significant improvements in ratings of panic and generalized anxiety, phobias, avoidance, and depression. However, in a double-blind study of 74 panic disorder patients, comparing trazodone to imipramine and alprazolam (Xanax), only the latter two effectively reduced panic and anxiety symptoms, with a high dropout rate for trazodone-treated patients primarily due to nonresponse.

Obsessive-Compulsive Disorder. Similarly, the data for trazodone's antiobsessional efficacy are mixed. Several case reports and small case series reported trazodone to be helpful for patients with obsessive-compulsive neurosis or disorder (OCD), including one report of nine patients who had failed to respond to clomipramine (Anafranil). However, a double-blind, placebo-controlled trial of trazodone in 21 patients with OCD reported no significant difference in OCD symptoms between those treated with trazodone (mean daily dose 235 mg) and those receiving placebo.

Posttraumatic Stress Disorder. Several small trials of trazodone use in

patients with PTSD have been published. One study retrospectively surveyed 74 chronic PTSD patients who had ever been prescribed trazodone for insomnia or nightmares. Of the 60 patients who had tolerated trazodone, 72 percent reported it to be helpful for nightmares and 92 percent reported improvement in sleep. A correlation of 0.57 between these two measures suggests that trazodone's beneficial effect on nightmares in PTSD may be partially independent of its sleep benefits. An open-label trial of trazodone in six patients with combat-related PTSD rated four of the six as much improved after 4 months of treatment. A 2011 literature review informing an algorithm for the treatment of PTSD proposed the use of low-dose trazodone following a trial of prazosin (Minipress) for nightmares and nighttime hyperarousal or for (persisting) initial insomnia (without nightmares) or after resolution of nightmares.

Adjustment Disorders

Two nearly identical studies of trazodone versus clorazepate (Tranxene) for the treatment of adjustment disorders in medically ill patients have been published. Both were randomized, double-blind, 28-day trials in patients meeting DSM-III-R criteria for adjustment disorder with anxious or depressed mood or mixed disturbance of emotion and conduct but without significant history of more serious psychiatric disorders. One population consisted of 18 patients receiving treatment for breast cancer, and the other 21 HIV-positive subjects. The outcomes were similar, each reporting significant symptom benefit from both medications, with nonsignificant trends suggesting greater efficacy from trazodone.

Bulimia Nervosa

Like other serotonergic antidepressants, trazodone has been tested for the treatment of bulimia nervosa, with some success. Several case studies have reported benefit on a range of illness measures. In an open-label, flexible-dose study of 13 subjects diagnosed with DSM-III bulimia, trazodone produced a significant decrease in the number of bingeing and purging (vomiting) episodes, carbohydrate cravings, and urges to binge eat. Bingeing and purging episodes were reduced to zero in four of ten subjects available for analysis and decreased by more than 50 percent in two others after about 8 weeks on the medication. In a 6-week, placebo-controlled study of 42 women meeting DSM-III-R criteria for bulimia nervosa, trazodone was superior to placebo in decreasing the frequency of bingeing and purging. In both of these trials, adverse effects were relatively mild and consistent with other studies of trazodone (sedation and dizziness) and in no cases resulted in withdrawal from the study, despite some isolated case reports of delirium in bulimic patients treated with trazodone. No trials exist to date that compare trazodone to other agents, such as the SSRIs.

Schizophrenia

Although it has no significant effects on the dopamine system, trazodone's actions at 5-HT_2 receptors are similar to those of atypical antipsychotics, suggesting a potential for efficacy in psychosis. However, this has not been borne out in clinical studies. One research group tested the efficacy of trazodone in the management of chronic schizophrenia in two small double-blind, controlled trials of 20 patients each. The first reported that trazodone produced significantly less deterioration than placebo in the Excitement and Hallucinatory Behavior item scores of the Brief Psychiatric Rating Scale (BPRS) over a 12-week period. The second compared trazodone to chlorpromazine (Thorazine), finding that chlorpromazine was significantly superior to trazodone in total BPRS score and several individual factor scores, although trazodone did improve depression scores on the BPRS. Subsequently, another group examined the potential for adjunctive trazodone use to reduce negative symptoms in chronic, residual schizophrenia using a double-blind, placebo-controlled design. Those investigators found a modest (10 to 15 percent) but beneficial effect for trazodone on two of three negative symptom scales, with only moderate clinical improvement seen in 3 of 26 trazodone-treated patients. Trazodone did not appear to worsen positive symptoms of schizophrenia. Of additional note, trazodone 100 mg has demonstrated some efficacy in reducing acute neuroleptic-induced akathisia in a small, placebo-controlled, double-blind crossover study in 2010.

Insomnia

From 1999 through 2010, trazodone was found to hold a stable (off-label) second position to the increased use of nonbenzodiazepine GABA-A omega-1 agonists as most commonly prescribed medication for insomnia (from the National Health and Nutrition Examination Survey of 32,328 adults) despite limited availability of double-blind, placebo-controlled trials demonstrating clear efficacy and safety of trazodone for insomnia treatment. This reflects physician prescriptions of trazodone for the treatment of primary insomnia, depression/anxiety/withdrawal-related insomnia, and antidepressant-induced insomnia, especially for patients at higher risk of sedative/hypnotic/anxiolytic use disorders or patients with comorbid depression. While trazodone is not associated with physiological dependence or withdrawal, a 2008 randomized, placebo-controlled trial of trazodone at 50 to 150 mg over the course of 12 weeks in patients with alcohol use disorder advised caution. The study found that trazodone was helpful for the treatment of insomnia during early recovery with rates of relapse similar to placebo. However, at 6 months postdetoxification the prior trazodone-treatment group demonstrated increased number of drinks per drinking day compared to placebo.

Trazodone is a 5-HT_{2A} antagonist that increases slow wave sleep, shortens sleep latency, improves sleep continuity and does not suppress REM sleep. In a 3-week, within-subjects randomized, double-blind trial, 16 patients with primary insomnia were given trazodone 50 mg or placebo 30 minutes before bedtime for 7 days and administered polysomnograms and MSLT on days 1 and 7. Trazodone produced small but significant impairments of short-term memory, verbal learning, equilibrium, and arm muscle endurance across time points. Compared to placebo, trazodone was associated with less middle insomnia, decreased stage 1 sleep, increased slow-wave sleep (by day 7), less daytime drowsiness (by day 7), and improved subjective experience of sleep by self-report. In another study of 14 patients with primary insomnia and Beck Depression Inventory (BDI) score >10 and 15 patients with primary insomnia and BDI score <10, trazodone CR 25 to 150 mg daily for 3 months improved sleep; however, for patients with elevated BDI scores, discontinuation of trazodone resulted in worsening sleep, while improvement in sleep quality was sustained for patients with lower BDI scores with trazodone. Compared to other off-label 5-HT 1/2A antagonists such as the atypical antipsychotic quetiapine, trazodone may have favorable efficacy. In a 2013 study (although nonrandomized, unblinded, and not placebo-controlled), of 30 inpatients receiving trazodone (mean dose 102 mg) and 31 inpatients receiving quetiapine (mean dose 182 mg), mean total sleep time hours (by subjective report and nursing sleep logs) were longer and nighttime awakenings fewer in the trazodone group compared to the quetiapine group. However, the trazodone group reported more frequent GI side effects. Trazodone has also been applied with some efficacy to treatment of insomnia in the postpartum period. In 54 postpartum patients with insomnia during the third trimester of pregnancy but without depression, EPDS scores were lower in patients treated with trazodone 50 mg or diphenhydramine 25 mg compared to placebo with no significant difference between the two active treatment groups.

Pain

Trazodone is among the various antidepressants that have been examined for their analgesic potential in a wide variety of chronic pain syndromes. Two case series of open-label trazodone trials for painful diabetic neuropathy, with sample sizes of 6 and 31 patients, respectively, reported fairly dramatic symptom relief in the majority of patients. Trazodone has also been reported to be beneficial in a double-blind, comparative study with amitriptyline for deafferentation pain and in a double-blind, placebo-controlled study of pediatric migraine prophylaxis, although two systematic literature reviews question these latter findings. Two uncontrolled open-label studies in 2010 and 2011 suggest that trazodone may help with

aspects of fibromyalgia. In one study, pain interference with daily activities, sleep, and depression were improved without direct mitigation of pain intensity. In the other study, pregabalin (Lyrica) added to trazodone reduced fibromyalgia overall severity, depression, pain interference with daily activities, and pain intensity. Trazodone did not prove to be effective in double-blind, placebo-controlled trials for fibromyalgia, chronic low-back pain, dysesthetic pain following traumatic myelopathy, or rheumatoid arthritis. Thus, little evidence exists supporting the use of trazodone in most chronic pain syndromes.

Behavioral Disturbances

Trazodone and other serotonergic medications have been used in place of sedative hypnotics and antipsychotics to manage aggression and other behavioral disturbances in certain patient populations, such as children with disruptive behavioral disorders and geriatric patients with cognitive disorders. It is postulated that trazodone targets disturbed serotonergic brain pathways that are believed to underlie such behaviors.

Childhood Disruptive Behavioral Disorders. One uncontrolled open trial studied the effectiveness of trazodone in the management of impulsive and aggressive behaviors in an inpatient group of 22 children diagnosed with DSM-III-R disruptive behavioral disorders (ADHD, conduct disorder, and oppositional-defiant disorder) comorbid with other psychiatric symptomatology. These children, aged 5 to 12, had been unresponsive to other inpatient and outpatient therapeutic interventions, including an average of 4.7 documented medication trials. Thrice-daily dosing of trazodone at an average dose of about 5 mg/kg per day for a duration of 3 to 4 weeks resulted in clinical improvement in 65 percent of the children, with most maintaining this benefit (per parental report) at 3 to 14 months' follow-up. The medication was well tolerated by the majority of the children, with transient orthostatic hypotension being the most frequently noted adverse effect (50 percent). A larger (also uncontrolled) study examining the connection between sleep and behavioral disturbances in 51 young children with opsoclonus-myoclonus syndrome reported that trazodone improved sleep in 95 percent and reduced rage attacks in 33 percent of those children treated.

Neurocognitive Disorders. Several open-label case series and double-blind, controlled trials have been published examining the effect of trazodone on agitation in elderly patients with neurocognitive disorders. These case series, typically small and with a mixed population of elderly patients with various neurocognitive disorders, overall reported beneficial effects of trazodone. A Cochrane Database review of the existing controlled studies found similarity in efficacy and tolerability of trazodone to placebo

and haloperidol as a treatment of behavioral disturbances of neurocognitive disorders, and subsequently, the review concluded that trazodone might improve some measures of agitation and psychosis for some patients with neurocognitive disorders.

Sexual Dysfunction

Trazodone has been associated with an increased risk of priapism and also has been the subject of several case reports of enhanced sexual desire and functioning in both sexes. These findings have led researchers to evaluate its potential benefit for treating disorders of sexual function, particularly male erectile dysfunction. In general, studies of treatments for sexual disorders in women have been disproportionately sparse; however, trazodone is being studied in combination with bupropion for the treatment of female hypoactive sexual desire disorder (see DSM-IV-TR definition, results pending as of November 2014). In 2009, one small open-label preliminary study of SSRI-induced sexual dysfunction in men and women with depressive/anxiety/somatic-symptom disorders found significant improvements in both men and women for all domains of sexual function and satisfaction measured. In this study, the improvement was additionally noted to be independent of improvement on measures of depressive/anxiety symptoms. In vitro, trazodone has been shown to have a high affinity for human penile α_1 receptors and moderate affinity for α_2-adrenergic receptors, lending experimental support to this endeavor.

Trazodone reportedly improved objectively assessed erectile measures in several small, uncontrolled case series of patients with impotence. However, double-blind, placebo-controlled trials of trazodone use for erectile dysfunction present different results. Three separate double-blind, placebo-controlled trials, the first in 69 patients taking 150 mg daily for 4 weeks, the second in 51 patients with 50 mg daily dosing for 3 months, and the third in 34 patients taking 200 mg daily for 4 weeks, all failed to find significant differences between active medication and placebo. The results of a review and meta-analysis of the literature on trazodone treatment for erectile dysfunction reported a nonsignificant trend of improvement with trazodone, particularly at higher doses, with a subgroup analysis favoring benefit if the dysfunction is psychogenic in origin.

Other Disorders

Trazodone has been studied as a potential treatment for a wide range of other psychiatric and medical syndromes, mostly via case reports or open-label trials. These include dysthymia, depression following stroke, tic disorders, chest pain due to esophageal dysmotility, sleep apnea, menopausal symptoms, and benzodiazepine, alcohol, and opiate use disorders or withdrawal. Although varying degrees of efficacy have been

reported, the overall lack of data, particularly from trials with more stringent study methodology, prevents one from drawing any firm conclusions regarding trazodone's potential use in these conditions.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

In both premarketing trials and postmarketing surveillance, the adverse effects seen with trazodone therapy have generally been benign, mostly limited to dry mouth, headache, nausea, drowsiness, fatigue, and dizziness, the latter in part secondary to orthostatic hypotension. Unlike TCAs, trazodone is virtually devoid of anticholinergic side effects, including major cardiac conduction abnormalities, thus explaining its benign profile following overdose. The adverse reaction for which trazodone is most widely recognized, although infrequent, is priapism.

Cardiovascular System

Trazodone appears to have a relatively benign cardiovascular profile. The most troublesome cardiovascular adverse effect is postural hypotension, which can be severe enough to produce syncope in susceptible patients, particularly the elderly or those with concurrent medical illness or taking other medications with cardiovascular effects. Adjustments in the dosage or dosing intervals of trazodone or concurrent medications, together with precautions regarding postural changes, can usually mitigate this problem if trazodone use is otherwise warranted.

No consistent effects of trazodone on cardiac contractility or the interventricular conduction system in humans or animals have been noted, except for possible nonspecific lengthening of the PR interval. However, several case reports of cardiac abnormalities associated with trazodone use exist in the literature, including ventricular arrhythmias, QT prolongation, and complete heart block. Most, but not all, of these effects were seen either associated with trazodone overdose or in individuals with pre-existing heart disease, suggesting caution in this latter category of patients.

Genitourinary System

The most concerning side effect attributed to trazodone is priapism, a painful unremitting erection that requires emergent medical attention. It can occur as a complication of various medical illnesses such as sickle cell disease, but a majority of cases have implicated medication use. The α-adrenergic receptor antagonists, such as trazodone, chlorpromazine, and prazosin, are hypothesized to induce priapism by inhibiting sympathetically controlled detumescence. The incidence of priapism during trazodone therapy is estimated at 1 in 1,000 to 1 in 10,000 cases. Although it is most likely to occur within the first 28 days of initiating treatment with trazodone, it has occurred as late as 18 months into treatment and at a wide

range of therapeutic dosages. A past history of prolonged erections appears to be a general risk factor for priapism. At least two cases of clitoral priapism associated with trazodone use have also been reported in the literature.

All patients on trazodone therapy need to be warned of the risk and medical significance of priapism, as patients may be reticent to acknowledge it and seek treatment. Once priapism develops, it is considered a urological emergency requiring immediate medical intervention. Patients should be advised to discontinue trazodone and seek emergency care in the event of an erection lasting more than 1 hour. The likelihood of morbid complications of impotence, cavernosal fibrosis, and gangrene is directly related to a delay in initiating treatment. Various medical interventions (ice packs, oral adrenergic medications) have produced inconsistent results, but are usually attempted before more definitive surgical procedures are instituted. One of two surgical interventions (intracavernosal irrigation with an α-adrenergic agonist or shunting between the corpus cavernosa and spongiosum) will usually produce detumescence, but impotence may still be the outcome in as many as half of these cases.

Central Nervous System

Trazodone frequently produces CNS side effects of drowsiness (20 to 40 percent) and dizziness or light-headedness (20 to 30 percent), particularly early in treatment. Drowsiness has been the side effect most frequently leading to discontinuation, although it can be a welcome benefit for those patients with severe insomnia. Headache, fatigue, nervousness, and confusion have lower incidence. Isolated cases of delirium induced by trazodone have been reported in patients with pre-existing cerebral or metabolic abnormalities.

Trazodone shows little, if any, risk for lowering the seizure threshold in patients. There have been isolated case reports of increased seizure activity associated with trazodone use, although these are far less prevalent than with TCAs. In patients with a known history of seizure disorder, it is prudent to initiate therapy with trazodone at lower doses and titrate the dose more gradually.

As is the case with other antidepressants, trazodone has been reported to precipitate manic episodes in patients with diagnoses of both major depressive disorder and bipolar disorder. Trazodone's potential for increasing the risk for hypomania or mania appears to be lower than that of TCAs. Finally, trazodone also carries the black box warning (applied to all antidepressant medications) for increased risk of suicidal ideation, especially in children, adolescents, and young adults.

THERAPEUTIC INDICATIONS

Trazodone has an FDA indication for major depressive disorder, and research supports its general efficacy and tolerability for this indication. Currently, the most common off-label use of trazodone is for the treatment of insomnia, particularly insomnia associated with the use of other antidepressants such as the SSRIs, for which it remains a reasonable option for some patients. For other conditions, as are described above, the findings are tentative and would require replication in larger samples before treatment recommendations can be made.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effect reported by patients using trazodone is drowsiness. Patients should be warned that this side effect may be exacerbated by alcohol or other concomitant medications, thus impairing their ability to safely engage in potentially hazardous tasks, such as driving. Orthostatic hypotension resulting in syncope can occur, particularly in the elderly or medically ill, and may cause significant injury through falls. Adjusting the dosage of trazodone or concurrent medications and ingesting trazodone with meals may diminish this effect, but continued caution should be exercised when prescribing trazodone to elderly patients. There are no reported withdrawal or discontinuation syndromes associated with trazodone. A 2014 review found some cases of dose-independent trazodone-induced liver injury (hepatocellular by immuno-allergic mediation), with one resulting in liver transplant. A 2011 meta-analysis indicated that trazodone was correlated with higher all-cause mortality compared to SSRIs and TCAs in treatment of elder depressed patients.

Priapism, although infrequent, is the side effect that is most concerning due to its potential for producing serious, irreversible injury. All patients should be strongly cautioned to discontinue trazodone and seek immediate medical attention in the event of prolonged or painful erections.

There is no evidence that trazodone possesses mutagenic or carcinogenic potential based on studies in rats receiving doses up to 300 mg/kg for 18 months. Trazodone is designated pregnancy category C, as it has produced fetal anomalies in animal studies at 15 to 50 times the maximum human dose, but it has not been adequately evaluated in human pregnancy. One multicenter study compared the pregnancy outcomes of 147 women who had exposure to either trazodone (n = 58) or the related phenylpiperazine antidepressant, nefazodone (n = 89), with the outcomes from women exposed to other antidepressant (n = 147) or nonteratogenic medications (n = 147). They found no statistically significant differences among the three groups for any of the end points of interest, including miscarriage rate, rate of major malformations, gestational age, and birth weight. As with all medications that have an unclear potential for fetal effects, use in pregnancy should only be considered if the potential benefit outweighs the risk. Trazodone is excreted into human breast milk, with one

study in six lactating women reporting a milk/plasma ratio of about 15 percent, indicating that exposure to nursing infants would be low.

Trazodone has a very high therapeutic index, with an LD_{50} of around 500 mg/kg in experimental animals. Data from hundreds of documented cases of overdose support its safety in all but a small fraction of cases, with the majority of those involving other concurrent medications. The main symptoms that occur when trazodone is taken in overdose are excessive drowsiness and vomiting, although isolated cases of seizures, hyponatremia, priapism, respiratory arrest, QT prolongation, cardiac arrest, and coma have been reported. One postmortem toxicological review of trazodone-related deaths concluded that trazodone played a primary role in the deaths by massive overdose of only three individuals who attained blood concentrations above 9 mg/L.

DRUG INTERACTIONS

Significant changes in prothrombin time (PT) and international normalized ratio (INR) in patients receiving warfarin (Coumadin) therapy and increased levels of digoxin (Lanoxin) and phenytoin (Dilantin) have been reported in isolated cases of patients receiving trazodone concurrently, most likely due to interactions via trazodone's high binding to plasma proteins. An in vitro study reported that the metabolism of trazodone to its principal metabolite (mCPP) via CYP3A-mediated clearance was significantly inhibited by ketoconazole (Nizoral), ritonavir (Norvir), and indinavir (Crixivan), suggesting caution in prescribing trazodone to individuals treated with CYP 3A4 inhibitors, including HIV-infected individuals who are commonly prescribed these medications. One patient taking fluoxetine and trazodone developed sedation and an unsteady gait, with the finding of a 30 percent increase in trazodone levels. However, this was an isolated report, as most patients tolerate this combination without difficulty.

As discussed earlier, trazodone may potentiate the sedative or hypotensive effects of other pharmacological agents, requiring caution when used in such combinations. In combination with MAOIs to treat insomnia, trazodone appears to be safe. No cases of hypertensive crisis have been reported, and one reported case of nocturnal myoclonus resolved after discontinuation of trazodone. There have been several isolated reports of serotonin syndrome associated with trazodone use. Most of these occurred when trazodone was prescribed in combination with a variety of serotonergic psychotropic medications, including buspirone (BuSpar), fluoxetine, sertraline, paroxetine, venlafaxine, nefazodone, and amitriptyline with lithium (Eskalith). One case occurred when trazodone alone was prescribed to a 73-year-old patient who was later suspected to suffer from Lewy body dementia.

LABORATORY INTERFERENCE

Trazodone generally exhibits no interference with urinalysis, spectrometry, or other laboratory tests. There is one isolated report of trazodone-related decreases in hematocrit, hemoglobin, red blood cell count, serum cholesterol, calcium, and albumin during a 6-week comparison trial with fluoxetine, with the development of clinically insignificant pseudoanemia in 36 percent of the trazodone-treated and 20 percent of the fluoxetine-treated groups, respectively. Trazodone has also been reported to result in false-positive urine drug screen for amphetamine.

DOSAGE AND ADMINISTRATION

The manufacturer's package insert recommends initiating trazodone at 150 mg per day in divided doses (after meals), increasing by 50 mg per day in intervals of 3 to 4 days up to a maximum dose of 400 mg per day in outpatients and 600 mg per day in inpatients. Elder patients should use a starting dose of 100 mg daily. Once-a-day trazodone (Oleptro) can be started at 150 mg and increased as needed by 75 mg every third day to a maximum dose of 375 mg daily for the treatment of major depressive disorder. Oleptro is recommended to be taken on an empty stomach at bedtime, and it is noted the tablets may be bisected if needed without adversely affecting the extended-release properties of the tablet. There are not yet approved dosage recommendations for children or adolescents.

Trials of trazodone for the treatment of major depression suggest that the majority of patients begin to respond within the first 2 weeks of therapy, although this finding was in the context of objective, controlled studies, many with higher initial dosages. However, patients with significant insomnia or agitation may show an early response to trazodone's sedating effects. For the treatment of primary or medication-related insomnia, doses in the 50- to 100-mg range are usually sufficient.

Trazodone is available in scored 50- and 100-mg tablets and in 150- and 300-mg tablets that can be divided into halves or thirds for convenient dosing adjustment and administration. Oleptro is available in 150- and 300-mg tablets.

▲ 34.33 Tricyclics and Tetracyclics

J. CRAIG NELSON, M.D.

HISTORY

In 1957, Roland Kuhn, a Swiss psychiatrist, observed that imipramine (Tofranil) had antidepressant effects in a small sample of 40 patients. This serendipitous observation, like those before for lithium (Eskalith) and chlorpromazine (Thorazine), had far reaching import. It demonstrated that medications could be used to treat depression. It led to the development of a new class of antidepressant compounds. This clinical observation, coupled with Julius Axelrod's report of imipramine's role in blocking reuptake of norepinephrine, laid the foundation for the norepinephrine hypothesis of depression.

The study of the treatment of depression with imipramine and related compounds would drive the development of new methodology. For example, objective measures were required to assess change during treatment. Max Hamilton developed the Hamilton Depression Rating Scale to monitor change during administration of these new compounds. Other scales followed. Better methods of defining depression were needed, and the Washington University group proposed criteria for primary affective disorder, criteria that became the basis for the category major depression in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). Observation of substantial placebo effects in depression during clinical trials led to the appreciation of the need for placebo controls.

The field also learned the basics of pharmacological management of depression with imipramine and other tricyclics. The necessity for administering an adequate dose for an adequate duration was described. The need to continue treatment to prevent relapse and recurrence was identified. The observation of the substantial variability of the tricyclic concentrations in plasma stimulated a whole area of study of the pharmacology of these compounds. This research introduced psychiatry to the concept of *genetic polymorphisms* and the possible consequences of drug interactions.

After the introduction of imipramine, several other antidepressant compounds were developed that shared a basic tricyclic structure and relatively similar secondary or side effects. Later, other heterocyclic compounds were also marketed that were somewhat similar in structure and that had relatively comparable secondary properties.

CHEMISTRY

Tricyclic and tetracyclic compounds are categorized primarily on the basis of their chemical structure (Fig. 34.33–1). The *tricyclics* have a three-ring structure, hence, their name. The tertiary amine tricyclics, such as amitriptyline (Elavil) and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated to secondary amines, such as desipramine (Norpramin, Pertofrane) and nortriptyline (Aventyl, Pamelor). The tetracyclic compounds, maprotiline (Ludiomil) and amoxapine (Asendin), have a four-ring central structure. Five tertiary amines have been marketed in the United States—amitriptyline, clomipramine (Anafranil), doxepin (Sinequan), imipramine, and trimipramine (Surmontil). The three secondary amine compounds are desipramine, nortriptyline, and protriptyline (Vivactil).

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

Absorption. Absorption of the tricyclic and tetracyclic drugs occurs in the small intestine and is reasonably complete and rapid. Peak levels after ingestion occur within 2 to 8 hours. Exceptions are protriptyline, which is absorbed more slowly, with peak levels obtained between 6 and 12 hours, and maprotiline, which has peak levels occurring in 8 hours or more. Because the antidepressant action of these drugs occurs over several weeks, the timing of peak levels is relatively unimportant for efficacy but does have implications for side effects, especially during initial dosing.

Distribution. The tricyclic and tetracyclic compounds are basic lipophilic amines. As a result, they are concentrated in a variety of tissues throughout the body and have a high volume of distribution. In some organs, the heart for example, the drug is concentrated at levels exceeding those in plasma. Because of their lipid solubility, these compounds are extensively bound to plasma proteins. Binding of the tricyclic and tetracyclic drugs is generally 90 percent or greater. Exceptions are the hydroxymetabolites of the tricyclics, which have lower plasma protein binding.

Tricyclic compounds cross the placenta. Transfer of the tertiary compound amitriptyline is slightly higher than that for the secondary compound nortriptyline. Neonatal drug withdrawal can occur. The tricyclics are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small so that drug levels in the infant are usually undetectable or very low.

Metabolism and Elimination. After absorption, the tricyclics are taken up in the circulation, pass first through the liver, and metabolism of the drug begins. As a result of this *first-pass effect* the amount of the

compound that enters the systemic circulation is reduced.

Pharmacological profile of antidepressants and related compounds at human monoamine transporters. *Eur J Pharmacol.* 1997;340:249–258. Receptor affinity data adapted from Richelson E, Nelson A. Antagonism by antidepressants of neurotransmitter receptors of normal human brain in vitro. *J Pharmacol Exp Ther.* 1984;230:94–102.

Clearance of the tricyclic and tetracyclic compounds is principally the result of hepatic metabolism. Renal clearance accounts for only a small portion of drug elimination. Rates of hepatic metabolism vary widely from person to person. Elimination half-lives for most of the tricyclic and tetracyclic compounds are approximately 24 hours or longer, thus the drugs can be given once a day (Table 34.33–1). Amoxapine, which has a shorter half-life, is an exception.

There are two principal metabolic pathways: demethylation of the side chain and hydroxylation of the ring structure. Demethylation converts the tertiary amine to a secondary amine. Examples are the conversion of amitriptyline to nortriptyline and imipramine to desipramine. This process alters the activity of the compound. The tertiary amines are relatively more serotonergic, whereas the demethylated amines are relatively more noradrenergic. Hydroxylation of the compounds also occurs and results in hydroxymetabolites. The concentration 10-hydroxynortriptyline usually exceeds that of the parent. For desipramine, 2-hydroxydesipramine is present at levels of approximately 45 percent of the parent, but these ratios are quite variable. The ratio of hydroxymetabolite to parent increases in rapid metabolizers. Hydroxyimipramine and hydroxyamitriptyline are present at low concentrations and are clinically unimportant. The hydroxymetabolites are then conjugated and excreted. The conjugated metabolites are not active.

Hydroxynortriptyline and hydroxydesipramine are active compounds. Both have antidepressant activity. Hydroxydesipramine is comparable to the parent, in terms of norepinephrine reuptake blockade. There are two isomers of hydroxynortriptyline: E- and Z-10-hydroxynortriptyline. E-10-hydroxynortriptyline is present at levels four times higher than the Z-

isomer. E-10-hydroxynortriptyline blocks uptake of norepinephrine but is approximately 50 percent as potent as nortriptyline. The clinical significance of high levels of less potent hydroxynortriptyline is not entirely clear, but if high levels of hydroxynortriptyline interfere with the action of nortriptyline, this might explain the therapeutic window described for this drug. The hydroxymetabolites of nortriptyline and desipramine are less anticholinergic than their parent compounds but may have other effects. They appear to contribute disproportionately to the cardiac conduction abnormalities associated with the tricyclic antidepressants.

The principal metabolic pathway for amoxapine is hydroxylation. 7-Hydroxyamoxapine and 8-hydroxyamoxapine are produced. These compounds differ in their clinical activity. 7-Hydroxyamoxapine has high-potency neuroleptic properties but has a short half-life. 8-Hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

The tricyclics are metabolized by the cytochrome 450 (CYP) system. The CYP 2D6 pathway appears responsible for hydroxylation of desipramine and nortriptyline. Demethylation of the tertiary amine compounds appears to involve a number of CYP isoenzymes, including CYP 1A2, CYP 3A4, and CYP 2C19. These hepatic isoenzymes are under the control of specific genes, and the gene loci have been identified for several of these isoenzymes, including CYP 2D6. Approximately 5 to 10 percent of Caucasians are homozygous for the recessive autosomal CYP 2D6 trait, resulting in deficient hydroxylation of desipramine and nortriptyline. These individuals are known as poor metabolizers, whereas those with adequate CYP 2D6 isoenzyme activity are extensive metabolizers. Approximately 50 percent of those of Asian descent carry the 2D6*10 allele which results in reduced clearance by the 2D6 enzyme and are intermediate metabolizers. In addition, about 20 percent of Asians have a genetic polymorphism resulting in deficient CYP 2C19 metabolism. This pathway is involved in the metabolism of the tertiary tricyclic compounds.

FIGURE 34.33–2. Distribution of steady-state desipramine (Norpramin, Pertofrane) concentrations in 83 inpatients receiving desipramine (2.5 mg/kg/day). (Adapted from Nelson JC. Use of desipramine in depressed patients. *J Clin Psychiatry.* 1984;45:10–16.)

The variability in plasma concentrations that results from these metabolic differences is substantial, often described as a 40-fold variation among individuals (Fig. 34.33–2). Even among the extensive metabolizers, there can be moderate interindividual variability in the rates of metabolism.

The concept of *steady state* is important for clinicians to understand if plasma concentration monitoring is used. Steady state is that point, on a fixed dose, at which plasma concentrations of the drug plateau. Steady state is achieved after five times the half-life.

If blood level monitoring is used, a trough sample (before the next dose) is drawn when the patient has reached steady state. At steady state, drug concentrations are relatively stable, as long as the dose is constant, the patient is compliant, and no drugs with interactive effects are added.

When the drug concentration is measured, the total of the free and bound tricyclic fractions are reported. Few laboratories are prepared to measure free levels, and yet free levels are directly related to the concentration of drug in the cerebrospinal fluid (CSF). The free concentration is dependent on dose and hepatic clearance and is not affected by absorption, the volume of distribution, or plasma protein binding. The latter is often misunderstood. If the binding protein concentration falls, the total (free and bound) concentration declines, but

the absolute free concentration is unaffected. If another drug affects binding, the absolute free concentration remains unaffected. In these instances, the *free fraction* may rise because the bound portion decreases, not because there is a change in the free concentration.

The day-to-day biological variability of drug concentrations is not frequently described. In outpatients, the day-to-day variability of nortriptyline levels (the coefficient of variation equals the standard deviation divided by the mean plasma concentration) has been reported to be 25 percent. In inpatients at steady state, the coefficient of variation of desipramine is approximately 10 to 15 percent. (If the average plasma concentration is 150 ng/mL, two-thirds of samples obtained will be between 135 and 165 ng/mL.) Research studies of drug concentrations have frequently used the average of two or three plasma samples drawn at steady state to estimate the level more precisely. For clinical purposes, usually one sample is drawn, and the clinician needs to remember that, even if the laboratory error is low, the biological variability is sufficiently great that blood levels are better viewed as estimates than precise measures.

Recently assays have become available that can genotype specific isoenzyme pathways such as 2D6. Genotyping might be useful for predicting how an individual would metabolize a group of drugs that are cleared by a specific pathway. Alternatively, a plasma drug concentration is more informative about the actual amount of a specific drug present and takes into account variations in absorption, distribution, and adherence in addition to differences in metabolic rate.

For most of the tricyclics, kinetics are relatively linear, although there are some exceptions. Desipramine, for example, appears to have nonlinear kinetics in the usual dose range. The patients most vulnerable to nonlinear changes are the rapid metabolizers—patients who, at usual doses, have low bloods levels. In cases of overdose, nonlinear changes are more likely to occur, and the clinician cannot assume that usual rates of drug elimination are maintained.

The pharmacokinetics of drug treatment in the elderly are complicated. A number of changes occur. For example, the ratio of fat to lean body mass increases, and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness. Yet, the magnitude of these changes is usually relatively small in relation to the dramatic variability of hepatic metabolism. Metabolic changes with age appear to vary with the isoenzymes involved. The CYP 3A4 pathway, for example, slows with age. Most studies of the tertiary amines, such as imipramine, suggest that concentrations of these drugs are increased somewhat in the elderly. Concentrations of nortriptyline and desipramine, compounds metabolized primarily by CYP 2D6, are relatively unaffected by aging. Similarly, the relationship of drug concentrations to therapeutic effects appears to be relatively similar in younger and older adults for these

agents. Renal clearance of the hydroxymetabolites does decrease with age. Concentrations of hydroxynortriptyline may be substantially elevated in older patients.

In children, the clearance of tricyclic compounds is increased. Half-lives of imipramine are shorter, and ratios of desmethylimipramine to imipramine are higher, consistent with more rapid metabolism.

Pharmacodynamics

Mechanisms of Action. The tricyclic and tetracyclic antidepressants block the transporter sites for serotonin and norepinephrine and thus reduce uptake of these amines into the presynaptic neuron (Table 34.33–2). The tertiary amines have greater affinity for the serotonin transporter. The secondary amines primarily block the uptake of norepinephrine. Because the tertiary amines are demethylated to secondary amines, during the administration of amitriptyline, imipramine, or clomipramine, secondary amines are also present, thus serotonergic and noradrenergic effects occur. Because dopamine is inactivated by norepinephrine transporters in the frontal cortex, the tricyclics would be expected to increase dopamine concentrations in that region.

After the initial reuptake blockade, a sequence of events occurs. The tertiary tricyclic compounds, particularly clomipramine, inhibit the uptake of serotonin and concentrations of serotonin rise. In response, the presynaptic somatodendritic serotonin type 1A ($5\text{-}HT_{1A}$) autoreceptor reduces the firing rate of the presynaptic serotonin neuron, and concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, fall rapidly. Over a 2-week period, the presynaptic autoreceptor is desensitized, resulting in a normalization of the firing rate. At this point, serotonin transmission is enhanced.

Table 34.33–2.
Pharmacokinetic Parameters and Clinical Information for Tricyclic and Tetracyclic Drugs

Drug	Half-Life (hours)	Plasma Clearance (L/hour)	Antidepressant Dosage Range[a] (mg/day)	Presumed Therapeutic Plasma Concentrations (ng/mL)
Tertiary tricyclics				
Amitriptyline (Elavil)	5–45	20–70	150–300	—
Clomipramine (Anafranil)	15–60	20–120	150–300	>150[b]

Imipramine (Tofranil)	5–30	30–100	150–300	>200[b]
Trimipramine (Surmontil)	15–40	40–105	—	—
Secondary tricyclics				

Desipramine (Norpramin, Pertofrane)	10–30	80–170	75–300	>115
Nortriptyline (Aventyl, Pamelor)	20–55	15–80	50–150	50–150
Protriptyline (Vivactil)	55–200	5–25	15–60	—
Tetracyclics				
Amoxapine (Asendin)	5–10	225–275	150–300	—
Maprotiline (Ludiomil)	25–50	15–35	100–225	—

[a]Dose range is a crude guideline; some fast or slow metabolizers need doses outside this range.

[b]Includes parent compound plus desmethylmetabolite.

The tricyclic agents as a group sensitize or upregulate *postsynaptic* 5-HT_{1A} receptors. Changes in the sensitivity of the presynaptic and postsynaptic receptors occur over a 2-week period. The onset of these changes is more consistent with the timing of antidepressant response than the initial uptake blockade.

Depression is associated with an increase in postsynaptic serotonin type 2 (5-HT_2) receptor density. A variety of antidepressants, including the tricyclics, have been shown to downregulate the 5-HT_2 receptors. The 5-HT_2 receptors principally mediate excitatory effects, whereas the 5-HT_{1A} receptors have an inhibitory effect in the brain, thus these two systems act in opposition. In preclinical experiments, administration of a 5-HT_2 antagonist enhances the effects of serotonin. Thus, the downregulation of 5-HT_2 receptors with tricyclic treatment appears to facilitate the effects of serotonin at postsynaptic 5-HT_{1A} receptors. In addition doxepin, clomipramine, amitriptyline, trimipramine, and nortriptyline act as antagonists at the 5-HT_2 receptor.

The sequence of events in the noradrenergic system is more complicated and less well understood. Following reuptake inhibition, concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine that reflects the turnover of this neurotransmitter, fall rapidly, within 24 hours. Presumably, this is mediated by the presynaptic somatodendritic α_2-autoreceptor, which, sensing an increase in norepinephrine, lowers the firing rate of the presynaptic neuron. Different from the 5-HT system, the firing rate of the presynaptic noradrenergic neuron remains inhibited with chronic treatment. Norepinephrine concentrations, however, do increase at postsynaptic sites in the hippocampus and frontal cortex and norepinephrine transmission is increased. This may be mediated by desensitization of the *terminal* α_2-autoreceptor.

During chronic treatment the postsynaptic β-adrenergic receptor is downregulated or decreased in density. This downregulation was once proposed as a mechanism of tricyclic action. Instead, it appears more likely that it is a compensatory change. In fact, during continued administration of a noradrenergic reuptake inhibitor, the system remains upregulated.

This is reflected in the enhanced formation of the second messenger cyclic adenosine monophosphate (cAMP). Clinically, this is reflected as a persistent increase in heart rate.

Early theories of depression posited depletion of serotonin or norepinephrine, or both of these neurotransmitters. Administration of the tricyclic agents was thought to enhance the availability of both neurotransmitters. Subsequent theories suggested that the changes in presynaptic and postsynaptic receptors were a likely explanation for the delayed effects of these drugs in depression. Recent depletion studies suggest that the effects of antidepressant agents are mediated by serotonin and norepinephrine. Administration of a tryptophan-free diet rapidly depletes serotonin. Depressed patients, who have been successfully treated, experience transient return of symptoms after tryptophan depletion. Furthermore, relapse was most likely in those treated with serotonergic agents, whereas those treated with norepinephrine agents are relatively unaffected. Alternatively, administration of α-methyl-*para*-tyrosine, which interrupts the synthesis of catecholamines, causes relapse in patients successfully treated with noradrenergic agents, whereas those receiving serotonergic drugs are relatively unaffected. Tryptophan depletion in untreated depressed patients, however, has no effect on the patient's depression. These studies support the view that the actions of these two types of drugs are, in fact, mediated by serotonin and norepinephrine, but they do not necessarily imply that tricyclics are correcting *deficits* in these neurotransmitter systems.

Early theories of antidepressant action suggested that it might be possible to identify serotonergic and noradrenergic depressions based on the relative deficiencies of metabolites associated with each of these neurotransmitters and thus predict which type of antidepressant would be most effective. A number of studies investigated the predictive value of MHPG levels pretreatment, but a clear predictive link with a type of antidepressant was not established. These studies were, in part, hampered by the use of agents such as amitriptyline and imipramine, which are not selective.

The possible role of anticholinergic effects of the tricyclics in the mechanism of antidepressant action has not received much attention. These effects usually have been associated with unwanted adverse effects. Yet, as early as 1972, theories about the role of the cholinergic system in depression were advanced. Scopolamine, an anticholinergic agent, has rapid antidepressant effects given intravenously. Physostigmine and donepezil, which have cholinergic effects, have been noted to exacerbate depression or increase risk of relapse in patients with recurrent depression. Amitriptyline has anticholinergic effects at therapeutic doses and it is likely these actions would contribute to antidepressant activity; however, it would be difficult to disentangle the contribution of these effects relative to the

effects of monoamine reuptake inhibition.

Other possible mechanisms of action in depression have been explored including the effects of tricyclics on postsynaptic signal transduction, glucocorticoid receptors, neurotrophic factors, and gene expression. The antidepressants, including the tricyclics, appear to have neuroprotective effects. They raise levels of BDNF and promote neurogenesis in the hippocampus. A particularly intriguing finding is the observation of an association of decreased hippocampal volume with lifetime duration of *untreated* depression, implying that antidepressant treatment might protect against this outcome. Yet, at the present time, the role of these neuroprotective effects in mediating the actual antidepressant effects of tricyclics remains unclear.

The reuptake inhibition of the tricyclics and tetracyclic compounds also occurs in descending pathways of the spinal cord and contributes to analgesic effects. Animal studies suggest that serotonin and norepinephrine have independent synergistic effects on pain. In addition, the effects of tricyclics on sodium channels also contribute to their analgesic effects although these same effects appear to be responsible for the dose-dependent delay in cardiac conduction.

The tricyclic and tetracyclic compounds have *secondary* effects on a variety of other receptors (Table 34.33–2). In particular, these compounds block muscarinic receptors, producing anticholinergic effects. They block histamine-1 (H_1) receptors, and they block α_1- and α_2-adrenergic receptors. They affect fast sodium channels, and this explains their adverse cardiac effects. The potency of these various secondary effects varies considerably. Amitriptyline is the most anticholinergic. Doxepin is the most potent H_1 antagonist among the tricyclics, although it is less potent at this receptor than mirtazapine (Remeron).

Blood Concentrations and Relation to Response. Knowledge of the wide interindividual variability of tricyclic plasma concentrations led to the hope that drug level monitoring might ensure that therapeutic blood levels were achieved and might help to avoid toxic levels. In carefully selected endogenous or melancholic inpatients with major depression, treatment with adequate levels of imipramine or desipramine did result in response rates of approximately 85 percent. These studies suggested that adequate blood levels would help maximize response. Alternatively, the careful selection of patients in these studies may have resulted in samples that were not representative of typical clinical practice.

An American Psychiatric Association (APA) task force reviewing the evidence concluded that a relationship with blood levels and response had been demonstrated for imipramine, desipramine, and nortriptyline (Table 34.33–1). For imipramine, drug levels greater than 200 ng/mL were more effective than lower levels. For desipramine, levels greater than 115 ng/mL

were more effective. For desipramine and imipramine, blood levels in excess of 300 ng/mL were more likely to be associated with serious side effects. Effective plasma concentrations were also established for nortriptyline, but the relationship appeared to be curvilinear: Plasma levels between 50 ng/mL and 150 ng/mL were more effective than levels outside this window.

For amitriptyline, it has been difficult to establish a therapeutic relationship of levels and response. In part, this may be related to the fact that during amitriptyline administration, amitriptyline, nortriptyline, and hydroxynortriptyline are all present and active; and it is unclear if their effects are additive or if there is a more complicated relationship. During amitriptyline administration, responders usually have total amitriptyline and nortriptyline levels in the neighborhood of 150 to 250 ng/mL, but there is no good agreement between studies. For clomipramine, blood levels of 150 to 300 ng/mL (total of clomipramine and desmethylclomipramine) have been suggested for antidepressant effectiveness. Higher doses and levels are usually used in the treatment of OCD. The data relating blood levels and response are limited for the other tricyclic and tetracyclic compounds.

The clinical value of blood level monitoring has been the subject of much debate. Relationships between blood levels and response have been best demonstrated in melancholic inpatients. It has proven difficult to demonstrate a relationship of blood levels and response in depressed outpatients. In this group, placebo rates are high, the difference between drug and placebo is substantially reduced, and the effect of drug treatment is harder to detect. Moderately depressed outpatients may be a heterogeneous group and include patients who are not responsive to drug treatment. Finally, most studies are not designed to detect blood level–response relationships. Fixed dosing is required, and a significant portion of the sample must achieve plasma concentrations below the suspected threshold. If all patients achieve plasma drug concentrations that are above an effective threshold, no relationship with response will be found. It is logical to conclude that blood level relationships determined in severely depressed inpatients might be used as a guide for treatment of outpatients, but that has not been empirically confirmed. The case study provided here gives an example of blood level monitoring.

A 74-year-old man was admitted to the hospital with severe depression. Irritability was prominent. Desipramine was started but on 150 mg/day he had no response whatsoever. He was adherent to treatment. Some of his symptoms seemed atypical and diagnosis was questioned. A blood sample revealed a very low drug concentration. In fact the level suggested that if kinetics were linear, he would need a dose of 900 mg/day to achieve a therapeutic level. On 400 mg/day, the approved maximum dose, his level was still subtherapeutic. On 600 mg his level rose disproportionately, he achieved an adequate level, and responded. The case illustrates several issues. Blood levels can be useful for guiding dose adjustment in nonresponding patients. The extremely low plasma concentration on a conventional dose

suggested he might be an ultrafast metabolizer. Nonlinear kinetics are most likely to occur in fast metabolizers. Ironically, this 74-year-old man had the lowest concentration to dose ratio that these physicians had encountered in treating over 400 patients with desipramine.

The alternative question is whether blood level monitoring might help avoid toxicity. A variety of data support this view. The risk of delirium is substantially increased at amitriptyline plasma concentrations greater than 450 ng/mL and moderately increased at levels greater than 300 ng/mL. However, amitriptyline is the most anticholinergic tricyclic and is most likely to produce delirium. The risk of cardiac arrhythmia also is substantially increased at higher blood levels. First-degree atrioventricular block is increased with plasma concentrations of imipramine greater than 350 ng/mL and substantially increased at plasma concentrations greater than 450 ng/mL. The risk of seizures also increases in patients at higher doses and, presumably, higher blood levels, although a clear plasma level threshold has not been demonstrated for seizures. The risk of seizures for clomipramine is 1.66 percent with doses greater than 250 mg/day but is approximately 0.50 percent for doses less than or equal to 250 mg/day. In one large sample of patients with OCD at steady state on 250 mg/day of clomipramine, the average blood level was 155 ng/mL for clomipramine and 335 ng/mL for desmethylclomipramine, or a total of 490 ng/mL. For the older drugs, amitriptyline and imipramine, the risk of seizures also appears to be increased at doses greater than 250 mg/day. For patients who are especially vulnerable to delirium, delayed cardiac conduction, or seizures, adverse events can occur at levels below those cited above. After overdose, tricyclic blood levels greater than 1,000 ng/mL can be achieved, and the risks of delirium, stupor, cardiac abnormalities, and seizures are all substantially increased.

One of the problems in appreciating the relationship of toxicity to increased blood levels is that, although the risk may increase, actual rates are still low, and large samples are required to demonstrate any difference in risk. For certain types of toxicity, for example, delirium, there may be early warning signs, and the dose can be reduced unless the symptoms of delirium are mistaken for symptoms of the underlying psychiatric disorder. Alternatively, there may be no early signs of impending seizures or cardiac arrhythmia to alert the clinician to reduce the dose. Blood level monitoring might be most useful to reduce the risk of these particular side effects.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design

Early in the history of antidepressant studies relatively high rates of response to placebo were noted. As a consequence, open-label studies proved to be of limited value. Because of side effects, the tricyclics were started at low dose and then increased slowly. This tended to result in

inadequate dosing. Subsequently blood levels were employed to improve dosing adequacy; however, determination of effective blood levels itself proved challenging. Some early studies were quite brief (e.g., 3 to 4 weeks) and may have underestimated drug effects. Alternatively, many of the early studies were conducted in inpatients, in which drug–placebo differences were greater. As experience with the tricyclics grew, subtypes of depression were identified that were associated with greater or reduced response.

Interpretation

The clinical efficacy of the tricyclic and tetracyclic compounds in major depression is well established and has been extensively reviewed by John Davis and Alexander Glassman in the fifth edition of this text and in the Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guideline. Imipramine is the best-studied compound. In 44 placebo-controlled studies, imipramine was more effective than placebo in 30 studies. Overall, in studies reporting response rates (N = 1,334), 65 percent of the patients *completing* treatment with imipramine were substantially improved, whereas 30 percent of those on placebo were similarly improved. In a meta-analysis of *intent-to-treat* response rates for placebo-controlled studies of tricyclics in outpatients reported in the AHCPR guideline, response rates were 51 percent for imipramine and 30 percent for placebo. In most comparison studies, the other tricyclic and tetracyclic antidepressants have been found to be comparable to imipramine in efficacy.

In addition to efficacy in acute depression, the tricyclic compounds are also effective for maintenance treatment. Several early studies demonstrated that maintenance treatment with a tricyclic would reduce the relapse rate associated with placebo by approximately 50 percent. These studies, however, often used low doses. Subsequently, an important study by the Pittsburgh group found that, if the full dose of imipramine used for acute treatment was continued, nearly 80 percent of the depressed patients maintained their improvement, whereas only 10 percent of those on placebo remained well at the end of a 3-year period. In this study, maintenance psychotherapy had an intermediate effect, with approximately 30 percent of the patients remaining well. This study again confirmed the value of maintenance treatment and underscored the importance of continuing the full dose of imipramine. The magnitude of the findings may, in part, relate to the sample selected; namely, patients with recurrent depression who had been symptom free between prior episodes. In clinical practice, if patients with chronic depression, prior residual symptoms, or comorbid psychiatric disorders are included, the number of patients who remain in remission may be lower.

Efficacy in Subtypes

The efficacy of the tricyclic compounds varies in different subtypes of depression. Kuhn thought it was essential to establish the efficacy of imipramine in *endogenous* inpatients. The tricyclic compounds have been frequently studied in severely depressed inpatients and were found to be effective. It has been suggested that the tricyclics may be more effective than the SSRIs in severe major depressive disorders with melancholic features. The issue remains unsettled, in part, because of the paucity of studies of the SSRIs in severe melancholic depression. In addition, it was unclear if the suggested advantage of some tricyclics in severe depression was unique to tricyclics as a class or applied to those tricyclics, particularly clomipramine, that had potent effects on both serotonin and norepinephrine.

The tricyclic and tetracyclic compounds have often been studied in anxious depression. Three of the compounds—doxepin, amoxapine, and maprotiline—have FDA approval for use in patients with depression and symptoms of anxiety. For many years, clinical lore suggested that amitriptyline was most effective for anxious depression. Direct comparison studies, however, found little evidence that these compounds differ in their efficacy for treatment of anxiety associated with depression. Alternatively three studies found that, among depressed patients, those with high levels of anxiety responded less well to amitriptyline, imipramine, or desipramine than those with lower levels of anxiety. Yet, these drugs are still more effective than placebo in anxious-depressed patients, and it is not established that other classes of antidepressants are more effective in anxious-depressed patients.

In patients with atypical features (defined by DSM-IV criteria), imipramine is more effective than placebo but significantly less effective than the MAOI phenelzine. Little information is available regarding comparisons of the tricyclics and the SSRIs in atypical depression.

Major depression with psychotic features is less responsive than nonpsychotic depression to tricyclic antidepressants used alone. Several open studies and one prospective study found that the tricyclics, when combined with an antipsychotic, were effective in psychotic depression. Yet other trials did not find an antidepressant/antipsychotic combination more effective than nortriptyline, imipramine, or trimipramine monotherapy. One double-blind study compared the efficacy of amoxapine with the combination of perphenazine (Trilafon) and amitriptyline, finding amoxapine to have comparable efficacy in psychotic depression. It was suggested that the antipsychotic action of 7-hydroxyamoxapine might explain the efficacy of this compound in psychotic depression.

In controlled studies of patients with bipolar depression, imipramine was found to be less effective than tranylcypromine (Parnate) or fluoxetine (Prozac). These studies and others suggest that the tricyclics appear to be more likely to induce mania than the serotonergic agents or bupropion

(Wellbutrin).

In the AHCPR review of drug trials in late-life depression, tricyclic antidepressants appear to be effective, but, overall, drug and placebo response rates appear to be lower than in nonelderly patients. Efficacy in the elderly may have, in part, reflected cautious dosing because of safety and tolerance concerns. In children and adolescents, the tricyclic antidepressants have not demonstrated superiority over placebo. Recently, an FDA review of clinical trials of second-generation antidepressants revealed an increased risk of suicidal thinking and suicide-related behaviors in children, adolescents, and young adults under the age of 25. Although this risk has not been established for the tricyclics, the warning has been extended to all antidepressants.

The tricyclic antidepressants are effective in dysthymia. Controlled trials suggest both imipramine and desipramine are effective for acute treatment of dysthymia and for maintenance treatment.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Somatic symptoms that occur during treatment are the final result of the interaction of direct effects of the medication on specific organs and indirect effects of the medication on depression and its associated somatic symptoms. Depression is accompanied by a variety of somatic symptoms. Headache, constipation, poor memory, drowsiness, and difficulty sitting still have been observed in more than 50 percent of untreated inpatients with major depression. Other symptoms, such as palpitations, dry mouth, tremors, light-headedness, and poor coordination, are reported by more than 40 percent of depressed patients before treatment. The determination of whether a somatic symptom is an adverse drug effect or a symptom of depression involves a judgment about whether the symptom is new or has worsened during drug treatment. Severely depressed patients may not remember accurately the severity of a symptom prior to treatment. During treatment, the strongest predictor of overall somatic symptom severity is the level of depression at the time of assessment.

Antidepressant drugs do have adverse effects. The in vitro potency or affinity of antidepressant compounds for various receptor sites (Table 34.33–1) is one method for comparing the likelihood that various agents will produce side effects. The other pharmacological factor that needs to be considered is the bioavailability of the drug.

Central Nervous System

In the CNS, the principal action of the tricyclic and tetracyclic agents is to alleviate depression. These agents do not have a direct mood-elevating effect. They do not produce euphoria. Rather, they reduce the symptoms of depression. Apparently related to their effects on brain amines, these

compounds can cause or aggravate psychotic symptoms and can induce mania.

The central anticholinergic and antihistaminic effects of the tricyclics and tetracyclics can produce confusion or delirium. The incidence of delirium is dose dependent and increases at blood levels greater than 300 ng/mL and may rise to 67 percent in patients with blood levels greater than 450 ng/mL and in patients receiving the tertiary amines, particularly amitriptyline. Patients with dementia or early Alzheimer disease are more vulnerable to the anticholinergic effects of the tricyclics, and delirium can occur in these patients at lower drug concentrations.

Seizures can occur with all of the tricyclic and tetracyclic agents. Seizures are dose- and blood-level related. For clomipramine, the risk for seizures is reported to be 0.5 percent in doses up to 250 mg/day. At doses greater than 250 mg/day, the seizure risk increases to 1.67 percent. For maprotiline, the overall risk of seizures is reported to be 0.4 percent, but, again, the risk of seizures increases at doses greater than the maximum recommended dose of 225 mg/day. Determination of seizure risk for some of the older compounds was hampered by less rigorous data collection at the time of marketing. In one meta-analysis of data for imipramine, patients receiving less than 200 mg had a seizure rate of 0.1 percent. In patients receiving more than 200 mg/day, the rate was 0.6 percent. In patients receiving 250 to 450 mg/day, reported rates varied from 1 to 4 percent, but these samples were often small, thus, these rates had wide confidence intervals. Seizure rates for the secondary amines have not been well described. The mechanism by which tricyclics produce seizures is not well understood, although it is proposed that antidepressant drugs may act at the GABA receptor chloride–ionophore complex, inhibiting chloride conductance and consequently inducing convulsions. The risk of convulsions is clearly increased in patients with predisposing factors, including a prior history of seizures, brain injury, and concurrent use of neuroleptics. The risk of seizures is substantially increased after overdose.

A fine rapid tremor can occur with the tricyclic agents, tends to be dose dependent, and may be a clinical indication of an elevated blood level. Because the 7-hydroxymetabolite of amoxapine has neuroleptic properties, administration of amoxapine carries the potential risk of neuroleptic malignant syndrome, which has been reported, and tardive dyskinesia.

A 73-year-old male was referred for evaluation of his antidepressant. He had had a good response to desipramine but it had taken some time to achieve it. He now had a fine rapid tremor that was quite bothersome. Both the patient and his physician were concerned that reducing the dose would compromise antidepressant efficacy. A blood sample revealed a desipramine concentration over 300 ng/mL. His dose was adjusted to achieve a level of about 150 ng/mL. His tremor resolved but the antidepressant effect was maintained.

Several of the tricyclic compounds and maprotiline have clinically

significant antihistaminic effects. Doxepin is the most potent H_1-receptor blocker of the tricyclics, although mirtazapine and olanzapine are more potent. Central H_1-receptor blockade can contribute to sedation and delirium. Antihistaminic effects also appear to be related to the increased appetite and associated weight gain.

Autonomic Nervous System

The tricyclics block muscarinic receptors and can cause a variety of anticholinergic side effects. These include dry mouth, constipation, blurred vision, urinary hesitancy, and an ocular crisis in patients with narrow-angle glaucoma. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (Table 34.33–2). Amitriptyline is the most potent, followed by clomipramine. Desipramine is the least anticholinergic. Amoxapine and maprotiline also have minimal anticholinergic effects. Anticholinergic effects can contribute to tachycardia, but tachycardia commonly occurs in patients receiving desipramine, which has minimal anticholinergic effects. It seems likely that noradrenergic effects also contribute to increased pulse. Increased sweating is another secondary effect of the tricyclic compounds that can occur. The mechanism for this symptom is unclear but may be associated with noradrenergic effects.

Cardiovascular Effects

Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment. Orthostatic hypotension can occur with all of the tricyclics but is less pronounced with nortriptyline. It has been suggested that orthostatic hypotension is caused by α_1-adrenergic blockade; however, it is the postural reflex that is primarily affected. Resting supine blood pressure may be unaffected or may be raised. Orthostatic hypotension is most likely to occur or is most severe in patients who have pre-existing orthostatic hypotension.

Desipramine has been reported to raise supine blood pressure in younger patients, although it is not clear that this effect is limited to that age group. This effect may be similar to that reported for venlafaxine (Effexor).

Tachycardia occurs with all the tricyclics, not just the more anticholinergic agents. Supine and postural pulse changes can occur. Patients do not accommodate to the pulse rise, which can persist for months. Tachycardia is more prominent in younger patients, who appear to be more sensitive to sympathomimetic effects, and is one of the most common reasons for drug discontinuation in this age group.

The exploration of the effect of tricyclic antidepressants on cardiac conduction has received much attention. *Cardiac arrhythmia* is the principal cause of death after overdose. As a result, for many years, there

was great concern about the use of tricyclic antidepressants in patients with heart disease. The effect of these agents has now been well described. These agents have type I antiarrhythmic qualities or quinidine (Cardioquin)-like effects. Apparently, through inhibition of Na^+:K^+ adenosine triphosphatase (ATPase), the tricyclics stabilize electrically excitable membranes and delay conduction, particularly His-ventricular conduction.

At therapeutic blood levels, the tricyclics can have beneficial effects on ventricular excitability. Alternatively, in patients with pre-existing conduction delay, the tricyclic antidepressants can further delay conduction and cause heart block. High drug plasma levels further increase the risk of cardiac toxicity. For example, first-degree atrioventricular heart block is increased with imipramine plasma concentrations greater than 350 ng/mL and is increased more than 30-fold in patients with plasma concentrations greater than 450 ng/mL.

The tricyclic antidepressants do not appear to adversely affect cardiac contractility or cardiac output. Studies using radionuclide angiography indicate no adverse effect of imipramine or doxepin on cardiac output, even in patients with diminished left ventricular ejection fractions. However, it is noted that severe orthostatic hypotension was common in these patients.

Another potential hazard of tricyclic treatment was suggested by the Cardiac Arrhythmia Suppression Trial (CAST) studies, which found that type I antiarrhythmic drugs given after myocardial infarction actually increased the risk of sudden death. Alexander Glassman and associates suggested that the tricyclics may pose similar risks. Thus, the clinician considering long-term use of the tricyclics in patients with ischemic heart disease needs to weigh this possible risk against possible benefits.

Hepatic Effects

Drug-induced hepatitis can occur with these agents. Mild increases of liver enzymes are not uncommon and usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, acute hepatitis can occur quickly and is associated with high enzyme levels, for example, serum aspartate aminotransferase (AST) levels may be elevated 20-fold. The rise in enzymes can be hepatocellular or cholestatic in form and may precede clinical symptoms, especially in the hepatocellular form. This is a dangerous and potentially fatal condition. The antidepressant must be discontinued. The etiology is not well established but, in some cases, appears to be a hypersensitivity reaction. The risk of severe drug-induced hepatitis is not well established but appears to be between 1 in 1,000 and 1 in 100.

THERAPEUTIC INDICATIONS

Indications

The tricyclic and tetracyclic compounds have a variety of clinical uses. In fact, it is interesting to consider what these agents might have been called had their effectiveness in panic disorder, OCD, pain, or other syndrome been described before their antidepressant action was observed.

The FDA approved all of the tricyclic and tetracyclic compounds discussed in this section for use in the United States for the treatment of depression, with the exception of clomipramine. In Europe, clomipramine is also used for depression and, in fact, is regarded by many as the most potent antidepressant. Clomipramine acts on serotonin and norepinephrine, and the empirical data suggest that it is more effective than selective serotonin agents in severely depressed inpatients.

Although a variety of antidepressants appear to be effective in depressive disorders, this is not the case for OCD. In this instance, the serotonergic antidepressants, such as clomipramine, appear to be substantially more effective than noradrenergic tricyclics, such as desipramine. Among the tricyclic drugs, clomipramine is the only agent approved by the FDA for use in OCD.

Other Indications

The tricyclic agents have been used for a variety of other clinical indications without FDA approval. The tricyclic antidepressants are effective in panic disorder; in fact, imipramine was the first drug found to be effective in these patients.

Amitriptyline has been a popular drug for treatment of chronic pain syndromes and migraine headache prophylaxis. Over 60 placebo-controlled clinical trials of tricyclics or tetracyclics have been conducted in various chronic pain syndromes including headache, back pain, fibromyalgia, gastrointestinal discomfort, idiopathic pain, and tinnitus. In fact, the magnitude of their effects in chronic pain appears greater than that in depression. For example, in pain studies the average drug–placebo difference in response rates was 32 percent. The analgesic effects appeared, at least in part, to be independent of antidepressant effects. In humans, comparison studies suggested tricyclics with effects on both serotonin and norepinephrine were more effective than agents selective for one neurotransmitter. During treatment of pain, the usual dose of amitriptyline is lower (e.g., 75 mg/day) than that in depression, and effects occur more quickly, usually within the first 2 weeks. These differences suggest a different mode of action of amitriptyline in pain syndromes. The tricyclics appear to be of some benefit in chronic fatigue syndrome.

For many years, desipramine was commonly prescribed for ADHD in children. Reports of cases of sudden death, apparently of cardiac origin, in children younger than 12 years of age substantially reduced the use of this drug in younger patients. Imipramine has been used with FDA approval for treatment of nocturnal enuresis in children. Usual doses are 25 to 50 mg at

bedtime. It is doubtful, however, that the risk of cardiac problems would be substantially less with imipramine than with desipramine in young children.

Nortriptyline has been shown to be helpful for smoking cessation in controlled studies, but it is not approved for use in this syndrome nor has it been actively marketed for this condition.

Taking advantage of its anti-histaminic effects, topical doxepin (Zonalon) is FDA approved for use in pruritus associated with atopic dermatitis and lichen simplex chronicus. Doxepin (Silenor) is approved for use in insomnia at doses of 3 or 6 mg/day.

Tricyclic antidepressant drugs have been extensively studied in schizophrenic patients. However, in the absence of a major depressive syndrome, they appear to be of limited value, and their use for treatment of negative symptoms has been eclipsed by the introduction of the atypical neuroleptics.

PRECAUTIONS AND ADVERSE REACTIONS

Central Nervous System Effects

The central effects of the tricyclics can produce delirium and seizures. Both of these adverse effects are dose dependent and become more frequent at elevated blood levels. The incidence of delirium increases at blood levels greater than 300 ng/mL and becomes common in levels greater than 450 ng/mL, especially with amitriptyline. The clinician should be aware of this possibility because the signs of delirium may be mistaken for a worsening of the depression. This diagnostic dilemma can be especially problematic in patients with psychotic depression. Patients with concurrent dementia are particularly vulnerable to the development of delirium. Intramuscular (IM) or intravenous (IV) physostigmine (Eserine Salicylate) can be used to reverse or to reduce the symptoms of delirium. However, the short duration of action of this agent makes its continued use difficult.

Because delirium and seizures are dose- and blood-level dependent, the first goal is to reduce the risk by avoiding unnecessarily high serum concentrations. Some experts advocate routine blood level monitoring. This question continues to be debated. A strong case can be made for blood level monitoring in patients at increased risk, for example, the elderly, patients with dementia, or patients with a history of seizures. Blood levels can also be helpful in patients who fail conventional doses to determine that high doses are required to reach therapeutic levels.

The tricyclic antidepressants can cause a fine rapid tremor. This particular adverse event is often associated with elevated plasma concentrations and may improve with dose reduction.

Because the 7-hydroxymetabolite of amoxapine has neuroleptic effects, this agent can potentially cause tardive dyskinesia and neuroleptic

malignant syndrome. Although the occurrence of these adverse events is rare, the seriousness of the risk serves as a relative contraindication to this product, unless the clinical condition warrants the use of an agent with antipsychotic properties.

Autonomic Effects

The tricyclics can cause a variety of anticholinergic side effects, including dry mouth, constipation, visual changes, urinary hesitancy, delirium, and an ocular crisis in patients with narrow-angle glaucoma. Use of nortriptyline or desipramine, which is less anticholinergic, can help reduce the likelihood of these problems.

Usually, anticholinergic effects are annoying but not serious. In some circumstances, however, these effects can be severe. An ocular crisis in patients with narrow-angle glaucoma is an acute condition associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Paralytic ileus has been described but is rare.) Medication must be discontinued, and appropriate supportive measures must be instituted. Elderly patients appear most vulnerable to this adverse consequence. The frequency of severe anticholinergic adverse reactions is increased by concomitant neuroleptic administration.

Some anticholinergic effects may benefit from other interventions. Patients with urinary hesitancy may benefit from the use of bethanechol (Urecholine) at a dose of 25 mg three or four times daily. Patients with constipation often benefit from regular use of stool softeners. Patients with narrow-angle glaucoma, who are receiving pilocarpine (Pilocar) eye drops regularly, can be treated with a tricyclic, as can those who have had an iridectomy. Tricyclic agents do not affect patients with chronic open-angle glaucoma.

Cardiovascular Effects

Orthostatic hypotension is the most common reason for discontinuation of tricyclic antidepressant treatment. It is most likely to be problematic in patients with pre-existing orthostatic hypotension. The elderly are more likely to have pre-existing hypotension and are also more vulnerable to the consequences of orthostatic hypotension—falls and hip fractures. Orthostatic hypotension can occur at blood levels that are relatively low. Although the subjective experience of light-headedness usually improves with time, the actual orthostatic blood pressure change does not accommodate within a reasonable period of time (e.g., 4 weeks). As a consequence, unless the plasma level is elevated and the dose can be reduced, patients who experience serious symptomatic orthostatic hypotension may not be treatable with a tricyclic antidepressant.

Fludrocortisone (Florinef) has been used to raise blood pressure, but it is not very effective. If patients are taking an antihypertensive, it may be possible and helpful to reduce these agents. Orthostatic hypotension is less common with nortriptyline.

Tachycardia occurs with all the tricyclics, not just the more anticholinergic agents. The supine pulse rate commonly increases 8 to 10 beats/min. The standing pulse can be markedly elevated. Patients do not accommodate to the pulse rise, which can persist for months. Although an 8 to 10 beat/min increase in heart rate may be subjectively tolerated by the patient, in the elderly, a sustained increase in cardiac work can be detrimental. Tachycardia is more prominent in younger patients, who appear to be more sensitive to the sympathomimetic effects of these agents, and is one of the most common reasons for drug discontinuation in this age group. Propranolol (Inderal) at low doses may help to reduce the tachycardia, unless it is associated with significant hypotension.

Cardiac Conduction Effects

The tricyclic antidepressants have type I antiarrhythmic effects. In patients without conduction delay, the tricyclics are well tolerated. They may be helpful in patients with premature ventricular beats. However, in patients with pre-existing conduction delay, the tricyclic antidepressants can further delay conduction and can cause heart block. Patients with a QTc interval of 450 msec or greater are at increased risk and are not candidates for tricyclic antidepressant treatment. The risk of cardiac toxicity is increased in patients with high plasma levels. For example, first-degree atrioventricular heart block is increased with imipramine plasma concentrations greater than 350 ng/mL and is increased more than 30-fold in patients with plasma concentrations greater than 450 ng/mL.

Hepatic Effects

Mild increases of liver enzymes usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, acute hepatitis develops quickly, over 3 to 4 days, and is associated with high enzyme levels, for example, a 20-fold increase in AST levels. This can be life-threatening, and the antidepressant must be discontinued. If it is clear which drug caused the hepatitis, that drug should not be introduced again, because the next reaction may be more severe. However, it is not uncommon for the patients to be receiving several medications, so that the offending agent is hard to identify. If a random blood test indicates mildly elevated liver enzymes, enzyme levels can be followed for a few days to distinguish the more severe form of hepatitis from mild enzyme elevations.

Other Adverse Effects

Sexual dysfunction is a potential problem with a variety of antidepressant drugs but appears to be more frequent with clomipramine. Unlike many of the side effects that are more likely to be reported early in treatment, this side effect may be more bothersome to the patient in the second or third month of treatment after the depression has improved. Numerous pharmacological antidotes have been described but without much success.

Tricyclic antidepressants can cause allergic skin rashes. They are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported, but fortunately, these are very rare.

Overdose

Because the risk of overdose is increased in depressed patients, the target population for which antidepressants are used and the lethality of antidepressant drugs in overdose is of great concern. A tricyclic overdose of 10 times the daily dose can be fatal. Death most commonly occurs as a result of cardiac toxicity. However, seizures and CNS depression can occur. Amitriptyline is one of the leading causes of death by overdose for any single drug in the United States. A five year study (2000 to 2004) of single drug ingestions found more deaths from amitriptyline than all other TCAs combined and it accounted for 80 percent of fatalities from all antidepressant overdoses. The other tricyclic and tetracyclic compounds are also dangerous in overdose even if their use has diminished. Desipramine has the highest fatality rate (deaths per ingestions) among the tricyclics. Amoxapine has been reported to produce high rates of seizure in overdose. Because the second-generation antidepressants are safer in overdose, subtle differences in lethality between the tricyclic and heterocyclic compounds have become relatively unimportant.

Teratogenicity and Pregnancy-Related Risks

A definitive link between the tricyclic compounds and tetracyclic compounds, and teratogenic effects has not been established, although isolated reports of morphogenesis have been reported. Tricyclics cross the placenta and neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week before delivery. Recently, norepinephrine and serotonin transporters have been identified in the placenta and appear to play an important role in the clearance of these amines in the fetus. The understanding of the effects of reuptake inhibitors on these transporters during pregnancy is limited, but one study compared intelligence and language development in 80 children exposed to tricyclics during pregnancy with 84 children exposed to other nonteratogenic agents and found no deleterious effects of the tricyclics. The tricyclics are excreted in breast milk at concentrations similar to plasma.

The actual quantity delivered, however, is small so that drug levels in the infant are usually undetectable or very low. Because the risk of relapse is a serious concern in patients with recurrent depression, and these risks may be increased during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

DRUG INTERACTIONS

There are two principal types of drug interactions: pharmacodynamic and pharmacokinetic. Pharmacodynamic interactions are those in which the actions of two drugs interact. The effects may be deleterious. Because the tricyclics have acute effects on amine uptake, they are potentially dangerous when given with the MAOIs. The most dangerous sequence is to give a large dose of a tricyclic to a patient already on an MAOI. This can result in a sudden increase in catecholamines and a potentially fatal hypertensive reaction. If used cautiously, these two compounds can be used together to treat patients with refractory depression. Treatment is begun with lower doses, and the two compounds are started together, or the tricyclic is started first. Once begun, coadministration may reduce the risk of tyramine reactions; however, because the protective effect is variable and unpredictable, the usual MAOI diet is maintained.

Other pharmacodynamic interactions can occur. By blocking the transporters, the tricyclics block the uptake and thus interfere with the action of guanethidine (Ismelin). Quinidine poses two problems. First, the tricyclics have quinidine-like effects, thus, their effects on cardiac conduction are potentially additive with those of quinidine. In addition, quinidine is a potent enzyme inhibitor that can raise tricyclic levels, further adding to the problem.

Pharmacokinetic Interactions

A number of drugs can block the metabolic pathways of the tricyclics, resulting in higher and potentially toxic levels. Desipramine has been of particular interest, because its metabolism is fairly simple via the CYP 2D6 isoenzyme. Because there are no major alternative pathways, inhibition of CYP 2D6 can result in high desipramine plasma levels. Quinidine, mentioned previously, is a potent CYP 2D6 inhibitor. Several psychotropic drugs are 2D6 inhibitors including fluoxetine, paroxetine (Paxil), duloxetine (Cymbalta), and bupropion. For example, fluoxetine 20 mg/day, on average, raises desipramine levels three- to fourfold in extensive metabolizers. In slow metabolizers, enzyme inhibitors have less of an effect, because the patient is already deficient in this enzyme. At moderate doses sertraline (Zoloft), citalopram (Celexa), and escitalopram (Lexapro) have less potent effects on CYP 2D6 but at high doses may have appreciable

effects in some patients. Venlafaxine, nefazodone (Serzone), and mirtazapine appear to have minimal effects on CYP 2D6. It would be expected that CYP 2D6 inhibitors would also block nortriptyline metabolism, but the magnitude of this interaction has not been well studied.

The other group of drugs commonly used in psychiatry, which interact with the tricyclics, is the antipsychotic drugs. Chlorpromazine and perphenazine, at antipsychotic doses, inhibit CYP 2D6. The magnitude of the effect appears to be somewhat less than that of fluoxetine. For example, perphenazine, on average, raises desipramine levels twofold, but this effect varies with dose and varies with the neuroleptic used.

Because the tertiary tricyclics are metabolized by several pathways (CYP 1A2, CYP 3A4, and CYP 2C19), inhibition of one of these pathway has less of an effect on these compounds. Drug interactions with the tertiary amines do occur but appear to be less robust than that for desipramine.

Enzyme induction also occurs. Unlike enzyme inhibition, which occurs quickly, enzyme induction requires synthesis of new enzyme. As a result, the full effect of an enzyme inducer may take 2 to 3 weeks to develop and, similarly, if the inducer is discontinued, takes 2 to 3 weeks to dissipate. Barbiturates and carbamazepine (Tegretol) are two potent inducers commonly encountered in psychiatry. Although CYP 2D6 is a noninducible isoenzyme, phenobarbital (Barbita) reduces the availability of desipramine by approximately 40 percent. Apparently, CYP 3A4 is induced, becomes a more important pathway, and metabolism of desipramine is increased. It can be difficult to attain an effective blood level with a tricyclic in the presence of barbiturates or carbamazepine. Phenytoin (Dilantin) is also an enzyme inducer, but the magnitude of its effects on the tricyclics appears to be less dramatic. Nicotine induces the CYP 1A2 pathway and may affect the tertiary tricyclics, but the secondary tricyclics, such as desipramine, are less affected.

Alcohol has a complicated interaction with the tricyclics. Acute ingestion of alcohol can reduce first-pass metabolism, resulting in higher tricyclic levels. Because of the association of alcohol use with overdose, this can be an important factor resulting in higher tricyclic levels after overdose. Alternatively, chronic use of alcohol induces hepatic isoenzymes and may lower tricyclic levels.

Although most of the known drug–drug interactions have focused on interactions involving the CYP450 system, there is a growing body of literature examining the role of P-glycoproteins (P-gp) in drug interactions. P-gp play an active role at the blood–brain barrier in the efflux of some drugs from the CNS. Several of the tricyclics—amitriptyline, desipramine, doxepin, imipramine, nortriptyline, and trimipramine—are P-gp substrates. Drugs such as verapamil and quinidine inhibit P-gp, potentially leading to increased CNS concentrations of P-gp substrates. Some

antidepressants such as sertraline and paroxetine are also P-gp inhibitors. The clinical consequences of these potential interactions in humans are not well established. Polymorphisms of the ABCB1 gene that encodes P-gp have been associated with differences in response to antidepressants that are P-gp substrates suggesting that changes in P-gp activity are clinically relevant.

LABORATORY INTERFERENCES

The tricyclic compounds are present at low concentrations (ng/mL) and are not likely to interfere with other laboratory assays. It is possible that they may interfere with the determination of conventional neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptics.

Two types of assays are performed for the tricyclic and tetracyclic antidepressants. After overdose, an immunoassay is commonly performed to determine if a tricyclic is present and to estimate the level. This assay is sensitive, simple to perform, and can be done quickly. The immune assays, however, are not specific, can cross-react with metabolites and other drugs, and thus are not precise quantitative measures. For therapeutic drug monitoring, a quantitative measure is needed and a slower turnaround time for the laboratory is usually acceptable. For this purpose, high-performance liquid chromatography (HPLC) is sufficiently precise and is usually employed. In a competent laboratory, the coefficient of variation is less than 10 percent. This assay is relatively specific; however, other drugs can interfere. Because there are many modifications of the HPLC technique, and because the drugs that interfere depend on these modifications (the extraction method, the column used), the interfering drugs vary by site. A clinician who frequently obtains tricyclic plasma levels is best advised to use one laboratory and to find out from that laboratory what agents interfere with his or her assay.

DOSAGE AND ADMINISTRATION

At one time, amitriptyline and imipramine were the two most commonly prescribed antidepressants in the United States, but because of their anticholinergic and antihistaminic side effects, their use declined and nortriptyline and desipramine became more popular. Nortriptyline has the least effect on orthostatic hypotension, and desipramine is the least anticholinergic. Because therapeutic plasma concentrations have been established for nortriptyline and desipramine, blood level monitoring can be used to ensure that a therapeutic level is achieved.

Most studies of nortriptyline find that an average dose needed to reach a blood level of 100 ng/mL is approximately 75 mg/day; however, there is considerable variability. For desipramine, the average dose required to reach a target level of 150 ng/mL is 3.0 mg/kg or 180 mg/day for a 60-kg

patient. Nortriptyline and desipramine can be adjusted to a full dose quickly, but the clinician needs to assess factors such as medical health, age, other medications present, and the severity of the depression, when deciding how quickly to adjust dose. The dose can be given once a day at bedtime and if tolerated, can be increased every 3 days. The target dose can then be determined in one of two ways. An average dose can be targeted (e.g., nortriptyline 75 mg/day) and blood levels employed only if the patient fails to respond. Alternatively a blood level can be drawn after 5 to 7 days on a moderate dose, 50 to 75 mg/day, and used to guide further dose adjustment for the trial. Because the kinetics of nortriptyline are linear, a proportional adjustment in dose can be made to reach a target level of 100 ng/mL. The advantage of the latter method is that one drug trial at an adequate blood level should establish if the drug is effective. Because nortriptyline has a therapeutic window, if the plasma level is near the upper limit of 150 ng/mL, a reduction in dose could be considered. Desipramine dose can also be adjusted relatively proportionately, with the exception that patients with low initial plasma levels (rapid metabolizers) are likely to have nonlinear changes. Plasma concentration–guided dose adjustment should reduce the time to achieve an effective dose (as opposed to a series of trials at gradually increasing doses) and should be of benefit in severe depression. Once the patient is at an adequate dose, treatment should then be continued for an adequate duration. At the time of the initial clinical trials of the tricyclics, trial duration was often short, 4 to 6 weeks. Recently, trials of up to 12 weeks have been advocated to achieve remission. Although it was suggested that tricyclics were more rapid acting than the SSRIs, this has not been confirmed. A 12-week comparison trial of nortriptyline and sertraline in late-life depression found no difference in the timing of response. A retrospective analysis of that data concluded that for both drug classes, a 12-week trial was useful to achieve remission, but that patients showing minimal improvement after 4 to 6 weeks were not likely to remit and other treatments should be considered. Doses and therapeutic plasma concentrations for other tricyclic and tetracyclic compounds are shown in Table 34.33–1.

If patients experience side effects, this approach may be altered. If patients on desipramine report insomnia, the dose can be given early in the day. Sedation and anticholinergic effects may diminish with time, and gradual dose adjustment may help manage these effects. Although subjective light-headedness may improve with time, blood pressure and pulse changes do not usually accommodate during the first 4 weeks, and gradual dosing does not help avoid these effects. In patients at high risk for side effects, the dose can be increased gradually to assess tolerance. If anticholinergic side effects occur, allowing more time between dose increases allows the patient to accommodate to these side effects.

Table 34.33–3.
Tricyclic and Tetracyclic Drug Preparations

Drug	Tablets	Capsules	Parenteral	Solution
Imipramine (Tofranil)	10, 25, and 50 mg	75, 100, 125, and 150 mg	12.5 mg/mL	—
Desipramine (Norpramin, Pertofrane)	10, 25, 50, 75, 100, and 150 mg	—	—	—
Trimipramine (Surmontil)	—	25, 50, and 100 mg	—	—
Amitriptyline (Elavil)	10, 25, 50, 75, 100, and 150 mg	—	10 mg/mL	—
Nortriptyline (Aventyl, Pamelor)	—	10, 25, 50, and 75 mg	—	10 mg/5 mL
Protriptyline (Vivactil)	5 and 10 mg	—	—	—
Amoxapine (Asendin)	25, 50, 100, and 150 mg	—	—	—
Doxepin (Sinequan)[a] (Silenor)	— 3, 6 mg	10, 25, 50, 75, 100, and 150 mg	—	10 mg/mL
Maprotiline (Ludiomil)	25, 50, and 75 mg	—	—	—
Clomipramine (Anafranil)	—	25, 50, and 75 mg	—	—

[a]Doxepin (Zonalon) is supplied as a 5% cream (30 g or 45 g).

Prospective Dosing Techniques

Conventional dosing requires administration of a given dose for a long enough period of time to determine if that dose is effective. Sometimes two or even three trials are needed to determine the effective dose. Once therapeutic blood levels were established for the tricyclics, methods were described for rapid dose adjustment to achieve an effective drug concentration quickly. Various methods were reported. They all involved obtaining one or more blood samples after an initial test dose from which a therapeutic dose could be estimated. Once the therapeutic dose of nortriptyline or desipramine was determined, the full dose could be given the next day. Prospective dosing methods were also reported for amitriptyline and imipramine; however, sedation and anticholinergic side effects limited rapid dose escalation of these drugs. Rapid prospective dosing methods are limited, however, by laboratory capability. The laboratory performing the assay must be prepared to determine drug concentrations accurately at low levels (below the therapeutic range) and must be able to report results quickly. Most laboratories are not prepared to do either. A more practical and clinically feasible method is to start the patient on a low, moderate, fixed dose, obtain a blood sample after 5 to 7 days on that dose, and then make further adjustments based on that level.

Exceptions

In elderly depressed patients, gradual dosing may be required to assess tolerance, but studies of desipramine and nortriptyline indicate that the final doses and blood levels required for response will be similar to those needed in younger patients.

In panic patients, lower starting doses are used, and dose is increased slowly to avoid exacerbation of panic attacks. In OCD, higher doses of clomipramine are used than those used in depression. In part, this is because OCD responds more slowly and less completely than depression and, thus, the dose is raised to ensure that the most effective treatment has been given.

If amitriptyline is used for pain, lower doses (e.g., 75 mg/day) are used. When effective, the action of the drug is observed within the first 2 weeks.

If doxepin is used for sleep, doses lower than those in depression are used, for example, 3 to 6 mg/day.

At this time, it is not clear when the tricyclic antidepressants would be used in children. It is recommended that desipramine should not be used in children younger than 12 years of age because of possible adverse cardiac effects, but the same logic applies to other tricyclics also. The tricyclic antidepressants have not been shown to be more effective than placebo in adolescents with depression, although this probably relates, in part, to diagnostic problems. The lethality of tricyclics in overdose should be kept in mind. Higher doses, on a milligram-per-kilogram basis, are likely to be required in younger patients than in adults to reach the same plasma level, but effective plasma level ranges have not been established in children.

Tricyclic and heterocyclic preparations are shown in Table 34.33–3.

▲ 34.34 Valproate

ROBERT M. POST, M.D., AND MARK A. FRYE, M.D.

Valproic acid (Depakene), and its formulation derivatives divalproex sodium (Depakote), extended-release (ER) divalproex sodium (Depakote ER), and valproate sodium injection (Depacon), represent one of the first-generation mood-stabilizing anticonvulsants. Valproate is currently approved by the U.S. Food and Drug Administration (FDA) for (1) monotherapy or adjunctive therapy of complex partial seizures that occur in isolation or in conjunction with other types of seizures, (2) monotherapy and adjunctive therapy of simple and complex absence seizures, and (3) adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has an FDA indication in these same epilepsy syndromes but additionally has indications for (4) prophylaxis of migraine and (5) treatment of acute manic episodes associated with bipolar disorder. Intravenous (IV) valproate sodium is currently FDA approved as an alternative in patients for whom oral administration is temporarily not feasible (i.e., unresponsive or otherwise on nothing-by-mouth [NPO] status). ER divalproex sodium is currently FDA approved for migraine prophylaxis and monotherapy and adjunctive therapy in complex partial seizures and acute mania.

HISTORY

The first clinical observations of valproate's anticonvulsant activity were in Europe in the 1970s. Shortly thereafter, the first reported evaluation of valpromide (the prodrug of valproate) in bipolar disorder was that of O. Lambert in France. Since that time, valproate has been extensively evaluated in bipolar disorder (particularly the manic phase as exemplified with the 1995 indication for acute mania) and, to a much lesser extent, in

other psychiatric conditions, such as schizophrenia, schizoaffective disorder, bipolar depression, panic disorder, posttraumatic stress disorder (PTSD), alcohol withdrawal, and target symptoms of impulsivity, agitation, and mood lability.

FIGURE 34.34–1. Molecular structure of valproate.

CHEMISTRY

Valproic acid (*N*-dipropylacetic acid) is a simple-chain branched-chain carboxylic acid (Fig. 34.34–1).

The commercial formulation derivatives available include valproic acid, which is available in syrup and capsules; valpromide (amide prodrug of valproic acid used in Europe); valproate sodium injection; divalproex sodium, which is an enteric-coated delayed-release complex of valproic acid and sodium valproate in a 1 to 1 ratio that is available in tablet and sprinkle formulation (can be opened and spread on food); and an ER formulation of divalproex sodium.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

All formulations of valproate are rapidly absorbed, with peak plasma concentrations obtained 3 to 4 hours after oral administration. The plasma half-life of valproate is 10 to 16 hours; when dosed in combination with drugs that induce cytochrome P450 enzymes (i.e., carbamazepine [Tegretol]), the half-life is shorter.

Table 34.34–1.
Common and Differential Effects of Valproate (VPA) Compared to Carbamazepine (CBZ) or Lithium (Li)

	CBZ	VPA	Li
Common effects			
GABA turnover	↓	↓	↓
$GABA_B$ receptors in hippocampus (chronic)	↑	↑	↑
GABA levels	(↑)	↑	(↑)
↓ GSK-3B	+	+	+

Brain tryptophan and 5-HT	↑	↑	↑
Dopamine turnover	↓	↓	↓
NMDA-mediated Ca++ currents	↓	↓	↓
Arachidonic acid turnover	↓	↓	↓
Myoinositol transport (SMIT)	↓	↓	↓
Stroke neuroprotection	+	+	+
BDNF	↑	↑	↑
Lithium-shared effects			
Inhibition of ERK MAP kinase path	−	+	+
↓ PKC	−	+	+
↓ MARCKS levels	−	+	+
↑ Bcl-2	−	+	+
↑ Neurogenesis	−	+	+
↓ β-Catenin	−	+	+
↑ AP-1 Binding	−	+	+
Carbamazepine-shared effects			
Na_i+ block	+	(+)	−
K efflux	↑	↑	−
[^{3}H] picrotoxinin binding	↓	↓	−
Release of aspartate, glutamate	↓	↓	−
Somatostatin levels	↓	↓	−
Histone, deacetylase inhibition	+	+	−
Block completed kindled seizures	+	+	−
Unique effects of each drug			
Inositol Monophosphatases	−	↓	↑
Absence seizures	↑	↓	−
Blocks kindling development	−	+	−
Inhibit after discharge spread in hippocampus in cortex	−	+	−
	+	−	−
Potential anticancer effects (AML)	−	+	−
Forms ester with coenzyme A	−	+	−
↑ PPARs	−	+	−

GABA, γ-aminobutyric acid; GSK, glycogen synthase kinase; 5-HT, serotonin; NMDA, *N*-methyl-D-aspartate; SMIT, *myo*-inositol transport system; BDNF, brain-derived neurotrophic factor; ERK, extracellular-signal-regulated kinases; PKC, protein kinase C; MARCKS, myristoylated alanine-rich C kinase substrate; AP, activator protein; AML, acute myelogenous leukemia; PPARs, peroxisome proliferator-activated receptors.

The ER formulation of divalproex sodium was designed for once-daily dosing, thereby maintaining lower maximum drug concentration (C_{max}) and higher minimum drug concentration (C_{min}) between dosing intervals. This would appear to be useful clinically, as treatment adherence is linked to the simplicity of treatment regimen, and some side effects correlate with peak drug levels. The ER formulation has 80 percent bioavailability of direct release (DR) divalproex sodium. A small (N = 35), healthy control, pharmacokinetic comparison study of two ER (given every day) versus DR

(given twice a day) dosages reported that there was no significant difference in area under the curve (AUC) when comparing 1,000 mg of ER to 875 mg of DR; however, there was a greater AUC in the dosage of 1,500 mg of ER versus 1,250 mg of DR. The ER formulation obtained a lower C_{max} and higher C_{min} than the DR formulation with less peak-trough fluctuations. Further study is encouraged in epileptic or bipolar patient populations at higher dosages, but increasing the DR dose by 20 percent to an approximately equivalent ER dose with clinical monitoring would be a reasonable switch strategy.

Valproate is highly protein bound, primarily to albumin. It is generally thought that, at serum levels less than 45 to 50 μg/mL, these binding sites are unsaturated; at higher serum levels, these binding sites become saturated, with the unbound valproate level increasing. The unbound portion of valproate is considered to be pharmacologically active and can cross the blood–brain barrier. When used in combination with other psychotropic agents, valproate has a higher degree of plasma protein binding such that it can displace these drugs and increase their free levels (i.e., lamotrigine [Lamictal] and carbamazepine).

Valproate is metabolized primarily by hepatic glucuronidation and mitochondrial β-oxidation. Several of valproate's metabolites, 2-propyl-2-pentenoic acid and 2-propyl-3-oxopentanoic acid, have potent anticonvulsant activity.

Pharmacodynamics

Valproate's anticonvulsant and mood-stabilization mechanisms of action have not been specifically identified and may not necessarily be the same. Its anticonvulsant effects are rapid in onset, while antimanic and antidepressant effects are slower in onset and appear to require chronic administration. Several hypotheses include enhancement of brain γ-aminobutyric acid (GABA) levels via multiple actions of synthesis and degradation, and modulation of other neurotransmitters, voltage-sensitive Na^+ channels, extra hypothalamic neuropeptides, secondary messenger systems, and neuroprotection. Comparative effects with two other antimanic mood stabilizers, carbamazepine and lithium (Eskalith), are listed in Table 34.34–1.

The GABA deficit hypothesis, as originally proposed by Emrich in 1980, suggested that unipolar and bipolar illnesses were characterized by a relative deficiency of GABA (the major inhibitory neurotransmitter in cortex), and that this deficit could be ameliorated with valproate treatment. Preclinical studies have shown that valproate enhances GABAergic function in specific regions of brain by a variety of presynaptic or postsynaptic mechanisms, or both, such as enhancement of GABA synthesis through activation of glutamate decarboxylase, prevention of GABA catabolism

through inhibition of GABA transaminase, direct release of GABA in response to calcium influx, reversal of the GABA transporter, and postsynaptic GABA type A ($GABA_A$) receptor activation effects. However, whether GABA enhancement is directly related to the antimanic effects of valproate remains controversial, and indirect inferences from the effects of other potent anticonvulsants that enhance brain GABA further suggest that this is unlikely. For example, other potent GABAergic drugs, tiagabine (Gabitril Filmtabs), gabapentin (Neurontin), and topiramate (Topamax), are not effective antimanic treatments.

In addition, GABA deficits, as measured in cerebrospinal fluid (CSF), by magnetic resonance spectroscopy (MRS), or plasma analysis, have not been consistently reported in clinical studies of affectively ill patients. GABA assessments after drug treatment have also produced inconsistent results. For example, lithium treatment normalized a relative deficit of CSF GABA in 23 euthymic bipolar patients. By CSF analysis, valproate treatment increased GABA in 31 pediatric epileptic patients and six schizophrenic patients; by MRS analysis, valproate increased occipital GABA in six euthymic bipolar patients. However, no increase in GABA, as measured by CSF analysis in six schizophrenic patients or by MRS analysis in five refractory epileptic patients treated with valproate has also been reported. Plasma GABA levels have been reported to be increased after treatment with valproate in three studies (two studies of normal controls and one study of pediatric epilepsy) and decreased in one study of acute mania. In this latter largest study to date, higher baseline pretreatment GABA levels in those patients randomized to valproate (N = 19) was associated with better clinical response; this relationship was not observed in patients randomized to lithium (N = 13) or placebo (N = 31).

The discordance between the previously mentioned CSF, MRS, and plasma studies remains unresolved; different study populations, collection and storage times of samples, lengths of treatment, and methodologies of GABA assay need to be standardized to better elucidate the role of GABA in bipolar disorder and the role for GABAergic mechanisms in the therapeutic effects of valproate in the various neuropsychiatric syndromes for which it is indicated.

Valproate's effect on less well-studied neurotransmitters and neuropeptides has included glutamate (increased release in mouse brain), serotonin (increased extracellular level in rat hippocampus and striatum), dopamine (increased extracellular level in rat), somatostatin (decreased CSF level), and corticotropin-releasing factor (CRF) (decreased CRF in median eminence, raphe nuclei, and decreased CRF messenger ribonucleic acid [mRNA] in the central nucleus of amygdala and paraventricular nucleus of hypothalamus). Although these neurotransmitters and neuropeptides have all been implicated in the pathophysiology of mania, depression, psychosis, or a combination of these, it is not known whether

valproate's modulation of these neurotransmitters and neuropeptides contributes to its mood-stabilizing properties.

Intracellular signaling systems similar to those of lithium have also been observed with valproate. Like lithium, valproate stimulates glutamate release and, through activation of the *N*-methyl-D-aspartate (NMDA) receptor, has been shown to increase inositol-1,4,5-triphosphate. Additionally, lithium, valproate, and carbamazepine, but not amitriptyline (Elavil), have been shown to inhibit the high affinity *myo*-inositol transport system in astrocytes; this inhibition of inositol and subsequent reduced intraneuronal level of inositol (*inositol depletion*) may be related to the mood-stabilization mechanism of valproate. However, although lithium decreases inositol monophosphatase activity, valproate increases it. Both inhibit the *myo*-inositol transport system (SMIT) as does carbamazepine.

Similar actions have also been observed with lithium and valproate in downregulation of protein kinase C (PKC) activity, downregulation of myristylated alanine-rich C kinase substrate (MARCKS) activity (a major substrate of PKC), and increased level of Bcl-2 (a neuroprotective protein). Further study is required to link any of these common actions of two drugs with different chemical structures but similar mood-stabilizing properties. PKC inhibition is a likely contributor to antimanic efficacy. In one open and two double-blind, placebo-controlled studies, the potent PKC inhibitor tamoxifen (Nolvadex), which also has antiestrogen receptor effects, has proven antimanic efficacy.

Like lithium, valproate increases Bcl-2, brain-derived neurotrophic factor (BDNF), and neurogenesis, but the increases in cortical gray matter seen with lithium have not been consistently observed with valproate. However, patients on valproate had increased volumes of their cingulate cortices and increased *N*-acetyl-aspartate (NAA) to creatine (Cre) or choline (Cho) ratios in hippocampus compared with those not treated with valproate. Since BDNF decreases during episodes of depression and mania, valproate's ability to increase BDNF could be important to its clinical actions.

Valproate is also positive in animal models of stroke and surprisingly is effective not only when given before middle cerebral artery ligation, but (like lithium) when given shortly after as well. In contrast to lithium, valproate inhibits histone deacetylase which could account for many of its effects on gene transcription. It is also possible that this effect contributes to valproate's teratogenicity (as described below) or to its possible therapeutic actions in conjunction with hydralazine (an inhibitor of DNA methylation) in reversing treatment resistance to chemotherapy of malignancies.

CLINICAL DRUG STUDIES

Acute Mania

The early uncontrolled studies of valproate (divalproex or valpromide) in acute mania suggested efficacy. Subsequent controlled studies of valproate in acute mania confirmed this view; these studies are reviewed in Table 34.34–2 and have included one single-site, placebo-controlled study; one multisite, placebo-controlled, parallel design study with lithium as an active comparison; one placebo-controlled adjunctive study to typical neuroleptic therapy; and six controlled, active comparison studies to lithium (two studies), haloperidol (Haldol) (one study), carbamazepine (one study), and olanzapine (Zyprexa) (two studies).

The first placebo-controlled studies by Harrison G. Pope and colleagues (1991) and Charles L. Bowden et al. (1994) were pivotal in receiving an FDA indication for acute mania. Post hoc analyses of the Bowden study have suggested that, although there was no difference in the response rate for patients with euphoric mania, patients with depressive symptoms (i.e., dysphoric mania) or a cumulative lifetime episode burden of greater than four prior depressive episodes or 11 prior manic episodes responded poorly to lithium. Furthermore, four distinct manic subtypes (anxious-depressed, psychotic, classic, and irritable) based on pretreatment symptom cluster analyses confirmed that the classic manic subtype responded similarly to divalproex and lithium, but the irritable manic subtype responded significantly better to divalproex than lithium ($P < 0.004$) or placebo ($P < 0.04$). The three treatments did not differ in response rates to depressive or psychotic subtypes.

These two studies have suggested that a serum valproate level of greater than 45 to 50 μg/mL is associated with an antimanic response. In the first study, the majority of patients randomized to valproate responded 1 to 4 days after achieving a serum level greater than or equal to 50 μg/mL. In the second study, patients who had achieved a serum level of greater than or equal to 45 μg/mL at day 5 were more likely to have a 20 percent or greater reduction in the manic syndrome and behavior–ideation subscales than those patients who had a serum level of less than 45 μg/mL. One study suggested a positive correlation between serum valproate level at day 3 and degree of manic improvement as measured by the Young Mania Rating Scale (YMRS). Finally, higher baseline plasma GABA levels may predict treatment response to valproate in acute mania.

A multicenter study of the divalproex ER preparation in acute mania was again highly positive compared with placebo for both mania and mixed patients and those with and without psychosis. Starting dose and rate of titration may have been too high because the side-effect profile was not diminished compared with the acute release studies. Serum levels of 71.3 to 85 μg/mL or higher appeared to be the therapeutic target, since those under this concentration show fewer good responses (smaller effect sizes

[0.4 to 0.8]) compared with those at higher blood levels (effect sizes 0.9 to 1.1). There was a hint of a positive blood level–response relationship with those above 95 μg/mL, showing effect sizes of 1.1 or the equivalent of –12 YMRS points, but it was not statistically dependable.

There is some evidence of a slightly lower bioavailability (AUC) with the ER preparation, which leads some to suggest that with a transition from the immediate release (IR) to ER preparation, slightly (20 percent) higher doses are required. The ER preparation was dosed on a once-daily basis in the morning, but clinically, one would recommend single bedtime dosing to enhance sleep and reduce side effects during awake time and increase compliance.

Because of valproate's robust effects in acute mania in adults, it was surprising that it failed to separate from placebo in a study of childhood- and adolescent-onset mania. Concomitant stimulant medication was allowed in that study, which may have confounded the results.

Given that there are many FDA-approved conventional mood-stabilizing agents for the treatment of acute mania (lithium, valproate, long-acting carbamazepine [Equetro], olanzapine, risperidone [Risperdal], quetiapine [Seroquel], aripiprazole [Abilify], and ziprasidone [Geodon]) and the extensive use of typical antipsychotics in acute mania (chlorpromazine [Thorazine] was FDA approved in 1970), controlled comparison studies provide important preliminary information regarding selection of an antimanic agent.

Although the typical antipsychotic agents have been extensively used for the treatment of acute mania, they represent a somewhat outmoded treatment because they are associated with more postmanic depressive symptom severity and breakthrough episodes of depression (vs. lithium) and their side-effect profile. Typical antipsychotics are associated with considerable side-effect liabilities, including neuroleptic-induced dysphoria, acute dystonia, extrapyramidal side effects, and, most importantly, long-term risk of tardive dyskinesia in some 20 to 40 percent of bipolar patients (even those treated intermittently). In one comparative study in psychotic mania, rapid loading of divalproex (20 mg/kg/day) was as effective as haloperidol and was associated with less need for adjunctive benztropine (Cogentin). In a larger, controlled, 3-week, double-blind study of 136 acutely manic patients treated with haloperidol or perazine (Taxilan), adjunctive valproate (N = 69, with a mean daily dose of 19.6 mg/kg and a mean serum level of 80.3 μg/mL) allowed for a 43 percent reduction of typical antipsychotic dosage compared to adjunctive placebo (N = 67) for which only a 14 percent reduction in neuroleptic dose was possible.

Table 34.34–2.

Controlled Studies of Valproate or Divalproex in Acute Mania

Study	Design (N)	Primary Outcome Variable	Results	Comment
Pope et al., 1991	3-week, randomized, db, pc, DSM-III-R mania, unresponsive to Li (*N* = 36)	% ↓ YMRS	VAL 54% ↓ vs. PLC 5% ↓ (*P* = 0.003), ITT (*P* = 0.013)	Response 1–4 days after achieving serum VAL >50 µg/mL
Bowden et al., 1994	3-week, multisite, randomized, db, pc, RDC confirmed mania (*N* = 179)	50% ↓ MRS	Mean dose/level DVPX: 2,000 mg/93.2 µg/mL) Li: 1,950 mg/1.2 mmol/L	All rapid-cycling patients (*N* = 8) randomized to DVPX; therefore, no comparative analysis possible
	DVPX vs. Li vs. PLC in 2:1:2 ratio. Dosage titrated to DVPX (150 µg/mL) and Li (1.5 mmol/L), except if adverse event was present		ITT: DVPX, 46% (*P* = 0.004 vs. PLC); Li, 49% (*P* = 0.025 vs. PLC); PLC 25%	48% of current Li responders reported past Li inefficacy or intolerance
Freeman et al., 1992	3-week, randomized, db, DSM-III-R mania (*N* = 27)	50% ↓ SADS-C mania	Li levels (0.8–1.4 mmol/L), mean DVPX level (98 ± 17 µg/mL)	Pretreatment depression significantly higher in DVPX responders vs. nonresponders (*P* <0.05)
	DVPX (titrated to 3,000 mg—lower dose for response or side effect) vs. Li (titrated to response, side effect, 1,800 mg q.d., or level 1.5 mmol/L)		Li 12/13 (92%) vs. DVPX 9/14 (64%)	Posttreatment mania scores higher in mixed vs. nonmixed manics treated with Li (*P* <0.05)
McElroy et al., 1996	1-week, randomized, sb, psychotic mania, rapid load DVPX (*N* = 21, 20 mg/kg/day) vs. HAL (*N* = 15, 0.2 mg/kg/day)	Mean change YMRS	DVPX 43% YMRS ↓; HAL 35% YMRS ↓	Equal efficacy Greater use of benztropine in HAL group
Hirschfeld et al., 1999	10-day, multisite, randomized, db, DSM-IV acute mania (YMRS ≥14) DVPX load (*N* = 20, 30 mg/kg/day on days 1 to 2, 20 mg/kg/day on days 3 to 10) vs. DVPX nonload (*N* =	Safety and tolerability DVPX load	84% DVPX load had level >50 µg/mL by day 3 vs. 30% DVPX	No difference in adverse event or YMRS change

	20) vs. Li (*N* = 19)		nonload

CBZ, carbamazepine (Tegretol); db, double blind; DVPX, divalproex sodium (Depakote); HAL, haloperidol (Haldol); HAMD, Hamilton Depression Scale; ITT, intent-to-treat analysis; Li, lithium (Eskalith); MRS, Mania Rating Scale; N.S., not significant; OLZ, olanzapine (Zyprexa); pc, placebo controlled; PLC, placebo; RDC, Research Diagnostic Criteria; SADS-C, Schedule for Affective Disorders and Schizophrenia-Change; sb, single blind; VAL, valproate; YMRS, Young Mania Rating Scale.

As reviewed previously, the post hoc analyses of comparison studies of lithium versus divalproex would suggest that depressive or irritable symptoms in mania are more effectively treated with divalproex. Other possible correlates of a relatively positive response are listed in Table 34.34–3. There is one large open trial in rapid-cycling patients of valproate prophylaxis as monotherapy in lithium-refractory patients (*N* = 43) or as add-on therapy (*N* = 101) with a greater than 70 percent antimanic or nonmixed response. The only comparison study of valproate and carbamazepine suggested greater efficacy and dose-dependent antimanic response with valproate.

Table 34.34–3.
Potential Correlates of Response to Valproate

	Strength of

	Association
Diagnosis-related factors	
Diagnosis of bipolar disorder [vs. schizoaffective or schizophrenia disorder]	+++
Dysphoric [or mixed mania]	+++
Bipolar II disorder	++
Clinical course variables	
Presence of rapid cycling	+
Decreasing or stable episode frequency	++
Later age of onset of illness (but see Fig. 34.34–2A,B)	+
Shorter duration of illness	+
Long and severe course of illness (see Figs. 34.34–2 and 34.34–3)	++

Modified from West SA, Strakowski SM, Sax KW, McElroy SL, Keck PE Jr, McConville BJ. Phenomenology and comorbidity of adolescents hospitalized for the treatment of acute mania. *Biol Psychiatry*. 1996;39(6):458–460 and Post RM, Speer AM, Obrocea GV, Leverich GS. Acute and prophylactic effects of anticonvulsants in bipolar depression. *Clin Neuroscience Res*. 2002;2(3–4):228–251.

Two comparative studies of divalproex versus olanzapine were similar in design, with the exception of dose and titration. In one smaller study

that started with a rapid loading dose of divalproex (mean dose of 2,115 mg vs. olanzapine mean dose of 15 mg), the mean reduction in manic symptoms and response rates was not statistically different. In the larger-powered study that started with a nonloading and lower divalproex dose (mean dose of 1,401 mg vs. olanzapine mean dose of 17.4 mg), response and remission rates were significantly in favor of olanzapine. A 12-week comparative study in acute mania suggested the superiority of quetiapine to valproate for efficacy, but with a higher side-effect burden.

Acute Bipolar Depression

Conventional mood stabilizers have been less well studied in the depressive phase of bipolar disorder. Several open trials have clearly suggested antidepressant properties with valproate, generally at lower doses than studies in acute mania. In a 12-week open trial of 19 patients with bipolar II depression, divalproex sodium monotherapy (with a mean dose of 882 mg every night and a mean level of 80.7 μg/mL), 63 percent of the cohort responded to treatment as defined by a 50 percent reduction in the Hamilton Rating Scale for Depression.

As presented in Table 34.34–4, a controlled study of divalproex monotherapy in acute bipolar I or II depression did not statistically separate from placebo at the 8-week study end point. The small sample size (N = 45) does not allow definitive conclusions about acute antidepressant efficacy of divalproex. However, in another small randomized-controlled trial including 25 patients, valproate not only showed superior antidepressant effects compared with placebo, but showed even more clinically and statistically robust antianxiety effects in monotherapy of bipolar depression. A more recent double-blind placebo-controlled study showed marked superiority of valproate over placebo with a moderately large effect size of 0.81.

Current guidelines emphasize the importance of maximizing mood stabilizer or atypical antipsychotic treatment and revision before the commencement of unimodal antidepressant therapy. Consistent with this recommendation, one small retrospective review of bipolar patients requiring antidepressant augmentation found lower mean levels of valproate (54 μg/mL ± 24 μg/mL at the time of antidepressant intervention) compared with a diagnostically matched comparison group not needing antidepressants with valproate (73 μg/mL ± 13 μg/mL).

Prophylactic Mood Stabilization

There are six controlled studies that have evaluated the efficacy of valproate or divalproex in long-term mood stabilization (Table 34.34–5). These studies include one open randomization comparing valpromide versus lithium monotherapy; one open randomization comparing valproate

versus lithium monotherapy in a child, adolescent, and young adult population; one placebo-controlled, adjunctive divalproex trial to lithium-maintained bipolar I patients; one 52-week, parallel design comparing lithium, divalproex, and placebo monotherapy in recently recovered manic patients; and one controlled comparison study between divalproex and olanzapine monotherapy in those patients who had presented in an acute manic episode.

Several conclusions can be drawn regarding these studies. First, one study suggested better prophylaxis against manic episodes versus depressive episodes. Conversely, the largest controlled study to date did not find any difference between divalproex, lithium, or placebo in time to recurrence of a mood episode or, specifically, a manic episode. However, almost 200 patients, who were initially enrolled as acutely manic, were unable to fully recover and thus were not randomized into the prophylactic phase; this methodological limitation may have yielded a type II error in a cohort of only randomized mildly ill patients, thereby making it more difficult to show differences between active drugs and the low rate of manic relapse even on placebo. A secondary outcome measure, however, suggested greater depression prophylaxis with divalproex than placebo in the monotherapy analysis and in a subgroup of patients who were subsequently treated with adjunctive antidepressant therapy (i.e., sertraline [Zoloft] or paroxetine [Paxil]) added to divalproex versus placebo.

Table 34.34–4.
Controlled Studies of Valproate and Divalproex Sodium in Bipolar Disorder (Acute Depression)

Study	Design	Primary Outcome Variable	Results	Comment
Sachs et al., 2002	8-week, multisite, randomized, db, pc, DSM-IV outpatient bipolar depression (*N* = 45:25 bipolar I disorder, 18 bipolar II disorder, 2 bipolar disorder not otherwise specified) DVPX (250 mg PO q.h.s with 250 mg q.o.d. ↑ based on efficacy and tolerability)	50% improvement in HAMD and YMRS <10	Mean dose, 1,391 mg; mean serum level, 61.5 µg/mL ITT:DVPX response 9 of 21 (43%) vs. PLC 6 of 22 (27%) (*P* <0.4)	DVPX HAMD improvement was numerically superior to PLC at every measured time point of study

Geddes et al., 2010	Ran, open 24 months		54% of 110 an event on combo 59% of 110 an event on Lithium 69% of 110 an event on valproate	Li + VPA superior to VPA alone

db, double blind; DVPX, divalproex sodium (Depakote); ITT, intent-to-treat analysis; Li, lithium (Eskalith); OAS-M, Overt Aggression Scale, modified; OLZ, olanzapine (Zyprexa); pc, placebo controlled; PLC, placebo; ran, randomized; SCL-90, symptom checklist-90; VAL, valpromide or valproate; WBC, white

blood cell count; YMRS, Young Mania Rating Scale.

In the 47-week acute mania comparison study of divalproex versus olanzapine, the median time to remission (YMRS ≤12) took significantly longer for divalproex (62 days) than for olanzapine (14 days, $P = 0.047$). Similarly, there was greater improvement in the YMRS with olanzapine versus divalproex at weeks 2 to 15 and week 23; however, from weeks 30 to 47, there was no difference in the two groups. Once remitted, there was no difference in relapse rates between the two groups.

In a second 18-month maintenance study of lithium versus valproate, those patients who had deteriorated or who were intolerant of lithium treatment had a higher response rate with a subsequent crossover to valproate in comparison to those patients who were initially treated with valproate with a subsequent crossover to lithium.

In a maintenance study comparing lithium plus valproate versus lithium alone, the combination was more effective than lithium alone; however, the adverse event profile was higher with the combination treatment. In the largest practical clinical trial (using a randomized open design), Geddes and colleagues found clear superiority of lithium compared to valproate, with the combination marginally better than lithium alone. Despite an indication only in acute mania, and some evidence of inferiority compared to lithium, there is wider use of valproate than lithium in the United States in the maintenance phase of bipolar disorder, case examples of which are illustrated in Figures 34.34–2A,B and 34.34–3. The latest Cochrane analysis in 2013 concluded that limited evidence supported the efficacy of valproate in the maintenance treatment of bipolar disorder.

Valproate in combination with lithium was evaluated in adults with rapid-cycling disorder in preparation for a blind randomization to monotherapy. Disappointingly, only 25 percent of the evaluable sample responded to the combination acutely, and only 19 percent of the intact to treat (ITT) sample responded. After randomization, relapses were about 50 percent on either lithium or valproate monotherapy, suggesting a very low valproate monotherapy response rate (about 12 percent) in this difficult-to-treat but common subtype of rapid cycling (which make up 40 to 60 percent of outpatients in some series).

In a parallel study in children and adolescents with mania, some 43 percent responded acutely to the lithium plus valproate combination, but upon randomization to either monotherapy, some two-thirds failed to maintain their improvement. However, the great majority re-responded to the combination when it was reintroduced. Most of these youngsters also required stimulant comedication and several required an atypical antipsychotic as well. These systematic prospective data in a double-blind maintenance study suggest that, as in many adult patients that valproate monotherapy is very often insufficient, and combination treatment with

lithium or an atypical antipsychotic is typically required in children for sustained mood stabilization.

A recent randomized multicenter study of childhood mania, comparing valproate, lithium, or the atypical antipsychotic risperidone, supported this viewpoint. Geller and colleagues found that risperidone was superior to both lithium and valproate. The percents with CGI-BP improvement of 2 or less were risperidone, 68.5 percent; lithium, 35.6 percent; and valproate, 24.0 percent. However, risperidone had more side effects such as weight gain and prolactin increases. When nonresponders were rerandomized to the addition of one of the other two treatments, those receiving risperidone as part of the regimen again fared the best.

In a secondary prevention study of children at high risk for bipolar I illness by virtue of both the presence of (1) subthreshold symptoms or a bipolar not otherwise specified presentation and (2) a positive parental history of bipolar illness, valproate was no more effective than placebo. Whether other monotherapies would fare better in this early attempt at secondary prevention remains to be established. Thus, because of the documented inefficacy of valproate monotherapy in a large double-blind study in childhood and adolescent acute mania, its inferiority to risperidone in another study, and its lack of prevention of the disorder in children at high risk, the combination of valproate with lithium or with an atypical such as risperidone may be of critical importance in management of these children. The role of valproate in conjunction with the better tolerated atypical antipsychotics in long-term treatment also needs to be further explored.

Schizophrenia and Schizoaffective Disorder

There are no controlled studies of valproate in the treatment of schizoaffective disorder. Clinically, the treatment regimen of schizoaffective disorder usually includes a mood stabilizer, such as valproate, carbamazepine, or lithium, and an atypical antipsychotic. Recent prevalence data have suggested that the use of valproate in combination with atypical antipsychotics has substantially increased.

Although mood stabilizers are not identified as first-line agents in the treatment of schizophrenia, valproate may be useful as an accelerating agent to antipsychotic therapy. In a 28-day, double-blind, parallel-group, multicenter trial of 249 patients who were hospitalized with an acute psychotic exacerbation of schizophrenia, subjects were randomized to one of four treatments: (1) olanzapine monotherapy (15-mg fixed dose by day 15), (2) risperidone monotherapy (6-mg fixed dose by day 15), (3) olanzapine plus divalproex (15 mg/kg/day on day 1, titrated as clinically indicated to a maximum dose of 30 mg/kg/day by day 12), or (4) risperidone plus divalproex. The mean daily doses of divalproex were 2,364 mg in the olanzapine group and 2,259 mg in the risperidone combination

group, respectively. The primary outcome variable was percentage change (baseline to final evaluation) in the total score of the Positive and Negative Syndrome Scale (PANSS). Over the 28-day study period, improvement in the PANSS score was evident in the monotherapy and combination groups. However, statistically significant differences favoring the combination groups were noted as early as day 3 and maintained significance through day 21. At the final day-28 visit, there was no significant difference in PANNS total score reduction in the monotherapy groups versus the combination groups. The acceleration of treatment response in the combination group was associated with improvement in positive symptoms, but not in negative symptoms. Weight gain was not significantly different between the olanzapine–divalproex group (8.3 lb) versus the olanzapine group (7.7 lb); however, there was significantly more weight gain in the risperidone–divalproex group (7.5 lb) versus the risperidone group (4.2 lb).

This study does suggest that time course of treatment response of antipsychotic therapy (specifically, positive symptom severity) can be accelerated with divalproex; further study is encouraged to evaluate potential pharmacoeconomic and long-term benefits.

FIGURE 34.34–2. **A:** Early-onset illness (at age 11) with depression and multiple comorbidities and ultimate failure to respond to lithium in 1985. **B:** Good prophylactic response to valproate in this lithium and carbamazepine-nonresponder. She did well on the combination of lithium and valproate and then on valproate monotherapy since 1990. She had no further hospitalizations for mania (from 1986 to the present), but had occasional depressive recurrences. Note shift in time scale from (A). (From Post RM, Leverich GS. *Treatment of Bipolar Illness: A Casebook for Clinicians and Patients. Treatment of Bipolar Illness*. New York: W.W. Norton & Co.; 2008:198–200.)

FIGURE 34.34–3. Valproate augmentation in a lithium-refractory bipolar patient with profound recurrent psychotic depression. Reemergence of the illness in 1986 was unresponsive to the reinstitution of lithium, buspirone, a variety of antidepressants, adjunctive antipsychotics, and minor tranquillizers. Carbamazepine, alone and in combination with lithium, was effective in reducing the amplitude of the manias, but had no impact on the patient's severe psychotic, delusional depressions. When carbamazepine was discontinued and valproate was added to lithium, the patient soon started to improve and reached a complete and sustained remission for the first time in 5 years. Her remission, illustrated in the figure from 1990 to 1998, persisted through 2008. ECT, electroconvulsive therapy.

Alcohol Withdrawal and Relapse Prevention

Divalproex, carbamazepine, and gabapentin have all been studied in the treatment of alcohol withdrawal. Although the intermediate (diazepam [Valium]) and long-acting benzodiazepines (lorazepam [Ativan] and clonazepam [Klonopin]) are the standard established agents for alcohol detoxification, comparative studies have shown that carbamazepine decreases global distress more than oxazepam and anxiety more than lorazepam.

In an open-label, 5-day study involving patients undergoing a standard protocol for alcohol detoxification, as needed dosing of lorazepam, with or without divalproex (500 mg by mouth three times a day), was given based on a Clinical Institute Withdrawal Assessment for Alcoholism, revised (CIWA-A-R) score. Although the CIWA-A-R score reduction was not significantly different, the cumulative lorazepam dosage was lower in the group that received divalproex. The treatment was well tolerated without significant side effects or hepatocellular enzyme elevation. In a second

study of 23 inpatients hospitalized for dysphoric mania complicated by substance use (primarily alcohol), treatment of the comorbidity with divalproex resulted in not only dysphoric symptom reduction (as measured by the YMRS and Hamilton Rating Scale for Depression), but also effective alcohol withdrawal and abstinence over the course of 20-week prospective follow-up. Mild hepatocellular enzyme elevation (not greater than three times normal) at the time of admission, presumably related to alcohol ingestion, decreased over the study period.

Alcohol relapse prevention (i.e., maintaining sobriety after alcohol detoxification) has also been evaluated with the mood-stabilizing anticonvulsants carbamazepine and valproate. In a 12-month, placebo-controlled study in 29 alcohol-dependent patients, carbamazepine treatment was associated with a decrease in the time to return to heavy drinking and a decrease in a number of drinking measures at 2- and 4-month follow-up. Recent data have suggested similar effectiveness with divalproex. Twenty-nine outpatients with alcohol dependence participated in a 12-week, double-blind, placebo-controlled, pilot trial of divalproex (mean divalproex level at week 12 was 88.2 μg/mL). There was a greater reduction in irritability in the divalproex treatment group, and a smaller percentage of divalproex-treated patients relapsed to heavy drinking (37 percent) compared with placebo-treated patients (63 percent; $P \leq 0.05$). There were no significant differences in side effects reported or abnormal laboratory values; in both treatment groups a reduction in hepatocellular enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST], and γ-glutamyltransferase [GGT]) during the course of the study was observed. Given the extensive comorbidity of alcoholism with other axis I disorders, particularly bipolar I and II disorders, treatment with valproate may stabilize mood and help treat components of alcoholism (withdrawal and relapse prevention). These results have now been replicated and extended.

In a 24-week, double-blind, placebo-controlled study of bipolar patients with comorbid active alcoholism maintained on lithium and psychosocial treatment as usual, valproate showed greater effects than placebo on several measures of drinking. Of the 25 patients randomized to placebo, 68 percent returned to heavy drinking compared with 44 percent of the 27 randomized to divalproex ($P = 0.02$). Liver function tests, ALT, and AST did not differ, while GTP (γ-67P) was higher in those on placebo and was correlated with the amount of alcohol consumed per week. Of those who did return to heavy drinking (four or more drinks per day for women; five or more drinks per day for men), time to relapse was also significantly delayed for those on divalproex (93 days) compared with 62 days on placebo ($P = 0.02$).

Although other agents are effective in primary alcohol dependence (i.e., naltrexone [ReVia] and acamprosate [Campral], which are FDA approved,

and now topiramate in two large randomized-controlled trials, and also gabapentin), none have been specifically studied in bipolar patients with comorbid alcoholism with the exception of valproate, making it a particularly good agent for such dual diagnosis patients. It is noteworthy that in patients with bipolar illness, women are 7.35 times and men 2.8 times more likely than those in the general population to have problems with alcohol use and abuse. Greater amounts of depression and anxiety were correlates of the women who abused alcohol, suggesting that it was a form of self-medication, and that earlier and more effective intervention on these target symptoms potentially could have lessened the incidence of alcohol comorbidity.

Panic Disorder

Several open-label studies suggest that valproate may be effective in treating panic attacks. In one open-label study of lactate-induced panic attacks, valproate effectively blocked the reintroduction of panic attacks on lactate rechallenge in 10 of 12 patients; furthermore, 71 percent of patients had a greater than 50 percent reduction in panic attack frequency, with 43 percent achieving complete remission. These data are consistent with the marked decreases in anxiety when valproate is used in the treatment of bipolar depression. However, in a double-blind, placebo-controlled, crossover study, 35 patients with panic disorder responded equally well to valproate and placebo.

Posttraumatic Stress Disorder

Valproate has been investigated in several open trials (total N = 53) of patients with combat-related PTSD. The first open trial noted a decrease in avoidance and hyperarousal but no change in intrusive symptoms. The latter two open trials used contemporary diagnostic criteria and rating scales. In the first 8-week study, adjunctive valproate (mean dose of 1,365 mg, mean serum level of 80 μg/mL) was associated with a significant decrease in intrusion and hyperarousal but no change in avoidant symptoms. In the second 8-week open trial, which included a 2-week washout with a majority of patients on monotherapy, valproate (mean dose of 1,840 mg ± 270 mg, mean level of 69 μg/mL ± 29 μg/mL) was associated with a significant reduction in all symptom clusters of intrusion, avoidance, and hyperarousal.

Further clinical studies of valproate in the extinction of conditioned fear would appear appropriate in light of preclinical data that valproate specifically increases the promotor of a BDNF variant that is involved in the new learning that is necessary for extinction of conditioned fear. It is likely that the effects of valproate as a histone deacetylase inhibitor are involved in this effect.

Impulse Control Disorder

Several impulse control disorders, such as intermittent explosive disorder, pathological gambling, and kleptomania, share some clinical features with mania. Valproate has been investigated in several case reports and open trials with generally positive results, particularly if manic or mixed symptoms were present. The only placebo-controlled study of valproate in an impulse control disorder evaluated intermittent explosive disorder. One hundred and sixteen patients with intermittent explosive disorder were part of a 12-week, randomized, placebo-controlled study evaluating valproate in the treatment of impulsive aggression; in this study, only patients with impulsive aggression associated with borderline personality disorder responded to valproate. A second controlled, single-blind study randomized patients with pathological gambling to lithium (N = 23, mean dose of 795 mg ± 261.5 mg/day, mean level of 0.8 mEq/L ± 0.1 mEq/L) or valproate (N = 19, mean dose of 873 mg ± 280 mg/day, mean level of 72 μg/mL ± 14 μg/mL). Using the Yale-Brown Obsessive Compulsive Scale modified for pathological gambling as the primary outcome measure, those taking lithium and valproate showed significant improvement.

Highly significant effects of valproate compared with placebo in a crossover design were seen in children and adolescents with explosive temper and a disruptive behavioral disorder (oppositional defiant disorder or conduct disorder). These children were also severely mood-dysregulated and some may have met criteria for bipolar not otherwise specified, but they were not bipolar II or bipolar I. A positive family history of bipolar disorder in first-degree relatives was also not a prominent feature of this group. These findings are of considerable importance because they suggest the utility of valproate in children with explosive aggression (86 percent response on valproate vs. 25 percent on placebo), even in those who do not meet strict criteria for bipolar disorder. The fact that these irritable, hostile, and aggressive children show marked improvement over placebo, and that in another study of children with more classic bipolar presentations meeting DSM-IV criteria, valproate did not separate from placebo, suggests the usefulness of valproate in just this area of greatest diagnostic controversy; those who are the highly impaired by their irritability and dyscontrol but may or may not end up in the bipolar diagnostic spectrum.

Further concerted study in this area and in those with conduct disorder would be of great clinical importance, because the therapeutic approaches to these large numbers of children remain obscure and based on only a sparse literature.

Borderline Personality Disorder

Several open trials have suggested valproate's effectiveness in several symptom domains in patients with borderline personality disorder (i.e.,

mood lability, irritability). There have been three placebo-controlled studies generally supporting these preliminary observations. In the first, 10-week, placebo-controlled study, 12 patients treated with valproate (mean dose of 750 mg) had nonsignificant improvement in global symptom severity and functioning compared to patients treated with placebo. A second, 6-month, placebo-controlled study of 30 euthymic bipolar II disorder patients who also met criteria for borderline personality disorder were randomized to divalproex (mean dose of 850 mg) versus placebo. The primary outcome variable was the mean change in symptom checklist-90 (SCL-90) scales of interpersonal sensitivity, anger and hostility, and depression and the Overt Aggression Scale, modified (OAS-M). In a last-observation-carried-forward analysis, controlling for baseline severity, divalproex was more effective than placebo in reducing interpersonal sensitivity, anger and hostility, and aggression.

Another 12-week, randomized, placebo-controlled study evaluated the effectiveness of divalproex in the treatment of impulsive aggression in patients with borderline personality disorder (N = 96), intermittent explosive disorder (N = 116), and PTSD (N = 34). The primary outcome variable was the mean score reduction in the OAS-M obtained during the last 4 weeks of treatment. In the intent-to-treat analysis, there was no significant treatment difference in OAS-M scores between those patients treated with divalproex versus those treated with placebo. However, when the data were analyzed by diagnostic subgroup, there were significant treatment differences in patients with borderline personality disorder (χ^2 = 3.95; P = 0.047) but not in those with intermittent explosive disorder or PTSD. In the data set that could be evaluated (those who completed at least 21 days), patients with borderline personality disorder and impulsive aggression treated with divalproex versus placebo had a significant decrease in measures of aggression, verbal assault, assault against objects, and assault against others but not in assault against self. As well, there was a significant reduction in irritability, as measured by the OAS-M Irritability score, and severity of illness, as measured by the Clinical Global Impression (CGI) Scale. The mean dose of divalproex was 1,404 mg (with a range between 500 and 2,250 mg), with a corresponding serum level of 65.5 μg/mL (with a range between 0 and 147 μg/mL).

Behavioral Agitation of Dementia

Several open-trial investigations had suggested valproate's effectiveness in reducing behavioral agitation associated with dementia. The dose was generally lower than that used in other conditions, most likely reflecting an older patient population and a pharmacokinetic profile characterized by decreased protein-binding capacity. However, the one double-blind, placebo-controlled, 6-week study of higher doses of divalproex in the treatment of manic symptoms in elderly demented patients was suspended

prematurely because of a disproportionate rate of adverse events (primarily sedation and thrombocytopenia) and dropouts (noncompliance) reported with divalproex compared to placebo. At the time of study suspension, 85 patients had been randomized to placebo, and 87 had been randomized to divalproex (median dose of 1,000 mg daily or 18 mg/kg/day, mean weekly serum valproate levels ranging from 55.3 to 68.9 μg/mL). Although there was no significant difference in the primary outcome as measured by the Bech–Rafaelsen Mania Scale, there was a greater reduction in the Cohen–Mansfield Agitation total score (noted as early as week 2 and maintained throughout the 6-week period) and the verbal agitation subscale score at week 6. This study suggests that, although agitation can be reduced with valproate, many elderly patients may not be able to tolerate an aggressive dosing strategy (18 mg/kg/day).

THERAPEUTIC INDICATIONS

Neurological Conditions

Valproate is currently approved by the FDA for (1) monotherapy or adjunctive therapy of complex partial seizures that occur in isolation or in conjunction with other types of seizures, (2) monotherapy and adjunctive therapy of simple and complex absence seizures, and (3) adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has an FDA indication in these same epilepsy syndromes but additionally has indications for (4) prophylaxis of migraine. The ER preparation is approved for seizures, acute mania, and migraine.

Psychiatric Conditions

Valproate and carbamazepine ER are currently the only mood-stabilizing anticonvulsants that are FDA approved for the treatment of acute mania associated with bipolar disorder. Based on extensive open studies and case series in treatment-refractory and rapid-cycling patients, valproate has also been widely used in the prophylactic treatment of recurrent mania and depression and has been recommended as a first-line option in many treatment guidelines. However, caution is urged in the use of valproate in women of childbearing age as emphasized below.

Valproate has been shown to be particularly effective in acute mania with depressive, dysphoric, and mixed symptoms, acute mania associated with a rapid-cycling course of illness specifier (four or more episodes in a 12-month period), and acute dysphoric mania complicated by substance abuse, particularly alcohol abuse and dependence (Table 34.34–3). Given its current neurological FDA indications, valproate may be particularly useful in bipolar disorder complicated by seizure disorder, electroencephalogram (EEG) abnormalities, head trauma, and migraine. Outside of formal DSM-IV-TR diagnoses, valproate appears to be effective

on target symptoms of irritability, aggressiveness, mood lability, and impulsivity.

PRECAUTIONS

Serious Adverse Reactions

Rare serious side effects—as noted in the FDA black box warnings—include hepatic failure, pancreatitis, and hyperammonemic encephalopathy associated with patients with urea cycle disorders. It is important to obtain baseline hepatic function tests before valproate treatment. However, baseline or serial laboratory monitoring does not necessarily predict severe hepatotoxicity or pancreatitis. Close clinical observation is far superior to routine clinical monitoring in this regard. Additional warnings include sedation in the elderly and thrombocytopenia.

Valproate is rated pregnancy category rating D, as noted by increased risk (1 to 4 percent) of neural tube defects, such as spina bifida (Table 34.34–6). Recent studies have also highlighted the notable occurrence of other teratological effects. The rate of any adverse outcome (a major congenital malformation or fetal death) was higher with valproate (20.3 percent) than with phenytoin (Dilantin) (10.7 percent), carbamazepine (8.2 percent), or lamotrigine (1.0 percent). The effects were not attributable to factors other than anticonvulsant exposure during pregnancy, and, notably, with valproate the adverse events were dose related.

In addition, behavioral teratological effects have also been reported. A syndrome of moderate to severe developmental delay has been identified, with a small percentage having severe retardation and an intelligence quotient (IQ) below 70. Thus, it would appear that avoiding pregnancy during valproate treatment or switching to other less problematic agents when planning for pregnancy is of very great importance. Although neural tube defects can be monitored for and detected with modern techniques (i.e., fetal ultrasound in weeks 18 to 20; α-fetoprotein; and if needed, amniotic fluid at 16 weeks), there is currently no way of predicting the behavioral deficits which, upon follow up of children exposed to valproate in utero, appear substantially more severe that with other anticonvulsants. For example, in those exposed to valproate, the IQ measured at 3 years of age averaged 9 points lower than those exposed to lamotrigine. Valproate's use in combination with other agents also appears to be an additional risk factor. Valproate has also been associated with a many fold increased risk for autism of childhood or lifetime onset. This clinical increased risk has been validated in animal models of fetal exposure to valproate.

Table 34.34–6.
Black Box Warnings and Other Warnings

More Serious Side

Effect	Management Considerations
Hepatotoxicity	Rare, idiosyncratic event Estimated risk 1:118,000 (adults) Greatest risk profile (polypharmacy, younger than 2 years of age, mental retardation) → 1:800
Pancreatitis	Rare, similar pattern to hepatotoxicity Incidence in clinical trials data is 2 of 2,416 (0.0008%) Postmarketing surveillance shows no increased incidence Relapse occurs with rechallenge Asymptomatic amylase not predictive
Hyperammonemia	Rare—more common in combination with carbamazepine (Tegretol) Associated with coarse (flapping) tremor and may respond to L-carnitine administration
Associated with urea cycle disorders	Discontinue valproate and protein intake Assess underlying urea cycle disorder Divalproex is contraindicated in patients with urea cycle disorders
Teratogenicity	Neural tube defect: 1–4% with valproate; high incidence of other congenital anomalies; developmental delay and IQ decreases prominent. Preconception education and folate-vitamin B complex supplementation and relative avoidance of valproate for women of childbearing potential
Somnolence in the elderly	Slower titration than conventional doses Regular monitoring of fluid and nutritional intake
Thrombocytopenia	Decrease dose if clinically symptomatic (i.e., bruising, bleeding gums) Thrombocytopenia more likely with valproate levels ≥110 µg/mL (women) and ≥135 µg/mL (men)

Adapted from *Physician's Desk Reference*. Oradell, NJ: Medical Economics Company; 2002.

Given the evidence of a highly elevated risk for neural tube and other teratological defects and for lower IQ, most neurologists attempt to avoid the use of valproate in women who wish to become pregnant. If the use of valproate is unavoidable because of failure of other agents, most would recommend the use of folic acid, and vitamins B6 and B12 in hope of ameliorating the known risks to the fetus, in addition to careful attention to the optimal forms of birth control. These cautions would appear even more appropriate to women of childbearing age who have bipolar disorder. The characteristics of mania itself, such as hypersexuality and poor judgment, make the risk of an unplanned or unwanted pregnancy even more likely. Thus avoidance of the use of valproate in these women would appear indicated, and in the absence of other alternative treatments, special emphasis on the importance of birth control and adjunctive use of folate, B6 and B12. It has been suggested that the analog of valproate valnoctamide has both anticonvulsant and antimanic efficacy and may have a lesser likelihood of congenital malformations based on studies in laboratory animals. This drug may have lesser potency as a histone deacetylase inhibitor which some have posited as the mechanism of valproate's teratogenic effects.

Valproate has been classified as compatible with breastfeeding, as case

reports have consistently reported low concentrations (1 to 10 percent of mother's serum level) of valproate in breast milk.

Several preclinical studies have suggested that valproate can stimulate human immunodeficiency virus 1 (HIV-1) and hepatitis C virus (HCV) replication. Although small clinical studies in HIV-1–infected and HCV-infected patients do not confirm these preclinical observations, close clinical monitoring is recommended.

In long-term toxicity studies in rats, valproate was associated with an increase in pulmonary adenomas and fibrosarcomas. There is no evidence to suggest a carcinogenic effect in humans, and to the contrary, there is considerable evidence of an antineoplastic effect in several tumor types, including chronic myelogenous leukemia (CML).

Minor Adverse Reactions

Common side effects include gastrointestinal (GI) distress, tremor, sedation, benign hepatic transaminase elevation, leukopenia, thrombocytopenia, hair loss, increased appetite, and weight gain (Table 34.34–7). Despite weight gain there are no increases in triglycerides or total cholesterol. Generally, most of the common side effects are dose related and can often be minimized by dose reduction, dose consolidation, or adjunctive pharmacotherapy. Valproate causes dose-related increases in homocysteine, and for this reason many would recommend routine cotreatment with folate to reduce this risk.

The relationship between valproate, polycystic ovaries, and polycystic ovarian syndrome (menstrual irregularity and clinical evidence of hyperandrogenism) remains controversial because patients with epilepsy and obesity appear to be at increased risk for the syndrome. Studies in women with bipolar disorder taking valproate or lithium have reported conflicting results. In one study of 22 outpatients, most patients reported menstrual irregularity, but none of them had evidence of significant hirsutism on physical examination or hormonal evidence consistent with polycystic ovarian syndrome. In another study of 32 bipolar outpatients, 7 patients currently on valproate and experiencing menstrual problems had evidence of hyperandrogenism (hirsutism and elevated testosterone).

Natalie Rasgon and colleagues again found a high incidence of menstrual irregularities in women with bipolar illness prior to treatment, and these increased further with valproate therapy. Hirsutism and significant elevation of serum testosterone were also not observed.

In contrast, data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) group did find statistically significant testosterone increases on valproate and, rarely, hirsutism. Thus, it would appear that there is a clear pretreatment increased risk of the polycystic ovarian syndrome (menstrual irregularities, weight gain, increases in testosterone, even without polycystic ovaries themselves) and polycystic

ovaries in women with epilepsy, which is further exacerbated by valproate. However, in women with bipolar disorder, the polycystic ovarian syndrome at baseline pretreatment is relatively uncommon and exacerbation by valproate less apparent and more inconsistent.

Table 34.34–7.
Some Valproate Side Effects and Their Potential Management

Side Effect (Frequency)	Potential Treatments	Support	Comment
GI distress (O)	Switch to enteric coated preparation Add H_2 blocker Give with meals or all H.S.	++ + +	Effect may be additive with lithium
Tremor (O)	↓ dose Switch to ER formulation Add Propanolol	+ + ±	Additive with lithium?
Weight gain (O)	Early diet and exercise instructions Augment with topiramate, zonisamide	++ ++ ++	Additive with lithium?
Alopecia (hair loss) (UC)	Prophylaxis with zinc and selenium supplements	+	Straight hair may grow back curly
Thrombocytopenia (low platelets) (UC)	Discontinue valproate	++	Monitor for bleeding
PCO syndrome (UC)	Treatment with oral contraceptives will prevent PCOs Switch to lamotrigine	++ ++	Menstrual irregularities may precede use of VPA and may increase on VPA Testosterone not ↑ in 4 of 5 studies Hirsutism rare
Hepatic enzyme elevation; <3 times normal (O)	Monitor direction and rate of change	+	Caution patient to advise you if RUQ pain, fever, malaise, fatigue, cola-colored urine, or jaundice occurs. Risk (1:600) in children <2 years of age for fatal hepatitis.
Hepatitis (VR)	Discontinue VPA	++	
Pancreatitis (VR)	Discontinue VPA, monitor amylase	++	Patient to advise you if severe GI pain, nausea, vomiting occurs
Hypothermia (VR)	Discontinue VPA	+	Especially with topiramate
Metabolic:			
A. Asymptomatic ↑ ammonia (UC)	↓ Dose, add l-carnitine ↓ Dose, add l-carnitine Discontinue VPA	+ + ++	Is there a history of urea cycle abnormalities in patient or family?
B. Coarse, "flapping" tremor (UC)	Discontinue VPA, add l-carnitine, folate Add folate	++ ++ ++	EEG background slowing and high voltage theta–delta activity 75% occurs in first week of Rx VPA may lower folate
C. Encephalopathy (VR)			
D. ↑ homocysteine (C)			
E. ↓ carnitine and			

acylcarnitine (?)			
Teratogenicity:	Avoid pregnancy while on VPA. Use oral contraceptives, other devices.	+++	Avoid VPA in planned pregnancies
A. Neural tube defects; Spina bifida in 1–2% of exposed (UC)	Use folate ≥1 mg/day, vitamin B6 and B12 prophylactically in women of childbearing age	+++	Especially avoid VPA in combination with other anticonvulsants
B. Developmental delays (mild to severe C,D)	Avoid pregnancy	++	

O, occasional; UC, uncommon; VR, very rare; C, common; D, dose related; PCO, polycystic ovaries; PCOs, polycystic ovarian syndrome; H_2, histamine; ER, extended release; VPA, valproate; RUQ, right upper quadrant; GI, gastrointestinal; EEG, electroencephalogram;?, ambiguous or uncertain.

Previous studies in epilepsy have been unable to fully assess baseline endocrine profile before valproate treatment, impact of nonspecific weight gain as a risk factor for development of the polycystic ovarian syndrome, and the extent to which epilepsy and bipolar disorder are independent risk factors unrelated to medication exposure. All aspects of the syndrome are reversible in patients with epilepsy, if valproate is discontinued and lamotrigine is substituted. Menstrual history and weight should be followed carefully in women of reproductive potential who begin treatment with valproate. Since the polycystic ovarian syndrome can be mitigated by birth control pills, this side effect should be described but should not preclude women with bipolar illness from treatment with valproate. More pressing is the need to inform women of the major risks to the fetus should they become pregnant as discussed above.

DRUG INTERACTIONS

Valproate and Other Psychotropics

Valproate is commonly prescribed in combination with other psychotropic agents. These combination therapies are generally well tolerated and are often more effective than valproate alone. Outside of several specific concerns, the most likely caution is the additive side-effect burden of the two medications. For example, lithium and valproate are often used in combination. Additive side effects of tremor or cognitive dulling can often be treated with dose reduction. Additive problems with weight gain can be more daunting. Recent use of the combination of bupropion ER 150 to 300 mg with naltrexone 50 mg has produced dramatic weight loss in many individuals but this regimen has not been systematically studied for valproate or its combination with lithium. Additive GI problems and

dyspepsia can be treated with adjunctive agents histamine 2 [H_2] antagonists.

Typical antipsychotics and valproate are often prescribed together, especially in acute mania. Again, increased sedation and an increase in extrapyramidal side effects have been reported. More recently, atypical antipsychotics and valproate have been used together, with increased sedation (olanzapine) and weight gain (risperidone) reported as side effects. It is noteworthy, however, that valproate may prevent the increases in cholesterol induced by some atypical antipsychotics. This is thought to be attributable to valproate's influence on peroxisome proliferator-activated receptors (P-PARs), which increase β-oxidation and are transcription factors in steroid–thyroid hormone–retinoic receptor super family.

Valproate has also been used as an adjunctive mood stabilizer and anticonvulsant in patients treated with clozapine. In fact, for patients who have had a seizure related to high-dose clozapine, valproate is the preferred agent over carbamazepine, given its risk of agranulocytosis. The combination is generally well tolerated, with the exception of sedation and weight gain.

There are clinical data to suggest greater efficacy of the lamotrigine–valproate combination for treatment of complex-partial epilepsy compared with either drug alone and relatively good tolerability. Given valproate's efficacy in acute mania and lamotrigine's efficacy in acute bipolar depression, it is likely that the two will be used together in psychiatric practice. Given valproate's plasma protein–binding capacity and its metabolic inhibition of lamotrigine, free levels of lamotrigine are doubled when used in combination with valproate; to reduce the risk of serious rash, the initial dose, rate of titration, and final dose of lamotrigine should be reduced by approximately 50 percent of the standard monotherapy recommendations when combined with valproate.

Two case series suggesting efficacy of the valproate–carbamazepine combination for refractory rapid-cycling bipolar disorder have been reported. The pharmacokinetics of this combination warrants clinical anticipation and monitoring, however, adjunctive carbamazepine, as well as its cytochrome P450 3A4 autoinduction and heteroinduction, generally reduces levels of valproate, which are typically not consequential. However, valproate increases levels of free carbamazepine and its active metabolite by displacement from plasma protein. Valproate also increases levels of carbamazepine-10,11-epoxide by inhibiting its metabolism via epoxide hydroxylase to the inactive diol metabolite. Thus the increases in the carbamazepine-10,11 epoxide may not be evident if only carbamazepine levels alone are measured. Given these pharmacokinetic interactions, side effects of the combination generally are related to increased levels of carbamazepine and its active carbamazepine-10,11 epoxide, potentially

yielding diplopia, ataxia, sedation, and confusion in those already near their carbamazepine side-effect threshold. Lowering the carbamazepine dose in anticipation of adding valproate will generally avoid this difficulty (Table 34.34–8).

Antidepressants are often used in combination with valproate, although the efficacy of this approach has recently been questioned. There are case reports of the tricyclic antidepressant amitriptyline increasing valproate concentrations and, conversely, valproate increasing the levels of tricyclics. Additionally, adjunctive fluoxetine (Prozac) has been reported to increase serum levels of valproate.

Table 34.34–8.
Pharmacokinetic Interactions of Valproate

Metabolic Interactions		
VPA→↑ Drug	**Drug→↑VPA**	**Drug→↓VPA**
Benzodiazepines	ASA	CBZ
CBZ-E	Cimetidine	± Lamotrigine
Ethosuximide	Fluoxetine	Phenobarbital
Lamotrigine[a]	Felbamate	Phenytoin
Phenobarbital	Erythromycin	Rifampin
Phenytoin	Phenothiazines	Folate
TCAs	Risperidone	
Binding interactions	Nimodipine	
	Discontinuation of enzyme inducers	
VPA→↑Free Drug	**Drug→↓Free VPA**	
CBZ	ASA	
Diazepam	NSAIDs	
Phenytoin		
Tiagabine		
Tolbutamide		
Warfarin		
Zidovudine		

VPA, valproate; CBZ-E, carbamazepine-10,11-epoxide; TCAs, tricyclic antidepressants; ASA, aspirin; CBZ, carbamazepine; NSAIDs, nonsteroidal anti-inflammatory drugs.

[a]VPA doubles lamotrigine levels and increases risk of serious risk.

Valproate and Other Drugs

In contrast to carbamazepine, the primary pharmacokinetic liability of valproate is related to its plasma protein–binding capacity and the inhibition of other drugs metabolized by the liver. For example, valproate increases the free concentration of diazepam by plasma protein–binding site displacement and also has been shown to decrease the serum level of a diazepam metabolite *N*-desmethyldiazepam. Close clinical monitoring of this coadministration is indicated to avoid any potential for diazepam

toxicity. Similar observations (i.e., binding displacement or inhibition of metabolism, or both) have been noted with ethosuximide (Zarontin), phenobarbital (Barbita), chlorpromazine, and aspirin. Because valproate has been shown to inhibit the secondary phase of platelet aggregation, close clinical monitoring is indicated when using the drug with other drugs that affect coagulation, such as aspirin and warfarin (Coumadin).

VALPROATE AND LABORATORY INTERFERENCE

Valproate occasionally interferes with results of laboratory tests. As a fatty acid, serum levels, if measured, reflect an increase. Valproate metabolites may produce a false-positive result in urine analysis for ketones.

DOSAGE AND ADMINISTRATION

In the outpatient setting, one should obtain a baseline hepatic panel and complete blood cell count before starting a patient on divalproex, although this can be ordered concomitantly with or after starting medications in more urgent treatment indications for hypomania or full-blown mania. An appropriate starting dose is 250 mg three times per day, with increases of 250 to 500 mg every several days to a therapeutic threshold (serum level greater than 50 mg/L). Once a steady-state dosage has been achieved, consolidating to bedtime dosing maximizes treatment adherence. The divalproex-ER preparation also lends itself well to single nighttime dosing. Rapid loading of divalproex (20 mg/kg/day) in acute mania has produced therapeutic serum levels more quickly than standard titration and has generally been well tolerated. However, high-dose intravenous valproate (20 mg/kg) over 30 minutes was not effective. This adds to the suggestion that actions induced by chronic administration of the drug are necessary to its antimanic and other psychotropic effects. These findings, taken with those of no greater rapidity of onset of antimanic effects with aggressive titration of the ER preparation compared with less aggressive regimens, suggest that more modest dosing strategies are likely to be as effective, produce fewer side effects, and be more clinically prudent.

▲ 34.35 Electroconvulsive Therapy

JOAN PRUDIC, M.D., AND YUANLI DUAN, M.D., PH.D.

Electroconvulsive therapy (ECT), also known as electroshock therapy, is a standard psychiatric treatment in which electricity is delivered through the scalp to induce a therapeutic seizure. First conducted in 1938 by two Italian physicians, Ugo Cerletti and Lucio Bini, on patients with schizophrenia, ECT has become the oldest somatic treatment for many psychiatric conditions, including depression, bipolar disorder, schizophrenia, and catatonia. Following professional guidelines, ECT is generally reserved for patients who have failed to respond to pharmacotherapy or have adverse reactions to standard pharmacotherapy, as well as those with severe symptoms such as suicidality, psychosis, or grave functional impairment, resulting in a need for a rapid and definitive response. It is estimated that about one million patients worldwide and 100,000 in the United States received ECT annually. Contrary to the sometime negative depiction of ECT, its safety and efficacy has been much improved with modification of various aspects of the technique such as optimization of the stimulus energy, electrode placement, the use and optimization of general anesthesia, as well as improvement in cardiopulmonary management. The application of ECT is regulated by the FDA, and there are regulatory and professional guidelines for proper consent procedures including situations where the patient lacks capacity. The mechanism of action of ECT remains an active area of hypothesis and research, although a great deal of information has been obtained with the availability of newer research tools.

HISTORICAL OVERVIEW

Convulsive therapies for major psychiatric illnesses predate the modern therapeutic era with the use of camphor reported as early as the 16th century, and several accounts of camphor convulsive therapies from the late 1700s to the mid-1800s. With the success of malarial fever therapy for general paresis, interest in biologic therapies for psychiatric illnesses increased in the early 20th century. By the 1930s, insulin coma and psychosurgery had also been introduced.

Unaware of the history of camphor convulsive therapy, Meduna made the observation that the brains of epileptics had greater than normal numbers of glial cells, while those of schizophrenics had fewer, and hypothesized that there might be a biologic antagonism between convulsions and schizophrenia. Following animal experimentation, camphor was (again) selected as the appropriate agent to use for the therapeutic induction of seizures. In 1934, the first catatonic psychotic

patient was successfully treated using intramuscular injections of camphor in oil to produce therapeutic seizures. Thirteen of a series of 26 patients treated similarly were reported to have had some degree of remission of psychosis. In 1937, a conference on convulsive therapies and insulin coma was held in Switzerland and the use of convulsive treatments spread.

Although effective, camphor was relatively long acting and was soon replaced by pentylenetetrazol. This agent was also associated with problems, principally patient rejection of the noxious sensations associated with GABA antagonism while conscious, for example, increased heart rate, feelings of terror, and myoclonus preictally.

Bini and Cerletti were interested in the use of electricity to induce seizures, and, after a series of animal experiments and observation of the use of electricity commercially, were able to safely apply current across the heads of animals for this purpose. In 1938, the first electroconvulsive treatment (ECT) course was administered to a delusional and incoherent patient, who improved with one treatment and remitted after 11 ECT. Electrical induction of convulsive therapy could be made more reliable and shorter acting than chemically induced convulsive therapies, and, by the early 1940s, had replaced them. In 1940, the first use of ECT occurred in the United States.

Throughout the 1940s, ECT was a first-line therapy for a variety of major psychiatric illnesses. In the ensuing decades, efforts to improve its acceptability and safety profile continued. In 1940 A. E. Bennett developed curare for use in the prevention of ECT-associated fractures, which had previously resulted from the severe muscle contractions associated with the tonic phase of the seizure induction. By the 1950s brief general anesthesia with succinylcholine replaced curare. Other improvements in anesthesia, most notably oxygenation throughout the treatment session and cardiac and oxygen saturation monitoring became standard. Efficacy in disorders other than schizophrenia was demonstrated, most notably major depression.

In an effort to reduce the retrograde memory problems that persisted for some patients after the initial recovery period post-ECT, explorations of nondominant electrode placement and alternative, more efficient, waveforms were undertaken in subsequent decades. The practice of ECT also benefited from the introduction of controlled trials methodology, which demonstrated its safety and efficacy, and from refinements made in diagnostic systems and the process of informed consent. In the 1980s and 1990s efforts to assure uniformly high standards of practice were underway with the publication of recommendations for treatment delivery, education and training by professional organizations in the United States, England, Scandinavia, and Canada among others.

With the current widespread use of pharmacologic agents as first-line treatments for major psychiatric disorders, ECT is now more commonly

used for patients with resistance to those treatments, except in the case of life-threatening illness due to inanition, severe suicidal symptoms, or catatonia. While the failure of subconvulsive stimulation to induce remission of psychiatric illness and the effectiveness of chemical convulsive therapy suggested that the seizure was necessary and sufficient for therapeutic benefit with ECT, it is now known that there is a dose–response relationship with right unilateral ECT, and that bilateral ECT is likely to be ineffective with ultrabrief pulse widths. Work continues to explore the underlying mechanisms and biologic characteristics of effective ECT treatments with a focus on making the treatment focus on appropriate neural networks with a more efficient stimulus as a method of reducing cognitive side effects. With the growing understanding that depression is a chronic disease for many patients, more emphasis has been placed on continuation and maintenance treatments following an acute course of ECT. Work has been published demonstrating the efficacy of both psychotropics and ECT in reducing relapse post-ECT.

Utilization of ECT has diminished since the middle of the last century, but, because ECT remains the most effective treatment for major depression and a rapidly effective treatment for life-threatening psychiatric conditions, ECT, unlike its contemporaneous somatic therapies, such as insulin coma, remains in the active treatment portfolio of modern therapeutics. Its use has shifted from public to private institutions, and it is estimated that approximately 100,000 patients have received ECT annually over the last few decades in the United States (Table 34.35–1).

Table 34.35–1.
Milestones in the History of Convulsive Therapy

1500s	Paracelsus induces seizures by administering camphor (po) to treat psychiatric illness.
1785	First published report of the use of seizure induction to treat mania, again using camphor.
1934	Von Meduna begins the modern era of convulsive therapy using intramuscular injection of camphor for catatonic schizophrenia. Camphor is soon replaced with pentylenetetrazol.
1938	Cerletti and Bini, conduct the first electrical induction of a series of seizures in a catatonic patient and produce a successful treatment response.
1940	ECT is introduced to the United States.
A. E. Bennett develops curare for use as a muscle relaxant at ECT.	
1951	Introduction of succinylcholine.
1958	First controlled study of unilateral ECT.
1960	Ottosson demonstrates that attenuation of seizure expression with an anticonvulsant agent (lidocaine) reduces the efficacy of ECT. In concert with other work suggesting that subconvulsive treatment produces only weak clinical responses, the hypothesis that seizure activity is both necessary and sufficient for efficacy is upheld.
1960s	Randomized clinical trials of the efficacy of ECT vs. medications in the treatment of depression yield response rates that are significantly higher with ECT.
Comparisons of neuroleptics and ECT show that neuroleptic medication is superior for acute treatment, although ECT may be more effective long-term.	
1970	D'Elia develops what has become the most common electrode positioning for right unilateral

ECT.

1976 A constant current, brief pulse ECT device, the prototype for modern devices, is developed.

1978 The American Psychiatric Association publishes the first Task Force Report on ECT with the aim of establishing standards for consent and the technical and clinical aspects of the conduct of ECT.

Late 1970s to Early 1980s

Randomized controlled trials demonstrate ECT is more effective than sham treatment for major depression.

1985 The National Institutes of Health/National Institute of Mental Health Consensus Conference on ECT endorses a role for the use of ECT and advocates research and national standards of practice.

1987 The belief that the seizure in itself is sufficient for clinical response is challenged by a report that the combination of dosage just above seizure threshold and right unilateral electrode placement, while producing a seizure of sufficient duration, is ineffective.

1988 Randomized controlled clinical trials of ECT vs. lithium demonstrate them to be equally effective in mania.

2000 In controlled trials, the dose/response relationship for right unilateral ECT is validated; high-dose right unilateral and bilateral ECT show equal response rates in major depression, but right unilateral electrode placement is associated with fewer adverse cognitive effects.

Convulsive treatment is induced with magnetic stimulation by Lisanby and colleagues.

2001 The largest modern controlled trial of relapse prevention post-ECT with continuation pharmacotherapy demonstrates a significantly better outcome for combined treatment with a tricyclic antidepressant (nortriptyline) plus lithium compared to nortriptyline alone or placebo during the first 6 months post-ECT.

2006 In a large controlled trial, continuation ECT, given in a fixed schedule without concurrent psychotropic medications, is demonstrated to be effective, but a fixed schedule is only equivalent to combination lithium/nortriptyline.

2008 Ultrabrief right unilateral ECT is shown to be equivalent to brief pulse right unilateral and bilateral ECT in efficacy, but difficult to distinguish from a healthy never depressed control group in cognitive performance, including retrograde memory. In the same controlled trial, ultrabrief bilateral ECT at 150 percent above seizure threshold was ineffective, confirming earlier observations that the seizure itself is not sufficient for efficacy.

2013 Feasibility study of Focal Electrically Assisted Seizure Therapy published.

ELECTRICAL INDUCTION OF SEIZURES

Factors in the Generation and Measurement of Electrical Stimulation for ECT

ECT is a form of brain stimulation in which induction of a seizure occurs when an applied electrical stimulus creates an electrical field with flow of current in excitable tissue of the brain sufficient to depolarize cell membranes of neurons synchronously. Fundamentally, the generation and behavior of the electrical stimulus has been conceptualized by Ohm's law:

$$V \text{ (voltage)} = I \text{ (current)} \times R \text{ (resistance)}$$

Voltage is the electromotor force (volts) causing current to flow; current is the rate of flow of electrons (amperes); resistance is the relative ability to pass current (ohms). Ohm's law assumes a direct current circuit, but ECT devices function on alternating current. In this environment, it is necessary

to replace resistance with the term impedance (Z). Impedance involves capacitance and inductance as well as resistance. Since biologic tissues, being nonferrous, have low inductive properties, the inductance term is usually assumed to have little relevance to impedance during ECT. Capacitance (F) is the ability to store charge (farads). Neural tissue has relatively low capacitance.

(10^{-12} to 10^{-10} F), and the electrode skin interface (estimated 0.4 μF), is the source of relatively more of this term.

Although it is possible to trigger a seizure with a single DC pulse of long duration, voltage and current may vary over time in the electrical stimulus as clinically used. A variety of stimulus waveforms have also been used to deliver the stimulus, including sine wave, rectified partial sine wave, brief pulse square wave, and ultrabrief pulse square waves. These different waveforms are not of equal efficiency in depolarizing neural tissue. By examining mammalian neurons, it has become evident that fast rising current results in firing at a lower current intensity, and hence, lower dosage. The slow rise of sine wave results in accommodation and increases in the threshold for neuronal firing. This observation has led to a preference for brief pulse waveforms which "instantly" achieve peak intensity (on the order of microseconds) over the relatively slower rising sine waveform, typically reaching peak intensity in several milliseconds.

Chronaxie, and hence optimal pulse duration, for human neuronal tissue are on the order of 0.1 to 0.2 ms. Furthermore, once nerves have fired, they enter a refractory period, and continued stimulation will not elicit further response. This has led to a reexamination of the need for longer duration stimulation per phase where much of the stimulus is delivered when the neuronal tissue is refractory. Even brief pulse waveforms with pulse widths on the order of 0.5 to 2 ms, commonly used in modern devices, may be expected to deliver excessive energy in the refractory period, although it is an order magnitude lower than with sine wave stimulation. Finally, it has been observed that increasing the frequency of pulses is less efficient in eliciting depolarization than increasing train duration of pulses when using a brief pulse device. This phenomenon is probably also related to the complex relationship of frequency to depolarization, a U-shaped curve in primates, resulting in maximal efficiency in depolarization around 20 Hz. Duration of a pulse train has a more linear covariation with depolarization.

Once the electrical stimulus is generated, current is distributed inversely to the resistance of the tissue compartments traversed. There are three major compartments: scalp (about 200 Ω); skull (about 18,000 Ω); and brain tissue (about 200 Ω). Because current flow is greatest across the lowest resistance, it has been estimated that 80 percent of current is shunted through the scalp. The skull obviously provides the greatest component of resistance, and skull anatomy, for example, the position and

size of sutures, skull thickness, etc., greatly influences the proportion of remaining electrical dosage that enters brain tissue. Differences in scalp and skull anatomy are thought to be a major source of the wide variation among individuals in the amount of electrical dosage required to elicit a generalized seizure or seizure threshold. These differences have been observed to be of the order of 100- to 200-fold. It has been theorized and modeled that interindividual anatomic variation in tissue layer thickness and conductivity could be compensated by varying the amplitude of the stimulus to produce a more focal and uniform electric field exposure, but the degree of adjustment required has not been determined thus far. CSF volume also affects the distribution of the electrical stimulus, with higher volume of fluid being associated with a weaker more focal distribution and field strength.

Another influence on current shunting is interelectrode distance: The closer electrodes are placed on the skull, the more shunting occurs. It is thought that right unilateral electrode placements can result in the creation of a virtual electrode occurring in the area between the two electrodes and, hence, in reduced amounts of electrical dosage required for seizure elicitation. This increased shunting may also result in lower current density in brain tissue.

The quantity of the electric stimulus delivered has been expressed as energy (joules) traditionally, and, in the modern era, as charge (millicoulombs). Substantial evidence indicates that current density in neural tissue is the critical factor responsible for seizure production and the subsequent neurobiologic effects of the electrical stimulation. Although it is not presently possible to measure charge density directly in human neural tissue during ECT, dynamic impedance can be used to approximate charge density because of its relationship to current shunting during stimulus delivery. When electrode site preparation and positioning are standardized, anatomic factors become the major determinants of impedance. If these factors are also constant during the treatment, impedance can then reflect current density in brain tissue.

With the development of other forms of electrical and also magnetic brain stimulation, there has been revived interest understanding and exploring the impact of electrical stimulation on brain tissue. The various elements of brain have differing electrical properties and vary markedly in excitability with myelinated axons being most excitable, and neuronal cell bodies and dendrites least. Tissue response also varies with distance from electrical source, in this case, the stimulating electrode. Although direct recording of the effects of electrical stimulation is not available for ECT, except in animal models, functional neuroimaging and computational modeling are expected to expand the current understanding of the physiology of the treatment.

Devices Used to Deliver ECT

Although constant current, constant voltage, and constant energy devices have been in use, most modern devices are constant current as constant voltage devices have become outmoded. The range of constant current is in the order of 0.5 to 0.9 A in these devices. Dosage is manipulated by varying the time of exposure to a fixed current (total charge). With brief pulse devices, the most commonly used constant current devices, frequency of pulses, pulse width, and duration of pulse train are parameters that can be used to vary the stimulus dosage. Because impedance varies directly with voltage, particular attention must be paid to impedance in a constant current environment. Commonly, impedance is tested prior to stimulus delivery by passage of a low-amplitude, high-frequency test stimulus. If impedance exceeds manufacturer limits, treatment stimuli are not permitted by the device, although some devices are equipped with override features. If too high, impedance is usually lowered by improving skin electrode contact, although other parts of the circuit may also need examination and adjustment. By keeping impedance within safe guidelines, local tissue damage is avoided. When impedance is too low, voltage will also be very low, and may not be sufficient to drive enough current flow to brain tissue where resulting charge density may not be great enough to cause synchronous neuronal depolarization and the desired biologic effects. Low impedance is usually the result of current shunting in the scalp, and is corrected by interrupting any alternative current pathway at the skin surface, for example, saline used to prepare the electrode site runs together and forms a continuous pathway at the scalp.

Calculation of stimulus energy in joules requires information about interelectrode impedance, which is not readily available. Charge is commonly used to measure the intensity of the stimulus used in treatment with brief pulse devices. Charge is the quantity of electrons flowing through a conductor over a given time period (coulombs), and can easily be computed from the parameters of a brief pulse constant current device.

Constant voltage devices allow current to vary inversely with impedance. The typical device generates a sine wave stimulus and has a range of 70 to 170 V. With these devices, high impedance will result in low current flow, which in turn, theoretically, may be inadequate to induce sufficient charge in neuronal tissue to result in neuronal depolarization. Because the practitioner does not have access to crucial information about impedance when using a constant voltage device, and it may be difficult to assess current intensity in this setting, and judgments about the adequacy of parameters can be difficult to make. The use of these devices in the United States has become outmoded.

ECT device output in the United States has been capped at 100 J, which corresponds to a charge of 500 to 576 mC, depending on the particular

device specifications. With ultrabrief pulse width, this range is adequate to deliver right unilateral ECT to almost all patients. ECT devices in the European Union and elsewhere can have an extended range up to 200 J to allow delivery of adequate dosage with brief pulse right unilateral electrode placement, which is mandated in some EU nations.

MECHANISMS OF ACTION

The relative inaccessibility of the central nervous system has made understanding the pathophysiology of psychiatric diseases a continually evolving process. As a consequence, the mechanisms of action of ECT, the oldest somatic treatment currently in use in the field of psychiatry, continue to be an active area of hypothesis and research. Past and present, theories abound, and a wide range of data, particularly at the preclinical level, is available on the effects of electroconvulsive stimulation (ECS).

Proposed mechanisms have involved theories in almost every domain. These include psychological constructs; structural explanations, for example, neural plasticity; interpretations based on electrophysiology and neurophysiology; biochemical theories encompassing neurochemistry, including neuroendocrine phenomena; and other molecular rationales, including genetic and epigenetic mechanisms.

Among psychological theories, there is no evidence that fear, regression, or increased medical attention account for the efficacy or side effects of ECT. As many of the most recent advances in the field have reduced the adverse cognitive effects of ECT while maintaining efficacy, there is little reason to believe that memory loss has much mechanistic validity. Extensive reviews of the preclinical and clinical literature have refuted the assertion that brain damage occurs, let alone, accounts for ECT's effects. Furthermore, current anesthesia practice assures that hypoxia does not occur. Sham ECT (anesthesia alone) is ineffective; hence, anesthesia is unlikely to play a role in mechanism of action.

Distinguishing the relevance of observed phenomena with ECS constitutes a major challenge in the area of mechanisms. Considerations include questions about the relevance of animal data, much of which has been derived from rodents, although there has been recent interest in primate work. This work suffers from the current lack of adequate animal models of the psychiatric syndromes for which ECT is utilized. In preclinical work, ECS is often given in a time course that does not closely follow the treatment course given to patients, that is, two to three times weekly. For example, stimulation is administered once or several times in one day in preclinical investigations.

ECT has a very broad spectrum of efficacy and action, as will become evident from discussions of indications for its use, of efficacy in a variety of syndromes, and of its side effects. The treatment is often studied in comparison with antidepressants or to a lesser degree other psychotropics.

It is known that there is overlap in mechanistic effects, but ECT has more therapeutic effects than any studied medication. Coupled with the fact that ECT has more indications for treatment, the challenge of ascertaining critical similarities and differences is significant. Because of the perceived invasiveness of the treatment, the severity of illness among treated patients, and the necessity for anesthesia, little work is currently being done with sham ECT. There are limited data available from weaker forms of the treatment, for example, right unilateral ECT at low or modest dosage which is now known to be a less effective form of the treatment.

Biochemical Actions

There is a substantial body or work comparing ECS with psychotropic (and other) medications whose actions and mechanisms have been assayed in vitro and in vivo, most often preclinically, but also in human studies. Not surprisingly, the major areas of interest have been neurotransmitter and peptidergic systems. A primary focus has been on monoamine effects, many of which are shared by ECS in animals, ECT in humans and psychotropics, especially antidepressants. Although it appears that both ECS and antidepressants downregulate β-adrenergic receptors, human studies of broader changes in noradrenergic pathways have been characterized by inconsistent outcomes. There are also variable data on the effects of antidepressants and ECT on serotonergic systems: Antidepressants typically downregulate 5-hydroxytryptamine receptors ($5HT_2$), whereas ECT leads to increased density of $5HT_2$ receptors (in rodents) and decreased binding (in primates). Although serotonergic transmission may be enhanced by both antidepressants and ECT, the mechanisms appear distinct. ECT is more effective than antidepressant medications, so defining what possible mechanisms are responsible for this phenomenon are of pharmaceutical as well as heuristic interest. Currently, the critical differences are not known. Both animal and clinical studies indicate increased dopaminergic functioning following ECS, particularly D1 and D3 receptor function. Although this effect may be an underlying mechanism for ECT's therapeutic effects in Parkinson disease, it does not help clarify the underlying process for the benefits conferred by ECT on patients with schizophrenia and other psychotic illnesses, where dopaminergic antagonism, at least in some brain regions, has been presumed to be critical.

Another major area of interest has been the variety of different neurotransmitter systems, which may form the biochemical foundation for the anticonvulsant effects of ECS. Because of the efficacy of anticonvulsant medications in mania, there is also speculation that the anticonvulsant effects of ECT contribute to its efficacy in mania. Most of this work is preclinical, and indicates mixed GABAergic activity, upregulation of

adenosine receptors, and blocking of anticonvulsant effects with opiate antagonists. Currently, GABAergic effects in humans are being explored neurophysiologically. It has been difficult to duplicate anticonvulsant effects of opiate antagonists in humans. The proconvulsant effects of caffeine, aminophylline, and similar compounds are observable in humans and are thought to be due at least in part to alterations in adenosine transmission, even though these agents have other biochemical effects which may also contribute. With increased interest in the exploration of the glutaminergic system in the etiology and possible treatment for depression, preclinical studies demonstrate increased glutamate levels in hippocampus after ECS in a depressive rat model. Unfortunately, it is not currently possible to conclude that alterations in any transmitter system are associated with the efficacy of ECT in any syndrome for which it is used.

Most recent preclinical research focuses on growth factors and molecular mechanisms. It appears that BDNF and NGF are both increased by a single ECS and chronic ECS, whereas neurotrophin is decreased. There is interest in linking these observations to those made of marked neural plasticity in some brain areas, for example, hippocampus, due to ECS, as will be discussed below. Work continues with a wide variety of other neuropeptides, for example, somatostatin, CCK, precursors of opiates and thyroid hormones, etc. Other areas of interest concern the effects of ECS on second messenger systems, genetic expression, and transcription regulation. The work, focused largely on molecular phenomena related to cell proliferation—both neuronal and vascular, plasticity, and resiliency—including antiapoptotic effects, is expanding steadily, but its clinical and functional significance remains to be defined.

Hypotheses related to neuroendocrine mechanisms were generated early in the history of the use of ECT and have persisted to the present. Most hypotheses reason that stimulation of diencephalic structures, especially the hypothalamus, is involved and perhaps critical to the efficacy of the treatment. Experimental designs generated by these hypotheses have involved indirect quantification of function, specifically various peripheral neuroendocrine measures. Examples include CRH, ACTH and cortisol, both acutely and subacutely; studies of oxytocin and vasopressin; measures related to growth and thyroid hormones. Currently, there is no consistent evidence that acute or subacute changes in neuroendocrine factors impact efficacy or cognitive effects. Similarly, the involvement of immune system in the therapeutic effect of ECT has also been investigated. The available data suggest that a single session of ECT induces an acute, transient immune activation as measured by cellular immune function (lymphocyte subpopulations and NK cell activity) and levels of circulating cytokines, whereas repetitive ECT treatment results in long-term downregulation of immune activation. More prospective, controlled studies with larger sample sizes are needed to confirm this finding.

Neurophysiology

With advances in the area of brain imaging, neurophysiology has become a focus of interest in investigating the mechanisms of action of ECT. It is known that large increases in global cerebral blood flow (CBF) and cerebral metabolic rate (CMR) occur along with increased blood–brain barrier permeability during a generalized seizure, including those electrically induced. In the postictal period there is functional suppression with decreases in CBF and CMR as well as varying degrees of bioelectric suppression on EEG. Changes are also topographically distributed. These reductions have been correlated with treatment outcome.

The magnitude of reductions in CBF in specific prefrontal regions is related to efficacy of ECT, and responders are more likely to exhibit postictal suppression and develop slow wave activity on EEG than nonresponders. As techniques have been refined, the possibility of identifying specific functional networks and associating them to efficacy has improved. Related work in efield modeling has yielded information concerning the way seizures are generated with various electrode placement and electrical dosing techniques as well. For example, studies comparing effective forms of bifrontotemporal, bifrontal, and right unilateral electrode placements indicate that the prefrontal cortex, particularly on the right, the anterior cingulum and associated subcortical areas including the right medial thalamus, brainstem, and midbrain tegmentum are involved. Ineffective forms of ECT, for example, low dose right unilateral, trigger seizures from the motor cortex, and involve the prefrontal area less. Positron emission scan (PET) investigations point to these areas as well, particularly Brodmann area 25, the anterior cingulum, and the thalamus. These observations are important to clarifying which brain regions are critical to the efficacy of the treatment, as well as to understanding the dose–response relationship of electrical stimulation above seizure threshold to efficacy that has been observed for right unilateral ECT. The examination of the functional connectivity using functional MRI before and after bilateral ECT treatment revealed a significant increase in and around the left dorsolateral prefrontal cortical region (Brodmann areas 44, 45, and 46), where the average global functional connectivity was considerably decreased after ECT treatment, corresponding to the improvement in depressive symptoms. There has been expanding work using brain imaging technologies to investigate networks related to the cognitive effects of the treatment as well. Although preliminary, this work confirms the involvement of the medial temporal lobe in anterograde amnesia and points to prefrontal cortex involvement in retrograde amnesia.

Although the neurophysiologic inquiries are continuing, they are hindered by the limited localizing value and coarse resolution of currently

available methods. The degree of covariance among various regions and the spatial distribution and magnitude of association are yet to be defined. There is also a need to better characterize topographies and to determine whether normalization, abnormalization, or independence of observations applies. Currently, investigational samples are small and heterogeneous as well.

Genetic and Epigenetic Mechanisms

In addition to focus on cellular level changes relevant to the antidepressant effect of ECS, advances in genomics have provided new insights about the gene expression and epigenetic changes associated with ECS. The first studies of ECS-induced gene expression were published in the early 1990s. Further studies have revealed regulation of distinct neurotrophic signaling pathways (BDNF, Neuropeptide Y, vascular endothelial growth factor, fibroblast growth factor), synaptic vesicle proteins (synaptosomal-associated protein, *Syt 3 and Syn 1*) and immediate early genes (*c-fos, Egr 1, and Nrn 1*). BDNF has received extensive attention because of its involvement in the etiology of depression and response to antidepressant treatment. It has been shown that the BDNF expression in the hippocampi is elevated immediately (in the few hours) after acute ECS and decreased afterward in a temporal dependent manner, while BDNF expression was decreased in the ventral tegmental area. The expression patterns highlight the widespread action of ECS and the spatial and temporal diversity of expression changes for each gene type.

A few studies also attempted to examine possible epigenetic mechanisms, that is, the process of modifying gene expression independent from the primary DNA sequences in the therapeutic effect of ECT. Evidence indicates a strong effect of ECS on the different epigenetic mechanisms in the rodent brain. One of the earliest studies by Tsankova et al. in 2004, reported histone modification at gene promoter regions in hippocampi of rats undergoing acute and chronic ECS in response to electrical stimulation. Increased levels of histone H4 acetylation at the promoters of the *c-fos, BDNF,* and *CREB* genes were observed after acute and chronic seizures, which, in general, corresponded with increased mRNA levels of these genes. Demethylation at the *BDNF-IX* and *FGF-IB* promoter regions, increased DNA methylation at the *Arc* promoter, and demethylation at the *c-fos* promoter region were also reported. Generalizing this work to clinical populations remains to be carried out.

Neuroplasticity

Recently, there has been increased interest in structural changes in the brain associated with psychiatric syndromes and response to treatment. This has been particularly so for microscopic changes associated with ECS,

as well as, antidepressant and other medications. It is observed that the delayed behavioral response to common antidepressant medications in rodents coincides with the delayed upregulation of neurogenesis, at approximately 3 weeks. Similarly, the rapid antidepressive action of electroconvulsive shock is associated with a rapid stimulation of neurogenesis, producing immature cells demonstrated to be highly excitable compared to mature neurons. Synaptic plasticity, in addition to cellular plasticity (neurogenesis), for example, sprouting of mossy fibers, alteration of cytoskeletal structure, increased connectivity in performant pathways have been observed in animals after ECS. In addition to neurogenesis after ECS, microenvironment changes have been observed: for example, upregulation of activated microglia cells, the immune cells of the CNS, and increased proliferation of astrocytes, angiogenesis in certain layers of hippocampus, which may potentially modulate neurogenesis process after ECS. These reports have also galvanized controversy over various aspects of technical validity of the observations. It is unknown whether such changes occur clinically, and, if they do, what significance to efficacy and cognitive side effects might be discovered.

INDICATIONS

Although, historically, the first diagnostic indication for ECT was schizophrenia, practice has evolved in the past 75 years. Approximately 85 percent of patients receiving ECT in the United States currently have major depression as the diagnostic indication for its use. The remainder have schizoaffective disorders, mania, and schizophrenia with a few other diagnoses such as Parkinson disease completing the inventory of indications. The clinical literature demonstrating the short-term efficacy of ECT in the major syndromes for which it is used is considerable, and includes randomized controlled trials with sham treatment or with medications as alternatives, outcome data from studies involving various treatment techniques, as well as uncontrolled data and surveys of expert opinion.

Beyond diagnostic indications, there are other clinical considerations commonly brought to bear in the prescription of ECT. Historically, ECT was a first-line treatment for the major psychiatric syndromes, but, with the development of psychopharmacologic treatments, use as a primary treatment has decreased, and resistance to medications has become the most common clinical indication. None the less, when patients require rapid clinical response because of the severity and danger of psychiatric symptoms or medical problems resulting from psychiatric causes, ECT may be given without a prior drug trial. This is also the case when there has been prior optimal response with ECT or the patient prefers the treatment over medications (Table 34.35–2).

Table 34.35–2.
Indications for Use of Electroconvulsive Therapy

Diagnoses for which ECT may be indicated
Major diagnostic indications
Major depression, both unipolar and bipolar
Psychotic depression, in particular
Mania, including mixed episodes
Schizophrenia with acute exacerbation
Catatonic subtype, particularly
Schizoaffective disorder
Other diagnostic indications
Parkinson disease
Neuroleptic malignant disorder
Clinical Indications
Primary Use
Rapid definitive response required on medical or psychiatric grounds
Risks of alternative treatments outweighs benefits
Past history of poor response to psychotropics or good response to ECT
Patient preference
Secondary Use
Failure to respond to pharmacotherapy in the current episode
Intolerance of pharmacotherapy the current episode
Rapid definitive response necessitated by deterioration of patient's condition

Mood Disorders

Major Depression. ECT is the most effective treatment for major depression currently available. It is commonly used as the standard against which other treatments, including innovative treatments such as repetitive transcranial magnetic stimulation, are compared. No treatment has ever been found to be superior to ECT in the treatment of major depression in a controlled trial.

Evidence for ECT's efficacy derives from several different sources. The introduction of the treatment occurred prior to the development of clinical trials methodology in the post war era. In the 1940s, open clinical series and case studies cited response rates of 80 to 90 percent with the use of ECT as a first-line treatment. Decreased chronicity of illness, decreased morbidity, and the suggestion of decreased mortality were frequently cited as benefits of ECT. From the 1950s through the 1980s, ECT was subjected to the randomized clinical trials with sham ECT and psychotropic medications as comparators. In the sham versus real ECT trials, anesthesia alone was used for comparison groups because of a concern that there were benefits from its repeated use. ECT was shown to be consistently superior, and the further use of sham conditions has been abandoned in studies of major depression. From the 1950s onward, there was also interest in the relative efficacy of antidepressants and ECT. In these reports ECT was found to be 20 to 40 percent more effective than medications, and there has not been a study that found medication to be superior to ECT. Most of

this work was conducted in the earlier decades of this period, and is limited by the possibility that modern pharmacologic standards would dictate more aggressive dosage and duration of treatment in the medication conditions. In this type of study, adequate blinding is not possible, and concerns about bias cannot be completely dispelled even if clinical raters do not know the treatment conditions. Many of the antidepressants investigated in the past have been superceded by newer compounds, such as the specific serotonin reuptake inhibitors, and pharmacologically unique agents such as bupropion and mirtazapine. Unfortunately, there is little data to inform comparisons of ECT and modern pharmaceuticals.

Although in an earlier era prior to modern advances in defining the phenomenology of depression, it was thought that various clinical criteria conferred a negative prognosis to the use of ECT, more recent observations have found ECT to be effective for all subtypes of major depression including unipolar and bipolar depression, melancholia, and psychotic depression. There have been suggestive data that psychotically depressed patients have a superior response to ECT, whereas there is suboptimal response with antidepressants alone and the recommended regimens of adequate doses of both an antidepressant and an antipsychotic are seldom given, perhaps due to poor tolerance of the combination. ECT may be particularly useful for psychotically depressed patients because the syndrome is often accompanied by severe symptoms and greater risk of suicide.

ECT can also be used safely in all populations of patients, including those often considered to be at special risk: the elderly, the medically ill, pregnant women, and adolescents. Each of these groups may require specific considerations and extra preparation and/or precautions to be taken prior to treatment. ECT has even been used to treat preadolescent children, although rarely.

Dilemmas persist among experts in the field about when to offer ECT in the course of treatment for major depression. The hierarchy of factors that need to be considered has not been resolved, but it is important to gauge the risk of not terminating an episode of depression while giving sequential trials of antidepressants along with augmentation and combination medications against the risk of the principal side effects of ECT, namely persistent retrograde memory deficits of varying significance. With recent improvements in technique, these cognitive effects have been reduced to the point where, they can be difficult to detect. Even with these improvements, an acute course of ECT will often disrupt the routines of daily life because of the recovery requirements accompanying general anesthesia. Another important consideration relates to the fact that major depression is a subacute and often chronic disease with a need for continuation and maintenance treatment. For ECT, acute response is followed by the need to determine adequate maintenance treatments, most

often pharmacologic, although maintenance ECT is also an option. This circumstance can also affect the timing of the choice of ECT versus pharmacology.

Finally, the response rates cited early in the history of ECT must be adjusted to the changing make-up of patient populations receiving the treatment. It appears that prior medication nonresponse within an episode, extended lengths of episode, and comorbidity with other psychiatric conditions may lower the expected response rate. Comorbidity with personality disorder, that may independently contribute to mood changes, can be especially problematic since patients with personality disorder can also suffer major depression, and it is difficult to define what phenomenology belongs to each syndrome and to determine expectations. This does not automatically mean that ECT should be withheld from these populations. Response rates to alternative treatments may be even lower, while response to ECT in antidepressant nonresponders can be expected to be 50 to 70 percent.

Mania; Mixed States and Rapid Cycling. Historically, ECT was a first-line treatment for mania as well, but pharmacologic strategies, particularly lithium, anticonvulsants, and atypical neuroleptics, have become the mainstay of treatment for the manic episodes. In the modern era, the use of ECT is generally reserved for patients who are resistant or intolerant to the usual medication treatments, including those with mixed states or rapid cycling, or who have very severe symptomatology, for example, manic delirium. Organizations issuing guidelines for the use of ECT to treat mania have assigned it to second-line (WFSBP; APA; CANMAT) or third-line status (NICE) for acute episodes; only APA recommended its use as a maintenance treatment for bipolar disorder.

Compilations of the evidence for the use of ECT in mania have reported 75 to 80 percent response rates. The bulk of the evidence comprises uncontrolled case series, undoubtedly because of the great difficulty in conducting usual clinical trials in this population, due to uncontrolled behavior, difficulties in assuring capacity to consent, etc. Sham versus real ECT studies, with patients on neuroleptics in both conditions, demonstrated superior outcomes for ECT patients both in response rates and in lower neuroleptic requirements. Controlled retrospective comparisons have found ECT to be equivalent to lithium, and at least as efficacious as typical neuroleptics, if not more so. Prospective work demonstrated equivalence to lithium in studies where all patients received neuroleptics as well as the study treatments. One small study comparing ECT to lithium and neuroleptic in patients who failed lithium or neuroleptic found ECT to be noticeably superior to combined pharmacology. There have been no comparisons of ECT to anticonvulsants. Early work that suggested the need for increased frequency in treatment

schedule and increased numbers of sessions to complete a treatment course has not been born out in modern studies, which have used standard treatment schedules.

A prospective trial and a retrospective controlled review have found that patients in mixed states are responsive to ECT, although increased numbers of treatments may be required compared to pure manic or depressed states. Case reports have indicated that ECT is also potentially effective in managing rapid cycling, where finding effective pharmacologic approaches can be particularly complex and difficult. Response rates are lower than for acute manic states.

Schizophrenia

Although schizophrenia is the second most common diagnostic indication for ECT, there is a lack of expert consensus about its use and wide disparity in practice. This may be due to the current understanding of schizophrenia as a chronic illness and to the scarcity of evidence supporting the efficacy of ECT for chronic symptoms. Especially since the advent of atypical antipsychotic medications, pharmacologic treatment remains the first choice.

ECT was introduced for use in schizophrenia and the earliest reports, consisting of case series and comparisons with historical cohorts and nonsomatic treatments, were quite positive. As with other observations from this era, there was a lack of scientific methodology in diagnostic and outcome criteria, which would not conform to modern standards. Real versus sham ECT studies were carried out with chronic patients in the 1950s to 1960s, and more acutely ill samples on neuroleptics in the 1980s. The earlier studies showed no advantage for ECT over anesthesia, but the later studies showed ECT to be superior to anesthesia alone. The source of the disparate outcomes is not clear, but, in addition to differences in chronicity, the presence of neuroleptics in the modern samples may be critical. Because of the positive reports of efficacy in the first decades of use, ECT was also used as the standard against which to compare newer somatic therapies, particularly neuroleptics when they were first introduced. Although subject to the usual limitations of such early clinical trials, it soon became apparent that, at best, ECT was equivalent to neuroleptics in short-term efficacy. At this point, pharmacology superceded ECT for the treatment of schizophrenia. One observation from this era has remained intriguing and might merit further consideration. In long-term follow-up, patients who had received ECT had superior outcomes.

Equal attention has been paid to examining combination of ECT with neuroleptics versus treatment with either modality alone. The combination treatment is generally superior to monotherapies but the evidence for such observations is considered to be less than definitive due to relatively small samples and disparity in methodology among the studies. It appears that

lower doses of neuroleptic are needed in combination treatments. A recent study of combination treatment versus monotherapy in maintenance treatment of schizophrenia again showed promise, particularly in the first weeks of treatment. Although few of these studies reached full standards for a clinical trial, lacking random assignment and full blinding, recent reviews suggest that ECT may be useful for treatment-resistant patients and those who easily relapse on monotherapy. Thus far, most of the published observations on the use of ECT in schizophrenics resistant to neuroleptics are somewhat impressionistic as well. Recent reports confirm the safety of using ECT and atypical antipsychotics, with the clozapine as the oldest and most reported agent. Most professional bodies issuing guidelines for the treatment of schizophrenia reserve ECT for patients who are nonresponsive or intolerant to clozapine.

Since ECT does not have a broader therapeutic spectrum than neuroleptics, it is not surprising that good prognosis patients for pharmacologic treatment are also those that do best with ECT. Evidence to support the traditional idea that the presence of affective symptoms improves the likelihood of response to ECT is inconsistent, and there is no controlled evidence concerning its use for schizoaffective patients. Uncontrolled observational evidence suggests efficacy of ECT in schizoaffective illness, but response falls short of that obtained in straight-forward affective disorder, and resembles response rates obtained for schizophrenia.

One last area of interest is the impact of ECT on the movement disorders resulting from neuroleptic treatment of schizophrenia. Extrapyramidal symptoms induced by neuroleptics are reversible by pharmacologic intervention, but also respond to ECT. Furthermore, there is evidence from several case series that ECT may protect against the development of tardive dyskinesia in neuroleptic treated patients, independent of the observation that combination treatments with ECT and neuroleptic require lower doses of neuroleptic. This observation is consistent with preclinical observations of the effects of ECS on the dopaminergic system and the effects of ECT on patients with Parkinson disease.

Other Diagnostic Indications

In general, ECT treatment for other indications is supported by case material only. The use of ECT will be rare and only when standard treatments cannot be tolerated or fail.

Psychiatric. There is only very limited information about the impact of ECT on other DSM-IV axis I disorders, and no evidence for clinically significant efficacy without the presence of another primary diagnostic indication. There has been interest in anxiety disorders because of the

overlap in symptomatology and pharmacologic therapeutics between affective and anxiety disorders, but the only published data concern obsessive compulsive disorder (OCD). Prospective work demonstrated acute response in OCD, but patients soon relapsed, and ECT is not recommended for this disorder. Because of the not infrequent presence of symptoms of panic in depressed patients undergoing ECT, the question of the impact of the treatment on these symptoms has been raised, but there are no studies of the effect of ECT on panic disorder. Comorbidity with posttraumatic stress disorder (PTSD) and depression has provided an opportunity to observe the effects of ECT on PTSD. A minority of patients with PTSD may be vulnerable to increased symptoms related to the syndrome, but there are also case series where PTSD improved independent of the response of depression to ECT. Even though dysthymia is on the spectrum with major depression, there is no demonstrated efficacy. Patients with double depression (dysthymia and major depression) have similar response rates to those with episodic major depression alone, but are left with higher levels of mild depressive symptoms at the end of treatment, suggesting that dysthymia is more difficult to ameliorate with ECT even in the setting of comorbid major depression. The delirium that can accompany withdrawal and toxic states induced by some substances, that is, alcohol, phencyclidine and stimulants, can be treated with ECT, but the underlying substance abuse syndrome is not significantly affected. This use of ECT is largely of theoretical interest.

Another area of concern is the issue of comorbidity with personality disorders. Here most of the work concerns cluster B disorders, especially borderline personality disorder. A secondary area of interest should be cluster A disorders because of their hypothesized overlap with axis I anxiety disorders. In general, comorbidity with one or more personality disorders is associated with poorer outcomes, especially higher relapse rates. The challenge for clinicians is to discriminate between affective symptoms that result from the personality disorder and those that constitute an ongoing affective episode. ECT is not considered to be a treatment for any personality disorder.

Neurologic. ECT has been used rarely for the treatment of several neurologic disorders, usually in situations where they are comorbid with a psychiatric disorder that is an indication for ECT. The most common of these is catatonia, a syndrome characterized by stupor, mutism and a variety of motor symptoms, including posturing, waxy flexibility, and catalepsy. Schizophrenia and bipolar disorder are the most frequent underlying diagnoses, but with the increased occurrence of autism in modern populations, this illness is becoming a more common diagnosis with catatonia. One of the more commonly reported uses of ECT in adolescence is for patients with developmental disorder accompanied by

pharmacologically refractory dangerous behaviors thought to be on the catatonic spectrum. Currently, benzodiazepines are the primary treatment for catatonia along with a primary pharmacologic approach to the comorbid psychiatric disorder. When catatonia is resistant to benzodiazepines, ECT may be used. The data supporting this approach are largely uncontrolled, but quite positive. The syndrome of lethal catatonia is characterized by stupor or excitement, hyperthermia, autonomic dysregulation, rigidity, and changes in consciousness. ECT can be quite effective and, in fact, lifesaving. Neuroleptic malignant syndrome is an iatrogenically induced form of lethal catatonia and is often treated with dopaminergic strategies as well as sedatives. Outcomes with ECT are equivalent to those obtained pharmacologically, but ECT has the advantage of being a treatment for the comorbid psychiatric syndrome for which neuroleptics must be discontinued. There is evidence that NMS is less frequent with atypical antipsychotics, and the use of ECT for NMS may become less necessary as practice changes.

Open- and sham-controlled data have demonstrated that the motor symptoms of Parkinson disease, especially rigidity and bradykinesia, are lessened by ECT, particularly in the "off" phase of treatment that characterizes the phase of the disease treated with L-dopa. These effects are of 4- to 6-week duration generally, but there are reports that maintenance ECT may be helpful as well. ECT is seldom used as a primary treatment for Parkinson disease, and is more frequently used to treat the comorbid depression that can occur with the disorder. The combination of ECT with levodopa/carbidopa may require decreasing medication dosage in order to stave off dyskinesia or delirium as complications of combined treatment. With the increasing use of clozaril and other atypical neuroleptics to manage the side effects of levodopa/carbidopa, the use of ECT for Parkinson disease has diminished.

The anticonvulsant effects of ECT are well characterized, and ECT has been used in epilepsy, although effects are time limited and ECT has no demonstrated superiority over anticonvulsant medications. When such patients are treated, including when they are treated for comorbid psychiatric conditions more commonly treated with ECT, dosage of anticonvulsant medications is usually not changed, except when therapeutic seizures cannot be elicited. Recent reviews have suggested that ECT might be of use in intractable seizures or status epilepticus, particularly if the condition is secondary to a transient cause such as viral encephalitis.

There are reports of lessening of pain syndromes when comorbid depression is treated with ECT. ECT has also been used to mitigate other movement disorders, for example, Tourette syndrome. Historically, there have been cases of delirium of both medical and psychiatric cause that respond to ECT, although the treatment is very, very seldom used for this

reason currently.

The remainder of ECT use in neurologic syndromes is as treatment for comorbid affective and, less commonly, psychotic syndromes. There are case reports and series of its use in post stroke depression and mood disorders accompanying dementia, mental retardation, even head trauma and brain tumors. In all of these diagnoses, the risk of cognitive side effects of ECT can be greater, and modifications of the treatment may be needed, for example, to avoid skull defects found with trauma or to minimize the ictal blood pressure changes for patients with modest, stable brain tumors.

PATIENT MANAGEMENT

Pretreatment Evaluation

Evaluation of patients for treatment with ECT should be done as close to the first treatment session as possible. Both psychiatric and medical assessments are needed in order to conduct a risk–benefit analysis for the advisability of ECT treatment of an individual patient. In general there are no absolute medical contraindications to ECT. Although cochlear implant is labeled as a contraindication, ECT has been reported to be administered safely to the contralateral side of the implant, and the implants themselves were not damaged by ipsilateral ECT administration in cadavers.

The psychiatric component of the pretreatment evaluation is generally conducted by a practitioner privileged to administer ECT, but there are often contributions from the patient's attending psychiatrist if different from the ECT provider. Establishing the indications for ECT will include a careful diagnosis as well as consideration of other clinical factors contributing to the recommendation for ECT, for example, severe suicidal risk. There may be local requirements and regulations for second opinions, especially in special populations such as adolescents and children.

Past treatment with ECT should be reviewed not only for response, but also to identify technical aspects and tolerance of the treatment. Knowledge of prior ECT treatments, including use of specific ECT records, will guide recommendations for the current course. Pharmacologic treatments should be evaluated for number, adequacy, tolerance, and degree of response. Psychotropic history can be an indication for ECT as well as a basis for recommendations concerning post-ECT continuation treatment. Decisions regarding the adjustment of psychotropic medications should be based on the degree to which they may enhance response, for example, maintaining an antipsychotic; the possibility that they may interfere with ECT, for example, anticonvulsants used as psychotropics; the possibility that medications may contribute to adverse effects, for example, lithium; and the need to maintain medications for patient management while ECT takes effect.

As part of the pretreatment evaluation there should be documentation

of the target symptoms to facilitate evaluations during the treatment course and decisions concerning the termination of acute treatment. In addition to behavioral assessments, cognitive evaluation pretreatment is also critical. At minimum, those aspects of cognitive function most likely to be affected should be documented at baseline: orientation and memory, including recall of recent and remote events. Evaluation of language and visual motor and perceptual abilities can also be valuable as well. Finally, patients' subjective assessment of their cognitive and memory functioning should also be documented, particularly since the predominant diagnostic indication for ECT, major depression, is often accompanied by both subjective and objective memory problems.

The medical component of the pre-ECT evaluation focuses on the patient's ability to tolerate anesthesia as well as ECT, and should be conducted by an ECT practitioner as well as an anesthetist. The general medical evaluation will be similar to that conducted for patients undergoing outpatient surgery, and will focus on, although not be limited to, cardiac (e.g., congestive heart failure, symptoms of coronary artery disease), pulmonary (e.g., lower respiratory tract infection), and neurologic systems (e.g., acute stroke, increased intracranial pressure), those most likely to be impacted by ECT. The patient's past experience with anesthesia should be elicited, as well as family history of capacity to tolerate anesthesia. A complete list of medications including herbal and over-the-counter medications as well as medication allergies is also needed. Most providers document a complete blood count and electrolytes as well as electrocardiogram. In addition, a chest x-ray, thyroid function tests, a complete metabolic panel, and a pregnancy test in women of childbearing age may be needed. A brief dental examination for loose or missing teeth and the presence of bridges and dentures is recommended. Testing of plasma pseudocholinesterase or dibucaine number is done as indicated by patient and family history. The risk of fracture of the long bones or spine has been averted by the use of muscle relaxants. Hence, spinal x-rays are done as indicated by the patient's history of skeletal injury or disease. Brain imaging is recommended when a questionable neurocognitive history, focal findings on neurologic or funduscopic examinations, or altered neurocognitive examinations are present. The basic medical evaluation should reveal whether there may be a need for further specialty consultations, testing, or labs. Many institutions involve an internist routinely, especially when conditions that can be affected by or interact with ECT, for example, diabetes, will need management during the course of treatment.

Taken as a whole, the pretreatment evaluation will result in recommendations for the modification of medications the patient may be receiving, both on a medical and a psychiatric basis; the modification of ECT technique; the modification of anesthesia technique; and the

management of both psychiatric and medical conditions during the ECT course.

Consent

Written informed consent is standard in the practice of ECT, and involves a discussion of the risks and benefits of the treatment with the patient and/or legally sanctioned surrogate. Procedures for consent are locally regulated, particularly at the state level, and familiarity with these regulations is essential. Consent can include both the anesthetic procedures and the electrical stimulation, although institutions may provide separate consents for each of these aspects of treatment. Consent forms generally cover several different areas and can be lengthier than the type of document used for other comparable medical or surgical procedures. Descriptions of the procedure and expected benefits are detailed. Risks of the treatment including possible cognitive and medical adverse effects, including death, should be documented. The possibility of relapse and nonresponse should be included. Expected participation by or behavioral restrictions of the patient, for example, NPO for several hours before treatment, are spelled out. Alternatives to treatment, including no treatment, should be discussed. In addition to a generic description, patients should understand the individual indications and rationale for ECT. They should know who can answer any questions about the treatment that may occur during the course of ECT. It should also be clear that consent may be withdrawn during the course of treatment. The amount of information given should be tailored to each patient, recognizing that too much information can obscure the process just as too little. Guidelines and sample consent documents are available from professional organizations.

Most patients referred for ECT have capacity to consent and can give it voluntarily. Generally, capacity is assumed to be present unless there is strong evidence to the contrary. Where doubt exists as to capacity, an independent consultation may be prudent. It is important to weigh the protection of autonomy and the opportunity to receive effective treatment in the consent process. While patients with capacity should not be coerced to receive treatment, seriously ill patients who lack capacity should not be unnecessarily obstructed from receiving it, especially when ECT is being recommended to prevent severe adverse outcomes such as increased morbidity or even death. Although regulations vary by jurisdiction, most allow for involuntary treatment with surrogate consent and/or legal review, which can include formal judicial review. Some jurisdictions mandate not only judicial review, but also review by the department of health for patients who lack capacity and object to ECT.

Surrogates must proceed through the consent process in a similar way to patients with capacity. Family members and other significant associates or companions are encouraged to become educated about ECT. Audiovisual

aids and written material may be provided to patients, family, and others as indicated. Finally, it should be remembered that consent is a process throughout the course of ECT, and clinicians should maintain an open exchange about procedures, response, side effects, and prognosis. Professional organizations recommend separate consent be obtained for continuation or maintenance ECT as the indication has changed from acute treatment to relapse or recurrence prevention, and the risk–benefit assessment may have changed as well. With the increased use of tapering an acute course of ECT to continuation treatments, many hospitals have instituted consents that include a specific number of ECT sessions and duration of consent, regardless of whether they may be classified as acute or continuation ECT.

Parameters of the ECT Stimulus

Controlled trials in ECT over the past two decades have involved measuring the impact of varying aspects of ECT technique, most frequently electrode placement and stimulus dosing strategies, on response rates and adverse cognitive effects. Other aspects of the ECT stimulus include direction and amplitude of the current, pulse width and pulse frequency. Research from a prior era had led to a belief that seizure elicitation was necessary and sufficient for efficacy, because subconvulsive stimuli were associated with lower response rates in several studies. When attenuation of electrically induced seizures with lidocaine was also associated with reduced efficacy, adequate seizure duration was also postulated to be necessary for therapeutic response. These tenets have been revised in light of observations from modern studies, and current practice has been directly impacted.

A series of studies since the 1980s demonstrated that, depending on the combination of electrode placement and stimulus dosage, seizures could vary in eliciting clinical response from 20 to 70 percent. Recent studies, utilizing an ultrabrief pulse stimulus configured the waveform in a more physiologic way in order to minimize excess electrical dosage, similar to the substitution of brief pulse waveform for the original sine waveform. Right unilateral electrode placements were particularly affected by dosage, and a dose–response relationship exists up to a stimulus intensity of 8 to 12 times seizure threshold. At electrical dosage six times seizure threshold, right unilateral ECT is equivalent to bilateral ECT in clinical efficacy, but maintains an advantage in producing fewer adverse cognitive effects. For electrical dosage above six times threshold, the advantage in acute cognitive effects may be eroded, but there is evidence that an advantage in long-term cognitive effects remains. These findings make dosage relations with seizure threshold particularly critical for right unilateral ECT. Ultrabrief right unilateral ECT at six times seizure threshold has been shown to be equally effective to both brief pulse bilateral ECT and brief

pulse right unilateral ECT; ultrabrief bilateral ECT at 2.5 times seizure threshold was an ineffective treatment in at least one randomized trial. Manipulation of waveform in this manner had even more powerful effects on cognitive outcomes than had electrode placement with results statistically indistinguishable from those obtained in cognitive testing of age, gender, and IQ matched medically and psychiatrically healthy controls on measures of retrograde amnesia. Combined with results of neurophysiologic and brain imaging studies of the effects of ECT, the clinical impact of the interaction of electrode placement and dosage also suggests that the antidepressant effects of ECT are dependent on the anatomic specificity of the effects of current density, rather than on seizure elicitation alone. It was also found that speed of clinical response can be enhanced as stimulus intensity was increased above seizure threshold for both unilateral and bilateral electrode placements.

Although there has long been a theoretical interest in greater localization of the effects produced by ECS in brain tissue, the neurophysiologic and clinical findings related to the interaction of electrode placement and stimulus intensity have rekindled interest in concentrating current density in prefrontal areas by manipulating electrode placement.

Electrode Placement. Historically, most practitioners have used bifrontotemporal electrode placement because of its reliability in producing efficacy and its ease of use. This electrode placement is also associated with more short- and long-term adverse cognitive effects, and is more likely to produce delirium, which may require interrupting a course of ECT and perhaps even terminating it before optimal therapeutic effects have been obtained. Hence, when bifrontotemporal ECT is used, attention should be paid to restricting dosage to a moderately suprathreshold to attenuate adverse cognitive effects as much as possible. It should be emphasized that the combination of ultrabrief pulse and bifrontotemporal electrode placement has not been demonstrated to be consistently effective. Treatment with bilateral electrode placements, particularly bifrontal configuration, is more likely to manifest EEG seizure without motor seizure, and EEG monitoring can be particularly useful in detecting the occurrence of a seizure at treatment.

Newer electrode placements include bifrontal configuration and asymmetric placements. There are limitations to these strategies, imposed by the fact that the high impedance of the skull and scalp causes spreading of the electrical stimulus and restricts possibilities for localization of the stimulus. Bifrontal electrode placement, with positioning far enough laterally to minimize interference with impedance relations, has been investigated and there have been several demonstrations that bifrontal electrode placements are equally effective to bifrontotemporal and

adequately dosed right unilateral electrode configurations. Evidence of advantages in sparing of cognitive effects is preliminary, and adequately powered investigations with more extensive and sensitive cognitive batteries are needed. Seizure threshold is likely to be relatively higher with bifrontal ECT.

The relatively better cognitive side-effect profile of right unilateral ECT should encourage wider utilization now that the efficacy of this electrode placement can be assured with adequate dosing strategies. In contrast to bilateral ECT, dosage closer to 500 percent above seizure threshold for right unilateral ECT is more likely to assure efficacy. ECT devices in the United States are restricted to an output in the range of 504 to 576 mC. Approximately 90 percent of patients have seizure thresholds which can accommodate optimal dosing with brief pulse right unilateral ECT, and the combination of right unilateral electrode placement with ultrabrief pulse width extends the range of US devices so that most patients can be treated within these constraints. Individuals with exceptionally high seizure threshold may require bilateral electrode placements to remain within the device restrictions. Maximizing interelectrode distance by using the d'Elia placement for right unilateral ECT may also be optimal. Many other right unilateral placements have been described, but there is little work to support their use (Fig 34.35–1).

There has been some concern that left-handed patients may require different electrode placement from right-handed patients, especially if unilateral placement is desired. Even when handedness is lateralized to the left, the anatomic localization of language function in 70 percent of left-handed individuals is the same as in those who are right-handed. Furthermore, there is evidence for independent lateralization of affect, with the right hemisphere involved in sustaining depressed mood regardless of handedness. In addition, no differences in efficacy have been found to be related to handedness when examined in studies. Because of limited indications that affective function and efficacy of ECT are associated with handedness, it is not generally used to guide the choice of electrode placement.

Stimulus Waveform. The original ECT devices used in the 1930s generated the electrical stimulus as a sine wave, with a rather wide pulse width, approximately 8.33 ms (60 Hz). Modification of the waveform to a bipolar rectangular pulse, 0.5 to 2.0 ms wide, represented an advance: diminishing nonessential electrical dose, dramatically reducing adverse cognitive effects, but preserving efficacy. Modern ECT devices retain this capability. However, neurophysiologic observations suggest that the optimal pulse width for neuronal depolarization is actually in the range of 0.1 to 0.2 ms. Thus, brief pulse width is inefficient and delivers unnecessary stimulation. While reductions of pulse width to this extent may not be

practical with current engineering of ECT devices, several reports, including randomized controlled trial evidence, employing a pulse width of 0.3 ms (known as “ultrabrief” in contrast to “brief”) have demonstrated that right unilateral ECT, typically at six times seizure threshold, is equivalent in efficacy to both right unilateral and bilateral ECT using brief pulse widths.

In one report, patients treated with the ultrabrief pulse width showed significantly less impairment in acute, subacute, and long-term cognitive side effects of anterograde and retrograde memory than patients receiving standard pulse width stimulation, for both right unilateral and bifrontotemporal ECT. In fact, those who received ultrabrief right unilateral ECT did not deteriorate in any cognitive measure relative to pre-ECT performance. A smaller randomized trial confirmed the equivalent efficacy of ultrabrief and brief pulse right unilateral ECT. A third report comparing ultrabrief right unilateral and ultrabrief bifrontal ECT at 1.5 times seizure threshold found no change or improvements in cognitive performance, while efficacy was similar for the two pulse widths. In effectiveness, open-label prospective and retrospective studies, findings have been more mixed although predominantly positive for the efficacy of ultrabrief right unilateral ECT and sometimes even ultrabrief bilateral ECT, but the lower quality of these designs must be factored into judging the outcomes presented.

FIGURE 34.35–1. Electrode placements. Position #1 represents the frontotemporal position, used for both electrodes, one on each side of the head, in conducting traditional bilateral ECT. For right unilateral ECT, one electrode will be in the right frontotemporal position, and the other will be just to the right of the vertex at position #2. Position #3 represents the frontal placement, used for both electrodes in conducting bifrontal ECT.

Seizure Threshold and Dosing. As indicated above, the intensity of electrical stimulus, that is, the degree to which electrical stimulus exceeds seizure threshold, affects the efficacy of right unilateral ECT, the speed of clinical response regardless of electrode placement, and the cognitive side effects produced. The effects are in the same direction for each of these domains: the higher the stimulus dosage, the better the efficacy of right unilateral ECT up to 8 to 12 times seizure threshold, the quicker the clinical response by one or two treatments over a course, and the greater the cognitive side effects. These observations have led to the promulgation of

dosing methods to refine stimulus intensity.

Strategies for determining stimulus dose include dosing based on empirical determination of seizure threshold (titration), formula-based dosing, and fixed dosing. Empirical titration involves an approximation of seizure threshold in the first treatment session, followed by a calculation of optimal dosage based on the results obtained. The stimulus intensity estimated on this basis is then generally used for the remaining sessions. The first electrical stimulus in the titration is set low enough that a seizure results in only a minority of patients. Restimulations at intervals of 20 to 60 seconds are given in the same session using progressively greater amounts of charge until a seizure is produced.

The dosage at which a seizure is elicited is termed the seizure threshold, and has been found to vary at least 50-fold in patients undergoing ECT. Because of this wide variation in seizure threshold, dosing based on empirical titration is thought to be the most precise method of stimulus determination. Furthermore, it is safe for most patients when conducted with adequate physiologic monitoring and the use of anticholinergic agents as appropriate to prevent the brief periods of bradycardia that may accompany subconvulsive stimulation. In controlled trials where dosing was based on empirical titration, patients benefited clinically beginning with the first treatment session even though dosage was given near threshold, a theoretical concern with right unilateral electrode placement. Seizure threshold, as empirically determined, increases over the course of ECT, but returns to levels observed in the first treatment session within a week of ending treatment. Other measures of convulsant activity, such as seizure duration, may take up to 60 days to return to values observed in the first treatment session.

Formula-based dosing uses factors known to influence seizure threshold, such as age, electrode placement, stimulus pulse width, gender, and concomitant medications including anesthetics, to estimate adequate stimulus intensity. Seizure threshold is generally higher in men than women, with bilateral electrode placement than with unilateral electrode placement, and with increasing age. It is currently unresolved whether bifrontal electrode placement results in differences in seizure threshold when compared with bifrontotemporal placement. The basis for these observations has not been extensively investigated. The simplest formulae use age alone, but even the most detailed and elaborate formula can only account for about 40 percent of the variance in seizure threshold observed in patients. Hence, there has been limited success obtaining precision in seizure threshold approximation and dosing using formulae.

Fixed dosing occurs when the same dosage of electrical stimulus is applied to all patients receiving ECT. It is obviously the easiest technically and maximizes the chances of clinical response especially for right unilateral electrode placement. Unfortunately, this dosing strategy can

cause patients with the lowest seizure thresholds to receive up to 20 times an adequate electrical stimulus, especially with bilateral electrode placement. For low threshold patients, fixed dosing enhances the possibility of increased adverse cognitive side effects as a result. If fixed dosing is used with right unilateral electrode placement, the expected benefit in adverse cognitive effects could be lost. It is felt that fixed dosing may only be appropriate for patients with such serious medical conditions that even one subconvulsive stimulus, as is still a possibility even with formula-based dosing, must be assiduously avoided. Fixed dosing at the maximum output of the device should be avoided.

Seizure threshold and subsequent dosage determination can also be influenced by which stimulus parameters are adjusted. Comparisons of adjusting frequency versus stimulus train duration on brief pulse devices have indicated that longer duration is more efficient in eliciting seizures than increased frequency, although the effect sizes are small. Recent work has also shown that frequency does not exhibit a linear function in the depolarization, an observation that contributes to understanding this relationship. Efficiency in seizure elicitation can also be optimized by using narrower pulse widths in setting the parameters on brief pulse devices. This strategy has the additional effect of extending the range of devices which are capped in stimulus output. There has been recent interest in optimizing pulse amplitude as well with initial indications that further efficiencies may be obtained. Use of unidirectional stimuli is still in the early stages of investigation.

Anesthesia and Treatment Procedures. Since ECT is given under brief general anesthesia, the treatment is usually performed in a specific treatment area which generally meets standards for the performance of day surgery, including the capacity to manage medical emergencies and to recover patients postictally. The staffing commonly consists of a psychiatrist privileged to administer ECT, an anesthetist, and one or more nursing personnel. Although the anesthetist maintains responsibility for anesthesia procedures, particularly airway management, the treatment procedures are conducted collaboratively.

Before anesthesia is induced, appropriate physiologic monitoring is instituted and continued until the patient is adequately recovered. Cardiac monitoring and pulse oximetry are standard; monitoring end-tidal carbon dioxide is also standard at many institutions. Automated noninvasive blood pressure monitoring, set at a short frequency, is common. Monitoring of seizure activity can consist of observing both motor and EEG seizure duration. Motor seizure duration can be determined optimally using the "cuff method." A blood pressure cuff is applied to the forearm or just above the ankle and inflated to a level above the anticipated maximum systolic pressure (>250 mm Hg) to prevent anesthetics from affecting muscle

contraction in the distal limb. Motor movements resulting from seizure induction can then be directly observed. The cuff should be ipsilateral to electrode placement for unilateral ECT. Ictal movements may continue longer in the face and neck. Use of the cuff method may not be appropriate for patients with severe peripheral vascular conditions, especially in the lower limbs. Many ECT devices have incorporated technology to allow at least 2-lead EEG monitoring with a frontal–mastoid montage preferred. Care must be taken to prepare EEG sites adequately and to take into account artifacts, for example, ECG, movement.

Oxygenation is provided using 100 percent O_2 via mask, and administered under positive pressure when respirations have stopped secondary to anesthesia medications. Respiratory support is discontinued when there is return of spontaneous respiration adequate to maintain clinically acceptable hemoglobin saturation on room air. Preoxygenation may begin even earlier in the sequence of treatment procedures when medical conditions such as obesity or pulmonary disease pose a risk to respiratory function. In rare circumstances, such as third trimester pregnancy, patients may be intubated.

There is variation in the use of anesthetic medications. Not all practitioners employ anticholinergic medications pre-ECT, and, unfortunately, controlled studies comparing ECT with and without these agents did not include those patients at greatest risk for cardiovascular conditions. Anticholinergic medications such as atropine and glycopyrrolate are used to dry secretions that may interfere with respiration under anesthesia and to decrease the vagally mediated bradycardia and even asystole that may occur immediately after the electrical stimulus is administered. The cardiac effects of anticholinergic agents are most useful in the following clinical situations: during seizure threshold titration, when subconvulsive stimuli will not be accompanied by compensatory catecholaminergic output; in the presence of agents that promote bradycardia, for example, β-blockers; when cardiac conditions characterized by some degree of electrical blockade are pre-existent. Anticholinergic agents may be contraindicated when they might provoke pre-existing arrhythmias or threaten cardiac compensation through increases in workload from higher heart rate. Although glycopyrrolate does not cross the blood–brain barrier under normal circumstances and could have an advantage over atropine, controlled comparisons with atropine have not detected differences in cognitive adverse effects or postictal nausea, perhaps because ECT disrupts the blood–brain barrier and diminishes this advantage.

Ultrabrief general anesthetics are used to induce unconsciousness while muscle relaxants are in effect and during seizure elicitation. Methohexital, a short-acting barbiturate, has been the preferred agent in the United States. Alternative anesthetics include another short-acting barbiturate,

thiopental; and short-acting agents from a variety of classes, including propofol, etomidate, and ketamine. Thiopental has been associated with a higher incidence of postictal arrhythmias compared to methohexital, and its pharmacologic properties can be associated with long recovery periods when higher doses are used. Propofol reduces hemodynamic changes accompanying ECT and typically produces a rapid, smooth recovery. Its antiemetic properties can be useful when patients develop nausea or vomiting. This agent also attenuates seizure duration, but studies comparing it to more standard agents have not detected differences in clinical efficacy or cognitive recovery. Agents that attenuate seizure duration, generally are associated with slightly shorter emergence and recovery although a recent review concluded that the differences while statistically significant may not be of sufficient magnitude to affect the choice of agent. Numerous reports have explored the addition of short-acting opioids, for example, remifentanil, to standard agents. With remifentanil, less of the standard agent is required and seizure durations can be longer. Etomidate does not affect seizure threshold and is associated with fewer cardiac side effects, especially when compared to propofol. Etomidate can also produce myoclonus, and repeated use in animals has been associated with reductions in adrenal function. Ketamine, an NMDA receptor antagonist has been associated with longer seizures in animals given ECS. Given the potential involvement of glutamatergic system in the etiology of major depression and schizophrenia, as well as the potent independent antidepressant effect of ketamine, the theoretically neuroprotective effect against cognitive impairment associated with ECT, the use of ketamine in ECT treatment has resurged. Insufficient study has been conducted to make firm conclusions regarding the (1) possible synergistic antidepressant effect of combination of low dose of ketamine and ECT; (2) additional therapeutic effects and cognitive protective effects of using ketamine as first-line anesthetic induction agent in ECT treatment. Unfortunately, ketamine's sympathomimetic properties can result in hallucination and unusual states of consciousness as well as increases in heart rate and blood pressure. Until recently, both etomidate and ketamine have been reserved as alternative or adjunctive agents for situations where seizure elicitation is difficult. Greater attention to adequate dosing of these anesthetic agents has become increasingly important as the increased use of cognitively sparing techniques, such as ultrabrief right unilateral ECT have been accompanied by reports of patients regaining awareness and remembering the effects of succinylcholine before full respiratory capacity returns to baseline.

Before the development of muscle relaxants, musculoskeletal injury, particularly fracture of the long bones or vertebrae, was not uncommon, as it is today. Curare was developed to reduce the tonic–clonic movements produced by electrical induction of a generalized seizure, but its use has

been superceded by succinylcholine, a depolarizing agent with rapid onset and brief duration. Myalgia can be a side effect of succinylcholine. The standard treatment of these myalgias, which are often present in only the first few treatments, is the use of common analgesics. Although modification of movement is the usual goal of using muscle relaxants, complete paralysis may be desirable when there is a history of skeletal disease, such as osteoporosis or recent fracture. When the use of succinylcholine is contraindicated, as in pseudocholinesterase deficiency, nondepolarizing agents can be employed. Agents available in the US market are rather longer acting; even when reversal is produced with an anticholinesterase such as neostigmine, it may be at least an hour before recovery is sufficient for transfer from the ECT treatment area to a recovery area is safe.

Although complications at ECT have involved the cardiovascular system most commonly, there is controversy regarding the routine use of agents, such as β-blockers, which reduce the increases in hemodynamic activity that accompany ECT. Controlled studies of routine use do not demonstrate advantages for active intervention, perhaps because the patients who benefit are a minority of the entire population of ECT recipients, most of whom easily tolerate the observed increases in heart rate and blood pressure for a few minutes. There has also been some concern that the hypermetabolic cerebral state induced by the treatment requires a corresponding increase in cardiovascular functional level to maintain adequate oxygenation and nutrient supply to the CNS. The conservative position is to restrict the use of pharmacologic intervention to those conditions where the need is unambiguous, for example, aneurysm, sustained hypertension, and/or tachycardia.

Because the application of the electrical stimulus directly stimulates contraction of the jaw muscles, a bite block is placed in the mouth just before the delivery of the electrical stimulus to protect the teeth and oral soft tissues. The duration of the stimulus can be several seconds, but typically is only a few. The duration of the seizure is commonly less than 1 minute. The relationship of duration to efficacy has been questioned because of recent findings, and it is clear that duration alone is insufficient to insure clinical adequacy. Seizures of less than 15 seconds can occur close to seizure threshold and are often considered abortive. Seizures of similar duration can also be observed in the elderly, late in a treatment course, and with markedly suprathreshold dosage, but such short-duration seizures may not be associated with lack of adequacy. These circumstances highlight the usefulness of empirical titration techniques to inform the practitioner more exactly about seizure threshold and dosage, and to guide what actions, if any, to take when short seizures occur. Seizures longer than 3 minutes, with either motor or EEG monitoring, are considered prolonged and should be actively controlled using intravenous anticonvulsants, such

as the short-acting barbiturate used to induce anesthesia or benzodiazepines. The occurrence of long-duration seizures is unusual, except in the youngest patients, and the cause of such long duration should be investigated, especially if it was not easily terminated.

Patients are recovered with monitoring of cardiovascular and respiratory functioning until physiologically stable. If not awake and oriented at that time, further recovery is needed until the patient is alert and reoriented. Many facilities require that the patient be fully ambulatory before leaving the treatment and recovery areas. Bed rest may be needed for a period of time. Side effects, such as headache and nausea, are monitored and treated as needed. Headache frequently responds to analgesics, especially COX inhibitors; patients with migraine may require more specific antimigraine treatments. Postictal delirium with agitation, disorientation, and lack of full consciousness, occurs in a minority of patients. Decreasing environmental stimulation and securing protection may be adequate management, but not infrequently, patients will require intravenous pharmacologic intervention with sedatives and prophylaxis at subsequent treatments.

Treatment Course. Typically, ECT is given two to three times weekly on nonconsecutive days. The latter frequency is common in the United States. Twice weekly treatment is equally effective compared to thrice weekly treatment, can take longer to reach efficacy, and is associated with fewer acute cognitive side effects. Other frequencies of treatment are more problematic. Daily treatment is seldom done now, but, at one time, was believed to speed efficacy dramatically and was used in the most urgent situations, for example, severe mania. This treatment schedule was also characterized by a risk of prolonged severe cognitive side effects, especially when a course known as regressive ECT was used. In addition to being logistically difficult to obtain in many places, the risks appear to outweigh the benefits, and daily treatment is no longer advised. Another approach to increasing frequency was eliciting more than one generalized seizure per session under continuous anesthesia, known as multiple-monitored ECT (MMECT). Similar to daily ECT, the goal was to accelerate clinical response with the additional advantage of decreasing the number of times anesthesia is delivered. Although there have been both reports of uncontrolled observations and one controlled trial concerning MMECT, the literature is clear that severe adverse events accompany this treatment approach with only modest gains in efficiency of response. Of most concern are reports of cardiovascular morbidity and mortality, as well as serious adverse cognitive effects including prolonged confusion. Although there may be a place for the use of MMECT, it is only in extremely unusual circumstances, for example, intractable seizures, and should be restricted to double stimuli/session. At the other end of frequency, once weekly ECT is

associated with weaker clinical response and more suitable for continuation ECT schedules where the goal is to maintain a patient's status as responder or remitter—as opposed to acute treatment, which is used to induce response.

The number of treatment sessions in a course of ECT should be individualized, as patients vary in this requirement from a few sessions to more than 15, especially when changes in treatment technique have been made. The course length cannot be predicted, although the average is from 6 to 12 sessions. Fixed course lengths are not appropriate for these reasons. Patients should be evaluated every one to two treatments for clinical response and adverse side effects, particularly cognitive effects. These assessments are best done between treatment days when the acute effects of anesthesia and ECT will interfere less with evaluation. Acute treatment should end when there is remission of target symptoms or when further improvement has not occurred over 2 to 3 sessions with optimal technique.

When response is inadequate, modifications can be considered. Such modifications can include intensification of stimulus energy by increasing charge through manipulations of the various parameters of the stimulus or by changing electrode placement. Seizure threshold increases over the course of treatment, so higher stimulus intensity may be useful later in a treatment course if response is inadequate, particularly if response was more robust earlier in the course but waned. If any medications with anticonvulsant properties, including barbiturate anesthetics or propofol, are being used, discontinuation or decreasing dosage should be evaluated, particularly when the patient has high seizure threshold. At least 10 treatments with optimal electrode placement and dosing should be given before nonresponse is declared. When course length exceeds 15 to 20 sessions, especially with modifications of technique, reconsideration of the use of ECT, with careful balancing of the risk of an unresolved episode of illness against the risk of accumulating adverse effects, should be undertaken. Additional consultation, with reassessment of primary and comorbid diagnoses, may be advisable.

ECT is the only treatment for major psychiatric syndromes that is discontinued when remission occurs. Hence it is not surprising that a significant proportion of patients who relapse do so within the first few weeks of termination of ECT, and then require further ECT. Often additional ECT is given along with medications that will be used for continuation and maintenance of remission. Although not yet examined in a controlled trial, tapering the termination of ECT, by decreasing frequency of sessions while medications are stabilized and produce their effects, may be a more effective strategy for relapse prevention.

Continuation Treatment. Continuation treatment, that is, treatment for 6 months beyond remission of an acute episode of illness to prevent

relapse, is standard practice for the major syndromes that are somatically treated. It is recommended and routine post-ECT as well. Populations that receive ECT are particularly likely to be characterized by risk factors for relapse: medication resistance and the presence of psychotic features. At least half and upward of 85 percent of ECT responders in some samples will relapse without continuation treatment particularly in the first several weeks post treatment. Aggressive continuation treatment should be initiated as soon as remission is evident, although initiation of pharmacology during the ECT course itself has not been shown to be of additional benefit for depression.

Continuation treatment with medications is the predominant practice post-ECT. This has been based on studies conducted in the 1960s in Britain and on clinical experience. The class of agent advised matched that used in the absence of ECT: antidepressants for unipolar depression, antidepressants and mood stabilizers for bipolar depression, mood stabilizers with or without antipsychotics for mania, and antipsychotics for schizophrenia. Studies in the 1970s found little support for the use of lithium alone as relapse prevention following depression, but some support for lithium as maintenance treatment after 6 months of remission to prevent recurrence once remission is firmly established. The first randomized prospective controlled study of continuation treatment post-ECT in unipolar patients confirmed substantial relapse rates on placebo (84 percent), but only moderate improvement in relapse rate on the antidepressant nortriptyline alone (60 percent). The relapse rate in unipolar depression was significantly reduced in this study by the addition of lithium to nortriptyline (39 percent) with most of the relapse in this arm of the study occurred in the first 5 weeks. Randomization had been stratified by medication resistance and (mood congruent) psychosis, but mood congruent psychotic patients did not relapse more frequently. Medication dosage was in the range used for acute treatment. A prospective trial of combination antidepressant and antipsychotic continuation treatment post-ECT did not find an advantage for combination treatment over antidepressant alone in an elderly population, and the combination treatment was found to be associated with greater frequency of side effects. A recent randomized controlled trial found no advantage for beginning nortriptyline or venlafaxine during the course of ECT in preventing relapse. Observations of community practice post-ECT yield relapse rates similar to those found in the RCT assignments using antidepressants alone. Little is known about the use of second- and third-generation agents or anticonvulsant mood stabilizers in relapse prevention, although preliminary evidence suggests that the combination of lithium and antidepressant is more effective than other medication combinations in maintaining remission. There is also preliminary work indicating that combining medications with continuation ECT or cognitive therapy is more

useful than monotherapy. There are preliminary studies suggesting that relapse prevention is more effective when using a class of antidepressants that was not shown ineffective prior to ECT treatment. Modern practice suggests sparing use of antidepressants in bipolar patients, but in continuation treatment post-ECT, antiepileptic drugs or antipsychotics have not been shown to be all that effective in preventing relapse to bipolar depression. Little work in pharmacologic relapse prevention post-ECT for any other diagnosis than depression has been done in the modern era.

ECT was introduced before the psychopharmacologic era; thus, administering ECT after an index episode was not uncommon early in the history of ECT. With ECT populations becoming increasingly medication resistant and various pharmacologic strategies still characterized by relapse rates in the range of 40 percent, there is renewed interest in continuation ECT for patients who relapse on continuation pharmacology. The first randomized controlled comparison of continuation ECT in a fixed schedule with the combination of nortriptyline and lithium did not show an advantage for ECT and confirmed relapse rates observed in prior studies; relapse escalated when the schedule of administration dropped below once weekly. Other prospective data have confirmed these observations. Recent prospective, controlled, nonrandomized data as well as post hoc analyses from the RCT support the practice of tapering ECT after an acute course, combining ECT and pharmacology as continuation treatments, and using a symptom-driven, flexible schedule of ECT administration to improve relapse prevention. An RCT of this latter approach is nearing completion.

Recommendations from professional organizations have guided various aspects of the practice of continuation ECT although these bodies use differing thresholds for evidence when recommending strategies, a circumstance most notable when the National Institute for Health and Clinical Excellence in the United Kingdom issued guidelines in conflict with the Royal College of Psychiatrists as well as other professional bodies in the Commonwealth and globally. Suitable patients for continuation/maintenance ECT should have recurrent illness, demonstrated response to ECT, intolerance of or relapse on continuation medications, and ability to comply with continuation ECT protocols, particularly behavioral prescriptions, such as fasting prior to the procedure, and restrictions, such as refraining from important decision making for a period of time following each treatment. Generally, continuation ECT utilizes the electrode placement and dosage which produced remission. A taper of ECT from the acute phase to continuation phase has become common. Treatment frequency is gradually extended between treatment sessions, as tolerated, to monthly or even less often. It is thought that if patients remain well 2 months or more, they are out of episode, and the discontinuation of continuation treatment can be entertained. Continuation ECT is almost always given in an outpatient setting. Cognitive

functioning should be monitored as well as the status of psychiatric symptoms and medical fitness for each session. There has been one promising but uncontrolled pilot study of the use of cognitive behavioral therapy to augment somatic continuation treatments post-ECT.

Maintenance treatments are those given beyond the 6-month continuation treatment period and the purpose of these treatments is prevention of recurrence. Because patients receiving ECT in current practice are almost always suffering from highly recurrent illness, maintenance treatment can be entertained for most ECT responders who do not relapse with continuation treatments. There are now several controlled observations of the use of maintenance ECT up to 4 years with positive outcomes in relapse prevention for depression. Japanese investigators have published a case series on the use of ECT as a maintenance strategy for treatment-resistant schizophreniform and catatonic illness. Individual decisions about maintenance treatment will be informed by the number, frequency, and intensity of prior episodes; the ability to tolerate continued treatment; the ability to comply with treatment; the experience when attempts to taper treatment are made; and patient preference. Again the standard will be maintenance medications. Maintenance ECT is also available, especially for those patients undergoing continuation ECT when medications have proven inadequate. Maintenance ECT is similar in many aspects to continuation ECT, and it is performed at the longest intervals to sustain remission. There is no evidence that a lifetime maximum number of ECT applies.

INTERACTIONS OF MEDICATIONS AND ECT

ECT can interact with medications given for psychiatric as well as medical conditions. As such, it may be necessary to make changes in a patient's drug regimen when a course of ECT is undertaken. These changes can include tapering, withdrawing, augmenting, or adjusting the timing of administration of medications. Some psychotropics and many drugs for medical indications are continued. Medications that are already a part of the patient's treatment regimen and are expected to mitigate physiologic changes that accompany ECT or protect against adverse reactions to ECT or anesthesia are often given the morning of treatment. Examples are antihypertensives, inhalers for pulmonary conditions, and steroids, although anesthetists may wish to substitute IV steroids for oral steroids pre-ECT. It appears that stress doses of steroids may not be necessary at ECT. The administration of β-blockers pre-ECT should be carefully evaluated because of the propensity of this class of agents to enhance bradycardia or precipitate asystole; use of atropine pre-ECT should be considered in this circumstance. Labetalol crosses the blood–brain barrier and attenuates rCBF at ECT; both esmolol and labetalol are anticonvulsant at doses used in this setting. Lidocaine and its analogs can interfere with

seizure induction, and should be withheld. Other medications that should be held until after recovery are diuretics, hypoglycemics, including insulin, depending on an individual evaluation of the patient's needs, and long-acting cholinesterase inhibitors for glaucoma that may interfere with anesthesia recovery.

Medications that can result in severe adverse reactions include theophylline and lithium. Theophylline is a member of a class of agents that are known to increase seizure duration, and theophylline can result in status epilepticus, even at therapeutic levels, when administered during an ECT course. In fact, caffeine, a short-acting member of the same class of medications as theophylline, had been used to increase seizure duration when seizure length was thought to be a critical parameter to ECT efficacy. Inhaled bronchodilators and steroids, as well as other oral and inhaled agents, have replaced theophylline in modern pulmonary practice to a great extent. If theophylline is part of the therapeutic regimen and ECT is undertaken, consultation to evaluate the possibility of a substitute regimen is generally sought. Lithium combined with ECT has been shown to result in confusional states, serotonin syndrome, and prolonged and/or focal seizures. Although it is not neurotoxic in all patients and the toxicity of the combination may be dose related, discontinuation of lithium is frequently undertaken in an acute course of ECT. For continuation and maintenance ECT, doses are often withheld for 24 hours prior to treatment, allowing for washout, and markedly diminishing the chance of negative interaction. Another class of medications that can pose increased risk are β-lactam antibiotics and ciprofloxacin, which are proconvulsant, and have been associated with seizures in non-ECT patients and tardive seizures during a course of ECT.

Anticonvulsants can increase seizure threshold, decrease seizure expression, and may interfere with the efficacy of ECT, particularly in depressed patients. Interference with clinical outcome appears less marked in manic patients administered ECT with anticonvulsants, but only case report and observational data are available. When used for control of a seizure disorder, anticonvulsants are continued without alteration, unless poor seizure expression along with weak response occurs. In this circumstance, levels of drug may be reevaluated in consultation with neurology. If anticonvulsants are used for psychiatric indications, they are generally discontinued, particularly in bipolar depression, to prevent a negative effect on clinical response.

Benzodiazepines are also anticonvulsants, but more often used for psychiatric indications. There are reports of diminished efficacy when benzodiazepines are used in conjunction with ECT, especially right unilateral electrode placement. As a result, this class of medications is tapered to the least necessary dose or discontinued. If use of benzodiazepines is considered necessary for management of severe

behavioral syndromes, agents with shorter half-lives are preferable and should be withheld several hours prior to treatment. Use of flumazenil to reverse benzodiazepines has been reported, but requires further study and benzodiazepines may need to be administered during recovery to abort possible withdrawal. Little is known about the interaction of other sedative/hypnotics with ECT.

Anesthetists have been averse to allowing the use of monoamine oxidase inhibitors (MAOIs) concurrently with elective anesthesia, due to a potential for interference with management of cardiovascular abnormalities that may arise at treatment. ECT seldom results in a situation where the use of vasopressors, that would not be metabolized because of interference by the recent use of MAOIs, is necessary. Hence, the literature includes many reports of the safe performance of ECT in the presence of MAOIs. Current practice allows for consultation between the psychiatric and anesthetic practitioners as to the best recommendation for any particular individual or practice setting.

An augmenting effect for neuroleptics when combined with ECT in schizophrenia can be accepted with some confidence. As discussed previously, the combination treatment is more effective than ECT alone, and may be more effective than medications alone. A few older studies even suggest that the long-term outcome of schizophrenia may be enhanced by combination treatment. Whether the acute or long-term effects carry over to other psychotic conditions is not clear; there is evidence that they play no augmenting role in nonpsychotic depression. Most of the published data involve the use of typical neuroleptics, It appears that low-potency typical antipsychotics may be proconvulsant; haloperidol and fluphenazine appear to have little impact on parameters of seizure quality. The use of ECT combined with atypical neuroleptics appears to be safe. Clozapine and olanzapine have been observed to have proconvulsant properties and quetiapine, anticonvulsant properties. Atypical antipsychotics are reported to have U-shaped functions with respect to convulsant properties. Because of these circumstances, dosing of neuroleptics should generally be in the moderate range. The only antipsychotic that cannot be combined safely with ECT is reserpine.

Earlier work with tricyclics (TCAs) and MAOIs provided some evidence to recommend the use of antidepressants to augment ECT. A recent RCT found that both nortriptyline and venlafaxine increased the response rate to ECT by about 15 percent; nortriptyline was associated with diminished adverse cognitive effects, whereas venlafaxine was associated with increased adverse cognitive effects. The combination of ECT and antidepressants is common practice in many parts of the world. Increasingly, in the United States psychotropics, including antidepressants, are continued during a course of ECT because of expanding limitations placed by insurers on utilization of mental health resources. It appears that

TCAs are safe in noncardiac populations, and SSRIs in most populations although they can increase seizure duration. After a series of cases where asystole occurred at doses of venlafaxine greater than 225 mg with the concurrent use of atropine, it may be advisable to limit the dosage of venlafaxine if it is combined with ECT. The well-known proconvulsant effect of bupropion prompts caution in combining it with ECT in the absence of data documenting a clear benefit in doing so. It is unknown whether newer medications now used more frequently for depression have augmenting effects.

Finally, there has been limited interest in pharmacologic approaches to mitigating the cognitive side effects of ECT. Preliminary data using physostigmine, thyrotropin-releasing hormone, and naloxone have been published, but whether clinically significant effects could be obtained remains in doubt.

PHYSIOLOGY, ADVERSE EFFECTS, AND CONTRAINDICATIONS TO ECT

ECT is generally low risk and one of the safest procedures performed under general anesthesia. Estimated risk of serious complications, occurring in about 1/1,000 patients, is similar to that of general anesthesia for minor medical procedures. Risk of death, likewise in the range of that observed for such procedures, is about 1/10,000 patients in modern populations undergoing ECT. It has been argued that this rate is less than the spontaneous death rate in comparable community-dwelling populations. Some believe that these rates of serious complications and death are lower than those related to the use of antidepressant medications. Mandated reporting of deaths occurring during and up to 14 days post-ECT in Texas, revealed only one death related to the procedure in the first 5 years. Although cardiac complications are considered to be the most common cause of morbidity and mortality, this death was due to laryngospasm. Cardiac deaths in this population were unrelated to ECT.

Cardiovascular System

The ECT procedure routinely results in parasympathetic outflow during and immediately after the electrical stimulus. Unopposed by anticholinergic medications, sinus bradycardia and even brief, clinically insignificant, asystole can occur as a result. In patients over 50 years old, supraventricular ectopic beats are common, but clinically insignificant. In vulnerable patients, vagally related arrhythmias can occur such as atrial, junctional, and nodal rhythms as well as atrial flutter, and atrial fibrillation. Following parasympathetic stimulation, sympathetic output increases, mainly during the electrical stimulation and postictally when the adrenal gland also releases catecholamines. As a consequence, heart rate, blood pressure, and, perhaps, most importantly, rate pressure product increase.

These increases peak immediately postictally and drop off within minutes to pre-ECT values, although in those over 50 years, normalization takes up to 1 hour for blood pressure and longer for heart rate. There can be a short period of decreased heart rate at about 5 minutes post-ECT. Related abnormalities of cardiac rhythm can include bigeminy and trigeminy, which are generally benign. Repolarization abnormalities such as T-wave changes and ST segment depression can appear infrequently. Ventricular tachycardia, usually nonsustained, and fibrillation can occur rarely. About 55 percent of those with pre-existing cardiovascular abnormalities will manifest some abnormality in the course of ECT. About 10 percent of one sample manifested transient increase in troponins of uncertain clinical significance.

With judicious pretreatment evaluation of both the risks and benefits of ECT, cardiac consultation, and the stabilization of any underlying cardiac disease, many of the more cardiac serious complications can be avoided. About 90 percent of these patients will be able to complete a course of ECT safely. For example, ECT has been administered to patients with histories of pulmonary hypertension, subacute MI, abdominal aortic aneurysm, and Takatsubo syndrome. Congestive heart failure patients with ejection fractions over 30 percent have been able to tolerate ECT. In patients with myocardial infarct, a period of time must be allowed for healing, but the risk relates not only to the time elapsed but also to the severity of resulting cardiac compromise. As with arrhythmias and congestive heart failure, stress testing can be informative in deciding whether a patient can tolerate ECT. The presence of a pacemaker or device to abort arrhythmias is not a contraindication to ECT. ECT has been administered without complication to stable patients with transplanted hearts.

Respiratory System

Along with cardiac complications, adverse events related to pulmonary functions are a leading cause of morbidity and mortality associated with ECT. Most of the effects are associated with anesthesia procedures, rather than the physiology of ECT itself. The use of muscle relaxants leads to the cessation of breathing and oxygen delivered by positive pressure through a mask substitutes. Where patients have underlying pulmonary disease, exacerbation of asthma or COPD is possible, as well as excess secretions and aspiration. Rare cases of negative pressure pulmonary edema have been attributed to inspiration against an obstructed airway or mechanical irritation precipitating laryngospasm; it can also be neurogenically induced, for example, as a complication of status epilepticus. With proper preparation pre-ECT and careful anesthetic technique, these events are uncommon. Obstructive sleep apnea poses risk or may even be discovered during ECT anesthesia; it can generally be managed acutely with preoxygenation, and the use of nasal pharyngeal airway or laryngeal mask.

Another rarely observed complication is prolonged apnea, resulting from slow metabolism of succinylcholine, due to pseudocholinesterase deficiency. Supportive therapy suffices to manage this complication, and subsequent sessions of ECT can be given with a nondepolarizing agent.

CNS

Seizure induction results in a hypermetabolic state characterized by increased blood flow with significant elevation in oxygen and glucose consumption. Increased blood–brain barrier permeability has been hypothesized due to capillary hypertension. Postictally, metabolic suppression develops. These physiologic changes have not been demonstrated to produce structural brain changes or damage in well-designed and controlled animal and human studies or by brain imaging or analyses of cerebrospinal fluid. There is insufficient energy, even at maximal output of a modern brief pulse device, to cause brain tissue injury by temperature elevation.

ECT can be complicated by prolonged seizure duration, defined as greater than 3 minutes by motor or EEG measurement, in 1 to 2 percent of treatment sessions. The risk is greater in adolescents and young adults. There is a risk of structural brain injury along with cardiovascular and pulmonary complications if the seizure persists beyond 30 minutes, even when oxygenation is adequate. Termination is undertaken using either parenteral benzodiazepines or the short-acting barbiturate used for anesthesia. If this fails, a standard protocol for status epilepticus treatment may be instituted. Patients who experience prolonged seizures need to be reassessed for underlying etiology. Prolonged seizures are more common in the presence of proconvulsant medications such as theophylline or lithium, and possibly trazodone, or when more than one seizure is induced in a single session. They are also associated with medical conditions that decrease seizure threshold, such as electrolyte abnormalities and epilepsy. Nonconvulsive status should be suspected if there is lack of recovery from anesthesia or abnormalities in mental status persist. This state may be detectable by EEG monitoring, but can be present when the typical 2-lead EEG does not exhibit abnormalities. Tardive seizures are rare. The rate of onset of new seizure disorder after ECT does not exceed baseline rates in the general population. Because of its anticonvulsant properties, ECT can be given safely to patients with epilepsy.

Before the development of brain imaging, deaths and neurologic deterioration were reported when ECT was given to patients with occult brain tumors and brain metastases. Evaluation, including radiologic procedures, of patients with neurologic findings or abnormal mental status now most often leads to the identification and treatment of such diseases prior to any administration of ECT. It is possible for ECT to be given safely to patients with small, slow-growing tumors without associated increased

intracranial pressure, such as meningiomas. ECT has also been given to patients with healed skull and brain trauma, including craniotomy, as long as any skull defect is avoided. Patients may also experience transient CNS symptoms of almost any variety, for example, various cortical sensory abnormalities.

Depression not uncommonly complicates CNS disease such as stroke and dementia. If patients with stroke are neurologically stable several weeks after a cerebrovascular event, ECT may be given. Attention should be paid to the treatment and stabilization of the underlying cause of the stroke as well as to the current neurologic status. Patients with dementia receive ECT for complicating depression, but are at risk for greater adverse cognitive effects, such as delirium or prolonged confusion. There is interest in using the treatment for agitation complication dementia, but little supporting, controlled evidence. Treatment using techniques focused on mitigating cognitive effects, such as right unilateral electrode placement, specific tailoring of dosage, brief pulse waveform, and twice weekly frequency, are often employed.

Dental

Due to direct stimulation of jaw muscles during delivery of the electrical stimulus, patients bite down, sometimes strongly, and unstable teeth may be broken or dislodged completely. Also vulnerable are front teeth with crowns or other dental modifications such as laminates. The approach to this complication is routine prophylactic screening and may necessitate dental consultation and procedures prior to ECT. If teeth are injured during treatment, care must be taken to remove any broken fragments before respiration resumes, when they may obstruct the patient's airway.

Musculoskeletal

With the consistent use of muscle relaxants, the most serious of these adverse effects is only of historical interest. Before the development of curare and later succinylcholine, fracture of the long bones or spine occurred in up to 10 percent of patients as a consequence of unmodified movements associated with seizure induction and expression. The usual patient, who receives enough muscle relaxant to modify movement rather than fully abolish it, has no significant musculoskeletal complications. Those with skeletal disease, for example, osteoporosis, are more fully paralyzed for treatment. Although this complication has been almost completely abolished, elderly patients remain at risk for falls during a course of ECT and appropriate fall precaution protocols should be used.

More common in the modern era and, ironically, often an adverse effect of depolarizing agents, is myalgia. These muscle pains are a consequence of the fasciculations produced during depolarization and are most prominent

after the first treatment but seldom present after a few more sessions. Although myalgia can be mitigated by the use of curare along with succinylcholine, it can also be managed symptomatically with analgesics with the advantage of not prolonging or complicating the treatment session.

Those patients with temporomandibular joint problems may experience an exacerbation of pain, resulting from the unmodified contraction of jaw muscles during stimulus delivery. Spasm can also be induced. Prophylactic approaches may be advisable, such as the use of dental appliances already in the patient's possession or the administration of prophylactic analgesics such as nonsteroidal anti-inflammatory medications. Symptomatic post-ECT approaches may also suffice.

Neurocognitive

Cognitive side effects are a major limitation to the use of ECT, although in recent years the syndrome of postoperative cognitive dysfunction has been detected in patients undergoing medical procedures requiring either regional or general anesthesia with up to 10 to 20 percent incidence, particularly those over 60 years. With ECT, these effects have been best described for depressed populations. Most of the reports of cognitive function in schizophrenic and even autistic populations show stable cognitive function after a course of ECT. The phenomena are made more difficult to discriminate because depression itself is accompanied by impairments in attention, concentration, and learning. Post-ECT, with remission of depression, attention, and concentration are improved. Several factors influence the likelihood and extent to which impairments develop, but response to treatment is not a variable in the development of the cognitive adverse effects of ECT. Furthermore, functions such as reasoning, creativity, and the ability to form memories, are not affected in any enduring fashion. Nondeclarative memory, that is, procedural memory and priming, does not appear to be affected either. It is also important to note that objective measurement and subjective report of cognitive side effects do not correlate for many measures of subjective memory with the exception of global assessment.

The first factor in the development of adverse cognitive side effects is time point in treatment, which influences not only severity, but the type, of effect observed. Disorientation, diminished processing speed, decreased anterograde and retrograde memory, and errors in visual–spatial function and word finding are greatest immediately after a treatment session. These effects diminish fairly quickly once the treatment course ends. There is preliminary evidence that reactivating and reconsolidating a semantic memory may make it particularly vulnerable to impairment. Except for retrograde memory impairment, other cognitive effects generally return to pre-ECT baseline or even improve over baseline with right unilateral ECT.

Diminished processing speed persists when sine wave ECT has been administered. Retrograde memory improves more gradually, but spotty deficits may persist, with recent memories for public information more vulnerable than older memories for personal experiences. Retrograde memory deficits may persist several months after treatment ends. In a community setting, 12.4 percent of patients manifested marked and persistent retrograde amnesia, defined as deterioration in autobiographical memory of at least two standard deviations from pre-ECT baseline at 6 months post-ECT. The only significantly correlated technical factor was the number of bilateral ECT; female sex was the only demographic or clinical factor to achieve significance.

Table 34.35–3.
Treatment Factors Influencing the Degree of Adverse Cognitive Effects from ECT

Treatment factor	Technique Associated with Fewer Adverse Cognitive Effects
Electrode placement	Right unilateral
Stimulus waveform	Ultrabrief (and brief) pulse
Stimulus intensity	Threshold determination; dosage closer to threshold
Number of treatments	Fewest necessary to achieve remission or plateau of target symptoms
Frequency of treatment sessions	Less frequent, e.g., twice weekly for acute treatment
Number of seizures per session	One
Simultaneous use of psychotropic medications	Discontinue lithium, sedatives; reduce dose of neuroleptics
Dosage of anesthetic medications	Adjust dosage to produce light anesthesia; ketamine

The likelihood of developing adverse cognitive effects is influenced by technical factors in the treatment: bilateral electrode placement; inefficient stimulus waveforms, most particularly, sine waveform, but including brief pulse; markedly suprathreshold dosing; greater frequency and number of treatments; and larger doses of anesthesia are more likely to result in deficits during the acute and subacute course of treatment. Bilateral electrode placement is associated with greater likelihood of persistent retrograde memory deficits long term. There is mixed data on the relative cognitive profiles of bifrontal versus bifrontotemporal electrode placement. In recent decades, sine waveforms, which are no longer recommended, have been largely replaced by brief pulse and, most recently, ultrabrief pulse stimulation, and much has been learned about optimizing right unilateral electrode placement and restricting dosage while maintaining efficacy. The advantage of ultrabrief pulse stimulation over brief pulse stimulation in cognitive side-effect profile has become more apparent in the past decade of increasing use of ultrabrief pulse waveforms (Table 34.35–3).

Patient characteristics and clinical factors also impact the frequency and severity of adverse cognitive effects. Those with baseline neurologic disease, MRI abnormalities, and baseline impairments in global cognitive functioning are more vulnerable to developing deficits, as well as older and female patients. The concurrent use of certain medications such as lithium or medications with anticholinergic effects also increases the risk of adverse cognitive effects. There have been no well-established pharmacologic approaches to attenuating adverse cognitive effects, although there is interest in using NMDA antagonists, such as ketamine anesthesia, antiglucocorticoid agents such as mifepristone, and thyroid hormone.

Perhaps because subjective memory correlates best with mood and the majority of patients respond to ECT in systematic research, most patients studied in these settings report improved cognitive function post-ECT. It has been difficult to distinguish these patients from controls in the subjective assessment of memory months after ECT in randomized controlled trials; in community settings, which are characterized by inclusion of a broader range of patients and ECT techniques, subjective complaints of memory impairment are more frequent and correlate to the number of bilateral ECT received. Nonetheless, generally favorable attitudes are expressed by patients who have received ECT, especially compared to attitudes of the general public, and the majority of patients would have treatment again if necessary.

Other Adverse Effects

Postictal agitation has an undefined etiology, but can be associated with various factors, including electrode placement, electrical dose over seizure threshold, seizure duration, anesthetic dose, concomitant use of medications, and anxiety or agitation pre-ECT. Although ranging in severity, the more severe forms of agitation require emergent management with decreased stimulation, medications such as short-acting benzodiazepines, haldol and ECT anesthetics, and even restraints. Prophylaxis may include switching electrode placement to unilateral, attention to electrical dosing, increasing the dose of anesthetic agent pre- and post-ECT, modifying the dose of succinylcholine to prevent awakening while paralyzed or to decrease lactate generation, and alteration of medication regimens to address agitation by the use of neuroleptics.

ECT may be associated with a number of less serious, although nonetheless, uncomfortable side effects as well. Headaches and nausea occasionally occur postictally. Headache has been reported to occur in up to half of all patients, although this figure seems unrealistically high. The etiology of postictal headache is unknown, and ascertaining cause is complicated by the presence or withdrawal of medications and the fact that anxiety often accompanies target illnesses for which ECT is used, such as

depression. The throbbing quality of the headache suggests a vascular component, and migraineurs certainly seem more vulnerable to developing this side effect. Symptomatic management with analgesics, including nonsteroidal anti-inflammatory drugs, is often sufficient, but use of these agents prophylactically, for example, intravenous ketorolac, may be required. Migraine sufferers may need to use triptans posttreatment.

Nausea may accompany headache or occur alone in a minority of patients. Again the etiology is complex, including the use of anesthetic agents. Antiemetics, including dopamine antagonists such as compazine, can be employed symptomatically. The use of $5HT_3$ antagonists, such as ondansetron, has gained in use recently.

FUTURE DIRECTIONS

There is interest in continued refinements of ECT technique. Common themes in these approaches are as follows: focusing the treatment spatially to optimize dosing in brain areas associated with putative neural networks involved in depression and other psychopathologies that are indications for ECT, and to diminish dosing in areas associated with adverse cognitive effects; improving the efficiency of a noninvasive electrical stimulus in direction and amplitude, even to a subconvulsive level. Methodologies such as magnetic induction of convulsive treatment and focal electrically assisted seizure therapy are examples of innovation designs under investigation. This research is parallel to investigations in magnetic stimulation, for example, rTMS, and to the renaissance of invasive electrical techniques, for example, vagal nerve stimulation and deep brain stimulation.

▲ 34.36 Brain Stimulation Methods

STEFAN B. ROWNY, M.D., AND MELANIE LUCAS, PH.D.

INTRODUCTION

Brain stimulation in psychiatric practice and research uses electric current, or changing magnetic field to induce currents within the brain, to alter neuronal firing. There is a growing list of tools capable of eliciting such neuromodulation, each with a different spectrum of action and therapeutic utility in psychiatric disorders. These tools either apply electrical or magnetic fields transcranially or involve the surgical implantation of electrodes to deliver electrical currents to a cranial nerve or to the brain tissue directly. The transcranial techniques include cranial electrical stimulation (CES), electroconvulsive therapy (ECT), transcranial direct current stimulation (tDCS, also called direct current polarization), transcranial magnetic stimulation (TMS), and magnetic seizure therapy (MST). The surgical techniques include Implanted cortical stimulator (ICS), deep brain stimulation (DBS), and vagus nerve stimulation (VNS). These methods are briefly described in Table 34.36–1. ECT and DBS will be discussed in separate chapters.

The historical roots of modern brain stimulation in psychiatry can be traced to the introduction of ECT in 1938 by Ugo Cerletti and Lucio Bini. Since then, electrical methods for neuromodulation have been in continuous use in psychiatry. ECT, which uses alternating electrical current applied to the scalp to induce a seizure, has been substantially improved

over the intervening decades, both in refinements to the electrical stimulus characteristics and the placement of electrodes, as well as in advancements to the accompanying anesthesia, particularly with the use of muscle relaxants (e.g., succinylcholine, atracurium). In 1949 another alternating current brain stimulation method, CES, was developed in the former Soviet Union. It was originally called "Electrosleep" and as the name suggests was initially used to treat insomnia. This method uses much lower levels of the alternating current than ECT, and is thus subconvulsive. In 1985, nearly 50 years after the first use of ECT, Anthony and colleagues published on the first use of pulsed magnetic fields to stimulate the brain with a procedure called TMS. TMS was initially used in neurology for studies of nerve conduction, but quickly caught the attention of psychiatrists eager to explore other, less invasive alternatives to ECT. This nonconvulsive, well-tolerated stimulation method through TMS has been approved by the FDA for treatment of depression. It also continues to be under active study, with some promising results in the treatment of various other psychiatric disorders like bipolar and anxiety disorders (i.e., posttraumatic stress disorder and obsessive-compulsive disorder), schizophrenia as described by Lefauchear and colleagues in 2014, addiction disorders—particularly nicotine dependence, and even depersonalization disorder. MST, a convulsive treatment derived from application of more powerful magnetic stimulation, was first tested in an animal in 1998 and in a human in 2000. Since then, MST has been under investigation in nonhuman primates and in humans as a more focal means of inducing seizures in an attempt to retain the unparalleled efficacy of ECT but with fewer side effects.

Two more invasive brain stimulation methods, DBS and VNS, were introduced about a decade following the first trials of TMS. Both DBS and VNS were first approved by the U.S. Food and Drug and Administration (FDA) in 1997 with indications for treatment of neurological conditions: VNS was originally approved as adjunctive therapy in reducing the frequency of epileptic seizures in adults and children aged 12 years and over; while DBS was initially approved for the treatment of essential tremor and Parkinson tremor. Currently, indications for DBS include treatment of all symptoms of Parkinson disease, including tremor, slowness and stiffness, and involuntary movements induced by medications, as well as symptoms of OCD that are not adequately controlled with medications or other therapies. At present, indications for VNS include adult treatment-resistant depression and epilepsy.

Table 34.36–1.
Brain Stimulation Methods: Definitions

CES	**Cranial Electrical Stimulation** Weak alternating electrical current is applied via saline soaked felt-covered electrodes, usually to the earlobes or bifrontal scalp location.

cTMS **Controllable Pulse Shape Transcranial Magnetic Stimulation**
A transcranial magnetic stimulator with a modified circuit that can induce nearly rectangular pulses, in contrast to conventional TMS that induces cosine waveforms.

DBS **Deep Brain Stimulation**
A wire electrode with multiple stimulating sites that is surgically implanted into the brain and chronically administers electrical stimulation.

ECT **Electroconvulsive Therapy**
Electricity is applied transcranially via electrodes placed on the scalp to induce a seizure under anesthesia.

MST **Magnetic Seizure Therapy**
High intensities of transcranial magnetic stimulation are applied to induce focal seizures under anesthesia, as a less invasive form of ECT.

PAS **Paired Associative Stimulation**
Transcranial magnetic stimulation is paired with peripheral nerve stimulation, resulting in Hebbian plasticity, altering functioning of the corticospinal tract.

tDCS **Transcranial Direct Current Stimulation, also called Direct Current Polarization**
Weak direct electrical current is applied to the scalp via sponge electrodes to polarize underlying brain tissue.

TBS **Theta-Burst Stimulation**
High-frequency bursts (e.g., 3 pulses at 50 Hz) of transcranial magnetic stimulation are applied at a regular frequency (e.g., 5 bursts per second). TBS can be given continuously (cTBS) or intermittently (iTBS).

TES **Transcranial Electrical Stimulation**
Alternating electrical currents applied to the scalp.

TMS **Transcranial Magnetic Stimulation**
Rapidly alternating magnetic fields are applied to the scalp to induce small, focused electrical currents in superficial cortex. Remote sites may be activated transsynaptically.

TNS **Trigeminal Nerve Stimulation**
Mild electrical current stimulates branches of the largest cranial nerve—the trigeminal nerve—either externally or subcutaneously aimed at modulating activity in brain areas such as the anterior cingulate cortex, nucleus solitarius, locus coeruleus, vagus nerve, and the cerebral cortex.

VNS **Vagus Nerve Stimulation**
An implanted pacemaker administers electrical pulses to the vagus nerve in the neck, activating the vagal afferents.

Frequently, initial developments in brain stimulation have been in the field of neurology. For example, TMS, DBS, and VNS originated as tools to treat neurological conditions but psychiatrists quickly saw the potential for those tools in the treatment of psychiatric conditions and brain stimulation techniques in psychiatry are gaining momentum and continue to evolve. It is not clear, however, whether those technologies and doses that are designed to treat neurological indications can be directly co-opted for the purposes of treating mental illness.

THERAPEUTIC NEUROMODULATION: TREATING PSYCHIATRIC DISORDERS THROUGH BRAIN STIMULATION

Mechanism of Action

Electrical Stimulation—Common Pathway. The brain stimulation tools considered in this chapter generate either electrical or magnetic pulses. However, both of these share a common final pathway—they affect the neurons electrically. That electrical effect may either be through the direct application of electricity and the resultant electrical field that reaches neurons or through the indirect induction of electricity via magnetic stimulation. The direct forms of electrical stimulation are exemplified in either *transcranial* delivery, as with ECT, CES, TNS, and tDCS, or surgical *intracerebral* delivery, as in the case of DBS or direct cortical stimulation (epidural or subdural). The indirect forms of electrical stimulation include TMS and MST, which induce electric fields in the brain through the application of alternating magnetic fields (Fig. 34.36–1). Of note, both the epidural and intracerebral modalities are more focal than the transcranial application of electricity because electrodes are placed directly in the neuronal tissue, bypassing the impedance of the scalp and skull. Magnetic stimulation methods also bypass the impedance of the scalp and skull, hence they are also more focal when compared to transcranial direct application of electricity. Magnetic stimulation is considered an indirect method of electrical brain stimulation in that changing magnetic field from these devices induces electricity in the brain according to the principle first described by Faraday in a law that bears his name, and later incorporated into Maxwell's equations, which unify all of electromagnetism. The magnetic modalities achieve their enhanced spatial resolution (focality) noninvasively, in contrast to the intracerebral and epidural methods, therefore these modalities are in the center of intensive research as they offer a promise of an unparalleled degree of spatial specificity without the need for surgery.

All but one of the brain stimulation modalities described here act by stimulating neurons; the one exception is tDCS, which does not stimulate but rather it polarizes. In this sense, the "S" of tDCS is a misnomer. It is more accurate to conceptualize tDCS as exerting a polarizing effect aimed at altering the likelihood of neuronal firing.

The action of the subconvulsive modalities of stimulation relies on the effects of the repeated stimulation of the targeted neural circuitry. However, in the case of the convulsive modalities (ECT and MST), the action is dependent upon the seizure induced by the stimulation and the effects of repeated seizure induction on brain processes. This is not to say that the form of stimulation that triggers the seizure has no impact on outcome. Indeed, it is well replicated that electrode placement and electrical stimulus parameters have a profound impact on the efficacy and side effects of ECT. Whether the same will be true for MST is under active investigation. Importantly, MST has the capability of inducing seizure in a more localized manner and thus to target brain regions and their neuronal networks thought to be implicated in depression, while avoiding those

responsible for untoward side effects.

Classification of tools that act to stimulate the brain electrically, using direct (electrical) or indirect (magnetic) means.

Comparison of Brain Stimulation with Psychopharmacology. Psychopharmacology and brain stimulation differ in several clinically relevant respects. Pharmacological agents rely on molecular action at the synapse or intracellular targets. They bind to either presynaptic or postsynaptic receptors, or other intracellular targets in order to affect their function. In contrast, brain stimulation induces action potentials via electrical depolarization of axons independently of receptor binding. Thus, not only does brain stimulation have the potential to work when medications have failed but also may act synergistically with medications as their sites of action and mechanisms of action are different. Because the chief mechanism of action in all modalities of brain stimulation is direct electrical modulation of the brain's neuronal activity, this approach avoids the systemic side effects seen with medications that orally introduce exogenous compounds, which are then distributed throughout the body to sites that have little to do with the intended target. These compounds may be secondarily metabolized to other biologically active metabolites. In contrast, brain stimulation has no exogenous compounds that circulate systemically in the bloodstream, does not undergo clearance, is not protein bound, and has no known interactions with the metabolism or clearance of psychopharmacological agents.

FIGURE 34.36–1. Classification of tools that act to stimulate the brain electrically using

direct (electrical) or indirect (magnetic) means.

Table 34.36–2.
Brain Stimulation versus Psychopharmacological Therapy

	Brain Stimulation	Psychopharmacology
Therapeutic agent	Electrical or electromagnetic	Neurochemical
Temporal characteristics	Phasic	Tonic
Delivery	Verifiable on electronic or clinical record	Dependent on patient compliance
Site of action	Axonal depolarization	Molecular target
Distribution	Focally applied to the brain	Systemic, throughout the body
Duration of availability	Milliseconds to seconds	Typical half-life of hours to weeks
Dosing parameters	Intensity, frequency, intertrain interval, number of pulses, site of stimulation	Milligrams, blood level
Metabolism	None	Hepatic
Clearance	None	Renal
Interactions with metabolism of other agents	None known	Possible

Brain stimulation is applied in a phasic fashion, which simply means that in contrast to medications that can remain biologically available in a patient's body for hours to weeks, or even months in the case of injectable depots, electricity can be turned on or off, with a flip of a switch. Most of the contemporary brain stimulation modalities that administer alternating electric current—either directly or via electromagnetic conduction (e.g., ECT, MST, DBS, VNS)—deliver pulses, or collections of pulses otherwise referred to as trains of pulses, with each pulse typically lasting 1 ms or less and trains of pulses lasting up to 30 seconds. The phasic nature of brain stimulation provides immediate washout that is not possible for pharmacological agents, which must be first metabolized and then cleared. While the transient on–off nature of brain stimulation has proved advantageous in research probing functional roles of certain brain areas, it poses a challenge to the induction of lasting effects that will persist beyond the period of the therapeutic stimulation (see Table 34.36–2).

Acute versus Prolonged Effects. Brain stimulation can have immediate or lasting effects (see Table 34.36–3). A single electrical pulse delivered at sufficient intensity can induce depolarization, trigger an action potential, release neurotransmitters at the synapse, and result in transsynaptic propagation with subsequent activation of a functional circuit. For example, brain stimulation applied to the hand area of the primary motor cortex may activate the corticospinal tract and induce a motor-evoked

potential in the contralateral hand. Such stimulation can result acutely in the induction of either a positive effect, as in the case of a muscle twitch or visualization of phosphenes, or a disruptive effect as in the case of visual masking. Although inducing a muscle twitch is an immediate, short-lasting effect, it allows one to examine the latency of this effect from the time of TMS single-pulse stimulation and thus to determine the nerve conduction delay, which may have value in the study of central motor pathways in clinical cases such multiple sclerosis and spinal injury.

Repetitive pulses delivered at fixed frequencies can exert even more powerful effects. Epstein and colleagues described in 1999 how repetitive TMS (rTMS) applied to the language-dominant hemisphere-induced arrest of the speech. Following termination of the stimulation, speech returned to normal. More recently, using interleaved functional neuroimaging with rTMS to examine network wide effects in a study with cats, investigators demonstrated behavioral impairments to visual attention with rTMS over the left intraparietal sulcus and interestingly also found downstream adaptive compensatory activity in areas of the visual attention network that were not stimulated.

Some of the more invasive brain stimulation modalities, such as DBS or VNS, are programmed to operate chronically, thus extending the acute action for as long as the stimulation is turned on. In the case of DBS, the pulses are typically given continuously at a high frequency, whereas in the case of VNS the pulses are given in trains lasting up to 30 seconds and typically repeated every 5 minutes. The less invasive modalities, such as rTMS, tDCS, CES, and even ECT, presumably require the induction of some form of neuroplasticity for their effect to become lasting.

Neuroplasticity. Persistent activation of a brain circuit can induce prolonged changes in the subsequent activities of that circuit. For example, repeated stimulation of the perforant pathway implicated in spatial memory learning and consolidation at high electrical frequency induces a lasting increase in the efficacy of that circuit; conversely, repeated stimulation with low frequencies depress it. These phenomena are termed long-term potentiation (LTP) and long-term depression (LTD), respectively, and are collectively known as neuroplasticity. Neuroplasticity is thought to occur through dynamic alterations in synaptic efficacy. Establishing evidence of longer-lasting neurochemical effects (i.e., LTP or LTD) from brain stimulation is crucial for establishing both the clinical utility and understanding the mechanism of action. Recent research in animal models offers evidence of lasting effects of high-frequency rTMS and there is evidence emerging in humans that rTMS can produce changes in synaptic efficacy that outlast stimulation induction. Initially described by Zhaoxiang Wang and colleagues, low-frequency rTMS (1 Hz or less) is believed to induce a sustained inhibitory effect on the excitability of the

motor cortex, whereas high-frequency rTMS (5 Hz or greater) produces facilitatory after-effects in excitability of the motor cortex. The work of Steve K. Esser, Reto Huber, and colleagues provided the first evidence, through coupling TMS with topographical EEG measurements of TMS-evoked potentials that these changes in excitability may come about as a result of an enhancement of a cortical potential. While such in vivo evidence is consistent with the hypothesis that TMS causes LTP without ex vivo experiments on excised human tissue, it is difficult to say with complete certainty whether these observations are true measurements of synaptic plasticity.

Table 34.36–3.
Acute and Prolonged Mechanisms of Action

Acute effects
Phasic activation of neural circuits
Observable motor responses (e.g., twitch)
Temporary disruption (e.g., speech arrest) or facilitation of ongoing processing (e.g., speeds reaction time)
Prolonged effects
Neuroplasticity
► Changes in synaptic efficacy akin to long-term potentiation or depression
► Alteration in neurotropic factors
► Modulation of cortical excitability
► Modulation of functional connectivity

Effect of Illness and Early and Late Brain Development on Brain's Response to Stimulation

Because brain stimulation exerts its acute effects by depolarization of neurons and over the longer term possibly through induction of lasting changes in synaptic efficacy, factors that influence neural transmission and plasticity may influence the brain's response to therapeutic stimulation. For example, investigators have found that infants and children have higher thresholds for activation of functional circuits in response to single pulses of TMS, presumably because myelination in their brains had not yet completed. Diseases of the central nervous system can also impact the response to stimulation. Fitzgerald and colleagues reported that patients with schizophrenia exhibited reduced plasticity in brain response to TMS when compared to healthy controls—specifically the patients failed to show inhibitory effects of low-frequency rTMS over motor cortex, possibly reflecting abnormalities in glutamergic functioning in schizophrenia.

Cortical atrophy due to normal aging or related to disease can reduce the total dosage of magnetic stimulation delivered because the strength of the magnetic field drops rapidly as a function of distance from the stimulating coil. Aging can also alter the brain's response to stimulation in a manner independent of the distance issue. Some investigators have

demonstrated an age-related differential response to rTMS over the motor cortex in older adults compared to younger subjects (45 years delineation of matched subjects), suggesting normal age-related changes in synaptic plasticity and the capacity for LTP and LTD that may reduce the efficacy of rTMS. These findings are in line with the generally accepted view that the efficacy of antidepressant treatment in the realm of pharmacotherapy is also highly age dependent (Levkovitz and Segal, 2001).

Relationship between Spatial Resolution and Invasiveness in Brain Stimulation

Each of the brain stimulation techniques can be separately classified with respect to the degree with which it can achieve precise focal targeting, that is, focality, and with respect to the degree of invasiveness, as seen in Figure 34.36–2. A high level of focality is important when brain stimulation is a tool being used to map regional brain functions and is also advantageous in clinical practice provided that a specific target is known or if stimulation of spatially adjacent regions might be counter therapeutic. On the other hand, if the target involves broad areas or is not precisely defined, then narrow focality may not offer benefits.

The least focal modalities are the noninvasive electrical stimulation methods such as tDCS, CES, and ECT. While ECT is more invasive by virtue of the need to use general anesthesia during the procedure and due to the induction of seizure, it is also nonfocal for the reasons it shares with the previous two methods—the electric current needs to traverse through the scalp and skull, which considerably impede the electric current, and which vary substantially from one individual to another.

FIGURE 34.36–2. Relationship between spatial resolution and invasiveness of the brain stimulation tools. DBS, deep brain stimulation; ECT, electroconvulsive therapy; MST, magnetic seizure therapy; tDCS, transcranial direct current stimulation; TMS, transcranial magnetic stimulation; VNS, vagus nerve stimulation. (From National Institute of Mental Health, National Institutes of Health, Department of Health and Human Services. Retrieved December 4, 2014 from http://www.nimh.nih.gov/news/image-library/index.shtml)

The most focal or precisely targeted method is DBS, where a thin lead usually containing a number of wires connecting electrodes placed close to its tip, is implanted directly into the targeted brain region. However, it is also the most invasive of all methods, requiring neurosurgical insertion of the stimulator lead, usually bilaterally, via a burr hole approximately the size of a quarter, which is drilled in the skull one for each of the leads. Somewhat less invasive but also less focal is VNS, which stimulates the vagal afferents on their way to the brain. The magnetic modalities like TMS and MST are considered more focal because the magnetic field passes through the scalp and skull without impedance, which is otherwise met by stimulation methods that directly administer electrical currents to the scalp. Magnetic flux has limited penetration (approximately between 2 and 4 cm), which is an important aspect of the stimulation's spatial resolution.

PSYCHIATRIC APPLICATIONS OF BRAIN STIMULATION

Dual Roles for Brain Stimulation: As a Probe of Brain Function in Health and Disease and as a Clinical Treatment of Psychiatric Disorders

Brain stimulation methods are used in psychiatric clinical and research practice along several parallel pathways. By virtue of their noninvasive nature, brain stimulation tools offer unique versatility as tools to examine normal brain function by transiently perturbing brain activity in creating temporary "virtual lesions" and monitoring the subsequent effects on cognition and behavior. Such investigation is particularly valuable for probing of brain areas implicated in the pathophysiology of psychiatric illness. Brain stimulation modalities are also used in the treatment of mental illness as novel therapeutic agents as shown in Figure 34.36–3.

Brain stimulation actively changes brain function and can induce measurable effects on brain activity that can be used to test causal relationship between brain and behavior. This is in contrast to neuroimaging or other methods to study brain function that passively acquire information about brain function and can only provide correlates of behavior. To demonstrate the utility of brain stimulation in testing causal relationship between brain and behavior, Pascual-Leone and colleagues in 1991 created a virtual lesion in the Broca area with rTMS, which consequently produced speech arrest in healthy participants. Using brain stimulation to investigate pathology, more recently investigators have compared the impact of rTMS on participants with autism spectrum

disorder to healthy matched volunteers to demonstrate differential effects of stimulation that suggest language-related neural network differences in those with autism spectrum disorder and neurotypical individuals.

In addition to examining brain–behavior relationships, the various stimulation modalities have the potential for delivering a therapeutic effect in the treatment of psychiatric disorders, primarily because brain stimulation modulates neuronal activity in a way that may be lasting, as reviewed in other parts of this chapter. The focal and temporal precision of some forms of brain stimulation poses a challenge of defining the disease-relevant anatomical and physiological targets for psychiatric disorders. The therapeutic use of neuromodulation in psychiatry will also require knowledge of the local and distributed effects of the various stimulation paradigms.

Integrating Brain Stimulation with Neuroimaging and Neurophysiology

The combination of brain stimulation and functional neuroimaging is a powerful research paradigm to explore and understand neural circuitry. TMS, DBS, and ECT have been successfully coupled with positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and electroencephalography (EEG) to investigate the modulatory effects of brain stimulation in both healthy and pathological populations. Commonly, physiological measures are performed sequentially *off-line* before and after brain stimulation to assess modulatory effects. However, for brain stimulation modalities such as TMS and tDCS, a simultaneous or *online approach* is now possible whereby stimulation and imaging occur in an interleaved manner. Whereas functional neuroimaging alone can indicate correlations between brain and behavior, simultaneous neuroimaging and brain stimulation can indicate causal brain–behavior relations.

With psychopathology increasingly conceptualized as dysfunction not only of one isolated brain area but rather on a network level, the combination of brain stimulation and neuroimaging is useful for examining of the dynamics of brain networks and the functional roles of network components, thus target sites for therapeutic stimulation. This is achieved by using brain stimulation to perturb or enhance one node of a network while monitoring activity in the entire brain. Results from such research allow elucidation of the functional connectivity of brain networks. For example, researchers have found that stimulation with TMS of the angular gyrus resulted in modulated activity to remotely connected nodes of the visuospatial attention network (enhanced activity in the contralateral V1 and V2), in addition to the behavioral effects of TMS. In another recent example, investigators delivered low-frequency rTMS to the intraparietal sulcus followed immediately with an attention fMRI task to demonstrate a decrement in activity in the targeted region and changes in activation of the corresponding contralateral region, as well as other regions in the visual

attention network. In this experiment, rTMS appears to have produced changes in activity not only at the site of stimulation, but also disrupted the interhemispheric balance of activity.

FIGURE 34.36–3. Research and clinical applications of brain stimulation in psychiatry. (From National Institute of Mental Health, National Institutes of Health, Department of Health and Human Services. Retrieved December 4, 2014 from http://www.nimh.nih.gov/news/image-library/index.shtml)

Interleaved brain stimulation and neuroimaging also present utility in guiding and localizing stimulation with much improved accuracy rather than relying on gross structural anatomy as reference, which is susceptible to interindividual variability. In turn, accurately navigated TMS may reduce variability in clinical response.

These examples illustrate how combining brain stimulation with neuroimaging and physiology can inform exploration of mechanisms of action of various brain stimulation modalities and lead to effective screening for stimulation paradigms hypothesized to have therapeutic effects based on their ability to modulate activity of specific circuitry implicated in the illness. However, combining neuroimaging methods with brain stimulation is not without some limitations. For instance, the hemodynamic response as measured in fMRI is only an indirect measure of neural activity and neuroimaging with interleaved brain stimulation is susceptible to artifacts.

BRAIN STIMULATION TOOLS

Transcranial Magnetic Stimulation

Definition. TMS is the application of rapidly changing magnetic field

to the superficial layers of the cerebral cortex, which locally induces small electric currents, technically referred to as "eddy or Foucault currents." These are circular electric currents induced within a given conductor by a changing magnetic field in that conductor. Michael Faraday originally discovered this induction through his experiments in 1831 and later quantified in Maxwell's equations that encompass all of electromagnetism. Thus, TMS may be referred to as electrical stimulation without an electrode, as it uses magnetic fields to indirectly induce electrical pulses in the targeted cerebral tissue. TMS device delivers strong magnetic pulses via a coil that is held on the scalp. Since magnetic fields are unaffected by the electrical impedance of the scalp and skull, this method of stimulation enables the focal stimulation of smaller areas of the brain than is possible with other noninvasive devices which use either alternating (ECT, CES) or direct (tDCS) electrical current for primary stimulation. TMS is an example of noninvasive, stimulation of focal regions of the brain delivered at levels well below subseizure threshold and as such, can be used for research or therapeutically without the need for anesthesia. It is a relatively new treatment modality in the psychiatric practice, with the original device approved by the FDA in 2008 for treatment of depression for patients who have failed a trial of one, but not more than one, antidepressant medication like an SSRI. This initial indication has been since expanded to include another device and to treat adult patients with major depressive disorder (MDD) who have failed to benefit from any number of antidepressant medications.

TMS, when given one pulse at a time without regular rhythm and at low rates of delivery, is referred to as single-pulse TMS. When repeated at regular rhythmic intervals that usually range from 1 to 25 Hz, this stimulation method is described as rTMS, which can be further functionally divided into "low-frequency rTMS" when stimulation frequency is 1 Hz or less, or "high-frequency rTMS" when higher frequencies are used, usually 5 to 20 Hz. Theta-burst stimulation (TBS) refers to high-frequency bursts (e.g., 3 pulses at 50 Hz) applied at a regular frequency (e.g., 5 bursts per second). TBS can be given continuously (cTBS) or intermittently (iTBS). cTBS is reported to induce inhibitory effects while iTBS is reported to exert excitatory effects.

History. In 1985, Barker, Jalinus, and Freeston from the University of Sheffield in the United Kingdom reported the first use of TMS to stimulate the human brain. Early stimulators were capable of producing only low frequencies, typically less than 0.3 Hz, but it was the single-pulse TMS that in those early explorations proved to be very useful in the study of motor conduction and mapping basic brain processes. While these studies used large round coils that lacked the focality of today's technology, even this early work with low-frequency stimulation was promising enough in the

experimental treatment of depression and schizophrenia to encourage further work and development of TMS as a promising treatment modality in psychiatry.

With the subsequent development of devices capable of much higher repetitive rates up to 20 Hz—higher brain functions like language, mood, and memory became accessible to stimulation. In 1996, Pascual-Leone and colleagues reported that antidepressant properties of daily TMS stimulation for 5 days to the dorsolateral prefrontal cortex (DLPFC) might have a prolonged effect that maintains beyond the acute period of stimulation. Studies such as this motivated an intense interest in the potential therapeutic value of focally applied rTMS targeted to the neuronal circuitry underlying not only depression but also other psychiatric disorders like anxiety disorders, schizophrenia, and others.

Mechanisms of Action. By Faraday's law, the induced electromotive force in a closed loop is directly proportional to the time rate of change of magnetic flux through the loop. As applied in TMS, changing magnetic field induces electrical current in the circuitry of the superficial cortex underlying the TMS coil. This electrical current is commonly referred to as "eddy current" for its circulating motion in a plane perpendicular to the plane of the magnetic field (also known as Foucault currents named after the French physicist who described the phenomenon). At sufficient intensity, electrical currents across the cerebral cortex affect cell electrochemical gradients and produce local neuronal depolarization, which may result in a propagated action potential. For example, when the TMS coil is positioned over the hand area of the cerebral cortex's motor strip, changing magnetic field generated by the repetitive pulses induces local currents immediately below the site of stimulation that cause the neurons in area M1 to fire. In turn, this action potential propagates through the polysynaptic corticospinal tract and results in a twitch in the contralateral hand muscle, which can be used to study the excitability of the corticospinal system. In summary, TMS uses magnetic field to indirectly induce focal electrical currents in the brain, thereby triggering the firing of functional neuronal circuits that can lead to observable behavioral effects. This effect can be easily demonstrated by simply moving the TMS coil across the cortical representation of neighboring muscle groups (the homunculus) with a series of single TMS pulses.

Single TMS pulses can exert other effects when moved to different cortical areas. When positioned over the primary visual cortex (V1), scotomas, or "blind spots" are often elicited. This effect was referred to as "visual masking" or creating a "virtual lesion" and it illustrates that TMS can transiently disrupt functions.

Activation of motor neurons resulting in a muscle twitch or disruption of visual perception with single-pulse TMS represents examples of the

acute effects of TMS-induced neuronal depolarization as shown in Table 34.36–3. The effects of single TMS pulses are believed to be immediate and short lived. The muscle twitch as induced by TMS to area M1 is nearly instantaneous, with the hand movement occurring approximately 20 ms after the TMS pulse is applied. Both the motor-evoked potential and visual masking operate on a similar timescale measured in milliseconds. While producing such a motor-evoked potential does not require the patient to engage in activity, a single magnetic pulse does not typically affect cognition by itself. Rather, interference or improvement of performance in a cognitive task is observable when a train of magnetic pulses are delivered immediately preceding or during the time when the participant is engaged in a cognitive task, such as in visual masking.

Traditionally TMS coils were limited to direct stimulation of the cortical surface, activating neurons at 1.5 to 3.0 cm beneath the scalp rather than deeper subcortical limbic structures. However, recent development and research of coil designs for stimulation of deeper brain areas, such as the H-Coil, suggest TMS may stimulate subcortical structures up to 6 cm beneath the scalp. The cost of deeper stimulation, however, may be spatially wider electrical field distribution in the brain (i.e., reduced focality).

TMS can exert longer-lasting effects when the pulses are repeated at regular intervals in a process of rTMS, or when TMS pulses are paired with other forms of stimulation, such as electrical stimulation of a peripheral nerve (as in paired associative stimulation), or when TMS is coupled with audiovisual stimuli, as in the example of classical conditioning of the brain response to TMS. The mechanisms underlying these lasting effects of TMS have been described by various researchers and are thought to be related to neuroplasticity and alterations in synaptic efficacy.

Treatment of psychiatric disorders with rTMS has been informed by attempts to focally alter pathological cortical excitability whereby irregular excitability has been linked to a specific illness. For example, reduced activity in the left DLPFC has been implicated in several studies as a physiological correlate of affective disorders. To correct this, numerous studies have applied high-frequency rTMS, which purportedly increases excitability, to the left DLPFC in an attempt to normalize activity in this region. In a related approach, some investigators who implicated abnormal interhemispheric balance in activation between the right and left DLPFC to mood psychopathology, have applied low-frequency rTMS to the right DLPFC, in an attempt to normalize this balance with stimulation trains believed to be inhibitory.

The potential therapeutic role of developing rTMS to focally modulate cortical excitability has been validated in animal studies, which suggests that rTMS, like ECT and antidepressant medication, can exert effects on neurotransmitter release, receptor expression and gene expression.

However, animal models of the effects of rTMS do not perfectly replicate the effects of rTMS on the human brain due to size differences and consequently how they impact the strength and distribution of the induced electric fields.

Side Effects, Interactions with Medications and Other Risks. Administration of TMS is a noninvasive, relatively benign procedure when applied by a knowledgeable professional to a subject who has been properly evaluated. However, it is not entirely without risk. The most serious known risk of TMS is an unintended seizure, but this risk varies depending on stimulation parameters and patient history. Namely, single-pulse stimulation is less likely to result in a seizure compared to rTMS and variations in dosage—the combination of frequency, power, train duration, and intertrain interval—may also change the risk of unintended seizure. In addition, subject factors such as the presence of a neurological disorder (epilepsy or a focal brain lesion) or use of seizure lowering medications may also result in greater likelihood of an unintended seizure. The FDA's safety guidelines for avoiding seizure with rTMS are summarized in Table 34.36–4.

Basic Studies. TMS has helped advance the basic understanding of normal brain function, as well as the pathophysiology of psychiatric illness. The combination of noninvasiveness, high temporal resolution and particularly the ability to make use of frequency-dependent effects are significant advantages of TMS. Furthermore, the ability for TMS to be coupled with neuroimaging to explore the functional role of areas of activation seen with PET or fMRI imaging makes it a valuable tool for understanding brain function (see Fig. 34.36–4). For example, Luber and colleagues reported on the use of fMRI-guided stereotaxically applied rTMS to test the functional role of brain regions implicated in working memory, finding that rTMS applied to the precuneus facilitated working memory performance. Such an approach informs one's understanding of the brain networks involved in normal brain function. Investigators have also delivered high-intensity TMS to participants during functional magnetic resonance image acquisition to demonstrate that stimulation of the left motor cortex was correlated with distributed cortical and subcortical activity in the bilateral premotor cortex, bilateral primary somatosensory cortex, bilateral second somatosensory cortex, left medial pontine nuclei, bilateral cerebellum, deep cerebellar nuclei, thalamic nuclei, and the basal ganglia (caudate and putamen). From such correlated changes in activity researchers are able to postulate brain areas that form distributed networks.

Clinical Studies. The use of rTMS in the treatment of MDD has been the most-studied therapeutic application of this technique. Evidence from a growing number of randomized controlled trials suggests a significant antidepressant effect with rTMS applied to the DLPFC. The largest study to date has been a multicenter trial conducted at four U.S. university hospital clinics reported by George and colleagues that included approximately 860 antidepressant medication-free patients with unipolar MDD who had not benefited from prior treatment. A total of 190 participants randomized to either active or sham treatment were included in the final analysis. Participants in the active treatment arm received daily left prefrontal rTMS for 3 weeks, with treatment standardized at 120 percent of the magnetic field intensity relative to the patient's resting motor threshold, at 10 pulses per second (10 Hz) for 4 seconds, and an intertrain interval of 26 seconds. The authors reported that TMS was effective in treating major depression with minimal side effects. Not all studies have been positive, however, and the average effect size in depression is moderate—less than with ECT, but comparable to that seen with traditional pharmacotherapy.

Use of TMS in the treatment of schizophrenia has yielded some promising results in experimental studies that used either low-frequency rTMS to inhibit temporal-parietal areas of the cortex linked to hyperactivity during auditory verbal hallucinations or high-frequency rTMS to the prefrontal cortex aimed at modulating dopamine hypofrontality linked to negative symptoms. In the first double-blind randomized trial of deep TMS for the negative symptoms of schizophrenia, investigators found statistically significant reduction in negative symptoms after treatment, although there was no statistically significant difference between the active treatment and sham groups. Ongoing research has also demonstrated some positive results of TMS as a treatment modality in anxiety disorders, including applications for obsessive-compulsive disorder, panic and Tourette disorders.

Current Status in Treatment Algorithms. In 2010, the APA included TMS within their Practice guidelines for the treatment of patients with MDD (3rd edition) recommending TMS as an initial treatment modality in the acute phase of depression. There are two FDA-approved TMS devices for use in adult patients with major depressive disorder: the NeuroStar TMS device manufactured by Neuronetics Inc. was approved in 2008 with the following FDA-approved indication: "for the treatment of MDD in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose and duration in the current episode"; and the Brainsway Deep TMS device that

excites or inhibits neurons deeper inside the brain by using an H-Coil was approved in 2013. The FDA-approved indication appears to be broader: "for the treatment of depressive episodes in adult patients suffering from MDD who failed to achieve satisfactory improvement from previous antidepressant medication treatment in the current episode." The Neuronetics device delivers 10-Hz frequency pulses for trains of 4-second duration with an intertrain interval of 26 seconds and a typical session duration of 37.5 minutes (total of 5 daily sessions of 3,000 pulses for 6 weeks), while the Brainsway device delivers pulses with 18-Hz frequency for 2 seconds with an intertrain interval of 20 seconds and total train duration of 20.2 minutes (5 daily sessions of 1,980 pulses for 4 weeks, followed by optional another 12 weeks of bi-weekly maintenance treatments). A treatment course with either device is applied to prefrontal cortex. rTMS treatments would most likely be considered as an alternative treatment modality to medications, prior to more invasive methods like ECT.

Table 34.36–5.
Transcranial Magnetic Stimulation Dosing Parameters

Scalp position, target localized method
Coil shape and orientation; number of coils
Circular; figure-eight; double-cone; H-coils; B-shaped; cloverleaf
Single pulse vs. paired pulse vs. repetitive vs. convulsive
Train: Frequency, duration, intensity, total pulses
Fast/high frequency at rates >1 Hz;
Slow/low frequency at rates <1 Hz;
Quadripulse repeated trains of four monophasic pulses separated by interstimulus interval
Intertrain interval
Number of trains/session
Number of session/day
Number of days/course
Taper/maintenance/reintroduction

Patient Selection. Patients who have failed a trial of one or more antidepressant medications are medication intolerant, and pregnant or postpartum patients avoiding use of medications may be appropriate candidates for TMS (Note: treatment of patients with Neuronetics device who failed two or more medication trials in the current episode, would be considered off-label based on its current FDA-approved indication). However, given the lower effect size of TMS, for urgent or severely refractory cases, ECT would remain the ultimate "gold" standard treatment.

Dosing. The major characteristics of TMS dosing are shown in Table 34.36–5. Each device's technical parameters, such as stimulation intensity, pulse frequency, intertrain interval, and total number of pulses

administered are the most basic adjustable elements of TMS dosing. In addition, coil shape and position relative to the target cortical area as well as the waveform shape and polarity, are also of important specific consideration (see Fig. 34.36–5). In general terms, the delivered intensity of rTMS is related to the distance of the coil from the target area of the cortex. Thus, increasing the distance decreases the intensity of the stimulation able to reach the brain. Such decreased intensity has been found to be negatively correlated with the antidepressant response and with the degree of brain activation as evidenced by functional imaging. It is important to note that despite the many aspects that go into each device's dosing characteristics, considerable individual variability in the response to TMS has been reported.

Future Directions and cTMS. TMS and other forms of magnetic stimulation hold a tremendous promise in psychiatric treatment due to their focality and noninvasiveness. However, much research is still needed to replicate preliminary findings with improved stimulators, optimize dosing, establish the patient characteristics that predict response, and examine the influence of concomitant medications on TMS effect. Research on the durability of clinical benefits of TMS is ongoing with some promising results. Using a large cohort of patients, investigators recently followed patients after their treatment for depression with TMS for 12 months posttreatment and found statistically and clinically meaningful durability of clinical benefits.

Other pursued directions are modification of pulse shapes to optimize stimulation as seen in controllable pulse shape TMS (cTMS), a device type that can generate rapid rate (<50 Hz) trains of mono/bi/polyphasic electrical pulses that are near rectangular in shape and vary in width, directionality, and amplitude. This work takes after the discovery in 1990s in the realm of ECT in which square or rectangular waves of variable width replaced the sinusoidal waveforms, generally now abandoned due to their inefficiency and creation of excessive cognitive side effects. In the first study examining cTMS use in human subjects, investigators found the cTMS device generated a broader range of pulse widths compared to conventional TMS devices, which these authors suggest could enable more accurate study of the pulse width dependence of cortical excitability.

Transcranial Direct Current Stimulation

Definition. tDCS is a noninvasive and nonconvulsive form of brain stimulation in which a very weak (0.5 to 2 mA) direct electrical current is applied using at least two surface scalp electrodes of which optimal placement continues to be investigated. This direct current (DC) form of electrical stimulation that can be distinguished from most other devices that stimulate with alternating currents in the brain such as CES, TMS,

ECT, MST, VNS, and DBS, does not directly result in neuronal firing by suprathreshold neuronal membrane depolarization, but rather tDCS elicits polarity-dependent alterations in the resting membrane potentials. These facilitating or inhibiting effects can last for up to 1 hour after stimulation and are thought to induce neuronal plasticity. The device is very portable and usually operated by 9V DC batteries.

FIGURE 34.36–5. Transcranial magnetic stimulation dosing parameters. Images clockwise from top left: NITRC [Online image] (2015). Retrieved December 4, 2014 from http://www.nimh.nih.gov/news/image-library/index.shtml)

History. There is history of ancient Egyptian, Roman, and Middle Eastern use of live electric catfish and torpedo fish as crude therapeutic interventions that involved use of DC stimulation for headaches and epilepsy. It was not until the 1960s that tDCS was empirically investigated. In Great Britain, Lippold and Redfearn (1964) reported that positive (*anodal*) currents induced elevated mood and motor activity and reduced anhedonia, whereas negative (*cathodal*) currents induced withdrawal and apathy. While subsequent attempts to replicate these findings failed, since

the 1980s there has been a growing body of evidence of positive effects from tDCS in cognitive and motor function. Of late, tDCS has experienced resurged interest due to its ease of application, small device size, low cost, and relative lack of risks and side effects as compared with treatments like ECT and TMS.

Side Effects. There are no known serious adverse effects of tDCS. It is well tolerated with low prevalence of mild adverse effects reported in the literature, which include mild tingling sensations, light itching sensation, skin irritation, mild burns, and headache.

Mechanism of Action. The exact mechanism of tDCS is assumed to be modification of the synaptic microenvironment—weak direct current shift of the resting membrane potential, either lowering or raising the threshold of activation—affecting the firing and conductance of neurons. Specifically, anodal electrodes excite the neuron shifting the resting membrane potential toward depolarization, while cathodal electrodes inhibit the neuron shifting potential toward hyperpolarization—effects which may be dependent on the subtype of cortical neuron being stimulated. Because tDCS works via polarization and does not affect action potential firing in cortical neurons, the term "transcranial direct current polarization" is favored by some investigators and both terms appear interchangeably in the literature.

Clinical Studies. Much of the experimental research on tDCS has been conducted with healthy controls demonstrating the effectiveness of this stimulation method in exciting and inhibiting brain activity. Preliminary research has also examined the effects of tDCS for neuropsychiatric disorders such as depression, schizophrenia, pain disorders, and epilepsy. While early research on the application of tDCS for depression produced mixed results, methodological improvements have reignited interest in research of tDCS as a therapeutic technique.

Current clinical psychiatric research is focusing on the potential effectiveness of tDCS in reducing depressive symptoms. A recent meta-analysis of seven randomized sham-controlled studies demonstrated significant antidepressant effects after left prefrontal anodal tDCS with a reduction of symptoms as measured by the Hamilton Rating Scale for Depression (HRSD) ranging from 14.6 percent to 80 percent in the active treatment group versus approximately 10 percent symptom reduction in a group receiving sham tDCS. In terms of the durability of this clinical response, four of the seven studies reported that antidepressant effects were sustained for 1 month after the end of treatment in the active DLPFC group. Further research is needed to replicate such findings.

Current Status in Treatment Algorithms. tDCS is not approved by FDA for psychiatric treatments and is thus considered an experimental research technology with much work needed to demonstrate its efficacy. Should sufficient evidence be attained and the device approved by the regulatory authorities, tDCS could represent an inexpensive and relatively safe alternative form of treatment to medications, prior to the more invasive stimulation methods like ECT or VNS. Within research, the typically applied stimulation protocols are two cephalic electrodes positioned below the cranial foraminae and fissures at 1- to 2-mA intensity, with stimulation up to 20 minutes per session.

Future Directions. Most of the current tDCS devices utilize large, saline-solution–soaked electrodes. Recent development of high-definition tDCS (HD-tDCS) devices that use small arrays of "high-definition electrodes" are under investigation for their increased focality compared to standard bipolar montages of traditional tDCS devices. Results of a HD-tDCS 4 × 1 montage that consists of once center electrode over the target and four surrounding return electrodes is promising in terms of increased excitation of a target area.

In general, current knowledge of tDCS safety, efficacy, indications, dose–response relationship, as well as predictors of response is limited and further exploration is needed.

Cranial Electrical Stimulation

Definition. CES, like tDCS, uses a weak (1 to 4 mA) current. However, with CES the current is alternating. It is traditionally applied via saline-soaked, felt-covered electrodes clipped onto the earlobes. Other placement strategies are also being currently investigated. For example, a study currently under way at Columbia University directed by Peter Bulow utilizes a cathode placed over the scalp area immediately in the vicinity of DLPFC and anode placed over right arm. The current of CES is in a similar range to that of tDCS with the major difference being that the current is alternating, creating either sinusoidal or modified square waves with a frequency range of 0.5 to 15,000 Hz, depending on the type of the stimulator.

History. CES was originally developed in 1949 in the former Soviet Union and used as an aid in inducing sleep. It was thus called initially "Electrosleep." In addition to the treatment for insomnia, it was also utilized as an aid in anesthesia, because of the observation that even when the current was reduced to a point of not causing excessive sleepiness, some patients seemed to benefit from the anesthetic effect of the stimulation. The device was brought to the United States and early research in America dates back to the 1960s. It was grandfathered-in by the FDA as

a Neurological Therapeutic Device for the treatment of insomnia, anxiety, and depression, and stress and the name CES, for Cranial Electrotherapy Stimulator, was suggested. In the 1970s CES was used by many US clinicians to treat substance abuse and substance abstinence syndrome in the belief that patients with a history of abuse were more susceptible to cross-addiction to psychotropic medications and because they were thought to be more resistant to the effects of such medications when compared to nonaddicted persons.

Mechanism of Action. The exact mechanism of action has not been elicited at this time and there is no agreement among researchers on the predominant mode of action. Previous hypotheses proposed that the stimulation with the alternating micro current affects the thalamic and hypothalamic brain tissue and facilitates the release of neurotransmitters. Claims have been made that through interaction with cell membranes, the stimulation produces changes in signal transduction associated with classical second messenger pathways including calcium channels and cyclic AMP. The most promising research to elucidate the mechanism of action comes from a neuroimaging study where researchers concurrently stimulated participants with CES. In this study, investigators found that CES at both 0.5 and 100 Hz (two commonly used frequencies in clinical practice) deactivated frontal and parietal area and significantly altered connectivity in the Default Mode Network. These researchers suggest CES may alter brain oscillation patterns, which is in line with previous EEG research of CES. While such research is promising, possible therapeutic effects are still not well understood.

Side Effects. It is believed that the CES stimulation is not harmful, primarily due to its low voltage power supply (9-V battery) and lack of any reported adverse event by the FDA. Local skin irritation, headache, nausea, as well as general feeling of dizziness have been reported. Device manufacturers do not advise the use of the device during pregnancy, in those with low blood pressure, or people who have arrhythmias or pacemakers.

Clinical Studies. While there is over 40 years of research on CES, many studies lack a sham comparator or control measure and many are open-label studies that lacked rigor. A recent Cochrane Review suggests that at the current time there are no high-quality studies comparing the use of CES with a sham for treatment of depression that warranted inclusion in the review, thus asserting that there is insufficient evidence to support the use of CES in treating acute depression.

In a pilot study using a small sample of 12 patients receiving CES for generalized anxiety disorder, investigators recently demonstrated that 6

weeks of CES at 0.5-Hz frequency and 300-μA intensity resulted in significant decreases in anxiety scores as measured by the Hamilton Rating Scale for Anxiety. While promising, much more research is needed.

Current Status in Treatment Algorithms, Patient Selection, and Dosing. Although the FDA approves a number of CES devices, the use of CES has not been studied sufficiently in the United States and it does not have a specific place in any algorithm of standard US psychiatric practice. Routinely, CES used for depression is delivered daily for a minimum of 3 weeks followed by a reduced schedule as needed for up to a year. It is reported to be generally well-tolerated, noninvasive treatment.

Future Directions. As with tDCS, basic issues of indications, patient selection, dose–response relationship, and efficacy are currently under active research and remain to be optimized.

Magnetic Seizure Therapy

Definition. MST is a novel form of a convulsive treatment, currently under development in several research institutions in the United States, Canada, England, Germany, and Australia. The treatment employs alternating magnetic field that crosses the scalp and the calvarium unaffected by their high electrical impedance, to in turn induce a more-localized electric current in the targeted regions of the cerebral cortex than is possible with ECT. The aim is to produce a seizure whose focus and patterns of spread may be controlled. Numerous publications characterize MST as an attempt to combine the potential benefits of unimpeded focality provided by magnetic fields, with the powerful antidepressant efficacy of ECT.

MST is a convulsive treatment, in many ways similar to ECT. It requires approximately the same preparation and infrastructure as ECT. However, MST is administered using a modified TMS device, one that can administer higher output than the conventional TMS devices, and thus relies on magnetic stimulation to induce a seizure, unlike external electrode electric stimulation in ECT. The MST procedure is performed under general anesthesia with a muscle relaxant. MST is at the stage of clinical trials, and is not presently FDA approved. Current studies concentrate on optimizing the efficacy through treatment applied to the putative depressive centers of the brain while avoiding those brain areas involved in memory formation and consolidation (medial temporal lobes) with the aim of lessening the acute cognitive side effects possible with ECT.

History. MST was first described as a convulsive treatment by Lisanby and colleagues in 2001. A 20-year-old inpatient with a medication-resistant depressive episode was reported to have been successfully treated in Bern,

Switzerland. The treatment resulted in a 50 percent reduction in depression scores, was well tolerated and had no adverse effect on Mini Mental State Exam Scores. Prior to this human treatment, magnetically induced seizures were first performed in rhesus monkeys in 1998 with a custom-modified TMS device, and later more extensive safety testing was completed with nonhuman primates.

The first trial of MST in the United States was performed at Columbia University in New York and reported fewer acute cognitive side effects with MST than with ECT in a within-subject, cross-over, blinded trial. The second center to perform MST in the United States was University of Texas, Southwestern Medical Center. Internationally, small human trials are either ongoing or have been recently conducted at centers in Canada, Australia, Wales, Scotland, and Germany.

Mechanism of Action. Induction of a seizure is hypothesized to be the underlying event responsible for the mechanisms of action of MST. As in ECT, these are not fully understood. However, due to its focality, MST appears to represent a tool better suited than ECT to study the mechanisms of action of convulsive therapy, through its potential of inducing seizures initiated in different regions of the brain. This focality of MST allows systematic investigation of the coupling between the site of seizure initiation and outcome. Furthermore, the quality of seizures induced by MST is believed to be distinct from those induced by ECT. MST-induced seizures show less impact on parasympathetic outflow, less generalization to hippocampus and deeper brain structures, and result in less serum prolactin surge.

Side Effects. Adverse effects from MST are largely connected to the risks associated with anesthesia and generalized seizure. In addition, MST magnetic coil produces a clicking noise that may potentially affect hearing. To mitigate that risk and prevent any cumulative damage both the patient and members of the treating team should wear earplugs.

Studies suggest MST results in less retrograde and anterograde amnesia than ECT. Specifically, investigators have demonstrated that there is significantly less acute memory disruption (i.e., anterograde amnesia on treatment days) with MST compared to right unilateral ECT. Though promising, this result should be replicated in a larger trial.

Currently, MST seizures are less well generalized and tend to produce less robust motor convulsions. For this reason, the dosage requirement of the muscle relaxant (usually succinylcholine) is lower than with conventional ECT. Shortening the period of paralysis could reduce the risks of the procedure by reducing the period of respiratory suppression. It should be noted however, that the attenuated robustness and generalization of the MST-induced seizures may be a function of cautious

dosing with new technology. Further studies are needed, both to in device development and efficacy dosing.

Clinical Studies. MST was used to treat a human patient for the first time in 2000 in Bern. A depressed patient received four convulsive sessions induced by a prototype MST device by Magstim (Magstim, Whitland, Wales, UK) using frequency of 40 Hz at 100 percent of that prototype machine's power intensity. Soon after, a second human treatment case was reported by the same center with both patients describing posttreatment relief of their depressive symptoms without experiencing any significant side effects. In 2003 after the first blinded, randomized, within-subject, crossover trial in 10 human patients, Lisanby and colleagues reported that there were less acute side effects of MST compared to ECT. A custom-modified Magstim device was used in this trial with the frequency increased to 50 Hz, a peak magnetic field of 1.2 T produced for 8 seconds, and a pulse width of 500 μs. One of the more important observations made in this trial was that although seizures were induced in all 10 patients, the seizure threshold was attained in several cases only at the very maximum of that device's power output. Since this experiment, there have been technological improvements such that MST devices are now capable of continuous stimulation at 100 Hz for up to 10 seconds (Magstim device) and even up to 250 Hz for a limited stimulation time (MagVenture device). It has been shown that antidepressant effects of convulsive therapy require a suprathreshold stimulation requiring at least doubling, and in some cases even six times more, the seizure-threshold power in order to achieve an optimal antidepressant result. Thus, the technological improvements in MST more reliably ensure induction of a seizure and may optimize clinical effects.

Convulsive treatment at 100 Hz was first used in 2004 in an ongoing study of rhesus monkeys, and starting in 2007, in human trials. Published results that compared MST to ECT in the nonhuman primates continue to show a superior safety profile of MST, even with the newer high-dose MST device prototypes. Pilot trials investigating the efficacy and safety of the 100-Hz MST in human patients demonstrate promising results. Most recently, investigators at Australia's Monash University and Alfred Psychiatry Research Centre reported on an open-label trial of 13 patients receiving three MST per week (a maximum of 18 treatments were provided) with a MagVenture device. These researchers found five out of the twelve patients who completed the study experienced a 50 percent reduction in depressive symptoms, and none of the 13 patients receiving treatment demonstrated changes in cognitive functioning after treatment.

A randomized controlled trial comparing the efficacy of MST to ECT in 20 patients with treatment-resistant depression was reported by Sarah Kayser and colleagues at the University Bonn. Six of ten patients receiving

MST in this study demonstrated a clinical response to treatment with 50 percent reduction in depressive symptoms as measured by the Montgomery Åsberg Depression Scale and the HRSD and there was no significant difference in efficacy or cognitive side effects when compared to the ten patients who received ECT. Notably, the patients in this study receiving MST were significantly quicker to recover and reorient immediately after treatment and did not experience the nausea, headache, or muscle pains that were evident in the ECT treatment group.

There is currently an ongoing double-blind human trial comparing MST to right unilateral ECT in treatment of severe depression in older adults at New York State Psychiatric Institute/Columbia University, an ongoing clinical trial of MST treating refractory depression, schizophrenia, and obsessive-compulsive disorder in Toronto, Canada, and also ongoing MST research in Australia at Monash University and Alfred Psychiatry Research Centre.

Current Status in Treatment Algorithms. No clinical algorithms exist for MST, as it is still an investigational protocol and treatments outside of research are not FDA approved. There are two MST devices being used within research: the MagPro MST device with Twin Coil and Dual Coil manufactured by MagVenture that delivers a biphasic waveform and pulse width of 370 μs allowing a maximal stimulation with 2,000 pulses at 100 pulses per second at 100 percent energy output (effective 70 to 75 percent energy due to power roll off at those levels) or 1,000 pulses at approximately 67 Hz at 100 percent energy output; and a MagStim MST device manufactured by MagStim in the United Kingdom which has a maximum capacity of 1,000 pulses at 100 Hz with a single round coil. As in ECT, where parameters such as electrode placement, pulse width, and dose are essential to maximize clinical benefit while minimizing risks of cognitive side effects, stimulation parameters, and coil placement are also important considerations in MST. Assuming the hypothesis that MST can approach the efficacy of ECT with fewer side effects is correct, this magnetically induced convulsive treatment will play an important role in referral for convulsive therapy. Furthermore, should future technological advances in delivery of MST, combined with the current improved understanding of the brain's circuitry implicated in depression, result in a treatment that is equally efficacious as ECT but with a more favorable side-effect profile, then it may replace the latter altogether. However, much more research is needed both in the realm of clinical treatment efficacy and technological device development.

Patient Selection. MST is investigated as a treatment alternative for those patients who have failed several adequate medication trials or whose symptom severity requires a fast treatment response, traditionally

requiring ECT treatment. Since general anesthesia is an integral part of the procedure, MST will most likely continue to be reserved for treatment-resistant patients after several classes of medications have been already tried.

Future Directions. MST is a novel treatment in early phases of clinical testing. Clinical treatment variables, including dosing, optimal coil placement, patient selection, and mechanisms of action are the topics of ongoing and future studies.

Vagus Nerve Stimulation

Definition. VNS is a direct, intermittent electrical stimulation of the left cervical vagus nerve via an implanted pulse generator. The stimulating electrode is wrapped around the left vagus nerve in the neck and is connected to the battery/generator usually implanted subcutaneously in the left chest wall. George and colleagues described VNS in a 2000 paper as an important new tool for brain research and therapy, where, as a result of external stimulation of the left vagus nerve, afferent signals are sent to the nucleus tractus solitarius and the connected limbic and cortical areas. Implantation surgery is completed under brief general anesthesia, usually performed as a day procedure, and involves two incisions—one in the chest for the battery/generator and another for the electrode in the left neck. Electrical parameters affecting the stimulation characteristics can be controlled by professional staff externally, with a programming wand. Patients have the ability to switch off the pulse generator by holding a magnet over the skin directly above the area where it is implanted.

History. In 2005, VNS was approved by the FDA for the adjunctive treatment of chronic, treatment-resistant depression. It had been previously approved for the treatment of resistant epilepsy. More than 50,000 patients worldwide have received VNS.

Mechanisms of Action. The majority of the fibers contained in the left vagus are afferents. It is estimated that as many as 80 percent of these fibers are upgoing afferents and thus chronic stimulation of these nerve fibers predominantly changes activity in the brainstem nuclei such as the nucleus of the tractus solitarius and other neighboring nuclei (e.g., Raphe) that alter serotonergic activity in cortical and limbic structures. Additionally, persistent stimulation of the vagal afferents is anticonvulsant, an effect that appears to be dependent upon the norepinephrine producing locus ceruleus.

Side Effects and Contraindications. Implantation of VNS is a minor procedure but carries a few risks. Besides the risk of perioperative

infection, the surgical implantation carries a small risk of vocal cord paralysis, bradycardia, or asystole. Stimulation also appears to be safe and generally well tolerated. The adverse events that have been reported are coughing, hoarseness dyspnea, reversible bradyarrhythmias, obstructive sleep apnea, neck pain, and most commonly, voice alteration. Long-term naturalistic study of VNS for major depression estimates less than 1 percent of patients have terminated VNS because of adverse events. Generally, there are no adverse cognitive side effects with VNS; to the contrary, research demonstrates performance on neurocognitive tests is significantly improved with VNS, likely due to the improvement in depression. However, modest cognitive impairment has been reported with higher stimulation parameters.

Outright contraindications to VNS include bilateral or left cervical vagotomy, use of short-wave diathermy and microwave diathermy, or therapeutic ultrasound diathermy. A special consideration may be that MRI in patients with implanted VNS device is not permitted, unless a special "send/receive" coil is utilized.

Clinical Studies. The first VNS study by Rush and colleagues in 30 treatment-resistant depressed patients reported in 2000, showed response rates of 40 percent after 10 weeks of open-label, adjunctive VNS treatment and initial remission rate of 17 percent. The response rate was sustained (46 percent) after an additional 9 months of VNS, while further significant increase in remission rates was observed, from 17 percent to 29 percent. Likewise, considerable improvements in function were also reported with long-term VNS treatment. Subsequently, in a report on an extended sample (n = 59), the short-term (3 months) and longer-term (24 months) effects of adjunctive VNS treatment revealed 10-week response rates of 31 percent (after 3 months), 44 percent (after 1 year), and 42 percent (after 2 years). Remission rates were 15, 27, and 22 percent, respectively, demonstrating continuous and stable improvement. By 2 years 81 percent were still receiving VNS. However, a large 10-week randomized, sham-controlled, blinded multicenter trial of VNS for treatment-resistant unipolar or bipolar depression later reported by Rush and colleagues failed to show a significant benefit on the primary outcomes between active and sham treatment after 10 weeks of treatment. However, an open-label long-term follow-up of the same cohort (n = 202), demonstrated increased response rates (27.2 percent response and 15.8 percent remission rates at 12 months), which was higher than response rates in a nonrandomized comparison group receiving treatment as usual (i.e., not VNS). The researchers did not attribute improvement in the VNS group to medication changes or a delayed placebo effect in such chronically ill patients.

Current Status in Treatment Algorithms. The FDA indicated VNS for the

adjunctive long-term treatment of chronic or recurrent depression in patients 18 years or older experiencing a major depressive episode in the setting of unipolar or bipolar disease who have not had an adequate response to four or more adequate antidepressant treatments. Consultation with another clinician experienced with treatment-resistant depression and VNS is recommended.

VNS treatment success rates are lower than those with ECT. Response to VNS is relatively slow—typically only 15 percent of patients respond in the first 3 months, increasing to approximately 30 percent, after 12 months. VNS may be worth considering, therefore, when patients have failed to respond to less invasive treatments, ECT was ineffective, or post-ECT relapse cannot be prevented with less invasive means. VNS might be helpful with longer-term relapse prevention, but results of controlled trials would be useful to guide practice.

Patient Selection. Stepwise approach to patient evaluation for VNS is outlined in Table 34.36–6. VNS is approved as an adjunctive long-term treatment for chronic or recurrent depressive episodes in adults with a major depressive episode that have not had a satisfactory response to four or more adequate antidepressant trials.

Consideration of what constitutes an "adequate" trial requires careful assessment of not only whether adequate dosages were prescribed for an adequate period of time but also whether the patient was reliably compliant. Optimally, such assessment should be substantiated by careful review of treatment records, pharmacy reports, and blood levels where appropriate. Failed trials should include different medication classes, including selective serotonin reuptake inhibitors (SSRIs) and selective serotonin/norepinephrine reuptake inhibitors (SNRIs), as well as tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) and various augmentation strategies with or without ECT. A second opinion from a psychopharmacologist specializing in treatment-resistant depression, knowledgeable about VNS, is advisable.

Table 34.36–6.
Evaluation for Vagus Nerve Stimulation

Does this patient meet the U.S. Food and Drug Administration labeling criteria?
Unipolar or bipolar disorder in a major depressive episode
Long-term major depressive episode (≥2 years)
Recurrent depression
Inadequate response to four or more adequate treatments
Have other causes of medication resistance been ruled out?
Medical, substance, personality disorders
Compliance with adequate doses and durations
Can the patient tolerate a slow-acting therapy?
Does the patient need acute response now?

Electroconvulsive therapy may be a better option for the acutely suicidal	
Get a second opinion	

Table 34.36–7.
Clinical Scenarios: Vagus Nerve Stimulation (VNS) or Electroconvulsive Therapy (ECT)

Acutely suicidal, in need of rapid response	ECT
Psychotic depression	ECT
Acutely depressed, medication resistant, never had convulsive therapy	ECT
Chronically depressed, able to tolerate slow onset of action	VNS
Had convulsive therapy before, but always relapses quickly despite adequate medication	VNS
Cannot be tapered off maintenance convulsive therapy, and it is not effective	VNS

Clinical scenarios when ECT might be favored over VNS, and vice versa, are outlined in Table 34.36–7. For example, VNS does not exert rapid antidepressant action and thus acutely suicidal patients and others in need of rapid response would be more appropriately treated with other strategies. VNS is indicated as a long-term treatment option only for those with chronic or recurrent course of illness.

ECT and TMS have been safely used in patients with an implant when the VNS generator was turned off during the treatments, which is necessary for ECT because of the anticonvulsant effects of VNS. It remains to be studied whether VNS could be useful in relapse prevention post ECT.

Dosing. There are varying stimulation parameters (i.e., current, pulse width, frequency, and duty cycle) that are determined by the treating doctor, which can be programmed into the pulse generator via telemetry. Optimum dose–response parameters are still being researched, although a large multicenter clinical trial did not find significant differences in efficacy in treating depression between "low" (output current of 0.25 mA, pulse width of 130 ms), "medium" (0.5 to 1.0 mA, pulse width 250 ms), or "high" (1.25 to 1.5 mA, pulse width 250 ms) at acute phases (8 to 22 weeks) or chronic phases of treatment (25 to 50 weeks).

The epilepsy literature suggests that there is a threshold current for efficacy. Because the adverse effects of VNS are known to be dose dependent, treatment parameters are often chosen to mitigate specific side effects. For example, lowering pulse width reduces neck pain, allowing patients to tolerate higher currents.

Future Directions. More research is required to establish the dose–response relationships for VNS. Future studies may explore optimal medication strategies to augment responses, test the potential role of VNS for long-term relapse prevention (e.g., after ECT), and study its mechanisms of action.

Implanted Cortical Stimulation

Definition. Cortical brain stimulation is a novel neurosurgical approach where electrodes are implanted directly over the surface of the cortex to provide electrical brain stimulation in a targeted superficial region. This approach is being studied for treatment of conditions like stroke, tinnitus, and treatment-resistant depression. Because of its novelty, different investigators use different names to describe it, ranging from implanted cortical stimulation (ICS), through cortical stimulation system, to cortical brain stimulation and direct cortical electrical stimulation (DCS). The stimulating electrode can be implanted relatively superficially in either epidural or subdural layers but the specific topographic placement of the stimulator varies depending on the condition being treated (see Fig. 34.36–6). For example, in psychiatric applications, investigators have reported on a trial involving an implanted cortical stimulator in the superficial brain cortex area overlying left dorsolateral prefrontal cortex. The electrodes are powered by a pacemaker-like device that is implanted in the upper chest area.

History. ICS is an invasive but reversible form of brain modulation and, like DBS and other less invasive neuromodulation methods, stems in part from the psychosurgical treatments for severe mental disorders performed during the 1940s and 1950s. These early forms were highly experimental and often resulted in significant adverse side effects due to physical surgery in the brain tissue. Today, with the advancement in the current understanding of the specific functional brain regions and their interconnections, as well as the relative ease of access to neuroanatomical and brain imaging studies, direct electrical stimulation is a safer way of either temporarily disrupting faulty function, enhance deficient functions, or otherwise reversibly modulate abnormal brain activity.

Trigeminal Nerve Stimulation

Definition. Research of trigeminal nerve stimulation (TNS) in humans has been ongoing since 2001 and has been most commonly studied as a therapeutic intervention for drug-resistant epilepsy. However, TNS has recently been also explored as an adjunct to pharmacotherapy in depression with positive results and clinical trials of TNS for ADHD are currently underway. At this time TNS is not approved for use outside of research however.

Mechanisms of Action. Due to the anatomy of the three bilateral afferent cutaneous branches of the trigeminal nerve with connections to the nucleus tractus solitarious, locus ceruelus, and raphe nuclei, noninvasive stimulation of the V1 branch of the trigeminal nerve has therapeutic

potential in the treatment of mood disorders and drug-resistant epilepsy.

FIGURE 34.36–6. Implanted cortical stimulator.

Clinical Studies. Studies exploring psychiatric applications of TNS are ongoing, but results are not available as of this writing. Within epilepsy research, typical TNS treatment utilizes stimulation for at least 12 hours a day for 18 weeks. In a recent multicenter trial comparing high-frequency (experimental active treatment) and low-frequency (active control) external TNS (eTNS) for the treatment of drug-resistant epilepsy, investigators reported that response rates for high-frequency eTNS at 120 Hz with a pulse duration <250 μs and maximum off-time of 90 seconds were significantly greater (30.2 percent reduction in seizures) than low-frequency eTNS at 2 Hz with a duty cycle of 2 seconds on and 90 seconds off and 50-μs pulse duration (21.1 percent reduction in seizures).

Side Effects and Contraindications. TNS is generally well tolerated with low incidence of headache and skin irritation. Some patients report sensory experiences of tingling or vibration and there have been reports of significant increase in heart rate, but no significant changes to blood pressure.

Future Directions. The simplicity of administering eTNS by applying a gel electrode on the forehead is a unique advantage over surgically implanted devices. Thus far, research demonstrates that bilateral TNS is more effective than unilateral stimulation and high-frequency TNS is more efficacious compared to low-frequency stimulations. As clinical benefits may increase with treatment course, longer treatment length may increase therapeutic effects.

ACKNOWLEDGMENT

The authors would like to acknowledge the contribution to the previous edition of this chapter, written together with Dr. Sarah Hollingsworth Lisanby.

▲ 34.37 Neurosurgical Treatments

BENJAMIN D. GREENBERG, M.D., PH.D.

Over the last two decades, neurosurgical treatments for psychiatric illness have received increasing attention. Such methods are applied to small, highly selected groups of patients with disabling and otherwise treatment-intractable illness. Current techniques differ markedly from the original crude freehand "psychosurgery," especially prefrontal lobotomy of the mid-20th century, which saw wide and indiscriminate use, but including other surgeries done with handheld instruments. Modern techniques and practices have evolved considerably. Stereotactic ablation via craniotomy ("open procedures"), now rely on MRI guidance, vastly improving the accuracy of lesion placements. MRI-guided radiosurgery allows stereotactic ablation without craniotomy. Deep brain stimulation (DBS), while requiring craniotomy for device implantation, is relatively flexible, and stimulation can be stopped or modified if it causes adverse effects. In the United States, DBS for intractable OCD received FDA humanitarian approval in 2009, and is an approved treatment in the European Union. Other uses of DBS in psychiatric populations remain investigational. This chapter focuses on neurosurgery for otherwise intractable OCD or major depression. For work in Tourette syndrome, readers are directed to the 2015 review by Schrock and colleagues referenced below.

General standards of care for psychiatric neurosurgery include strict criteria for patient selection in a formalized practice, and in the case of Humanitarian Use Devices (HUDs), oversight of use by a local Institutional Review Board (IRB). DBS device implantation or other psychiatric neurosurgeries are not approved unless a multidisciplinary committee reaches consensus regarding the appropriateness for a given candidate, based on diagnostic evaluations and assessments of prior treatments. The informed consent process unfolds over time, in the context of a thorough medical and psychiatric evaluation. At this writing, surgical intervention is mainly reserved for patients with severe, incapacitating OCD who have exhausted conventional behavioral and medication therapies. As experience has been gained, the ethical context of psychiatric neurosurgery has increasingly resembled that surrounding any high-risk procedure or research, for example, neurosurgery for movement disorders.

A large body of open-label clinical data has supported the effectiveness and relative safety of modern neurosurgical interventions. Major centers continue to gather outcomes prospectively. Controlled data, although still limited, have begun to appear. There is also an increasing body of systematically collected data on adverse events, allowing risk/benefit

judgments to be better informed. While there are intriguing hypotheses, the mechanisms of action of psychiatric neurosurgeries remain to be established, a situation which parallels developments in functional neurosurgery for movement disorders. While these treatments are sometimes criticized for this reason, neurosurgical interventions are similar to other therapies insofar as the most relevant issues are safety and efficacy, rather than correction of still poorly understood pathophysiological processes.

Lesion procedures developed largely empirically, and only later became influenced by theories implicating cortico-limbic systems in disordered behavior. However, neuroscience tools increasingly permit both hypothesis generation and testing regarding potential mechanisms of action. Thus, psychiatric neurosurgery is now developing in a scientific context where translation of data between clinical results to cross-species anatomical, neuroimaging and physiological studies of neural networks involved promise to illuminate causal relationships between defined interventions in neurocircuitry and therapeutic actions. Such multidisciplinary work may inform other device-based techniques, both invasive and noninvasive. Brain stimulation using implantable devices that can respond selectively to patterns of brain activity putatively associated with symptoms (i.e., closed-loop or "responsive" DBS) has become a special focus of interest. A new method for ablative neurosurgery has also emerged which, like radiosurgery, does not require craniotomy: high intensity focused ultrasound (HIFU). Closed-loop DBS in psychiatry is very early in development and will not be discussed further here. HIFU is seeing applications across neurosurgery, but work in psychiatric illness is just beginning.

HISTORY

Trephination in prehistoric times was likely the earliest surgery for psychopathology. Neurosurgical treatment in psychiatry was first reported in 1891. These bilateral cortical excisions in demented and depressed patients were described as yielding mixed results. In 1935, John Fulton and Charles Jacobsen reported that chimpanzees showed less fear in the "experimental neurosis" paradigm after frontal cortical ablation (lobectomy). The animals retained an ability to perform complex tasks, but fear expression was reduced. Egaz Moniz, a Portuguese neurologist, attended Fulton's 1935 lecture. Prompted by these findings, Moniz pioneered prefrontal leukotomy in collaboration with his neurosurgeon Almeida Lima. First by using alcohol injections and subsequently mechanically using a leukotome (a kind of surgical knife), Moniz and Lima performed "psychosurgery" on 20 severely ill institutionalized patients; 14 were said to have exhibited worthwhile improvement. In an era of overflowing asylums and few effective treatments for debilitating illness,

surgery was at first enthusiastically embraced. Moniz won a Nobel Prize in 1949 for this contribution.

From the mid-1930s until phenothiazines emerged in the 1950s, these techniques proliferated globally. Walter Freeman, a neuropsychiatrist, was perhaps the most zealous promoter of psychosurgery in the United States. Initially, he worked closely with neurosurgeon James Watts. They developed freehand procedures to achieve prefrontal lobotomy (i.e., severing white matter connections between the prefrontal cortex and the rest of the brain). Freeman and Watts reported on their first 200 cases in 1942. Although the benefits of the surgery were highlighted, others acknowledged a significant rate of complications, such as frontal lobe syndromes (including apathy and disinhibition), seizures, and even deaths. At its peak, lobotomy was being performed on approximately 5,000 patients per year in the United States alone. A review of 10,365 prefrontal lobotomies performed from 1942 to 1954 in Britain concluded that while 70 percent showed improvement, adverse effects included 6 percent mortality, seizures in 1 percent, and disinhibition in 1.5 percent. There were widespread reports of blunted personality and socially inappropriate behavior.

In the late 1940s and early 1950s, recognition of these risks prompted attempts to develop modified stereotactic surgical procedures that might yield better results. For example, Spiegel and Wycis, who began stereotactic neurosurgery in humans, reported in the 1940s that dorsomedial thalamotomies improved obsessive-compulsive symptoms. However, with the introduction of chlorpromazine (Thorazine) in 1954, medical management of psychiatric illness became newly possible. Thus, despite the advent of stereotactic neurosurgical techniques and a continued high prevalence of severe, treatment-refractory psychiatric illness, psychiatric neurosurgery was all but abandoned in favor of nonsurgical therapies. Later, as the limitations of neuroleptics and electroconvulsive treatment became known, there was a renewed interest in psychiatric neurosurgery at a few academic medical centers in the 1960s. Refinement of stereotactic methods and emerging theories regarding the role of the limbic system in emotion shaped a newer age of psychiatric neurosurgery. The pioneers of these contemporary procedures faced harsh opposition from political groups, as well as the general population, based largely on the results of crude and indiscriminately applied operations of an earlier era. Political and social pressure dissuaded all but a handful of neurosurgeons and psychiatrists from offering such treatments. Despite these societal influences, in the late 1970s the authors of a US National Commission report found, to their own surprise, that available evidence indicated that many patients benefited after lesion procedures. They advocated continued systematic research and a national data registry. Although the registry never materialized, gradually, over nearly five decades, research and

education regarding modern neurosurgery led to its legitimacy as a treatment for severe, otherwise intractable psychiatric disorders, now with more refined practices, and surgical procedures. Indications, expectations of benefit, and risks have become better defined.

PATIENT SELECTION

Indications and Contraindications

Although limited reports have suggested efficacy across a broad range of psychiatric conditions, with research expanding rapidly, the best established indications for psychiatric neurosurgery remain otherwise intractable OCD or major depressive disorder (MDD). In evaluating candidates, several factors are considered:

1. *Primary diagnosis:* The patient must meet clinical criteria for the diagnostic indication, and this disorder should be a primary cause of the patient's debility and suffering.
2. *Severity:* The patient must have chronic, severe, and debilitating illness; duration of the primary illness must exceed 1 year and typically exceeds five years. Severity is gauged on standardized instruments (e.g., patients with OCD typically have Yale-Brown Obsessive-Compulsive Scale scores of 26 to 30; patients with major depression typically have Beck Depression Inventory scores of 30 or higher), while debility should be indicated by a low level of functioning (e.g., a Global Assessment of Functioning score of 50 or less) and a poor quality of life.
3. *Adequacy of previous treatment:* Patients must have already tried an exhaustive array of other available established treatments, delivered by competent practitioners, which are documented in detail. Assessment of adequacy of previous evidence-based psychotherapies is also highly important, and often requires interviews with treating psychotherapists as well as reviews of medical records. Medication trials must similarly be judged adequate; where appropriate, high-dose antidepressant trials (for OCD in particular) should have been attempted, with a duration of each medication trial no less than 2 months.
4. *Psychiatric comorbidity:* Appropriate treatment must also have been rendered for any comorbid psychiatric disorder. Strong relative contraindications include active psychoactive substance abuse or severe personality disorders which may interfere with adherence to presurgical treatment trials, or interfere with the exhaustive evaluation and consent processes, or with the recommended postsurgical treatment and follow-up.
5. *Medical comorbidity and surgical fitness:* Structural brain lesions or significant central nervous system injuries of clinical significance are strong contraindications. Medical conditions that increase neurosurgical risks (e.g., cardiopulmonary disease) and age over 70 years represents a

relative contraindication for lesion procedures, while DBS may be used, as it is for movement disorders, in somewhat older cases. A history of past seizures is a risk factor for perioperative seizures after lesion procedures and must factor into the overall risk-benefit assessment.

6. *Access to postoperative care:* The extensive evaluations and subsequent psychiatric neurosurgery mark the beginning of a new episode of care. It is crucial that patients have access to adequate postoperative treatment, including a psychiatrist (typically the referring physician) who will accept responsibility for managing the case after discharge. Arrangements for postoperative care (e.g., intensive behavior therapy) should be confirmed ahead of time. Importantly, after lesion procedures, care can generally be delivered in standard treatment settings without the need for highly specialized psychiatric neurosurgery teams. For deep brain stimulation, access to specialized teams is essential, over the long term. Once implanted, DBS patients require clinical monitoring and device adjustment, which can be intensive and time-consuming, especially early in treatment. Device monitoring and replacements may need to occur on a relatively urgent basis. The continuing costs incurred can be substantial, and adequacy of third-party reimbursement needs to be ensured in advance to the extent possible. After either lesion procedures or DBS, family or significant others may be needed to support and accompany patients to follow-up care, similar to the level of support that is usually necessary throughout the intensive evaluation process. Currently, DBS for intractable OCD is eligible for reimbursement under an FDA HDE (humanitarian device exemption) approval in the United States. The procedure has full approval in the European Union. Other psychiatric uses of DBS remain investigational, an important consideration for reimbursement.
7. *Informed consent:* Under no circumstances should psychiatric neurosurgery be performed on unwilling patients. The patient must be able and willing to render an informed consent. Consent monitoring, including the use of structured consent feedback tools, may be considered to help ensure that the consent process is adequate. In rare instances, these procedures are performed with assent of the patient and formal consent from a legal guardian. In this context, age less than 18 years also represents a relative contraindication.

Multidisciplinary Case Review

Assessing candidacy differs somewhat from center to center and between nations, as governed by law. Across centers, however, there is consensus that decisions regarding candidacy must be made after thorough review of the patient's case, taking into account the written record, current clinical examination, and formal referral from the patient's treating psychiatrist. In US expert centers, the decision is typically made by an interdisciplinary

committee; in Britain and Belgium, psychiatric neurosurgery requires additional formal review and approval from duly constituted national commissions. The importance of systematic review was highlighted by a study of 91 cases reviewed by the Flemish Advisory Board in Belgium. Surgery was not approved in a substantial proportion of cases on initial review, either because the primary psychiatric diagnosis appeared incorrect (10 percent of cases) or because more information was required to ascertain that diagnoses or conventional treatment trials were adequate (20 to 50 percent of cases). These findings indicate the particular importance of case review by a group with the appropriate breadth of expertise.

PREOPERATIVE WORK-UP

In addition to the above clinical evaluation and formalized review, the preoperative work-up for psychiatric neurosurgery includes physical and neurological examinations, standard presurgical blood and urine laboratory tests, as well as an ECG, plus specialized tests of brain structure and function. A comprehensive preoperative assessment should include brain MRI, psychometric testing using neuropsychological batteries that assess multiple domains, and in some cases an EEG.

POSTOPERATIVE CARE

Immediate postoperative care includes the usual medical and surgical management following any stereotactic neurosurgical procedure. Special attention is paid to signs or symptoms of potential surgical complications, including infection, hemorrhage, seizures, or altered mental status. For ablative procedures, a postoperative MRI should be obtained to document the placement and extent of lesions, timed to optimally visualize the evolution of the lesions; for DBS, imaging by CT assesses potential post-implantation hemorrhage. Over the longer term, intensive postoperative psychiatric treatment is recommended, since the efficacy of the intervention may rely on synergy between the neurosurgical intervention itself and enhanced response to pharmacological or behavioral therapies. Although dosages of psychotropic medications might be reduced during the immediate perioperative period, the medication regimen should be readjusted as tolerated postoperatively. Moreover, in the case of OCD, intensive behavior therapy should be continued or resumed early, e.g., as soon as the first postoperative month for DBS, or by 3 months for lesion procedures including gamma knife radiosurgery, where clinical benefit evolves more slowly. Longitudinal assessment of patient adherence to medication and behavioral treatments is essential so treating clinicians can intervene to optimize care if patients change their regimens on their own (as has happened in some cases postoperatively).

For DBS, as noted above, electrode implantation is followed by immediate postoperative imaging (e.g., computerized tomography; CT

scan) to assess for potential hemorrhage, and to evaluate general device placement. This is followed by a several-week recovery period to enable resolution of local edema and stabilization of other factors (e.g., pneumoencephaly) that might influence the response to stimulation. Postoperative imaging to more accurately visualize device locations (e.g., CT scan for fusion with preoperative MRI) may take place at that time. Then, systematic electrode survey and adjustment of stimulation parameters is performed before initial settings are determined. This is usually done in the outpatient setting, and is often a time-consuming process, lasting hours over 1 or more days. Ongoing protocols for DBS entail frequent follow-up, especially during the initial 6 months after implantation, to enable optimization of stimulation parameters, patient monitoring, and management including coordination of pharmacological and behavioral therapies.

DESIGN AND INTERPRETATION OF CLINICAL STUDIES

It is critical to appreciate the inherent challenges surrounding research in this domain. The patient populations in question are very challenging and can require intensive management over the months and years of a clinical trial. These populations can be very heterogeneous. High rates of comorbidity are the rule. The total numbers are small. It was recently estimated that under 1 percent of treatment-seeking OCD patients are eligible for neurosurgery, and proportions of appropriate patients with major depression might be similar. As a result, the major US psychiatric neurosurgical centers collectively treat a small number of cases yearly. Thus, statistical power is limited, as are estimates of efficacy and adverse effect rates. The major academic centers might have their own surgery of preference (sometimes more than one). Although methods are converging, historically centers have employed somewhat different measures for assessing treatment response. Patient selection criteria have also varied somewhat across centers, again especially for the earliest studies of a particular technique. Consequently, it is often difficult to contrast or combine data across these different groups. Moreover, determining the cause of long-term postoperative improvement can be confounded by exposure to other new therapies as they emerge, or even by the longitudinal course of illness.

Given this landscape, it is perhaps not surprising that there is that there is only one report of a sham-controlled trial for lesion procedures in a psychiatric population (intractable OCD), in a small sample. There have been more, but still relatively few, sham-controlled studies of DBS at several brain targets, for OCD and otherwise intractable depression. This research, all of which is quite recent, is discussed below.

LESION PROCEDURES

Although numerous approaches have been tried from the mid-20th century to the present, four lesion procedures have been the most used. All four entail bilateral lesions, performed using stereotactic methods (Figs. 34.37–1 and 34.37–2).

Subcaudate Tractotomy

Subcaudate tractotomy was introduced by Geoffrey Knight in Great Britain in 1964 as one of the first attempts to limit adverse effects by restricting lesion size compared to prefrontal lobotomy. By targeting the substantia innominata (just inferior to the head of the caudate nucleus), the goal was to interrupt white matter tracts connecting orbitofrontal cortex and subcortical structures. The surgery involved placement of radioactive yttrium-90 seeds at the desired centroid, yielding lesion volumes of approximately 2 cc on each side. Subcaudate tractotomy is used primarily in OCD and major depression. It is sometimes used as a procedure subsequent to anterior cingulotomy when the latter has been judged to have suboptimal outcome. This procedure is currently used by itself the least often among lesion methods described here, except in its continuing application as part of limbic leukotomy (see Limbic Leukotomy).

FIGURE 34.37–1. Sagittal schematic of target sites for surgical procedures linked to postoperative MRI images. Site 2: anterior cingulotomy linked to postoperative sagittal MRI (A, 1⁄4 anterior; P, 1⁄4 posterior). Site 3: subcaudate tractotomy linked to postoperative axial MRI. (From Greenberg BD, Rauch SL, Haber SN. Invasive circuitry-based neurotherapeutics: stereotactic ablation and deep brain stimulation for OCD. *Neuropsychopharmacology*. 2010;35[1]:317–336.)

Anterior Cingulotomy

Fulton was first to propose that the anterior cingulum as a target in

psychiatric illness. The first cingulotomies were performed for intractable pain (a practice which continues, along with newer research into DBS of the anterior cingulum for the same condition). It was noted that pain patients with comorbid anxiety or depressive conditions had better responses. H. Thomas Ballantine Jr. and colleagues later demonstrated the relative safety of anterior cingulotomy and studied its efficacy for a broad range of psychiatric indications. In the half-century since this work began in 1962, the group at Massachusetts General Hospital has performed over 1,000 anterior cingulotomies. The surgery is conducted under local anesthesia and two or three approximately 1-cc lesions are made on each side by thermocoagulation through bilateral burr holes. The target is within anterior cingulate cortex (Brodmann areas 24 and 32), at the margin of the white matter bundle known as the cingulum (Fig. 34.37–1). Originally determined by ventriculography, since 1991 anterior cingulotomy has been MRI-guided. Since the practice is to make the smallest possible lesion consistent with effectiveness, a subgroup of patients may return months after the first operation for a second procedure. This may be an extension of the first set of lesions, or addition of subcaudate tractotomy. There has also been investigational use of DBS at the ventral capsule/ventral striatum target after cingulotomy. Indications for anterior cingulotomy include major depression and OCD.

Limbic Leukotomy

Limbic leukotomy was introduced by Desmond Kelly and colleagues in England in 1973. The procedure combines subcaudate tractotomy and anterior cingulotomy. The lesions have typically been made via thermocoagulation or with a cryoprobe. Historically, the precise placement of the lesions was guided by intraoperative stimulation; pronounced autonomic responses were believed to designate the optimal lesion site. The indications for limbic leukotomy include major depression, OCD, and other severe anxiety disorders. There is also evidence that this procedure might be beneficial in cases of otherwise treatment-intractable repetitive self-injurious behaviors or severe tic disorders.

Anterior Capsulotomy

Anterior capsulotomy was first performed by Tailarach and colleagues in France. Later, Lars Leksell and colleagues further developed the procedure in Sweden. Anterior capsulotomy or its newer variant, Gamma Knife capsulotomy, are used in Scandinavia, the United States, Belgium, Brazil, and elsewhere. The procedure places lesions within the anterior limb of the internal capsule, which impinges on the adjacent ventral striatum, thereby interrupting fibers of passage between prefrontal cortex and subcortical nuclei including the dorsomedial thalamus (Fig. 34.37–2). The original

anterior capsulotomy procedure is performed using thermocoagulation via burr holes in the skull. For 20 years capsulotomy has also been performed using the Gamma Knife as an alternative which avoids craniotomy. Typically, gamma capsulotomy lesions are smaller than those induced by thermocapsulotomy, remaining within the ventral portion of the anterior capsule. Hence, the term "gamma ventral capsulotomy" is coming into use to describe this procedure. In contrast to thermocapsulotomy, gamma ventral capsulotomy may be performed as an outpatient procedure, with an overnight hospital stay usually the most that is required. The relative advantages and disadvantages of this radiosurgical approach are the focus of ongoing research, including a small controlled study of gamma ventral capsulotomy for OCD, the first of its kind for a lesion procedure in psychiatry. The rates of adverse effects appear lower for any anterior capsulotomy procedure when smaller volumes of tissue are lesioned. Anterior capsulotomy, while primarily used for OCD, has also seen use in major depression and other severe anxiety disorders.

FIGURE 34.37–2. Axial schematic of target sites linked to postoperative MRI images.

Site 1a: anterior capsulotomy (thermocapsulotomy) linked to postoperative axial MRI (A, 1⁄4 anterior; P, 1⁄4 posterior). Site 1b: gamma ventral capsulotomy linked to a coronal MRI. Site 4: ventral capsule/ventral striatum (VC/VS) deep brain stimulation linked to postimplantation coronal CT scan fused with preoperative MRI. (From Greenberg BD, Rauch SL, Haber SN. Invasive circuitry-based neurotherapeutics: stereotactic ablation and deep brain stimulation for OCD. *Neuropsychopharmacology*. 2010;35[1]:317–336.)

Deep Brain Stimulation

DBS for psychiatric illness is not a new idea, although the devices, surgical techniques, and theoretical models of relevant neurocircuitry have all advanced. For example, in 1948, Pool used stimulation via a silver electrode in the caudate nucleus in an attempt to treat a woman with depression and anorexia. Modern DBS began 50 years later, when Nuttin and colleagues reported a small series of cases treated with otherwise intractable OCD who received DBS, initially based on the anterior capsulotomy target. The procedure involves placement of small-diameter brain "leads" (e.g., approximately 1.3 mm) with multiple electrode contacts into subcortical nuclei or specific white matter tracts. The surgeon drills burr holes in skull bone under local anesthesia and then places the leads, guided by multimodal imaging and stereotactic landmarking. Usually this is done bilaterally.

The subject is typically sedated but awake during surgery. Later, the "pacemaker" (also known as an implantable neurostimulator or pulse generator) is implanted subdermally (e.g., in the upper chest wall) and connected, via extension wires tunneled under the skin, to the brain leads. Since various combinations of electrodes can be activated, at adjustable polarity, intensity, and frequency, DBS permits a considerable range of ways one can modulate brain function. Thus, parameters can be optimized for individual patients. This might achieve improved efficacy and more favorable adverse effect profiles in comparison with ablation. The process of optimizing stimulation parameters for individual patients, typically performed by a specially trained psychiatrist in an outpatient setting, is quite time-consuming and requires attentive, long-term follow-up. In cases where no beneficial settings can be identified despite extensive efforts, the electrodes can be inactivated, and device components may be surgically removed. The surgical risks of device removal include infection and hemorrhage, as for implantation. There are important psychiatric risks of device removal, which patients may view as the end of a "last resort" episode of care. See Outcomes with DBS for further details.

TREATMENT OUTCOMES

For all ablative procedures, outcome cannot be fairly assessed for a considerable postoperative period, which could extend from 6 months to 2 years. While effects of DBS may develop sooner, e.g., within several months postoperatively, long-term follow-up remains essential to assess the

durability of responses. Early descriptions of ablation outcomes, all in open-label studies, used global measures such as the Pippard Postoperative Rating Scale, with ratings of (1) symptom-free, (2) much improved, (3) slightly improved, (4) unchanged, and (5) worse. Most studies considered meaningful benefit if a patient were symptom-free or much improved. Increasingly, reports employed disorder-specific severity measures, e.g., the Yale-Brown Obsessive-Compulsive Scale (YBOCS) for OCD, or specific depression scales. Increasingly, sham-controlled trials include both clinician- and patient-rated measures of symptom burden, functioning, and quality of life. Below we further review the four neuropsychiatric neurosurgical procedures by surgical approach.

Outcomes with Subcaudate Tractotomy

In 1975, results of subcaudate tractotomy were reported. Follow-up was 2.5 years on average. Optimal data, including structured interviews, were available for a subset of 134 of an initial 208 patients. Improvement was judged clinically significant in 68 percent of patients with MDD, 50 percent of patients with OCD, and 62.5 percent of those with other anxiety disorders. Individuals with schizophrenia, substance abuse, or personality disorders did poorly. Patients were usually ambulatory by the third postoperative day. Postoperative adverse events included transient headache and confusion or somnolence, which were typically transient (lasting 1 or more weeks). Longer-term adverse effects included mild undesirable personality changes in 6.7 percent, and seizures in 2.2 percent. Transient disinhibition syndromes were common. One patient died due to migration of an yttrium seed, and three others committed suicide.

In 1994, a large-scale review of 1,300 subcaudate tractotomy cases was conducted and concluded that the procedure enabled 40 to 60 percent of patients to lead normal or near normal lives. The suicide rate was 1 percent versus 15 percent in a comparison group similarly affected by with major affective disorders. There were no reported deaths due to other causes in this series. The seizure rate was comparable to that of previous reports. In contrast to the earlier report, the 1994 review did not find enduring personality changes. The investigators proposed predictors of positive response, including MDD diagnosis, sudden onset of symptoms, emergence of illness in the second half of life or peripartum, positive family history of psychiatric disorder, and previous positive response to electroconvulsive therapy (ECT). Physiological responses elicited during intraoperative electrical stimulation of the target area before it was lesioned were also thought to predict better responses. As noted above, subcaudate tractotomy is now rarely done as a single procedure.

Outcomes with Anterior Cingulotomy

In 1987, Ballantine and colleagues retrospectively reviewed 198 cases with mean follow-up after cingulotomy of 8.6 years. They judged there was significant improvement in 62 percent of patients with affective disorders, 56 percent with OCD, and 79 percent with other anxiety disorders. Most recently, a prospective report was published by the MGH group on 64 consecutive patients undergoing cingulotomy for intractable OCD between 1989 and 2009. Changes in symptom severity were assessed at the most recent follow-up using the YBOCS and the Beck Depression Inventory. A full OCD response was defined as a YBOCS score reduction of ≥35 percent, with improvements in the 25 to 34 percent range defined as partial responses. At a mean of 10.7 months, 35 percent of OCD had a full response, while 7 percent responded partially. Of the 64 patients, 30 had a second procedure (repeat cingulotomy or subcaudate tractotomy). At a mean of over 5 years (63.8 months), improvement rates climbed to 47 and 22 percent for full and partial responses, respectively. Of patients (24 of 64) who responded with a partial response at the mean follow-up of just under one year, 20 (83 percent) retained at least a partial response at the final follow-up, a mean of about 5 years later. Severity of comorbid major depression decreased modestly from baseline: Beck Depression Inventory scores improved by 17 percent at last follow-up.

Psychiatric adverse events included suicide in 2 of the 64 patients, 1 of whom with a prior history of both major depression and a previous suicide attempt. The second suicide occurred 8 days after a surgery which had no neurological complications, in a patient with comorbid bipolar depression. Other adverse events included: transient memory impairment (n = 5) which resolved over days to months; transient urinary retention (n = 2) lasting days, or worsening of pre-existing urinary incontinence (n = 1); postoperative abulia (n = 4) lasting days, in 1 case after initial cingulotomy and in 3 after subsequent limbic leukotomy; intraoperative (n = 3) or postoperative single seizures (n = 1); and recurrent seizures (n = 1) requiring anticonvulsant treatment. In 1 patient, a postoperative infection progressed into a subdural empyema requiring repeat surgery. There were no intracranial hemorrhages.

Outcomes with Limbic Leukotomy

In the 1970s, before the era of MRI-guided surgery, Kelly and colleagues published a series (n = 66) studied prospectively with a mean 16 months of follow-up. Improvement was judged significant in 89 percent of patients with OCD, 78 percent with major depression, and 66 percent with other anxiety disorders. In a separate report regarding 49 patients with OCD, they noted that 84 percent were improved at 20 months. Short-term side effects included headache, lethargy or apathy, confusion, and lack of sphincter control lasting from a few days to a few weeks. Following limbic leukotomy, it is common for postoperative confusion to last at least days,

and patients are often not discharged from the hospital in less than 1 week. There were no reported seizures and no deaths; however, enduring lethargy was present in 12 percent of cases, and one patient suffered severe memory loss due to improper lesion placement.

In 2002, Montoya and colleagues reported on 21 patients who underwent limbic leukotomy for OCD or major depression at MGH. Using stringent criteria, they reported 36 percent to 50 percent responders, respectively, at a mean follow-up point of 26 months. The adverse event profile was similar to that previously reported, with apathy, urinary incontinence, and short-term memory deficits infrequent and transient. Of note, in 2002, Price and colleagues published a series of five consecutive cases which suggested that limbic leukotomy might be beneficial for patients with severe self-mutilation, in the context of repetitive self-injurious, tic-like behaviors.

Outcomes with Anterior Capsulotomy

Thermocapsulotomy. As the name implies, in thermocapsulotomy, thermal lesions are made, usually via radiofrequency heating. This procedure involves craniotomy (hence its other name, "open capsulotomy"). The ablation initially involved a large portion of the dorsal-ventral extent of the anterior limb of the internal capsule. In the 1970s, Leksell and colleagues reported on their first 116 cases of thermocapsulotomy. In that early study they noted a favorable response in 50 percent of those with OCD and 48 percent of those with major depression. A subsequent review of the earlier experience with capsulotomy uncovered adequate data on 213 of 362 cases. Of these, 64 percent were deemed to have benefitted significantly on global scales. Short-term side effects included transient headache, incontinence, and confusion, the latter lasting up to 1 week. Patients were typically ambulatory in hours to days following the operation, with the length of hospital stay influenced by the duration of confusion. A subset of 24 patients, followed prospectively, had one case of intracranial hemorrhage and one episode of seizure. Fatigue was present in 29 percent, 17 percent had poor memory, and 8 percent exhibited lack of attention to appearance ("slovenliness"). Weight gain was a common, enduring side effect with a mean increase in body mass of about 10 percent.

A smaller 2008 study in 25 OCD patients who underwent thermocapsulotomy, gamma knife anterior capsulotomy, or both combined. It used disorder-specific rating scales and measures of adverse effects. Even though these patients had failed to respond to treatments unavailable to the earlier cohorts (thus their illnesses might be expected to be more refractory than in the early experience), effectiveness was in fact comparable to that in the early work: 48 percent response and 36 percent remission rates were seen on YBOCS OCD severity ratings. This series also

demonstrated a notable adverse effect burden. Forty percent were judged to have clinically significant frontal impairment (problems with executive functioning, apathy, or disinhibition). Most in this group had had repeated thermocapsulotomy and/or high-dose gamma knife radiation, which today would be avoided, resulting in larger lesions. Also in contrast to the earlier work, MRI was available. Interestingly, smaller lesions, less lateral in extent in the coronal plane and also posteriorly, were associated with not only fewer adverse effects, but also greater symptom reduction.

More recently a small prospective series of eight patients with severe chronic major depression received thermocapsulotomy for that illness. Lesions involved a large proportion of the dorsal-ventral extent of the capsule on MRI. At 24 to 36 months postoperatively, half of the group were responders having at least a 50 percent reduction in BDI scores. One patient developed a progressive vascular dementia with parkinsonism caused by autopsy-proven arteriolosclerosis. The response rate, in a group of patients receiving contemporary standard treatment, was similar to that reported for depression in the 1970s by Leksell.

Gamma Ventral Capsulotomy. In gamma knife radiosurgery, lesions are made without craniotomy, which means that the procedure can typically be performed on an outpatient basis. The Leksell Gamma Knife is used. Over 200 beams of radiation from cobalt sources are focused, using stereotactic methods and MRI guidance, on surgical targets in the brain, in intractable OCD. The most common approach has been to place two lesions ("shots") in the ventral portion of the anterior limb of the internal capsule using 4 mm collimators to guide the radiation. Lesions are either staged over two surgeries or combined in a single procedure. More recently, single lesions in the ventral quadrant of the capsule have been used in attempt to minimize total radiation doses and also to focus on ventral prefrontal cortico-basal ganglia-thalamic fibers, hypothesized as possibly the most relevant to therapeutic benefit in OCD.

Five-year outcome data illustrate the delayed nature of the response. Therapeutic benefit was achieved over 1 to 2 years and was essentially stable by 3 years. Full responses (a YBOCS OCD severity improvement by >35 percent) developed in over half of cases by 2 to 3 years after surgery. Partial responses averaged approximately 10 percent at 2 to 3 years postop.

Adverse events after the double-shot procedure (two lesions made bilaterally on the same day) included cerebral edema and headache (with onset delayed by months to years), small asymptomatic caudate infarctions, and possible exacerbation of pre-existing bipolar mania. One patient developed a mild frontal syndrome, including apathy, that resolved gradually over a period of years. Three patients developed radionecrotic brain cysts, the onset of which was delayed by 3 or more years. In two cases cysts were asymptomatic. In contrast, in the third case, cyst development

was progressive and associated with serious neurological sequelae: symptomatic increased intracranial pressure requiring shunt placement and ongoing neurosurgical management.

A controlled trial of gamma ventral capsulotomy carried out at the University of São Paulo, Brazil is unique in the psychiatric neurosurgery literature. Sixteen patients with rigorously defined intractable OCD were enrolled; eight received active GVC and eight received sham surgery in which they entered a specially constructed antechamber attached to the Leksell Gamma Knife. The groups were followed for 1 year, after which individuals in the sham group were offered actual surgery. There was no change in the sham group during the 1-year follow-up period. In contrast, two patients (25 percent) in the active GVC group showed reductions in OCD severity during the masked phase of 35 percent or greater on the YBOCS. Given the small sample, the effect did not reach statistical significance. In the group receiving active surgery first, five of the eight patients (62.5 percent) went on to respond during follow-up after the masked phase. Four of the eight patients who initially received the sham procedure underwent later active GVC. Two of these later responded, for an overall response rate of 58 percent after the active procedure. In this study, a longer masked sham period, which would have been optimal scientifically given the delayed nature of the response (see above) was not chosen given the ethical concern that severely ill individuals not undergo unduly long follow-up after a sham surgery.

Adverse events included manic episodes in two patients (17 percent), each of whom had a previous history of subclinical hypomanic symptoms. These individuals responded to addition of mood stabilizers to their medication regimens. One patient, who had no previous history of substance abuse, developed drug dependence 4 years after GVC. The most serious adverse event was related to substantial radiation-induced perilesional edema in one patient 8 months post-GVC. This was accompanied by delirium, confabulation, and visual hallucinations, all of which responded to corticosteroids within a few days. However, memory deficits and executive function impairment persisted for 5 months, after which the patient returned to his baseline level of neuropsychological functioning. At month 54 after surgery, the same patient developed a brain cyst of 6-mm diameter. This cyst was not associated with neurological or neuropsychological impairment.

Outcomes with DBS

Obsessive-Compulsive Disorder. Collaborative work in the 1990s led to the development of DBS at the ventral anterior limb of the internal capsule and adjacent ventral striatum (the VC/VS) for otherwise intractable OCD. The first implantation was performed by Nuttin and colleagues in Belgium. Stimulation target development was most directly informed by the prior

experience with anterior capsulotomy, both thermocapsulotomy and gamma knife ventral capsulotomy, which was itself based on thermocapsulotomy. The combined report focused on open-label data in 26 patients in total; at some study centers patients also underwent a masked crossover to DBS discontinuation from active stimulation. Across the four centers—Leuven/Antwerp, Butler Hospital/Brown University, the Cleveland Clinic, and the University of Florida—over 60 percent of patients showed therapeutic responses at last follow-up (a full response was defined as a 35 percent or greater reduction in YBOCS OCD severity). In the group as a whole, responses tended to stabilize after about 3 months of stimulation.

Cognitive functioning was not adversely affected by DBS. Adverse events included hemorrhage after implantation in two patients (~8 percent); in one of them apathy resulted, which resolved over 3 months. One patient (~4 percent) had a single seizure intraoperatively without recurrence. One patient developed a superficial surgical wound infection which responded to antibiotics. In two patients (~8 percent) a DBS system wire broke, requiring surgical replacement. Complications due to stimulation itself or stimulation interruption were the most common, including four (~16 percent) patients with worsened depression or suicidal thinking similar to events in their presurgical course of illness. In three of them, this worsened depression occurred during a blinded crossover to sham stimulation. Mild hypomania, judged as stimulation-related but nonserious, was seen in eight patients (31 percent). In all cases, hypomania was either reversible with a change in stimulation, or resolved over days without a DBS parameter change.

In a study of DBS at an anatomical target closely related to the VC/VS, the nucleus accumbens (NAcc), 16 patients underwent 8 months of open-label treatment which included (as did the VC/VS study) exposure-based behavior therapy and ongoing pharmacotherapy. The open phase was followed by a double-blind crossover phase with randomly assigned 2-week periods of active or sham stimulation, followed by open maintenance DBS. In the open phase, 56 percent of patients responded. In the double-blind, sham-controlled phase (n = 14), YBOCS scores were significantly lower for active versus sham stimulation. The most prominent stimulation-related adverse was elevated mood or hypomania in 50 percent of patients, judged nonserious in all cases. One patient (6 percent) had a surgical wound infection, while five (31 percent) reported forgetfulness and three (19 percent) reported word-finding difficulties. However, objective testing in this as in other studies of psychiatric DBS, found either a lack of cognitive deterioration, or improvement. This is unlike the situation in DBS for movement disorders, where stimulation may be associated with cognitive decline in Parkinson disease.

A controlled crossover study investigated effects of DBS at a different

target within the general cortical-basal ganglia-thalamic circuitry implicated in OCD, the subthalamic nucleus. Of a total group of 16 patients, half were randomized to active DBS and half to sham stimulation, after which each group crossed over to the other condition in double-masked fashion. There was a significant difference between active and sham DBS in favor of the active treatment. Adverse events included an intracerebral hemorrhage on device insertion in one patient (6 percent) leading to a permanent motor deficit in one hand, and infection leading to pulse generator removal in two patients (12 percent). One patient was described as having stimulation-related hypomania, and one with mania related to DBS. Both effects were reversible.

Other DBS stimulation targets within the general circuitry of interest include the inferior thalamic peduncle and ventral caudate nucleus, each used in OCD in small studies. In this respect, development of psychiatric DBS has followed, on a smaller scale, the path of stimulation for movement disorders, where several targets have been pursued. As in movement disorders, overlapping or converging effects of DBS at different anatomical sites on the neurocircuitry involved are likely and remain a focus of research.

Major Depression. One continuing line of research into DBS for major depression began with observations from functional neuroimaging pointing to the subgenual cingulate cortex as a node in circuits involved in the normal experience of sadness, symptoms of depressive illness, and responses to depression treatments. In the initial publication of its type, a small open-label study found that patients with unipolar depression refractory to four or more treatment trials improved after stimulation of white matter tracts adjacent to subgenual cingulate cortex. A larger prospective trial had similar findings. Another open-label study, which included patients with bipolar as well as unipolar depression, found benefit after subgenual DBS in the bipolar patients as well as those with unipolar depression, without induction of hypomania. A large industry-supported controlled trial of subgenual DBS, however, has not encouraged continuing commercial development of the method. The stimulation target continues to be refined based on updated hypotheses concerning which neural pathways, amendable to identification on diffusion MRI prospectively, might be most important to modulate.

Another line of research on DBS for depression was prompted by the VC/VS DBS OCD research discussed above, and on the reported antidepressant effects of anterior capsulotomy on which the VC/VC stimulation target was initially based. The OCD patients in both the lesion and DBS experience had high rates of comorbid depression, as expected in that population. Responders displayed rapid improvements in mood and motivation, which preceded reductions in core OCD symptoms. An open-

label study of DBS at the VC/VS target for depression without comorbid OCD enrolled patients meeting a very high threshold for treatment refractoriness and found clinically significant antidepressant responses in roughly half of the patients. Induction of transient, reversible mood elevation, occasionally reaching the diagnostic threshold for hypomania, was the most significant adverse effect of active stimulation. In contrast, an industry-led controlled feasibility trial was negative, due to low response rates in both the active and sham stimulation groups.

Current State of Psychiatric Neurosurgery

Despite progress and the promise of advances in conventional medication and behavioral therapies, there remains a small proportion of individuals with intractable OCD or major depression who would be judged as potential candidates for neurosurgical treatments. These remain severely affected and have inadequate responses to conscientiously applied standard care. As with any treatment, the potential risks and benefits of psychiatric neurosurgery must be weighed against the potential risks and benefits of foregoing these approaches in individuals likely to remain burdened with severe illness and very poor quality of life. The conclusion reached in previous editions of this volume, then based almost entirely on open-label lesion procedure outcomes, was that about half of carefully selected psychiatric patients may meaningfully benefit from neurosurgery over a period of years after such procedures, and that a subset might show outstanding improvement. Although data remain incomplete, and cases of attempted and completed suicide have continued to occur after psychiatric neurosurgery, these procedures are still judged as likely to reduce mortality, as evidenced by data on comparative suicide rates. Nonetheless, patients who undergo and fail to benefit from these “last resort” procedures are at particularly high risk for completed suicide.

There has since been only one controlled trial of a lesion procedure, gamma ventral capsulotomy for OCD, in a small sample. While benefit at the end of the 1-year masked phase was not significant, at longer follow-up improvement was seen after the active procedure, consistent with the previous open-label experience. A follow-up study of a different sample of patients who underwent anterior capsulotomy for OCD with thermal and/or gamma knife procedures suggested that lesion size and location matters to both efficacy and adverse effect burden, which, together with other small-scale open-label work, has led to modifications of lesion methods for ventral capsulotomy. Other functional or structural neuroimaging data suggest that subsets of individuals might be identified prospectively as most likely to benefit after anterior cingulotomy for depression or DBS for OCD. Such methods are still early in development.

As for DBS, at present, some controlled data support application of DBS for OCD at a series of anatomically related brain sites. A US multicenter

controlled study of VC/VS DBS for intractable OCD finished enrollment of the last patient in its sample in 2015, with results expected within a year. Based on open-label data supporting a probability of benefit and relative safety, DBS for OCD is available in the United States under a humanitarian (HDE) FDA approval. Small numbers of patients continue to receive that procedure, typically at expert centers. DBS for OCD has full regulatory approval in the European Union. For intractable depression, initial controlled DBS trials have been disappointing. Small-scale research continues to test refinements of DBS targeting, or novel brain sites for stimulation.

Given the current landscape, clinicians are faced with a number of issues when considering a particular clinical or research procedure for a given patient who might be judged a candidate for neurosurgery. The first, for OCD in particular, is consideration of a lesion procedure versus DBS. DBS may be acceptable to patients who would not choose to undergo lesion procedures, although the reverse is also true, given the long-term treatment context of DBS. Despite its advantages of reversibility and adjustability, DBS implantation carries risks, and requires that patients be treated by highly specialized teams willing and able to provide long-term care. The logistics and expenses involved, including inconsistent coverage by insurers, can represent significant barriers. In contrast, psychiatric care can be delivered in standard treatment settings after lesion procedures. However, although the relative risks of enduring adverse effects after psychiatric DBS remain to be clearly established, at this stage ablative methods appear to carry a greater potential for them. Rates of adverse outcomes are relatively low when modern lesion procedures are performed by highly experienced multidisciplinary teams, something also seen with DBS for movement disorders, where there has been the most experience. This represents a particularly strong rationale for referral of appropriate patients to expert psychiatric neurosurgery centers.

RESEARCH AND FUTURE DIRECTIONS

The best evidence on which one could base treatment recommendations would be adequately powered, long-term, prospective comparison studies using random assignment of individuals to different surgical methods. That is unlikely to become available. As noted above, the small number of appropriate patients, the experience and preferences of expert centers for particular methods, and the preferences of patients themselves for one method over another, are all impediments in this regard. In contrast, long-term follow-up studies, systematic reviews, and ongoing research pointing towards individualized predictors of response have occurred and should be encouraged.

An example is a 2015 systematic review, by Pepper et al., comparing outcomes of anterior capsulotomy to those of DBS for OCD. A total of 170

cases were identified across 20 studies. DBS targets were the VC/VS or the closely related NAcc. After DBS (n = 62) there was a 40 percent decrease in YBOCS scores, while after capsulotomy (n = 108) YBOCS OCD severity decreased 51 percent. There was a 9 percent higher likelihood of remission after capsulotomy than after DBS. The authors noted no overall difference in complication rates, although the pattern of complications was different (lasting adverse effects tend to be more common after capsulotomy). The follow-up period was very different: 19 months for DBS versus 61 months for capsulotomy, which may allow for further development of improvement after capsulotomy, and conversely might not allow assessment of how many DBS patients experienced device failures or were no longer receiving stimulation for a variety of reasons.

Another 2015 systematic review, by Brown and colleagues, also based on observational data, compared outcomes of anterior cingulotomy to those of anterior capsulotomy for OCD. Ten studies involving 193 total participants were included; the capsulotomy dataset was similar to that in the review above. Mean follow-up was 47 months for cingulotomy and 60 months for capsulotomy. At last follow-up, 41 percent were responders after cingulotomy, while 54 percent responded after capsulotomy. Serious or permanent adverse events, characterized as the number of events per procedure, was 5.2 percent across cingulotomy studies and 21.4 percent across capsulotomy studies, although in the latter, half of those events were attributable to very high-dose, multiple target gamma knife procedures (which no longer would be performed) across three patients. Excluding those, the rate of serious complications in the capsulotomy group dropped to 12.8 percent.

A key research direction is the use of increasingly high-resolution structural and functional imaging methods which can assess changes in the relevant networks, for example their connectivities, prospectively after lesion procedures to test and generate hypotheses about which brain network alterations are most relevant to therapeutic improvement and also to adverse effects. Such MRI-based methods are at present not easily applicable to DBS studies for reasons of safety during imaging. As is possible in studies of ablative methods, work in DBS can make use of multiple modalities of neuroimaging at baseline to test for morphometric, fiber tract, and local and network activity as individual predictors of outcomes. Both kinds of work take place in a context where the anatomy of fiber connections affected by lesions and by stimulation has become increasingly better defined, in both humans and in animal models (Fig. 34.37–3).

FIGURE 34.37–3. Schematic representation of reciprocal connections between prefrontal cortex regions and the ventral portion of the anterior limb of the internal capsule and the adjacent ventral striatum (VC/VS). Prefrontal cortex: VC/VS connections are color-coded to delineate pathways linking specific prefrontal regions. Other connections of the VC/VS represented: THAL, mediodorsal and midline nuclei of the thalamus; SN/VTA, substantia nigra and ventral tegmental area; Amy, amygdala; Hypo, hypothalamus; STN, subthalamic nucleus; Raphe, raphe nuclei; PPT, pedunculopontine tegmental nucleus. (From Greenberg BD, Rauch SL, Haber SN. Invasive circuitry-based neurotherapeutics: stereotactic ablation and deep brain stimulation for OCD. *Neuropsychopharmacology*. 2010;35[1]:317–336.)

In summary, current neurosurgical treatment continues to represent a viable option for appropriately selected patients with severe and treatment

refractory illnesses. Evidence is most robust for OCD, but there are no studies directly comparing one technique to another even for that diagnostic group. As evidence has accumulated, it has become increasingly clear that the patterns of risks, burdens, and benefits, while they overlap, are distinctly different for DBS versus ablation. Research intended to inform psychiatric neurosurgery is proceeding along a number of fronts. Neuroimaging techniques might be a potential aid in individual patient selection by predicting treatment response. Structural and/or functional neuroimaging might be used to tailor surgical interventions on an individual basis. Ablation or DBS might enhance the benefits of subsequent behavioral or medication therapies that proved ineffective before surgery. Both kinds of treatments are being studied in the context of an increasing focus on the neurocircuitry underlying both syndromic illness and dimensions of psychopathology. Insights gained from invasive methods have the potential to inform development of noninvasive, circuit-based treatments for psychiatric illness, such as transcranial magnetic or electrical stimulation.

▲ 34.38 Combination Pharmacotherapy

CHARLES DEBATTISTA, M.D., AND ALAN F. SCHATZBERG, M.D.

Historically, the combination of psychotropic medications for the treatment of major psychiatric disorders has been frowned upon. The practice of "polypharmacy" was often seen as evidence of poor clinical judgment. A patient who was on three or four psychotropics was one whom many clinicians and impartial observers would characterize as overmedicated and perhaps improperly diagnosed and cared for. The significant limitations of monotherapy with antidepressant, antipsychotic, and mood-stabilizing agents have become increasing apparent. For many

patients, monotherapy results in insufficient benefit. There are three primary reasons for combining medications in psychiatric practice. Perhaps the most common reason for polypharmacy is that many patients do not respond adequately to a single agent. For example, in acute trials with antidepressants, most unipolar depressed patients are either partial or nonresponders to monotherapy. Medications are thus frequently combined to enhance antidepressant response. A second, related reason for combining therapy is that not all aspects of a given illness may respond to a single agent. This may be particularly true in bipolar disorder where monotherapy with a single mood stabilizer has become "the exception rather than the rule." Treating the manic phase or the depressed phase may require different or combinations of medications. Finally, medications are sometimes added to counteract the side effects of the original medication. Thus, patients on typical antipsychotics are usually given an anticholinergic agent to mitigate extrapyramidal side effects.

In addition to the advantages of combination treatment, there can be important downsides to combining psychotropic agents. The most important of these are the risks of pharmacodynamic and pharmacokinetic drug interactions. Cytochrome P450 interactions can result in either substantially higher or lower serum levels which might increase side effects or render the one or more agents less effective. For example, the combination of paroxetine and imipramine can substantially raise the serum levels of imipramine and potentially increase antimuscarinic, hypotensive, cardiac conduction, or sedating effects of the imipramine. Likewise, pharmacodynamic interactions can be equally serious. For example, combination of an MAOI and a serotonergic agent may result in a potentially lethal serotonin syndrome. Thus, clinicians must carefully weigh the risks and benefits of all combination treatment.

COMBINATION STRATEGIES IN THE TREATMENT OF MAJOR DEPRESSION

Lithium–Antidepressant Combinations

Given the limited efficacy of antidepressant monotherapy in the treatment of major depression, augmenting agents or combination strategies are frequently employed in clinical practice to enhance response. Conventionally, augmentation is used to describe the addition of an agent that is not viewed as a primary antidepressant by itself (i.e., thyroid hormone). Combination has been used when a known antidepressant is added to another (i.e., bupropion [Wellbutrin] and fluoxetine [Prozac] combination).

Lithium (Eskalith) has been the best-studied augmenter to standard antidepressants in such patients. However, lithium augmentation has become less popular with clinicians in the past 15 years secondary to the potential toxicity of lithium, the requirement for laboratory monitoring,

and the availability of other augmenters. Nonetheless, lithium is still used by many clinicians to boost antidepressant response in partial and nonresponders to monotherapy with an antidepressant.

The early reports of lithium augmentation indicated that the addition of lithium to a TCA trial resulted in clinical improvement within 72 hours in patients who had failed to respond to a TCA alone. Since then, at least 50 studies have been completed on lithium augmentation, and the vast majority have suggested some acute benefit for the addition of lithium to antidepressant. However, many of these reports suggest maximum benefits may not be seen for weeks. Furthermore, the addition of lithium also appears to prevent relapses in unipolar patients more effectively than an antidepressant alone. Response often occurs at low doses (600 to 1,200 mg/day) and at relatively low serum levels. Current data would suggest that serum levels in the range of 0.5 to 0.8 mEq/L are effective in lithium augmentation of antidepressant effects.

Although most studies of lithium augmentation have employed TCAs, a number of studies have evaluated the efficacy of lithium augmentation of SSRIs. The most recent of these trials is the National Institute of Mental Health (NIMH)-funded Sequenced Treatment Alternatives for Resistant Depression (STAR*D) trial. In patients who had failed monotherapy with citalopram (Celexa) and an augmentation trial with either buspirone (BuSpar) or bupropion, only 15.9 percent of patients achieved a remission level response with the addition of lithium. This was a numerically but not statistically lower level of response than those patients who were augmented with thyroid hormone at that point in treatment. Since most lithium augmentation trials do not indicate the degree of treatment resistance in the study population, the STAR*D data may be the most relevant to date on the limitations of lithium augmentation in resistant-depressed patients. There may be certain characteristics in depressed patients that predict response to the addition of lithium to their antidepressant regimen. Depressed patients may be more likely to improve with lithium augmentation if they exhibit significant psychomotor retardation, have significant anorexia and weight loss, and have low serum cortisol levels.

Thyroid Supplement–Antidepressant Combinations

After lithium augmentation, thyroid augmentation of antidepressants remains perhaps the second most studied strategy in the treatment of resistant depression. To date, over 30 studies have been completed on thyroid augmentation in resistant depression. However, thyroid supplementation may be less consistently effective than lithium and has also faded in popularity with the advent of new augmentation options.

Trials that have compared thyroid to lithium augmentation directly, have generally suggested that thyroid augmentation is at least as effective

as lithium augmentation. The few head-to-head trials of thyroid to lithium augmentation have tended to favor thyroid augmentation.

Although most trials employing thyroid augmentation have involved the use of TCAs, a number of trials also suggest efficacy when thyroid supplements are added to SSRIs. A number of case reports and small studies have suggested that liothyronine (Cytomel) (triiodothyronine or T_3) at 25 to 50 mcg/mL/day, when added to various SSRIs, does potentiate its effects. The largest and most systematic thyroid augmentation of an SSRI trial to date is the STAR*D trial. In this trial, patients who had failed two other trials (monotherapy with citalopram and augmentation with bupropion or buspirone) were treated with triiodothyronine or lithium augmentation. About 25 percent of patients on T_3 augmentation of citalopram achieved a remission level response compared to about 15 percent of the lithium-augmented patients. Among the limitations of the STAR*D trial was that it was an open-label trial, and patients had the option of not participating in a given randomization. Not all placebo-controlled studies have shown the benefit of thyroid augmentation.

The question of whether T_3 is more effective than supplementation with levorotatory thyroxine (T_4) has not been adequately addressed in the literature. Most studies have employed T_3, and the only head-to-head study favored T_3 over T_4. Since the half-life of T_4 is relatively long and the study was short (2 weeks), it cannot be conclusively interpreted for the superiority of T_3. Indeed, there are positive studies employing T_4 in thyroid augmentation. Although side effects were not common in this trial, the use of supraphysiological doses of thyroxine for an extended period might be problematic for some patients.

Patient characteristics of responders to thyroid augmentation include females and those with a history of thyroid abnormalities. There is growing evidence that patients with mild thyroid abnormalities (slightly elevated TSH, normal T_3 and T_4) are less likely to respond to antidepressants alone but respond to the addition of a thyroid supplement. Women over the age of 50, perhaps because they are most susceptible to hypothyroidism, also appear to have high responses to thyroid augmentation. More recently, Lerer's group has reported that responders to T_3 could be identified by their having lower T_3 levels and by being carriers for a specific allele on an SNP for the deiodinase converting enzyme for T_3 to T_4. This finding is in need of replication but could explain why some patients appear to derive great benefit from thyroid augmentation. Cytomel from the onset in combination with antidepressants has in a larger scale trial proven not more effective than adding placebo.

Stimulant-Like Agent–Antidepressant Combinations

There are a variety of stimulants and stimulant-like agents that have been useful augmenters in depression. Amphetamines have been used since the early 1930s for the treatment of depression. In addition, dopamine agonists such as pramipexole (Mirapex), dopamine reuptake blockers including bupropion, nondopamine and wake-promoting agents such as modafinil (Provigil) have shown some promise as augmenters in the treatment of depression.

The use of stimulants as augmenting agents in the treatment of depression has been applied to special populations including medical and geriatric patients. Amphetamines tend to be used to target fatigue, hypersomnia, and cognitive difficulties in depressed patients. When combined with TCAs, methylphenidate and the amphetamines inhibit the cytochrome P450 CYP isoenzyme 2D6 and artificially increase TCA serum levels.

Although most amphetamine augmentation studies have involved TCAs, a few have shown benefits in combination with MAOIs and SSRIs. Pharmacodynamic interactions between the stimulants and MAOIs can be problematic. Most controlled trials with amphetamine in the treatment of major depression have not shown benefits as a monotherapy. By far, the largest and most comprehensive studies to evaluate a stimulant to augment standard antidepressants involved lisdexamfetamine combined with and SSRI or SRNI. Subjects who failed to respond to 8 weeks of antidepressant monotherapy were randomized to an additional 8 weeks of lisdexamfetamine or placebo combined with the antidepressant. The two phase III trials involving over 800 patients failed to show an advantage of adding the lisdexamfetamine over adding a placebo the antidepressant monotherapy.

There are now several dopamine agonists approved for the treatment of Parkinson disease including pramipexole. Preliminary work with pramipexole as an adjunctive agent to SSRIs has suggested that it may have a role in the treatment-resistant patients in doses of 1 mg/day (starting doses are lower). Ropinirole (Requip) is also actively being investigated as an adjunctive treatment in resistant depression. In addition, pramipexole and ropinirole clearly treat restless legs, including restless legs exacerbated by the use of SSRIs.

Modafinil and armodafinil are nonstimulants that are approved by the FDA for the treatment of excessive sleepiness associated with narcolepsy, obstructive sleep apnea, and shift work sleep disorder. The lack of a more significant abuse potential for modafinil and armodafinil have led to their application as adjunctive agents in the treatment of depression with the same symptom targets as the stimulants: fatigue and hypersomnia. Several studies have indicated that modafinil is well tolerated and appears to be useful in depressed partial responders to SSRIs. While meta-analyses of completed randomized trials with combination treatment with modafinil

and armodafinil have generally suggested efficacy to these drugs in bipolar and unipolar patients, recent registration trials of armodafinil for the treatment of bipolar depression failed to demonstrate adequate efficacy.

Bupropion has weak dopamine reuptake–blocking properties but may act primarily as a noradrenergic agent. It is among the most common augmenting agents used today in resistant depression. The combination of bupropion with SSRIs is simple and usually well tolerated. Studies completed to date have been retrospective or open. The largest of these open trials, the STAR*D trial, reported a remission rate of about 30 percent in patients who had failed to achieve remission on citalopram alone. As with many augmentation trials, it is not clear whether longer treatment with citalopram alone may have resulted in the improvement. In fact, the CO-MED trial demonstrated that starting with the combination of escitalopram and bupropion was no more effective than treating with escitalopram alone in achieving antidepressant remission or response. Nonetheless, the experience of US clinicians supports the use of the bupropion augmentation.

Antidepressant–Antipsychotic Combinations

Although antipsychotics have been used in combination with antidepressants for many years in the treatment of psychotic depression, the atypical agents also appear to be useful augmenters and adjunctive agents in the treatment of unipolar and bipolar depression. The pharmacology of the atypicals, including their 5-hydroxytryptamine type 2 ($5\text{-}HT_2$) antagonism, has long been thought to imbue them with antidepressant properties. In addition, they clearly help a number of symptom domains in depressed patients including sleep, appetite, and agitation. As of this writing, several second-generation antipsychotics have FDA approval in the adjunctive treatment of resistant depression. Thus, they are only a class of agents that are specifically FDA approved to augment the effects of standard antidepressants.

Olanzapine (Zyprexa) was the first of the second-generation antipsychotics to seek approval in the adjunctive treatment of depression. The combination of 10 to 20 mg/day of olanzapine with fluoxetine in the treatment of various types of depression including resistant depression. In 2007, the olanzapine-fluoxetine combination (Symbyax) was approved for the treatment of resistant depression. Combination pills, however, tend not be popular with clinicians. Many clinicians prefer the more flexible dosing options of combining two different agents. Since both olanzapine and fluoxetine are generically available, there is also a cost advantage of using two generic agents over one branded drug.

Aripiprazole (Abilify) has long been of interest in the treatment of depression because it is a partial agonist of dopamine and a $5\text{-}HT_{1A}$ agonist

in addition to its 5-HT_2 effects. Randomized controlled trials have demonstrated that the addition of aripiprazole to an SSRI or venlafaxine (Effexor) is more effective than the addition of placebo in relieving depressive symptoms. As a result, aripiprazole was FDA approved in the adjunctive treatment of major depression. The relative lack of weight gain, sedation, or metabolic effects in aripiprazole compared to other second-generation agents such olanzapine have made it among the most frequently prescribed antidepressant-augmenting agents. However, akathisia and some weight gain were noted in the aripiprazole augmentation trials.

Quetiapine (Seroquel), the first monotherapy approved for bipolar depression, also appears to be useful in many unipolar patients. Several of registration trials demonstrated that the addition of 150 to 300 mg/day of quetiapine to standard antidepressants improved antidepressant response. Thus, quetiapine was approved as adjunctive treatment for major depression in 2009. Other second-generation antipsychotics including lurasidone (Latuda), ziprasidone (Geodon), and risperidone (Risperdal) also appear effective in some open-label and controlled studies as adjunctive agents in unipolar depression. While lurasidone is approved as a treatment for bipolar depression and schizophrenia, it also appears has demonstrated efficacy in at least 4 registration trials of the treatment of depressive symptoms associated with schizophrenia. As with other combination strategies, the potential benefits of augmenting with a second-generation antipsychotic must be weighed against the possible side effects of weight gain, EPS, and metabolic effects.

Sex Steroid–Antidepressant Combinations

It is known that estrogen-deficiency states, such as the postpartum period, may increase the risk of depressive symptoms in some women. In addition, estrogen possesses some antidepressant properties including MAO inhibition and serotonin agonist properties that are dose and duration specific. However, estrogen supplementation has been inconsistently useful in the treatment of depressed women. Some studies found that estrogen had no significant antidepressant effect when used alone for perimenopausal depression. In addition, other studies have found estrogen to be an effective prophylaxis against recurrent affective illness in the postpartum period. However, there are few adequately controlled studies, and a number of studies have not shown substantial benefit.

The combination of estrogens with antidepressants has sometimes been useful. For example, there have been case reports of oral contraceptives augmenting the effects of antidepressants in patients with refractory depression. In addition, postmenopausal women may respond better to fluoxetine if they are on hormone replacement therapy than if they are not. Recent studies of estrogen augmentation of SSRIs in both pre- and

postmenopausal women have not shown a consistent benefit. However, 0.1 mg of transdermal estradiol (Alora) was suggested to accelerate SSRI response in some perimenopausal women. The potential benefits of estrogen augmentation must be balanced against the defined risks to long-term treatment with unopposed estrogen, and the benefits have not been clearly established in the treatment of depression. Overall, the data suggest maximal benefit during the perimenopausal phase.

Dehydroepiandrosterone (DHEA), a corticosteroid precursor of both androgens and estrogens, is used over the counter in many older patients with claims of enhanced mood, energy, and sexual vigor. There are a few controlled trials that indicate that DHEA may be efficacious in the treatment of major depression, minor depressive symptoms, and dysthymia. The safety of DHEA has been called into question because of its potential to enhance the growth of sex-steroid tumors and possible virilizing effects in women.

Other Antidepressant Combinations

A variety of other antidepressant combinations are used in the treatment of resistant depression with varying degrees of scientific support. Given the poor response of antidepressant monotherapy, the question of whether combining antidepressants from the onset of treatment would improve remission or response rates was evaluated a large multi-center trial. The CO-MED trial (2011) evaluated whether the combination of escitalopram and bupropion, or the combination of venlafaxine and mirtazapine from the onset of treatment was superior to monotherapy treatment with escitalopram or venlafaxine alone in achieving a remission or response. There appeared to be no benefit from starting with treatment with combination treatment versus monotherapy.

Trazodone (Desyrel) has been used primarily as a hypnotic to treat depression or emergent insomnia. Although some small open studies have suggested an augmenting role for the use of trazodone combined with SSRIs, there is little evidence of benefit beyond the hypnotic effects of the drug. Likewise, buspirone, a generically available anxiolytic, has been applied as an augmenter to SSRIs with inconsistent benefits. Double-blind trials for buspirone augmentation of SSRIs in the treatment of OCD have been negative, and only open studies in depression suggest some benefit of adding buspirone to an SSRI. The STAR*D study found that among patients who had failed to achieve remission to citalopram alone, about 30 percent of patients achieved remission with the addition of buspirone. This is the same rate found to remit with bupropion augmentation in the trial.

The β-blocker pindolol (Visken) has some support in the literature as an augmenter to SSRIs but little support among clinicians. There have been multiple controlled trials of pindolol augmentation with most being positive. The relative lack of use among clinicians may be related to the

perception that pindolol is not efficacious, to concerns about the implication of β-blockers in inducing depression, and some wariness of possible pharmacokinetic interactions between β-blockers and CYP 2D6 inhibiting SSRIs such as fluoxetine and paroxetine (Paxil). Mirtazapine, like trazodone, can treat depression-associated insomnia and may help stimulate appetite in depressed elderly patients. The combination of venlafaxine and mirtazapine in patients who had failed three other trials in the STAR*D trial, and the combination of venlafaxine and mirtazapine showed more of an improvement in depressive symptoms and was far better tolerated than was the MAOI tranylcypromine (Parnate). However, the overall response rates in the mirtazapine SNRI combination and tranylcypromine groups were not statistically different. Only about 10 percent of patients achieved remission.

COMBINATION STRATEGIES IN THE TREATMENT OF BIPOLAR DISORDER

Combination of Two Mood Stabilizers

Mood stabilizers typically refer to agents that are used to treat one or more poles of bipolar illness and might also have utility in the maintenance treatment of bipolar disorder. Mood stabilizers have historically included agents such as lithium, divalproex (Depakote), carbamazepine (Tegretol), and perhaps other anticonvulsants. Although agents such as atypical antipsychotics might also be appropriately referred to as mood stabilizers, in this section mood stabilizers will refer to lithium and anticonvulsant agents that have demonstrated utility in bipolar disorder. Approximately two-thirds of patients with bipolar affective disorder are treated with two more medications as maintenance therapy. In addition, atypical antipsychotics are now frequently added during acute psychotic episodes to antidepressants, and sedative/anxiolytics are used to manage sleep, anxiety, and agitation. Thus, monotherapy is the exception in the treatment of bipolar disorder rather than the standard of care.

Lithium is commonly combined with anticonvulsants such as valproate, carbamazepine, and lamotrigine in the treatment of patients with refractory mania, in maintenance treatment, and in the treatment of bipolar depression. There are few prospective data using such combinations; however, a number of reports have indicated that lithium–carbamazepine combinations are effective in patients who have failed to respond to these two agents given separately. Retrospective reviews have generally found the combination of lithium and carbamazepine to be useful and synergistic. There is also evidence that this combination may be particularly useful in rapid-cycling bipolar disorder. The combination of lithium and carbamazepine appears to be well tolerated. In addition, the combination may have a cumulative antithyroid effect. There is no evidence of increased neurotoxicity or blood dyscrasias with the combination.

Dosing schedules of the lithium and carbamazepine should parallel regimens used for prescribing each drug alone. Therapeutic serum levels of both drugs should be monitored and maintained.

Perhaps the most common mood stabilizer combination in recent years has been the addition of valproate (Depakote) to lithium in patients who have manic breakthroughs or are unresponsive to lithium monotherapy. There are still relatively few prospective studies that have examined the efficacy of this combination. One naturalistic study indicated that the addition of valproate to lithium is more likely to be effective if the lithium level is above 0.6 mEq/L. Open-label studies have suggested that the combination of valproate and lithium may be more effective than either agent alone in the treatment of rapid-cycling bipolar disorder. For example, one study reported that eight of nine rapid-cycling patients with bipolar disorder, most of who failed to respond to the combination of lithium and carbamazepine, responded when lithium was combined with valproate. However, other studies have not necessarily supported an advantage of addition valproate to lithium in the treatment of rapid-cycling bipolar disorder. Likewise, while the combination of valproate and lithium is commonly thought to be more effective in preventing cycles of mania and depression than monotherapy, there is little data to support this idea. The large trial to date to evaluate the efficacy of the valproate/lithium combination in the maintenance treatment of bipolar 1 disorder, the BALANCE study (2010), failed to show an advantage of the combination treatment over lithium alone. However, the combination was more effective than valproate monotherapy. The combination of lithium and valproate seems to be well tolerated, and the dosing should aim to achieve adequate serum levels for both drugs.

The combination of valproate with carbamazepine has fallen out of favor in the past decade. Unfortunately, only anecdotal data support the combination of valproate and carbamazepine in the treatment of resistant bipolar disorder. In addition, a CYP450-based interaction increases the risk of carbamazepine toxicity. Also, the two taken together may result in even greater leucopenia than either alone.

A variety of other anticonvulsants such as gabapentin (Neurontin), topiramate (Topamax), lamotrigine (Lamictal), tiagabine (Gabitril Filmtabs), levetiracetam (Keppra), and oxcarbazepine (Trileptal) have been combined with lithium and divalproex in the treatment of resistant bipolar patients. With the exception of lamotrigine, most of the reports detailing the benefits of combining standard mood stabilizers with these other anticonvulsants in the treatment of bipolar disorder have been anecdotal. For example, many open-label studies have supported a role for the treatment of bipolar disorder with gabapentin. At this time, no controlled trials have demonstrated a clear benefit of gabapentin in any phase of bipolar disorder as either an adjunct or a monotherapy. In one large-scale,

double-blind study, gabapentin was no more effective than placebo when added to lithium. In that study, the lithium dosage could be adjusted during the trial, and this may have mitigated against finding statistically significant differences. However, gabapentin may still benefit some symptoms in bipolar patients. For example, one small controlled trial has suggested that while gabapentin does not show acute benefits, it may augment the effect of standard mood stabilizers in preventing relapse in bipolar patients. Gabapentin is well tolerated in combination with most mood stabilizers and appears to benefit anxiety and agitation associated with a variety of conditions. A chemically related compound, pregabalin (Lyrica), has shown utility in the treatment of generalized anxiety but has not been extensively evaluated in the treatment of bipolar disorder.

Lamotrigine has shown benefits in the maintenance treatment of bipolar disorder and in some studies in the treatment of acute bipolar depression, but its efficacy in the treatment of acute mania has not been demonstrated. Open-label augmentation with lamotrigine for bipolar depression in the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) did not show significant benefits on the primary outcome measures when compared to either risperidone or inositol. However, the patients treated with adjunctive lamotrigine had lower depression ratings than patients treated either with adjunctive lamotrigine or inositol. The benefits of lamotrigine make it likely that it will be increasingly employed as an adjunctive treatment to lithium, an atypical antipsychotic, or valproate in the treatment of the depressed phase of the illness. There does not appear to be significant pharmacokinetic interactions between lamotrigine and lithium. However, a risk for interactions does exist in the combination of lamotrigine with either valproate or carbamazepine. Valproate doubles the serum level of lamotrigine, thus increasing the risk of rash, while carbamazepine, on the other hand, cuts the lamotrigine serum levels in half.

The addition of oxcarbazepine, tiagabine, levetiracetam, and topiramate to lithium or valproate has not been extensively studied in the treatment of bipolar disorder. Oxcarbazepine is thought to carry fewer risks of pharmacokinetic interactions than does its chemical cousin carbamazepine. Thus, oxcarbazepine may be easier to combine with standard mood stabilizers than carbamazepine. However, some enzyme induction still occurs with the drug. Earlier studies have supported the efficacy of oxcarbazepine in the treatment of mania and hypomania.

Topiramate has been studied primarily as an adjunctive agent in the treatment of bipolar disorder. Open trials suggest that the addition of topiramate to a standard mood stabilizer may help the depressed phase of the illness and improve symptoms in refractory patients. However, most controlled trials have failed to show a benefit of topiramate in bipolar disorder. The most common current rationale for combining topiramate

with a mood stabilizer is to mitigate the weight gain associated with standard therapy. Topiramate has been associated with weight loss averaging up to 5 kg in 8 weeks as adjunctive treatment in bipolar disorder.

Tiagabine has not been proven effective or practical, thus far, in the treatment of acute mania. The drug requires a slow titration secondary to potential side effects, including sedation and a risk of seizure, with loading doses. However, open trials of tiagabine as an add-on to a standard mood stabilizer in refractory bipolar disorder have reported benefits at low doses (1 to 8 mg/day).

Levetiracetam was approved as an adjunctive treatment for partial seizures in 2000. A number of small case series have suggested some benefit of adding 1,000 to 4,000 mg/day of levetiracetam to standard mood stabilizers in the treatment of resistant mania. Likewise, adjunctive treatment with zonisamide (Zonegran) may have benefits for both the manic and depressed phase of bipolar disorder in open-label studies. Like topiramate, zonisamide has been associated with weight loss.

Mood Stabilizer–Antipsychotic Combinations

Antipsychotics have long been used as adjunctive treatments in bipolar disorder. Historically, the antipsychotic was used to treat acute mania or the psychotic symptoms and agitation associated with mania. Most of the second-generation antipsychotics are now approved for the treatment of acute mania, and a number are now approved in the depressed and maintenance phase of bipolar disorder.

Most patients who are hospitalized with a manic episode will be treated with an antipsychotic soon after admission. The combination of lithium with typical antipsychotics has generally been well tolerated. However, pharmacodynamic interactions may increase the risk of EPS in patients treated with the combination. The pharmacodynamics risk of an EPS interaction appears greater with higher lithium serum levels.

Case reports and open studies have reported that adding atypical antipsychotics to lithium or valproate may augment antimanic effects. In addition, controlled trials employing risperidone and olanzapine have shown benefit in augmenting antimanic effects of mood stabilizers. In a pooled analysis of five large controlled trials of second-generation antipsychotics combined with lithium in the treatment of acute mania, there appeared to be about a 20 percent advantage of the combination treatment over monotherapy with lithium or the antipsychotic.

Given that the second-generation antipsychotics appear effective in preventing mania, the antipsychotic is commonly added to lithium or valproate when there are breakthrough symptoms on monotherapy. However, to date there is very little controlled data to evaluate the efficacy of the antipsychotic/mood stabilizer combination in prevention of bipolar cycling. Likewise, while several second-generation antipsychotics are now

approved in the treatment of acute bipolar depression, it is not clear if adding lurasidone, quetiapine, or olanzapine to a mood stabilizer increases the efficacy in any way. Adequately controlled studies on antipsychotic/mood stabilizer combination in the treatment of acute bipolar depression have not been done to date. Still, the combination of one of the approved antipsychotics with either lithium or lamotrigine makes intuitive sense. The utility of antidepressants or second mood stabilizers in bipolar depression is more questionable at this time.

The combination of lithium with the atypical antipsychotic clozapine (Clozaril) is occasionally used in the most treatment-resistant bipolar patients. A potential disadvantage of lithium combined with clozapine is that most of the known cases of NMS associated with clozapine have been associated with concurrent lithium use.

Carbamazepine–antipsychotic combinations may result in a pharmacokinetic interaction that reduces the serum levels of concurrent antipsychotics. A higher dose of the antipsychotic may be required.

Mood Stabilizer–Antidepressant Combinations

The treatment of bipolar depression remains a vexing problem. The mood stabilizers, even in combination, are often inadequate to prevent or treat the depressed phase of the illness alone. On the other hand, the addition of an antidepressant may increase the risk of a switch into mania or rapid cycling. It is even unclear whether the addition of an antidepressant has any benefit in most patients. The few controlled studies to date have not necessarily supported the benefit of adding an antidepressant to a mood stabilizer. For example, the STEP-BD did not find that the addition of antidepressant to lithium or valproate was more effective than adjunctive placebo in the treatment of bipolar depression. In fact, there was a nonsignificant trend favoring the placebo group in a number of secondary measures. However, the rates of switching were also not different between the groups.

TCAs may be more problematic than other classes in exacerbating the illness, but all effective antidepressants, including electroconvulsive therapy, have potential to switch a bipolar patient into a manic episode. Other SNRIs including venlafaxine may share a greater proclivity for inducing switches than bupropion. Bupropion may be less likely to induce rapid cycling or mixed states than either TCAs or venlafaxine, but there have been reported cases of bupropion-induced mixed states and manic episodes. In addition, the data on switch rates with bupropion is limited, although some studies including the Stanley Foundation study on antidepressant treatment in bipolar disorder have suggested that the switch rate into hypomania may be lower with bupropion than with some agents including SNRIs. The addition of antidepressants, including TCAs, to lithium does not appear to increase the risk of switching any more than

lithium alone. Thus, most antidepressants probably can be added to lithium without substantially increasing the risk of a switch. By extrapolation, it would be expected that the addition of an antidepressant to valproate or carbamazepine might also mitigate the risk of a switch to mania. However, prospective trials are lacking on antidepressant–anticonvulsant combinations in the treatment of bipolar depression.

An important question is whether the addition of a second mood stabilizer is more efficacious for the treatment of bipolar depression than the addition of an antidepressant. Although antidepressants may destabilize bipolar cycling in the long run, at least one acute study has suggested that adding an SSRI may be as useful as adding a second mood stabilizer. This finding may be more a reflection of the lack of efficacy of adding a second agent to a mood stabilizer rather than an indication that both antidepressants and a second mood stabilizer are equally effective.

COMBINATION STRATEGIES IN THE TREATMENT OF SCHIZOPHRENIA

Combining Two Antipsychotics

The combination of two or more antipsychotics in a schizophrenic patient who has inadequately responded to one agent is commonly attempted but has been rarely studied. An earlier onset of illness, a longer duration of illness, more frequent hospitalizations, and the presence of violence as a symptom of schizophrenia is more likely to be associated with treatment with a combination of antipsychotics. The augmentation strategy that has been perhaps most investigated in resistant schizophrenia has been the combination of clozapine with another antipsychotic. Since 40 to 70 percent of patients fail to achieve an adequate response to clozapine, clinicians have typically added a second antipsychotic. For example, a number of small studies have suggested a modest benefit of adding risperidone to clozapine-nonresponsive patients. Case reports and small open studies have also suggested a potential role for amisulpride (Solian) and aripiprazole in patients who do not respond to clozapine alone. A meta-analysis of 19 studies examining the combination of antipsychotics in the treatment of resistant schizophrenia concluded that there may be an advantage of combining antipsychotics in some resistant patients. However, the combination of antipsychotics has also been associated with more side effects including an increased risk of parkinsonism and elevated prolactin levels.

Risperidone has been combined with typical antipsychotics to produce some improvement in chronic schizophrenic patients studied prospectively. In addition, risperidone has been added to clozapine with benefit refractory schizophrenic patients. The primary risks of combining antipsychotics may be the increased risk of EPS or the risk of hypotension with low potency and atypical antipsychotics.

Antidepressant–Antipsychotic Combinations in Schizophrenia

Antidepressants are frequently combined with antipsychotics in the treatment of schizoaffective disorder and psychotic depression. In addition, antidepressants have shown benefit in the treatment of negative symptoms. Trazodone produces significant but modest improvements in negative symptoms compared to placebo when added to a standard antipsychotic. Likewise, the addition of a low-dose MAOI or moderate doses of nefazodone (Serzone) to a typical antipsychotic has been found to benefit negative symptoms. Controlled trials of adding SSRIs and mirtazapine to antipsychotics have been reported to benefit negative symptoms. Furthermore, the addition of mirtazapine has also been suggested to help antipsychotic-associated akathisia.

Mood Stabilizer–Antipsychotic Combinations in Schizophrenia

Some reports have suggested that lithium can augment standard antipsychotics in the treatment of schizophrenia. However, most controlled studies have not shown much benefit. In addition, the combination of lithium with standard antipsychotics may increase the risk of EPS.

Lamotrigine has been effective in some studies as an augmenter to clozapine in treatment-resistant schizophrenia. For example, in a double-blind study, 200 mg of lamotrigine was more effective than placebo in improving negative symptoms as well as general psychopathology in treatment-resistant schizophrenia patients who had not responded to clozapine alone. However, a more recent study of the addition of lamotrigine to other second-generation antipsychotics did not show an advantage of adding lamotrigine in the treatment of positive or negative symptoms of schizophrenia. In addition, lamotrigine has been observed to reduce alcohol cravings in at least one study when added to standard antipsychotics in the treatment of schizophrenics with alcohol dependence.

The addition of carbamazepine to standard antipsychotics has not been clearly beneficial. On the other hand, a clear disadvantage of adding carbamazepine to many antipsychotics is that carbamazepine can induce the metabolism of the concurrent antipsychotic and reduce serum levels. Oxcarbazepine is less likely than carbamazepine to have a pronounced effect on the CYP450 system.

Valproate has been added to typical and atypical antipsychotics in resistant schizophrenia and catatonia. The data suggest that there may be a role for the addition of valproate in controlling agitation and perhaps impacting some positive and negative symptoms in schizophrenia. In addition, valproate augmentation of risperidone and olanzapine has been associated with more rapid improvement in schizophrenia. However, most studies have not shown a significant advantage of adding valproate to an antipsychotic in the treatment of schizophrenia.

The use of newer anticonvulsants in combination with antipsychotics is largely untested in schizophrenic patients. The use of gabapentin has anecdotally been beneficial to treat anxiety and agitation in some schizophrenic patients. Likewise, there are anecdotal reports of tiagabine being used for agitation in combination with both typical and atypical antipsychotics in some patients. Depressed schizoaffective patients have sometimes benefited from the addition of lamotrigine. Valproate has been applied for the treatment of agitation in schizophrenia.

Other Augmentation Strategies in Schizophrenia

Abnormalities in glutamate transmission have been proposed to play a role in the pathophysiology of deficit symptoms in schizophrenia. As a result, studies have examined the role of glycine and *D*-cycloserine as augmenters to antipsychotics. Glycine is an amino acid that is an agonist of the NMDA receptor. Early open trials have suggested that glycine helps some schizophrenic patients but worsens symptoms in others. *D*-cycloserine, another agonist of the NMDA receptor, may improve negative symptoms and neuropsychological functioning in patients on standard antipsychotics but not clozapine.

Cyproheptadine (Periactin) is a general serotonin antagonist used primarily to treat migraines and allergies. Its serotonin antagonist properties have made it of interest to clinicians treating negative symptoms since all atypical antipsychotics are also 5-HT_2 antagonists. Cyproheptadine also has the advantage of being anticholinergic and can help with EPS. The problem with cyproheptadine is that most patients find it quite sedating, and 24 mg/day is a large dose for many patients. It is unclear whether smaller doses might work just as well.

FUTURE DIRECTIONS

The monotherapy of major depression, bipolar disorder, and schizophrenia is often insufficient to achieve adequate therapeutic response. Thus the combination of psychotropic agents is often attempted in order to improve outcome. Although augmentation strategies have been best demonstrated in the treatment of resistant depression, combination treatment is common in the treatment of bipolar disorder and increasingly common in the treatment of resistant schizophrenia. Studies such as STAR*D and STEP-BD have provided additional insights into the utility and limitations of combination pharmacotherapy. However, much remains to be learned about optimal strategies for combining agents in the treatment of resistant-psychiatric disorders.

▲ 34.39 Reproductive Hormonal Therapy: Theory and Practice

DAVID R. RUBINOW, M.D., AND PETER J. SCHMIDT, M.D.

The 19th-century medical literature contained several presumptions about the pathophysiology of mood disorders in women, largely based on anecdotal observations of reproductive endocrine dysfunction (e.g., amenorrhea) in psychiatrically ill women. These inferences, in turn, were translated into therapeutics. Thus, numerous reports also documented the beneficial effects on mood and behavior associated with medical or surgical

manipulations of a woman's reproductive function. In addition to their interest in the role of reproductive function in psychiatric disorders, medical researchers in the late 19th century also developed a general interest in glandular secretions that potentially could modify physiology. Early experiments in humans with preparations derived from animal glands including thyroid, adrenal, ovary, testes, and spleen provided the directions for the developing fields of endocrinology and immunology. In his seminal lecture in 1889, Charles-Édouard Brown-Séquard not only originated the formal study of endocrinology, he also reported the potential psychotropic effects of gonadal secretions. His description of the invigorating effects of testicular extracts resulted in a brief but widespread use of these compounds (as well as other interventions intended to increase the body's testicular or seminal fluid levels) in a variety of therapeutic settings. In addition to extracts of both testes and ovaries, investigators experimented with extracts of the thyroid and adrenal glands in psychiatric patients. This interest in the therapeutic use of thyroid and adrenal extracts enjoyed more enduring success with the recognition of their beneficial effects in the treatment of myxedema and Addison disease, respectively. However, the widespread use of gonadal extracts ultimately met with criticism due to some disappointing results and the realization that these extracts were not the "fountain of youth." Their subsequent clinical use was largely restricted to the treatment of menopause-related hot flushes (ovarian extracts). Nonetheless, the observation that ovarian extracts inhibited ovulation in rabbits was sufficient to maintain medical interest in the potential role of gonadal extracts for the control of human fertility. This process of promise and disappointment, passionate advocacy and evidence-based caution, is the story of both the birth and the ongoing existence of endocrinology. Many of the claims of the organotherapists were refuted by observations that most of the endocrine preparations were inactive when administered orally. Nonetheless, the so-called "practical men," the practitioners whose therapeutic zeal was not about to be extinguished by study results to the contrary, continued to claim efficacy of endocrine preparations for all manner of illnesses. An additional source of the pendular swing of practice, and one particularly noteworthy for reproductive preparations, was the recognition of previously undiscovered side effects, a phenomenon that is particularly relevant for the therapeutic use of estradiol, the primary active substance in ovarian extracts. Efforts to improve techniques of extraction and purification of biologically active substances from the gonads were fueled by the hope that factors regulating reproductive function would be identified. By the late 1920s and early 1930s, many gonadal steroids were isolated and characterized including estrone, estradiol, progesterone, and several androgens. Moreover, during the next 10 years chemists identified modifications of the steroids that could alter their absorption (i.e., acetylation) and potency (e.g., addition of

ethinyl group or removal of C-19 methyl groups). These findings initiated a resurgence in the medical use of gonadal steroids. Estrogen replacement therapy was used to treat menopausal symptoms in the 1950s, and oral contraceptives (i.e., mestranol and norethynodrel [Enovid]) were developed and first approved by the FDA in 1960. The use of gonadal steroids in women once again was widespread, and several papers were published reporting the therapeutic benefits of these compounds in involutional melancholia, premenstrual syndrome, and postpartum depression. However, their widespread usage was restricted—the pendular swing—after reports in the 1970s of increased rates of endometrial cancer secondary to unopposed estrogen replacement and increased rates of thrombosis and pulmonary emboli in women taking oral contraceptives. In the last two decades of the 20th century, popularity for gonadal steroid therapy resumed due in part to the reports of the enhanced safety of both hormone replacement therapy (HRT) (due to the protective effect on the endometrium of the addition of progesterone) and oral contraceptives (due to the lower doses of estradiol and new progestins) and to the reported beneficial/disease protective effects of gonadal steroids on several tissues including the musculoskeletal, cardiovascular, and central nervous systems. The discovery of several other factors involved in the control of reproduction also led to new drug development. The decapeptide GnRH was isolated and sequenced in the 1970s, and the observation that continuous GnRH infusion resulted in the downregulation of pituitary GnRH receptors led to the development of several GnRH agonists. These agonists were used to suppress reproductive endocrine function in a variety of medical conditions including hormone-dependent cancers and endometriosis. In combination with gonadal steroids, preparations of GnRH agonists provided physicians with a strategy to control reproductive function and regulate the exposure to specific gonadal steroids without resorting to surgery. Thus physicians could selectively eliminate and/or replace reproductive factors considered to be the potential source of a medical or psychiatric problem.

More recently, however, reports of increased risk of breast cancer and, particularly, the Women's Health Initiative demonstration of increased, not decreased, risks of both heart disease and dementia after hormone therapy have resulted once more in a mass exodus from reproductive hormonal therapy (HT). Subsequent findings suggest that the pendulum again may have swung too far (this time, in the direction of avoiding hormone therapy). Nonetheless, the conclusions that follow about the practical and potential applications of hormonal therapy in psychiatric disorders must be viewed in the evolving context in which HT now resides.

Reproductive steroids are powerful and complex neuroregulators. If one is to knowledgeably, responsibly, and creatively employ reproductive steroids in the psychotherapeutic armamentarium, some familiarity with

the structure and related complexity of activities of these compounds is required.

STRUCTURE AND ACTIONS

Gonadal steroids, like all steroid hormones, are derivatives of cholesterol, and all share a core four-ring structure. Despite the wide array of steroid hormones, the synthesis of individual steroids is performed by a much smaller number of enzymes with multiple sites of action in the hormone synthetic cascade. Indeed, during the 1980s the cloning of the cDNAs and genes of several steroidogenic enzymes led to the realization that multiple different steroids could serve as substrates for the same steroidogenic enzyme in most tissues. In the past two decades, there has been an explosion of findings that have demonstrated the enormous complexity of steroid synthesis. These findings include the identification of multiple isozymes for steroid synthetic enzymes (including 14 different isozymes of 17-beta hydroxysteroid dehydrogenase encoded by several different genes) and the presence of a range of alternate synthetic pathways leading to steroid production in both health and disease states (e.g., the "backdoor pathway" from progesterone to dihydrotestosterone without the usual androgen intermediates). In humans, plasma low-density lipoproteins are the major source of tissue cholesterol used for synthesizing steroids. The first step in steroid synthesis takes place in the mitochondria. The mechanism by which cholesterol is transported and deposited onto the outer mitochondrial membrane remains only partially understood. However, in steroidogenic cells, steroidogenic acute regulatory protein (STAR) and other members of the STAR-related lipid transfer family of proteins control the availability of cholesterol within the mitochondria, where it is cleaved in a series of steps by the P450 side chain cleavage enzyme (P450scc) to produce pregnenolone. Pregnenolone then serves as the precursor of the family of steroid hormones, individual members of which as stated above are generated through the actions of a relatively small number of enzymes with multiple sites of action (see Fig. 34.39–1). The resulting end products of this cascade are determined by the tissue in which the metabolism is occurring and the enzymes present in that tissue. For example, testosterone in both men and women may be the end product and act directly at the androgen receptor, or it may be reduced to a form with greater affinity for the androgen receptor (dihydrotestosterone), converted to a form with less affinity for the androgen receptor (androsterone—also a neurosteroid active at the GABA receptor), or aromatized to estradiol and act through the estrogen receptor. Recently, a new level of complexity has been introduced by the discovery of tissue-specific variations in the activity of steroidogenic enzymes. For example, 17-beta hydroxysteroid dehydrogenase exists in both oxidative and reductive forms: the type 2 isoform in the gut is oxidative and converts

estradiol to estrone (thus "inactivating" orally administered estradiol), while the type 1 isoform in the ovary and placenta is reductive and "activates" estradiol via its conversion from the less potent estrone. Further, a genetic variation in 5-alpha reductase type 1, an enzyme that converts testosterone to dihydrotestosterone and is localized in skin and the central nervous system, has been associated with enhanced hirsutism in women with polycystic ovarian syndrome. Thus polymorphic variants of steroidogenic enzymes can produce tissue-specific alterations in exposure to steroids with accompanying alterations in phenotype. Moreover, as an example of the multifunctional roles of steroidogenic enzymes, 5-alpha reductase also is the rate-limiting step in the conversion of progesterone to its neurosteroid metabolite allopregnanolone, which is active at the GABA receptor. Finally, given the structural similarities shared across different types of steroid hormones, steroids are classified by the particular receptor that mediates their actions rather than the structural elements of the hormone or the tissue of origin. By this classification, reproductive steroids are those that act via the androgen receptor, estrogen receptor, or progesterone receptor systems.

FIGURE 34.39–1. Synthetic pathways for steroid hormones. Circled numbers identify synthetic enzymes: 1, cytochrome P450 (CYP) 11A (P450 side chain cleavage enzyme); 2, 3β-hydroxysteroid dehydrogenase; 3, CYP21 (21-hydroxylase); 4, CYP11B2 (11β-hydroxylase, 18-hydroxylase, 18-oxidase); 5, CYP17 (17α-hydroxylase, 17,20-lyase); 6, 17β-

hydroxysteroid dehydrogenase (or oxidoreductase); 7, aromatase; 8, 5α-reductase; 9, CYP11B1 (11β-hydroxylase). (From Rubinow DR, Schmidt PJ. Androgens, brain, and behavior. *Am J Psychiatry*. 1996;153(8):974–984.)

FIGURE 34.39–2. Genomic action of steroid hormones. Estradiol acts by binding (activating) its intracellular receptor, which dissociates from heat shock protein. The activated receptor undergoes a conformational change that facilitates the binding of a coregulator (in this case, a coactivator) with enzymatic properties. The receptor dimerizes, and the receptor/coregulator complex both binds the DNA hormone response element and recruits a variety of transcription factors. The DNA is then remodeled to facilitate transcription of mRNA, which is exported to the cytoplasmic ribosome for protein synthesis.

The classic genomic action of steroid hormones occurs after the steroid binds (activates) its intracellular receptor, which, after undergoing phosphorylation, binds (usually as a dimer) to a hormone response element on a gene and directs or modifies transcription of that gene (see Fig. 34.39–2). Note that in contrast to the membrane-bound receptors of neurotransmitters and neuropeptides, which act on the genome through a signal transduction cascade, the steroid hormone receptors are intracellular and are transcription factors that can directly bind to DNA. Further, once

the ligand–receptor complex binds to the hormone response element (which is located on or near the promoter of the gene), the result can be either the initiation or repression of transcription of messages coding for an enormous array of proteins, including synthetic and metabolic enzymes for neurotransmitters, neuropeptides, receptor proteins, transporters, and second messengers.

Alas, while accurate, this mechanistic description is glaringly inadequate, and it is in the missing complexity that the explanation for so many ostensibly idiosyncratic responses to hormones lies. First, an additional source of transcriptional variance is found in the different forms of the gonadal steroid receptors. For example, isoforms of the androgen and progesterone receptors exist that have different transcriptional effects, and two separate estrogen receptors, alpha and beta, have been identified, coded for by genes on the 6th and 14th chromosomes, respectively. These estrogen receptors have different distributions in the brain, different transcriptional actions, and even possess additional isoforms (e.g., insertional and deletional variants of ER beta). Additionally, recent studies have identified splice variants of steroid receptors present in some disease states, including a splice variant in the androgen receptor that lacks a ligand-binding domain but is constitutively active (and, therefore acts on the androgen receptor in the absence of steroid) and contributes to the development of hormone-refractory prostate cancer. Second, the activated steroid receptor regulates transcription by binding protein intermediaries called coregulators. Some coregulators stimulate transcription while others inhibit it. The activities of these coregulators are tissue specific, and different types of coregulators interact with specific isoforms of the steroid receptors. Thus, the relative expression of coregulators and receptor isoforms within different tissues could underlie, in part, opposite effects of the same hormone in different tissues. Approximately 350 of these coregulators have been identified, with coregulators usually part of assemblies consisting of up to eight different regulators. Since the coregulator function is altered by covalent modification of its constituent amino acid residues, it has been estimated that there are 10^{13} possible different functional states that can be created in response to hormone activation. Third, activated hormone receptors can influence the transcription of genes that do not possess hormone response elements through interactions with other cellular proteins called cointegrators, which translate hormone signals to oncogene and signal transduction–related genes. Fourth, hormones display acute nongenomic actions; that is, they can, in a receptor isoform–specific fashion, allosterically modify the activity of neurotransmitter gated ion channels, can directly bind and regulate ion channels, and can initiate signal transduction through binding membrane rather than cytoplasmic or nuclear receptors. Fifth, hormone receptors can be activated, even in the absence of hormones, by a variety of

neurotransmitters and growth factors. In this fashion environmental stressors may amplify the response to even minimal levels of a hormone signal. Sixth, hormones may influence each other's activity by competing for cofactors or by producing opposite effects on genes regulated through integrator proteins.

What are the practical implications of this biologic complexity? First, hormones of a given class (i.e., different hormonal preparations) are not going to produce similar effects on all tissues. For example, medroxyprogesterone differs from progesterone in at least two ways: first, the latter but not the former can be metabolized to neuroactive compounds called neurosteroids, which regulate $GABA_A$ receptor activity; and second, medroxyprogesterone inhibits the enzyme that converts pregnenolone to progesterone (i.e., 3-beta hydroxysteroid dehydrogenase) thereby further decreasing substrate for the production of endogenous neurosteroids. At a cellular level, it is unlikely that the equine estrogens used so frequently in HRT produce the same conformational changes in the ER as estradiol and hence would have a different profile of actions. Indeed, the genetic effects of conjugated equine estrogens are not identical to those of estradiol. Second, hormone plasma levels are only part of the story. Hormone effects are context specific and reflect the constituents of the milieu that bathes the cell as well as the specific constellation of expressed proteins within the cell. Depending on one's genetic background, then, one might expect that the same hormone level would elicit a range of possible effects. This has been clearly demonstrated in animal studies in which exogenous estradiol exerts 100-fold differences in effects on reproductive development across rodent strains, accounting for far more of the variance than the plasma level of estradiol achieved. Third, recognition of the critical nature of intracellular proteins and hormone signaling/transcription suggests a strategy for future drug development, namely designing drugs that will facilitate or disrupt binding interactions between the receptor and specific cofactors. This strategy has already borne fruit in the development of selective estrogen receptor modulators (SERMs) and selective androgen receptor modulators (SARMs) (discussed below).

WHY REPRODUCTIVE HORMONAL THERAPY?

It is biologically plausible that reproductive steroids might display psychotropic properties, as their pattern of neuroregulatory effects is highly convergent with those presumed to underlie psychotropic efficacy.

Indeed, wherever one finds a system believed to play a role in the etiology or treatment of depression, modulatory effects of gonadal steroids are observed as well. The neurotransmitter systems implicated in depression—serotonin, norepinephrine, dopamine, acetylcholine, GABA, glutamate—all are regulated by estradiol. Estradiol's regulation of the serotonergic system, for example, is extensive, involving serotonin

synthesis (tryptophan hydroxylase), receptors (transcripts, protein, and binding) (e.g., 5-HT1A, 2A), and transporter. Additionally, estrogen increases sensitivity to dopamine and cocaine and is believed to contribute to the increased vulnerability to substance abuse in women. Recent hypotheses about mood dysregulation center on deficits in neuroplasticity and neuronal/glial survival, with attendant observations that cell survival proteins like Bcl-2 or growth factors like BDNF are low in depression. Stress decreases BDNF in animal models, and both Bcl-2 and BDNF are increased by antidepressants and mood stabilizers, effects also seen after exposure to estradiol. Cell survival is regulated by the actions of several signal transduction systems, including ERK, Akt, WNT/beta catenin. In a brain region–specific fashion, estradiol increases ERK and cell survival in neurons (although it decreases both in glia), increases AKT and neuronal survival, increases trkA and phospho-CREB, and decreases GSK-3 beta. Similar effects are seen with antidepressants and mood stabilizers on ERK (increased) and GSK-3 beta (decreased). Finally, estrogen appears to play a major role in neuronal excitability, as it directly and acutely (in seconds to minutes) modulates both calcium and potassium ion channel activity.

Similarly, many areas of the brain that have been implicated in depression, including prefrontal cortex (PFC), amygdala, hippocampus, striatum, and thalamus contain estrogen receptors and are modulated by estradiol. For example, in the first demonstration of the effects of estradiol and progesterone on regional cerebral blood flow in humans, Berman et al., showed that both estradiol and progesterone increased cerebral blood flow in the dorsal lateral PFC, inferior parietal lobule, and posterior inferior temporal cortex compared with a hypogonadal condition produced by gonadotropin-releasing hormone agonists. More recent studies suggest that estradiol and progesterone regulate other brain regions in humans including the orbitofrontal cortex, amygdala, striatum, and midbrain—areas involved in the reward system. Further, regional functional connectivity—a better measure of network activity—is modulated both by the menstrual cycle and exogenous reproductive steroid administration, with the nature of the alterations both brain region specific and steroid dependent. Finally, the importance of gonadal steroids in affective regulation is suggested by studies demonstrating the role of estradiol in stress amplification, of ER beta in anxiety in female rats, and of ER alpha in arousal.

Progesterone is metabolized to the neurosteroid allopregnanolone, the levels of which have been shown to be decreased in depression and increased during treatment with a selective serotonin reuptake inhibitor (SSRI). Indeed, SSRIs increase the activity of the neurosteroid synthetic enzyme 3-alpha-hydroxysteroid oxidoreductase, and it has been hypothesized that the resultant increase in allopregnanolone may underlie the therapeutic efficacy of SSRIs in premenstrual dysphoria. Progesterone,

through allopregnanolone, modulates both the conformation and the ligand sensitivity of $GABA_A$ receptors, with a role for allopregnanolone implicated in both the genesis and treatment of anxiety (depending upon the time course of administration) and in the sensitivity of $GABA_A$ receptor to the anxiolytic benzodiazepines. Finally, allopregnanolone also exerts neuroprotective effects by reducing the expression of proapoptotic proteins and apoptotic DNA fragmentation, thereby reducing cell death and gliosis, which have been associated with depression. Neuroprotection may be mediated by immune regulation in depression, and both progesterone and allopregnanolone reduce the expression of the "proinflammatory" cytokine TNF-α, which is elevated in individuals with major depression. Thus, allopregnanolone (or progesterone) may exert antidepressant effects by reducing the physiologic impact of stress, promoting neuroprotection, and protecting against the immune activation and cytokine hypersecretion associated with major depressive disorder. As such, both progesterone and therapies that target progesterone metabolism might be expected to modulate mood.

TYPES OF REPRODUCTIVE HORMONE THERAPY IN AFFECTIVE ILLNESS

Reproductive hormone therapies serve two principal functions. First, they potentially may replace traditional pharmacotherapies if the latter have proved ineffective or are accompanied by unacceptable side effects. Second, some reproductive hormone therapies can also serve as short-term trials to inform patients and their health care providers about possible links between the secretion of a particular hormone and the presence or exacerbation of symptoms (e.g., GnRH agonist–induced ovarian suppression in menstrual cycle–modulated affective disorders, as described below).

Hormone Suppression in Premenstrual Dysphoric Disorder

A variety of hormonal therapies have been employed in premenstrual dysphoric disorder (PMDD). Currently the best evidence of efficacy exists for gonadotropin-releasing hormone agonists, compounds that reversibly suppress pituitary secretion of the gonadotropins FSH and LH and hence turn off ovarian steroid secretion. GnRH-induced ovarian suppression works in about two-thirds of women with PMDD, the same percentage (although not necessarily the same individuals) as are successfully treated by SSRIs. GnRH therapy should be considered for those women who do not respond to SSRIs, particularly if they have severe symptoms. While few predictors of therapeutic response to GnRH agonists exist, one report suggests that the presence of symptoms in the follicular phase predicts lack of efficacy (although the women in this report would not meet criteria for PMDD and more likely experienced a premenstrual exacerbation of a

chronic depressive illness). Because of the largely unknown risk of compromising fertility, and of nonreversible reduction in bone mass, this treatment should be reserved for those who do not intend to subsequently have children and should be administered only in consultation with a gynecologist and with full consideration of risks and benefits. Recently, concerns over the safety of long-term GnRH agonist–induced gonadal suppression in both fertility and bone health have been offset in part by reports of the return of normal reproductive function and bone mass in the majority of children with precocious puberty who were treated with these agents for several years. Nonetheless, prudent clinical practice would entail the use of GnRH agonists for not greater than 3 months without consultation with a woman's gynecologist and without consideration of the addition of bone-sparing adjunctive estradiol (which, if given continuously, would not be expected to reverse the efficacy of the GnRH agonist). Preliminary data suggest that while exposure to sequential hormone replacement (i.e., discontinuous or interrupted) does precipitate a recurrence of PMDD symptoms, continuous exposure does not. Consequently, continuous administration of oral contraception may show therapeutic efficacy in PMDD despite the inefficacy of discontinuous or sequential administration. Indeed, the shortened pill-free interval appears critical for the reported efficacy of an oral contraceptive approved for PMDD. If efficacy is demonstrated in ongoing trials, an alternative to SSRIs will be available. It should be noted that continuous oral contraception administration requires monitoring of the endometrium to avoid endometrial hyperplasia, but several oral contraceptives are approved to be administered continuously for 3 months at a time. One additional advantage to a therapeutic trial of GnRH agonist is that the results can determine the role of cyclical variation of steroid secretion in PMDD. If the patient does not respond to GnRH agonist–induced suppression (nonresponse is reported in about 30 percent of women with PMDD despite adequate ovarian suppression), you should look no further for a reproductive hormone etiology or intervention. Other hormones studied as potential treatments for PMDD include progesterone and estrogen. Despite early claims to the contrary, the majority of studies overwhelmingly refute the efficacy of progesterone in PMDD. While estradiol is described as superior to placebo in several studies, evidence to date must be regarded as preliminary and insufficient to support the recommended use of estradiol for the treatment of PMDD. Indeed, the doses of estradiol required to effectively treat PMDD suggest that in this condition estradiol is acting to inhibit ovulation and interfere with normal cyclic ovarian hormone secretion. No studies have examined the therapeutic potential of GnRH antagonists, which have recently become available in an oral preparation. Finally, preliminary evidence in a small sample of women with PMDD suggests that stabilizing neurosteroid levels across the menstrual cycle by

inhibiting 5-alpha reductase type 1 (the rate-limiting enzyme for the conversion of progesterone to allopregnanolone) with the medication dutasteride results in the elimination of PMDD symptoms. These findings hold great potential for understanding the role of neurosteroids in PMDD but must be viewed with caution until larger trials with longer treatment duration can confirm these results.

Although not unrelated to the treatment of women with PMDD, a trial of GnRH agonist–induced ovarian suppression can be undertaken in some women who present with a recurrent affective disorder and in whom the clinical presentation suggests a menstrual cycle recrudescence of affective symptoms. In this clinical scenario the results of the trial of ovarian suppression informs future decisions to include (or not) hormonal therapies to augment existing mood-stabilizing pharmacotherapy.

Estradiol Administration in Perimenopausal Depression and Postpartum Depression

Perimenopausal Depression

A 48-year-old gravida 2 para 2 married Caucasian female presented with an 8-month history of depressed mood, anhedonia, increased anxiety, tearfulness, avoidance of social activities, disturbed sleep, and decreased concentration. She did not feel that she was sad so much as, paradoxically, both more worried about even relatively trivial matters and less engaged by events in her life. She felt herself to be more emotionally reactive, finding herself becoming tearful in response to almost any emotionally laden situation. On questioning, the patient reported hot flushes, worse at night; however, daytime flushes were associated with marked anxiety, a racing heartbeat, and an enhanced sense of worry. Her menstrual cycle had been somewhat erratic in length for 2 years, and in the last year she had skipped several menses with periods of amenorrhea lasting 2 to 3 months. The patient had no past personal or family history of depression. Laboratory testing revealed plasma FSH levels ranging from 25 to 40 IU/L and estradiol levels of 50 to 60 pg/mL.

FSH levels greater than two standard deviations above the mean for women of reproductive age combined with irregular menstrual cycles and amenorrhea characterize the menopause transition and the first year postmenopause (i.e., the perimenopause).

Therapeutic trials of estradiol therapy (ET) have been conducted in perimenopausal and postmenopausal women with depression, dating back to 1934. Depression risk increases during the perimenopause, and depression is cited as a primary reason for resuming menopausal hormone therapy (HT). Community-based epidemiologic studies document a 1.5- to 3-fold greater risk of first onset and recurrent depressions in women during the perimenopause compared with those who are premenopausal (or who are several years postmenopausal). Observational studies report the emergence of depressive symptoms after the discontinuation of HT in 5 to 10 percent of women.

The role of estradiol (E2)—either declining or low levels—in the

precipitation of perimenopausal depression is unknown, largely due to the associational and indirect nature of the evidence linking ovarian function and depression and to the inability to accurately measure the low levels of plasma estradiol levels in some perimenopausal women. Correlative studies with plasma FSH or response to hormonal therapy do provide indirect evidence of the relevance of changes in reproductive hormones to mood disturbances. However, even prospective epidemiologic studies cannot test the estradiol withdrawal hypothesis, because perimenopausal changes in the secretion of several hormonal and metabolic factors could confound the effects of estradiol withdrawal. In other studies of the role of ovarian steroids in affective disturbance (e.g., PMDD and postpartum depression), changes in ovarian steroids (in the context of otherwise normal levels) have been shown to directly trigger depression, but only in a subset of women with histories of mood disorders linked to reproductive function. Recently, a study directly examined the hypothesis that declining ovarian function—estradiol "withdrawal"—underpins depression occurring during the perimenopause. The authors further sought to examine whether the response to experimentally induced estradiol withdrawal differed in women with a past perimenopausal depression compared with those without any past depression. Results showed that women with a past perimenopausal depression who were blindly withdrawn from ET experienced a significant increase in depression symptoms. Women with past perimenopausal depression who continued on estradiol and control women with no past history of depression remained asymptomatic. Thus, in women with past perimenopausal depression, the recurrence of depressive symptoms during blinded estradiol withdrawal suggests that normal changes in ovarian estradiol secretion can trigger an abnormal behavioral state in these susceptible women. These data are the first direct evidence that, in some women, estradiol withdrawal could contribute to the onset of depression during the perimenopause.

While several studies clearly suggested the beneficial effects of estrogen on mood in perimenopausal women, the antidepressant efficacy of estradiol remains unclear. A double-blind, placebo-controlled trial demonstrated that 3 weeks of estradiol significantly decreased depression ratings compared with placebo in perimenopausal women. A full or partial therapeutic response was seen in 80 percent of subjects on estradiol but in only 22 percent of those on placebo, consistent with the observed effect size ($d = 0.69$) in a previous meta-analysis of studies examining estrogen's effect on mood. The therapeutic response to estradiol was observed in women with major or minor depression and was observed irrespective of the antecedent presence of hot flushes, thus removing a major confound complicating interpretation of earlier studies (i.e., effects of estradiol on mood might merely be consequent to resolution of hot flushes and associated sleep disturbance). Efficacy of estradiol was similarly

demonstrated by other investigators in perimenopausal women with major depression but not in postmenopausal women. The small samples and short duration of treatment in trials of ET in perimenopausal depression notwithstanding, the best case for ET in the treatment of depression (either as monotherapy or as an adjunctive therapeutic agent) can be made in perimenopausal rather than postmenopausal women. It is further noteworthy that there are at present no clear predictors (including estradiol levels) of response to estradiol in women with perimenopausal depression.

While initial reports suggested beneficial effects of estradiol on both cognitive performance (e.g., verbal memory) and cognitive pathology (i.e., Alzheimer dementia), consistent, perhaps, with its neuroprotective effects, subsequent reports demonstrate a far more restricted impact on cognition if any (e.g., limited to women with perimenopausal symptoms). The timing of starting ET relative to the menopause has been proposed as one factor explaining the otherwise discordant observations (of the effects of ET on cognition) between the observational studies and the recent randomized controlled trials from the Women's Health Initiative (WHI). Thus, in several studies women who take ET during the late menopause transition or early postmenopause have a lower risk of dementia than those starting ET later. This construct of a reproductive stage-dependent differential "risk" for both the benefits of ET on cognitive performance and the adverse effects in young peri- and postmenopausal women compared with older postmenopausal women has recently been tested. Two primary prevention, randomized, controlled trials examining the effects of ET on cognitive performance in younger and older postmenopausal women have recently been completed. Preliminary results of both the Kronos Early Estrogen Prevention Study (KEEPS) and the Early versus Late Intervention Trial with Estradiol (ELITE) showed that the effects of ET on measures of cognitive performance (including verbal and working memory) did not differ from those of placebo, nor did young postmenopausal women show more beneficial effects of ET on cognitive performance than older women. Thus, neither the therapeutic nor the prophylactic benefits of ET on cognition in postmenopausal women are supported by currently available data. Further, beliefs about other indications for use of estrogen in the treatment of perimenopausal depression have been complicated by the HERS (Heart and Estrogen/Progestin Replacement Study) and WHI reports, which contradict the long-held view that estrogen protected against the development of heart disease in women. Since the cardio-protective effects previously reported were so substantial as to offset the increased risk of breast cancer after >4 years use of estradiol, particularly given the efficacy of estradiol in the prevention of osteoporosis, many physicians recommended HT as prophylaxis against future heart and bone diseases. With the demonstration that, to the contrary, estrogen combined with the progestin medroxy-progesterone may increase the risk of coronary

heart disease and stroke (during the first year of treatment), estradiol prophylaxis can no longer be recommended. However, estradiol treatment may still be indicated in women with perimenopausal symptoms (hot flushes, vaginal dryness) and depression, particularly in those who fail standard antidepressant treatment, who have a strong risk of osteoporosis, or who are intolerant of other acute treatments of perimenopausal symptoms. Indeed recent analyses of the WHI demonstrate that the adverse effects of ET on cardiovascular outcomes were largely confined to older women (and those at a greater distance from the menopause) compared with younger perimenopausal women, thus supporting the critical window or "gap" effect for the effects of estradiol on the cardiovasculature and providing some reassurance regarding the health effects of ET during the perimenopause.

Nausea is the most common side effect of ET administration. At conventional ET doses, this complaint seldom interferes with eating, and no weight loss has been reported. Breast engorgement, endometrial hyperplasia and bleeding are also common side effects of ET, which may enlarge pre-existing fibroid tumors of the uterus.

The relationship between estrogen, both endogenous and exogenous, and the development of endometrial carcinoma has been suggested by several different lines of investigation. Numerous retrospective case control studies published since 1975 have indicated that postmenopausal exposure to unopposed estrogens for more than 1 year results in a 2- to 12-fold increased relative risk for endometrial cancer. However, the addition of progesterone to ET decreases the risk of endometrial hyperplasia and endometrial cancer to equal or below that of women receiving no hormonal treatment. The optimal regimen to prevent hyperplasia and thus, inferentially, the risk of carcinoma, consists of 12 to 13 days of progestin treatment each month when estrogens are administered. There is an increased incidence of thromboembolism and stroke in women receiving ET and some SERMs; however, stroke is less likely in younger-aged perimenopausal women. Blood pressure, on average, appears to be unaffected by ET, although both increases and decreases have been reported. High doses of oral estrogens have been reported to elevate hepatocellular enzyme levels and, less commonly, cause cholestatic jaundice. The risk for gall stones and hepatocellular adenomas has been reported to be increased in association with oral contraceptive use, and although uncommon these complications may also occur with the use of more physiologic doses of estrogen. Most studies have suggested an increased relative risk of breast cancer after 4 or 5 years of use, similar to the risk expected if the onset of menopause is delayed for a comparable length of time; recent analyses, however, suggest that the increased risk is related to current use and the risk normalizes after cessation of HT. Additionally, it is recognized that ET (estrogen alone) is associated with

considerably less risk of breast cancer than combined estrogen and progestin formulations. Finally, the risk for breast cancer using hormone therapy for 5 years is associated with an increased "absolute risk" of only 0.67 percent, which some authors compare to the increased risk conferred by obesity and many other common exposures. For a more detailed review of the benefits and risks of menopausal ET, the reader is referred to recent updates from the Endocrine Society and the North American Menopause Society.

Estrogens may precipitate migraine headaches, and depression has also been reported to occur with the use of estrogens, but these reports are usually in the context of concurrent progestin use as in the oral contraception pill. If estradiol is to be used in the treatment of depression (see Table 34.39–1), then one should consider using the 50-microgram estradiol patch (transdermal estradiol [TDE]). The patch delivers estradiol, the form of estrogen that mediates most of its physiologic effects and does not cause an undesirable increase in the plasma proteins that mediate some of the adverse effects of estrogen. Levels achieved with this method are equivalent to levels in the early follicular phase and are slightly above the threshold necessary to preserve bone (60 pg/mL). In women without a uterus, estradiol may be given by itself and does not appear to have the risks associated with the combination of estradiol and progestin. Although ET does increase the risk of venous thromboembolism (VTE) and stroke, TDE and low-dose estrogen are not accompanied by an increased risk of VTE. If a progestin is needed, micronized progesterone tablets may be used, which deliver progesterone rather than medroxy-progesterone. Of note, progestins may differ markedly in their molecular effects, physiologic effects, and side effects. For example, second-generation progestins (e.g., norethisterone or levonorgestrel) are more androgenic than third- (e.g., desogestrel) or fourth-generation (e.g., drospirenone) progestins but, as a consequence, are more able to oppose the adverse (inducing) effects of estradiol on the liver and are less likely to result in VTE. Finally, individuals can show 20-fold differences in the blood level achieved with the same form of estrogen, so one must be prepared to change doses or preparations if necessary after soliciting reports from the patient about side effects, adverse effects, or lack of efficacy.

Table 34.39–1.
The Following Conditions Constitute Risk Factors or Contraindications* to Initiating Treatment with Estrogen

Women with a history of carcinoma of the breast*, or women with a family history of the following: premenopausal breast cancer or bilateral breast cancer in a first-degree relative; multiple family members (greater than three relatives) with postmenopausal breast cancer
Women with a history of uterine cancer*, endometriosis, ill-defined pelvic lesions*, particularly undiagnosed ovarian enlargement, undiagnosed vaginal bleeding*

(Active thrombophlebitis or thromboembolic disorders, or history of ischemic cardiac disease, pulmonary embolism, retinal thrombosis, or thrombophlebitis)*; (*risk factors for thromboembolic phenomena include cigarette smoking, varicose veins, prolonged periods of immobilization [including prolonged travel], and active heart disease*).

Known or suspected pregnancy*: Estrogens may cause fetal harm when administered to a pregnant women

Known hypersensitivity to estrogen or progestin (if prescribed) or the excipients (inactive compounds) contained within these medications. For example: Provera–calcium stearate, corn starch, lactose, mineral oil, sorbic acid, sucrose, talc; Alora–sorbitan monooleate, acrylic adhesive

History of cerebrovascular disease (stroke), epilepsy, hypertension, hypercalcemia

Cholecystitis or pancreatitis

Recurrent migraine headaches

Diabetes mellitus

History of familial hyperlipoproteinemia

Porphyria

Despite current concerns regarding ET and the requirement of adjunctive progestins for endometrial protection in women with an intact uterus, the specificity of actions of some of the newer selective estrogen receptor modulators (SERMS) and selective androgen receptor modulators (SARMS) (and hence the promise of separating therapeutic from toxic effects) suggests that estrogen receptor activators may occupy a useful niche in the future psychopharmacologic armamentarium. The recent introduction of tissue-selective estrogen complexes (TSECs), which combine estrogen with a SERM (some of which may be unable to enter the CNS), also holds promise for the delivery of individualized ET for those women who choose to employ hormonal therapies. Indeed, TSECs may have advantages over several SERMs (i.e., raloxifene and tamoxifen) since recent trials have documented that some TSECs (e.g., conjugated estrogen + bazedoxifene) are associated with a lower risk of VTE. These newer therapies could avoid the need for the addition of progestins (and the potential associated adverse effects) and could lead to therapies designed to optimize estrogen receptor activity. Further, there is emerging data that estradiol may be useful in the prevention or treatment of postpartum depression, a common psychiatric illness seen following approximately 10 percent of pregnancies.

Postpartum Depression. Despite the absence of endocrine abnormalities in this disorder, women with PPD show an enduring abnormal mood response to reproductive hormones. A previous study demonstrated that exposure of euthymic women with a history of postpartum depression to high doses of estradiol and progesterone followed by abrupt hormone withdrawal produced depression not seen in women lacking a history of postpartum depression. In parallel, supplemental reproductive steroids have been administered during the immediate postpartum in an attempt to prevent or treat postpartum

affective disorders. An open trial in women at risk for puerperal psychosis demonstrated that high-dose estrogen treatment resulted in a lower than expected 1-year recurrence rate (9 percent compared with an expected 35 to 60 percent without prophylaxis). Varying doses of estrogen (Premarin ranging in dose from 0.625 to 10 mg/day or intravenous estradiol 25 mg q8h) were administered immediately postpartum and then tapered over 4 weeks. It was suggested that estrogen administration could attenuate the rapid puerperal drop in estradiol levels, thereby reducing the negative impact of the postpartum "estrogen withdrawal state" on mood. In a follow-up study, investigators tested the suggestion that estradiol withdrawal caused postpartum depression in a double-blind, placebo-controlled study of estradiol in 61 women who developed major depression within 3 months of delivery. Eighty percent of the patients receiving estradiol (estrogen patch) experienced a significant reduction in depression severity after 3 months of treatment, compared with 31 percent of the placebo-treated group. Decreased mood symptoms on ET were observed in women regardless of concurrent antidepressant use, and estrogen's antidepressant effects were rapid and observed after 2 to 3 weeks of treatment. A similar rapid response to estradiol was also recently reported in an open label trial of sublingual estradiol, similar to the timing of the response to estradiol in perimenopausal depression. Double-blind, placebo-controlled trials of estradiol in the treatment of postpartum depression are ongoing and will help define the role of estradiol monotherapy in PPD.

Androgen Administration in Midlife Depression

Several investigations have suggested that the change in mood, cognition, and libido during the perimenopause/postmenopause may reflect deficiencies in androgens rather than (or in addition to) estrogens. Indeed, midlife in both men and women is characterized by a steady decline in the production of androgens such as dehydroepiandrosterone (DHEA) and androstenedione, which are mostly of adrenal origin yet contribute up to 50 percent to circulating androgen levels (testosterone, dihydrotestosterone) in women. Nonetheless, the definition of low testosterone levels is severely compromised by the current inability to accurately measure peripheral levels of testosterone in women or hypogonadal men (similar to the methodologic obstacles for measuring low estradiol levels). These assay limitations preclude the clear identification of men or women in whom androgen secretion is deficient (and in whom testosterone therapy would be indicated). Indeed, recent clinical practice guidelines recommend against making a diagnosis of androgen deficiency in women because of both the lack of a well-defined syndrome and the unavailability of reliable data correlating peripheral androgen levels with specific signs or symptoms. Moreover, the practice guidelines discourage the prescription of

either DHEA or testosterone therapies in women because there are only limited data supporting therapeutic benefits for the targeted symptoms and there are no long-term studies examining the risks of androgen therapy. That said, androgen therapy clearly benefits both mood and sexual function/libido in males who are clinically hypogonadal. Further, several investigators and a recent meta-analysis have shown that androgens improve a variety of elements of sexual function (desire, arousal, fantasies) when administered as sole treatment (ovariectomized women) or in combination with estradiol (postmenopausal women). Medical literature dating back to the isolation of testosterone in 1935 is replete with reports of the antidepressant efficacy of testosterone, androgen/anabolic steroids, and adrenal (and ovarian) androgens like DHEA. While most of these reports were uncontrolled, one study in ovariectomized women again demonstrated the superiority of testosterone to placebo in the mitigation of depressive symptoms. If androgens can improve mood, are they effective only in the context of clinically demonstrable androgen deficiency, the demonstration of which is severely limited, as noted above, by the inability to accurately measure low androgen levels? Further, even if shown to "improve well-being" (as was DHEA in older men and women), is androgen treatment effective in clinically significant affective disorders? A study that attempted to answer these questions entailed administration of the prevalent but weak androgen DHEA in a double-blind, placebo-controlled fashion to men and women with midlife-onset major and minor depression. Administration of 90 mg of DHEA for 3 weeks significantly decreased symptoms of depression compared to baseline and was significantly superior to effects seen with placebo. About 50 percent of subjects showed a beneficial effect, which was predicted neither by baseline DHEA (or its metabolites, testosterone and estradiol) nor by the change in hormonal measures following treatment. Nonetheless, this trial was small and DHEA was administered for only 6 weeks. Indeed, a recent meta-analysis concluded that in women with normal adrenal function the administration of DHEA is not indicated for complaints of either depressed mood or decreased sexual interest or arousal. This meta-analysis, however, does not answer the question of DHEA's efficacy in clinically significant depression since the majority of the reviewed studies were not sufficiently powered to evaluate DHEA's effects in depression. As should, by now, be clear, this, like other forms of hormone therapy, has attendant nonuniform benefits and risks. DHEA, for example, may improve bone mineral density with chronic administration, thus helping to prevent age-related osteopenia (although with the exception of small improvements in lumbar spine density in women, a recent meta-analysis found little evidence that DHEA had significant effects on bone density in women). It has been suggested, however, that DHEA administration, while not increasing total plasma testosterone levels in men, might be concentrated in the prostate, where

local conversion to testosterone could accelerate the growth of androgen-dependent tumors.

FUTURE DIRECTIONS

There is little question that reproductive hormones can regulate mood and that manipulations of reproductive hormones can, in some instances, dramatically alter the course and expression of affective illness. It is equally clear that these hormonal effects are not universal and appear in subgroups of individuals who appear differentially sensitive to these central actions of reproductive steroids. A major task for the future will be to identify the mediators of this differential sensitivity. Identification of the genetic or other predictors of vulnerability to reproductive endocrine–related mood disorders would assist the prediction of those who would respond to reproductive therapies and those who might be at risk for adverse effects. Indeed, the main constraint on the effective incorporation of reproductive hormonal modulators into the psychotherapeutic armamentarium as primary psychotropic agents or adjunctive therapies (e.g., in those who experience incomplete responses to other psychotropic agents) is the inability to predict the likelihood of adverse medical outcomes (e.g., breast cancer). Additionally, it is now clear that direct assays of sex steroids in populations with low levels of sex steroids (i.e., postmenopausal women, elderly men, and young children) are no longer acceptable evidence to confirm endocrine "deficiency" states, although even if accurate, single plasma hormone levels will not detect the pharmacodynamic differences across individuals that may result in marked phenotypic variation. The specificity and complexity of the actions of individual hormonal agents preclude generalization about the likely therapeutic or adverse outcome of exposure to a given hormone. Slight structural differences between the hormonal agents available in a given class can translate into dramatic differences in cellular and physiologic effects (and hence efficacy and risk), as can the timing of administration of these agents (i.e., their continuous or discontinuous administration). While generating current uncertainty, the specificity of actions of individual hormonal preparations, steroidogenic enzyme inhibitors, and steroid receptors antagonists creates extraordinary opportunity for the development of tissue-specific pharmacologic agents. The SERMs already available, for example, not only possess the beneficial effects of estradiol in some tissues (e.g., bone) but additionally block the potentially harmful effects of estradiol in other tissues (e.g., breast). Current knowledge, then, of tissue-specific coregulators will increasingly permit the design of reproductive agents that select and restrict the tissues affected and the actions elicited. In this fashion, the goal of psychopharmacologic precision will be greatly advanced.

▲ 34.40 Drug Treatment of Erectile Disorder

CARIDAD PONCE MARTINEZ, M.D., FADI HADDAD, M.D., AND ANITA H. CLAYTON, M.D.

INTRODUCTION

Erectile dysfunction (ED), also referred to as impotence, is defined as the inability to obtain or maintain an erection sufficient for sexual activity. The DSM-5 lists ED as erectile disorder (Table 34.40–1), while the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) codes it as failure of genital response. A man with lifelong erectile disorder is not able to obtain an adequate erection since becoming sexually active after puberty. In acquired erectile disorder, a man

has disturbance of erectile function after a period of relatively normal sexual function. The disorder can be situational, in that it is specific to certain types of stimulation, situations, or partners, or it can be generalized. Severity of the disorder can be mild, moderate, or severe, depending on the level of distress the symptoms cause in the individual.

Table 34.40–1.
DSM-5 Diagnostic Criteria for Erectile Disorder

A. At least one of the three following symptoms must be experienced on almost all or all (approximately 75–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
   1. Marked difficulty in obtaining an erection during sexual activity.
   2. Marked difficulty in maintaining an erection until the completion of sexual activity.
   3. Marked decrease in erectile rigidity.
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
C. The symptoms in Criterion A cause clinically significant distress in the individual.
D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify type: Lifelong or acquired type
Specify type: Generalized or situational type
Specify severity: Mild, moderate, or severe

The diagnostic criterion of duration of at least 6 months is new to the DSM-5, although no systematic research has validated this criterion. In fact, the International Society for Sexual Medicine's 2010 summary of recommendations on sexual dysfunctions in men establishes that a 3-month duration of symptoms is sufficient to make a diagnosis. In cases of trauma or surgically induced ED, the diagnosis can be made even sooner.

Erectile disorder is the most common type of sexual dysfunction in men, with an estimated prevalence in the US male population aged 20 years or older of 18.4 percent, equivalent to more than 18 million men. In the Massachusetts Male Aging Study, which surveyed approximately 1,700 men longitudinally, the prevalence of all ED was 39 percent in 40-year-old men and 67 percent in men aged 70 or older. After adjusting for age, the strongest correlates for ED were markers of cardiovascular disease—hypertension, diabetes, and heart disease. It is important to note that ED does not occur in all aging men. Instead, good health and the availability of a sexual partner are often stronger factors in determining satisfactory sexual function.

Normal erectile function involves psychological and biological processes. In general terms, erectile disorder can be classified as

psychogenic, organic, or mixed. Psychogenic factors such as performance anxiety, traumatic experiences, relationship problems, moral prohibitions, and psychosocial stressors can negatively impact erectile function. This type of erectile disorder tends to occur on a situational basis, has a sudden onset, and concurrently, men can experience normal erections with masturbation, at night, or upon awakening. Organic processes can be vascular (e.g., arterial insufficiency, venous leakage), neurological, endocrine (e.g., hypogonadism, hyperprolactinemia), substance induced, or due to a systemic illness. In these cases, ED tends to be more insidious in its onset and erections are deficient in most contexts (masturbation, nocturnal).

A vasculogenic etiology is the most common among organic etiologies of erectile disorder. Current evidence suggests a strong correlation of cardiovascular disease and ED, with a common pathophysiological basis of endothelial dysfunction, inflammation, and low testosterone. ED is also associated with coronary heart disease, stroke, and all-cause mortality. The presence of vasculogenic ED in young men can be a particularly early indicator of future cardiovascular disease, and these patients should receive an appropriate cardiovascular workup for risk stratification.

Most cases of ED have both biological and psychogenic features. Even in cases of clear organic etiology like perineal trauma, impaired sexual function can result in psychological consequences such as low self-esteem, low self-confidence, and even anxiety or depressed affect, which can further exacerbate the dysfunction. Involvement of sexual partners during evaluation and treatment is important in examining their expectations for diagnosis and treatment.

Risk factors for ED can be examined in accordance with etiology. Some neurological disorders (e.g., multiple sclerosis, stroke, Alzheimer disease) are associated with ED, and the risk of nerve injury leading to ED is very high in patients undergoing radical pelvic surgery. Endocrine risk factors include hypogonadism, hyperprolactinemia, and hypothyroidism. Some risk factors for vasculogenic ED are atherosclerosis, hypertension, hyperlipidemia, obesity, smoking, diabetes mellitus (DM), and pelvic irradiation. Among men with DM, 50 to 75 percent develop ED; the prevalence of ED in diabetics is three times that seen in nondiabetics. Many substances can cause or contribute to ED. The most common medications are antiandrogens, antihypertensives (thiazide diuretics, beta blockers, calcium channel blockers), antiarrhythmics (e.g., digoxin), and many psychotropic drugs (tricyclic antidepressants, selective serotonin reuptake inhibitors [SSRIs], phenothiazines, and butyrophenones). Use of recreational, illegal, or controlled substances such as marijuana, alcohol, cocaine, and opiates may also increase risk of impaired erectile function.

A comprehensive diagnostic interview is an important feature in an evaluation for erectile disorder. Information about psychiatric history,

medical and surgical history, sexual history, family history, and psychosocial history including habits and lifestyle should be obtained. Validated self-administered questionnaires can be used to aid the diagnostic process, and the most well known of these is the International Index of Erectile Function (IIEF). A detailed sexual history provides information about the extent of the disorder (duration, context, severity) and also helps to differentiate erectile disorder from other types of sexual dysfunction, such as hypoactive sexual desire disorder or premature ejaculation. The goal of such an assessment is to determine the presence of causes or risk factors for erectile disorder.

In addition to the interview, an evaluation for ED includes a general physical examination with particular emphasis on the nervous, vascular, and genital systems. Laboratory studies are used to determine endocrine causes of ED and also to identify associated comorbid conditions like hypercholesterolemia or DM. The International Society for Sexual Medicine recommends ordering tests to measure fasting glucose, HbA1c, lipids, and total testosterone levels. Supplementary tests such as Doppler ultrasonography or nocturnal penile tumescence are often reserved for specialists, and do not generally provide information that would alter the treatment course.

TREATMENT

Lifestyle Changes

There is a clear association between cardiovascular disease and increased risk of ED, therefore management of cardiovascular risk factors may improve sexual function. The adoption of a Mediterranean diet, weight loss, exercise, and smoking cessation are all beneficial. Eliminating illicit substance use may also improve erectile function. In men with obstructive sleep apnea (OSA), treatment with CPAP is associated with some improvement in sexual function. Finally, gastric bypass surgery can increase testosterone levels and therefore improve sexual function in men with morbid obesity.

Phosphodiesterase-5 Inhibitors

Nitric oxide (NO) mediates tumescence by increasing the levels of cGMP, which in turn leads to smooth muscle relaxation in the corpus cavernosum that allows the penis to dilate and admit blood.

PDE-5 is an enzyme that catabolizes cGMP. Phosphodiesterase-5 (PDE-5) inhibitors competitively inhibit the PDE-5 enzyme and increase intracavernosal cGMP thereby leading to an increase in both the number and duration of erections in men with ED.

Sufficient psychological and environmental cues that lead to sexual arousal and stimulation are required for PDE-5 inhibitors to work.

An evaluation of the underlying cause of ED is necessary prior to initiation of PDE-5 inhibitor treatment. These agents are contraindicated in men treated with nitrates and are to be used cautiously in men treated with alpha-adrenergic blockers.

Treatment response seems to be largely dependent on proper use and administration (Table 34.40–2).

Sildenafil. The efficacy of sildenafil in treating ED has been demonstrated by numerous clinical trials. A meta-analysis of 27 trials in 6,659 men with ED showed a marked difference in the percentage of successful sexual intercourse between sildenafil and placebo (57 vs. 21 percent, respectively).

Sildenafil was also found effective for treatment of ED in the setting of various medical conditions including DM, prostate cancer treatment and parkinsonism.

Sildenafil could also have psychological benefits in men with ED as shown by improvement in the mean Self-Esteem subscale score of the Self-Esteem and Relationship (SEAR) questionnaire (a psychometric instrument specific to ED).

Sildenafil should be taken 1 hour prior to a planned sexual encounter. The dose ranges between 25 and 100 mg with 50 mg being the usual dose. Lower dosing is recommended for use in geriatric men (older than 65 years), liver disease, and renal impairment. The duration of action is on average 4 hours.

Vardenafil. Vardenafil shares similar structure and pharmacokinetic profile with sildenafil. It is also efficacious in ED secondary to DM and nerve-sparing prostatectomy. An advantage is its availability in an oral disintegrating form with a more rapid onset of action. The dose range is 10 to 20 mg. Nothing is known about potential transfer of the product through oral or orogenital contact after use of the orally disintegrating formulation.

Tadalafil. Tadalafil is structurally distinct from sildenafil and vardenafil. There are no head-to-head comparisons with other PDE-5 inhibitors but it appears to be effective in the treatment of ED, with a longer duration of action.

Table 34.40–2.
Phosphodiesterase Type 5 (PDE-5) Inhibitors

Medication	Clinical Use	Dosing	Drug Interactions
Sildenafil	Use as needed for treatment of organic	Taken 1 hour before sex and effective for up to 4 hours Dose: 50 to 100 mg 25 mg is recommended in geriatric	Strong inhibitors of CYP3A4 (erythromycin, ketoconazole, itraconazole, grapefruit and its juice) elevate sildenafil

	or psychogenic ED	patients, patients with renal impairment, hepatic failure, use of potent CYP3A4 inhibitors and alpha-blocker therapy	concentrations
Vardenafil	Same as sildenafil	Taken 1 hour before sex and effective up to 4 hours Dose 10 to 20 mg 5 mg is recommended in geriatric patients, patients with renal impairment, hepatic failure, use of potent CYP3A4 inhibitors, and alpha-blocker therapy Oral disintegrating tablet (ODT) dose is 10 mg	Same as sildenafil
Tadalafil	Same as sildenafil	Duration of action is up to 36 hours Dosing: 10 to 20 mg as needed before sex **or** Daily treatment 2.5 to 5 mg once daily Dose adjustment is needed for renal or hepatic impairment	Same as sildenafil
Avanafil	Same as sildenafil	Onset of action is 15 to 30 minutes Dosing: 100 to 200 mg taken at least as 15 minutes before sexual activity 50 mg dose should be taken 30 minutes before sexual activity	Avanafil should be avoided with CYP3A4 inhibitors Grapefruit and grapefruit juice should be avoided within 24 hours of use

Avanafil. Avanafil is a new agent, currently approved in the United States and Europe for treatment of ED. Compared to other agents of the same class, it is more selective to PDE-5 and has a more rapid onset of action. Dosing ranges between 50 and 200 mg. It should be administered 30 minutes prior to sexual activity at 50 mg, while the 100 and 200 mg can be taken 15 minutes in advance.

ADVERSE EFFECTS AND PRECAUTIONS. All PDE-5 inhibitors share a similar side effect profile which is related to their vasodilatory properties. Common side effects include flushing, headache, and dyspepsia.

Sildenafil can cause “blue vision” in approximately 3 percent of men. This is caused by a cross-reactivity of the drug with the PDE-6 inhibitor present in the retina. Blue vision is transient and disappears spontaneously. This side effect has not been reported with other PDE-5 inhibitors.

Rare cases of nonarteritic anterior ischemic optic neuropathy were reported in men taking sildenafil and tadalafil.

Rare reports have indicated a risk of sudden unilateral hearing loss with sildenafil, vardenafil, and tadalafil. This side effect occurred within the first 24 hours of drug administration and is temporary in approximately one-third of the patients. No direct causal relationship has been demonstrated but the FDA requires labeling of all PDE-5 inhibitors to include this risk. It

would be recommended for providers to warn patients about this risk during the first 24 hours of treatment.

DRUG INTERACTIONS. All PDE-5 inhibitors are contraindicated in men on nitrates. Concurrent use with alpha-adrenergic antagonists causes symptomatic hypotension. Drugs that block the CYP3A4 metabolic pathway can prolong the half-life of sildenafil and thus should be avoided.

CHOICE OF DRUG. Current data indicates that all PDE-5 inhibitors are of equivalent efficacy and side-effect profile, therefore choice of agent is based on patient preference, cost, and desired duration of action.

CONCERN OVER RECREATIONAL USE. Sildenafil use leads to a marked reduction in the postejaculatory refractory time, thus, men may be capable of having a second erection in a shorter time frame after ingestion. This leads to recreational use of sildenafil. There are case reports of stroke in men taking high-normal doses (100 mg) of sildenafil.

Supplements Containing PDE-5 Inhibitors. One-third to one-half of over the counter natural supplements marketed to enhance sexual performance, contain prescription strength doses of sildenafil or tadalafil. The FDA has issued a warning against use of the above supplements for concern over severe hypotension in men on nitrates.

Testosterone

Testosterone regulates sexual desire and modulates almost every component involved in erectile function. There is significant overlap between hypogonadism and ED. The diagnosis of testosterone deficiency is made on the basis of the clinical symptoms of hypogonadism and consistently subnormal serum testosterone concentrations (below 8 nmol/L or 231 ng/dL) at 8 to 10 AM on three occasions.

Testosterone improves libido in men with low testosterone levels, but does not necessarily improve ED. As adequate testosterone levels are necessary for NO function, the addition of testosterone to PDE-5 inhibitors may improve erectile function in hypogonadal men who did not respond to initial treatment with PDE-5 inhibitors.

Testosterone is available in different formulations and preparations including oral tablets, transdermal gel/solution or patch, buccal application, subcutaneous implants, and intramuscular injections. Dosing varies depending on the formulation. Dosing is gradually titrated to restore the serum testosterone concentration to a normal range of 13.9 to 27.0 nmol/L or 400 to 700 ng/dL. The timing of serum testosterone measurement varies depending on the preparation used. Monitoring serum testosterone should be done 2 to 3 months after treatment initiation and

after changing the dose. Monitoring is then extended to every 6 to 12 months once the dose is stabilized.

Testosterone is contraindicated in men with a history of prostate cancer.

Common side effects of testosterone therapy include exacerbation of benign prostate hyperplasia, worsening of OSA, erythrocytosis, venous thromboembolism, and skin irritation in patients using the transdermal formulation. Unintentional transfer of transdermal testosterone products through contact should be avoided.

Clinical Vignette 1

Mr. B. is a 55-year-old man with medical history of obesity, hypertension, and hyperlipidemia, and psychiatric history of OCD who had been treated with a high dose SSRI and cognitive behavioral therapy for many years. In the past year, he developed generalized ED, yet there had been no change in his medications or in his long-term relationship. Medical workup revealed abnormal lipid profile, elevated HbA1C and low testosterone. Transdermal testosterone treatment was initiated and his dose was titrated over 3 months to achieve normal serum testosterone. There was a minimal response in terms of his ED with normalized testosterone levels. Tadalafil 5 mg daily was added to his regimen with good response. He was referred to his endocrinologist for more intensive management of his metabolic issues.

Intracavernous Injections

Alprostadil is a synthetic formulation of the endogenous prostaglandin E1, injected locally into the corpora cavernosa. An initial dose of 5 to 10 μg is recommended in vasculogenic males, and a smaller dose in the case of neurogenic ED (2.5 μg). The first intracavernosal agent to be approved by the U.S. Food and Drug Administration (FDA) for treatment of ED, alprostadil, acts by increasing levels of cyclic AMP within the corporal smooth muscle, causing muscular relaxation. This reaction lowers the vascular resistance inside the corpora cavernosa, increasing blood flow to the penis, and resulting in an erection. The erection can occur even in the absence of sexual stimulation. Alprostadil is considered efficacious, relatively safe, and fast acting (2 to 3 minutes), but high patient discontinuation rates indicate some concerns regarding long-term tolerability. Ideal candidates for treatment with intracavernous therapy include those who fail or have a contraindication to first-line treatments, such as those concomitantly using nitrates; patients who desire a rapid onset of erection, and patients with insufficient improvement with oral therapy. Possible adverse events include penile pain, priapism (rare), and penile fibrosis and curvature (uncommon, related to chronic injections). Intracavernous injection of alprostadil is contraindicated in patients with conditions that predispose them to priapism (e.g., sickle cell anemia, multiple myeloma, leukemia), severe penile fibrosis, vision problems that limit safe self-administration of injections, and use of monoamine oxidase

inhibitors which would limit use of phenylephrine if priapism occurred.

Alprostadil is also available for intraurethral administration (medicated urethral system for erection, MUSE), and the literature reports success rates of 43 to 69 percent. This form of administration is less invasive and has superior tolerability, although there are many reports indicating lower efficacy than intracavernous injection. Disadvantages include systemic side effects (hypotension, syncope), pain, and cost. Other medications often used in combination with alprostadil include papaverine, phentolamine, and vasoactive intestinal polypeptide. The combination of prostaglandin E, phentolamine, and papaverine (Trimix) has been found to be particularly effective.

Treatment Options without FDA Approval

Yohimbine. Yohimbine has been used for many decades in the treatment of ED. It is an alpha-2 adrenoceptor antagonist with central and peripheral effects, although its site of action in producing an erection is probably not peripheral. Placebo-controlled trials on patients with different types of erectile disorder have shown at most, a modest effect. Due to conflicting evidence, yohimbine is currently not recommended in the management of erectile disorder.

Melanocortin Receptor Agonists. The melanocortin-4 receptor modulates erectile function and sexual behavior, as supported by evidence in studies of mice, rats, and primates. In humans, bremelanotide (not yet approved for any indication) has been studied in the treatment of male and female sexual dysfunction, including ED. By acting on receptors in the hypothalamus, bremelanotide stimulates peripheral production of NO in the corpora cavernosa of the penis, leading to an erection. Interestingly, this mechanism of action allows initiation of erections even in the absence of visual sexual stimulation, and minimal external stimulation, unlike other pharmacological treatments. Additional advantages include low incidence of side effects, rapid onset of action, short half-life, and because it does not cause systemic vasodilation, it could be used with nitrates. Some phase 2 studies have reported efficacy and safety of bremelanotide as monotherapy, and in combination with sildenafil in the treatment of male erectile disorder.

Apomorphine. Apomorphine is a nonselective dopamine agonist that acts within the central nervous system to enhance natural signals that occur during sexual stimulation. In a sublingual preparation, it has been approved for use in the treatment of erectile disorder in Europe, but not the United States. Its rapid onset after administration (71 percent erections achieved within 20 minutes) allows for utilization on demand, usually at doses of 2 to 3 mg. Side effects may include mild to moderate nausea,

headache, dizziness, and in rare cases, vasovagal syncope. Apomorphine can be used with nitrates. In 28.5 to 55.0 percent of the cases, men are able to achieve an erection sufficient for intercourse. However, studies comparing its efficacy with that of sildenafil demonstrate significantly lower efficacy and patient satisfaction rates. Therefore, current use is limited to patients with mild/moderate or psychogenic erectile disorder.

Mechanical and Surgical Treatment

Vacuum constriction devices apply continuous negative pressure to the penis, drawing blood into the corpora cavernosa, which is then retained by an elastic band applied at the base of the penis. Efficacy can be as high as 90 percent regardless of the etiology of erectile disorder. Associated side effects include pain, numbness, bruising, and delayed ejaculation. Advantages include its use on demand and low cost of the device. One relative contraindication is anticoagulation therapy. This form of treatment can be beneficial for patients who have failed oral PDE-5 treatment and refuse intracavernosal injections.

Vascular surgery, including arterial bypass and venous ligation surgery, can improve vasculogenic erectile disorder. Given that such procedures target the etiology of the erectile disorder, in appropriate candidates, the surgery can be curative.

Surgical implantation of an inflatable or malleable (semi-rigid) penile prosthesis is an invasive and irreversible form of treatment, generally reserved for patients who have failed other types of treatment (third-line treatment). Most men prefer implantation of the inflatable three-piece device, as it provides a more “natural” erection. If successful, the rates of satisfaction are high, up to 70 percent. Adverse events include prosthesis infection (2 to 4 percent of cases), penile fibrosis, and mechanical failures. Mechanical failures can be as high as 50 percent by 10 years.

PSYCHOTROPIC-INDUCED ERECTILE DISORDER AND ITS MANAGEMENT

The most studied psychotropics with regards to impact on sexual function are antidepressants, given serotonin’s role in sexual function. SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) can negatively affect all stages of the male sexual response cycle. Nefazodone and mirtazapine have lower rates of sexual dysfunction than SSRIs. Bupropion, a dopamine and norepinephrine reuptake inhibitor; and buspirone, an agonist of 5-HT1A receptors, are not associated with sexual dysfunction and can be used as augmenting agents to treat antidepressant-induced sexual dysfunction, or as alternative agents to treat depression in men with ED. There is evidence supporting the use of PDE-5 inhibitors in men for treatment of ED induced by antidepressant medications.

Unlike antidepressants, the data on antipsychotic-induced sexual

dysfunction is scarce. Antipsychotics cause ED via dopaminergic antagonism within the tuberoinfundibular system, which causes elevation in plasma prolactin levels. Head-to-head comparisons are unavailable, but studies suggest that drugs that cause more hyperprolactinemia like risperidone and the conventional antipsychotics are more likely to cause ED, as compared to olanzapine, clozapine, quetiapine, and aripiprazole.

There is insufficient evidence regarding the treatment of antipsychotic-induced ED. Some authors have proposed dose reduction and switching to a prolactin-sparing second-generation antipsychotic as possible strategies. PDE-5 inhibitors may also be of benefit.

Clinical Vignette 2

Mr. J. is a 30-year-old man with no active medical problems and history of MDD whose initial treatment with a maximum dose of SSRI achieved a partial response. Risperidone 1 mg was added as an inexpensive augmenting agent resulting in a full remission of his depressive symptoms. Within a month he developed ED. No change in the relationship with his wife preceded the ED but he began to question his attractiveness to his wife and began avoiding sex. Despite his wife's supportive response to his ED, he developed anxiety associated with sexual activity and behavioral avoidance. He did not spontaneously report this side effect to his psychiatrist until questioned directly. The onset of ED seemed to correlate with the addition of risperidone to the high dose of SSRI. Interpersonal issues appeared to be the result of the ED rather than the cause. Sildenafil was added at 50 mg prior to sexual activity. At followup Mr. J. reported complete resolution of the ED and remained on the same medication regimen.

FUTURE DIRECTIONS

There are a variety of drugs currently under investigation for the treatment of ED. Many of these have novel therapeutic targets, including vasorelaxation (associated with the NO-cGMP pathway or independent from it), inhibition of vasoconstriction (e.g., Rho-kinase inhibitors), anti-inflammatory and anti-fibrotic therapies, regeneration products, and central nervous system targets.

Low-intensity extracorporeal shock wave (LI-ESW) therapy in the treatment of erectile disorder appears to function by recruiting endogenous stem cells and increasing expression of vascular endothelial growth factor, thereby stimulating angiogenesis. It is currently available for clinical use in countries like Israel and Canada, but not in the United States.

Additional avenues for treatment in the future include drug-eluting peripheral stent systems (Zotarolimus-Eluting Peripheral Stent System) in patients with internal pudendal artery stenosis, tissue engineering for the replacement or repair of corporal bodies, topical application of nanoparticles to achieve erection, and penile implants with drug delivery apparatus. Gene therapy uses transfected genetic material to correct molecular defects. The penis provides an ideal target tissue for gene therapy because of its external location and internal structure. Genes encoding vasoactive intestinal peptide, brain-derived neurotrophic factor,

and maxi-K (calcium-sensitive potassium) channels have been proposed targets, among others. To date, there has been a single phase I clinical trial in 21 men regarding the maxi-K channels, with encouraging results.

AUTHORS' RECOMMENDATIONS

The evaluation of male erectile disorder includes a thorough interview, with focus on medical, surgical, sexual, and psychosocial history. Vasculogenic ED is the most common type of organic erectile disorder, so a cardiovascular workup should be completed in patients with vascular risk factors.

- PDE-5 inhibitors should be used as first-line treatment for ED in men with normal testosterone levels.
- Testosterone replacement should be the first-line treatment in hypogonadal men with ED.
- In hypogonadal men who also have a concomitant vascular or metabolic disorder, testosterone treatment alone might be insufficient to restore erection; combination treatment with a PDE-5 inhibitor is recommended.
- Additional treatment options for men who do not respond to PDE-5 inhibitors (or have a contraindication to use) include intracavernous injections, intraurethral administration, and mechanical/surgical treatment.
- Augmentation with bupropion or buspirone may be an option in patients whose depression responded well to an SSRI/SNRI and are experiencing significant ED.
- In patients who did not fully respond to SSRI/SNRI treatment and have significant ED, switching to a medication with less ED risk (mirtazapine, buspirone, bupropion) may be the appropriate next step in treatment.
- The treatment for erectile disorder should be individualized, taking into account patient and partner's preferences, comorbid conditions, likely etiology of ED, and concomitant medications.

▲ 34.41 Vilazodone

LOURDES ILLA-SANCHEZ, M.D.

INTRODUCTION AND HISTORY

Vilazodone (VIIBRYD) is a novel dual-acting serotonergic antidepressant that combines the effect of an SSRI with 5HT1A-receptor partial agonist activity. It was approved by the FDA for the treatment of adults with major depressive disorder (MDD) on January 21, 2011, after nearly a decade of development. First developed by Merck and GlaxoSmithKline in 2001, development stopped in 2003 after several unsuccessful phase II trials. Development resumed in 2004 by Genaissance, later purchased by Clinical Data, Inc. A new drug application was submitted on March 22, 2010, and the FDA issued a new U.S. Patent on 11/16/10. Based on two successful phase III trials, vilazodone was approved by FDA in January of 2011. Clinical Data, Inc. was later purchased by Forest Laboratories, Inc. in February of 2011.

Chemistry

Vilazodone's chemical structure is 2-benzofurancarboxamide, 5-[4-[4-[5-cyano-1H-indol-3-yl]butyl]-1-piperazinyl]-, hydrochloride (1:1) (Fig. 34.41–1). Its molecular weight is 441.535. It was designed to have combined activity as a SSRI and an 5HT1A receptor agonist by combining indole-butyl-amine and chromenonyl-piperazine structural elements into a single molecular entity.

FIGURE 34.41–1. Chemical structure of vilazodone.

Pharmacological Actions

Pharmacokinetics. Vilazodone's activity is due primarily to the parent drug. Its pharmacokinetics are dose-proportional, and peak concentrations occur at 4 to 5 hours after administration. It has a terminal half-life of about 25 hours and achieves steady state in approximately 3 days. Vilazodone's absorption is largely dependent on food intake, with a reported bioavailability of 72 percent when administered with food. The drug is widely distributed and is 96 to 99 percent protein bound. Vilazodone is extensively metabolized, with only 1 and 2 percent recovered unchanged in urine and feces, respectively. It is primarily metabolized by CYP3A4, with minor contributions from CYP2C19 and CYP2D6.

Pharmacodynamics. Vilazodone exhibits a unique dual mechanism of action. Like SSRIs, it blocks the reuptake of serotonin, while simultaneously having partial agonist activity at the serotonin 5HT1A receptor. Due to its dual SSRI/partial 5HT1A mechanism of action, it is often referred to as a serotonin partial agonist/reuptake inhibitor (SPARI). In preclinical trials, vilazodone has been shown to bind with high affinity to the serotonin reuptake site, potently and selectively inhibit the reuptake of serotonin and bind selectively with high affinity to 5HT1A receptors. In animal models, adding 5HT1A partial agonism to SSRIs results in more rapid and robust elevations of 5HT levels than seen with SSRIs alone. While this mechanism has been thought to possibly result in rapid onset of antidepressant efficacy, this has not to date been confirmed in human clinical trials. Taken without food, vilazodone's blood concentrations can be reduced by as much as 50 percent when compared to the fed state, which may result in reduced effectiveness in some patients. For this reason, vilazodone should be taken with food.

Clinical Drug Studies

Design. Vilazodone's development program consisted of 24 phase I trials, 5 placebo-controlled phase II trials, and 3 phase III trials (2 double-

blind, placebo-controlled 8-week trials and 1 open-label 52-week trial). Despite important data provided by these studies, a few issues regarding study design deserve mentioning. The first relates to the phase II dosing strategies (Table 34.41–1). Only two of the phase II trials used a fixed dose titration schedule, with a maximum dose of 20 mg/day. These two trials showed a trend for a decrease in depressive symptoms at 20 mg/day, suggesting a possible treatment effect for the vilazodone 20 mg/day group. The other three phase II trials used flexible dosing strategies. While two of the studies used doses up to 100 mg/day, the flexible-dose designs limited their usefulness in providing dose-response information. The phase III trials design used vilazodone at 40 mg/day but did not include a 20 mg/day arm, despite the earlier phase II results. Additionally, three of the phase II trials included an active comparator. However, none of the active comparator drugs separated from placebo, indicating that the trials lacked assay sensitivity. Another issue involves the design of the only long-term phase III trial, which was an open-label study and lacked a placebo-control group. To date, there have been no long-term placebo-controlled studies on vilazodone's long-term efficacy and tolerability. Phase IV trials are needed to evaluate vilazodone's long-term effectiveness and safety profile. Results from a multicenter, randomized, double-blind, placebo-controlled, relapse prevention 28-week study are expected to be published in 2015. Finally, it has been suggested that vilazodone's potential advantages may include a rapid onset of action as well as decreased sexual dysfunction due to its 5HT1A partial agonism. However, the design of the phase III studies lacked an active comparator, which would have been necessary to support both of these assertions.

Table 34.41–1.
Summary of Phase II Trials

Study	Study Design	Dosing	Vilazodone Dose/Day	Placebo/Comparator	Study Length	*N*	Ages (years)	Stu Da
244	Multicenter, randomized, double-blind, placebo-controlled	Flexible dose	20–100 mg/day	Placebo fluoxetine 20 mg/day	8 weeks	410	18–65	2/(
245	Multicenter, randomized, double-blind, placebo-controlled	Flexible dose	10–20 mg 40–60 mg 80–100 mg	Placebo Fluoxetine 20 mg/day	8 weeks	481	18–70	3/(

246	Multicenter, randomized, double-blind, placebo-controlled	Fixed dose	10 mg 20 mg	Placebo citalopram 20 mg/day	8 weeks	616	18–70	12/
247	Multicenter, randomized, double-blind, placebo-controlled	Flexible dose	5–20 mg	Placebo	8 weeks	509	18–70	12/
248	Multicenter, randomized, double-blind, placebo- and active-controlled	Fixed dose	5 mg 10 mg 20 mg	Placebo	8 weeks	1,120	18–70	12/

Interpretation of Drug Studies. The FDA's approval of vilazodone was based on results from two phase III 8-week, multicenter, randomized, double-blind, placebo-controlled studies in adults with a major depressive episode (Table 34.41–2). The phase III trials had very similar designs as well as similar inclusion and exclusion criteria. In both studies, inclusion

criteria were a score of at least 22 on the 17-item Hamilton Depression Rating Scale (HAM-D-17) and at least 2 on item 1 (depressed mood). Exclusion criteria were serious psychiatric or medical comorbidity, history of inadequate response to two consecutive antidepressants, pregnant, lactating, or planning to become pregnant. Subjects receiving another antidepressant or excluded medication underwent a washout period. Participants were 18 to 65 years old in the first trial and 18 to 70 in the second. Patients randomized to vilazodone were titrated over 2 weeks to a dose of 40 mg/day. In the first trial only, subjects who did not tolerate 40 mg/day were allowed to reduce to 20 mg/day. The primary outcome measure was the Montgomery–Åsberg Depression Rating Scale (MADRS), and secondary outcomes were the HAM-D-17, Hamilton Rating Scale for Anxiety (HAMA), Clinical Global Impressions Severity of Illness scale (CGI-S) and Clinical Global Impressions Severity of Improvement scale (CGI-I). Sexual functioning was assessed in the first study using the Changes in Sexual Functioning Questionnaire (CSFQ) and in the second study using the Arizona Sexual Experiences Scale (ASEX). In both trials, treatment response was defined as a MADRS total score reduction from baseline to endpoint of at least 50 percent and remission as a MADRS total score less than 10 at end of treatment.

The majority of participants enrolled had moderate to severe depression at baseline. In both trials, vilazodone was superior to placebo in reducing depressive symptoms as measured by the mean change in MADRS total score. Vilazodone separated from placebo at week 1 in the first trial but not until week 6 in the second trial. Whether the separation at week 1 was clinically significant is unknown. It should be noted that the effect sizes in these trials were modest (0.23 and 0.30) and that the suggestions of early response were not supported by the results.

It has been postulated that vilazodone may be particularly effective in treating patients with MDD and symptoms of anxiety, given that its unique mechanism of action includes 5HT1A agonism, a property shared by the known anxiolytic, buspirone. A post hoc analysis of the two 8-week phase III trials classified patients as having anxious depression or nonanxious depression. Among anxious depressed patients, those treated with vilazodone showed significantly greater decreases in both depression and anxiety symptoms versus those on placebo. Although these results suggest a possible role for vilazodone in the treatment of depressed patients with prominent anxiety symptoms, active comparator studies are needed to determine whether vilazodone has any advantages over other antidepressants.

Table 34.41–2.
Summary of Phase III and Phase IV Clinical Trials

Study	Phase	Study Design	Intervention Arms	Study Length	*N*	Study Dates	Results
Rickels	III	Multicenter, randomized, double-blind, placebo-controlled	Vilazodone 40 mg placebo	8 weeks	410	2/06–5/07	► Vilazodone—significantly greater improvement vs. placebo on MADRS & HAMA and CGI ► Response: vilazodone 40%, placebo 28% ► Separation from placebo at week 1
Khan	III	Multicenter, randomized, double-blind, placebo-controlled	Vilazodone 40 mg/day placebo	8 weeks	481	3/08–3/09	► Vilazodone—significantly greater improvement on MADRS, HDRS-17, HARS, CGI vs. placebo ► Separation from placebo not until week 6 ► Response: vilazodone 44%, placebo 30% ► No significant differences in remission rates
Robinson	III	Multicenter, open-label	Vilazodone 40 mg/day	52 weeks	616	12/07–5/09	► MADRS: baseline—30; weeks 8–11; weeks 52–7 ► Common AEs: diarrhea, nausea, headache; most mild–moderate ► Vilazodone—no significant effect on BP,

							pulse, weight, labs, EKGs
Croft	IV	Multicenter, randomized, double-blind, placebo-controlled	Vilazodone 40 mg/day placebo	8 weeks	505	12/11–2/13	► Vilazodone—superior to placebo on MADRS, HAM-A, CGI
NCT01473381	IV	Multicenter, randomized, double-blind, placebo- and active-controlled	Vilazodone 20 mg Vilazodone 40 mg placebo Citalopram 40 mg (assay sensitivity)	10 weeks	1,120	12/11–6/13	► Results unpublished ► Initial findings suggest significantly greater improvement for all treatment arms compared with placebo in MADRS, CGI

Whereas both placebo-controlled phase III trials demonstrated significant differences in treatment response, neither showed a significant difference in remission rates. It has been proposed that the lack of remission may be attributed to the brief nature of the phase III trials and that longer duration of treatment may be necessary to observe remission, a finding frequently encountered in clinical practice. Results from a recent randomized, placebo-controlled phase IV trial represent the first available information regarding remission rates among depressed patients treated with vilazodone. Post hoc analysis of phase IV data found significantly higher remission rates in patients treated with vilazodone (34 percent) than those in the placebo group (22 percent). In this phase IV trial, significantly more patients on vilazodone (49 percent) had early improvement at 2 weeks compared to placebo (35 percent), supporting the possibility of an early response.

Head-to-head comparator studies are needed to compare vilazodone's efficacy and side-effect profile with that of other established antidepressant agents, as existing studies are limited to comparisons with placebo. A second phase IV trial comparing vilazodone with placebo included citalopram for assay sensitivity. Although results are yet unpublished, initial findings suggest that all active treatments showed significantly greater improvement in depression and global disease severity versus placebo. Additional studies are currently underway, evaluating the safety and effectiveness of vilazodone for the treatment of MDD disorder relative

to citalopram, and comparing the effects of vilazodone, paroxetine, and placebo on sexual functioning. Data on vilazodone's efficacy and tolerability compared to other antidepressants will help delineate vilazodone's role in the treatment of MDD and ultimately assist clinicians in selecting an antidepressant agent that will meet the needs of individual patients.

Effects on Specific Organs and Systems

Vilazodone was not associated with any significant changes in laboratory tests, blood pressure, heart rate, or weight during placebo-controlled trials.

Cardiac. Vilazodone was not associated with any clinically significant effects on electrocardiograms, arrhythmias, or QTc abnormalities. Four patients treated with vilazodone in phase III trials discontinued treatment because of palpitations, compared with no patients on placebo. However, in a study of vilazodone in doses up to 80 mg/day, no QTc abnormalities were observed.

Platelets. Vilazodone may affect platelets given that SSRI blockade of platelet transport proteins leads to decreased serotonin within platelets and slight inhibition of platelet aggregation. In clinical trials, however, no increased risk of bleeding was observed in patients treated with vilazodone versus placebo, and rates of bleeding events were similar in both groups. As with all SSRIs, the product labeling includes similar language, advising caution when coadministering vilazodone with drugs that potentiate the risk of bleeding.

Hyponatremia. Although no cases of hyponatremia were reported in the clinical trials of vilazodone, hyponatremia has occurred with treatment with SSRIs and SNRIs. It is potentially lethal, and risk factors include older age, concomitant use of diuretics, volume depletion, and other medications or medical conditions causing hyponatremia. The mechanism of action is thought to be due to the development of the syndrome of inappropriate antidiuretic hormone secretion (SIADH). In patients with symptomatic hyponatremia, vilazodone should be discontinued and appropriate medical intervention instituted.

Therapeutic Indications

To date, the only FDA-recommended indication for vilazodone is for the treatment of MDD in adults. Its efficacy was established in two 8-week, randomized, double-blind, placebo-controlled trials in adult patients with a diagnosis of MDD. However, given that several SSRIs and 5HT1A agonists such as buspirone are FDA approved for the treatment of anxiety disorders such as GAD, social anxiety disorder, panic disorder, and separation

anxiety disorder, as well as obsessive compulsive disorder, PTSD, premenstrual dysphoric disorder, and eating disorders, it is reasonable to think that vilazodone may likely also prove useful in treating these conditions. Several clinical trials are currently underway to evaluate vilazodone's safety, efficacy, and tolerability in GAD, PTSD, social anxiety disorder, and separation anxiety disorder.

Precautions and Adverse Reactions

Safety and Tolerability. The safety of vilazadone was evaluated using data from 2,177 patients who participated in phase III clinical studies, representing 552 patient-years of exposure. The rate of discontinuation due to adverse events in clinical trials is considered an indicator of tolerability. Vilazodone appears to be well tolerated overall. In pooled phase III data, discontinuation rates due to adverse effects were relatively low (7 percent vilazodone, 3 percent placebo). Rates of discontinuation due to lack of efficacy were not significantly different between the vilazodone and placebo groups. While no one single adverse event was responsible for discontinuation in >1 percent of the patients, the most common adverse event type leading to discontinuation were gastrointestinal complaints (2.3 percent vilazodone versus 0.2 percent placebo). Adverse events significantly more common in vilazodone patients compared with placebo were diarrhea, nausea, dizziness, insomnia, vomiting, abnormal dreams, gastroenteritis, restlessness or akathisia, palpitations, tremor, feeling jittery, and paresthesia; although in most cases symptoms were considered to be mild to moderate. Only 6.4 and 8.8 percent of participants in the two phase III trials reported a severe adverse event, compared to 5.6 and 5.4 percent in the placebo groups, respectively. In the vilazodone-treated group, symptoms in the first trial were diarrhea, fatigue, flatulence, gastroenteritis, palpitations, and paresthesias. In the second trial, symptoms reported were insomnia, nausea, vomiting, headache, and decreased libido.

Serious Adverse Events. There were no deaths in the vilazodone clinical trials in subjects taking vilazodone. Among all of the clinical trials, there were three deaths. These included a homicide in a phase I study and two suicides in a phase II study. Neither of the suicides was exposed to vilazodone. A total of 76 patients experienced a nonfatal serious adverse event in phase II and phase III trials, with similar rates for the vilazodone and placebo groups.

Gastrointestinal. The most commonly observed adverse events of vilazodone are gastrointestinal in nature. Fortunately, they tend to be mild or moderate in severity and appear to be transient in nature. In the placebo-controlled phase III trials, diarrhea was reported by 28 percent of

vilazodone-treated patients (versus 9 percent placebo) and nausea by 23 percent vilazodone-treated patients (versus 5 percent placebo). Slow dose titration over 2 weeks is recommended to minimize gastrointestinal adverse events.

Sexual Dysfunction. In the phase III placebo-controlled studies, 8 percent of vilazodone-treated patients versus 0.9 percent of placebo-treated patients reported at least one sexual adverse event, most commonly decreased libido (3.7 percent vilazodone, 0.2 percent placebo). Men tended to have a higher incidence of sexual adverse events than women, 15.5 versus 5.2 percent respectively. Pooled data from all phase III trials showed that 50 percent of men and 68 percent of women reported sexual dysfunction at baseline and that sexual function usually improved in both vilazodone and placebo groups, with over 91 percent of patients reporting stable or improved sexual function at the end of treatment. While data indicate that sexual dysfunction is a significant adverse event associated with vilazodone, it may be less severe since no patient treated with vilazodone discontinued treatment due to sexual dysfunction. However, whether vilazodone has a favorable profile regarding sexual dysfunction compared to other antidepressants will remain unknown until data from comparator studies is available.

Suicidality. Vilazodone carries the same warning as other SSRIs regarding suicidal thoughts and behaviors in children, adolescents, and young adults, based on data showing an increased risk of suicidal thinking and behavior (although no completed suicides) in children, adolescents, and young adults (ages 18 to 24) with MDD and other psychiatric disorders. In pooled phase III placebo-controlled vilazodone trials, suicidal ideation was experienced by one (0.2 percent) patient receiving vilazodone and three (0.7 percent) patients on placebo. Seven (1.2 percent) patients in the 52-week open-label study also experienced suicidal ideation. Suicidal behavior was identified by one (0.2 percent) vilazodone-treated patient and one (0.2 percent) patient in the placebo group in the pooled phase III placebo-controlled trials, and by two (0.3 percent) patients in the 52-week open-label trial. In a recent phase IV trial, among patients receiving vilazodone, there was one suicidal ideation and one suicide attempt. Patients treated with antidepressants should be monitored closely for clinical worsening or suicidality, especially upon drug initiation or the dose change.

Overdose. Limited data exist regarding overdose of vilazodone. Four patients and the child of a patient experienced an overdose of vilazodone at doses between 200 and 280 mg. Symptoms included serotonin syndrome, lethargy, restlessness, hallucinations, and disorientation. All patients

recovered.

Activation of Mania/Hypomania. As with all antidepressants, caution should be used when prescribing vilazodone to patients with a history or family history of bipolar disorder, mania, or hypomania. In clinical trials of vilazodone, six patients were identified as having probable treatment-emergent mania or hypomania, five receiving vilazodone and one placebo.

Discontinuation Syndrome. A discontinuation syndrome has been reported upon discontinuation of serotonergic antidepressants, especially when discontinued abruptly. While it is generally self-limiting, there have been reports of serious discontinuation symptoms. A gradual discontinuation of vilazodone is recommended to avoid a possible discontinuation syndrome.

Serotonin Syndrome. As with all SSRIs, the development of serotonin syndrome is possible with vilazodone, alone or when administered concurrently with other serotonergic drugs, including triptans, tricyclic antidepressants, fentanyl, lithium, tramadol, tryptophan, buspirone, and St. John's Wort, and with drugs that impair metabolism of serotonin, such as monoamine oxidase inhibitors (MAOIs). Two subjects in the vilazodone clinical trials were identified as having serotonin syndrome. The first was a patient in a phase II trial who received vilazodone 80 mg; the other was a patient in the 52-week, open-label, phase III study who took an overdose of approximately 240 mg of vilazodone. Patients should be monitored closely for possible serotonin syndrome. If symptoms occur, vilazodone and all other serotonergic agents should be discontinued immediately and supportive management initiated.

Nervous System. Although vilazodone has not been studied in patients with seizure disorders, the product label advises that caution be used when prescribing vilazodone to patients with seizure disorder. In addition, headache was reported as an adverse event in 20 percent of patients in the 52-week open-label study.

Sleep. In the two phase III trials, insomnia and abnormal dreams were reported by 6 and 4 percent of patients on vilazodone, versus 2 and 1 percent, respectively, of those receiving placebo. Decreased REM and increased slow-wave and delta-wave activity were reported in a single dose study of 10 healthy men.

Reproductive. Vilazodone is classified as Pregnancy Category C. There are no published data on vilazodone during pregnancy or during labor and delivery. In animal studies, however, vilazodone was not teratogenic in rats

or rabbits at doses of 48 and 17 times, respectively, the maximum recommended human dose (MRHD). Developmental toxicity was observed, but only at doses much higher than the MRHD. The FDA package insert carries the same warning regarding potential neonatal toxicity as is listed with other antidepressants. In the absence of clinical data on vilazodone, clinicians should consider potential risks associated with other serotonergic antidepressant agents. Although the overall rate of major malformations with SSRI exposure during pregnancy is consistent with that observed in the general population, data regarding the impact of antidepressant exposure during pregnancy on rates of miscarriage, preterm delivery, and low birth weights are mixed. Similarly, considerable debate exists regarding the association between SSRI use in pregnancy and persistent pulmonary hypertension (PPHH) of the newborn. However, it is estimated that if present, the absolute risk is very small. In fact, the FDA has concluded that it is premature to reach definitive conclusions regarding the risk. Another potential risk of prenatal antidepressant exposure is the development of poor neonatal adaptation syndrome (PNAS) as a result of third trimester exposure to serotonergic antidepressants. This syndrome is believed to be mediated by direct serotonergic toxicity or withdrawal effect, and the majority of cases are mild in severity. It is estimated that PNAS may occur in approximately 10 to 30 percent of neonates exposed to serotonergic antidepressants, although a population-based study of nearly 120,000 birth records failed to demonstrate an increased risk of PNAS in infants exposed to antidepressants. More research is needed in this area, and clinicians caring for a pregnant woman should carefully consider the risks and benefits of antidepressant medications as well as the risks of untreated depression to both the pregnant woman and the fetus.

Lactation. There are no published data regarding the excretion of vilazodone in breast milk. Animal studies have demonstrated that vilazodone is excreted into the milk of lactating rats. Risks and benefits should be carefully weighed and discussed with patients.

Fertility. There are no data on the effect of vilazodone on fertility in humans. In animal studies with rats, impairment of male fertility was observed with vilazodone at 30 times the MRHD, but not at 6 times the MRHD. No effect on fertility was observed in female rats.

Carcinogenicity. In mice studies, the incidence of hepatocellular carcinomas in males was increased at 16 times the MRHD but not at 5 times the MRHD. Similarly, the incidence of malignant mammary gland tumors was significantly increased at 16 times the MRHD but not at 1.8 times the MRHD. Vilazodone was not carcinogenic in rats at doses up to 36 times the MRHD.

Mutagenicity. According to the package insert, vilazodone was not mutagenic in the in vitro bacterial reverse mutation assay and was negative in the in vitro V79/HGRPT mammalian cell forward mutation assay. Vilazodone was clastogenic in two in vitro mammalian cell chromosome aberration assays but was negative for clastogenic activity in an in vivo rat bone marrow chromosome aberration assay and a micronucleus test. Vilazodone was also negative in an in vivo/in vitro unscheduled DNA synthesis assay in rats.

Drug Interactions

Since vilazodone is metabolized primarily by CYP3A4, 3A4 inhibitors or inducers can potentially affect its plasma concentration. If coadministered with a strong inhibitor of CYP3A4, it is recommended that the vilazodone dose be reduced to 20 mg daily. If coadministered with 3A4 inducers, the package insert states that the dose of vilazodone may be increased based on clinical response (not to exceed 80 mg/day). Due to the minor contributions from CYP2C19 and CYP2D6 in the metabolism of vilazodone, plasma levels of vilazodone are not expected to be affected by coadministration of inhibitors of these isoenzymes. The likelihood of vilazodone affecting other drugs appears to be low. A study of healthy adults found that vilazodone does not affect drugs metabolized by CYP1A2, 2C9, 2D6, or 3A4. While in vitro studies suggest that vilazodone may inhibit CYP2C8 substrates, this has not been tested in vivo.

Vilazodone's interaction with other highly protein-bound drugs has not been evaluated, but given its high protein binding, coadministration with other highly protein-bound drugs may result in increased free concentrations of the other drug. Coadministration of vilazodone with MAOIs is contraindicated, due to the risk of serotonin syndrome. At least 14 days should elapse between discontinuation of either an MAOI or vilazodone and initiation of the other. Due to potential for serotonin syndrome, caution is advised when coadministering vilazodone with other serotonergic drugs. It is also possible that concurrent use of vilazodone with NSAIDs, aspirin, or oral anticoagulants may potentiate the risk of bleeding.

Dosage and Administration

Vilazodone is supplied in 10-, 20-, and 40-mg tablets. A 30-day starter kit is available which contains (7) 10-mg tablets, (7) 20-mg tablets and (16) 40-mg tablets. Tablets should be stored at 77°F (25°C) with the following ranges permitted: 15°C to 30°C/59°F to 86°F. Vilazodone should be taken with food. The recommended dose for vilazodone is 40 mg daily, and should be titrated over 2 weeks, starting with 10 mg/day for 7 days, 20 mg/day for the next 7 days, and then 40 mg/day. No dose adjustments are

recommended for mild, moderate, or severe hepatic or renal impairment.

Geriatric Patients. No dose adjustment is recommended for use in geriatric patients. This is based on results from a study demonstrating similar pharmacokinetics in patients >65 years old and those of ages 24 to 55 years. Nonetheless, the product labeling cautions that greater sensitivity of some older individuals cannot be ruled out and that elderly patients may be at greater risk for hyponatremia.

Pediatric Patients. Vilazodone is not FDA approved for use in pediatric patients. A clinical trial is being conducted to evaluate the efficacy, safety, and tolerability of vilazodone relative to placebo in adolescents 12 to 17 years of age with MDD.

Future Directions

The need for effective new antidepressant treatments is evident given the high prevalence of depressive disorders and the relatively low response and even lower remission rates of existing antidepressant agents. Vilazodone is the first in a novel class of antidepressants, SPARI, named after its dual serotonin reuptake inhibitor and partial 5HT1A agonist mechanism of action. Although additional data are needed to determine vilazodone's relative efficacy and tolerability compared to other antidepressants, its unique mechanism of action has garnered considerable attention. There is growing interest in the role of the 5HT1A receptor for the treatment of depression and anxiety. More specifically, attention is being focused on 5HT1A's potential to indirectly modulate glutamate transmission. New clinical trials examining vilazodone's impact on glutamate levels in the anterior cingulate cortex may further expand vilazodone's role and widen its clinical applications.

35 Child Psychiatry

▲ 35.1 Introduction and Overview

CAROLY SUE PATAKI, M.D.

ADVANCES IN CHILD AND ADOLESCENT PSYCHIATRY

Over the last decade the field of child and adolescent psychiatry has demonstrated significant gains in knowledge of the neurotransmitters, neural circuits, and brain systems involved in a variety of childhood psychiatric symptoms and disorders. Efforts to link this knowledge to improved treatments for childhood psychiatric disorders have met with some success. Data from large randomized controlled studies have shown efficacy of medications, cognitive-behavioral therapy, and their combination, for certain disorders in youth including obsessive-compulsive disorder (OCD); several anxiety disorders: generalized anxiety disorder, separation anxiety disorder, social anxiety disorder; and major depressive disorder.

Genetic research, including genome-wide linkage scans seeking to identify gene loci, have focused on several childhood disorders, including attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorders (ASDs), Tourette syndrome (TS), and OCD. Neuroimaging studies have elucidated the brain development of typically developing children, as well as in children with psychiatric disorders. For example, neuroimaging studies have revealed that whereas total brain volume remains virtually stable after the age of 5 years, there are two dynamic processes—synaptic pruning and myelination—that continue through adolescence and early adulthood and profoundly influence cognitive and social decision making and behavior. Furthermore, neuroimaging studies have led to the conclusion that girls and boys differ in the timing of maximal gray matter volume and its normal decline after puberty, in that the process occurs about 1 year earlier in boys than in girls. A variety of neuroimaging techniques, such as magnetic resonance imaging (MRI), functional MRI (fMRI), diffusion tensor imaging (DTI), computerized

tomography (CT), single photon emission computerized tomography (SPECT), and positron emission tomography (PET) have been increasingly employed to uncover both morphology and function of various parts of the brain to further understand childhood psychiatric disorders such as ADHD, mood disorders, OCD, and anxiety disorders, including posttraumatic stress disorder (PTSD).

The current *Diagnostic and Statistical Manual of Psychiatric Disorders*, 5th edition (DSM-5), published in 2013, has modified criteria for several childhood disorders in an effort to refine and match the criteria with available scientific evidence and expert consensus. It is well known that youth with the same psychiatric disorder, as defined by the DSM-5, may present with heterogeneous symptom constellations. Diagnostic categories have played an important role in providing explanations of symptoms to patients, communication between clinicians, and providing a method for researchers to devise systematic studies. A limitation of a categorical (disorder) approach, rather than a dimensional (symptom or neurobiological domain) approach in child psychiatric treatment research is that youth often present with overlapping symptoms of several disorders or present with multiple comorbid disorders. In fact, it is quite common for children to present with more than one psychiatric disorder. This clinical heterogeneity among childhood psychiatric disorders makes it a challenge to determine which constellation of symptoms will be most responsive to a given treatment.

In an effort to advance the *precision* of future psychiatric research, the National Institute of Mental Health (NIMH) developed the Research Domain Criteria (RDoC) project (2008) which focuses on observable behavior and neurobiological measures, rather than DSM-5 disorders. RDoC domains and examples of each include *negative valence domain* (fear, loss), *positive valence systems* (responsiveness to reward, habit), *cognitive systems* (attention, working memory), *systems for social processes* (social communication, attachment), *and arousal/modulatory systems* (arousal, sleep–wake). An example of how this model might be applied is in a study of impairing anxiety, a fear-induced startle response might be measured in people with different relevant genetic polymorphisms and a subjective level of distress could also be measured. In this way, a more specific constellation of variables could be associated with specific responses to either fear-inducing stimuli, or potential treatments. The goal of this project is to identify a more specific set of symptoms and traits that mediate the expression of behaviors and predict response to potential treatments.

An in-depth description of the clinical presentation, course, and treatment as well as updates on the scientific advances in childhood psychiatric disorders is presented in the following chapters.

CLASSIFICATION OF CHILDHOOD PSYCHIATRIC DISORDERS AND HIGHLIGHTS OF MODIFICATIONS IN DSM-5

The current version of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5), provides a categorical classification reflecting evidence-based and expert consensus of current childhood disorders. Children and adolescents who meet criteria for the same psychiatric diagnoses often present with heterogeneous clinical pictures. DSM-5 defines a psychiatric (mental) disorder as *a syndrome characterized by clinically significant disturbance in an individual's cognition, emotion regulation, or behavior that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities.*

The first edition of the World Health Organization's *International Statistical Classification of Diseases* to contain a section for mental illness was the sixth (ICD-6). The first formal draft of a US variant of this document, the DSM, was developed shortly thereafter, in 1952, by the Committee on Nomenclature and Statistics of the American Psychiatric Association.

Dennis Cantwell, M.D., along with many colleagues, was instrumental in advancing the classification of child psychiatric disorders through suggested revisions to the DSM in an effort to facilitate empirical investigation. These efforts were first realized in the development of the DSM-III in 1980. The DSM-III included explicit diagnostic criteria for each disorder, use of the multiaxial system, and a diagnostic focus on phenomenology rather than etiology. The DSM-5 does not include the multiaxial system, however, it allows for specifiers to denote important psychosocial factors.

Although both categorical and dimensional approaches have merit in describing psychiatric syndromes in youth, the DSM system uses only categorical criteria to identify psychiatric disorders. The overlap of behavioral and mood symptoms across multiple childhood and adolescent disorders made defining the boundaries challenging. In addition, it soon became evident that in more severely psychiatrically impaired youth, comorbidity is the rule rather than the exception.

Highlights of changes in childhood psychiatric diagnostic criteria in DSM-5 include the following:

Autism spectrum disorder is a new DSM-5 disorder characterized by core deficits in two areas: (1) social communication/social interaction, and (2) restricted pattern of interests, behaviors or activities. This new disorder included the previous five pervasive developmental disorders: autistic disorder, Asperger disorder, childhood disintegrative disorder, Rett disorder, and pervasive developmental disorder not otherwise specified.

Social (pragmatic) communication disorder—a new DSM-5 disorder characterized by persistent deficits in the social uses of verbal and nonverbal communication, however, without a restricted pattern of behaviors or interests.

Specific Learning disorder—new disorder which encompasses the previous disorders: reading disorder, mathematics disorder, disorder of written expression, and learning disorder not otherwise specified. Specifiers indicate which skills are affected.

Disruptive mood dysregulation disorder—a new DSM-5 disorder characterized by children and adolescents with persistent irritability and frequent episodes of severe tantrums.

There are several additional modifications to previous disorders which will be detailed in the corresponding chapter.

DEVELOPMENTAL PERSPECTIVE: IDENTIFYING THE EMERGENCE OF A CHILDHOOD PSYCHIATRIC DISORDER

Onset

Onset of a psychiatric disorder is a challenging concept in child and adolescent psychiatry because it is often difficult to pinpoint reliable landmarks for sufficient symptoms and impairment. Defining the onset of a disorder by a single impairing symptom might lead to the inclusion of a heterogeneous group of disorders, whereas inclusion of only a rigid set of symptoms might exclude important subtypes. Age at onset of a childhood or adolescent psychiatric disorder is a variable of considerable importance because the emergence of a known constellation of symptoms at a younger-than-expected age might reflect increased vulnerability genetically or environmentally. For example, an earlier-than-expected age of onset of major depressive disorders has been associated with an increased probability of depressive disorders in first-degree relatives and implies an increased genetic vulnerability.

Onset of Child and Adolescent Psychiatric Disorders

The investigation of age at onset of a psychiatric disorder can be applied to models of delayed onset of illnesses. For example, degeneration is a model of delayed onset of disease that characterizes conditions such as Alzheimer disease and Parkinson disease—that is, gradual loss of target neurons over time results in a predictable behavioral and neurological deficit. Developmental failure (i.e., a lack of physiological development within the nervous system at the appropriate time) is another model of delayed onset of a disease process.

A theory of delayed onset of a disorder, the two-hit model, hypothesizes that the emergence of a disorder is related to a “primary” genetic vulnerability triggered by exposure to a second event that may be

environmental. For example, the rate of emergence of bipolar disorders increases markedly during adolescence, is maximal in young adulthood, and then gradually diminishes. One model to explain the emergence of a disorder with this distribution is a genetic predisposition (first hit) leading to vulnerability for the disorder and a second exposure, possibly the process of puberty itself or an adverse life event (second hit), that results in the emergence of the disorder.

Genetic anticipation is defined as the emergence of more severe forms of a genetic disorder in successive generations. This mechanism has been shown to contribute to the severity of pathology in a number of genetic disorders that are caused by mutations of DNA triplet repeat nucleotide sequences. Increases in repeat patterns of three nucleotides (e.g., GAC GAC GAC) increase the length of DNA sequences and result in pathological genes. Triplet repeat expansion has been shown to be the mechanism of a number of genetic disorders, including Huntington disease and fragile X syndrome. Anticipation has been suggested as a possible explanation for increasingly severe psychopathology in successive generations in psychiatric disorders. The investigation of possible molecular bases of anticipation in psychiatric disorders, such as the increased density of genetic triplet repeat expansions shown in Huntington disease and fragile X mental retardation, is on the horizon.

Neuroimaging Studies in Child and Adolescent Psychiatry

Neuroimaging studies have provided evidence of the dynamic changes that occur in developing brains. fMRI, in studies by Swartz and colleagues (2012), has shown, for example, that children with ASDs have hyperaroused amygdalae leading to deficits in habituating to a variety of stimuli including sounds, sad faces, and certain tactile feelings. This may contribute to the typical sensory sensitivities in children. Singh and colleagues (2012) employed fMRI to show that adolescents with bipolar disorder have less activation in superior frontal brain regions after a negative experience, compared to healthy adolescents, which may be indicative of deficits in executive control over emotional decisions. Child and adolescent brains have been described by clinicians and researchers as "works in progress," with a series of predictable pattern of biological processes that extend into and beyond adolescence. The neuroimaging work of Giedd, Rapoport, Rosenberg, Castellanos, and others has revealed the typical wave of high production of gray matter among developmentally normal adolescents emerging just before puberty. Furthermore, investigations have documented the links between the pruning and myelination processes in various sites in the brain and the subtle increases in social and emotional problem-solving abilities that typically emerge in later adolescence. Other investigations have identified areas of the brain targeted in children who learn first and second languages early in life. fMRI

scans have determined the spatial relationship of language centers in children who have first and second languages. In such children, both language centers appear in the same cortical region whereas when a second language is acquired in adult life, the new language center is not represented in the same cortical region as the first language. MRI studies have also provided evidence that adolescents process emotional stimuli differently than adults. Using fMRI and presenting pictures of faces depicting various emotions, Yurgelun-Todd and colleagues showed that in young teens, who typically have difficulties with the task, the amygdala (a brain center for fear reactions) is activated during the task of identifying the emotions presented; whereas in older teens, who perform better on the task, the frontal lobes are more active in the process of identifying emotions in the stimuli. There were also additional findings indicating that language tasks correlated with activation of temporal lobes in young teens and of frontal lobes in older teens.

GENE X ENVIRONMENT INTERACTIONS: RISK AND PROTECTIVE FACTORS

There is a convergence of evidence regarding the interactional effects of genetic vulnerability and environmental events on the development of many psychiatric disorders. Much research has focused on the alleles of the serotonin transporter gene and sensitivity to adverse events and stress. The impact of age and developmental stage that a stressful event is experienced adds another factor in the equation, and finally, positive relational and environmental variables may increase resiliency. Risk factors include all variables that increase the probability that a given child or adolescent will develop psychopathology. Protective factors decrease the risk of developing psychopathology. Demographics, psychosocial factors, biological factors, genetics, family environment, and external environment interact to produce risk and protection from psychiatric disorders. Rarely can a single risk factor account for the entire variance between the emergence and inhibition of a psychiatric disorder. Thus, the study of psychiatric risk is complicated and multifactorial. Risk factors often studied for influence on the emergence of psychiatric disorders among children and adolescents include family history of psychiatric disorders, social class, intellectual function, adverse life events, temperamental factors, and the quality of family and peer relationships. Developmental delays, child maltreatment, and high levels of family conflict increase the risk of psychiatric disorder. Protective factors that have been identified and studied include individual temperamental predisposition, positive family relationship, and success experiences academically and socially.

INTERVENTIONS FOR PSYCHIATRIC DISORDERS IN YOUTH

Interventions to address psychiatric symptoms and disorders in youth include clinical, targeted, and universal interventions.

Clinical interventions provide treatment to a family with a child or adolescent identified as having a psychiatric problem. Psychosocial, psychopharmacological, and other environmental interventions can be compared with a placebo condition and with each other to assess efficacy. Approximately one-half of families who begin psychiatric treatment terminate prematurely, thus, the nature and delivery of the treatments also merit investigation.

Targeted interventions are designed for children identified as at increased risk of a psychiatric disorder but whose families are not seeking treatment. Children at risk may be identified either by an external factor, such as a family characteristic (e.g., offspring of a parent known to have a psychiatric disorder) or through a behavior (e.g., defiance or aggression in the classroom). A given child may be monitored or receive a psychosocial intervention on the basis of the risk factor—whether psychiatric disorder is already present or not; however, these interventions may not be welcomed by the family, or threshold for interventions may not be correlated with a clinically relevant situation.

Universal *interventions,* also termed *primary prevention,* are received by all children and families within a specific geographical distribution. They may occur throughout a targeted school or community or on a citywide, statewide, or national basis. This strategy obviously reaches more children than any other method of intervention, but questions arise about the benefit and need of the intervention for the population at large, as well as the cost–benefit ratio.

Study of the risk factors and protective factors is leading the field to develop the most effective combination of prevention strategies for children and adolescents. More effective treatments are being investigated in order to match the treatment to the individual. Future goals include mitigating risk factors, enhancing protective factors, and when prevention is not possible, to provide efficacious treatments.

▲ 35.2 Normal Child Development

GABRIELLE SHAPIRO, M.D., ROBERT J. JAFFE, M.D., AND ALEXANDER KOLEVZON, M.D.

INTRODUCTION

Imagine an infant reciting Shakespeare, a toddler calculating trigonometry angles, or an 8-year-old driving to grade school each morning. The thought of children performing mundane adult tasks highlights the obvious: humans are born with a very limited skillset and develop a more complex one over time. In essence, development is the acquisition of new skills and the multiplex reactions to these additions. Whether it is the capacity to walk, talk, empathize, or think about the future, suddenly a capacity is there that previously was not. At no time in life is the explosion in newfound possibilities more pronounced than in early childhood, the focus of this section.

With a basic understanding of development, clinicians of every discipline can benefit their patients. Pathology can frequently be traced back to childhood, offering clues as to its inception and psychological sequelae. Often, adult patterns of symptom presentation or behavioral interaction with the environment mimic patterns from childhood.

Until the 1600s, children were viewed as “small adults” and expected to

work and socialize in an adult manner. Children were sources of cheap labor during the Industrial Revolution. This era's end, coupled with compulsory school laws in the United States, meant that by the early 20th century the vast majority of children were attending schools. John Dewey was essential in viewing schools as a vehicle through which childhood development could be fostered. G. Stanley Hall formally studied children and adolescents, and blazed a trail for the relatively recent surge in psychological theories by Sigmund Freud, Erik Erikson, Jean Piaget, and John Watson, to name a few.

Though the field remains ripe for further exploration, some critical concepts have emerged over the past 100 or so years. Normal development can be conceived of as what a typical child will go through in an average expectable environment. This section will highlight the ages when different changes are typically seen. It is imperative to understand that each new advance has a range of when its existence should be expected. Significant lags are thought of as developmental delays (with the exception of premature babies) whereas marked abnormalities in development are developmental disorders.

There is a debate as to whether development is a continuous or discontinuous process. What is clear is that the direction of the curve is not always positive, as there is a normal degree of progression and regression. It is normal during the acquisition phase of new skills for them to come and go. An example is a fluidly speaking 3-year-old who, upon the birth of a younger sibling, will revert to baby talk. This is distinct from a frank loss of a solidified skill, a symptom which should always prompt inquiry.

Current research offers evidence that the mechanism for growth comes from the interplay of genetics and the environment. Though the relative contribution of each remains an area of debate, this transactional model has become the established paradigm. Genetic background primes an individual and provides potential, but can be altered positively and negatively based on environmental stimulation. Identical twins reared in the same household do not develop identical personalities. There is evidence that children shape their environment and elicit different responses from their environment, affecting how they develop. Some aspects of development are more genetically determined, whereas the environment may play a greater role in others. When pertinent, this section will highlight relative contributions.

This chapter will cover nine areas of development from birth through adolescence. The domains of brain, language, cognitive, social, emotional, motor, sensory, gender, and psychosexual development will each be addressed. Developmental lines are also interdependent, maturing on their own yet influenced by one another. For example, language fosters advances with emotional and social development.

Finally, the scope of this chapter is on normal childhood development

only. Clinical correlates will be interspersed throughout to highlight the importance of understanding normal development in practice. There is also a comprehensive master table (Table 35.2–1) arranged by age on one axis and developmental domain on the other. This is intended as a quick reference to identify skills typically developed at a certain point in time or to follow one domain longitudinally.

BRAIN DEVELOPMENT

Unlike some other species, humans are born with an immature central nervous system (CNS). An infant is entirely dependent on others and is governed by innate reflexes, yet in time becomes a creature capable of complex cognitive, social, emotional capabilities and remarkable physical and verbal skills. How does one go from someone who cannot hold his own head up to an athlete who can sense his orientation in space and manipulate his body accordingly? This section will focus on the physical changes to the brain during infancy and childhood which allow for all the capacities described in the rest of the chapter.

Table 35.2–1.
Child Development Resource Table

Periods:		Gestational-Infancy: 0–2 Years			
	Theories	**0–2 Months**	**2–7 Months**	**7–12 Months**	**1–**
Emotional Development	(Integrated Theory) Acquisition of Basic Emotions	Stage 1: Infant has innate emotions and emotional responsiveness —emotions are available and easily stimulated at birth			Stag c e r
	Emotional skills	Touching evokes love, loud noises evoke fear. Restrictions evoke rage. The brain pathways for the forming of emotions begin to develop	Emotions begin to become self-regulated as the brain pathways of emotion grow	Self-regulation of emotion continues to develop	Shar e emb Dis oth
		Infants have a "social smile"	Begin to laugh		Begin er

	Emotional Behavior	in response to human voices. They display the ability to respond to emotions of others	and display more control over smiles. Anger is able to be shown as well	Ability to induce responsiveness increases	exp fe inf att ap lik alo
Social Development	John Bowlby Attachment Theory	Preattachment (0 to 6 weeks)	Attachment making (6 weeks to 8 months)	In month 8, clear-cut att begins to develop >> anxiety	
	Margaret Mahler Attachment Theory	Autistic Phase (0 to 6 weeks)	Develops a symbiotic relationship with the caregiver (6 weeks to 8 months), and the beginnings of differentiation	Differentiation continues	Rapp (18
	Robert Selman's Stages of Perspective Taking				

	Erik Erikson's Social Stages (Psychosexually Influenced)	Stage 1: Crisis: Basic Trust vs. Mistrust Virtue: Hope			C
	Social Behaviors	Infant acknowledges the caregiver as "different," recognizing caregiver's smell, voice, touch	Infant is able to differentiate self from caregiver and begins to manifest separation anxiety		Chil co car dev l ca a
Psychosexual Development	Freudian Psychosexual Stages	Oral Stage			
	Gender Identity				Gend and c
	Gender Role				Ster l
	Gender Relationship				Sex n v
	Psychosexual Skill	Ego directs sucking needs			Chi st obj lik 1.5 can se p

			oth clo hai as p 2.5 lac ov
Moral Development	Piaget's Stages of Moral Behavior Related to Cognitive Phases		
	Piaget's Two-Stage Theory of Moral Judgment (Cognitively Based)		
	Kohlberg's Six-Stage Theory of Moral Reasoning (Cognitively, Socially, and Emotionally Influenced)		
	Freud's Concept of Superego as Conscience		

	(Psychosexually Influenced)				
	Gilligan's Sex Theory of Moral Development (Cognitively and Psychosexually Influenced)	Agrees with K			
	Moral Skills	Sense of rightness is limited to the self >> Never having been hu isolated, baby knows that unresponsiveness to touch is wrong others. Cannot judge "right" and "wrong." The child must neg want			
Cognitive Development	Piaget's Stages of Cognitive Development	**Sensorimotor Stage:** Object permanence (8–9)			
	Cognitive Achievements	Recognizes faces (1st 2) Sleeps 16–18 hours, 2 naps	Eye-hand (4)	Hand/hand transfer (6–8) Self from caregiver (8)	Uses Follow Sleeps Names Know
Physical Development	Language Achievements	Cries (birth)	Coos (3–4)		First Combi
	Perceptual Achievements	All senses are active Can recognize mother's voice Can see patterns, shapes, and contrast	Eye tracking (2) Stereopsis (3) Follows 180 degrees (4) Monocular depth (6–7)	Near adult visual acuity (8)	
	Motor Achievements	Reflexes (birth)	Supports head (2–4) Rolls over in both directions Sits unsupported (6–7) Pat-a-cake (6–8)	Crawls (8–9) Pincer grasp (9) Stands (9–10) Cruises (10–12)	First w Po Beg s Eats/

There are two important and related concepts affecting development: *critical periods* and *plasticity*. Critical periods are windows of opportunity for growth in certain areas. This window offers an opportunity for tremendous gains, but is also vulnerable to disruption. For example, the first few years appear to be important for language, in particular the first year for a perceptual map of phonemes. Plasticity enables the ability of one part of the brain to compensate for another. An example is the primary auditory cortex in congenitally deaf individuals which assists in processing visual and somatosensory stimuli.

Early in life there are many changes occurring within the brain. Along with the rest of the body, the brain is growing substantially during the first few years. By age 5, it has tripled in size and is at 95 percent of its adult mass (1.2 kg for adult women and 1.3 kg for men). Growth occurs bottom-up in a caudocranial manner with the pons, medulla, and spinal cord ahead of the cerebellum, which is ahead of the cortex. This explains why infants rely on reflexes and instincts and lack coordination.

Histologically, the adult brain consists of billions of neurons configured into trillions of synapses. Early on it is a hotbed of activity. Neuronal *proliferation* and *differentiation* explode in utero and continue into the first year of life, particularly in the cortex. Though neurogenesis slows and was previously thought to halt, recent evidence has shown that two areas in adult brains possess the ability for new neurons, the subventricular zone and hippocampal dentate gyrus. These newly formed fetal and infantile neurons must get from their place of origin to their destination, which they accomplish in a task called *migration*. This journey is what lays down cortical columns and continues through the first 6 to 7 months of life, with the later neurons settling in the cortex. Once the neurons have reached their destination (and in certain cases even during migration), the cells experience dendritic and axonal outgrowth. This extension is particularly heavy during the first year, and continues over the following 18 months.

The settled and grown neurons rapidly interact with one another with an explosion of new synapses during the first 2 to 3 years of life. By age 2, the toddler has roughly twice the number of synapses an adult will have. This number gets reduced as the child's synapses are *pruned* from 18 months to age 20, with the majority occurring between 7 and 15 years. During this process the brain becomes more energy efficient, strengthening the connections that are needed while ridding itself (and the metabolic demand) of those that are not. Just which synapses are deemed necessary is a direct reflection of one's environment, a nature–nurture interaction which is fundamental to brain development.

To communicate with each other, the nerve cells need receptors and neurotransmitters. Serotonin appears first, followed by norepinephrine and dopamine, with acetylcholine and GABA produced later in fetal life.

Finally, the neurons become myelinated from birth to adulthood, a

process of insulation which increases transmission speed. In general, *myelination* occurs first in the spinal cord and lower brain, with the cerebellum fully myelinated by age 4, the corpus callosum at 8 to 12 years of age, and the cortex from age 10 into young adulthood.

The manner in which these brain changes occur is a result of complex interactions between genes and environment. Biologically, genes initiate the process of brain development through organizer genes and homeoboxes such as *Sonic hedgehog, Delta,* and the *Hox* genes among many others. The endocrine system is also involved with insulin-like growth factor (IGF) and thyroid hormones playing roles. Environmentally, illnesses and toxic exposures can alter development. Diet and nutrition is thought to have an effect, as industrialized nations demonstrate faster growth than do developing ones. For example, an increase in docosahexaenoic acid may be linked to greater visual acuity. By kindergarten and even earlier, some children from disadvantaged backgrounds have been shown to lag behind in language and vocabulary and may have heard 30 million fewer words in the home. Neglect in infancy has been linked to a significantly reduced midsagittal area of the corpus callosum. Clearly, genes alone do not account for brain development.

Genetic programing allows for brain development so that the infant can learn new skills. These capabilities facilitate interactions with the environment, which then precipitates further genetic modification. For example, motor skills afford one the chance to throw a ball and learn what happens to it. Repetition stimulates the same neural pathways, strengthening the synapses. Neurotrophins and prostaglandins affect synaptogenesis and long-term potentiation, a process that underlies learning and memory. Underuse of a neuronal pathway due to lack of exposure leads to its pruning and atrophy, mediated by genes. In short, genes lead to abilities which feedback and control other genes, affecting synapses and pathways. Thus, both the skills governed by genetics as well as the environment in which they evolve are integral to development.

LANGUAGE DEVELOPMENT

Language is so essential and omnipresent in everyday life, it is hard to imagine that it does not exist at birth. Though the ability to *communicate* is present from day one, language development is a process that takes years to develop. Speech delay is a common cause for clinical presentation, and language delays may be associated with later psychiatric comorbidities. Moreover, an undiagnosed speech delay is present in patients presenting for other reasons. Therefore, an understanding of normal language development is indispensable for all providers.

The development of language begins in utero, where a fetus has been shown to recognize its mother's voice. On delivery, an infant clearly lacks the ability to speak, but yet still requires a way to demonstrate needs. This

is achieved through facial expressions such as cries. An attuned parent can often tell what a baby needs (such as a feeding or diaper change) based on the particular type of cry. Though the exact timing of each step may differ, the overall process is quite constant. At about 3 to 4 months, typical infants make cooing (vowel) sounds followed by single syllable consonant babbling. These are learned by imitating others, and carry no meaning at this age. Repetitive vowel-consonant sounds (such as mama) may appear, but without meaning these are not considered first words. Meaningful words are produced at about 12 months, with single words intended to convey entire phrases. It is not unusual for words to come and go at this stage, and loss of a spoken word should not be cause for alarm. At 18 months, word combinations appear and about 25 percent of words are intelligible to strangers. At 24 months there are about 300 words, 50 percent of which are intelligible. By 30 months there are 500 words. At 36 months, 75 percent are intelligible to strangers.

Grammar develops significantly from months 20 to 36. As children learn the rules of speech, incorrect verb tenses are common ("I goed to school"). The same child may have used this correctly in the past, which likely reflected an imitative phrase rather than a novel one, and is considered normal. By age 4 most expressive language is developed and appropriately used. Nearly 100 percent of words should be intelligible to strangers, even though pronunciation mistakes may be present. Over the next 2 years children are able to connect sentences with one another logically. At ages 5 to 6, language centers slow their development, highlighting the importance of early language and the challenges of learning a second language later in life.

From a theoretical perspective Noam Chomsky emphasized the universality of linguistic structure and that all humans develop the ability to understand and produce language. This stands in contrast to a behavioral theory of language, championed by B. F. Skinner. Skinner believed that children imitate others and have their language reinforced through the environment. Factors such as large family size and lower social class correlate with later development and fewer words. Expanding on these environmental variables, the quality of verbal stimulation plays an important role. Hearing words from reading is more effective than just hearing spoken words; significantly more "unique words" are perceived through books, likely exposing children to words they would not otherwise encounter. Recent fMRI studies show that children with a higher reading exposure had greater activation in the left parietal-temporal-occipital association cortex, integrating the auditory with the visual and potentially stimulating imagery and narrative comprehension.

Clinical Correlate

A 24-month-old boy is referred from the pediatrician for severe behavioral outbursts. Upon

taking a history, you discover that he only knows about 25 words and cannot make word combinations. You astutely hypothesize that the tantrums are the manner in which this child is expressing himself, and aim to identify the reason for the speech delay. Your differential includes hearing and vision difficulties, and vision and hearing tests are ordered. Deficits in other areas are explored for signs of a broader developmental delay including Intellectual Disability and Autism Spectrum Disorder. Environmental contributors such as neglect or trauma must be ruled out. An auditory processing disorder is also a possibility. Finally, you conclude the delay is due to a speech or language learning disorder. A speech and language referral helps identify the nature of the delay and breaks speech down into further subcomponents: articulation (pronouncing sounds), syntax (the arrangement of words in a sentence), semantics (meaning of words), and pragmatics (appropriate social use of words). With speech therapy, the child makes linguistic gains and his behaviors subsequently improve as he now has other means to regulate and express himself.

COGNITIVE DEVELOPMENT

Cognition can be conceived of as what happens to sensory information once it reaches an individual. How this occurs is substantially more detailed and involves perception, understanding, memory, learning, reasoning, problem solving, and language. A discussion on cognitive development would be incomplete without mentioning *Jean Piaget*. He proposed four stages of cognitive development, with changes occurring through *assimilation* and *accommodation*. Assimilation, he argued, is taking in new information and fitting it in with an existing understanding, or *schema*. It is fitting new data into old ideas. This contrasts with accommodation, in which the new experience or sensory data causes the old schema to be altered so that it is in accord with this new information. For example, a child has an understanding of a tree, which is comprised of a trunk and branches. In the summer when leaves appear, the basic concept of tree remains the same but it has expanded to include this new knowledge. Later on the child encounters a bush and calls this a tree as well. The child is taught the differences between a bush and a tree and a new bush schema is formed. Though parts of Piaget's theories have come under question, he added tremendous insight into how children think differently from adults. This has consequences for everyone interacting with children, and is especially noteworthy for those in the educational and health care systems. Given his significance to the field, this section will be structured around Piagetian stages.

The first of Piaget's stages is *sensorimotor,* occurring between birth and approximately age 2. As the name implies, at this stage the infant is mostly limited to sensory information and simple motor responses. Within 2 months the infant can pay attention to faces and even recognize them. They can follow things with their eyes. By 4 months there is eye–hand coordination, as the infant can reach for something he sees. Recognizing familiar faces and important objects improves and extends to greater distances. At 6 months they show curiosity for things out of reach, and once within reach, they tend to put them in their mouths. Eye tracking further develops over the next few months, as the infant can even follow the path of

something as it falls. Picked up objects can be transferred from hand to hand smoothly. At 9 months, peek-a-boo is a particularly fun game, notably because at this age the infant is grappling with *object permanence*. To an infant lacking this skill, anything that cannot be perceived cannot exist. By the age of 1, there are clear signs that schemata are forming and are being used. A 12-month-old typically can follow directions and use things correctly, such as a cup. These schemata strengthen and broaden over the next 6 months and at 18 months they often clearly show knowledge of what a typical item is used for, such as a brush. As schemata are forming, a sense of humor can be seen when these expectations are playfully breached. Following simple instructions such as "sit down" implies an ability to understand language and know what to do with it. This implicates gains in memory and learning. By the age of 2 the individual can find hidden items, clearly demonstrating the achievement of object permanence. Make-believe games begin to take on a pleasurable role. Rudimentary organizational skills are demonstrated by sorting shapes and colors. Two-step instructions can be followed and four-block towers can be built.

The second stage Piaget described is *preoperational,* ranging from about 2 to 7 years of age. Symbolic play is a key feature of this time period. Pretend play and make believe, role playing, and symbolization (such as a stick representing an airplane) appear. A hallmark of this stage according to Piaget is that toddlers exhibit *egocentrism,* meaning they lack the ability to take another's point of view. Children in this stage lack the understanding of *conservation*. The classic example is if equal amounts of water are poured into a tall skinny glass and a short wide glass, those who have not mastered conservation yet will say the tall skinny glass has more water in it. This skill develops from ages 6 to 11 and may differ for various units of measurement.

Clinical Correlate

With egocentrism, children cannot take on another's point of view and are susceptible to misattribution. This normal stage in development leaves one vulnerable should a major stressor occur. For example, loss of a parent, divorce, or terrorist attacks demand explanation, and typical children with egocentrism are likely to blame themselves for the event. Though with age they may cognitively realize the situation was not their fault, the initial memory and experience was recorded in that way and guilt and self-blame may be present. Whether treating a child in real-time or an adult decades later, recognizing where the patient was developmentally at the time of tragedy is paramount for processing.

At age 3, children can copy a circle, complete three-to-four piece puzzles, and build a six-block tower. By age 4, they can understand the idea of same and different. They can start to understand time, begin to understand numbers and counting, draw two-to-four limbed bodies, name colors, and copy a square. At 5, they can count to 10, draw six-part bodies, copy a triangle, and start printing some letters.

The third Piagetian stage is *concrete operations,* from roughly ages 7 to

11. Order, rules, and organization are hallmarks of this time period. As the name implies, children at this age have difficulty with abstract and hypothetical thinking but are learning how to logically think about concrete things. Children implement inductive reasoning, generalizing from the specific (an example would be dad drives a red car, therefore all dads drive red cars). Deductive reasoning remains a challenge, requiring the child to understand something specific based on a generalized rule. Two other important cognitive skills emerge during this stage: *conservation and reversibility*. Children who have mastered conservation now realize that, as in the example above, there is the same amount of water in both glasses regardless of height. Additionally, children in this age group develop the capacity to see things from someone else's point of view, marking the end of egocentrism. This contrasts somewhat with theory of mind research. *Theory of mind* is the ability to recognize someone else as another entity with his/her own thoughts and feelings and emerges between ages 4 and 5. Learning *that* someone else thinks differently than oneself is one thing, anticipating *what* that person may be thinking or feeling is more complex and develops later.

This ability and others further develop in Piaget's final stage *formal operations* from age 12 and older. Here deductive reasoning develops, with many math and science implications. The ability to think abstractly appears, allowing for better planning and organization and problem-solving. Trial and error is no longer necessary to come to a conclusion, results can be anticipated. Though cognitive milestones have been discussed in the context of Piagetian stages, it is worth noting other developmental theories which help predict how and why children acquire the aforementioned skills. *Information Processing Theory* holds that children are goal-directed problem solvers who work to achieve certain ends. Improvements in memory, processing speed, planning, and logic help facilitate learning and solving which leads to more efficient approaches and greater knowledge. Change occurs continuously, gradually, and more subtly than in a stage-based paradigm as Piaget proposed. Similarly, *Lev Vygotsky* postulated that children continuously grow as social creatures heavily influenced by their social and cultural environments. The *dynamic systems theories* attempt to incorporate many factors viewing children as constantly evolving products of their past and present adapting to the context of their physical abilities and social environment.

Sleep wields tremendous influence on cognitive and physical development and has its own unique process. At birth, infants sleep 16 to 18 hours per day, including nighttime sleep and their two or more daytime naps. By age 1 there is typically just one nap, and daily totals are down to 15 hours. This is further reduced to 13 to 14 hours by age 2 and 12 hours by age 4, with naps typically ceasing. Common adult patterns of 7 to 10 hours are seen by ages 10 to 14. On polysomnography, rapid eye movement

(REM) sleep dominates the first year. By ages 3 to 4, deep non-REM sleep achieves a more adult-like share. It is worth noting that sleep can be highly individualized and influenced by culture. The importance of sleep cannot be overstated, with impacts on memory, learning, and physical growth. Recent evidence has shed light on the glymphatic system, which eliminates neurotoxic waste (proteins including beta-amyloid and metabolites) from the CNS during sleep. Finally, some sleep phenomena which in and of themselves are not pathological, including nightmares, are often reported, typically at age 5. Sleep terrors (also called night terrors) and sleepwalking occur in NREM stage 3 and are not uncommon in healthy children. Other normal sleep phenomena include hallucinations while falling asleep (hypnagogic hallucinations) and on waking (hypnopompic).

SOCIAL DEVELOPMENT

Social maturation is traditionally divided into four phases beginning with the attachment period and ending with late adolescence. There are many theories that attempt to explain social development (see Table 35.2–1).

Attachment theories explain the development of the sense of self. "Attachment is a deep and enduring emotional bond that connects one person to another across time and space" (Ainsworth, 1973; Bowlby, 1969). Infants have their primary needs met by a caretaker, typically a parent, and the emotional bond that forms between them becomes the foundation for the child's social, emotional and cognitive development. This *affective bond* provides the context for the "emerging pattern of dyadic regulation of emotion" (Stroufe, 2000).

The infant's behavior directed toward the caregiver becomes organized based on needs; thus, the quality of this attachment impacts their survival both biologically and psychologically. A healthy attachment supports the infant's exploration and mastery of the world. There are phases in the development of attachment that begin with *pre-attachment* at ages 0 to 6 weeks. From 6 weeks to 8 months, attachment progresses based on the responsiveness of the caretaker, and from 8 months to 2 years *reciprocal* relationships begin and the child organizes around their acquisition of mobility and the "secure base experience."

The historical leaders in attachment theory include John Bowlby, Harry Harlow, Rene Spitz, Mary Ainsworth, and Mary Main. Disorders of attachment are included in the *Diagnostic and Statistical Manual for Mental Disorders,* 5th Edition and their criteria will be reviewed in the chapter on abnormal child development.

Bowlby developed his theory by borrowing from evolutionary thinking and derived from the idea that the attachment of mother and infant was "due to a species-typical behavioral pattern to promote infant survival." He also incorporated ideas from Piagetian cognitive theory and the concept that "with increasing schema comes increasing complexity of thought" and

applied them to the intensifying connection of the infant's attachment behaviors.

Two researchers in the 1940s and 1950s provided the seeds for the idea that an infant has more than basic physical needs. Psychologically, the infant needs and craves human contact. This was demonstrated in the Harlow studies of rhesus monkeys preference for cloth monkeys and in Spitz's *hospitalism* research which confirmed a failure to thrive in infants who had their biological needs met but did not have a primary attachment figure with whom they had physical contact. Spitz described the concept of *anaclitic depression*, where separation from the caregiver leads to depression, withdrawal and loss of milestones.

Ainsworth's *Strange Situation Experiment* identified four types of infant attachment:

Avoidant—needs frequently not being met by the caretaker
Securely Attached—needs were generally met by the caretaker
Ambivalent—needs inconsistently met
Disorganized-Disoriented—correlated with a history of maltreatment.

Margaret Mahler's more complex theory proposes a sequence of attachment which, if successful, enables an individual to establish a secure sense of self. An infant who is securely attached and has established *basic trust* also experiences appropriate separation anxiety when away from the primary attachment figure.

Mary Main has developed an attachment interview for adults to assess the quality of their childhood attachments. She also described a new attachment classification to apply to Ainsworth's Strange Situation test, the disorganized/disoriented attachment classification.

Advances in biotechnology support the possibility that attachment begins in utero. Thomas Verny, M.D., in his book *The Secret Life of the Unborn Child* (1981), began the discussion of this and the idea of the "attachment pregnancy," and guides for parents to foster healthy in utero attachments have been popular recently.

The changing dynamics of gender roles for parents as well as the changing identity of the nuclear family have led to new research which has generally supported the concept that there are no great differences in quality of attachments in lesbian, homosexual, or transgender families with their children.

Successful secure attachments in infancy correspond to later psychosocial functioning and are characterized by better peer relationships, more cooperation with parents and teachers, greater security in unfamiliar social situations and in the exploration of new environments. A child's sense of self is generally more secure with positive early attachments, which are the foundation of emotional development. There are many consequences of abnormal attachments that will be discussed in the

sections on psychopathology including feeding problems, disruptive behavior disorders, and impaired ability to sustain lasting relationships.

Morality

There are societal and cultural norms that guide one's behaviors and actions. The internalization of these standards is a process that begins at birth when infants become aware that their behavior elicits a corresponding behavior in their caretaker, such as when a parent hugs a smiling happy infant. This cause-and-effect relationship is observed by infants and young children and becomes the basis for the rules that developing children assimilate and accommodate into their moral foundation. Children feel sadness and shame when they are punished or see that their behaviors bring displeasure to their parents or other important adult figures. Therefore behavior is shaped by the fear of punishment, and life can be explained and organized within the framework of cultural rules and a sense of fair play. Children tend to go from the fear of punishment to the desire to confess. As children enter adolescence and reach puberty, they develop guilt and the ability to be critical of their own behaviors and transgressions. In many cultures this is the age when children's lives become their responsibility and their conscience must be their guide.

There are many different theories of moral development but the most famous is that of *Lawrence Kohlberg,* which built on the foundations of Piaget's theory of cognitive development. Kohlberg's work was criticized for being too culturally biased toward the middle class male and, despite revisions over the decades, is still controversial. *Carol Gilligan* in 1982 offered an alternative theory, which corresponds to morality growing in parallel to empathy. Her theory had a gender basis, with males' moral development developing into a system dominated by "the ethics of justice and the assertion of rights" whereas "woman's ends in compassion and an ethic of caring."

EMOTIONAL DEVELOPMENT

The ability to acquire and express emotions and feelings is essential to adult functioning. Learning to identify, understand, express, communicate, and modulate affect is key to successful relationships. An infant's task is to learn to be emotionally responsive and not react to internal feelings and anxiety. This is achieved through the maturation and the development of coping skills. There are many theorists who have attempted to describe emotional maturation, with achievements highlighted in Table 35.2–1.

More recently, theories integrating the neurobiology of brain maturation with social interaction have focused on the interaction between genetics, environment, and behavioral patterns to explain emotional

development and maturation.

All of the theories to describe emotional maturation can basically be divided into four stages with basic milestones. Stage I is the acquisition of basic emotions that are learned through the interaction of the infant with others, including the use of mimicry. Mirror neurons, which are neurons that fire when one acts or observes an action, are proposed as being an essential pathway for this acquisition of a repertory of emotions by the infant. Stage II involves the development of self-conscious emotions, which are derived from approval or disapproval experienced and include shame, envy, embarrassment, pride, and guilt. The ability of emotional self-regulation is the task of Stage III, which continues into middle childhood. Stage IV is marked by true empathy, the ability to understand and share the feelings of another.

Temperament

Temperament has fascinated scientists since ancient times when Galen of Pergamum made his prophecy "that much of human behavior can be predicted according to an individual's temperament."

Stella Chess and Alexander Thomas made important contributions to the study of temperament in the 1970s. They defined three major clusters which are dependent on the perceived sense of ease with which children interact with their environment. The three different styles were assessed through the categorization of nine types of behavior that they defined as dimensions of temperament, including activity level, regularity/rhythmicity, approach or withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span and persistence. Their longitudianl study sample showed the following distribution which was generalized to apply to the general population:

1 in 10 children had a *difficult* temperament
1 in 6 were categorized as *slow to warm up*
4 in 10 were characterized as having an *easy temperament*.

The *goodness of fit* between parent and child as described in their book, is an important factor in working with parent–child relational problems therapeutically. Jerome Kagan, inspired by Galen, also did work on temperament and described two main types of temperament: inhibited and uninhibited. He stated that "temperament refers to stable behavioral and emotional reactions that appear early and are influenced in part by genetic constitution." Behavioral geneticists are now exploring specific genetic polymorphisms that contribute to temperament. Some research cites polymorphisms in serotonin transporter and promoter region genes as having an effect on personality development. Additionally, polymorphisms in the dopamine, serotonin, and norepinephrine transporter genes affect

temperament.

MOTOR DEVELOPMENT

Perhaps more than any other developmental domain, gross and fine motor development is highly intertwined with progress in other areas. Motor development begins in utero, and is experienced by a pregnant mother as kicking. At birth, a premature CNS renders infants with little control over their actions. At this stage reflexes are prominent, such as the grasping, rooting, sucking, swallowing, startle, and Moro. These reflect CNS functioning and disappear at predictable time periods.

Cortical columns are being laid down during the first 6 to 7 months of life and synapses are exploding in number, allowing for greater complexity and control of actions. At 2 to 4 months of age, infants can support their own head and make smoother movements in their extremities, demonstrated by shaking their toys. Some infants may be able to roll over from their stomach to back, and by 6 months they can roll over in both directions. Also at 6 to 7 months, they can sit without support and may start to rock back and forth as if they are trying to crawl, which they will be doing over the next 2 to 4 months. A developing sensory system involving all modalities but particularly hearing, proprioception, and vision facilitate the emergence of new skills, and will continue to help them hone. Hand-to-hand transfer occurs at 7 to 8 months, first grossly then more finely, aided by a *pincer grasp*. This is when something is held between the thumb and index finger, first seen at about 9 months, and with practice develops strongly over the next year.

Clinical Correlate

Infants are unable to roll over from their stomachs to backs before 6 months, a primary reason the American Academy of Pediatrics has recommended babies be placed to sleep on their backs in order to reduce the chance of Sudden Infant Death Syndrome (SIDS).

A 9- to 10-month-old infant can stand with support, and may start walking while holding onto furniture, a practice called *cruising*. Walking typically is reported at 12 months with a normal range of 9 to 15 months. Highlighting the interdependent nature of development, the newfound ability to walk corresponds with Margaret Mahler's separation-individuation subphases of practicing and rapprochement.

By 18 months the now toddlers can drink from a cup, eat with a spoon, and help dress themselves. Athletic abilities emerge at age 2, with running, kicking, throwing, jumping, climbing, and copying straight lines. Simultaneous cognitive development is crucial as these skills require a coordinated effort involving attention and planning. A 3-year-old's athletic skills become more refined and the child can climb stairs and show off the skill of riding a tricycle. By the age of 4, movements continue to improve,

with catching skills and hopping abilities. Visuomotor coordination is needed and spurs development through activities such as sports and art, the latter aided by an ability to hold a pencil appropriately. These actions strengthen synapses in the developing cerebellum, which is fully myelinated by age 4, and in turn facilitates further coordination. This level of dexterity allows pouring and simple food cutting behavior to occur, which is much improved by age 5. At this time the child can engage in basic gymnastics such as somersaulting and can hop and begin to skip. Hand preference is typically established by age 5. The ability to tie shoelaces generally appears within the next year or 2.

Toilet training is influenced by culture, but myelination of pyramidal tracts allows for sphincter control by 18 months and children can start toilet training as early as age 2. They typically develop bowel control before bladder, and the vast majority of Western children are toilet trained by ages 3 to 4. Nighttime bladder control is typically achieved months to years later between ages 5 and 7.

As with all development, it is imperative to keep in mind that the listed ages should be considered normal ranges. There is a high degree of variability, and the amount of delay as well as pervasiveness of delays should inform clinical suspicion of abnormality. Typically a 3- to 5-month delay in the early milestones (sitting without support, standing holding on, first steps) is granted before there is concern, and a larger 10- to 15-month window for later complex achievements (such as climbing stairs, jumping). Family history is important, as gross motor development is considered to be highly influenced by genes. Environment and stimulation is of course important too, particularly in fine motor development such as utensil or pencil use and in sharpening gross motor sporting skills. Inquiring whether a skill has been lost or never developed is also a crucial piece of the clinical history.

SENSORY DEVELOPMENT

Imagine walking on a crowded city street at rush hour: neon lights flashing, sirens wailing, mysterious scents wafting, fellow pedestrians obliviously making contact. In a mere instant, the body is flooded with a barrage of stimuli. That the mind can perceive, organize, and make sense of it all to the point where such a moment would be considered unremarkable, is in itself quite remarkable.

Infants are born with all of their primary senses working in some capacity, some more developed than others. Within the first year, however, there is tremendous growth across the sensory modalities. As with other domains, there is a split into how important nature or nurture is in sensory development. For senses fairly functional at birth, genetics are playing a large but not exclusive role. For those areas that require more development after birth, any predisposition becomes dependent as well as modifiable via

environmental factors.

Hearing is functional and fairly developed by birth, and in fact there is evidence that even in the womb infants can distinguish their mother's voice. Despite this functionality, there is evidence that the softest sound an adult can hear would need to be amplified four times for an infant to perceive it. Children eventually reach adult levels of acuity as early as age 2. At birth, infants will turn their heads toward a sound in a phenomenon known as *auditory localization* and demonstrate a preference for voices. That infants can recognize music should come as no surprise, given the melodic nature of lullabies. Infants can discern consonant tones from dissonant ones, and can be seen bouncing up and down to the music's beat.

Given how much humans rely on vision, it is surprising that this sense is the least developed at birth. In the early months, infants require great contrasts in color to make distinctions. Their color-sensing retinal cones are immature and inefficient at capturing light. Their visual acuity is quite poor, with vision estimates ranging from 20/120 to 20/800 at birth. There is an explosion of improvements made as the cells that will make up the visual cortex proliferate, reach their destination, and then make and break connections. During the first 6 months, 18,000 new visual synapses have the potential to form. Infants have near-adult levels of visual acuity by 8 months, and by age 6 their vision is full.

A number of visual experiences appear to be present at birth. Research has shown that infants possess *perceptual constancy,* where an object is known to be a constant size or shape. Infants also possess the depth cue known as *optic expansion,* where an object getting closer is perceived to be approaching. They can also differentiate human faces. Eye tracking begins at 2 months, and infants are drawn to moving stimuli. Along with this newfound skill comes the ability to take in more of an object and process it. This phenomenon is particularly noteworthy when it comes to looking at faces, as 2-month-olds will scan a face much more comprehensively, and will spend significantly more time looking at eyes and mouths. This has implications for social, emotional, and language development.

At 3 to 4 months, depth perception is improved via *stereopsis,* where the quickly maturing visual cortex uses the slightly different images perceived by each eye to calculate depth. At 6 to 7 months, infants can demonstrate monocular depth, perceiving depth with one eye.

Infants (much like adults) have a preference for sweets, beginning in utero. An ingenious study by de Snoo (1937) demonstrated that when saccharin was injected into amniotic fluid, the fetus would drink more of it and excrete it via their mothers, helping to decrease high amniotic fluid volumes. Odor perception is inferred to take place in the womb as well, based on the fact that amniotic fluid has discernible scents and that this fluid comes into contact with olfactory receptors. After birth, infants show clear preferences for their mother's scent.

Touch is inferred to begin in utero, when a fetus may be seen grasping the umbilical cord, touching other parts of its developing body, and even sucking its thumb. Learning one's orientation in space helps developing proprioceptive skills. Initially after birth infants will explore new objects orally, putting everything in their mouths. They eventually develop stronger motor and visual skills and learn their environment through touch.

The human mind is able to integrate stimuli from various senses (and even multiple stimuli of just one sense) into a cohesive explanation through what is called *intermodal perception*. This ability allows one to successfully navigate the busy city street, all while listening to music.

GENDER IDENTITY

There are multiple theories of gender identity development, including biological, cognitive, developmental, and social learning theory. There are differences between gender identity, sexual identity, and sexual orientation. Gender development begins in utero. During the first trimester, fetuses with a Y chromosome have hormonal masculinization produced by the release of androgens, and feminine hormones and development are inhibited. The fetus with only X chromosomes develops ovaries at the end of this trimester. This is essentially how infants are born, with most of the development of secondary sex characteristics beginning in latency for girls and at preadolescence for boys.

A person's *gender identity* can be the same or different from their sexual assignment at birth.

The concept of gender identity is defined as the person's personal experience of whether they are male or female. A person comfortable with their gender assignment at birth is termed *cisgender*. People with gender identity disparity and discomfort can be gender non-conforming or *transgender,* and some societies define a third or other gender. Societal gender standards are typically binary and impact a developing child's social identity.

Most theories and research support that core gender identity is formed by age 3. Gender dysphoria is a marked incongruence between one's experienced or expressed gender and assigned gender. Gender dysphoria can be caused by attempting to reassign a child's gender and can lead to serious consequences, including depression and severe anxiety. It is thought that, between the ages of 6 and 8, gender identity is coalesced. However, recent evidence suggests that a percentage of people may later shift identities after puberty. Due to the historical changes in Western societal attitudes toward sexuality, research is being done on gender identity development and disorders as well as parenting styles such as genderneutral parenting that are helpful for the gender nonconforming child.

The *S.A.G.E. Test,* the sex and gender explorer is one of many new tests developed to assess gender identity.

Gender roles and gender relationships in society have changed drastically within the last century, as have sexuality and the acceptance of nonbinary sexuality; as social identities change with this new acceptance of different gender and sexual roles, so will parenting and child-rearing practices. The days of defining gender and sex roles in infant toys, clothes, and play are changing. The United States military now allows women in combat and men are staying home to care for children. Mental health professionals need to assist in maximizing a child's development by supporting an understanding and acceptance of new forms of family, gender, and sexual identities.

PSYCHOSEXUAL DEVELOPMENT

Sigmund Freud's contributions to psychiatry and understanding of the mind are the subjects of numerous textbooks, and even institutions in and of themselves. As this chapter is dedicated to development, this section will solely focus on a portion of Freud's theory, that of psychosexual development and its contributions to character formation, from his 1905 piece *Three Essays on the Theory of Sexuality*.

Freud postulated that children go through successive stages in childhood: oral, anal, phallic, latency, and genital. Their names correspond to the erogenous zone from which Freud believed *psychic energies* attach to (or cathect) at different times of life. Psychic energies are instinctual drives which motivate the individual, and at the time this theory was proposed that drive was sexual (aggressive motives would later be emphasized as well).

Unresolved conflicts can arise at any time during any phase, leading to a variety of personality types. In the *oral phase* (from birth until about age 1), an infant's main desire according to Freud is in breastfeeding (or bottle feeding—a warm caregiver is more important than the mode of feeding). Toward the end of the first year comes the emergence of teething and biting, aggressive tools. Undergratified suckling needs (such as neglect or emotional indifference) can lead to jealousy, envy, and a seeking and consuming nature. The typical example is the oral fixation, someone constantly chewing or smoking. A clinging dependency may also be seen and manifested by being unwilling or afraid to let go of someone or something for fear there will not be more. On the contrary, one whose needs have always been met may expect things will always work out and maintains an optimistic nature. This belief may lead to passivity and inactivity, on the other hand, and the potential for fewer coping skills when a need is not met. An infant's sexual (and aggressive) drives can be met with numerous responses by his caretaker, which can lead to a fear of losing the caretaker. To placate these fears, the baby will implement a

defense such as denial of aggression, which, while adaptive in infancy, can be destructive later in life.

In the *anal stage* (ages 1 to 3), the psychic energy has shifted and control becomes a central theme: control over one's autonomy, control over one's impulses, control over one's body and sphincters. Parental demands increase and compliance and rebellion with these requests are at odds here, contributing to the "terrible twos." Whereas the oral stage is a symbiotic one between the caregiver and the infant, the newly developed abilities to walk and talk make the anal stage marked by separateness, or the *dyad*. Frustration and aggression abound as the toddler is struggling to meet expectations and master control. Tolerating ambivalence toward others, learning to titrate aggression, and accepting that caregivers will not leave or withhold their love is crucial toward a successful resolution. It is in this stage where the anal-compulsive character originates, with the Freudian hallmark triad of pedantry, parsimony, and miserliness. A love of order and cleanliness embodies this person, who translates into the obsessive-compulsive personality type. The opposite is one who lives in disordered chaos.

The phallic phase (ages 3 to 6) is marked by the child's sexual desires for his/her opposite-sex parent. An obstacle to this achievement is the same-sex parent, who elicits murderous wishes from the child. In boys this is known as the *Oedipus complex,* in girls *Electra*. These forbidden thoughts evoke fears of bodily injury, notably castration anxiety in boys. Fear of injury is indeed typically seen during this time. These fears as well as impractical realities eventually force the child to give up his quest and alternatively identify with the same-sex parent. In doing so, he internalizes his parents' rules and mores, ending the phallic phase with the formation of a superego. There are now three entities involved (child plus mom and dad), and conflicts in this phase lead to issues in triadic relationships. Unresolved conflicts in this stage may lead to myriad traits, from self-evident Oedipal ones to difficulties with following rules.

Latency follows from resolution of the Oedipal complex until puberty. Freud believed this time was one of relative calmness sexually, though not entirely static. Psychic energy is invested in academic and social avenues as the child goes through grade school. This phase is dominated by school and peers, learning socialization and rules. Values and ideals are solidified as the newly formed superego evolves from an external presence to an internalized one.

Though outside the scope of child development, following latency, Freud described the genital phase, where the genitals (as in the phallic stage) again become the source of libidinal energy, but now the pubertal adolescent has biological potency. This newfound ability confers its own set of conflicts, and the teenager moves from within the family to outside the family.

It is important to bear in mind that these character types are simplifications. In addition, this theory is psychological and does not account for innate tendencies which were indeed noted by analysts as well. Finally, when conflicts occur they are from repeated behavior patterns between a child and the important caretakers. Though many are skeptical about the veracity of Freud's theories, his contributions are irrefutable. The impact of early experiences remains crucial to understanding an individual, as does the relationship to family members. The significance of an unconscious, that feelings occur outside of one's awareness, has enormous bearing on how one conceptualizes the mind and treats patients clinically.

CONCLUSION

In summary, development is the acquisition of new skills or abilities and the various responses both intra- and inter-personally. Humans are born with a genetic background, and the environment contributes to which pathways get further strengthened or pruned. Changes in the brain allow for new possibilities in the developing child. Small advances begin to accumulate and more possibilities arise. By the end of childhood, a person who started as mostly innate reflexes has become capable of writing essays about the future, performing complex athletic activities, establishing a sense of identity, and engaging in deep reciprocal relationships. However, although this section has focused on child development and all the significant achievements that are made during that period, it is important to note that development continues throughout the lifespan.

Acknowledgments

The authors would like to acknowledge Maureen Fulchiero Gordon, M.D., who authored the last edition of this chapter, and Jean Thomas, M.D., for their contributions to this chapter.

▲ 35.3 Adolescent Development

ARDIS C. MARTIN, M.D., AND CAROLY SUE PATAKI, M.D.

Adolescence is a critical period characterized by neurobiological and physical maturation leading to enhanced psychological awareness and higher-level social, cognitive, and emotional interactions with peers and adults. The most striking social and behavioral changes in adolescence include (1) increased affiliation with a peer group, (2) striving for more autonomy from parents, (3) increasing ability to "mentalize," that is, understand what others are thinking and feeling, (4) an increase in risk-taking behaviors, and (5) greater sensation seeking. A convergence of data from neuroimaging studies, including the work of Blackmore and Mills (2014) have been able to identify certain regions of the adolescent brain specialized to produce increased mentalizing, and other regions of the brain that remain immature, but are adaptive to changing environmental demands through their "plasticity." The varying levels of maturation in diverse regions of the adolescent brain leads to a seeming paradox, for example, between an adolescent's increased ability for empathic social thought process and at the same time reckless risk-taking behaviors. This apparent "mismatch," that is, varying degrees of maturity across different regions of the adolescent brain has been referred to by some researchers as the "Dual System Model." The work of Strang, Chein, and Steinberg (2013) supports a view that increased risk taking in mid-adolescence may be, in part, due to an increased reactivity of the social and emotional regions of the brain in the context of less mature cognitive control brain development. The social and emotional reactivity system is believed to be localized

mainly in the ventral striatum and ventromedial prefrontal cortex, whereas the cognitive control system is believed to be localized in the lateral prefrontal, parietal, and anterior cingulate cortices. Emerging evidence from neuroimaging studies supports a correlation between increased adolescent social awareness and mentalizing abilities and activity in three specific brain regions including the medial prefrontal cortex (mPFC), the posterior superior temporal sulcus (pSTS), and the temporoparietal junction (TPJ). However, as older adolescents transition into young adulthood, there is a decrease during mentalizing tasks in the activation of the mPFC. Thus it appears that during the development of mentalizing abilities, the mPFC is a critical brain region, however, once the process is developed, in adulthood, this region no longer predominates, and other brain regions may take over this function. Giedd (2014), and other colleagues, using neuroimaging to track adolescent brain development find that gray matter in the brain, such as the PFC, does not grow larger after puberty, on the contrary, it matures by becoming more specialized, that is, by a process termed "pruning," which ultimately leads to a diminished size. Gray matter is at its peak volume in girls at approximately age 11 years, and in boys, at approximately 13 years. On the other hand, white matter, representing myelinated brain regions continues to increase throughout childhood and adolescence. The continued increase in white matter reflects increasing "connectivity" and continued ability for the brain to adapt to new cognitive demands throughout adolescence. Thus, the increasing and less specialized white matter growth allows for greater cognitive adaptive brain function, with a resulting delay in its maturation in adolescents. Consequently, adolescents experience a longer period to learn and respond to novel cognitive information and develop new responses, however, this delays the brain maturation guiding cognitive control and decision making.

DEFINITION

Adolescence is the period of maturation between childhood and adulthood heralded by the physiological signs and surging hormones of puberty. It is a time when peer relationships deepen, autonomy grows, and intellectual pursuits intensify and a sense of social belonging is sought. Adolescence is a time of accelerated social and psychosexual exploration, culminating in an integrated concept of "self." Adolescents can be viewed as neurobiological "works in progress," often consumed by academic, interpersonal, and emotional challenges, and exploring new territories using their talents, and experimenting with social identities.

WHAT IS NORMAL ADOLESCENCE?

The conceptualization of adolescence as a continual struggle, with its defining feature intense psychic pain and severe turmoil, was a historical notion. The hypothesis that most adolescents experience enduring severe

psychological distress, intense depressive symptoms, severe mood lability, and a disruption of their usual conduct was not borne out by epidemiological studies. Although certain psychiatric disorders, such as major depression, schizophrenia, and bipolar disorders, emerge with greater frequency in adolescents than in younger children, the majority of adolescents are free of psychiatric disorders. For up to approximately 75 percent of youth, adolescence is a period of successful adaptation to physical, cognitive, and emotional changes, largely continuous with their previous functioning. Thus, the majority of adolescents display reasonable autonomy in decision making, increasing independence in completing academic work, and successful peer relationships without significant alienation from their families or the emergence of conduct-disordered behaviors. Psychological maladjustment, self-loathing, disturbance of conduct, substance abuse, affective disorders, and other impairing psychiatric disorders emerge in approximately 20 percent of the adolescent population. Adolescent adjustment is, in general, continuous with previous psychological function; thus, psychologically disturbed children are at greater risk for psychiatric disorders during adolescence. Adolescents with psychiatric disorders are at increased risk for greater conflicts with families and for feeling alienated from their families. Although up to 60 percent of adolescents endorse occasional distress or a psychiatric symptom, this group of adolescents functions well academically and with peers and describes themselves as generally satisfied with their lives. Studies conducted since the 1980s indicate that most adolescents endorse more acceptance than rejection of their parents' values and lifestyles, and few report feelings of isolation or alienation from their families.

The developmentalist Erik Erikson characterized the normative task of adolescence as *identity versus role confusion*. In other words, adolescents, faced with the task of applying childhood talents, strengths, and experiences to their evolving physical and emotional selves, must be able successfully to change "who they are" so as to build a more mature identity. The integration of past experiences with current changes takes place in what Erikson termed *ego identity*. Adolescents express various aspects of their psychological selves by becoming fans of heroes or other well-known musical or political idols. Some adolescents appear consumed by their identification with a particular idol, whereas others are more moderate in their expression. Adolescents who feel accepted by a peer group are less likely to become consumed by adoration of an idol. Adolescents who are socially isolated, feel socially rejected, and become overly identified with an idol to the exclusion of all other activities are at higher risk for serious emotional problems and require psychiatric evaluation.

Adolescence is a time to search for ideals and social values that can be carried into adulthood. Erickson used the term *moratorium* to describe that interim period between the concrete thinking of childhood and a more

evolved complex abstract thinking and ethical development. He defined *identity crisis* as a normative task of adolescence in which adolescents pursue alternative behaviors and styles and then successfully mold these different experiences into a solid identity. A failure to do so results in *identity diffusion*, or role confusion, in which there is a lack of cohesive or confident sense of identity. Adolescence is the time to bond with peers, experiment with new beliefs and styles, fall in love for the first time, figure out who one wants to be and where one fits in, and explore creative ideas for future plans. The literature leads to the conclusion that the majority of adolescents go through this developmental process with basic optimism and good self-esteem, maintain good peer relationships, and sustain basically harmonious relationships with their families.

STAGES OF ADOLESCENCE

Early Adolescence

Early adolescence, from 12 to 14 years of age, is the period in which the most striking changes are noticed—physically, attitudinally, and behaviorally. Growth spurts often begin in these years for boys, whereas girls may have had rapid growth for 1 to 2 years prior. At this stage, many adolescents express a sense of identification with a particular peer group, often a same-sex group of peers join together, and may identify belonging to a peer group with markers including clothing, hair styles or affiliation with certain activities. Both boys and girls begin to identify themselves as distinct members of their families, and often critique usual family habits, insist on spending time with peers with less supervision, and may question previously accepted family values.

In the early stage of adolescence, there may be some degree of withdrawal from family activities with, increased interest in spending time with peers, greater awareness of style and appearance, a stated goal of becoming more independent, and claims of needing less parental involvement. A new awareness of sexuality may be displayed by increased modesty and embarrassment with their physical development or may exhibit itself in an increased interest in the opposite sex.

Early adolescents engage in subtle or overt displays of their growing desire for autonomy, sometimes with challenging behaviors toward authority figures, including teachers and school administrators, and exhibit disdain for rules. At this age, some adolescents begin to experiment with cigarettes, alcohol, and marijuana. The Youth Risk Behavior Surveillance System (YRBSS) surveyed all public and private schools from grades 9 to 12 throughout the United States (more information is available at http://www.cdc.gov/yrbs). The 2011 report indicated that 37.6 percent of ninth graders had tried smoking cigarettes and 6.8 percent of male ninth graders had smoked at least one cigarette every day consecutively for 1

month. Cigarette smoking that included more than 10 cigarettes per day was reported by 5.7 percent of girls and 9.4 percent of boys in the ninth grade. The YRBSS reported that 30.2 percent of ninth-grade girls and 29.3 percent of ninth-grade boys consumed at least one alcoholic drink in the month preceding the survey. Over the last 5 years, lifetime alcohol, that is, at least trying alcohol at least once, was almost 62 percent in both boys and girls in the ninth grade. Heavy drinking, defined as at least five drinks of alcohol in a row, was present in 13 percent of ninth-grade girls and 15 percent of ninth-grade boys. Marijuana was reported by 26.4 percent of ninth-grade girls and 34.9 percent of ninth-grade boys at least once, and current use of marijuana was present among 18 percent of ninth graders. Overall, the prevalence of current and binge drinking among 9th to 12th graders has decreased between 2009 and 2011 while the prevalence of one or more time use of marijuana and daily current use has increased over the same time frame. With regard to other illicit drug use (cocaine, heroin, hallucinogens, and amphetamines) among 9th to 12th grades, only the prevalence of ecstasy use has increased between 2009 and 2011.

During early adolescence, there is significant variation in the timing of acquiring new behaviors. For example, some 12 year olds identify with popular music or wearing "adolescent" clothing, whereas other adolescents are ot seeking to reinvent themselves with a more mature appearing image. Epidemiological surveys have not provided evidence for this notion that adolescence is characterized by overwhelming alienation, profound angst, and significant disruption of family relationships. In this age group, most adolescents spend at least twice as much time with their families as with their peers.

Suzanne, a 14-year-old freshman in high school concerned about being compared to her older sister, who was known as a troublemaker. Suzanne felt that her teachers didn't value her for being her "own" person and automatically assumed that she was a poor student, always looking for a way to avoid schoolwork. Suzanne secretly smoked cigarettes, occasionally drank alcohol, and had tried smoking marijuana, however, she found it extremely annoying that her parents were always checking up on her. She rationalized that her parents' intrusion was just because her older sister had been suspended several times for going to school intoxicated. Suzanne spent most of her time out of school in her room with her door closed, doing homework while watching TV, instant messaging to her friends on her computer, and text messaging, snap chatting, and using Instagram with her friends. Although Suzanne had enough friends, and enjoyed singing in the school choir, she found herself feeling anxious much of the time and fearing that she had forgotten to finish all of her homework or studied enough for a test. She found going to class more and more unpleasant, and decided that classes were a waste of time. Suzanne began to find the school rules increasingly irritating, especially being "locked" out of the classroom if she was a few minutes late. Suzanne felt that the teachers were too strict, and never gave her the benefit of the doubt. To avoid getting into trouble for being late, Suzanne began to cut classes then she began to cut the whole day of school if she thought she was late in the morning. Before long, she had fallen behind in her work but was too embarrassed to tell her parents. She told her friends, and they helped her get some of the schoolwork, but she had missed so much work that it was difficult to catch up. Since it was getting close to her first progress report and Suzanne could not talk to her parents, she finally went to her school counselor to say that she was not going to many classes because it was too stressful to get there on time and that she was in danger of failing. The school counselor convinced Suzanne to tell her parents about her academic problems, and, begrudgingly, she agreed to a meeting with the counselor and her parents. Suzanne's parents

were shocked to find out that she was so stressed, and near failing, since she consistently said that everything was fine as long as everyone left her alone. After the meeting, Suzanne realized that instead of trying to be so independent she was actually being self-destructive. Suzanne agreed to accept her parents' help with a ride to school in the morning, and despite some initial resistance tutoring sessions were started. Suzanne worked hard with her tutor, improved her grades, and began to leave her bedroom door open more often at home. She also turned to parents and sisters for help if she did not understand something and found that they were actually helpful. Suzanne ended up with three A's and one B for the first grading period and was proud of herself. Suzanne felt less stressed and more confident after the first grading period, she was more connected to her family, and looked forward to spending more time with friends in the remainder of her freshman year.

Middle Adolescence

During the middle phase of adolescence (roughly between the ages of 14 and 16 years), peer groups begin to shift to coed, and become more predominant in their importance. Concrete signs of greater autonomy are beginning to emerge, such as learning to drive, and in some states, obtain a driver's license by the age of 16 years. Along with a greater lifestyle of autonomy adolescents are also presented with increased responsibilities, especially in the area of social judgment. Conflict may arise when empathy and social awareness are paired with poor impulse control and decision making, potentially leading to health risks, car accidents, and alcohol, and drug use. Sexual behavior intensifies in this phase of development, initiating romantic relationships are more complicated, and self-esteem becomes a pivotal influence on positive and negative risk-taking behaviors.

The 2011 YRBSS reported more frequent cigarette use among white students (8.6 percent) and Hispanic students (5.8 percent) than black students (3.4 percent). Use of alcohol, that is, report of at least one alcoholic drink within 1 month of the survey time, was 42 percent for 10th graders and 47 percent for 11th graders. The prevalence of heavy drinking—five drinks or more in a row—increased with each increasing grade from 9th to 12th grade. Tenth graders reported rates of heavy drinking, 18.4 percent, which increased in 11th graders, 25.2 percent. Marijuana use was found to be somewhat higher among boys than girls across all high school grades, and the overall prevalence of current marijuana abuse was 26 percent among 11th graders. The prevalence of cocaine use was reported to be higher in boys than girls, and lifetime cocaine use was 7.5 percent among 11th graders and 8.5 percent among 11th-grade boys.

In this phase of development, adolescents tend to identify with a group of peers who become highly influential in their choices of activities, styles, music, idols, and role models. Adolescents' underestimation of the risks associated with a variety of recreational behaviors and their sense of "omnipotence," mixed with their drive to be autonomous, frequently cause some conflict with parental requests and expectations. These conflicts, however, for the most part, do not result in the destruction of meaningful relationships with parents or siblings. For most teens, the process of

defining themselves as unique and different from their families can be achieved while they still maintain alliances with family members.

Sean, a 16-year-old junior in high school, had just gotten his driver's license. He realized that he was lucky to have received his parents' old car as soon as he had turned age 16 years, but he was overwhelmed when his friends called constantly for rides. Sean drove his younger brother to school each morning, and this created tremendous friction between them since Sean was always ready early and his brother, Jake was always late. Sean would threaten to leave without him in the morning, and on some days he actually did. His parents would then become angry with him for leaving his brother since that meant that one of them would need to take him and inevitably be late to work. Sean was a confident driver but felt pressured by his parents and by his peers, and considered not driving to school for the rest of the year. When nobody hassled Sean, he would leave in time for school, find a parking place at the crowded lot, and make it to class on time. He drove himself to his karate class, where he functioned as an assistant teacher. Sean, however, felt unable to say no to giving his friends rides, even when they brought beer and smoked marijuana in his car. Sean would half-heartedly object, however, he had never been popular, and believed that he would lose the few friends he had, if he did not take risks. Sean did not feel comfortable telling his parents about this, and so he continued to allow his friends to bring beer into his car until he had a "close call" in which a police car was tailing him, but did not pull him over. Sean began to panic, and had to stop his car on the side of the road. Sean's friends congratulated him for not getting caught, however, they didn't understand how much stress he was under. After this, Sean told his parents that he no longer wanted to drive to school, and he told his friends that his parents had taken away the car. Although Sean did lose some of his old friends which disturbed him, he felt more in control of his life. Sean began to spend more time playing his guitar and played online interactive computer games. He went through a period of social isolation and sadness, but over time, he developed new friendships with peers who didn't use drugs or alcohol, and played the same online games. He looked forward to applying to college and was glad to leaving the social situation in his high school. Sean put energy into studying and taking challenging courses in high school, including multiple "advanced placement" courses, which he found stimulating, and he felt that his decision to shun drugs and alcohol, despite the loss of some peers, was the right decision for him.

Late Adolescence

Late adolescence (between the ages of 17 and 19 years) is a time when the adolescent cognitive brain processes, impulse control and decision making begin to catch up with the social brain and behavior. During this phase, exploration of academic pursuits, musical and artistic tastes, athletic participation, and social bonds leads an older teen toward greater definition of self and a sense of belonging to certain groups or subcultures within mainstream society. As Erickson aptly described, through this exploration, an adolescent gradually moves toward a solid "identity formation." Well-adjusted adolescents can be comfortable with current choices of activities, tastes, hobbies, and friendships yet remain open to the idea that their "identities" will continue to be refined during young adulthood. Peer interactions are primary, and some bridges may be formed with family members to increase communication and social repartee. This transition spans the completion of high school and at least the first year of college, where exploration of new relationships and interests, often in a new setting away from home, is initiated. Prior to finishing high school,

however, the use of cigarettes, alcohol, and marijuana is higher than in the lower high school grades. The 2011 YRBSS reported that 13.6 percent of 12th graders had had the occasion to drive while they had been drinking alcohol, and 27.4 percent of 12th graders had been passengers with drivers who had been drinking alcohol. The prevalence of current frequent cigarette use was reported to be 10.8 percent among 12th graders. Alcohol use within 1 month of the survey was reported by 48.4 percent of 12th graders and 51.2 percent of 12th-grade boys, with episodic heavy drinking of more than five consecutive drinks in a row occurring in almost one-third (31.5 percent) of 12th graders. Nationwide, current marijuana use was reported by 31.1 percent of 12th-grade boys and 24.7 percent of 12th-grade girls. The prevalence of having ever used ecstasy was reported by 12.6 percent of 12th-grade boys and 9.9 percent of 12th-grade girls.

Neuroimaging studies provide evidence suggesting that during late adolescence and even into adulthood, the prefrontal cortex neural networks continue to facilitate working memory, prospective memory (the ability to keep in mind an intention to do something in the near future while multitasking), perspective taking (understanding another person's point of view), and responding to others while keeping one's feelings in mind. This phase of adolescence is an exciting time for the development of finely tuned cognitive abilities, social skills, and enduring relationships.

Samuel, 18½ years old, was in his second semester of college. The novelty of being away from home was wearing off, and he was pleased that his relationships with college friends felt deeper and more important to him than his high school peers. Samuel had entered college without any idea about a potential career, and during his first semester he had taken what he termed "random" classes. In high school, Samuel had been especially talented in languages, history, and math. He loved to travel and never gave much thought to what it might be like to be settled in a career. Samuel's parents had encouraged him to explore interests during high school, however, they made it clear that when he got to college, he was expected to set a career goal as quickly as possible, so that his college years wouldn't be wasted. So far, Samuel had met a number of classmates who had entered college already focused on future careers, so he began to feel pressure to decide on a future plan. Samuel agonized about the possibilities, and wondered why so many peers seemed to be so sure of their future goals and plans, while he felt very confused. Samuel felt somewhat alienated by his lack of direction, and he began to have insomnia. When Samuel mentioned his insomnia to his friend Mia, she was surprised by his level of stress, and told him she viewed him as an open and social person who made friends easily, and got along well with everyone. Samuel felt that his versatility made it even more difficult to find a major where he fits best. Finally, Mia challenged Samuel's parents' expectation to figure out the rest of his life right now. Instead, she suggested that he take at least two more quarters of classes in the liberal arts curriculum before making a decision about which career was the best match for him. Samuel realized that Mia's approach to life was very reasonable, and free of the pressures to plan his future right now, make commitments early, and see them through. Samuel had been influenced to believe that quitting or changing can be a sign of weakness. Mia's approach promoted considered life decisions based on positive experiences rather than on a timeline that didn't seem to fit. After much thought, Samuel took Mia's advice and decided to allow himself another year to decide on a major in and what to pursue as a career.

COMPONENTS OF ADOLESCENCE

Physical Development

Physical growth, along with the onset of sexual development, is identified as the "hallmark" of adolescence. Puberty is the process by which adolescents develop physical and sexual maturity, along with reproductive ability. Pubertal development begins in response to a surge of gonadotropin-releasing hormone from the hypothalamus. The hypothalamus is influenced by a multitude of physiological and psychological factors, and the onset of puberty may be delayed or altered in situations of severe nutritional deprivation. Gonadotropin-releasing hormone acts on the pituitary gland to release the gonadotropin-luteinizing hormone and follicle-stimulating hormone. These two hormones, in turn, act to stimulate the production of a variety of androgens, testosterone, estradiol, and other peptides. Physical development during puberty is also regulated by two additional hypothalamic peptides, growth hormone–releasing hormone and somatostatin, both of which promote the release of growth hormone from the pituitary gland. Puberty unfolds over time in conjunction with the pulses and feedback loops of these gonadotropins. The first signs of the pubertal process are an increased rate of growth in both height and weight. This process begins in girls by approximately 10 years of age. By the age of 11 or 12 years, many girls noticeably tower over their male classmates, who do not experience a growth spurt, on average, until their 13th year. Even more striking are the differences in the development of secondary sexual characteristics in girls versus boys approximately 13 years old. By age 13 years, many girls have experienced menarche, and the majority have developed breasts and pubic hair. The initial appearance of pubic hair in both genders may occur before puberty, during adrenarche, which is dependent on hormones secreted by the adrenal glands, rather than by gonadal development. Some components of pubertal development are identical in boys and girls and include an increase in height, weight, muscle, and fat, whereas others, such as breast development or growth of facial hair, are specific to only one gender. There is wide variation in the normal range of onset and timing of pubertal development and its components. There is a set sequence, however, in the order in which pubertal development proceeds. Thus, secondary sexual characteristics in boys, such as increased length and width of the penis, for example, will occur after the release of androgens from developed enlarged testes.

Table 35.3–1.
Sexual Maturity Rating (SMR) of Girls and Boys

SMR	Girls	Boys
Stage 1	Preadolescent, papilla elevated No pubic hair	Penis, testes, scrotum preadolescent No pubic hair

Stage 2	Breast bud, small mound; areola diameter increased	Penis size same, testes, and scrotum enlarged, with scrotal skin reddened
	Sparse, long pubic hair, mainly along labia	Sparse, long pubic hair, mainly at the base of the penis
Stage 3	Breast and areola larger; no separation of contours	Penis elongated, with increased size of testes and scrotum
	Pubic hair darker and coarser; spread over pubic area	Pubic hair darker and coarser; spread over pubic area
Stage 4	Breast size increased	Penis increased in length and width
	Areola and papilla raised	Testes and scrotum larger
	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs
Stage 5	Breasts resemble adult female breast; areola has recessed to breast contour	Penis, testes, scrotum appear mature
	Pubic hair increased in density, area; extends to thighs	Pubic hair increased in density; area extends to thighs

Sexual maturity rating (SMR), also referred to as *Tanner stages*, range from SMR 1 (prepuberty) to SMR 5 (adult). The SMR ratings include stages of genital maturity in boys and breast development in girls, as well as pubic hair development. Pubic hair development is a less reliable measure of sexual maturity, however, because it may emerge in response to androgens from the adrenal glands before the pubertal process has actually begun. Table 35.3–1 outlines SMRs for boys and girls.

The primary female sex characteristic is ovulation, or the release of eggs from ovarian follicles approximately once every 28 days. When adolescent girls reach SMR 3 to 4, ovarian follicles are producing enough estrogen to result in menarche, the onset of menstruation. When adolescent girls reach SMR 4 to 5, an ovarian follicle matures on a monthly basis and ovulation occurs. Estrogen and progesterone promote sexual maturation, including further development of fallopian tubes and breast development.

For adolescent boys, the primary sex characteristic is the development of sperm by the testes. In boys, sperm development occurs in response to follicle-stimulating hormone acting on the seminiferous tubules within the testes. The pubertal process in boys is marked by the growth of the testes stimulated by luteinizing hormone. There is no discrete sign of the formation of viable sperm, but it must be assumed that at the time that ejaculatory capacity occurs, viable sperm are likely to be present. An adolescent boy's ability to ejaculate generally emerges within 1 year of reaching SMR 2. Secondary sexual characteristics in boys include thickening of the skin, broadening of the shoulders, and the development of facial hair.

In general, the majority of adolescents adjust well to the changes in their physical growth and maturation. Inasmuch as overall identity formation is a gradual process, adolescents incorporate their developing

physical identities into their evolving adult selves.

Cognitive Maturation

Cognitive maturation in adolescence encompasses a wide range of expanded abilities that fall within the global category of "executive functions" of the brain. These include the transition from concrete thinking to more abstract thinking; an increased ability to draw logical conclusions in scientific pursuits, with peer interactions, and in social situations; and new abilities for self-observation and self-regulation. These result in an adolescent's capacity to develop hypotheses, express altruism, create idealistic scenarios, and develop hopes and dreams for the future. Adolescents acquire increased awareness of their intellectual, artistic, and athletic gifts and talents, yet it often takes many more years into young adulthood for them to establish a practical application for these abilities.

The cognitive developmental theorist Jean Piaget has been a central influence on the way in which clinicians and researchers understand the cognitive strategies of children throughout development and the changes that occur during adolescence. The central cognitive change that occurs gradually during adolescence is the shift from concrete thinking (*concrete operational thinking*, according to Piaget) to the ability to think abstractly (*formal operational thinking*, in Piaget's terminology). This evolution occurs, according to Piaget, as an adaptation to stimuli that demand an adolescent to produce hypothetical responses, as well as in response to the adolescent's expanded abilities to provide generalizations from specific situations. Recent magnetic resonance imaging (MRI) studies showing evidence of a preadolescent increase in cortical gray matter in the brain, possibly due to a wave of increased production of synapses, may be a physical correlate of the adolescent's ability for expanded abstract reasoning. The development of abstract thinking is not a sudden epiphany but, rather, a gradual process of expanding logical deductions beyond concrete experiences and achieving the capacity for idealistic and hypothetical thinking based on everyday life. Younger adolescents may be able to verbalize an understanding of complex abstract constructs and still react to situations in rigid and concrete ways. For example, a young adolescent may be able to verbalize an understanding of the link between drug and alcohol use and health risks but cannot imagine it happening to himself or herself. Similarly, adolescents often believe that they can "beat the odds," even when they understand the mathematical meaning of the probability of an event occurring. Adolescents often use an omnipotent belief system that reinforces their sense of immunity from danger, a false sense of immortality, even when confronted with logical risks. Some degree of child-like magical thinking continues to coexist with more mature abstract thinking in many adolescents. Despite the persistence of magical thinking into adolescence, adolescent cognition departs from that of

younger children with regard to an increased ability for self-observation and the development of strategies to promote strengths and compensate for weaknesses. For example, an adolescent who becomes aware of a weakness in completing academic work or tests during the time allotted in school may realize that he or she knows the material but cannot perform well in timed examinations and will make a request of the teacher to receive additional time on examinations. The ability to develop strategies for survival and use proactive methods of making them happen increases during the period of adolescence. One of the important cognitive tasks in adolescence is to identify and gravitate toward those pursuits that seem to match the adolescent's cognitive strengths in academic courses and in thinking about future aspirations. Piaget believed that cognitive adaptation in adolescence was profoundly influenced by social relationships and the dialogue between adolescents and peers, making social cognition an integral part of cognitive development in adolescence.

Socialization

Socialization in adolescence encompasses the ability to find acceptance in peer relationships and in turn the development of more mature social cognitions enabling the adolescent to accept others. It is common knowledge that, for early adolescents, the skills for developing a sense of belonging to a peer group, are of central importance to a sense of well-being. Being viewed as socially competent by peers is a critical component in building good self-esteem for most early adolescents. Peer influences are powerful and can foster positive social interactions, as well as apply a pressure in less socially accepted behaviors or even high-risk behavior. Belonging to a peer group is, in general, a sign of adaptation and a developmentally appropriate step in separating from parents and turning the focus of loyalty toward friends. Social cognition—the way in which adolescents use logic and reason in their assumptions about peers and in their peer interactions—has been explored by Robert Selman. (See Asher and Gottman, 1981.) After interviewing children and adolescents with respect to their interpretation of various social interactions, he identified stages of social cognition. In school-aged children and preadolescents, Selman described social cognitions as "fair weather cooperation." That is, the friendships are characteristically on-again/off-again, depending on the level of affiliation or disagreement in the last social interaction. Thus, children between the ages of 6 and 12 years are able to engage in exchanges of ideas and opinions and acknowledge feelings of peers, but the relationships often wax and wane in a discontinuous way on the basis of altercations and good times. Friendships deepen with repeated good times, but, for some school-aged children, a variety of peers are often interchangeable—that is, a companion is sought when a given child has free time, rather than out of a desire to spend time with a specific friend. As

adolescence ensues, friendships become more individualized, and personal secrets are likely shared with a friend rather than a family member. A comfort level is achieved with one or several early adolescent peers, and the group may "stick together," spending most free time together. In early adolescence, a blend of these two social modes may emerge, small "cliques" may arise, and, even within the cliques, competition, and jealousies regarding which dyads are "preferred" or higher ranked within the clique may result in some discontinuities in the relationships. In later adolescence, the peer group solidifies, leading to increased stability in the friendships and a greater mutuality in the quality of the interactions.

Moral Development

Moral reasoning among adolescents depends on the maturation of cognitive strategies for problem solving, societal conventions, exposure to familial attitudes, and personal values adopted. Morality is a set of values and beliefs about codes of behavior that conform to those shared by others in society. Adolescents, like younger children, tend to develop patterns of behaviors characteristic of their family and educational environments and by the imitation of specific peers and adults whom they admire. Moral development is not strictly tied to chronological age but, rather, is an outgrowth from cognitive development. Piaget described moral development as a gradual process parallel to cognitive development, with expanded abilities in differentiating the best interests for society from those of individuals occurring during late adolescence. The development of trends in moral judgment has been divided into levels by Lawrence Kohlberg, who posed "moral dilemmas" to children and adolescents and subsequently characterized their responses. According to Kohlberg, morality can be divided into preconventional, conventional, and postconventional. Before adolescence, decisions regarding actions that are loosely defined as "right" and "wrong" are dependent on the anticipated consequence to those actions. School-aged children, for example, denoted as using level 1 of preconventional morality, may define actions that result in a negative consequence or punishment as "wrong" simply due to the consequence that may ensue. The most important defining feature of "right" then becomes being able to "get away with it," and it only becomes "wrong" if there is punishment associated with it. Some young adolescents, still functioning within the category of preconventional morality but one level higher (level 2), may define "right" and "wrong" as synonymous with what is perceived as fair and reciprocal. Thus, the philosophy of "an eye for an eye, and a tooth for a tooth" may prevail in this stage of morality. During adolescence, conventional morality, level 3, becomes prevalent, with the view that there is a "right" and a "wrong" determined by society, often without the possibility of mitigating or extenuating circumstances. Adolescents espousing this level of morality are often rigid in their concept

of "good" and "bad" and unable to find a role for motivation in their judgment of behaviors. Thus, adolescents may often take the viewpoint of applying the harshest punishments that society can offer when asked to judge complex moral situations—for example, a poor man robbing a pharmacy to obtain a life-saving medication for his child. Later in adolescence, at level 4, a greater understanding of societal rules may be espoused within the context of conventional morality. It is generally not until late adolescence or early adulthood that the complexities of moral decision making are recognized and incorporated into their thinking. Postconventional morality (level 5), according to Kohlberg, implies the ability to interpret complex moral dilemmas in which the best moral decisions of an individual may come into conflict with the moral standards of society. At this level of thinking, adolescents are more flexible in their understanding of "right" and "wrong." The concept of *extenuating circumstances* is understood at this level of moral thinking, allowing exceptions to rules that are ordinarily followed. Kohlberg postulated a final, higher level of postconventional moral development that he labeled level 6, in which an individual is able to recognize a universal moral imperative that might take priority over standard societal moral values.

Although Kohlberg's and Piaget's notions of moral development focus on a unified theory of cognitive maturation for both sexes, Carol Gilligan emphasizes the social context of moral development leading to divergent patterns in moral development. Gilligan points out that, in women, compassion and the ethics of caring are dominant features of moral decision making, whereas for men, predominant features of moral judgments are related more to a perception of justice, rationality, and a sense of fairness.

Self-Esteem

Epidemiological surveys suggest that the majority of adolescents rise to the challenges of their physical and emotional development with optimism and solid self-esteem. Self-esteem is a conglomerate measure of one's sense of self-worth based on perceived success and achievements, as well as a perception of how much one is valued by peers, family members, teachers, and society in general. The most important correlates of good self-esteem are one's perception of positive physical appearance and high value to peers and family. Secondary features of self-esteem relate to academic achievement, athletic abilities, and special talents. Adolescent self-esteem is mediated, to a significant degree, by positive feedback received from a peer group and family members, and adolescents often seek out a peer group that offers acceptance, regardless of negative behaviors associated with that group. There are also developmental factors that influence adolescents' cognitions about themselves that affect global ratings of self-esteem in this age group. Studies comparing reported self-esteem across

the lifespan indicate that there are trends in self-esteem ratings that are age related. Starting in adolescence, there are also gender differences in reported self-esteem. A study investigating global measures of self-esteem in school-aged children—adolescents, 13 to 17 years old, and older teens to young adults, 18 to 22 years old—found group differences depending on age. Overall reported self-esteem was found to be highest in school-aged children as compared to adolescents and young adults, and boys and girls were identical in their self-reports. During adolescence, global reports of self-esteem decreased throughout, with adolescent girls experiencing a drop twice that of adolescent boys. Self-esteem, at a group level, continued to drop during the high school years, rose in young adulthood during the college years, and continued to rise in early to mid-adulthood. Girls continued to rate themselves with generally lower self-esteem into adulthood. The question arises as to how most adolescents surveyed report relative good adjustment and yet, at the same time, experienced a drop in self-esteem. These data appear to reflect the "inflated" self-esteem of school-aged children, who may be seeing themselves as better, smarter, and more capable than they really are. During adolescence, it is quite possible that even well-adjusted individuals realize that they are not as exceptional as they used to believe they were. Adolescents seem to be more aware of their shortcomings and, therefore, had lower self-reported scores on self-esteem measures. In young adulthood, however, and into mid-adulthood, along with expanded cognitive abilities for self-regulation, reported self-esteem increases and continues to increase well into mid-adult life.

ADOLESCENT BRAIN DEVELOPMENT: CORRELATIONS WITH EMOTIONAL, SOCIAL, AND COGNITIVE CHANGES

It is now widely accepted that emotional, social, and cognitive brain processes continue to develop throughout childhood and early and late adolescence. The structural and functional development of various regions of the adolescent brain interacts with the social environment to influence social sensitivity, cognitive decisions, and risk-taking behaviors.

The work of Blakemore and Mills (2014) and other researchers have consistently suggested that a network of specific brain regions is involved in social cognitive processes. For example, an adolescent's increasing ability to understand the mental states and thereby the behaviors of others, "mentalizing," also called "theory of mind," has been associated with a network of brain regions including the dorsal medial prefrontal cortex (dmPFC), the TPJ, pSTS, and the anterior temporal cortex (ATC). These brain gray matter regions have been shown to continue to develop in volume, cortical thickness, and surface area throughout adolescence before stabilizing in young adulthood. During adolescence the overall gray matter does not mature by growing larger, instead it is pruned to be more

specialized. However, the prefrontal cortex, parts of which are involved in mentalizing and other portions are involved with judgment, impulse control and long-range planning continue to undergo dynamic changes into the early 20s.

A variety of tasks related to mentalizing such as recognizing the meaning of facial expressions, have been shown to activate the mPFC, and in fact, this brain region has also been shown to become diminished in size and more specialized between late adolescence and adulthood. Social emotions such as embarrassment, shame, guilt, and pride require an understanding of what others may be thinking or feeling (mentalizing) about someone, whereas fear does not. In adolescence, increased sensitivity to peer opinions is a hallmark trait, the corresponding brain regions in adolescents may be activated. Functional MRI study investigating neural activation during tasks related to viewing or reading social emotional scenarios found that adolescents recruited the dmPFC and even more intensely than adults given the same tasks.

In a recent study of an online communication game requiring the subject to understand the mental state of the online player in order to make correct decisions, a mid-adolescent group made less mistakes than a mid-childhood group, but more mistakes than a young adult group. This result supports that notion that social development is still in play and not maximized even in late adolescence and that social sensitivity and social skills increase into young adulthood.

On the other hand, brain regions associated with risk taking and sensation seeking include the amygdala, nucleus accumbens, (NAcc) and the prefrontal cortex (PFF). A study investigating the time course of maturation of the brain regions associated with risk-taking behaviors found that relatively earlier maturation of the amygdala and/or the nucleus accumbens (NAcc) compared to the prefrontal cortex suggested a mismatch between these structures. The amygdala has been found to increase in volume from late childhood until mid to late adolescence with less growth after the age of 16 years. On the other hand, the prefrontal cortex showed little change in gray matter volume in childhood and continues to decline into young adulthood. More research is needed in order to draw conclusions about adolescent risk-taking behaviors and sensation seeking in view of these differentially developing brain regions.

In contrast to gray matter, white matter volumes increase throughout childhood and adolescence and reflect a developing integration or “connectivity” of brain function regions which are myelinated.

During the course of adolescence significant qualitative changes in thinking are demonstrated in greater ability to discriminate emotional cues, increased self-awareness, selective attention to information, and increased response inhibition. Perhaps the most dramatic changes in cognitive abilities are an increased capacity for abstract reasoning,

planning, and affect modulation. Over the past two decades, MRI and functional MRI (fMRI) have become important modalities for studying both the structure and the function of adolescent brains. Two areas of the brain consistently shown by MRI to evidence structural changes during adolescence are the prefrontal cortex and the parietal cortex. Neuroimaging studies indicate that the prefrontal cortex matures more slowly than other areas of the brain and that its development is correlated with increased capacity in adolescents to inhibit behavioral responses. The prefrontal cortex is known to mediate "executive function," that is, skills involving working memory, selective attention, and voluntary response inhibition. In addition to executive function, the prefrontal cortex is believed to be involved in social and cognitive abilities such as self-awareness and the development of an understanding of another person's perspective. Recent studies have provided evidence of a linear improvement in performance by age on certain tasks within executive function, such as those involving selective attention, working memory, and problem solving. This lends support for an increase in performance in these tasks as a function of the pruning and synaptic reorganization of the prefrontal cortex.

Social cognition—in particular, recognition of facial expressions of emotion—has been studied in healthy adolescents. The amygdala, a region of the brain known to be associated with emotion processing, was found by functional MRI to be activated in adolescents shown fearful facial expressions and in response to happy faces compared to neutral faces. Among adolescents, left amygdala activity when presented with fearful faces decreased in girls but not in boys. Female adolescents also demonstrated greater activation of the dorsolateral prefrontal cortex, whereas male adolescents did not show this pattern. It was hypothesized that the pattern of diminished amygdala and increased prefrontal activation in female adolescents reflects increased maturity in the regulation of emotional experiences in them compared to male adolescents. Structural and functional MRI studies implicate puberty as a period of synaptic reorganization in the prefrontal and parietal cortex, which may place the adolescent brain in a sensitized state with respect to the development of executive functions and social cognitive skills. Clearly the adolescent brain continues to develop structurally, and the relationships of these structural changes to behavioral and emotional responses warrant further investigation.

CURRENT ENVIRONMENTAL INFLUENCES AND ADOLESCENCE

Adolescent Sexual Behavior

Sexual interest and experimentation are critical components of adolescent development for boys and girls. Sexual experimentation in adolescents often begins with fantasy and masturbation in early adolescence, followed

by genital touching with the opposite sex or, in some cases, same-sex partners, oral sex with partners, and initiation of sexual intercourse at a later point in development. In one study of urban adolescents, at least one-third reported some form of genital sexual activity in the last year with a partner, and approximately 10 percent reported oral sexual behavior with a partner. The balance between healthy adolescent sexual experimentation and emotionally and physically safe sexual practices has been one of the major challenges for society in the new millennium.

Trends in adolescent sexual activity are monitored by the YRBSS, which measures the self-reported prevalence of health-risk behaviors, including sexual activity. Surveys obtained for the years 2010 to 2011 provide detailed information regarding sexual activity in adolescents and risks associated with these behaviors. Among high school students across the nation, 47.4 percent reported that they had had sexual intercourse during their life, and 33.7 percent of high school students reported that they were currently sexually active. Among those who were currently sexually active, 60.2 percent reported that they or their partner had used a condom during their last sexual intercourse. The prevalence of having had sexual intercourse at least once was higher among black males (66.9 percent) than Hispanic males (53 percent), followed by black females (53.6 percent) and Hispanic females (43.9 percent). The overall rate of having had sexual intercourse in high school among white students was 44.3 percent, with white females (44.5 percent) reporting it slightly more frequently than white males (44 percent). A total of 15.3 percent of students report that they had had sexual intercourse with at least four persons during their lifetime. Among the 33.7 percent of currently sexually active students nationwide, 18 percent reported that either they or their partner had used birth control pills as a contraceptive before their last sexual intercourse.

Eighty-four percent of high school students had received instruction that includes information about acquired immunodeficiency syndrome (AIDS) or HIV infection. Nationwide, 12.9 percent of students had been tested for HIV.

Factors That Influence Adolescent Sexual Behavior. Factors impacting sexual behavior in adolescents include peer groups, psychosocial factors, temperamental and personality traits, externalizing and internalizing psychiatric symptoms, gender, cultural and religious background, racial factors, family attitudes, and sexual education and prevention programs.

A recent longitudinal study of predictors of sexual initiation and high-risk sexual behaviors in young adolescents indicated that externalizing factors, specifically a history of violent delinquency in middle school and substance use, were associated with sexual initiation in early adolescence.

A survey of more than 400 female adolescents of varied racial backgrounds found that higher levels of impulsivity were associated with a

younger age at first experience of sexual intercourse; a higher number of sexual partners; sexual intercourse without the use of contraception, including condoms; and a history of sexually transmitted disease (chlamydia). The level of impulsivity was not found to be significantly associated with age, race, or education. Although this investigation focused only on girls, it is likely that similar results might be obtained for boys.

Historically, male adolescents have initiated sexual intercourse at a younger age than female adolescents, and recent report from the Guttmacher Institute (www.guttmacher.org) suggest that approximately 11 percent of girls and 14 percent of boys report age of first experience of sexual intercourse to be before age 15 years. In general, adolescents who initiate sexual intercourse at younger ages are also more likely to have a greater number of sexual partners.

There is a suggestion from surveys of urban adolescents that early initiation of sexual intercourse, before age 15 years, is more frequent among African-American boys than in Hispanic boys and more frequent in Hispanic boys than in white boys.

The additive effects of more highly educated families, social and religious youth groups, and school-based educational programs can be credited with a decline in high-risk sexual behavior among adolescents in the 1990s. Responsible sexual behavior among adolescents has been determined as one of the 10 leading health indicators for the next decade. One urban school–based intervention designed to promote sexual abstinence in middle schoolers and support safe sexual practices in those students who continue to be sexually active reported that successful abstinence was only possible in those students who had not initiated sexual intercourse by the time of the intervention.

Risk-Taking Behavior

Risk-taking behaviors are the product of cumulative contributions from brain development in particular regions of the adolescent brain and the social environment. These contributions include the possibility of overactive reward-related circuitry as in the ventral striatum, as well as the influences of peer acceptance. In experimental circumstances, adolescents may rate the potential reward of a risky action as inflated, however, at times adolescents also rate the relative risks of actions as inflated.

Reasonable risk taking is a necessary response to increasing autonomy in adolescence, leading to confidence in forming new relationships and competence in sports and in social situations. However, high-risk behaviors among this generation of adolescents are associated with serious negative consequences and can take many forms, including drug and alcohol use, unsafe sexual practices, self-injurious behaviors, and reckless driving. Alcohol is the most commonly used substance among adolescents and is associated with a multitude of coexisting high-risk behaviors, such as

motor vehicle accidents resulting in injury and death, academic deterioration, fighting, and criminal behaviors. According to the National Institutes of Health survey, heavy drinking (defined as at least five consecutive drinks at one time) was reported by almost one-quarter of high school seniors. But overall, alcohol use among teens is at a historically low level with declines in daily use by 10th and 12th graders (0.9 percent and 2.2 percent, respectively). Adolescent frequent and heavy use of alcohol was associated with future antisocial behavior, as well as increased levels of depression. Furthermore, even lower levels of alcohol use predicted similar problems as teens entered young adulthood. This implies the need for preventive interventions during adolescence for those teens who use alcohol, even if drinking behavior does not appear to be frequent or serious.

Illicit drugs, including marijuana, cocaine, heroin, hallucinogens, "ecstasy," and amphetamines, also pose a serious health risk among adolescents. A recent National Institute on Drug Abuse survey indicated that, in young adolescents, more than 8.5 percent used an illicit substance in a given month, and, in older adolescents, approximately 25 percent used illicit drugs in a given month. In younger adolescents, boys and girls had similar rates of drug use, whereas older adolescent boys had slightly higher rates. Although there are vast differences between adolescents who had experimented on rare occasions with marijuana and adolescents who engaged in daily drug use, the large numbers of adolescents engaged in these behaviors at every level is cause for public health concern. Furthermore, use of illicit substances is also associated with youth crimes and violent behaviors. In 2010, there was an all-time low in the number of violent crimes among adolescents. In the last few years, rates of violent crime victimization, including aggravated assault, robbery, rape, and homicide, according to Child Trends Data Bank, are in the range of 30 crimes per 1,000 adolescents per year. This rate is higher than the rate of crime victimization in adults. Male adolescents are more likely than female adolescents to be the victims of serious violent crimes, with older adolescents, 15 to 17 years old, being more likely to be victims than their younger adolescent counterparts, 12 to 14 years old. These grave statistics indicate a need to identify risk factors and to find protective factors for today's youth.

Identifying adolescents with high-risk behavior is not always feasible until the high-risk behaviors have resulted in academic or legal consequences. Once this occurs, a given adolescent can be identified as being at "high risk" for future difficulties and, optimally, should be monitored by a counselor through school, an outside therapist, and, in some cases, through the legal system. It is not always easy for an outsider, at first glance, to separate adolescents engaging in normal experimentation from those embroiled in high-risk behaviors. When there is evidence that an adolescent is engaged in frequent alcohol or drug use, reckless behavior,

or criminal activities, urgent psychosocial interventions are needed. In less obvious cases, adolescents who have ongoing academic difficulties, do not participate in any athletic or other extracurricular structured activities, and are socially isolated may also be in need of psychiatric evaluation.

A survey of high-risk behaviors in adolescents in a primary care medical clinic setting found that the presence of tattoos and body piercings was associated with a higher probability of high-risk behavior. In the general population, approximately 10 to 13 percent of adolescents have tattoos, compared to 5 percent of the total population, including all ages. Body piercings have also become more prevalent among mainstream adolescents over the last two decades. Of the more than 500 adolescents surveyed in this study, 13.2 percent reported at least one tattoo, and 26.9 percent reported at least one body piercing, other than in their ear lobe, at some point in their lives. Both tattoos and body piercings were more common in girls than in boys (16.6 vs. 8.1 percent for tattoos, 36.7 vs. 10.1 percent for body piercing). Adolescents who endorsed possession of at least one tattoo or body piercing were more likely to endorse the use of gateway drugs (cigarettes, alcohol, marijuana), as well as experience with hard drugs (cocaine, crystal methamphetamine, and "ecstasy"). Female adolescents who had tattoos or body piercings, especially younger adolescents, were more likely to endorse a history of suicidal ideation or behaviors. Male adolescents with tattoos and female adolescents with body piercings were more likely to report a history of involvement in physical fights, carrying a weapon, or bodily injury as a result of physical fighting. Adolescents with tattoos or piercings were more frequently sexually active than were adolescents without them and at greater risk for unsafe sexual behavior.

Adolescents may choose clothing, hairstyles, and/or body decorations as a means of fitting in with a selected peer group, or to attract attention and distinguish themselves as special or different from others. The presence of tattoos or body piercings does not necessarily indicate high-risk behaviors in adolescents, however, in certain peer groups it is associated with risky lifestyles. Conversely, many adolescents with serious high-risk behaviors do not possess tattoos or body piercings. Given the serious consequences of alcohol and drug use and violence among adolescents, inquiry into these behaviors should be an integral part of every health care evaluation.

Adolescent Use of the Internet and Social Media

The Internet and social media are ubiquitous among adolescents and serve as platforms to socialize, communicate, and share talents, as well as a myriad of personal information, affecting all aspects of life for today's adolescents. The "digital revolution" the explosion and integration of multiple technologies into daily life) among adolescents, as discussed by Giedd (2012), has highlighted the adaptive nature of the adolescent brain

in its ability to embrace and incorporate these technologies. According to Giedd, the amount of time it took for 50 million users to develop (pace of "penetration") with respect to older technologies such as television was 13 years. However, for newer technologies the pace of "penetration" is moving at record speed. For the Internet, it was 4 years, for Facebook it took about 3½ years, for Twitter about 3 years, for iPads 2 years, and for Google+ it took only 88 days to gain 50 million users!

Recent reports indicate that about 90 percent of children and adolescents use the Internet in myriad ways, including instant messaging, visiting social networking sites, blogging, chatting in chat rooms, posting photos, videos, and stories, and obtaining information by visiting numerous websites. Positive effects of the Internet identified for adolescents include exponentially increased communication with both friends and family and increased access to academic information, and familiarity with social and cultural habits of people around the world. Concerns raised regarding teens' access to a constant and overlapping barrage of stimuli, however, include the ubiquitous "multitasking" that seems to characterize adolescent practices in the United States. While adolescents may be under the impression that doing their homework while chatting with a friend, listening to music, instant messaging and viewing facebook seems like an efficient way to get more done in the same amount of time, however, the brain is actually rapidly shifting between tasks leading to interruption of attention to potentially vital tasks. For example, an MRI study of a simulated driving task with or without competing stimuli showed significant impairment in driving performance during competing conversation, in addition to a sizable reduction in activation in the parietal lobe.

Some adolescents use the internet to learn about health-related issues and for self-help. In this regard, several health-related, adolescent-friendly websites are available that provide information on a variety of psychological and medical topics. One such site is http://www.teenshealth.org, a US-based website, provides information about general and healthy living information for kids, teens, and parents, including information on mental health, sexual health, causes of illness, a question and answer section, and information on different coping skills. Mind Your Mind (http://mindyourmind.ca) is a Canadian website for youth by youth, which provides resources to help teens manage their stress and mental health issues and includes personal stories, music, and a blog. There are significant risks associated with Internet use, especially for adolescents who share personal information and communicate with strangers on line. According to the recent Third Youth Internet Safety Survey, a national telephone survey that sampled 1,600 Internet users between the ages of 10 and 17 years who used the Internet at least once per month for the previous 6 months, 11 percent of youth who used the Internet

were found to be targets of some type of online harassment within the previous year, increased from 2005 (9 percent). Other sources report that approximately 11 percent of youth online are the targets of unwanted sexual solicitation, decreased from 2005 (13 percent). More than two-thirds (66 percent) of the youth who were the victims of the harassment incidents knew the harasser in person before the events. There were a few more female adolescent harassers (48 percent) than male (43 percent). Thirty-four percent of targets reported an aggressive offline incident that involved either a telephone call or in-person contact. Those youth who were victimized had higher rates of harassing another youth online. Those youth who were the targets of adult harassment were often asked to send pictures of themselves or received a telephone call or a visit in person from the adult. Approximately 33 percent of youth who reported that they were harassed online experienced distress related to it. Internet safety programs urge youth to avoid sharing personal information and not to communicate with strangers online.

It is clear that adolescent culture in the United States is dominated by technology in a variety of ways and is a vital part of teen social interactions. Social media technologies have enabled adolescents to connect with a vastly larger scope of other teens than they could meet in daily life. Teens are not necessarily more or less social due to social media, however, the opportunities are broader to interact with more people using more diverse modalities.

The Effects of Online Gaming and Massively Multiplayer Online Role-Playing Games

Up to 90 percent of youth in the United States play video games, ranging from sports games to cooking games, to many games utilizing violent strategies in order to "win" or move to more advanced levels. The effects of violent videogames on adolescents are controversial. Some studies have documented that teens who routinely play violent videogames become "desensitized" to violence with repeated exposure, which has been demonstrated on MRI. On the other hand, there is no evidence of increasing real-world violent events historically during the explosion of video gaming use. In fact, over the last two decades in which the videogame industry has boomed, rates of violent juvenile crime have diminished. The explanation for this is not clear, however, what is clear is that adolescents do not have difficulty distinguishing video game violence from appropriate responses in real-world situations.

Massively multiplayer online role-playing games (MMORPGs) are highly sophisticated multiplayer universes in which players create an individualistic character (avatar). In this medium, millions of adolescents along with children and adults immerse themselves in a graphic virtual environment and can interact with each other through their avatars on a

daily basis. Researchers have questioned the potential dangers of such gaming among adolescents with regard to their social development, self-esteem, and aggressive behavior. One study investigated the social interactions that occurred within such games. The most popular of this genre of game is World of Warcraft, with City of Heroes, Ultima Online, Everquest, Lineage II, and RuneScape less often played. Based on an online questionnaire, it was reported by players that 76.2 percent of male and 74.7 percent of female players had made good friends within the context of the game, and that the vast majority of players were also playing with real-life friends or family. Another study investigating adolescents who played video games compared to those who did not play these games found no differences between gamers and nongamers in time spent with their parents or friends or in sports or leisure activities; however, gamers were found on average to spend less time with reading and on homework.

Child Psychiatric Examination

▲ 36.1 Psychiatric Examination of the Infant, Child, and Adolescent

ROBERT A. KING, M.D., PRUDENCE W. FISHER, PH.D., MICHAEL H. BLOCH, M.D., ARMIN PAUL THIES, PH.D., AND MARY E. SCHWAB-STONE, M.D.

Core features of the clinical diagnostic assessment of the child are identification of the reasons for referral, evaluation of the nature and extent of the child's emotional or behavioral difficulties, and determination of factors in the child, family, and environment that cause, exacerbate, or potentially ameliorate those difficulties. Although information gathering and differential diagnosis are the primary aims of such assessment, the evaluation process should also facilitate the development of an alliance with the clinician around understanding the child's difficulties and pursuing the treatment recommendations that emerge from the evaluation.

Psychiatric assessment of the child or adolescent is undertaken for a variety of purposes, including outpatient office or clinic evaluation to determine the need for treatment; emergency department assessment of safety issues and need for hospitalization; consultation with pediatric, school, or legal services; as a component of family or other mode of treatment; and for research purposes. Although the structure and style of the assessment vary to some extent depending on the purpose and setting, certain elements are common to all of the assessments.

Because decisions about intervention follow from evaluation, clinical assessment may rightly be regarded as a cornerstone of child and adolescent psychiatry. Clinical evaluation of the child or adolescent is challenging and complex, in that the clinician must draw on multiple sources and a range of techniques for eliciting information on various aspects of the child's functioning. This information must then be integrated from multiple theoretical perspectives, using the clinician's knowledge of development and psychopathology to arrive at a diagnostic formulation that can guide treatment planning effectively.

The initial portion of this section focuses on the comprehensive clinical assessment of the child and adolescent; subsequent subsections discuss

more specialized types of assessment, such as the assessment of infants and adolescents, psychological testing, laboratory assessment, and clinical research assessment instruments.

CLINICAL INTERVIEW OF THE CHILD

The psychiatric assessment of the child requires a comprehensive approach that evaluates the child's developmental progress in various domains and positive adaptive capacities, as well as the presence of the pathognomonic symptoms of specific disorders. A developmental approach to the assessment of the child is essential because children differ from adults in certain key respects.

Distinctive Features of Childhood Psychopathology

First, psychiatric disturbances in children often consist of a lack of developmental progress in one or more domains rather than the presence of specific symptoms that are pathognomonic of adult disorders. For example, a nursery school child's failure to develop useful social language or interactions or a school-aged child's inability to meet the developmental expectation of separating from parents and settling into the school day may prompt the parent, school, or both to request an assessment.

Second, the child's developmental status may affect the clinical presentation of various syndromes. For example, in children, depression often presents with irritability and somatic complaints, whereas excessive guilt or depressive delusions are rare.

Third, development brings expectable periods in which distressing emotions or behavior may occur as part of a normal transition, for example, the separation anxiety of a child starting preschool or the oppositionality of the adolescent.

In many cases, clinical conditions represent severe forms of symptoms found in milder form in nonreferred children. Fears, tantrums, moodiness, or restlessness are relatively common in childhood and occur transiently at different stages. Assessment may be sought by concerned parents needing guidance on how to understand and manage these developmental manifestations. Thus, the clinician must judge whether the behavior is likely to resolve with time and without substantial deleterious effect on the child or family or whether, instead, the level of distress, compromised functioning, or symptom persistence indicates the need for clinical intervention.

To distinguish transient or normative difficulties from those that are more clinically worrisome, the evaluator must possess a solid knowledge of normal and abnormal child development. This developmental frame of reference includes an understanding of what behaviors can be expected normally in children of different ages, the time frame within which various

behaviors normally wax and wane, and the natural history of psychiatric disturbances at different stages in development, including knowledge of the ages at which particular syndromes are more or less likely to present.

Another difference in the adult and child psychiatric assessment is that many children coming to clinical attention have difficulties that cannot be neatly subsumed under the rubric of a single diagnostic label. Thus, comorbidity is usually not the exception but the rule in childhood disorders. Even in epidemiological studies of children and adolescents, as many as one half of those who meet diagnostic criteria for one disorder also meet criteria for at least another disorder. This high rate of comorbidity, found even in nonreferred populations, may have several sources. Many traditional nosological entities draw their definition from clinical experience with adults; although childhood analogues clearly exist, the appropriate descriptive boundaries may not be the same. Furthermore, impairing symptoms in childhood tend to have a ramifying effect by interfering with the ongoing acquisition of key developmental skills in multiple areas. Finally, regardless of whether the origins of a given form of childhood psychopathology lie in biological factors, family or social environment, or interactions among these realms, these pathogenic forces often produce symptomatic difficulties that cut across many diagnostic lines.

Distinctive Aspects of Child Assessment

Except for patients brought involuntarily for evaluation, most adults coming for psychiatric assessment acknowledge, at least implicitly, some degree of self-perceived distress and wish for help, no matter how ambivalent the wish may be. In contrast, for most children, the responsibility for initiating and following through with a psychiatric evaluation lies with the parents. In many cases, children's behavior is a greater source of distress to others—parents, teachers, and peers—than to the children. Other children, even while acknowledging distress, view the locus of the troubles as purely external, and hence see little need for evaluation, even if they comprehend the process. In any event, the lack of any stated wish for help or active role in seeking the evaluation colors the child assessment process from the start. As a result, explicit attention must be paid to assessing the child's view of the problem and to cultivating the child's engagement in the process.

A related aspect of the child psychiatric assessment involves the need for the clinician to assess and to accommodate to limitations in the child's ability to reflect, to conceptualize, and to report experiences and internal states. These capacities emerge only gradually with maturation and are influenced by normal and pathological factors. Thus, the clinician's communication must be attuned to the child's developmental level and may require play, stories, drawing, and other alternative modes of interaction in

addition to direct discourse.

Context and the Need for Multiple Informants

Even more so than for an adult, the child's functioning and psychological well-being are strongly related to the social context—the family, school, and community settings—in which the child lives and develops. Thus, to evaluate the nature and severity of the child's psychiatric status, information is needed about the child's relationship to, and functioning in, these diverse settings. The fit of the child and social environment can be appraised from what parents say about their relationships with the child and from the child's direct report, as well as from play and drawings; however, direct observation of the content and tone of parent–child interactions in the office setting also provides much useful additional data. In some cases, a home visit may provide invaluable information. [Here and throughout, "parent(s)" is used to refer to the child's primary care-giver(s), regardless of biological relationship.]

It is also important to gather information on the child's functioning in school, a task that often requires speaking with the child's teacher or guidance counselor, in addition to reviewing school reports and educational assessments. Here, too, direct classroom observation can provide invaluable in vivo information. For children involved with child welfare, juvenile justice, or other institutional systems, information from caseworkers, probation officers, and institutional caretakers is essential.

Special Types of Assessment

The main emphasis of this section is on the assessment of children and adolescents, especially those capable of participating verbally in the assessment process. Because developmental considerations shape the evaluation process, infants and toddlers, on one hand, and adolescents, on the other, require specific modifications of the general approach outlined in this section. Nonverbal or language-impaired children, such as those with pervasive developmental disorders or intellectual disabilities, also require specialized assessment techniques.

Although the prototype for clinical assessment of the child is the office consultation or clinic visit, evaluations occur in a variety of settings, including schools, pediatric wards, residential treatment centers, detention centers, and hospital emergency departments. Procedures necessarily vary with the setting and reasons for carrying out the assessment. The following general model for the outpatient evaluation can be adapted to fit more specific clinical situations. More-specialized types of evaluation are discussed later in a separate subsection.

Preliminary Contact

In the initial phone call to the clinician or clinic intake office, it is helpful to gather some basic information about the nature of the chief complaint; to set the time, date, and place of the first appointment; and, if relevant, to discuss issues of fee or insurance coverage.

During the evaluation, the clinician wants to see the parents alone, the child alone, and the parents and child together. The order in which these should be done and the corollary issue of who attends the first meeting should be discussed at the initial contact. This decision is usually made with reference to the child's age. When evaluating a young child, the parents are often seen first, without the child. This allows the clinician to obtain a history and to discuss how to prepare the child for the evaluation. However, the adolescent should usually be included in the initial interview so that the youngster does not identify the clinician as an agent of the parents, which may interfere with the adolescent's willingness to talk with the clinician and impair the formation of a treatment alliance. If children or adolescents are to attend the initial appointment, the clinician should discuss in the initial call how they are to be prepared for the appointment.

In the initial phone contact, the issue of which adults will attend should also be discussed. When the family is intact, the presence of both parents is optimal. When this is not the case, the clinician and parent should discuss whether a noncustodial parent, stepparent, or other adult should be present.

Parent Interview

In the initial parent interview, the clinician seeks to understand the parents' view of the problems that have led to the referral, including the nature of the child's current difficulties, the explicit and implicit reasons for the timing of the referral, and the effect of the child's difficulties on the parents, individually and as a couple, and the well-being and functioning of the family as a whole. A detailed history of the child's development and a review of family medical and psychiatric disorders are obtained. Finally, the clinician seeks to understand how the family is functioning in its community and cultural setting. This includes a careful appraisal of the strengths of the child and the family, in addition to the history of the presenting symptoms and areas of impairment.

Child's Current Difficulties and Reasons for Referral. In child psychiatry, referrals are usually initiated by the parent or parents rather than the child. Similarly, parents are key in determining whether a recommendation for treatment is followed. Over and above the need to gather information about the child's symptoms and functioning, the parent interview provides an opportunity to develop an alliance with the parents around the goals of identifying and helping the child's difficulties. Success of this process requires understanding the parents' expectations and concerns regarding

the evaluation and its outcome. How these issues are addressed depends on the nature of the child's problems and the parents' knowledge of and previous experience with psychiatric evaluations and treatment. Attention to the parents' view of the evaluation process allows the clinician to address unrealistic fears or excessive expectations about what can be accomplished in a given time and to reduce family stress when parental anxiety is too high.

In taking a history of the current problem, the clinician obtains a detailed picture of the parents' current emotional and behavioral concerns about the child. Parents should be asked to describe specific instances of the child's problematic behavior, frequency, intensity, duration, circumstances in which the behavior occurs, their responses, and the child's responses to it. The extent to which the symptoms cause functional impairment is ascertained by asking about the level of the child's distress, interference with social and academic activities, effect on ongoing development, and effect of the child's behavior on others. The clinician should also inquire directly about behaviors or symptoms not reported by the parents but known to be commonly associated with the presenting problem or with disorders that the presenting problem may suggest. Thus, one goal of the initial parent interview is to develop a detailed picture of the presenting problems, their course, their effect on functioning and on the family, and what has been tried to help alleviate them.

The clinician is also interested in the implicit and explicit reasons that the child has been brought for help at this particular moment. Often, the reason lies in an escalation of troublesome behavior or in the deleterious effect of a deficit emerging into sharper relief (e.g., a learning disability or attention deficit becoming more apparent as the child faces the increased demands of a new grade). In other cases, the child's behavior may not have changed but some change within the family or loss of compensatory support may have made it impossible for the parents to tolerate or to ignore previously bearable behavior. These *iatropic factors* (factors propelling families to seek clinical attention) are often complex. In surveys of the general child population, rates of diagnosable psychiatric disorder (defined as meeting diagnostic and impairment criteria) approach 20 percent, yet the number of children actively seeking or receiving clinical services is far lower. Perceived barriers to services alone do not account for this low rate of seeking help.

Throughout the history taking, the clinician strives to understand the meaning and function of the symptoms in relation to the factors in the child and environment that influence them. A given symptom (e.g., a period of anxiety, theft, or hallucinations) may have quite different meanings, functions, and clinical implications in different children. Thus, detailed information on precipitating circumstances, behavioral concomitants, and consequences and alleviating factors is needed, much as

is the case in taking a medical history. However, this information must be interpreted within the broader developmental and family contexts in which the symptoms occur; thus, while gathering history, the clinician simultaneously takes in information about these contextual elements. History taking and diagnostic formulation are not distinct processes; during the interview process, clinicians continually formulate and test tentative hypotheses that guide further questions and the diagnostic possibilities under consideration.

To understand the child's presenting problems, developmental status, and family and social context, the clinician must learn about the child's strengths, interests, talents, and areas of adequate or superior adjustment. Such information is essential for a full diagnostic understanding of the child and helps the clinician to appraise the child's overall adjustment and functioning. Moreover, in planning for treatment, factors that may help to counterbalance or remediate the child's vulnerabilities must be identified. Finally, the clinician's appreciation and discussion of the child's strengths and areas of good functioning provide support and reassurance at a time when the child's problems and limitations have been the parents' major focus of attention.

The parent interview should also cover the practical and administrative aspects of the diagnostic assessment, including discussion of fees, scheduling, confidentiality, and, if applicable, permission to obtain information from school personnel and other clinicians. If the child was not included in the initial interview, the clinician should discuss appropriate preparation of the child for a meeting.

Developmental History. The developmental history is a detailed accounting of the child's development across physical, cognitive, linguistic, social, and emotional domains. One task of this part of the parent interview is to ascertain the timing and sequence of developmental events from pregnancy to the present. Parents vary in their ability to provide precise information on the timing of specific milestones; however, an adequate sense of the course of development can often be obtained by having the parents compare the patient's progress in a particular domain with that of sibling or peers. Asking parents about the timing of changes in the family, such as moves or other memorable life events, may help to provide a chronological framework for remembering features of the child's development. Besides gathering descriptive information about the child's development, this part of the interview often allows one to tap the emotional aspects of the parent–child relationship by querying the parents' hopes, worries, expectations, and life circumstances in relation to different developmental events.

It is useful to conceptualize the child's past and current development in the following domains: cognitive and academic development; family

relationships; peer relationships; physical development and medical history; emotional development and temperament; development of conscience and values; interests, hobbies, talents, and avocations; and unusual circumstances.

COGNITIVE AND ACADEMIC DEVELOPMENT. The child's pattern of cognitive strengths and weakness should be traced from early childhood, including verbal and attentional skills. Although academic performance is important (including areas of particular strength and weakness), important information about aspects of emotional and social development also flows naturally from the discussion of how the child progressed from one school year to the next. Thus, in tracking cognitive development and academic success, one should ask about the child's ability to separate from parents and to attend school regularly, interpersonal relationships with peers and teachers, motivation to learn, ability to function independently, tolerance for frustration and delay of gratification, attitudes toward authority, and ability to accept criticism, among others. A grade-by-grade history of the schools attended can be obtained during this part of the interview, as well as the reasons for any changes. Whether child has ever received a special education classification should be queried and the supporting evaluations and resulting services and accommodations classification should be reviewed. When the child's behavior or progress at school is among the reasons for the psychiatric evaluation, one should obtain permission to communicate with the child's teachers, counselors, or other school personnel and to review the school records, including results of standardized tests.

FAMILY RELATIONSHIPS. The parent interview should include assessment of how the child relates to each family member and how the child fits into the overall family system. The child's reactions to major family changes should be noted (e.g., deaths; birth of siblings; marital separation, divorce, or remarriage; and changes in caretaking arrangements, custody, or visitation), as well as parental responses to those reactions. Compliance with family rules and standards should be queried, as should consequences when the child does not comply (i.e., the usual mode of discipline or limit setting) and the child's response to such interventions.

PEER RELATIONSHIPS. The clinician should gather information about how the child relates to peers, including the number of friends, preferences regarding age and gender of friends, and any major changes in peer group; the child's satisfaction with these relationships; their relative reciprocity and stability; activities and interests shared with peers; and parents' feelings about the child's close peers or lack thereof. The parents' perspective on the child's social skills and deficits should be assessed, including their sense about any difficulties the child has in this domain.

Episodes of bullying or being bullied, and the consequences thereof, should be queried. For adolescents, this part of the history includes issues such as the capacity for intimate relationships, romantic interests, sexual activity, and concerns over sexual orientation or gender identity.

PHYSICAL DEVELOPMENT AND MEDICAL HISTORY. Assessment of physical development includes fine and gross motor development, toilet training and its lapses, eating behavior and attitudes, and sleep patterns. Precocious development or delays in physical growth or pubertal maturation should be noted. In this context, parents should be asked systematically about medication, illnesses, hospitalizations, emergency room visits, operations, episodes of loss of consciousness, seizures, head injury, or other serious injuries, as well as the child's reactions to these and their effect on subsequent health and activities. Inquiry about tics, difficulties with hearing or vision, lead exposure, and other specific conditions may be suggested by the clinical presentation. When necessary, medical reports should be obtained and reviewed.

EMOTIONAL DEVELOPMENT AND TEMPERAMENT. Although some of these aspects of emotional development and temperament will have been covered in taking the history of the presenting problems, the clinician should fill in gaps with a systematic review. This domain of assessment includes the child's present and past mood and capacity for affect regulation, anxieties, and ability to adapt to changes and situations that are new, challenging, or frustrating. Prevailing mood as perceived by the parents should be assessed; the clinician should ask specifically about self-injury and suicidal ideation, gestures, or attempts, especially if the child has shown depressive symptoms, including irritability. Worries, fears, and other manifestations of anxiety should be covered, and the level of any distress and impairment should be explored. The generalized or specific nature of symptoms, situational evokers, historical precipitants, and effects on the child in terms of impairment or distress are relevant. It is also important to note unusual fears, excessive shyness or withdrawal, and obsessive or compulsive symptoms.

The child's capacity to regulate aggression falls within this domain and should be reviewed. The clinician should ask about circumstances in which the child becomes angry or aggressive, the mode of expressing anger (i.e., verbal, physical, or both), the effect on others, and the child's reaction to and processing of such feelings and behavior. In this context, the clinician seeks to evaluate how the child manages aggression and whether the child is too aggressive or too fearful of his or her anger or that of others. Specific aggressive symptoms (e.g., bullying, fire setting, vandalism, or cruelty to animals) should also be inquired after.

DEVELOPMENT OF CONSCIENCE AND VALUES. The clinician should assess the

development of conscience to gauge whether it is too harsh, lax, or overly focused on particular issues. The effectiveness of conscience in helping the child conform to family and societal expectations is important. Religious or ethical concerns and their concordance with those of the family can be addressed in this phase of history taking. The family's expectations with regard to the child's values and future life choices should be ascertained from the parents' perspective, and areas of potential discord should be noted.

INTERESTS, HOBBIES, TALENTS, AND AVOCATIONS. Although this line of inquiry is also pursued with the child, it is useful to obtain the parents' perspectives on the child's interests and activities and to assess the parents' approval, involvement, and support for them. Indications of parent–child conflict should be probed and may provide useful information about the relationship. The presenting difficulties may have affected the child's ability to focus on or to engage in previously enjoyable areas of interest or activity, such as sports or music.

The quantity and type of television programs, movies, screen time, and video games that a child is permitted provide important information on the child's interests and the quality of parental limit setting. Access to and use of the Internet, instant messaging, and social Web sites should be assessed, as well as the degree of parental supervision and monitoring.

UNUSUAL CIRCUMSTANCES. When present, the clinician should assess the child's experience of immigration or exposure to unusual or potentially traumatic circumstances, such as sexual or physical abuse, family or community violence, natural disaster, or armed conflict. If a history of such experience exists, the child's immediate and subsequent reactions and the nature of the response from parents or other adults should be assessed.

Family and Community Background. Children develop in the contexts of the family and community, and these provide opportunities and challenges that influence and shape the course of that development. The clinician should gain a picture of the child's functioning in these contexts and their influences on the child. Although the clinician learns a great deal about these areas from taking the history of the presenting problem and the developmental history, direct questioning may also be needed.

PARENTS. The clinician should assess the parents as individuals and as a couple, including strengths, weaknesses, and areas of conflict or difficulty. If the child resides with someone other than the parents (e.g., a relative or foster parent), the clinician should obtain information on the history and circumstances of that relationship, including how the child came to be in that adult's care. It is also necessary to determine what the child's previous experiences were with the parents and the nature of the bond with them.

The clinician should similarly assess the current caregivers and their parenting relationship with the child.

If the child is adopted, information is needed on the circumstances, the parents' feelings and expectations about the adoption, the child's age at adoption, the child's adjustment at the time and later, and how the child and family members currently view the fact of the adoption. The clinician should also determine how the adoption has been discussed with the child and any concerns or questions about the biological parents.

When taking the developmental history, it is often natural to inquire about the parents' feelings and involvement with the child at different stages. Parents' past attitudes and behavior are likely to shed light on their responses in the current situation; hence, one wants to know how they felt about past difficulties and what they have done to help and to support the child. The parents' individual views on the causes of the child's difficulties, and the extent to which they agree or disagree on this and other aspects of the child's care and management, affect how they respond to the clinician's recommendations. Information on the parents' backgrounds and histories with their families of origin helps the clinician to understand and work with their responses to their child.

The clinician should ask about the parents' ethnic and religious backgrounds. They may be a source of shared identification and values to be imparted to the child or a source of conflict between the parents or between an adolescent and the parents. If the clinician is not sufficiently familiar with the culture or language of the family to understand the cultural context of clinically relevant aspects of the child and family's situation, a respectful request for explanation should be made.

The parents' education and occupation may bear on how they understand and respond to the evaluation. How knowledgeable and worried they are may depend on their past experiences and familiarity with psychiatric issues. Financial resources and insurance coverage should be ascertained because this may be a source of stress or worry and may pose practical constraints on the treatment options available to the family.

The clinician should gain an understanding of how the family system functions, with whom the child lives, and the nature of relationships between household members and the child. Other issues to explore are boundaries and alliances within the family and the child's affinities and conflictual relationships with parents, siblings, and other household members. Family communication and problem solving should be assessed, including how issues of separation or disagreement are handled. The emotional tone of the family (e.g., tense, anxious, critical, competitive, warm, or supportive) can be ascertained by observing interactions and by direct inquiry. Stresses on the family as a whole or individual members (e.g., moves, migration, illness, accidents, job loss, or economic or legal difficulties) should also be addressed.

COMMUNITY. The clinician should understand the community or neighborhood in which the family lives and their feelings and identification with it. Information on the family's involvement with civic, community, and religious activities (and the extent to which the child participates) should be ascertained. The clinician also needs to know about issues of safety and adversity (e.g., poverty, poor housing, and high rates of crime or urban violence) in the neighborhood. In some communities, mental health resources are viewed positively; in others, their use is stigmatized, which may adversely affect the child. These issues should be assessed and understood because they may affect how and where the child receives any indicated treatment.

Family Medical and Psychiatric History. A careful family medical and psychiatric history is needed to identify any medical or psychiatric disorders with potential genetic or environmental implications for the child. Among those to be routinely considered are psychotic disorders, mood disorders, anxiety disorders, tic and obsessive-compulsive spectrum disorders, alcohol or substance use disorders, attention-deficit disorders, learning disorders, and antisocial personality disorder, as well as metabolic and neurological disorders. The effect of any family members' symptoms, hospitalizations, or incarcerations should be probed, with particular reference to the child.

Special Issues in the Parent Interview

INFORMANT DIFFERENCES. Although parents' concerns usually play a major role in initiating the evaluation, parents may perceive the child's problems differently and may disagree about their severity and the need for treatment. Parents' accounts of the child's difficulties and of various aspects of the developmental history may not agree completely with each other or with those of the child, teachers, or records of past events. To note these discrepancies is not to denigrate the reliability of parents as informants but rather to emphasize the necessity of multiple informants.

Informants provide differing accounts of children's problems for a number of reasons. Thus, discrepancies should be noted and regarded as potentially useful data regarding what they reflect about the clinical situation. Informants may interact with the child in different settings that vary in the extent to which the child expresses disturbing feelings and problematic behavior. This is commonly true for behaviors expressed most dramatically in settings that challenge the child in vulnerable areas (e.g., the school's demand that a child with attention-deficit/hyperactivity disorder [ADHD] sit still and pay attention). Information about such situation-specific symptoms is best provided by those who spend the most time with the child in that setting. These different perspectives on the

child's behavior may also have led to tension between informants who see the child discrepantly. (This is often true with divorced or separated parents, whose child may show quite different behavior in the context of each parent's home.) The clinician should be aware of these different perspectives and the feelings that they generate, so that the focus is maintained on evaluating and providing services for the child, with adults working together rather than at cross-purposes.

Another reason for discrepant reporting involves differences in how the informants evaluate the child's behavior. Observers may judge the same behavior by differing standards or expectations for many reasons. The clinician's appreciation of the informant's psychology or cultural background is useful for understanding and working with such differences. For example, when one parent is overly worried about the child having a serious disorder and the other is too ready to chalk up symptoms as something the child will "just grow out of," the clinician must navigate carefully to allow both parents to move to a reasonable middle ground that best serves the child's needs. In such instances, understanding each parent's defensive style helps the clinician to avoid appearing to collude with one parent and alienating the other.

Discrepant reporting also results from differences between informants in their willingness or ability to report their views to the clinician. For example, parents may be quick to report a behavior that they find disturbing or annoying, whereas a child may be unable to describe the problematic behavior verbally, may not appreciate the level of disturbance that it creates for others, or may not report it because of feelings of shame or fear of being blamed or punished.

Generally speaking, methodological studies and clinical experience suggest that parents are more likely than children to report disruptive or externalizing behaviors, such as restlessness, impulsiveness, opposition, or aggression. Conversely, children may be more likely to report anxious or depressive feelings and symptoms (including suicidal thoughts and acts) of which the parents may be unaware. Because children may be immature in their capacity to report information, such as frequency and duration of symptoms, parents are usually more accurate informants about chronological details. The child, however, may be the only source of information on events, such as sexual abuse, exposure to violence, or behavior that occurred in peer contexts (e.g., bullying). Generally, children become more reliable reporters of specific symptoms with age, with prepubertal children tending to be less reliable reporters of symptoms than their parents.

Mothers and fathers also differ in their experiences with their children, depending on the child's age and gender, shared interests, parental availability, and the respective temperaments and personalities of the parents and child. Although mothers have been reported to be more

reliable informants than fathers, in practice it is wisest, for gathering the fullest information possible and for fostering an alliance with the parents, to involve both parents from the outset. When appropriate, other informants, such as siblings, grandparents, or child care givers, may be called on to contribute information, but only after the implications for the family system and the child's specific relationships with household members are carefully thought out.

Parents and teachers may view the nature and severity of the child's difficulties differently because of the situation-specific nature of some presentations. When present at home and at school, symptoms such as hyperactivity and inattention may carry a different clinical significance and prognosis than those noted in only one (but not both) of the settings. Parents and teachers may also differ in their appraisals of the child's behaviors. For example, a stressed and preoccupied mother may be oblivious to her child's behavior, whereas an observant teacher with years of experience with similar-aged children may readily identify the child as distressed or disruptive.

For the clinician conducting the assessment, the issue is not which informant is right but how to understand the differences in viewpoint most effectively for the patient's benefit. Thus, eliciting and synthesizing information from multiple informants is a critical aspect of the clinical evaluation of children and adolescents.

INTERVIEW TECHNIQUES WITH PARENTS. The clinician should use a variety of interview techniques to elicit information from parents. The type and quality of information obtained are, in part, determined by the methods used and the clinician's skill and comfort in using them. A series of empirical studies confirm that systematic factual information and details about onset and timing of symptoms are generally most easily elicited by specific and direct questions, whereas an understanding of feelings and relationships in the family is usually gained most effectively by means of more open-ended, indirect questioning strategies.

In the initial interview, parents should have the opportunity to tell their story in their own way. For rapport to develop, they must feel that they have been able to express their concerns in their own words and were heard and empathically understood. An open-ended beginning also avoids narrowing down too quickly on a single aspect of the child's situation and conveys the clinician's interest in many different aspects of the child's situation. Subsequent probing can clarify details and can help to shape the clinician's understanding of diagnostic and potential treatment issues.

Parents are most likely to be nondefensive and comfortable about sharing personal information when they feel that the clinician is trustworthy, interested, understanding, and nonjudgmental. Clinicians must thus convey respect and empathy and avoid seeming aloof or

excessively familiar. They should discuss the child and family's situation in a natural way, using words and concepts that the parents can understand. The range of questions and the tone of the inquiry convey the clinician's interest in the whole child (including strengths, interests, and talents) and an appreciation that the child is not merely the repository of a set of symptoms.

EXPECTATIONS AND ANXIETIES. Parents may hold strong preconceived ideas about the nature of their child's problem and the kind of help needed. Because of the extensive coverage of issues relating to psychotropic medications in the popular press, many parents have drawn conclusions about the appropriateness of medications in general and in relation to their child's needs. For example, parents may arrive convinced that their child needs fluoxetine (Prozac) or that methylphenidate (Ritalin) is an addicting and inherently harmful drug.

Preconceptions or parental anxiety or conflict may also be played out around the issue of blame for the child's problems. In such situations, a parent may maneuver to have the clinician arbitrate or to agree that the teacher, school, or other parent is responsible for the child's behavior and distress. The clinician should be alert to such situations and should handle them without making either parent feel defensive or discounted. If ignored, such hidden or overt agendas can have a deleterious effect on the assessment process and the likelihood that treatment recommendations will be accepted or successfully implemented.

Parents may bring other entrenched, preconceived agendas to the clinical evaluation process. A parent may insist that the evaluation confirm that the child has been abused (e.g., by a former spouse) or does not have a psychiatric problem but a medical one. Alternatively, the parent may demand that the clinician agree that there is nothing wrong with the child. In such instances, clinicians must explain carefully and clearly that they will conduct a thorough assessment and provide thoughtful professional advice, adding that the assessment must be done openly, without preordained conclusions. This may not satisfy some parents, and some situations may simply not be workable.

Bringing a child for psychiatric evaluation is a charged and emotionally difficult step for nearly all parents, and it is only taken after much worry and disappointment that various accommodations, home remedies, or school-based adjustments have not sufficed. Children are the repositories of parents' dearest hopes (and often darkest fears) for themselves. Although a parent may rationally conclude that seeking consultation is reasonable and necessary, admitting that one's child (or oneself) needs help is always painful. Submitting one's child and one's parenting to professional scrutiny stirs many anxieties, as well as positive expectations of help, even in the most enlightened parents.

Parents often bring unspoken anxieties about the child's possible diagnosis or prognosis to the evaluation. These anxieties may be based in the parent's personal or family experience with psychiatric disturbance or may derive from accounts in the popular media. For example, is the child's uneven development a sign of autism or retardation? Do the facial grimaces mean that the child is developing a disabling tic disorder? Is the child's moodiness a harbinger of a serious mood disorder or suicide? Other parental anxieties may be guilty ones. Is failed parental rearing or transmitted heredity somehow to blame for the child's difficulties? Is the child fated to share the parent's (or other relative's) painful struggle with depression, anxiety, or psychosis? Does the parent's relationship to the child seem to recapitulate some distressing aspect of the parent's own early family experience?

The clinician must be aware of such parental anxieties and must remain alert for hints of them as the evaluation progresses; some parents are too anxious or ashamed to be forthcoming about them. By and large, it is best to have these concerns aired, even if they cannot be settled at the initial stage of the evaluation and perhaps cannot be settled for some time. When such anxieties are revealed or suggested indirectly, the clinician must express an interest in them with sensitivity. Respect and concern for these anxieties can be conveyed without dismissing them or providing premature or unfounded reassurance. The clinician may need to acknowledge the limits of knowledge about cause or prognosis in individual cases. Parents often seek psychiatric assessment after years of worry, having been given well-meaning (but inappropriate) reassurances that the child would grow out of it. Frank discussion of these issues may provide some relief to the parents, albeit perhaps not definitive answers to their questions.

PREPARATION OF THE CHILD. At some point in the initial interview, the clinician and parents should discuss the preparation of the child for his or her first appointment. Children have many reactions to a first visit to the psychiatric clinician, and parents must anticipate their child's possible reaction and prepare their response. Children may feel anxious because they cannot envision what will occur or because the evaluation may feel like a punishment. Some children fear that the assessment will reveal some profound or irremediable problem (this may be projected onto the clinician or parent with the reproach, "You think I'm crazy"). Many younger children fear shots or having to get undressed for a physical examination. In most cases, the child is probably aware of many of the parental or school concerns that have led to the evaluation and may feel a sense of relief (which can nevertheless coexist with anxiety) about the possibility of getting some help. The child's anxiety or defensiveness may be reduced if the purpose of the visit is put in supportive (rather than pejorative or accusatory) terms. The parents might be encouraged to tell the child

something like, “We know you’ve been having a hard time at school [or feeling upset and sad or having trouble with friends], so we are going to see Dr.—, who is used to helping kids with that sort of problem and can maybe figure out what would help.” For younger children, explanatory terms, such as a *feelings doctor* or a *talking doctor* who helps children with problems and worries, may be useful. The parents must give permission and encourage children to tell the clinician about their concerns, even those that might seem to involve private family matters not otherwise spoken about to others.

Child Interview

In the child interview, the clinician directly assesses the child’s psychological functioning, developmental status across different domains, and perceptions and experiences of the presenting problems. Like the parent interview, the child interview also provides an important opportunity to establish rapport. Such rapport reduces the level of stress experienced by the child during the assessment process, enhances the child’s engagement and willingness to share information, and facilitates the child’s cooperation with subsequent recommendations for intervention. Thus, from the outset, the clinician should convey empathy and interest in understanding and helping the child.

There has been debate regarding the reliability, validity, and clinical usefulness of various approaches to the child interview, but it is generally agreed that the direct child interview is an essential component of a comprehensive clinical child assessment. It provides observational data and diagnostic and historical information that are not accessible from other sources. In particular, information about feelings and moods, level of distress, and the child’s view of significant events is essential for a full diagnostic understanding of the child’s problems. For their own reasons, parents may not understand or fully appreciate the importance of these issues, or the child or adolescent may not have divulged them. The child may be guarding important information, such as secrets about abuse, bullying, sexual or antisocial activities, substance use, suicide attempts, pathological patterns of eating, or collusive family dynamics. Certain symptoms, such as compulsions, premonitory tic urges, obsessive or suicidal thoughts, or hallucinations, may be apparent only to the child. Other symptoms may escape or mislead the untrained eye; detection of tics or a thought disorder may require direct clinical observation.

There are many varieties of child interviews, depending on the nature of the presenting problem, the clinical setting, and the purpose of the assessment. Thus, the scope, focus, duration, setting, and predominant techniques used vary, depending on, for example, whether the assessment is an emergency department evaluation of a suicidal threat, a pediatric ward consultation of a regressed or uncooperative child, a forensic custody

evaluation, an investigation of alleged child abuse, or the evaluation of a child who is academically underachieving, anxious, or manifesting tics.

The clinician approaches the child interview with a developmentally based understanding of child and adolescent functioning and psychopathology. Within this framework, the clinician expects to obtain information relevant to the diagnostic questions raised by the presenting problems and so systematically reviews the major domains of symptomatology. The order and manner of conducting the child interview vary with the child's age and developmental status, the nature of the presenting problems, the setting and context, and the clinician's style. The constant elements in the interview process are the orienting framework chosen and the clinician's clinical skill in engaging and eliciting relevant data from children of varying ages and capacities with diverse problems and concerns. Some data may emerge spontaneously; some require questioning or other deliberate means of eliciting information.

Components of the Child Interview. The components of the child interview are often conceptualized under two broad headings: History taking and the mental status examination. *History taking* involves inquiry into the significant areas of the child's life and functioning, past and present, including the presenting problem. The *mental status examination* consists of an assessment and description of the child's appearance and functioning as manifested in the interview. Although these aspects of the child interview can be conceptually distinguished, they usually proceed concurrently. For example, the interviewer may ask a specific question, such as who lives at home with the child or how the child gets along with a sibling or a teacher. From a history-taking point of view, the child's response provides some information about these facts, as well as how the child feels about them. Although the child's response is thus of interest for the historical information it reveals, the child is also providing the clinician with data relevant to the mental status examination (e.g., how the child conceptualizes the response, how verbally fluent the child is, how readily the child engages, how confiding or suspicious the child is toward the interviewer). Similarly, while engaging a young child in play with figures or puppets, the clinician can simultaneously gather information for the mental status examination (e.g., speech, relatedness, and conceptual skills) and inferential data about the child's feelings, fantasies, and conflicts.

Several distinctive characteristics of clinical work with children bear on the manner of conducting the child interview and mental status examination and on interpreting the data that they yield. The focus of history taking and the mental status examination of the child is developmental, that is, it seeks to describe the child's current presentation in various domains and to compare the child's functioning in these areas with that expected for the child's age and phase of development. Another

distinctive aspect of the child interview involves the child's potential lability and propensity to react in more immature ways when tired, sick, anxious, or stressed by an unfamiliar situation. Although one can sometimes gather sufficient information for an assessment from a single interview, usually more than one interview is needed to assess the child's optimal or characteristic level of functioning.

Mental Status Examination. For the mental status examination, the child psychiatrist observes and assesses the following areas:

Physical appearance: Includes physical development, presence of minor congenital anomalies, style of hair and dress, cleanliness, and other indicators of the quality of self-care or parental attentiveness (or its lack) to the child's physical appearance and hygiene.

Manner of relating to examiner and parents: Includes ease of separation, how confiding or guarded the child seems toward the clinician, eagerness to please or to impress, flirtatious behavior, readiness to make excuses or to minimize, passive withholding, or open defiance. The child's behavior toward the examiner is compared to that observed or reported toward the parents or other adults. Reactions to the clinician's physical appearance, gender, or ethnicity (especially if different from that of the child) should be noted.

Affect: The child's predominant mood and range of emotion during the interview and appropriateness of mood.

Coping mechanisms: As manifested toward the clinician, expressed in play, or described by the child in relation to important others; age-appropriateness of the child's dependent longings, sexual interests and impulses, and aggressive feelings, with respect to intensity, object, and mode of expression; child's control or modulation of such urges (e.g., finding alternative or socially permissible means of satisfying them); strategies used for coping when anxious or frustrated.

Orientation to time, place, and person: Whether children are accurately aware of the date, where they are, and who they are. This can be evaluated by asking the child "What is the year? season? date? day? month?" or "Where are we?" (name of building, town, state, country).

Motor behavior, including activity level: Coordination, presence of unusual postures or motor patterns (e.g., tics, compulsions, or stereotypies, such as hand flapping or twirling).

Quality of thinking and perception: Includes presence of hallucinations, delusions, thought disorder, and flight of ideas and adequacy of hearing and vision.

Speech and language: Includes reading and writing; articulation, inflection, pitch, rhythm, and fluency of the child's speech; richness, limitation, or idiosyncratic aspects of vocabulary and syntax; presence of echolalia or persistent neologisms; misuse of pronouns and gender;

delayed or deviant social use of language; and lack of accompanying nonverbal communicative behavior (e.g., lack of facial expression or eye contact with interlocutor). When evidence of delays or problems in these realms exists, formal speech and language evaluation by a qualified specialist may be warranted.

Overall intelligence and fund of knowledge: Capacity for classification, abstraction, and inference appropriate to age; counting, alphabet, days of the week, months of the year, reading, writing, computational abilities; geographical and historical facts.

Attention, concentration, and impulsivity: Level of attention to an activity or topic of discussion, degree to which child jumps from activity to activity, need for physical limits, distractibility (e.g., by outside noises).

Memory: Immediate short- and long-term memory (e.g., repeat three items and recall at 5 and 30 minutes).

Neurological functioning: Fluctuating alertness, tremor, nystagmus, choreiform movements, abnormal gait, neurological soft signs, and cerebral dominance (preferred hand, foot, eye, or ear); testing for neurological soft signs can be incorporated in a game-like fashion (e.g., ball throwing, walking on a line, heel-to-toe walking, evidence of hand overflow when walking on outside of feet, and timing 20 repetitions of finger tapping, successive finger tapping, and alternating pronation–supination of the hand are relatively reliable components of a standardized exam for neurological soft signs).

Judgment and insight: Especially concerning the presenting problem; this is most usefully judged after the child has had the opportunity to develop some rapport with the clinician because the child's initial impulse may be to deny or to minimize the parents' presenting concerns.

Preferred modes of communication: Is the child open to talking directly about the presenting problems and the significant aspects of his or her life, or is the child more comfortable with indirect modes of expression, such as play or drawing?

Reliable detailed assessment of a child's speech and language capacities, intelligence, academic attainment, attentional and executive functioning, and memory requires standardized psychometric testing. Some simple tasks, such as those used in the Mini-Mental State Examination (as adapted for children by R. A. Ouvrier and colleagues), can be incorporated in a game-like fashion into the interview of the child to provide a rough screen of higher mental functions, such as orientation, attention, memory, language, and constructional ability (Table 36.1–1).

Although the clinician should usually evaluate all areas of the mental status assessment, the emphasis and detail given to the different elements vary with the presenting problem and the type of assessment. For example, in an agitated, potentially delirious child on a pediatric ward, particular attention is paid to the child's orientation, alertness, memory, verbal

coherence, neurological functioning, and the possible presence of hallucinations.

Child Interview Techniques. A range of techniques is used in the psychiatric interview of the child or adolescent. The choice and timing of techniques depend on the child's developmental, cognitive, and linguistic level; the emotional difficulty of the issue being addressed; and the degree of rapport between child and clinician. Being able to gauge the potential usefulness of a technique at a particular moment and feeling comfortable with shifting from one technique to another as the occasion demands are important acquired skills for those conducting child and adolescent clinical assessments.

PLAY TECHNIQUES. Children younger than 7 years of age have limited capacities to recount their feelings or interpersonal interactions verbally. For these younger children, as well as a number of older ones, play is a useful adjunct to direct questioning and discussion and is often a less challenging mode for the child. Some children find it easier to communicate in displacement; thus, imaginative play with puppets, small figures, or the interviewer can provide useful inferential material about the child's concerns, perceptions, and characteristic modes of regulating affects and impulses.

Table 36.1–1.
Mini-Mental State Examination

		Score	Points
Orientation			
1. What is the	Year?	—	1
	Season?	—	1
	Date?	—	1
	Day?	—	1
	Month?	—	1
2. Where are we?	Country	—	1
	State or territory	—	1
	Town or city	—	1
	Hospital or suburb	—	1
	Floor or address	—	1
Registration			
3. Name three objects, taking 1 second to say each. Then ask the patient all three after you have said them. (Tree, clock, boat.) Give one point for each correct answer. Repeat the answers until patient learns all three.		—	3
Attention and calculation			
4. Serial sevens. Give one point for each correct answer. Stop after five answers.		—	5
5. Spell WORLD backward.		—	5
Recall			

6. Ask for names of three objects learned in Q.3. Give one point for each correct answer.	—	3
Language		
7. Point to a pencil and a watch. Have the patient name them as you point.	—	2
8. Have the patient repeat "No ifs, ands, or buts."	—	1
9. Have the patient follow a three-stage command. "Take a piece of paper in your right hand. Fold the paper in half. Put the paper on the floor."	—	3
10. Have the patient read and obey the following: "CLOSE YOUR EYES." (Write it in large letters.)	—	1
11. Have the patient write a sentence of his or her choice. (The sentence should contain a subject and an object and should make sense. Ignore spelling errors when scoring.)	—	1
12. Have the patient copy the design printed below. (Give one point if all sides and angles are preserved and if the intersecting sides form diamond shape.)	—	1

From Ouvrier RA, Goldsmith RF, Ouvrier S, Williams IC. The value of the Mini-Mental State Examination in childhood: a preliminary study. *J Child Neurol*. 1993;8(2):145.

The skilled interviewer can facilitate the child's engagement in play without prematurely introducing speculations or reactions that might distort or cut short the presentation of certain types of material. During the course of play, the clinician follows the sequences of play content, noting themes that emerge, points at which a child backs away from the story line or shifts to a new sequence or activity, and situations in which the child gets stuck or falls into a repetitive loop. To facilitate the play component of an interview, the interview room should have a supply of human and animal figures or dolls and appropriate props. These should be relatively simple because elaborate toys can become distractions rather than serve as vehicles for the expression of the child's fantasies. Stock figures (such as Barbie, Star Wars, or Disney characters) may impose specific story lines and thus may limit access to the child's concerns.

Not only is the content of the child's play a rich source of information, but careful observation of the form of play also provides important information for the mental status examination. During imaginative play, the clinician can observe the child's coordination and motor capacities, speech and language development, attention span, readiness to engage the interviewer, capacity for complex thought, and affective state. Absence of imaginative play or very limited, concrete, noninteractive play may indicate an autism spectrum disorder.

Games, such as cards or board games, are also useful for putting the child at ease and developing rapport. These provide opportunities to observe the degree of the child's engagement in and enjoyment of the

shared activity; how the child manages competition, including reactions to winning or losing; or whether the child is prone to cheating. Some play activities (e.g., throwing a ball back and forth or easy card games, such as War) are simple enough to permit ongoing conversation while helping to discharge tension and diminish the pressures of the interview situation. As with toys, elaborate games (e.g., chess) should be avoided; games that demand much cognitive energy and concentration usually preclude discussion of issues relevant to the assessment and may become a means of avoiding issues involved with the child's difficulties.

PROJECTIVE TECHNIQUES. In addition to imaginative play, projective techniques often help provide an indirect picture of concerns that the child may be reluctant or unable to report directly. These techniques can help the child to feel more comfortable with the clinician, are often experienced as fun, and may provide access to concerns that are important to the diagnostic formulation.

One commonly used technique is picture drawing. The child can be asked to draw a picture, leaving the choice of subject up to the child or, alternatively can be given a specific request (e.g., draw a person or the child's family doing something). When the picture is finished or nearly so, it is helpful to compliment the child's effort and to express interest in what is happening in the drawing. The child's elaboration provides information that may not be readily apparent from the drawing itself. The content and form of the drawing offer a window on the child's emotional concerns and aspects of intellectual and visuomotor development. For example, the relative size and placement or omission of family members in a family drawing may be important nonverbal indicators of the child's perceptions or feelings about the family. Aggressive or sexual themes may be reflected more readily in drawings than in words. Self-image may be indicated through depictions of the child as nonhuman, grotesque, inconsequential, or of the opposite gender. The clinician should become familiar with the developmental progression and norms for human figure details, such as limbs, joints, facial features, and clothing, which can provide a useful rough estimate of intellectual maturity. Various systems have been developed for systematically assessing the cognitive and emotional aspects of children's drawings. In addition, the child's behavior and speech while drawing may yield useful information (e.g., throwing the picture away unfinished and saying that it is no good).

Frequently used verbal projective techniques include asking what animal the child would most or least like to be or who the child would pick to take along to a deserted island. It is useful to ask what the child would do with three magic wishes; if elaboration is needed, the clinician can explain that the wishes could be to have anything, to have the world be different in any way, or to change oneself in any way. Children's responses are often

revealing. Some may needily or impulsively wish for material possessions, such as a video game or a billion dollars. Other responses may reveal longings to change distressing circumstances, such as "for my mom and dad to get back together again," "not to have tics anymore or to get teased about them," or "to have a dad who doesn't yell at me all the time." Still other children appear uncomfortable wishing for something for themselves, preferring instead seemingly altruistic responses, such as "no more poverty or wars." Children's responses can be used as the starting point for further exploration. For example, the child who wishes for "a big house and lots of money" may be asked who else would live there and what they would do. Children who wish for "no more fighting in the world" can be asked if there are some particular fights that they would especially like to stop.

Some interactive imaginative techniques useful to interviewers comfortable with them provide elements of playing a game, which may appeal to the child. The squiggle drawing game developed by Donald Winnicott consists of the clinician drawing a curvy line and asking the child to turn it into a picture of something; the child then draws a curvy line that the therapist elaborates, and so on, taking turns. The Despert Fables are a series of incomplete, affectively evocative stories that the child is asked to complete.

Asking the child to tell about a dream or a book, movie, or television program can provide information about the child's interests and preoccupations. (If the clinician is familiar with the plot, the distortions the child may introduce can be informative regarding the child's cognitive and emotional style.) Inquiring about what the child would like to do for a living when grown up can provide insight into the child's aspirations, values, and concerns, as well as those of the family.

DIRECT QUESTIONING. Direct questioning about the current problems and other aspects of the child's life requires tact, attention to the child's level of cognitive and linguistic development, and regard for the effect of the questions on the child's self-esteem. The goal of such discussion is to determine how children see their world and their functioning in it, including attachments and antipathies, pleasures and anxieties, and strengths and weakness, which may include the difficulties that led to the evaluation.

It is important to phrase questions in language that is appropriate to the child's developmental level and verbal capacities. Children may become confused or made more anxious by technical words or abstract or complicated questions. Closed questions often yield little information. For example, "Do you get along OK with your brother?" may bring forth a simple "yes" or "no," whereas open-ended or descriptive questions are more likely to elicit a richer picture of how a child thinks and feels (e.g., "What sort of guy is your brother?" or "Tell me about your last play-date

with Danny.”). Some usefully evocative questions include “What sorts of things make you mad (or make you feel afraid)?” “What is your saddest (or happiest) memory?” “What do you like to daydream about?” If it is important to establish the order or duration of events, school-aged children do better if the questions are anchored to markers in their lives (e.g., “Did that happen before or after your birthday?” or “Have you had trouble with that since school got out?”). Several empirical studies by Michael Rutter and colleagues have examined the effects of various interview styles on the information elicited from children and parents.

Although direct questions are often needed to initiate or to focus discussion, settling into a direct question format may constrict the interview process and give children the impression that the clinician just wants to hear the facts and is not so interested in the child’s feelings and experiences. Young children frequently respond in a manner that they believe to be socially desirable, whereas older children are often reluctant to acknowledge, even to themselves, feelings of sadness or vulnerability. Clinicians should convey, by demeanor and tone of voice, their interest in the child’s real feelings.

When discussion of feelings seems difficult for the child, it may be useful for the clinician to acknowledge the link between a situation and the child’s affective response (“Some kids might have felt mad if that happened to them; how about you?”). However, the clinician must avoid leading a child whom the clinician does not yet know well by assuming experiences or feelings. Probing a bland, equivocal response may prove useful; for example, in response to “Okay, I guess,” the clinician may say, “Sounds like you’re not quite sure.”

The assessment should convey respect for the child and should protect the child’s self-esteem. Many children feel ashamed or guilty about the difficulties that have brought them to the evaluation. When the clinician conveys a nonjudgmental understanding, using language that suggests that the difficulties are problems to be helped rather than transgressions, the child is more likely to be forthcoming. The child has come to the evaluation because of problems, but one should also talk with the child about strengths. For example, in inquiring about school, it may be useful to say, “Tell me about the parts of school you like best” before asking “Are there subjects [classmates, teachers] that give you trouble?” or “What are the rough spots at school?” It may be better to ask the socially isolated child “Do you sometimes have trouble making or keeping friends as much as you’d like?” and then “What do you think the trouble is?” rather than “Do you have any friends?” (especially if the truthful answer to this question is “no”).

Structure and Sequence of the Child Interview. When interviewing the child, the clinician has in mind an overall map of the functional and

historical areas to be covered; however, the format and sequence of any given interview are responsive to the individual child, the presenting problems, the unfolding pattern of the interview, and the clinician's personal style. For example, in every assessment, the clinician should ask about the cardinal symptoms of depression, anxiety, and disruptive behavior disorders, but when, how, and in what order this is done vary from one interview to another.

BEGINNING THE INTERVIEW. There are various ways to start the interview. The one chosen should be comfortable for clinician and child and should set the stage for a productive interchange. Many clinicians prefer not to address the presenting problem(s) immediately at the outset. Some clinicians, for example, remain quiet and let the child look about the room and begin playing or talking without prompting or guidance. This approach imposes a minimum amount of structure; the clinician can see how the child reacts to the materials present in the playroom and to the clinician. It also provides information about how the child handles the situational anxiety that is often evoked by the first meeting with the clinician. However, this unstructured approach may leave many children disoriented and uncomfortably uncertain as to the clinician's goals and intentions. Other clinicians are more direct in attempting to place the child at ease and begin by inviting the child to explore the available play materials ("What looks interesting?"). Others open the interview by inquiring about neutral or pleasurable topics ("Tell me about what you like to do for fun."). The clinician must read the child's cues regarding level of comfort and urgency in deciding when to address the problems that led to the evaluation. Some children prefer to first talk about nonthreatening topics, whereas others expect to get down to business and talk about their problems right away.

Although it may be useful to establish some initial rapport around neutral or interesting topics, most children understand that they have not come for a conventional social encounter. Hence, relatively early in the interview, it is useful to ask what the child's ideas are about the purpose of the meeting. It is usually best to do this in a matter-of-fact manner by asking, "What did your mom and dad tell you [or what do you know] about why they wanted you to come and see me today?" If the child has already met with the clinician together with the parents as part of an earlier contact, the clinician will have asked something similar at that time and may have heard about the child's view of the presenting problem and its history. If so, the clinician can follow up by saying, "Last time, mostly your mom and dad said what they thought about things. Today, we have a chance to talk more about how things look to you. Are there any things we talked about then that we should talk about today?" Asking what the child knows or thinks about the purpose of the evaluation shows the clinician's interest in the child's view of the situation and allows the clinician to hear

how the child describes or assumes responsibility for the problem (or repudiates it as someone else's concern). Asking for the child's view up front, before the child has become deeply engaged or focused on some aspect of the interview process, allows the clinician to address misapprehensions. It also provides an opportunity for the clinician to explain, in terms that can be understood and potentially acknowledged by the child, the issues (at least as the clinician understands them) that have prompted the assessment.

ASSESSMENT OF MAJOR REALMS OF FUNCTIONING. Throughout the assessment, the clinician elicits and assimilates information to develop a picture of the child's functioning in the realms of family, school, peers, and recreation. Discussion of the presenting problem reveals information, particularly with respect to impairments, in these domains; however, additional discussion of the child's experiences in these areas enhances the picture of the child's life and level of adaptation. It is often useful to begin exploration of each of these realms by asking for objective facts (e.g., "Who lives at home with you?" "Whom do you like to play with [or hang out with]?" "What school do you go to? What grade are you in?" or "What do you like to do for fun?"). This can be followed up with probes for more subjective views: "How do people in your family get along? Are there any problems at home? Things people fight about? Things you get in trouble for? Things people at home do that you don't like?" This approach is intended to open up discussion of the major realms of functioning, not simply to elicit rote responses.

It is often helpful to begin by inquiring about the child's recreational activities ("What do you like to do for fun?"). This allows the clinician to learn about the child's interests, preoccupations, and talents and may provide a less threatening or problematic starting point than the areas of peer and academic functioning. Family functioning can be approached by asking who lives at home, how the child gets along with each person, and how family members get along with each other. One can also inquire more specifically "What do you like to do with your dad [or other relative]?" or "What is your brother like?" In the case of nontraditional family structures or families of divorce or separation, the clinician may inquire about the history of the current arrangement and what sort of relationship is maintained with the noncustodial parent(s).

INQUIRY ABOUT PSYCHOPATHOLOGICAL SYMPTOMS. Just as a medical evaluation includes a review of key symptoms in the major systems, the child psychiatric evaluation should include a set of questions that screens for symptoms of common or major disorders. The family or child may not see a link between one behavior or area of distress and another and may not volunteer symptoms that seem unrelated to the presenting problem. Comorbidity is relatively common in children with psychiatric disorders.

Thus, the child psychiatric clinician must routinely question across the major areas of psychopathology. Using developmentally appropriate language, this inquiry should cover depressive symptoms (e.g., low self-esteem, anhedonia, and suicidal ideation or behavior), self-harm (e.g., cutting), excessive anxiety or fears, obsessions and compulsions, hallucinations and delusions, and antisocial behaviors. For example, one should ask "Do you feel sad or grumpy a lot of the time? Do you often feel like crying?" If the answer is positive, one can follow up concerning persistence ("Does that last for more than a few minutes?"), frequency ("Does that usually happen every week [or most days]?"), and context ("What sorts of things make you feel that way?"). To inquire about suicidal ideation, one can begin by asking, "Do you ever feel that life is so hard, you wish you weren't alive [or would be better off dead]?" following up with the more explicit "Have you ever tried to hurt yourself [or done anything to try to make yourself dead]?" Exposure to potentially traumatic experiences should be routinely covered, and developmentally appropriate language should be used (e.g., "Have any really scary things ever happened to you?").

MENTAL STATUS EXAMINATION. Throughout the clinical interview, the clinician observes and notes information relevant to the domains of the mental status examination. Some abnormalities or deficits may be evident through this process; however, other areas require direct examination, which can usually be incorporated in a playful way into the clinical interview. Although intensive developmental, psychometric, language, and neurological assessment usually cannot be subsumed within the clinical interview, a brief semistructured evaluation requires only approximately 5 to 10 minutes and provides useful information. This generally involves drawing, copying a design, and engaging in simple tests of orientation, recall, general knowledge, and language (e.g., naming three objects; repeating a phrase such as "No ifs, ands, or buts"; a three-stage command, such as "Take a piece of paper in your right hand, fold the paper in half, put the paper on the floor"; a writing sample [such as asking the child to write a sentence of his or her choice]; and a brief screen of neurological soft signs).

CLOSING THE INTERVIEW. In winding up the interview, the clinician can check for concerns that have not been covered and that also signal that the interview is coming to a close by asking, "We've talked about a lot of things; are there any other things that would be important for me to know about you?" Similarly, one might ask, "I've asked you a lot of questions; do you have any questions you want to ask me?" The clinician should also give the child a general idea of what will be done with all the information the child has shared and some sense of what happens next. For example, one might explain, "I'm going to think over what I've heard from you and your folks and meet again with them (and you) to talk about what might help with—.

Are there any particular things I should be sure to mention?" If the clinician already has a sense of what interventions might be helpful, this may be tentatively broached with the child, keeping in mind the parents' right to hear and decide on those recommendations.

SPECIAL ISSUES IN THE ASSESSMENT OF ADOLESCENTS

The clinical assessment of adolescents requires familiarity with the distinctive dynamics of adolescents and their characteristic patterns of managing conflicts, anxiety, and interactions with adults.

The adolescent's attitude toward the evaluation has important implications for how the assessment process unfolds. In contrast to the adult patient (who usually takes the responsibility and initiative for seeking help) and the child patient (who is simply brought by parents), many adolescents are cautiously ambiguous as to whether there is a problem with which they want help or whether they are merely passively complying with their parents' initiative.

One important initial decision concerns who is to be seen in the initial interview: the parents, the adolescent, or all together. Seeing adolescents alone first has the advantage of emphasizing their active participation in the process and underlines the clinician's interest in their perspective; however, it may mean that crucial elements of the history are not available to the assessor. Furthermore, some embattled youngsters may protest that they are being identified as the patient or bearer of a problem that they feel resides in their parents or in the family as a whole. The clinician may need to explain explicitly that the evaluation is not a judicial proceeding to assess blame but rather an attempt to understand what the problems are.

In some cases, when the adolescent balks at being seen at all, the clinician may need to meet with the parents alone to facilitate the youngster's participation in the evaluation. Regardless of when the adolescent is seen, the parents should, at some point, be seen alone to explain their concerns about the child, to obtain a full developmental and family history, and to hear about aspects of their spousal and parenting relationship that may be clinically significant but that may not be appropriate to discuss initially in the adolescent's presence.

Meeting with the adolescent and parents together is usually helpful. This provides an opportunity to explore how family members interact, their convergences or divergences of perspective, and their capacity to work together therapeutically. Such conjoint interviews usually require active structuring by the clinician, so that the purpose is framed as an occasion to talk together. Without such active intervention, the family session can easily deteriorate into an adversarial proceeding in which the parents complain about the adolescent, who, in turn, retreats into hostile or guarded silence.

Confidentiality

The assessment of adolescents often raises complex issues of confidentiality. Although the parents and the adolescent must know that the adolescent's communications are kept confidential, they must all understand from the onset that this does not extend to situations that pose a clear danger to the patient or others. For example, if the adolescent reveals significant suicidal ideation or a recent suicide attempt of which the parents are unaware, parents must be informed for the youngster's safety. Having made clear that the parents need to know, the task is then to negotiate whether the adolescent prefers to tell the parents directly or to have the clinician inform them. It is usually best to have the adolescent undertake this responsibility, but sometimes, after discussion with the youngster, the clinician must be the one to speak with the parents, preferably in the adolescent's presence. Less clear-cut situations in which the adolescent reveals problematic but not imminently dangerous antisocial or sexual behavior or substance use must be decided on an individual basis. Treatment may not be possible without some confidentiality; however, confidentiality must not become collusion.

Developmental Issues

Adolescents' usual strong push toward autonomy is often linked to a wariness of feeling vulnerable, dependent, or controlled. Tolerating feelings of ambivalence, guilt, or other painful affects or internal conflicts does not come easily to adolescents. In addition, adolescents are prone to externalize their concern or embarrassment over self-perceived shortcomings or difficulties. As a result, even adolescents who consciously desire help often approach a clinical assessment with the fear that revealing what they perceive as shameful weaknesses leaves them vulnerable to criticism, control, or regressive dependency. Fear of acknowledging vulnerability or dependency may result in bland denials of any problems or insistence that "I can handle it by myself" or "I don't need a shrink; I can talk about my problems with my friends." Externalizing their conflicted feelings about autonomy versus dependence, adolescents may fluctuate between grievances about parental overprotectiveness and complaints about perceived lack of care. Reversal of affect and counterphobic defenses may mask anxiety, shame, or other painful affects. The skilled clinician learns to look beyond surface behavior and to notice when an adolescent "doth protest too much."

Although many adolescents seem intolerant of self-reflection, an unrealistic belief in the omnipotence of thought often helps to support denial and avoidance. Even when confronted with a pattern of long-standing maladaptive behaviors, the adolescent may insist "I can stop any time I really want to" or "I don't do that any more" (i.e., not since

Saturday).

The lability of adolescents' moods and their truncated time perspective often make it useful to extend the evaluation over time to distinguish the transient issues from those that are more enduring.

Technical Issues in the Adolescent Interview

Interviewing adolescents requires tact, flexibility, a sense of humor, and clinicians who have come to terms with their own adolescent issues. Condescension, sarcasm, competitiveness, or excessive passivity on the part of the interviewer is likely to result in failure. However, although conveying a genuine interest in the youngster is essential, seductiveness, overfamiliarity, or the failure to maintain an adult role is likely to frighten the adolescent. The interviewer should resist the temptation to be too "with it" or too "cool"—nothing is more dated than last year's slang. Because adolescents can so easily feel defensive, criticized, or embarrassed, the interviewer must learn to talk frankly yet tactfully about areas of apparent difficulty. Many embattled adolescents see adults as either for them or against them. Hence, the clinician needs to convey a genuine empathic interest in the adolescent's view of a situation without implying collusive, uncritical acceptance of it or entering into an adversarial dispute.

The general observation that it is important to learn about youngsters' strengths and interests, as well as their problems and vulnerabilities, is especially true of adolescents. Without appearing squeamish or avoidant of the problem areas, the clinician should inquire about the adolescent's interests, hobbies, recreations, and friendships. Knowledge about the areas of accomplishment, talent, and gratification is required for a full picture that includes the youngster's adaptive and compensatory strengths and assets. Furthermore, such an inquiry helps to facilitate rapport and conveys an interest in the adolescent as a whole person rather than simply a bearer of problems. A too-exclusive focus on pathology puts many youngsters on the defensive, and an opportunity to talk about more neutral areas or those of greater mastery or confidence helps the adolescent to feel less on the spot. Instead of the interviewer straining to demonstrate familiarity with the latest band or winning team, letting adolescents teach the interviewer about the details of their interests lets the youngsters enjoy a sense of mastery, control, and a degree of parity with the adult interviewer that helps to put them at ease. Indeed, what Hilde Bruch called the *constructive use of ignorance* is often a useful technical element of the adolescent interview. This consists in being able to ask about some missing piece in the story or about some puzzling impasse with an ingenuous curiosity (rather than prosecutorial zeal) that invites the adolescent's self-reflection.

Table 36.1–2.

Developmental Growth Tasks of Adolescence

1. Gradual development as an independent individual
2. Mental evolution of a satisfying, realistic body image
3. Harnessing of appropriate control and expression of sexual drives
4. Expansion of relationships outside of the home
5. Implementation of a realistic plan to achieve social and economic stability
6. Transition from concrete to abstract conceptualization
7. Integration of a value system applicable to life events

Reprinted with permission from Gross RT, Duke PM. Adolescence. In: Levine MD, Carey WB, Crocker AC, Gross RT, eds. *Developmental Behavioral Pediatrics*. Philadelphia, PA: WB Saunders; 1983.

Although interviewing and taking the history of the adolescent cover the same general areas outlined previously, certain domains are of particular salience with the adolescent. These relate to the core developmental tasks of adolescence: developing increased autonomy and individuation from parents; taking over the tasks of physical self-care; developing a satisfying, realistic body image in the face of pubertal changes; mastering burgeoning sexual and aggressive impulses; consolidating an identity, including ethical values and vocational goals; developing a network of satisfying peer relations; and in later adolescence, developing a capacity for romantic intimacy with an appropriate partner (Tables 36.1–2 and 36.1–3).

In the realm of values, ideals, and aspirations, the clinician should explore the adolescent's values and the models whom the adolescent wishes to emulate or to reject. To what extent do these values complement or conflict with those of the parents? What expectations and aspirations (realistic or not) does the adolescent have concerning the future?

The world of peers and friends should also be explored with adolescents. With whom do they hang out? What crowd do they see themselves part of? How do they get along with peers, and what do they do for fun? Asking teenagers to describe a close friend provides a chance to learn how they think about people and relationships and to assess their capacity for empathy.

In this context, it is also important to inquire about the adolescent's use of the Internet and social media. How much time does the youngster spend on line or on a mobile device? What is the balance of in-person interactions with local acquaintances versus purely electronic ones? Has the youngster had any concerning experiences online, such as cyber-bullying or sexting?

The topic of friends leads naturally to the topic of romantic and sexual interests and relationships. Exploration of this area requires tact, and the clinician cannot always be sure of receiving a candid response. Nonetheless, as with questions concerning depression or substance use, the clinician's tone can convey the sense that the inquiry into these sensitive areas is motivated by a genuine and legitimate wish to understand the adolescent. One can begin by asking whether the teenager dates and

whether there is anyone of either sex with whom the youngster is close. If so, who are they, and what attracted the adolescent to them? Are the adolescent's interests reciprocated? How has the relationship gone? Does the teenager note any recurrent patterns in terms of the type of person to whom he or she is attracted or how such relationships have unfolded in the past? Have any of the teenager's relationships developed into sexual ones? Has the adolescent had other sexual experiences? (Here one must be open to hearing about possible episodes of sexual abuse or concerns about sexual orientation.)

Because of the high prevalence of depression, self-harm, suicidal ideation, and even suicide attempts in the general population, specific inquiry about these areas as outlined previously is particularly important. The clinician should also inquire matter-of-factly about whether the adolescent smokes, drinks, or uses drugs illicitly, and, if so, with what frequency, in what amounts, in what contexts, and with what consequences.

ASSESSMENT OF INFANTS AND TODDLERS

The assessment of infants and toddlers poses special challenges for the clinician. First, the evaluation of young children requires specific and detailed familiarity with the cognitive, linguistic, motor, and adaptive developmental landmarks from birth to 6 years of age, as well as the specialized techniques needed to assess these competencies. Second, although direct observation of the child is an important source of data, the preverbal or limited verbal capacities of the child severely restrict the historical material that can be obtained from the direct interview of the child. Third (and perhaps most important), infants and young children cannot be assessed, diagnosed, or treated apart from their caregiving environment, which includes not only the parents but also other members of the extended family and child care and other care providers.

Table 36.1–3.
Growth Tasks of Adolescence by Developmental Phase

Tasks	Early: 10–13 Years of Age	Middle: 14–16 Years of Age	Late: 17 Years of Age and Older
1. Independence	Emotionally breaks from parents, and prefers friends to family	Ambivalence about separation	Integration of independence issues
2. Body image	Adjustment to pubescent changes	Trying on different images to find real self	Integration of a satisfying body image with personality
3. Sexual drives	Sexual curiosity, occasional masturbation	Sexual experimentation, opposite sex viewed as sex object	Beginning of intimacy and caring
4. Relationships	Unisexual peer group,	Begin heterosexual peer	Individual relationships more

	adult crushes	group, multiple adult role models	important than peer group
5. Career plans	Vague and even unrealistic plans →		Specific goals and specific steps to implement them
6. Concept-ualization	Concrete thinking →		Ability to abstract
		Fascinated by new capacity for thinking	
7. Value system	Drop in superego, testing of moral system of parents	Self-centered →	Idealism, rigid concepts of right and wrong, other oriented, asceticism

Reprinted with permission from Gross RT, Duke PM. Adolescence. In: Levine MD, Carey WB, Crocker AC, Gross RT, eds. *Developmental Behavioral Pediatrics*. Philadelphia, PA: WB Saunders; 1983.

The developmental tasks of infancy include achieving physiological homeostasis; developing stability of state and learning to negotiate transitions between states; organizing basic physiological rhythms of wakefulness and feeding; coping with novel stimuli; perceiving coherent patterns of experience; mastering simple sensorimotor schema; establishing a specific and secure relationship with a caretaker; maintaining a positive affective tone; developing expressive and receptive channels of communication (including vocalizations and facial and gestural cues); and forming schemas of causality, intentionality, object permanence, and affect. The older infant or toddler must grapple with regulating and socializing bodily functions (e.g., eating, toileting, and sleeping), learning to concentrate and regulate shared attention, acquiring the capacity for imaginative play and more complex forms of imitation, dealing with the challenge of socialization (including development of more complex forms of social perception, communication, and empathy and negotiating conflicts of will with caregivers and peers), regulating negative and positive mood and aggression, and forming core gender identity. Development can proceed at a different pace in each area and may go awry or be delayed in any or all of them.

The goal of the developmental assessment of infants and toddlers is to depict their functional capacities in each of these areas, the relationships among the various domains of their development, their ability to adapt, and the range of coping strategies that they use in doing so, as well as the caregiving environment as it affects them, the quality of caregiving interactions, and the effect of their developmental status on the caregiver. As with older children, the purpose of the assessment is to define what, if any, interventions are necessary, while at the same time helping to form an alliance with the parents that facilitates implementation of any recommendations that may come out of the assessment. The assessments process itself, properly done, increases parents' sensitivity, awareness, and reflectiveness about their child's development.

The most common referral problems for infants and toddlers involve the following:

1. Developmental delays (e.g., specific delays, such as delayed, absent, or deviant motor or speech development, or general delays in multiple areas of development).
2. Psychophysiological dysregulation (fussy behavior, disturbances of sleep or feeding, rumination, eczema, self-stimulatory behaviors [e.g., head banging, rocking], and failure to thrive).
3. Behavioral disturbances (excessive tantrums, excessive negativism, aggression, and hyperactivity).
4. Disturbed social development (lack of apparent awareness of or interest in others, response to abuse, neglect, or multiple placements or repeated or prolonged separations).
5. Medical or genetic problems (e.g., prematurity and genetic syndromes), exposure to toxins (such as lead or fetal alcohol syndrome).
6. Exposure to environmental stressors (such as maternal depression, change of caretaker, domestic violence or other trauma, reaction to transitions, e.g., beginning preschool or out-of-home child care, parental marital separation).

Because so many aspects of early development are interdependent, the significance of difficulties in one functional domain cannot be understood without reference to the child's developmental status in other areas. For example, speech, language, and hearing difficulties profoundly affect personal and social development. Assessment of motor or adaptive competency that involves interaction with the caregiver or assessor is affected by disturbances in relatedness and hence yields findings that appear erratic or uneven. Infants and toddlers are particularly sensitive to environmental stresses, which may delay the appearance of phase-appropriate skills or may lead to transient regressions.

Technical Issues in the Development of the Infant and Young Child

The assessment of the young child usually requires several sessions. In addition to sessions spent with the parents alone to gather history and to present the results of the assessment, familiar adults must be present during the assessment of the child; this is necessary to place the child at ease in the assessor's presence and to permit direct observation of child and caregiver interaction. Furthermore, the behavior of infants and young children is highly state dependent (and sensitive to fatigue or illness), and one usually needs to see the child on more than one occasion to have a sufficient sample of characteristic behavior.

The general principles of history taking from the parents and assessment of the caregiving environment follow those outlined previously. However, particular emphasis is given to the parental perception of the

pregnancy with the child—whether the conception was planned or came at a good time in the life of the family and what the effect of the child's arrival was on the parents individually, on older siblings, and on the family as a whole. The history should explore parental (and grandparental) expectations for the child, the meaning that the child has for them, whom the infant reminds them of, and what they perceive as the child's best and worst traits.

The developmental history for the young child includes prenatal, perinatal, and postnatal complications, including maternal illness, medication and substance use, and neonatal status. In addition to the areas outlined previously, assessment of the child's behavioral organization should include the regulation of physiological state, alertness, and activity patterns. Children's ability to console themselves and to adapt to new situations and their response to separations are also key areas of evaluation. The history should also include the history of child care arrangements (nannies, relatives, out-of-home child care) and the child's reactions to new care environments or changes in these arrangements. (Many young children spend about as many waking hours in the care of a paid caregiver as they do with their parent(s), hence, in many cases, it may be very useful to hear the report of these extra-familial caretakers.)

The child's mastery of various gross motor, fine motor, language, adaptive, and personal-social milestones should be systematically assessed by history and in the direct evaluation of the child. In taking such a history, the assessor may be aided by a variety of screening instruments, such as the Vineland Adaptive Behavior Scales II. It is useful to inquire about the timing of the child's mastery of these milestones relative to those of any siblings; this also helps to gauge parental expectations and to learn more about sibling dynamics. The Vineland scales provide a semistructured interview format that can be easily woven into a developmental history.

Within the first few months of life, children begin to manifest distinctive and often enduring behavioral styles or temperament. Table 36.1–4 shows the nine temperamental categories and three distinctive constellations of temperament as defined by Stella Chess and Alexander Thomas. The goodness of fit, or degree of consonance between the child's temperament and the parents' expectations or demands of the child, is an important predictor of future development and parent–child interactions.

Particularly salient aspects of the parental interview include a detailed history of the parents' childhoods and history of care, out-of-home placement, separations, and experience in their families of origin. The effect of the child on each parent and their marital relationship should be assessed, as well as the appropriateness and degree of congruity in their respective expectations of the child.

Adequate caregiving for the young child requires a delicate balance among gratification, comfort, support, and frustration that is appropriate

to the child's developmental phase. It is important to hear (and to observe) which aspects of parenting and which features of the child's behavior the parent feels most comfortable with or most challenged by. The clinician should assess the parents' overall level of psychological functioning; the parental difficulties that adversely affect a young child's development do not always involve such gross failures as serious neglect or abuse but may involve problems more difficult to identify, such as persistent maternal or paternal depression. To help obtain a concrete picture of the parent, child, and their interaction, it is useful to ask for a detailed description of a day in the life of the child. In addition to providing data regarding the child's capacities, responses, and temporal organization, such a description provides clues to the parents' attunement and affective responses to the various elements of the child's behavior.

Table 36.1–4.
Temperament Categories

Activity level: The motor component present in a given child's functioning and the diurnal proportion of active and inactive periods.

Rhythmicity (regularity): The predictability or unpredictability in time of any function; it can be analyzed in relation to the sleep–wake cycle, hunger, feeding pattern, or elimination schedule.

Approach or withdrawal: The nature of the initial response to a new stimulus, be it a new food, a new toy, or a new person. Approach responses are positive, whether displayed by mood expression (e.g., smiling and verbalizations) or motor activity (e.g., swallowing a new food, reaching for a new toy, and active play). Withdrawal reactions are negative, whether displayed by mood expression (e.g., crying, fussing, grimacing, and verbalizations) or motor activity (e.g., moving away, spitting new food out, and pushing new toy away).

Adaptability: Responses to new or altered situations. One is not concerned with the nature of the initial responses, but with the ease with which they are modified in a desired direction.

Threshold of responsiveness: The intensity level of stimulation needed to evoke a discernible response, irrespective of the specific form of the response or the sensory modality affected. The behaviors used concern reactions to sensory stimuli, environmental objects, and social contacts.

Intensity of reaction: The energy level of response, irrespective of its quality or direction.

Quality of mood: The amount of pleasant, joyful, and friendly behavior (as contrasted with unpleasant, crying, and unfriendly behavior).

Distractibility: The effectiveness of extraneous environmental stimuli in interfering with or altering the direction of the ongoing behavior.

Attention span and persistence: *Attention span* concerns the length of time a particular activity is pursued by the child. *Persistence* refers to the continuation of an activity in the face of obstacles to the maintenance of the activity direction.

Qualitative analysis, supplemented by factor analyses, led to the formulation of, in addition, three constellations of temperament made up of various combinations of the individual categories, which appeared to have functional significance. These are as follows:

Easy temperament: The combination of biological regularity, approach tendencies to the new, quick adaptability to change, and a predominantly positive mood of mild or moderate intensity. This group comprised approximately 40 percent of the study population.

Difficult temperament: The opposite of easy temperament, namely, biological irregularity, withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional expressions of high intensity. This group comprised approximately 10 percent of the study population.

Slow-to-warm-up temperament: Withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional reactions of low intensity. Such individuals are often labeled shy. This group comprised approximately 15 percent of the study population.

Adapted from Chess S, Thomas A. Temperament and its clinical applications. In: Lewis M, ed. *Child and Adolescent Psychiatry*. 3rd ed. Baltimore, MD: Lippincott Williams & Wilkins; 2002:221.

Although much of the clinical observation is focused on the child's behavior and capacities, direct observation of the parent–child relationship is essential. Inviting the family to interact in the playroom as they usually would at home allows observation of their interaction in unstructured parent–child or family play; assigning various structured tasks may also be useful. Observing the child in interaction with each parent separately helps to reveal relationship-specific patterns of behavior. Among the dimensions of parental behavior to be assessed are the ability to engage the child (verbally and nonverbally); the quality and affective tone of this engagement; the parent's attunement to the child's cues; parental vigilance, protectiveness, and limit setting; the parent's facilitation or restriction of autonomous play by the child; thematic content; and the degree of mutual pleasure during play. Instruments and methodologies exist for formally assessing parental responsivity and parent–young child interaction, such as the Home Observation for Measurement of the Environment (HOME) and the Parent–Child Early Relational Assessment (PCERA). Some of these use standardized protocols or structured video recording and analysis. Some yield impressionistic global scores, whereas others provide detailed frame-by-frame coding of parent–child interactions. Although these methods are used primarily for research purposes, familiarity with the various facets of such instruments is clinically useful.

Observation and Examination of the Infant and Toddler

The direct examination of the young child draws on three levels of observation: The child's response to structured assessment items during formal testing, the child's response to other interactions with the assessor and the assessment environment, and the spontaneous interactions of the child and parent in a naturalistic setting. When observation of the child and parents takes place in the clinic, it is essential to remember that the unfamiliar setting may elicit behavior that is not characteristic of the home setting.

Structured Assessment Instruments. A variety of instruments exists for the structured assessment of infants and young children, and each has somewhat different goals, theoretical orientation, and psychometric properties (Table 36.1–5). These instruments do not yield diagnoses; they detail the child's development in various areas relative to a normative population. Some of these developmental tests are screeners designed to

help pediatricians or trained paraprofessionals identify children with significant motor, social, or language delays who need fuller evaluation, whereas others are complete batteries evaluating a full range of developmental competencies. For example, the Bayley Scale of Infant and Toddler Development III (Bayley-III), which is administered by a trained assessor, can be used to assess children 1 to 42 months of age; it includes scales yielding standard scores for cognitive abilities, gross and fine motor skills, receptive and expressive communication, and self-help competencies, as well as a behavior rating scale for assessing qualitative aspects of the child's behavior during the assessment.

Table 36.1–5.
Selected Formal Tests of Infant and Toddler Development

	Age	Domains[a]	Norm Sample	Reliability/Validity	Com
Neonatal Assessment Tests					
Graham/Rosenblith Behavioral Test for Neonates		M, TA, V, A, MT	Not applicable	Encouraging early findings	Curr s
Brazelton Neonatal Behavioral Assessment Scale—2	37–44 weeks GA	NI, B, PS	Not applicable	High interrater reliability, weak test-retest, poor predictor beyond first year	Mos u n
Infant/Toddler Development Tests					
Bayley Scales of Infant Development–III	1–42 months	Mental, M, B	Large, representative	Excellent for mental, adequate for psychomotor, varied for behavior	Mos u v ir
Mullen Scales of Early Learning	0–68 months	GM, FM, VR, RC, EC	Large, representative	Adequate to exceptional	Mos fo a p
Battelle Developmental Inventory	0–95 months	PS, Ad, GM, FM, EC, RC, Cg (and sub-domains)	Small, representative	Numerous psychometric concerns cast significant doubts (see text)	Use c d m fl
Griffiths Abilities of Babies	0–24 months	Lm, PS, HS, EH, P	Small, all from London	Mixed results	Mos E
Infant Psychological Development Scales	NA	See text	Not applicable	Adequate to exceptional reliability	Mos P ir
Screening Tests					

Battelle Developmental Inventory Screening Test	6–95 months	PS, Ad, GM, FM, EC, RC, Cg	Small, representative	Strong correlation with full BDI	Suff li fu
Bayley Infant Neurodevelopmental Screen	3–24 months	N, RC, EC/M, Cg	Large; representative	Excellent reliability; promising validity	
Birth to Three Developmental Scale	0–36 months	EC/RC, Cg, PS, M	Small; questionable representation	Strong interrater reliability, but little evidence of validity	
Child Development Inventory	15–72 months	GM, FM, EC, RC, Ad, PS, L, N	Small; from St. Paul, MN	Little evidence of reliability and validity	300 r
Denver Developmental Screening Test—II	0–72 months	GM, FM/Cg, PS, EC/RC	Large, all from Denver area	See text	See
Developmental Activities Screening Inventory—II	0–60 months	15 sensory and problemsolving areas	>200 disabled children	Little evidence of reliability; valid for severely delayed	Can w la a ir c
Developmental Indicators for the Assessment of Learning—Revised	24–72 months	M, AS, EC/RC, B	Large; representative	Acceptable reliability and validity	One s a
Diagnostic Inventory for Screening Children—4	0–60 months	FM, GM, RC, EC, AM, VM, Ad, PS	Small; all from southwest Ontario	Excellent reliability; limited validity	
Developmental Observation Checklist System	0–72 months	Cg, EC/RC, PS, FM/GM, Adj, PS&S	Adequate; representative	Sound reliability and concurrent validity	Pare o
Developmental Profile —II	0–114 months	M, Ad, PS, AS, EC/RC	Large	Adequate reliability and validity	Pare o

[a]A, auditory responsiveness; Adj, adjustment; Ad, adaptive, self-help or daily living; AM, auditory attention and memory; Ar, articulation; AS, academic or pre-academic skills; B, behavior; Cg, cognitive or problemsolving; EC, expressive communication/language; EH, eye-hand coordination; FM, fine motor; GM, gross motor; HS, hearing and speech; L, letters; Lm, locomotor; M, motor or physical; MT, muscle tone; N, numbers; Nl, neurological intactness; P, performance; PS, personal-social; PS and S, parental stress and support; RC, receptive communication/language; TA, tactile-adaptive; V, visual responsiveness; VM, visual attention and memory; VR, visual reception. A slash mark (/) indicates that multiple domains are assessed in the same scale or subtest.

From Gilliam WS, Mayes LC. Clinical assessment of infants and toddlers. In: Martin A, Volkmar FR, eds.

Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2007:309–322.

Although tests such as the Bayley-III may show good reliability and concurrent validity, their ability, when administered to children younger than 3 years, to predict later performance on intelligence quotient (IQ) assessments or later adaptive functioning is highly variable. Among the reasons for this weakness of prediction are sources of error, such as the rapid pace of development during this period and the child's susceptibility to state or environmental effects (e.g., fatigue and unfamiliar test setting), as well as the intervening effects of social and family environment and the heavy emphasis infant tests place on perceptual and motor skills that may have relatively little to do with information-processing capacities. However, very low scores on repeated measures are highly suggestive of continuing difficulties.

The mental status examination of the infant and young child can be organized using a schema such as that shown in Table 36.1–6.

Diagnostic Formulation of the Assessment of Infants and Young Children

Although intellectual disability and autism spectrum disorders can be at least tentatively diagnosed in infants and toddlers, the most widely used official diagnostic system—the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10)—generally lack a developmental perspective and diagnostic criteria or categories suitable for infants and young children. The Zero to Three/National Center for Clinical Infant Program's *Diagnostic Classification of Mental Health and Development Disorder of Infancy and Early Childhood, Revised Edition* (DC:0–3R) provides a diagnostic schema for this age group that complements the DSM.

The appropriate outcome of a thorough clinical assessment of the young child thus extends far beyond an attempt at a specific categorical diagnosis. The diagnostic formulation should provide a detailed picture of the strengths and weaknesses in the child's social, emotional, cognitive, linguistic, motor, and perceptual development; the quality of the child's temperament, attachment, and regulatory capacities; hypotheses regarding the etiology of the child's difficulties; and potential exacerbating or risk factors and protective or ameliorative factors in the child and family. This formulation, which should be shared with the family in a comprehensible and usable form, should provide the basis for recommendations regarding intervention or further assessment.

SPECIAL TYPES OF ASSESSMENT

This section describes the comprehensive clinical assessment of the child.

Although the clinician must be aware of the many facets of history taking, interview, and observation described here, certain clinical settings or tasks may call for a narrower focus of inquiry or distinctive emphasis for the evaluation. For example, an urgent situation may require therapeutic intervention before a comprehensive assessment can be completed; in such cases, the immediate evaluation focuses on defining the crisis and selecting the most suitable immediate intervention. Thus, the emergency room or crisis center evaluation focuses on precipitants and extent of the current decompensation, predisposing vulnerabilities, the exacerbating factors affecting the child and family and the ameliorative resources available to the family in such situations, the risk of danger to self or others, and other issues germane to making an immediate disposition (including assessing the potential need for hospitalization). The assessment of suicidal ideation, threats, or attempts or aggressive outbursts is perhaps the most common clinical context for such urgent evaluations. Children exposed to acute trauma (e.g., natural catastrophe or violence) are often screened outside of the traditional clinic setting in a combination of emergency assessment and crisis intervention. The noncompliant, acutely agitated, or delirious child in the pediatric setting raises yet another set of assessment issues (Table 36.1–7).

Various specialized consultative purposes also require distinctive techniques or procedures or specific areas of inquiry. (The American Academy of Child and Adolescent Psychiatry has prepared valuable practice parameters providing guidance for assessment and treatment of children and adolescence in forensic settings, detention or correctional facilities, schools, community systems of care, and pediatric settings, as well as youngsters presenting with certain specific conditions, such as substance abuse, suicidal behaviors, aggression, exposure to trauma, etc.)

For example, forensic evaluations raise special issues of role definition, confidentiality, and privilege and require familiarity with the legal issues involved. Clinicians must be clear about whether they are serving as neutral impartial advocates for the best interests of the child at the behest of the court or as consultants to one party or another. Although the clinician treating or assessing the child for clinical purposes may have information valuable to a forensic evaluation, it is usually in the best interests of the therapy and the legal proceedings for the evaluator to be someone other than the therapist.

The assessment of children or adolescents who may have been physically or sexually abused is a common form of forensic evaluation. In addition to assessing the child's competency and credibility, the examiner may also be asked for recommendations regarding whether the child should testify in court (and, if so, how) and whether removal of the child or alleged perpetrator from the home is needed, as well as any therapeutic interventions that may be required. A forensic evaluation requires careful

documentation of parent and child interviews. The suggestibility of younger children raises the danger of false accusations and false denials and requires meticulous safeguards against repetitive, suggestive questioning.

Child custody evaluations also require careful definition of the assessor's role with all concerned. Specific attention must be given to the best interests of the child in terms of continuity and stability of care, the quality of parent–child attachment and attunement, the child's stated preferences, the mental health of each parent, and the level of parental conflict and its effect on the child. Consultations for the juvenile court regarding youthful offenders or children in need of services and probate or commitment hearings represent other forms of forensic evaluation. Other specialized forms of evaluation include medication consultations and consultation to day care centers, schools, or pediatric specialty clinics (e.g., pain or oncology clinics).

STANDARDIZED ASSESSMENT INSTRUMENTS FOR CHILDREN AND ADOLESCENTS

While psychosocial and environmental factors must inform clinical decision-making, the systematic assessment of symptoms, behavior and impairment is an essential part of clinical evaluation. Numerous tools—diagnostic interviews and rating scales—have been developed that elicit comprehensive information about psychiatric symptoms and diagnoses. The use of standardized instruments provides some protection against the risks to which traditional clinical approaches may be prone, for example, tendencies to make diagnoses too quickly, collecting information selectively that confirms initial impressions, ignoring contradictory information, and applying diagnostic criteria idiosyncratically. The relatively structured diagnostic measures are likely to yield more reliable diagnoses than those made from less systematic approaches, and these features in turn improve the likelihood of obtaining meaningful findings from research efforts, which depend on assessment of diagnoses in a consistent manner across a number of study participants.

Table 36.1–6.
Infant and Toddler Mental Status Examination by Anne L. Benham, M.D.

I. Appearance
   Size, level of nourishment, dress and hygiene, apparent maturity compared to age, dysmorphic features (e.g., facies, eye and ear shape and placement, epicanthal folds, and digits), abnormal head size, cutaneous lesions.
II. Apparent reaction to situation
   Note where and with whom the evaluation takes place.
   A. Initial reaction to setting and to strangers: Explores; freezes; cries; hides face; acts curious, excited, apathetic, or anxious (describe).
   B. Adaptation

1. Exploration: When and how child begins exploring faces, toys, stranger.
2. Reaction to transitions: From unstructured to structured activity; when examiner begins to play with infant; cleaning up; leaving.

III. Self-regulation

A. State regulation: An infant's state of consciousness ranges from deep sleep through alert stages to intense crying. Predominant state and range of states observed during session, patterns of transition (e.g., smooth vs. abrupt), capacity for being soothed and self-soothing, capacity for quiet alert state. (Some of these categories also apply to toddlers.)
B. Sensory regulation: Reaction to sounds, sights, smells, light and firm touch; hyperresponsiveness or hyporesponsiveness (if observed) and type of response, including apathy, withdrawal, avoidance, fearfulness, excitability, aggression, or marked behavioral change; excessive seeking of particular sensory input.
C. Unusual behaviors; mouthing after 1 year of age; head banging; smelling objects; spinning; twirling; hand flapping; finger flicking; rocking; toe walking; staring at lights or spinning objects; repetitive, perseverative, or bizarre verbalizations or behaviors with objects or people; hair pulling; ruminating; or breath holding.
D. Activity level: Overall level and variability (note that toddlers are often incorrectly called hyperactive). Describe behavior; for example, squirming constantly in parent's arms, sitting quietly on floor or in infant seat, constantly on the go, climbing on desk and cabinets, exploring the room, pausing to play with each of six to eight toys.
E. Attention span: Capacity to maintain attentiveness to an activity or interaction, longest and average length of sustained attention to a given toy or activity, distractibility. Infants: Visual fixing and following at 1 mo of age, tracking at 2–3 months of age, attention to own hands or feet and faces, duration of exploration of object with hands or mouth.
F. Frustration tolerance: Ability to persist in a difficult task, despite failure; capacity to delay reaction if easily frustrated—e.g., aggression, crying, tantrums, withdrawal, and avoidance.
G. Aggression: Modes of expression, degree of control of or preoccupation with aggression, appropriate assertiveness.

IV. Motor

Muscle tone and strength, mobility in different positions, unusual motor pattern (e.g., tics and seizure activity), intactness of cranial nerves (e.g., movement of face, mouth, tongue, and eyes, including feeding, swallowing, and gaze [note excessive drooling]).

A. Gross motor coordination. Infants: Pushing up, head control, rolling, sitting, standing. Toddlers: Walking, running, jumping, climbing, hopping, kicking, throwing and catching a ball. (It is useful to have something for the child to climb on, such as a chair.)
B. Fine motor coordination. Infants: Grasping and releasing, transferring from hand to hand, using pincer grasp, banging, throwing. Toddlers: Using pincer grasp, stacking, scribbling, cutting. Fine motor and visual-motor coordination can be screened by observing how the child handles puzzles, shape boxes, a ball and hammer toy, small cars, and toys with connecting parts.

V. Speech and language

A. Vocalization and speech production: Quality, rate, rhythm, intonation, articulation, volume.
B. Receptive language: Comprehension of others' speech as seen in verbal or behavioral response (e.g., follows commands), points in response to "where is" questions, understands prepositions and pronouns (include estimate of hearing, especially in child with language delay, e.g., response to loud sounds and voice; ability to localize sound).
C. Expressive language: Level of complexity (e.g., vocalization, jargon, number of single words, short phrases, and full sentences); overgeneralization (e.g., uses *kitty* to refer to all animals); pronoun use, including reversal; echolalia, immediate or delayed; unusual or bizarre verbalizations. Preverbal children: Communicative intent (e.g., vocalizations, babbling, imitation, and gestures, such as head shaking and pointing), caregiver's ability to understand infant's communication, child's effectiveness in communication.

VI. Thought

The usual categories for thought disorder almost never apply to young children. Primary process thinking, as evidenced in verbalizations or play, is expected in this age group. The line between fantasy and reality is often blurred. Bizarre ideation, perseveration, apparent loose associations, and the persistence of pronoun reversals, jargon, and echolalia in an older toddler or preschooler may be noted in a variety of psychiatric disorders, including pervasive developmental disorders.

A. Specific fears: Feared object, worry about being lost or separated from parent.
B. Dreams and nightmares: Content is sometimes obtainable in children 2–3 yrs of age. Child does not always perceive it as a dream; for example, "A monster came in the front door."
C. Dissociative state: Sudden episodes of withdrawal and inattention, eyes glazed, "tuned out," failure to track ongoing social interaction. Dissociative state may be difficult to differentiate from an absence seizure, depression, autism, or deafness. The context may be helpful (e.g., a child with a history of neglect freezes in a dissociative state as mother leaves the room). Neurological or audiological evaluation may be warranted.
D. Hallucinations: Extremely rare, except in the context of a toxic or medical disorder, then usually visual or tactile.

VII. Affect and mood

The assessment of mood and affect may be more difficult in young children because of limited language, lack of vocabulary for emotions, and use of withdrawal in response to a variety of emotions, from shyness and boredom to anxiety and depression.

A. Modes of expression: Facial, verbal, body tone and positioning.
B. Range of expressed emotions: Affect, especially in parent–child relationship.
C. Responsiveness: To situation, content of discussion, play, and interpersonal engagement.
D. Duration of emotional state: Need history or multiple observations.
E. Intensity of expressed emotions: Affect, especially in parent–child relationship.

VIII. Play

Play is a primary mode of information gathering for all sections of the Infant and Toddler Mental Status Examination. In young children, play is especially useful in the evaluation of the child's cognitive and symbolic functioning, relatedness, and expression of affect. Themes of play are helpful in assessing older toddlers. The management and expression of aggression are assessed in play as in other areas of behavior. Play may be with toys or with the child's own or another's body (e.g., peek-a-boo, roughhousing), verbal (e.g., sound imitation games between mother and infant), or interactional or solitary. It is important to note how the child's play varies with different familiar caregivers and with parents versus the examiner.

A. Structure of play (ages are approximate).
   1. Sensorimotor play
      a. 0–12 months of age: Mouthing, banging, dropping and throwing toys or other objects.
      b. 6–12 months of age: Exploring characteristics of objects (e.g., moving parts, poking, and pulling).
   2. Functional play
      a. 12–18 months of age: Child's use of objects shows understanding and exploration of their use or function (e.g., pushes car, touches comb to hair, and puts telephone to ear).
   3. Early symbolic play
      a. 18 months of age and older: Child pretends with increasing complexity; pretends with own body to eat or to sleep; child pretends with objects or other people (e.g., "feeds" mother); child uses one object to represent another (e.g., a block becomes a car); child pretends a sequence of activities (e.g., cooking and eating).
   4. Complex symbolic play
      a. 30 months of age and older: Child plans and acts out dramatic play sequences, uses

imaginary objects. Later, child incorporates others into play with assigned roles.

5. Imitation, turn taking, and problem solving as part of play.

B. Content of play. The toddler's choice and use of toys often reflect emotional themes. It is desirable to have on hand toys that tap different developmental and emotional domains. An overfull playroom may be overwhelming or overstimulating and may reduce meaningful observations. Young toddlers of both sexes often gravitate to dolls, dishes, animals, and moving toys, such as cars. The examiner's choice of specific materials may facilitate the expression of pertinent emotional themes. For example, a child traumatized by a dog bite may more likely re-enact the trauma if a dog and doll figures are available. The child's reaction to scary toys, such as sharks, dinosaurs, or guns, should be noted, especially if they are avoided or dominate the session. Does aggressive pretend play become real and physically hurtful? By 2.5–3 yrs of age, a child's animal or doll play can reveal important themes about family life, including reactions to separation, parent–child and sibling relationships, experiences at day care, quality of nurturance and discipline, and physical or sexual abuse. The examiner must use caution in interpreting play, viewing it as a possible combination of re-enactment, fears, and fantasy.

IX. Cognition

Using information from all previously mentioned areas, especially play, verbal and symbolic functioning, and problem solving, roughly assess the child's cognitive level in terms of developmental intactness, delays, or precocity.

X. Relatedness

A. To parents: How in tune do the child and parent seem? Does the child make and maintain eye, verbal, or physical contact? Is there active avoidance by child? Note the infant's level of comfort and relaxation being held, fed, molding into caregiver's body. Does the toddler move away from the caregiver and check back or bring toys to show, to put into his or her lap, to play with together or near the caregiver? Comment on physical or verbal affection, hostility, reaction to separation and reunion, and use of transitional objects (blanket, toy, caregiver's possession). Describe differences in relating if more than one caregiver is present.

B. To examiner: Young children normally show some hesitancy to engage with a stranger, especially after 6–8 months of age. Appropriate wariness in young children may result in a period of watching the examiner, staying physically close to a familiar caregiver before engaging, or showing some constriction of affect, vocalization, or play. After initial wariness, does the child relate? Does the child engage too soon or not at all? How does relatedness with a stranger compare to that with a parent? Is the child friendly versus indiscriminately attention seeking or guarded versus overanxious? Can the examiner engage the child in play or structured activities to a degree not seen with caregiver? Does the child show pleasure in successes if the examiner shows approval?

C. Attachment behaviors: Observe for showing affection, seeking comfort, asking for and accepting help, cooperating, exploring, controlling behavior, and responding to reunion. Describe age-related disturbances in these normative behaviors. Disturbances often are seen in abused and neglected children; for example, fearfulness, clinginess, overcompliance, hypervigilance, impulsive overactivity, and defiance; restricted or hyperactive and distractible exploratory behavior; and restricted or indiscriminate affection and comfort seeking.

From Thomas JM, Benham AL, Gean M, Luby J, Minde K, Turner S. Practice parameter for the psychiatric assessment of infants and toddlers (0–36 months). *J Am Acad Child Adolesc Psychiatry*. 1997;36(10 Suppl):21S–36S.

The advent of many of these tools can be traced to two related developments in psychiatric clinical thinking and research since 1980. First, the introduction of explicit, criterion-based diagnostic systems such

as the Research Diagnostic Criteria and the DSM-III followed by the DSM-III-R, the DSM-IV, most recently the DSM-5, as well as the research version of the ICD-10 facilitated the development of standardized interviews and questionnaires, which specify the relevant elements of a diagnosis. Second, in recent decades there has been a rapid expansion in psychiatric research, creating a need for tools for research assessment. Thus, working synergistically, major changes in the diagnostic system, the impetus provided by emerging research findings, and the increasingly apparent advantages of using standardized diagnostic tools in research (and, more recently, in clinical settings) are key developments that have presented the field with an array of psychiatric assessment techniques and thus with a corresponding growing body of research literature on their characteristics and utility.

Because the inventory of symptomatic and diagnostic tools for children and adolescents has rapidly expanded over recent years, it is important for those evaluating and treating youth to be familiar with the literature and the clinical and research relevance of these tools.

Table 36.1–7.
Differential Psychosocial Diagnosis of the Uncooperative Patient

Inadequate understanding of the nature of illness or injury, treatment details, or staff expectations and intentions
Anxiety and regression
Separation anxiety
Concerns over bodily integrity
Response to immobilization
Denial
Idiosyncratic sources of anxiety
Inadequate pain control
Depression
Exacerbation of pre-existing psychopathology, especially oppositional or conduct difficulties
Family issues
Parental anxiety or hostility toward staff
Parental psychopathology: Depression, psychosis, or factitious disorder by proxy
Prior family experiences with illness
Cultural issues
Developmental issues (especially adolescence)
Emphasis on autonomy, ambivalence regarding dependency
Emphasis on activity, peer involvement
Self-consciousness about body
The body as a means of expressing psychological issues
Mature decision to refuse treatment

From King RA, Lewis M. Differential psychosocial diagnosis of the uncooperative patient. *Child Adolesc Psychiatr Clin North Am.* 1994;3:531.

Issues in Developing Diagnostic Methods

The task of developing diagnostic tools in psychiatry is a complex and challenging one, given the complicated nature of the symptoms and their clusters and patterns over time. In addition, developing measures to assess psychopathology in children and adolescents is more challenging than the comparable task with adults. These challenges include the need to incorporate an understanding of aspects of development into the framing and wording of questions about symptoms and into the process of discriminating normative from pathological behaviors. Many behaviors only become "symptoms" when they occur at too high a frequency or at the wrong age (e.g., separation problems and oppositional behaviors). In addition, many symptoms reflect an underlying substrate of psychopathology with phenotypic manifestations that differ during different developmental stages. Moffit referred to these variations as a function of the "heterotypic continuity" of disorders. Antisocial behavior provides an illustrative example: what is difficult temperament in early months and years may progress to the characteristics of oppositional defiant disorder in middle childhood, then to conduct disorder in later childhood/adolescence, and eventually become manifest as adult antisocial personality disorder.

Another challenge in the development of structured interviews or scales is the necessity of obtaining information from both the child and another informant, usually the parent and at times the teacher, because developmental stage can limit the capacity of children to report on their own behaviors/symptoms. Investigators have repeatedly found poor agreement between different informants with respect to symptom presence and hence diagnosis; yet, as has long been realized by clinicians, there is general agreement that information obtained from any informant is diagnostically useful. There is no consensus, however, on how best to combine the information across informants or as to whether to combine the information at all. Some kinds of information may be uniquely accessible to one or another informant—for example, teachers may be better reporters of attention problems than parents, whereas parents are likely to be better reporters of eating behaviors and irritable mood. For alcohol or other substance use, youth consistently report more symptoms than parents do, and similar results have been found for sexual behavior and conduct disorder.

Characteristics of informants may influence how they report on symptoms and behavior. Parents who have anxiety disorders tend to report greater levels of psychopathology in their children than do independent observers. Mothers who are depressed tend to over-report behavior problems and symptoms in their children, even when contextual variables and child gender have been controlled for. Complicating this issue, children

of depressed mothers have been found to have more behavioral problems than children of nondepressed mothers. At younger ages, children often do not have the ability to compare themselves to others, which can affect their reports on oppositional behavior or hyperactivity.

Further challenges to the development of diagnostic measures include the problem of how to integrate concepts of social context and adaptive functioning into a symptom-based assessment. These factors are difficult to isolate conceptually and to operationalize without producing an overly long and complex measure.

Still another difficult aspect in developing structured diagnostic and symptom measures is the lack of a readily available gold standard with which to compare results from structured measures so as to modify and improve them. In the history of diagnostic methodological development, the psychometric properties of reliability and validity have been touted as the bases for determining what measure was best. It is important for users to understand these concepts and to be familiar with a proposed instrument's performance in these respects. Briefly, the reliability of an assessment method is often conceptualized as the extent to which the results of an assessment can be repeated or reproduced, whereas validity is conceptualized as the extent to which the instrument measures what it purports to measure.

There are various types of reliability. *Inter-rater reliability* involves the stability of an assessment when it is administered by different raters (in the case of psychiatric diagnostic interviews, by different interviewers). *Test–retest reliability* reflects the stability of results over time, that is, when an instrument is administered on two occasions, separated by a period of time in which the degree of real change in the condition being measured is expected to be trivial. To assess the test–retest reliability of child psychiatric diagnostic instruments, the measure is often administered twice, 1 to 2 weeks apart. The 1 to 2 week interval is chosen to minimize precise memory effects (i.e., the child or parent is not likely to remember, and thus repeat, exact responses to a great number of the questions previously asked). The relatively long duration of many child psychiatric conditions makes it likely that changes between the first and second administrations reflect unstable aspects of the measure rather than real changes in the disorder. For interviews, assessment of test–retest reliability is particularly complicated as a different interviewer administers the "retest" interview. This is necessary for two reasons. First, taking the same assessment from the same interviewer a second time may lead the respondent to leave out symptom reports, assuming that the interviewer already knows about the respondent's experience with an area of symptomatology or, conversely that the phenomena should be reported differently because the interviewer is going over the same issues a second time. Second, the interviewers themselves may recall the first interview and

this knowledge might lead them (consciously or unconsciously) to conduct the second interview differently than they would with a respondent they did not already know. Thus, test–retest reliability for diagnostic interviews will necessarily be somewhat limited by inter-rater reliability. In addition, discrepancies between the initial administration and the subsequent interview usually result from the informant reporting fewer symptoms at the second administration—the "attenuation effect." This has been found in all forms of repeated psychiatric inquiry and likely represents a systematic bias in reporting. *Internal consistency* is a third type of reliability and refers to the extent to which items designed to assess aspects of a known disorder (e.g., depression) are measuring the same underlying construct. In omnibus measures, the internal consistency of different diagnoses or domains may be assessed separately because these instruments by design assess a wide range of behaviors and symptoms rather than a single construct. Thus, the component items for each diagnosis would not be expected to correlate with the items from other diagnoses.

The validity of a measure is more difficult to assess than is its reliability. There are various ways to conceptualize and to assess validity. To assess what is termed *construct validity,* the psychiatric diagnoses or scores generated by a particular instrument are usually compared to those generated by an expert, or criterion, assessment. Statistical methods are then applied to quantify the degree of agreement about whether diagnoses are present or absent. In the methodological evaluation of the validity of an instrument, agreement is determined diagnosis by diagnosis, so that it can be revised in areas of poor agreement with the criterion. The essential challenge in determining the construct validity of a measure is to compare its performance to some standard that is known to be diagnostically correct. The problem in the field of psychiatric assessment is to determine that standard, because there is no laboratory test to provide objective evidence for the presence of a disorder. Pure clinical assessments of child psychiatric diagnoses are notorious for varying from one clinician to another; thus, the so-called "standard" is a moving target. Indeed, structured interviews and scales were developed in large part to improve the poor psychometric properties of nonstandard assessments. This situation has led to an approach that considers an instrument's performance within the nomological net of theory and findings about the condition being assessed. Stated briefly, this means that, to the degree that an instrument's findings converge with accumulated thinking and knowledge in the field, one may have relative confidence that, at least at this point, the instrument validly measures what it claims to assess. The major diagnostic assessments have shown considerable convergence in their evidence for reliability and validity; thus, in the complex process of instrument development, it is important to be aware when a new measure is falling below existing standards in these respects.

Despite—or perhaps because of—these various challenges, extensive research efforts have been directed toward refining psychiatric assessment methods in child and adolescent psychiatry. These endeavors have yielded a number of measures for use in research contexts; however, some of those described in the following discussion have also found appropriate adjunctive roles in clinical settings. The following discussion of methods first examines interview methods, which yield categorical diagnoses, and then reviews scales that cover symptom dimensions, often with respect to a specific form of psychopathology, for example, depressive symptoms.

Diagnostic Interviews

There are numerous "omnibus" diagnostic interviews for children and adolescents. Each of these is designed to be administered both to the parent (about the child/adolescent) and depending on his/her age, also to the young person. The exact content of the various diagnostic interviews may differ, but each covers a wide range of the more common psychiatric disorders of childhood and adolescence other than the autism spectrum disorders. Each version addresses the DSM diagnostic criteria (and often the ICD criteria as well), and updates for DSM-5 have either been prepared or are underway.

The omnibus diagnostic interviews differ from one another in several important respects, which should be taken into account when choosing among them. The first issue to consider is the purpose of the assessment (e.g., to identify a measure for research or to address a need for clinical treatment or triage? to establish diagnosis(es)? to identify co-morbidity? to measure severity?). Consideration of the purpose of the assessment also involves matters of the time frame of interest (current only? past year? ever? current and ever?). Practical issues also inform plans for implementation, including: how long it takes to administer the interview, whether the same interviewer must interview both parent and youth; qualifications for administrators/interviewers (is it necessary to have a clinician administer the assessment?); the standard training procedures and supervision; scoring procedures (are there specific rules or algorithms? is a computer program necessary; if so, what are the available reports? is scoring based on clinical judgment? is an expert editor/reviewer necessary? how transparent is the scoring? what data will the interview yield—diagnoses only or symptoms and scales as well?); infrastructure considerations (necessary staff, computer/analytic capabilities; office space to conduct private interviews); and, finally costs (including license fees, copying costs, storage). It is strongly recommended that before choosing an instrument, one obtain a copy of the interviews under consideration and critically review the contents to understand how symptoms and criteria are conceptualized by their authors.

Respondent-Based versus Interviewer-Based Interviews. Perhaps the most fundamental distinction between the different diagnostic interviews is the degree of structure they impose. In the past this was often characterized as "highly structured" versus "semi-structured," but more recently it has been conceptualized as the respondent-based versus the interviewer-based approach. The respondent-based interview (RBI) has been described by Shaffer and coworkers as a "precise script" to obtain clinical information from the informant. The RBI has precisely worded and ordered questions and equally structured response options; thus, the authors essentially transformed the diagnostic criteria into questions that should be easily understood by anyone. The RBI is totally dependent upon how clearly the questions are written and are understood by the respondent. A primary question that is answered positively leads to a branching sequence of nested questions that specify symptom frequency, intensity, duration, and degree of associated impairment. These questions help determine the significance of the reported behavioral-emotional state and aim to determine whether it reaches a certain clinical threshold. Alternatively, an initial negative response allows "skip out" of these specific questions. The relative advantages of the RBI include the potential for methodological development and also issues of economy and public health applicability. Because this type of interview is given in the same way each time, it is possible to study its performance and then modify it with a relative degree of confidence in the rationale for changes. Another advantage is the potential for relatively economical data gathering. Because the structure of this type of interview drives its administration, a range of administrators (e.g., including research assistants, college students and others with little psychiatric/medical background) can be trained in administration of an RBI, thus, substantially reducing research or clinical costs. The primary interviewer qualification is that one can read out loud (with expression). Furthermore, the use of a computerized version from which the administrator reads virtually eliminates administrator error, and diagnostic results can be made available quickly and efficiently because the computer assembles the information according to preprogrammed diagnostic algorithms. Even more cost-effective is self-administration using visual or auditory prompts or both, which bypass the need for and the expense of interviewers. The potential of RBI's as screening tools in community settings is another attractive aspect of this method.

Interviewer-based interviews (IBIs), however, use the skills of the clinically trained interviewer to make judgments about the presence and clinical significance of reported phenomena. Thus the IBI is totally dependent upon the interviewer's clinical skill and quality of training. IBIs contain some degree of structure, in that definitions are provided about what constitutes a symptom, but although questions are provided to prompt the clinician-administrator, it is expected that the interviewer will

pursue inquiry until clinical judgment is satisfied about whether a symptom is present. This allows for a degree of flexibility and responsiveness to the body of clinical data that are ordinarily used to determine the significance of reported emotions, moods, and behavior—for example, observation of affective state in response to a query or other observational data, such as eye contact, posture, and voice inflection.

Because the choice of interview type and then of the specific interview depend on the intended use, before selecting a measure, it is worthwhile to examine some of the extensive literature developed on these methodologies. Briefly, RBIs probably do not do well in diagnosing extreme and atypical phenomena (e.g., psychosis), because this method "assumes" that respondents (youth or parents) interpret the question as intended by the interview developer and also that the respondent has the capacity to reflect and to self-observe about the presence or absence of the symptom. IBIs are more flexible and responsive to the state of the respondent and hence could take less time to administer. For example, an astute clinician can usually assess manic symptomatology fairly quickly and efficiently in a previously high functioning youth. In practice, however, these interviews typically take as long as an RBI. In addition, with the IBI the careful clinician should catch most instances of the respondent misunderstanding the intent of the question, whereas the RBIs have little capacity to self-correct for this inevitable source of error. IBIs, although more costly than RBIs to administer, are particularly appropriate for clinically based research in which subtle diagnostic distinctions may be critical for defining relatively diagnostically "pure" samples and in which sample sizes are small enough to justify the expense of hiring interviewers trained in making these judgments.

RBIs, however, as noted previously, have many flexible and innovative applications in research and public health contexts. They have also found recent application in an increasing number of clinical contexts, for example, as efficient aids in collecting comprehensive symptom and diagnostic information at clinic or even inpatient intake. Because they systematically review symptoms across all domains, this type of screen sometimes uncovers significant symptomatology, such as suicidal tendency, that was not queried or not revealed on initial clinical interview. But, while the RBIs are, to some extent, mechanical and lack the personal element of the skilled clinical interview, it has been shown that many adolescents, in particular, appreciate the privacy of the computer-based methods (a familiar modality for many youth).

RBIs are particularly useful for epidemiological studies in which large sample sizes (i.e., in the thousands) require many interviewers, making the use of trained clinicians prohibitively expensive. These studies investigate issues of the prevalence of disorders, developmental patterns of psychopathology, psychosocial correlates, and risk and protective factors,

topics that often require large samples to provide enough statistical power to examine the study hypotheses. The ultimate choice of a measure requires careful weighing of the goals that it is intended to serve, the resources available, and the pragmatics of the situation.

RBIs and IBIs have been developed with the goal of reducing error in the collection of information relevant to making diagnoses. Error in the counting and combining of symptom data to determine a diagnosis can be minimized with RBIs or IBIs by the use of specified algorithms, usually computer applied, to establish whether sufficient symptoms are present for the diagnosis and whether they meet DSM criteria for intensity, frequency, and duration. Ultimately, the method that best serves the ends of error reduction, logistics, economy, (relative to the intended goal), and general appropriateness remains an informed judgment call. As opposed to the early 1980s (advent of DSM-III) when the development of structured and semi-structured instruments began, there now exists considerable theoretical and empirical information on which to base decisions about instrument choice.

Respondent-Based Interviews. The Diagnostic Interview Schedule for Children (DISC) is the most extensively developed and studied of the RBIs. Initial work on the DISC began in 1980, and since then, it has gone through numerous updates to maintain alignment with the DSM system in its iterations, as well as with methodological testing in both clinical and community settings. The DISC was specifically designed for use in large epidemiologic and community studies where it could be administered by "lay" (clinically untrained) interviewers who would read questions verbatim to parent (concerning children ages 6 to 18) and to child (ages 9 to 18) with most answers confined to "yes" and "no." Since it appeared, the DISC has also been used in clinical research studies, screening projects, clinical treatment settings and in juvenile justice settings. The current version, DISC-IV, is compatible with DSM-IV and ICD-10 (also the revised third edition of the DSM [DSM-III-R]) and covers three time frames—past 4 weeks, past year, and lifetime, although the accuracy of recall for the lifetime frame is questionable. An updated DISC-5, addressing DSM-5 as well as DSM-IV criteria, is in development. DISC diagnostic modules are self-contained, so that a user might select to administer only those modules of interest in a particular context. In the DISC, a uniform question structure has been applied in that for each criterion being assessed, an initial stem question is asked, which if endorsed, is then followed by contingent questions that elicit increasingly more specific types of information about characteristics of the potential symptom. This structure builds a great deal of efficiency into the interview. Given the complexity of information required for DSM diagnoses, administration of the whole interview using paper protocols is no longer practical, so the DISC is given

with the aid of a computer. Computer-assisted versions ensure fidelity to the intended structure of the questioning, as well as reducing lost time due to the interviewer's need to consider what the next question should be. There is a computerized version, the Voice-DISC, which can be self-administered. In addition to symptom questions, the DISC includes questions in each diagnostic section that inquire about associated impairment and perceived severity of impairment. These questions are asked if a respondent meets a certain base level of symptomatology for a given diagnosis—about half of what would be required for a DSM diagnosis.

An extensive literature is now available on the DISC and its associated technologies. Diagnoses are derived by application of a set of extensively developed computer algorithms that score the interview for informants separately and by combining information across informants. The DISC has few symptom skips so that it is possible to generate symptom and DSM criterion scale scores, further increasing its flexibility and general usefulness, especially in research settings. Of importance, respondent acceptability has been demonstrated to be quite good, despite some (but not an overwhelming) perception that it is a bit lengthy. A modified version, the Young Child DISC is administered to parents only and is used to assess childhood symptomatology down to age 4. The Young Adult DISC, with parallel self and "other informant" versions, is also available. A Spanish-language version has been developed and extensively tested. In addition, the DISC-IV has been translated into a number of other languages and has found various innovative applications around the world. Particularly exciting are those in which it can assist in clinical contexts where trained mental health clinicians are in short supply (e.g., its use in juvenile justice facilities, orphanages, and regions of the world with few mental health practitioners per capita). Of course, no RBI can substitute for thoughtful clinical practice, and the developers of this method have been clear that its use is adjunctive and facilitative, and not diagnostically definitive, when applied in clinical settings.

The Children's Interview for Psychiatric Syndromes (ChIPS) is a highly structured interview that was designed for use with lay interviewers to screen for current psychiatric disorders. The authors recommend that interviewers have at least a bachelor's degree in a field associated with mental health (e.g., psychology, social work, and psychiatric nursing). The first version of the ChIPS was specifically designed for interviewing children ages 6 to 12 years (unlike the DISC, which is not given to children under age 9); for later versions the age range was extended to include adolescents. Development of the parallel parent version (P-ChIPS) followed the child version. For each diagnosis, "cardinal" symptoms—those that are most frequently endorsed by youth who may have a particular disorder—are assessed first and, if not endorsed, the interviewer skips to the next diagnosis, making the interview briefer to administer than the DISC. The

interview is scored by the interviewer using a scoring booklet that provides rules for scoring DSM diagnoses.

The Diagnostic Interview for Children and Adolescents (DICA) and the Missouri Assessment for Genetics Interview for Children (MAGIC) both assess "lifetime" diagnoses and for some disorders, current diagnoses. The DICA had IBI and RBI versions (the latter being computer based) but only the RBI version is still in use. The MAGIC is a later version of the DICA, developed by the same team; although allowing for some interviewer discretion on probing, it was designed for administration by trained lay interviewers, with many specific probes and clearly specified procedures for clarifying responses and eliciting and coding symptoms, resembling an RBI more than IBI. Both the DICA and the MAGIC have parallel youth and parent versions and there are two youth versions, one for administration to children in the age range from 6 to 12 years and one for adolescents ages 13 to 17 years. The Parent and Youth forms are scored separately by well specified computer algorithms.

The Development and Well Being Assessment (DAWBA), which is widely used throughout Europe, although less so in the United States, assesses current diagnoses (the exact time frame varies by diagnosis). The DAWBA was designed to provide a shorter alternative to typical diagnostic interviews by including many "skips" and screening questions. It also makes use of a companion screening questionnaire, the Strengths and Difficulties Questionnaire (SDQ). The DAWBA employs a two-part procedure beginning with an RBI comprising both closed-ended, precisely specified questions (answered "yes" or "no" or using a choice of 2 to 3 relevant options) as well as open-ended questions (to which the answers are typed verbatim into an open text field by the interviewer or, in a self-administered version, directly by the respondent). The open-ended questions obtain supplementary information about the symptoms and accompanying functional impairment. Thus, like the DISC, and the MAGIC, the DAWBA does not require clinical training to administer. There are parent and youth versions and a teacher questionnaire. When the interviews and questionnaires are completed, all information is forwarded to a clinical rater who has been trained by the authors of the DAWBA. This clinician reviews and assigns diagnoses based on the transcripts of the interviewer notes and answers to the structured questions from all available informants (usually parent and child, and sometimes the teacher). Preliminary scoring yields "likelihood" estimates, and provisional diagnosis is done by computer. The scoring rules used for the DAWBA are not made available for review. The DAWBA and the SDQ have been translated into many languages.

Interviewer-Based Interviews. Various IBIs, developed to meet different research needs, have found use in clinical settings. Some

frequently used interviews include the Schedule for Affective Disorders and Schizophrenia for Children (K-SADS); the Child and Adolescent Psychiatric Assessment (CAPA), the Anxiety Disorders Interview Schedule for Children (ADIS-C); and the MINI International Neuropsychiatric Interview for Children and Adolescents (MINI-KID). In addition, a youth version of the Structured Clinical Interview for DSM-5 (SCID), a widely used adult measure, is being planned. For each of the existing measures, a literature is available that defies summary in a single section. Following are some brief comments about the available IBIs.

The K-SADS, originally developed for use in studies of child/adolescent depression was based on the SADS, an adult research instrument, and was the first widely used IBI for children and adolescents. Unlike the SADS, the K-SADS has kept pace with changes to the DSM. There are a number of different versions of the K-SADS, reflecting the modification of this measure by researchers at different sites with differing specific interests and assessment philosophies. Most assess current and lifetime diagnoses. Some versions incorporate severity scales for the criteria assessed, allowing their use in the examination of change, whereas others use more categorical scoring. All versions of the K-SADS contain probes that are "suggested," but there are no questions that must be asked, because all versions of the K-SADS assume that the interviewer has been clinically trained and is experienced in assessing youth psychopathology. Nonetheless, many research studies use trained research assistants to administer the interview. Each version begins with an unstructured introductory module during which information about the child's presenting problem(s) and a short clinical history are obtained along with demographic information and information about current functioning. This is used to set the context for further inquiry. The interviewer then proceeds through a series of modules that assess different diagnoses. For most of the K-SADS versions, the same person interviews both the parent and the child and, when necessary, works to resolve differences; an exception is the Washington University K-SADS, which does not employ consensus ratings and uses different interviewers for each informant. For the other versions, the authors recommend that for younger children the parent be interviewed first, whereas for adolescents, the recommendation is to interview the youth first; in practice, however, many have found that it makes more clinical sense to interview the parent first, regardless of the young person's age. Consensus ratings for each diagnostic criterion are made, based on the interviewer's clinical judgment using information from both informants and from any other source (e.g., clinical records). Diagnoses are then assigned by the interviewer using a series of score sheets. A computer assisted version of the K-SADS is in preparation. An early childhood version (K-SADS-EC) (parent informant only) has been prepared and used in studies of preschool depression. (A web-based,

computer administered version of the K-SADS is currently undergoing testing. This interview will use a different format using completely specified questions and response options, thus becoming an RBI, rather than an IBI.)

The CAPA is a comprehensive measure that, in addition to psychiatric symptomatology and impairment, covers family, environmental, and psychosocial problems, life events, the effect of the child's problems on the family, and mental health service use. The time period assessed is last three months. Unlike the other interviews, the CAPA is not organized into obvious diagnostic modules. The CAPA contains a number of questions that should be asked exactly as written, with follow-up questions that are less specified. Unlike the K-SADS, the CAPA was designed for administration by nonclinicians who undergo extensive training in how to administer the interview. This is accomplished by providing detailed definitions and rules that govern the assessment of reported phenomena and determination of whether they should be rated as symptoms. Thus the onus is on the interviewer to assure that the questions are understood and the information provided is relevant. A clinically experienced supervisor reviews each CAPA interview before final ratings are made. Young Adult (YAPA) and Preschool Versions (PAPA) of the instrument are available. Like the DISC and MAGIC, the CAPA is scored according to well-specified computer algorithms.

The ADIS-C, derived from the A-DIS, an adult interview, was originally developed for use in studies of childhood anxiety. The time frame for inquiry is current and lifetime; the interview provides extensive coverage of anxiety disorders, and is particularly strong in this area, with less extensive coverage of other symptom areas. "Thermometers" are used to obtain severity, fear/avoidance, distress, and interference information and a clinician severity rating is made for each diagnosis (which makes possible tracking symptom change). The ADIS-C is designed to be administered by a clinician with experience in assessing child psychopathology. Like the K-SADS, the ADIS-C relies on a reconciliation procedure to sort out disagreements between parent and youth and the scoring is done by the clinician administering the interview, rather than by computer algorithm.

The MINI-KID a youth version of the MINI, a widely used research interview for adults, was designed to quickly assess the presence of current psychiatric disorders of youth. Like the MINI, the MINI-KID incorporates a branching structure with each diagnostic section containing screening questions, which if not endorsed, allows the interviewer to skip the rest of the section. Unlike the administration procedure for all of the other diagnostic interviews for youth, parents and children are interviewed together, with discrepancies between informants addressed by the clinician interviewer during the interview. For adolescents, sometimes only the adolescent is interviewed, depending on setting and user choice. Of all the

IBIs, the MINI-KID takes the least time to administer (the authors estimate half an hour), due to the many skips and the efficiency of combining parent/youth interviews. Diagnostic criteria are documented within each of the disorder sections and on a summary sheet by the clinician administering the interview.

Rating Scales

A large repertoire of questionnaires and rating scales have been developed to assess symptomatology and various aspects of behavior and adaptive functioning. Different measures have been designed for completion by parents, teachers, and children. These focus on a broad range of symptoms ("omnibus" measures) or on a more specific area (e.g., depression and anxiety). The development of each scale involves testing its psychometric properties, that is, the functioning of the scale with respect to the types of reliability, validity and matters of administering it to large and diverse samples to determine norms and clinically relevant cutoffs.

A number of specific aspects of scale functioning must be considered in selecting a scale in practice or research. Again, a basic issue is the nature of the intended use, that is, to address a research question or for aid in clinical assessment and planning. Intended use determines which domains of symptomatology and functioning must be covered and is tied to the nature of the sample or population with which it will be used. For example, the major scale requirements may vary for studies that assess clinical patients receiving an intervention designed to change symptom occurrence over time versus community populations in which the prevalence of a disorder(s) would be relatively stable or else likely to change in response to an imposed condition (e.g., intervention) or the changing developmental stage of a cohort tracked over time. In considering which scale to use for a particular purpose, the psychometric characteristics of various scales should be compared and factored into a decision, together with specific characteristics of the children or adolescents to be assessed. One obvious example is age. Given that developmental stage and not solely chronological age determines the young person's capacity to abstract at the level required by the particular scale's questions, the appropriateness of such questions to the youngster's activities and opportunities are all factors very important to accurate assessment. The young person's cultural context also may bear on symptom reporting for various reasons, such as acceptability of reporting certain types of symptoms, culture-specific theories of etiology, or expectations of what is normative in behavioral or emotional expression.

Thus, although a particular scale may appear to provide a convenient tool for clinical or research use, many features of its demonstrated functioning, of the young people themselves, and of their social contexts must be incorporated into the choice of a measure. Similarly, the critical

reader will want to consider such factors in interpreting findings from the research literature. Finally, there is the issue of cost, as many of these measures must be purchased, which can be prohibitively expensive in low resource settings.

Comprehensive (Omnibus) Rating Scales. Probably the most widely used comprehensive symptom rating scales are those that constitute the Achenbach System of Empirically Based Assessment (ASEBA) family of instruments (http://www.aseba.org). There are forms for school-age children—the Child Behavior Checklist for Ages 6 to 18 (CBCL/6 to 18), the Teacher Report Form (TRF/6 to 18), and the Youth Self Report (YSR/11 to 18); forms for younger children—the Child Behavior Checklist for Ages 1½-5 (CBCL/1½-5) and the Caretaker-Teacher Report Form (C-TRF); as well as forms for young and older adults to report on themselves. The ASEBA forms average 99 to 120 items and generate several syndrome scales. In addition, there are clinician-completed forms, including the Direct Observation Form (DOF), which is completed after observing classroom behavior. Important features of this system of measures include its empirical development and the large population sample on which it was normed, as well as testing on large samples of clinically referred children. The availability of age-based and gender-based norms provides a convenient way to screen for overall levels of symptomatology, and when scored, the CBCL yields a profile of problem areas and competencies. The CBCL is stable over relatively brief intervals (i.e., good test–retest reliability) but also reflects changes resulting from treatment. The CBCL, TRF, and YSR have been widely used in epidemiological and clinical research, in many clinical settings and in translated forms in numerous countries. These measures can be a useful clinical screening tool, as well as an efficient way for clinics to gather uniform information for characterizing the populations served as well as changes in those groups over time. Computerized data entry and scoring have greatly eased the use of the ASEBA measures and allow for comparisons of reports across informants.

The Behavior Assessment System for Children (BASC-3) is another widely used assessment system for evaluating aspects of behavior and personality in children and adolescents aged 2 to 21 years. It consists of parent and teacher rating forms, a Structured Developmental History form and a Student Observation System (for rating classroom behavior), and, for youngsters 8 to 21, a Self-Report of Personality (for thoughts and feelings). The parent and teacher measures have forms appropriate for ages 2 to 5 years, 6 to 11 years, and 12 to 21 years (the latter also has a youth form); each form has between 139 and 175 questions. A distinctive feature of the BASC is its emphasis on positive aspects of the child's adjustment, in addition to rating symptoms and problem behaviors. An additional feature of this system is its coverage of problems related to school functioning,

such as difficulties in social or study skills, and it has built-in validity checks. Norms have been established for children by age, gender, and clinical status. This system has been designed for application in clinical, educational, research, and program evaluation contexts. Use and interpretation of the BASC are eased by the availability of computer software that generates profiles and allows consideration of different informants' viewpoints.

The Conners Rating Scales-Revised is another family of instruments that are widely used in research and clinical settings. These include short and long forms of scales for parent administration CPRS-RS, CPRS-R-L, teacher administration (CTRS-R-S, CTRS-R-L), and self-report (CASS-S, CASS-L). These scales collect information on child oppositional behavior, cognitive difficulties, hyperactivity–impulsivity, anxiety and shyness, perfectionism, social problems, and psychosomatic complaints. The Conners scales have been developed and tested on samples of children and youth 3 to 17 years of age, for parent and teacher forms, and 12 to 17 years on the adolescent forms. These measures have shown excellent psychometric properties, and norms are available, as is computer software to aid in administration and scoring. The Conners scales have long been the standard instruments for the assessment of ADHD in children and adolescents, and their use for ADHD and Disruptive behaviors is described below.

In contrast to the omnibus scales described above, the SDQ, which has been gaining in popularity is very brief and is made freely available. The SDQ was designed to be used as a short screen to identify children (ages 2 to 17 years) with behavioral problems. The SDQ comprises 5 subscales, from a total of 25 items; it has cross informant forms (parent, teacher, and self) and has been translated into over 75 languages.

Other omnibus scales, which are available but have found less use in recent years include the Revised Behavior Problem Checklist (RBPC), the Louisville Behavior Checklist (LBC), and the Personality Inventory for Children (PIC). The RBPC focuses on symptoms of conduct disorder, socialized aggression, attention problems and immaturity, anxiety and withdrawal, with auxiliary scales for psychotic behavior and motor tension-excess. It was designed for use by parents and teachers of children and youth ages 5 to 17 years. Although generated using factor-analytic studies of clinical samples, it has also been normed on nonreferred children and youth. The LBC and the PIC are both comprehensive rating scales for parent report that do not have corresponding versions for other informants. The LBC consists of 19 scales that cover a wide range of behaviors and symptomatology. The PIC was developed on the model of the Minnesota Multiphasic Personality Inventory (MMPI) and also comprises a variety of component scales.

Disorder-Related (Domain Specific) Scales. Each of the scales described above was designed to collect information across a range of symptoms and competencies. More narrowly focused symptom rating scales have been developed to permit a more detailed quantitative assessment of specific symptom realms. These latter scales may be useful in quantifying the presenting severity of certain symptoms to establish a baseline against which response to a therapeutic intervention can be compared. A number of these scales are self-report measures. These have the advantage of providing an opportunity for the child to report on symptoms that might be difficult to conceptualize or verbalize. Sometimes parents or children (especially adolescents) are initially more willing to report an area of difficulty in the seemingly more anonymous context of a questionnaire than in a face-to-face interview. However, self-reports also carry the risk of the child misunderstanding questions or feeling compelled to provide socially desirable responses rather than acknowledge behaviors and feelings that the child believes might meet with disapproval. Fundamentally, the focused symptom approach may also ignore important interactions across domains of psychopathology, because of the focus on one particular area of symptomatology. With these potential limitations in mind, child self-report measures can provide useful adjunctive information in clinical and research settings.

SCALES FOR ASSESSING INTERNALIZING SYMPTOMATOLOGY'DEPRESSION. The Beck Depression Inventory (BDI) is a widely used scale for depressive symptoms in cognitive, behavioral, affective, and somatic domains. It has found wide use with adolescents. Because it is an "adult" measure, there is no corresponding parent version. The BDI was originally developed to measure the severity of depressive symptoms in patients who had been diagnosed with depression; it is also used to screen patients to identify depression and to monitor treatment outcomes. The BDI has been widely studied and used in clinical and nonclinical populations, with generally good psychometric properties. As with other scales, a fine-grained examination of the literature shows specific areas in which it falls short of ideal; for example, different cut-points are needed, depending on the population (inpatients vs. outpatients; male vs. female). Unlike the earlier version of the BDI, which did not provide complete coverage of the DSM depression criteria, the newest version, BDI-II, covers all of the depression symptom criteria in the DSM system and extends the time frame of inquiry to 2 weeks, again to reflect the DSM duration requirements for Major Depressive Episode. Nevertheless, varying degrees of stability that are inherent to psychopathology in adolescence must also be kept in mind in the overall determination of the functioning of any scale. Generally speaking, positive results from various psychometric studies, ease of use, scoring and interpretation have made the BDI an attractive instrument in

both clinical and research contexts.

The Children's Depression Inventory (CDI) is a self-report measure for assessing symptoms of depression in children 7 to 17 years of age. It shares a conceptual basis with the BDI and comprises five factors: dysphoric mood, acting out, loss of personal and social interest, self-deprecation, and vegetative symptoms. As with many measures of child psychopathology, various psychometric properties vary by characteristics of the sample used, especially patient versus community status, gender, and age. As noted for the BDI, participant characteristics play important roles in interpreting psychometric results because, for example, the capacity to conceptualize and report on symptoms improves with age. Hence, scales reaching into the younger school-age years are likely to show more variability in assessments of reliability and in examinations of agreement between child and adult informants. Levels of agreement with other measures related to depressive psychopathology and its known correlates have provided support for the validity of the CDI. It has been widely used across a range of populations; thus, as with the BDI, the availability of considerable information relevant to its performance with different groups of children and youth makes it attractive to those considering it for use in various research and clinical populations. Parent and teacher informant forms are available. Many useful results have emerged from studies using the CDI, further adding to its attractiveness as a measure of depressive symptomatology. One criticism of the scale is that adolescents may find it too "babyish."

The Center for Epidemiologic Studies-Depression Scale (CES-D) was developed first as a rating scale for depressive symptoms in epidemiological studies of adults, but it has also been extensively widely used with adolescents, and a modification (CES-DC) was developed specifically for use with younger individuals. Both are freely available. There is no corresponding parent measure. Psychometrically, the CES-DC functions sufficiently well in some domains for adolescents but, overall, does not hold up well for children. Both instruments are brief and easy to use, and, particularly in adolescents, some aspects of reliability and validity meet performance standards. However, for both measures, problems with discriminant validity pose limitations, suggesting that they may be most appropriately considered as screening tools for general psychopathology in adolescent populations.

The Mood and Feelings Questionnaire (MFQ) is another freely available brief self-report measure designed to screen for and assess core depressive symptoms for children and adolescents. Originally designed for use in epidemiological studies, the MFQ has also found use in clinical settings and screening programs. There are long (32 item) and short (13 item) versions of the scale, and parallel parent and youth reports. Although these questionnaires have demonstrated good psychometric properties and discrimination for depression appears better than for other self-report

measures, they are not as widely used as the other scales.

The Quick Inventory of Depressive Symptomatology (QIDS) and QIDS-A (a version for adolescents that includes an extra item assessing irritability) are short forms of the Inventory of Depressive Symptoms (IDS) and are confined to the symptoms of Major Depressive Episode. In addition to a self-completed questionnaire, there is a corresponding clinician rated version, as well as a structured interview guide; all are freely available. The QIDS has strong psychometric properties and is useful for tracking treatment response.

Two related scales, the Reynolds Adolescent Depression Scale (RADS) (for ages 11 to 20) and the Reynolds Child Depression Scale (RCDS) (for ages 7 to 13), are widely used measures to assess a wide range of symptoms associated with depressive disorder. Symptoms are rated on a 4-point Likert-type response scale that yields scores on four subscales (dysphoric mood, anhedonia/negative affect, negative self-evaluation, and somatic complaints). Both the RADS and the RCDS function very well in terms of reliability (both internal consistency and test–retest). The validity of the RADS is supported by relationships with other measures of depressive symptomatology and related constructs. It has been used with diverse populations, providing a broad base of evidence for its functioning, as well as normative comparison data. The strong psychometrics, basis in the highly specified symptomatology of the DSM system, and the linkage of the two scales for use in longitudinal studies or across a broad age range in a single study are advantageous features of these measures. The RADS and RCDS are often used as screening measures to identify depressed youth (there is no corresponding parent measure), and there is some evidence that these measures may be sensitive to clinical change, so they hold promise for evaluating treatment outcomes.

The Hamilton Rating Scale for Depression (HRDS), another freely available measure, differs from the aforementioned measures in being a clinician-rated scale. It is the most commonly used clinician rating scale for depression. Developed for assessing depressive symptoms in adults, the HRDS has also been used in studies of adolescents. The HRDS was initially developed to measure the severity of symptoms in patients who had a depressive illness and was widely used in psychopharmacological and other treatment studies evaluating outcomes of different treatments for depression. The original scale had 21 items, of which only the first 17 were scored; there are alternative versions with 23 items and also versions with fewer items. Not all of the versions have been psychometrically evaluated. Although internal consistency and inter-rater reliabilities have generally yielded acceptable to excellent results, specific training in its administration and the use of a structured or semistructured protocol for administering the HDRS improves the psychometric properties. The validity of the HRSD has not been as convincingly demonstrated in

adolescent populations as for adults. The main application has been in treatment outcome studies, in which findings have supported its sensitivity to the effects of certain psychopharmacologic agents, as well as to other specific therapeutic modalities.

The Children's Depression Rating Scale-Revised (CDRS) is a clinician-rated symptom inventory related to the HRDS but designed for the assessment of school-aged children. It uses clinician expertise by including their ratings of behavior observed during the interview and by having clinicians generate scores based on information from each parent and child considered alone, as well as a combined score that integrates information from both informants. Psychometrically, aspects of reliability have ranged from adequate to excellent, depending on the study and type of reliability considered. There is some support for validity, and the CDRS has found substantial use in clinical research generally and treatment outcome studies specifically. Overall, the unique features of the CDRS, clinician rating, and use of multiple informants have made it attractive for studies conducted in settings in which the use of clinicians is feasible and their skills in eliciting and integrating information are advantageous for the study design.

SCALES FOR ASSESSING INTERNALIZING SYMPTOMATOLOGY'ANXIETY. The Hamilton Anxiety Rating Scale (HARS) focuses on anxiety symptoms and, like its depressive symptom counterpart, the HDRS, is a freely available clinician-rated scale, which has been used with adolescents. The HARS is generally administered to both adolescent and parent to yield an overall rating. It covers both psychological and somatic components of anxiety (focusing heavily on the latter), with psychological symptoms showing better internal consistency than somatic ones. Other aspects of reliability are moderate to excellent, depending on the type of reliability examined, while validity is not strongly supported. The use of clinicians for the assessment and the use of multiple informants are potentially advantageous features, although more study is needed to elucidate the psychometric performance of the HARS and its utility as a treatment outcome measure.

The Pediatric Anxiety Rating Scale (PARS) is another clinician rating scale that is freely available. The PARS, modeled on the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS), was developed for a study on child anxiety to target symptoms that the researchers thought were not adequately covered by the HARS. In administering the PARS, the clinician first reviews the child's specific symptoms of anxiety and then makes severity ratings on seven dimensions using a six-point scale. The psychometrics of the PARS are good and the scale is useful for tracking treatment response. However, administration can be lengthy.

The Multidimensional Anxiety Scale for Children (MASC) is an empirically derived self-rated scale for children and adolescents that

comprises the four major factors of anxiety, namely physical symptoms, social anxiety, harm avoidance, and separation anxiety. With respect to scale construction, the MASC maps onto the diagnosis of generalized anxiety disorder, and individual factors capture the specific diagnoses of separation anxiety disorder and social phobia. With respect to psychometrics, various types of reliability and validity have been moderate to excellent. It has attractive structural features in capturing and distinguishing particular types of anxiety symptoms, and some results indicate that it distinguishes the constructs of anxiety and depressive symptoms in young people and also that it is sensitive to treatment effects. The MASC has been translated into over 15 languages. The most recent form, MASC-2, has a corresponding parent version. Less is known about the psychometrics of the MASC-2 and its parent version than about some other measures, and further findings are anticipated on its statistical performance for specific research purposes.

The Screen for Child Anxiety Related Emotional Disorders (SCARED) is a freely available self-rated scale developed for children and adolescents ages 9 through 19 years, with a parallel form to be completed by parents. It maps onto the criteria for DSM-IV anxiety disorders of five types: somatic/panic, generalized anxiety disorder, separation anxiety disorder, social phobia, and school phobia. The overall scale and subscales show reliabilities comparable to those of other well-functioning scales, and there is evidence for convergent and discriminant validity of the SCARED with respect to other assessment measures and types of psychopathology. The SCARED has been shown to be sensitive to treatment effects. There are long (41 item) and short (5 item) versions of the scale, and the instrument has been translated into many languages.

The Revised Children's Manifest Anxiety Scale (RCMAS), a downward extension of the adult Manifest Anxiety Scale, was developed to assess trait anxiety in school-aged children, although it has also been used with adolescents. Unlike many of the other scales, it does not have a parent informant version. The RCMAS has three component subscales: physiological, worry/oversensitivity, and fear/concentration. It has been in use longer than the MASC and the SCARED, and thus experience has yielded a number of studies that document the psychometric properties of the RCMAS. Concurrent validity has been supported through comparisons with other measures of anxiety, although examination of discriminant validity has found that ADHD symptomatology may be rated for those who are primarily anxious. The many studies using the RCMAS have yielded numerous contributions to the understanding of assessment issues in anxiety disorders among the young and the role of anxiety in children and youth from various ethnic/cultural groups and diverse stressful social contexts. Some construct and other methodological limitations have been noted; many of which may have their origin in the inception of the RCMAS

prior to the newer, DSM-linked measures.

The State-Trait Anxiety Inventory for Children (STAIC), also based on an adult instrument, is another youth-only self-completed measure. The STAIC comprises two subscales, each of 20 items; one quantifies "state" with the other quantifying "trait" anxiety. The subscales can be used independently. The STAIC has demonstrated acceptable psychometric properties and has somewhat better specificity than sensitivity. It has been shown to be sensitive to change and useful in assessing response to stress.

SCALES FOR ASSESSING EXTERNALIZING SYMPTOMS'ADHD AND RELATED SYMPTOMS. Several scales developed by C. Keith Conners and colleagues are commonly used to assess and monitor ADHD and other externalizing disorders. The current is the Conners 3 (third edition), which has parent, teacher, and self-rated versions, all with good psychometric properties. There are long and short versions for each form, The Conners-3 assesses symptoms of ADHD, Conduct Disorder and Oppositional Defiant Disorder, with each symptom being rated on a 4-point scale and also includes the Conners ADHD index, and a Global Index and sophisticated computer software that aids in administration and scoring. Other commonly used Conners instruments include the Conners Abbreviated Symptom Questionnaire, Hyperactivity Index (CASQ-HI), the Conners ADHD Index and Inattention/Overactivity with Aggression (IOWA) Conners Scale, and the Conners, Loney, and Milich (CLAM) Scale. The CASQ-HI is a brief (10 item) checklist of the 10 most "medication-sensitive" hyperactivity items from the longer Conners' scales. In addition to assessing treatment response, the CASQ-HI has often been used to screen for ADHD; however, it has been criticized as potentially missing children whose primary problem is inattention. The Conners ADHD Index addresses this possible weakness in identifying inattentive symptomatology in that the 12 items that comprise the index were derived to discriminate between children with ADHD and without ADHD. The IOWA Conners Scale has two subscales: Inattention/Overactivity (IO) and Oppositional Defiant (OD). For each subscale, items were selected to have the least overlap with the other scale. In practice, however, the scales correlated moderately in clinical samples. The CLAM Scale combines the CASQ with the IOWA Conners. All of these scales are brief, widely applied, have demonstrated good psychometric properties, and have been used to identify children in need of intervention and to track treatment response. In addition, Conners has developed scales for preschool children and for identification of adults who have ADHD.

A second "family" of scales focusing primarily on ADHD has been developed by Swanson and colleagues, all of which are made freely available. The most widely used of these is the short version of the Swanson, Nolan, and Pelham (SNAP-IV) Rating Scale, which comprises a checklist of the DSM-III, DSM-III-R, and DSM-IV ADHD and ODD criteria

rated on a 4-point scale and allows comparison between the different diagnostic formulations. The scale can be completed by either parent or teacher. The longer SNAP-IV contains items for other DSM diagnoses as well, and a more abbreviated version of the SNAP-IV contains only the ADHD items. The Strengths and Weaknesses of ADHD-symptoms and Normal-behavior (SWAN) Scale includes the same DSM ADHD symptom types as the SNAP-IV, but each is written so that it can be considered as an area of strength or weakness (e.g., the SNAP-IV "often is distracted by extraneous stimuli" appears as "ignores extraneous stimuli" on the SWAN). The parent or teacher is asked to consider each symptom as a dimension and rate the strengths or weaknesses of the child using a 7-point metric that compares how the child does in comparison to other children, ranging from "far below average" to "far above average."

Finally, the Swanson Kotkin, Agler M-Flynn, and Pelham (SKAMP) rating scale was created to monitor the classroom behavior of a child, rather than DSM symptoms; it contains 10 items about typical target behaviors addressed by psychosocial interventions. The SKAMP is completed by the child's teacher and is incorporated in the full teacher version of the SNAP-IV. The main disadvantage of the Swanson family of scales is the limited psychometric or normative data on their functioning.

In addition to the Conners and Swanson scales, there are a number of other brief symptom checklists keyed to the DSM criteria that can be used to assess ADHD and other related behaviors. These include the ADD-H Comprehensive Teacher Rating Scale (ACTeRS), the Attention Deficit Disorders Evaluation Scale (ADDES; home and school versions), the Yale Children's Inventory (YCI; a parent rating scale designed for children with learning disabilities), the Vanderbilt AD/HD Diagnostic Teacher Rating Scale, the Vanderbilt AD/HD Diagnostic Parent Rating Scale, the ADHD Rating Scale, and the ADHD Symptom Checklist.

OTHER SCALES FOR EXTERNALIZING SYMPTOMATOLOGY. The Eyberg Child Behavior Inventory (ECBI) is a parent-completed rating scale, with its companion, the Sutter-Eyberg Student Behavior Inventory (SESBI-R), a teacher completed measure, was designed to assess a wide range of disruptive behavior symptoms in children aged 2 to 16 years. These easy to use scales have found wide use in treatment studies and in clinical settings and must be purchased. For each of the behaviors assessed (36 on the ECBI and 38 on the SESBI-R), the informant rates the frequency of the behavior on a 7-point scale (never to always) and then rates whether the behavior is "currently problematic." Two scores are generated—the Intensity Score (based on the frequencies) and the Problem Score (calculated using ratings on how problematic each behavior is). Normative data for these scores are provided. The scale scores have good internal consistency for gender, ethnic, and age groups, and although they are not tied to DSM diagnoses,

the ECBI has shown good discriminant and concurrent validity, strong temporal stability, and evidence of construct validity.

The Antisocial Process Screening Device (APSD) was designed to identify psychopathy and can be completed by either parents or teachers about children ages 6 to 13 years. This 20-item scale is based on Hare's Psychopathy Checklist-Revised. Items on the APSD address callousness, narcissism, and conduct problems that are related to poor impulse control. The scale has acceptable internal consistency, there is some evidence for construct validity, and norms are available for the scale. Sensitivity and specificity have not yet been established, and there are no recommended "cut offs" for diagnosing antisocial psychopathology.

The New York Teacher Rating Scale for Disruptive and Antisocial Behavior (NYTRS), which is freely available, includes symptoms of Oppositional Defiant Disorder and Conduct Disorder and deviant peer interactions as they occur in the school setting. The NYTRS has four subscales—defiance, peer problems, physical aggression, and delinquent aggression—and two composite scores (antisocial behavior and disruptive behavior) and also a global impairment score can be derived. The limited psychometric evaluation of the scale has shown promising results.

The Children's Aggression Scale (CAS), based on the Overt Aggression Scale (OAS) and the Buss-Durkee Hostility Index (BDHI), was developed with a specific focus on aggression, rather than a DSM diagnosis, as exhibited by youth ages 5 to 18 years. There are parallel parent and teacher versions (no self-report version), and CAS has shown good psychometric properties, and has been normed.

In addition, several other scales have been developed to monitor aggression and hostility. These include: The OAS, which is used widely in inpatient settings; modifications of the BDHI; the Vitiello Aggression Questionnaire (VAQ), which differentiates proactive from reaction aggression; and the Direct and Indirect Aggression Scale (DIAS). Unfortunately, normative data for most of these scales are not available for youth, although initial psychometric analyses look promising.

SCALES ASSESSING ADJUSTMENT AND IMPAIRMENT. Instruments also exist for assessing levels of adaptive functioning and impairment, globally or with respect to specific domains. The Children's Global Assessment Scale (CGAS) is an easy-to-use quantitative scale for the clinician's rating of overall impairment. The CGAS has good psychometric properties and has been translated into over 20 languages. A parent-completed version of the CGAS is also available. The Columbia Impairment Scale (CIS) and the Brief Impairment Scale (BIS) are both self-completed rating scales of impairment that tap four major areas of functioning: interpersonal relations, broad psychopathological domains, functioning in school or at a job, and use of leisure time with parent and youth (ages 9 and older)

versions. The WHO Disability Assessment Schedule (WHO-DAS) was adapted for youth as part of the DSM-5 revision process. This scale includes parent rated and youth rated questionnaires as well as a clinician rated components. The CGAS, CIS, BIS, and WHO-DAS are all free of charge.

The Vineland Adaptive Behavior Scales 2nd Edition (Vineland-II) provide a comprehensive age-normed framework for systematically recording and assessing the development of children and adults (multiple versions for birth to age 90) with respect to various realms of adaptive functioning. For youth, there are self-report, parent-report, and teacher rated forms. The Vineland has been widely used in both clinical and research settings.

Various structured and semi-structured formats for performing or recording portions of the child mental status examination have also been developed. Some, such as the child version of the Mini-Mental State Examination, contain specific standardized items for screening cognitive functions. Other instruments, such as the Mental Health Assessment Form, provide a format for organizing mental status data derived from a semistructured clinical interview.

Limitations of Structured Measures in Clinical Assessment

Interviews and scales, such as those described previously, can, at times, be adjuncts in clinical assessment if thoughtfully chosen and administered with sensitivity to their meaning in the overall process of the evaluation. For example, they can help to ensure a comprehensive review of symptoms or provide a standardized baseline measure of severity for later determination of intervention efficacy. They cannot, however, replace an individualized child psychiatric interview or be relied on as the sole basis for establishing diagnoses or planning treatment. Most standardized interview schedules focus on symptoms and behaviors, with little attention paid to coping mechanisms, situational context, and adaptive strengths that the clinical interview affords. Such factors may be as crucial to the clinical assessment and treatment planning as the presence or absence of a given pathognomonic symptom or categorical diagnosis. This limitation is acknowledged by the authors and indeed, for many of these instruments, the user is required to seek permission from the authors and sign a license or complete a qualification form before being allowed to administer the instrument to ensure proper professional use. Some, like the DISC, require that the user agree that the interview not be used in place of thorough clinical evaluation in making treatment decisions.

The researcher interested in selecting measures for a study protocol must review carefully the existing measures in the area of interest and consider the psychometric characteristics of potential measures as well as the appropriateness of the measures for the study sample and the goals of

the study. It is useful to begin by examining up-to-date critical reviews of these measures to evaluate the interviews/scales being considered and actually test them out on volunteers, or if not available, with clinically savvy colleagues who can role play in developmentally and symptomatically authentic ways. If the researcher is not experienced with biostatistics, it is highly recommended that the basic psychometric papers be reviewed by a statistician colleague. Combining information from these different perspectives will maximize the chances that the time and effort put into data collection will yield information that is interesting and ultimately useful to the fields of child psychopathology, treatment, psychosocial intervention, and ultimately prevention

In clinical settings there are many challenges that must be addressed when introducing standardized measures. Perhaps the most formidable of these has to do with perceptions and attitudes of clinical staff who are unfamiliar with how standardized instruments might be usefully included as part of clinical practice. Some clinicians may be unconvinced that adding additional procedures could improve their usual practice in evaluating patients and making clinical decisions because they have great faith in their own clinical judgment. Some worry that their patients and families will feel "put off" by having to complete questionnaires or structured assessments (although research suggests that this is not usually a problem) and that including specific instruments may constrain their inquiry. Others may be overwhelmed by and resentful of any additional paper work. Clinics often include standard measures as part of an intake process but sometimes the information gathered is not given to the evaluating clinician. It is important not to include measures that aren't perceived as valuable clinically. A different sort of problem can lie in the over-reliance on or "reification" of a measure, especially with less experienced clinicians, who may assume a score on an inventory is more "valid" than their clinical observations, even though none of these measures should be considered as perfect. As an example, a depressed child who has become withdrawn, has insomnia and problems concentrating, and isn't sleeping might not endorse symptoms on a depression inventory, but that doesn't mean the child isn't depressed. The child's clinician should take account of the child's affect, rate of speech and reports of how the child is interacting with peers and family, etc. before concluding that depression is not present. However, children and adolescents and their parents will often more readily admit symptoms on a self-completed questionnaire, so responses on the questionnaire shouldn't be ignored. Often self-completion forms can be clinically useful by giving a clinician a starting place with a non-communicative patient. In such instances, it is useful to provide the questionnaire itself to the clinician rather than just a score, so that the clinician can review it with the patient or parent. When using any of the measures in a clinical setting, it is important to consider carefully the procedures for generating the most

useful information from the measure and sharing that information with the clinical team.

PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL ASSESSMENT

Psychological assessment using tests of personality and cognitive abilities can be a valuable part the child psychiatric evaluation. Psychological evaluation provides a unique perspective on the child's condition by generating information complementary to that obtained from history, observation, and interview. Combined with history and observation, such psychological data may clarify relationships among various etiological factors or may help direct the selection of appropriate intervention. Although partly inferential, the clinical information derived from projective tests of personality is less influenced by certain reporting biases (e.g., social desirability) than self-report. Psychological testing also provides data that are more quantitative than the qualitative information provided by the child's history, presenting complaints, and clinical presentation.

The quantitative character of test findings is more important in the assessment of cognitive abilities than in personality assessment, because the child's relative strengths and weaknesses in mental processing can be estimated only grossly from history and clinical observation. Such clinical estimates are also necessarily less accurate. The ability to discriminate meaningful differences among various domains of functioning helps clarify the particular pattern or syndrome evidenced by the child. The assessment of cognitive functioning also reveals cognitive impairments that may underlie or influence the psychological condition under investigation (e.g., whether poor social judgment in a child with conduct disorder also results from a nonverbal learning disability). Furthermore, the manner in which any cognitive impairments or strengths interact with the child's psychological disorder can be delineated. Findings from tests of personality also identify important dynamics that affect the child's clinical condition.

Referral for Psychometric Assessment

A referral for a psychometric assessment of the child is a request for a professional consultation from which an opinion regarding the referral questions can be expected. The referral for psychological examination is analogous to that made to a neurologist or radiologist, who uses his or her assessment methods and particular expertise to contribute potentially valuable information that can then be considered, evaluated, and integrated into the psychiatric evaluation. Referrals are, therefore, best worded in terms of the information that is needed, the issues to be resolved, or the decisions that must be made, rather than requesting that specific tests be administered.

Referral questions can be broad in scope, such as requesting a second

opinion regarding the child's condition from the unique perspective of psychological test findings. Requests for assistance delineating differential diagnoses or identifying idiosyncratic attributes of the child that may affect treatment are narrower referral questions that, nonetheless, still require relatively broader psychological examinations. In contrast, more narrowly focused questions, such as the adequacy of the child's reality testing, may permit more focused examinations. However, the extent to which psychological evaluations can be restricted to a narrowly defined referral question has a lower limit. Usually, a critical mass of data is required to interpret test findings properly.

Referrals for psychological examination should be made to professionals who use the appropriate instruments and can interpret the results. Just as psychiatrists may specialize in the treatment of adult, child, or geriatric patients or may develop a special expertise with certain disorders, so psychologists also develop specialized skills in assessing certain groups of children or syndromes. Just as in medicine, board certification in clinical psychology or pediatric neuropsychology is one method for identifying psychologists with specialty qualifications. The American Psychological Association directory or various directories of certifying boards are useful references in the search for an appropriate examiner.

Although it is still best to state a referral question, referrals are frequently made for a particular type of evaluation (e.g., psychological vs. neuropsychological). A request for a psychological evaluation is commonly understood by the psychologist to mean assessment of personality and intelligence, with only a screening of achievement or other cognitive functioning, unless a more thorough examination is specifically requested. In contrast, a request for a neuropsychological evaluation is assumed to mean comprehensive assessment of cognitive functioning, including intelligence, complex mental processing, attention, memory, language, perception, and motor functioning, with only a screening of social and emotional behavior.

The primary purpose of neuropsychological evaluations is not to detect brain damage. Rather, comprehensive assessment of cognitive functioning, attention, memory language, perception, and motor functioning permits the identification of deficits that cause academic, social, or developmental disabilities or that impede psychiatric treatment. Such assessments also identify the child's areas of strength and weaknesses and help provide the basis for prescribing rehabilitative interventions that may be delivered as special education, occupational therapy, physical therapy, or vocational or cognitive rehabilitation. By parsing the psychological and cognitive impairments that contribute to the child's functional disability, such assessments also help delineate the interaction between the child's psychological disorder and cognitive impairments. Although

neuropsychologists are familiar with the cognitive sequelae of various neurological conditions and can be particularly helpful in the assessment of children with neurological disorders, any child requiring a detailed assessment of cognitive functioning is appropriate for referral.

Psychological Test Batteries

Table 36.1–8 contains a list of commonly used psychological measures for various domains of functioning. A comprehensive examination samples all of the domains, whereas a more focused evaluation selects a subset. In the most general sense, a battery of tests consists merely of a collection of tests to measure a variety of mental functions. There are loosely defined batteries that are routinely administered in psychological examinations. For example, the psychological battery for a child often includes the Wechsler Intelligence Scale for Children-V (WISC-V) or the Kaufman Assessment Battery for Children-III (K-ABC-III) as the measure of intelligence. In addition, there may be a measure of achievement in basic linguistic skills and math, such as the Test of Achievement from the Woodcock-Johnson Psychoeducational Battery—Fourth Edition (W/JPB-IV)—or the Wechsler Individual Achievement Test—Third Edition (WIAT-III). A test of visuomotor integration or visual construction, such as the Beery-Buktenica Test of Visual Motor Integration (VMI) or the Rey-Osterreith Complex Figure, is also usually administered. Finally, a variety of personality tests and behavior rating scales are used.

Some published test batteries consist of measures of various mental functions that have been developed together and can usually be combined into composite or factor scores. For infants and preschool children, psychometric instruments primarily focus upon development, including motor, sensory, perceptual, and language development and the development of conceptual reasoning. Comprehensive developmental quotients are derived from many of these instruments. The Bayley Scale of Infant and Toddler Development III (Bayley-III) and the Mullen Scales of Early Learning are two notable examples. The Woodcock-Johnson Psychoeducational Battery—Fourth Edition (W/JPB-IV)—and the NEPSY-2 are appropriate for school-aged children and examine a variety of smaller domains of functioning.

Personality Measures

Personality tests for the young school-aged child consist primarily of projective tests of personality. Projective tests contrast with objective tests of personality in that projective tests use limited structure and ambiguous stimuli to which the child can respond in a virtually unlimited variety of ways. Perhaps the best-known example of a projective technique is the Rorschach Test. Other projective tests commonly used for the young,

school-aged child include the Robert's Thematic Apperception Test (RTAT) and the Children's Appreciation Test (CAT), which require that the child compose a story in response to a picture depicting a scene that is suitable for children. A variety of tests administered to this age group require the child to draw, such as the Draw-A-Person (DAP) test, the House-Tree-Person (HTP) test, and the Kinetic Family Drawing (KFD). (Methods exist for scoring children's drawings to assess cognitive and visual motor development, as well as affective content.) For the most part, the interpretation of responses to projective tests of personality is inferential; that is, the meaning is not self-evident in the response. The inferences are based on accumulated clinical experience reported in the literature, symbolic interpretation or analogous reasoning based on a theory (e.g., psychoanalytic theory), and, to a much lesser extent, empirically established norms. The notable exceptions are the scores derived from the RTAT and the Exner and Rorschach-Performance Assessment System (R-PAS) scoring systems for the Rorschach test, which have norms and have been extensively studied in empirical research.

Objective personality tests are usually more structured than are projective tests, in that the stimuli have limited ambiguity, and only a select number of responses are permitted. In most objective measures, individuals are asked whether various statements are true or false for them. Objective measures of personality for younger children are usually limited to behavior rating scales or structured reports by parents or caregivers. The Personality Inventory for Children—Second Edition (PIC-2) and the Behavior Assessment System for Children—Second Edition (BASC-2) are good examples of these measures. There are objective tests of personality available for adolescents, which are self-reports. The Minnesota Personality Inventory-Adolescent (MMPI-A), the Millon Adolescent Personality Inventory (MAPI), and the Millon Adolescent Clinical Inventory (MACI) are three well-known examples. These tests yield personality profiles based on the relative deviations of scales that measure various psychological attributes.

Validity and Reliability

Although the validity and reliability of individual tests, as measures of specific mental functions, are established with group data, the reliability and validity of findings for the individual child are also a concern for the examining psychologist. Test batteries provide some advantages in determining the reliability and validity of individual test results. An integrated battery contains some overlap in the testing of mental functions, permitting comparative assessment of the consistency of the child's performance across measures. In addition, if there is a theoretical or empirical basis for knowing that some mental abilities are associated with each other, then consistent findings across measures of those abilities

strengthen the confidence in the findings for the individual child. Examinations that focus on a few mental functions, by administering a limited number of tests, do not permit detection of transient performance factors that may cause spurious scores. In addition, no test is a pure measure of the target variable; therefore, performance on a single test may be impeded by impairment of a mental function necessary for performing the task but not the function that the test purports to measure. If previous psychometric evaluations have been performed, reliability of findings for a particular child can be estimated from the consistent of findings across examinations.

Finally, the assessment of children with motor, language, hearing, or visual impairments presents a special challenge. Every psychological measure requires a modality of perception, mental processing, and modality of expression. To assess children with impairments in any of these functions, tests are selected with forms of input and expression that avoid the obviously impaired functions. Children with pervasive disorders of mental processing require assessment methods appropriate for their level of functioning. In such cases, it is frequently more helpful to characterize the impairments in terms of criterion-referenced measures, which list abilities mastered, or in terms of the child's standing among children of the same diagnostic group.

Table 36.1–8.
Commonly Used Psychological and Neuropsychological Tests for Children and Adolescents

General Ability/Intelligence Tests	For Ages (years)
Differential Ability Scales, Second Edition (DAS-II)	2:6–17:11
Kaufman Assessment Battery for Children, 2nd ed. (KABC-2)	3:0–18:11
Stanford-Binet, Fifth Edition (SB-5)	2:0–89:11
Wechsler Scales	
Wechsler Preschool and Primary Scale of Intelligence, 4th ed. (WPPSI-IV)	2:6–7:7
Wechsler Intelligence Scale for Children, 5th ed. (WISC-V)	6:0–16:11
Wechsler Adult Intelligence Scale, 4th ed. (WAIS-IV)	16:0–90:11
Wechsler Abbreviated Scale of Intelligence™ 2nd ed. (WASI-II)	6:0–90:11
Woodcock Johnson Tests of Cognitive Abilities, 4th ed. (WJ-IV)	2–90+ years
Achievement Test Batteries	
Kaufman Test of Educational Achievement, 3rd ed. (KTEA-III)	4:0–25:11
Peabody Individual Achievement Test—Revised (PIAT-R)	4:0–50:11
Wechsler Individual Achievement Test, 3rd ed. (WIAT-III)	4:0–85:0
Wide Range Achievement Test 4 (WRAT4)	5–94 years
Woodcock Johnson Tests of Achievement, 4th ed. (WJ-IV)	2–90+ years
Neuropsychological Test Batteries	
Delis-Kaplan Executive Function System (DKEFS)	8–89 years
Halstead-Reitan Neuropsychological Test Batteries	5–8, 9–14, 15+ years

Luria-Nebraska Neuropsychological Battery—Children's Revision	8–12 years
Luria-Nebraska Neuropsychological Battery (LNNB)	15+ years
NEPSY: A developmental neuropsychological assessment, 2nd ed. (NEPSY-II)	3–16 years
Reitan-Indiana Neuropsychological Test Battery	5–8 years
Nonverbal Tests[a]	
Comprehensive Test of Nonverbal Intelligence, 2nd Ed. (C-TONI-II)	6:0–89:11
Leiter International Performance Scale Revised, 3rd ed. (Leiter-3)	3:0–75+
Naglieri Nonverbal Ability Test-Individual Administration, 2nd ed. (NNAT-2TM)	4–18 years
Test of Nonverbal Intelligence, 4th ed. (TONI-4)	6:0–89:11 years
Beery-Buktenica Test of Visual-Motor Integration (VMI)	2–18 years
Rey-Osterreith Complex Figure	9 years-adult
Adaptive Behavior	
AAMR Adaptive Behavior Scale-School, 2nd ed. (ABS-S2)	3–21 years
AAMR Adaptive Behavior Scales-Residential and Community, 2nd ed. (ABS-RC2)	–79 years
Adaptive Behavior Assessment System, 2nd ed. (ABAS-II)	0–89 years
Scales of Independent Behavior-Revised (SIB-R)	infancy-80+ years
Vineland Adaptive Behavior Scales, 3rd ed.	0–90 years
Vineland Social-Emotional Early Childhood Scales (SEEC)	0–5:11
Diagnostic Instruments	
Child and Adolescent Psychiatric Assessment (CAPA)	8–17
Children's Interview for Psychiatric Syndromes (ChIPS)	6–18
Diagnostic Interview for Children and Adolescents (DICA)	6–18
Diagnostic Interview Schedule for Children (DISC-IV)	6–17
Schedule for Affective Disorders and Schizophrenia for School-aged Children (K-SADS)	6–18
Structured Clinical Interview for DSM-IV Childhood Diagnoses (KID-SCID)	7–17
Projective Tests	
Children's Apperception Test	3–10
Draw-a-Person Technique	5–17
Kinetic Drawing System for Family and School	5–20
Rorschach Inkblot Test	5-adult
Roberts Apperception Technique for Children: 2	6–18
Rotter Incomplete Sentence Blank	Adolescent-adult
Thematic Apperception Test	6-adult

[a]The KABC-2, DAS-II, and SB5 also yield nonverbal composite scores.

From Tsatsanis K. Psychological and neuropsychological assessment of children. In: Martin A, Volkmar FR, eds. *Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook.* 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2007:357–371.

Interpretation of Psychometric Findings

The interpretation of psychometric findings is predicated on standardized administration of the tests. In addition, the proper interpretation of psychometric findings generally requires knowledge of parametric and nonparametric statistics, mastery of the literature concerning test performance and test construction, familiarity with the construction and psychometric properties of the specific tests employed, and knowledge of

the literature regarding those instruments.

The results of psychological examination are often best integrated in a concluding discussion of the findings as they pertain to the referral question. The results of a neuropsychological examination are organized around a discussion of various functions with a concluding integration. The interpretation of test results includes consideration of the immediate context in which the tests were administered (e.g., performance factors, such as fatigue, anxiety, rapport, level of cooperation and motivation of the child). There are generally three levels of analysis for the test scores: (1) pathognomonic symptoms, (2) levels of performance, and (3) syndromes or patterns. There is no direct interpretation for single scores. During syndrome analysis, scores are interpreted within the context of the results of other measures, which is the most powerful form of analysis in terms of the ability to extrapolate beyond the immediate tests data. This capacity to extrapolate is based on known characteristics of children evidencing the syndrome. Finally, when testing children, one must bring a developmental perspective to findings, so that future difficulties can be anticipated with the changes that occur as the child grows older.

Psychometric findings are communicated more easily if the clinician receiving them understands some basic principles of psychometrics. Most people cluster around some average score for most measures of mental abilities, and fewer individuals score high or low. The distribution approximates a binomial distribution in the form of an inverted U, known as the *normal curve*. Raw scores are frequently the number of correct responses during a test and are not usually reported. Percentile scores indicate the percentage of persons obtaining raw scores equal to or less than the raw score obtained by the individual. In the normal distribution, small changes in raw scores close to the average (where many people are grouped) result in relatively large shifts in the percentile rank, whereas large shifts in raw scores at the high and low ends of the distribution may change the person's percentile rank little.

To compensate for the variations in the rate of change of percentile scores, and to make performance levels comparable across tests, raw scores are converted to standard, or deviation scores that indicate the extent to which the individual deviates from the mean or average. By convention, the average standard score for most psychological tests is 100, and the standard deviation is set at 15 IQ points or standard score points with these psychometric properties. By the use of standard scores, performance levels for measures of specific mental abilities can be compared with IQ or with other test results. Standard scores also give the best indication of significant differences among scores, because the intervals between scores of the same magnitude are equal anywhere along the distribution of scores. Statistical significance occurs when the probability is low that a difference between scores could have occurred by chance, as the result of inherent

error variance in the test. By convention, a level of .05 probability is set as the standard for statistical significance. Although two scores may significantly differ, that does not mean that the difference is meaningful or has clinical significance. Many statistically significant differences occur frequently in the normal population. For example, a difference of 15 points between the Verbal and Performance IQ scores of the WISC-IV is statistically significant; however, a difference of this magnitude or greater occurs in approximately one-fourth of the normal subjects used to standardize the test. Of course, a difference of this magnitude could have clinical significance in a particular case, if the adverse effect of the difference was exacerbated by other factors.

Some tests for children allow calculating standard scores from age norms or grade norms, for example, the Woodcock-Johnson Psychoeducational Battery and the Kaufman Tests of Educational Achievement. The difference between these two methods of calculation illustrates the importance of understanding tests scores in relation to the normative reference group. A standard score based on age norms compares the performance of a child to that of other children the same age. A standard score based on grade norms compares the child's performance with that of other children in the same grade. If the child has been retained in grade to compensate for learning problems, the standard score based on grade norms is artificially inflated, masking the extent of the child's impairment. However, an achievement score based on grade norms indicates how well the child has mastered the curriculum at the grade level. In general, grade scores (grade and months) and age scores (years and months), as opposed to standard scores, should be interpreted cautiously, because their psychometric properties are poor, and the implications of the scores vary across levels. Clinical decisions should not be based upon these types of scores.

There has traditionally been a concern about reporting IQ scores, because people do not understand that the scores are not absolute and immutable. Reporting the standard error of measurement or confidence intervals helps others realize that scores have inherent error and vary to some extent over successive administrations of the test, even when the test is valid and reliable by present standards. Confidence intervals are the range of scores believed to contain the true score at a specified level of probability. The WISC-IV and WJPB-III scoring programs, for example, will calculate confidence intervals for standard scores, at 90 percent and 95 percent probability. Higher levels of confidence necessitate larger ranges of scores.

Report of the Psychometric Findings

Ordinarily, the child's parents are informed of the results of a psychological or neuropsychological evaluation. Because tests scores are easily

misinterpreted, reports of psychological test findings should not be given to the child or parents unless a qualified professional is present to explain the findings and to answer questions. It is helpful if the referring clinician indicates how much feedback is to be given. In many situations, especially if the findings could create distress for the child or family, the referring clinician may wish to provide the feedback. If a written report is desired, then a report can be written for the family that does not include confusing technical information and is designed to minimize adverse effects of sensitive findings. In other cases, the referring clinician may choose to have the psychologist provide the feedback. Alternatively, the referring clinician may decide to meet with the psychologist and family together, so that the psychologist can explain any technical aspects of the evaluation and its findings, whereas the referring clinician can place the findings within the context and perspective of the overall assessment and treatment recommendations.

PEDIATRIC AND OTHER ADJUNCTIVE EVALUATIONS

Pediatric Evaluation

Close collaboration with the child's pediatrician is usually an important component of any evaluation. The pediatrician is a valuable source of information about the child's developmental and medical history and can contribute a unique long-term perspective on the child and family. In addition to a general review of systems, the pediatrician should assess the child's current and past physical growth, including head circumference, height, weight, and pubertal status. Screening of hearing and vision, with more detailed testing as indicated, is important because deficits in these areas can manifest themselves in learning, language, and social delays or seeming inattention or opposition. History taking includes abnormal movements or absence spells suggesting seizures, abnormal postures, and tics. The physical examination notes difficulties in muscle tone and strength; asymmetrical, abnormal, or primitive reflexes; tremor; and gait or postural disturbances.

Table 36.1–9.
Clues to Developmental Disability from the Physical Examination

Area	Findings	Implication
Growth	Head circumference	Microcephaly correlates highly with cognitive deficits
		Macrocephaly may indicate central nervous system abnormalities (e.g., hydrocephalus) or storage disorder
	Linear growth	Small size may indicate genetic disorder or embryopathy (e.g., fetal alcohol syndrome) or endocrine abnormality (e.g., thyroid)

		Large size may indicate genetic disorder (e.g., cerebral gigantism or Sotos' syndrome)
Congenital anomalies	Organ defects	Storage disorders (e.g., mucopolysaccharidoses); may have enlarged organs
	Major anomalies	Major anomalies, such as heart defects, may be associated with developmental delays
	Minor anomalies	Minor anomalies, such as wide-set eyes, low hairline, or extra digits, may suggest a genetic syndrome
Skin	Hyperpigmentation	—
	Tumors or fibromas	Skin lesions may be seen in neurocutaneous syndromes, such as neurofibromatosis or tuberous sclerosis.
Eye findings	Lens dislocation Corneal clouding Cataracts Retinal pigmentation	Abnormalities inside the eye may suggest metabolic disorders or congenital infections.

Adapted from Levy SE, Hyman SH. Pediatric assessment of the child with developmental delay. *Pediatr Clin North Am.* 1993;40:465.

Especially in children with intellectual disability or autism spectrum disorder, a thorough history and physical examination can provide important clues to an underlying detectable medical cause. For children with developmental difficulties, a careful history of perinatal risk factors is taken; the pediatric examination includes careful evaluation for major or minor congenital anomalies, dysmorphic features, dermatological abnormalities (hyperpigmentations, tubers, and fibromas), or ophthalmological findings (lens abnormalities and retinal pigmentation) (Table 36.1–9). Loss of previously acquired developmental milestones or the presence of congenital anomalies, dysmorphic features, microcephaly or macrocephaly and other growth problems, abnormal skin pigmentation or lesions, and symptoms suggesting seizure activity or other neurological abnormality warrant more detailed genetic, metabolic, or neurological evaluation (Table 36.1–9).

Diagnostic Laboratory Tests

The clinical usefulness and cost-effectiveness of routine laboratory tests for children who present with psychiatric problems have not been thoroughly studied. Most guidelines for performing these tests for children have historically been developed using data from studies of adults. Adult studies generally suggest that routine laboratory tests are not clinically useful in typical psychiatric settings, such as outpatient clinics and most inpatient units, although laboratory screening tests may be of some use in psychiatric settings in which patients are at high risk of medical illness, such as the emergency room, substance abuse treatment centers, AIDS clinics, and geriatric clinics, as well as for those who have new-onset psychosis, depression, or dementia or when evaluating children with developmental disturbances, such as intellectual disability or autistic spectrum disorder.

Similarly, routine screening laboratory measures are more likely to yield clinically significant information when clinical symptoms of physical illness are present.

Evidence suggests that if anything, routine laboratory testing is less useful in pediatric compared to adult populations, where medical comorbidity that causes psychiatric manifestation is less common. The few studies of the use of routine laboratory tests in child psychiatry patient populations have yielded similar conclusions. One review of routine laboratory screenings (e.g., thyroid function tests, electroencephalogram [EEG], chest x-ray, chemistry panel, urinalysis, complete blood count, electrocardiogram [ECG]) in 100 consecutive adolescent inpatient admissions reported variable rates of abnormal values, depending on the specific test, but in only 1 of these 100 patients did the tests produce a change in diagnosis from functional to organic—and even then the diagnostic information proved to have little clinical relevance. Most laboratory abnormalities in this study were regarded as minor and did not indicate a need for clinical follow-up.

Similarly, more specialized diagnostic laboratory evaluations (EEG, computed tomography [CT], magnetic resonance imaging [MRI], or chromosomal analyses) also provide a relatively low yield of clinically useful information. In a study of 200 consecutive child psychiatric inpatients, these evaluations were performed only when clinically indicated; despite their judicious use, the tests provided clinically relevant information in only 7 patients (3.5 percent of the total patient sample) or in 7 of 136 tests (5.1 percent of all tests performed). Chromosomal analyses proved to be the most informative of all these tests, yielding new medical diagnoses in 5 of 32 (15.6 percent) selected children for whom they were performed. A study of 111 putatively high-risk inpatients with new-onset adolescent psychoses produced similar conclusions. In this population, routine endocrine and neuroimaging screening evaluations failed to provide any information of diagnostic usefulness in any patient (although inconsequential laboratory abnormalities were present in 15.4 percent of the neuroendocrine screens and 11 percent of the neuroimaging screening tests). More specialized neuroimaging technologies, such as positron emission tomography (PET), single photon emission computerized tomography (SPECT), and functional MRI (fMRI), currently have no routine clinical or diagnostic usefulness in child and adolescent psychiatric populations.

Two useful screening diagnostic tests in child psychiatric practice include (1) urine drug screening and (2) testing for sexually transmitted diseases in high risk patients. Substance use can cause a wide range of neuropsychiatric symptoms and mimic a large spectrum of psychiatric conditions. The high prevalence of substance abuse in adolescent populations has prompted recommendations that toxicology screens be

obtained for (1) all adolescents who have psychiatric symptoms or who exhibit acute behavioral changes; (2) high-risk adolescents, such as delinquents and runaways; and (3) adolescents who have recurrent accidents or unexplained somatic symptoms. Similarly, children and adolescents should be screened for risk factors associated with sexually transmitted diseases. Children and adolescents at risk due to either a history of sexual activity (or sexual abuse) or intravenous substance use should be evaluated for sexually transmitted diseases, including HIV infection and syphilis.

In contrast to routine screening, targeted laboratory testing in specific child psychiatric syndromes can be quite useful in (1) detecting the etiology of conditions or (2) uncovering treatable, high-risk medical comorbidities. For instance, children with intellectual disability or autism spectrum disorder may particularly benefit from targeted diagnostic testing. In general, the more severe the child's disability, the greater is the likelihood of an identifiable (albeit not necessarily treatable) cause. For example, one study found that a medical cause could be identified in 60 to 70 percent of children with severe intellectual disability versus only 35 to 55 percent of children with mild intellectual disability. Chromosomal abnormalities, especially trisomy 21 (Down syndrome) or fragile X syndrome, account for more than one half of cases of intellectual disability. Children with autism spectrum disorder have relatively high rates of intellectual disability, seizure disorder (20 to 40 percent), and tuberous sclerosis (3 to 9 percent). Most experts would therefore advocate a Wood's lamp examination to search for tubers, an EEG to exclude seizures, and high-resolution chromosome analysis to exclude known genetic syndromes in children who display features of autism spectrum disorder or intellectual disability. Identification of genetic causes of autism is now possible in more than 10 percent of affected children and, as current knowledge of specific genetic syndromes advances, high-resolution DNA sequencing is likely to increase one's ability to discern specific subtypes of neurodevelopmental disorders.

Lead testing is also indicated in cases of intellectual disability because chronic lead ingestion due to pica can cause substantial retardation; conversely, many children with retardation or pervasive developmental disabilities from other causes indulge in pica and may accumulate a substantial lead burden.

A comprehensive discussion of every diagnostic testing recommended for every psychiatric disorder that manifests in childhood is beyond the scope of this chapter. The authors refer the reader to disorder-specific chapters of this textbook for a more comprehensive discussion regarding diagnostic laboratory testing for specific psychiatric conditions.

Finally, periodic laboratory testing (as well as tracking height and weight) is also important when starting certain psychiatric medications or monitoring for potential adverse during ongoing administration.

DIAGNOSTIC FORMULATION AND RECOMMENDATIONS

In the diagnostic formulation, the clinician attempts to integrate the data gathered through the assessment process into a coherent account of the child's difficulties, the factors that appear to have predisposed the child to develop the problem, the concomitants and consequences of the problem, and the factors that maintain the problem or that might ameliorate it. It is not always possible to provide a complete formulation at the conclusion of the initial assessment; under such conditions, the best that the clinician may be able to provide is a differential diagnosis that can point toward the appropriate treatment options and the subsequent steps needed to establish a diagnosis.

One product of the assessment may be the assignment of a diagnosis of one or more categorical psychiatric disorders using the diagnostic schema of DSM-5 or ICD-10. Although these nosological systems have done much to standardize diagnostic practices and to improve the quality of research, one must be aware of their clinical limitations as applied to children. Many children experience sufficient symptoms, distress, or impairment to be regarded as psychiatrically disturbed and to warrant therapeutic intervention without meeting the full criteria of a categorical psychiatric disorder. Furthermore, as currently conceptualized, the DSM-5 classification is descriptive and atheoretical; it specifies neither presumed etiology nor treatment for the various diagnostic categories. If the assessment process is to provide a picture of the child that suffices to guide intervention, the resulting diagnostic formulation must go beyond simply assigning a categorical psychiatric diagnosis (if one is warranted). As noted in the introduction, comorbidity is often the rule rather than the exception in childhood, and many children have complex patterns of developmental and behavioral difficulties that are not adequately captured by a list of multiple categorical diagnoses. Children who share a given categorical diagnosis may differ in crucial respects that influence current severity, natural history, and treatment response. Examples of potential risk (or exacerbating) factors and protective (or ameliorative factors) include intelligence, compensatory skills, family and community resources and supports, and vulnerabilities, such as comorbid pathological personality traits, neurological impairments, or co-existing general medical conditions.

The clinician's diagnostic formulation should thus supplement the assignment of any formal categorical diagnoses by attempting to identify, as far as possible, the potential causes, predisposing factors, and current determinants of the child's difficulties. On the basis of this information and the clinician's expertise regarding the various interventions available for the diverse forms of childhood psychopathology and developmental difficulties, the clinician formulates appropriate recommendations for the treatment of the child's problems.

Communicating Findings and Recommendations

Communicating the findings and recommendations that result from the assessment to the parents and child is an essential part of the evaluation process and may require one or more sessions. Depending on the problem and the child's age and level of comprehension, presenting the findings usually involves meeting with the child and parents, separately or together.

Several principles must be observed to maximize the likelihood that the parents and child hear, understand, and experience the clinician's findings and recommendations as helpful. First, the clinician must communicate a sense of the child as a whole person, with strengths and abilities, as well as problems and vulnerabilities. This perspective conveys a sense of the clinician's appreciation and empathic understanding of the child, reduces defensiveness, and helps to mitigate the fear that there is only bad news.

The findings and recommendations are most useful to the family and likely to be implemented if the interpretive session is a dialogue rather than a lecture. The clinician must use language comprehensible to the parents and child, must avoid jargon, and must keep technical terms to a minimum. When technical terms are necessary, they should be explained clearly, so the parents and child understand them; terms that are merely descriptive to the clinician may hold frightening or negative connotations for the child or family. The clinician should allow ample opportunity for the parents and child to discuss the recommendations. This provides a chance to judge whether the clinician's formulation made sense to the family, to address any differences of opinion, and to explore the feasibility and acceptability of the recommendations offered. Remaining areas of uncertainty or ambiguity about the assessment or recommendations should be clearly noted and discussed.

If the assessment is a consultation requested by an agency, a school, or another clinician, the findings and recommendations should be communicated to the referring party in appropriate terms after being discussed with the parents and child and with their consent. If further evaluation or treatment is indicated but is best done by someone else, the clinician should offer to assist in appropriate referral.

▲ 36.2 Psychiatric Assessment of Preschool Children

HELEN LINK EGGER, M.D., AND CAROLY SUE PATAKI, M.D.

INTRODUCTION

The infant/preschool mental health field has made real strides in recent years in demonstrating that clinically significant psychiatric symptoms and disorders are already present and highly impairing in early childhood. Recent epidemiologic studies of children ages 2 to 5 years old have shown that the overall rate of psychiatric disorders in preschoolers is remarkably similar to overall rates reported for older children and adults. For example, the preschool rate of "serious emotional disturbance," defined as psychiatric disorder(s) that are associated with significant impairment, was 12.1, 9.1, and 7.1 percent in three different community preschool studies, compared with a median rate across community studies of 13.2 percent in older children and adolescents and 15.6 percent in adults. The growing recognition of the mental health needs of preschool children reveals a large gap in mental health services. Few clinicians have training in the assessment and treatment of young children. This section provides an overview of the components of comprehensive, empirically based psychiatric assessments of preschool children and their families.

DEVELOPMENTALLY APPROPRIATE CRITERIA FOR PSYCHIATRIC SYMPTOMS AND DISORDERS IN PRESCHOOL CHILDREN

Historically, young children's emotional and behavioral problems have been approached dimensionally, with cut-points set to characterize subsets of children at the extreme of the distribution of (1) normative behaviors and emotions and/or (2) temperament traits. In these models, extremes of problems or temperament traits have typically been regarded as precursors of, or risk factors for, later psychopathology rather than as psychiatric disorders similar to those identified at later stages of life. Although symptom checklists or temperament measures often provide clinically useful information about the young child, they do not have the symptom coverage (particularly for rare but highly concerning symptoms such as suicidality or stereotypies) nor details about the characteristics of symptoms (e.g., frequency, onset, duration) to enable the clinician to make a diagnosis. There have been two approaches to the diagnostic classifications of early childhood psychopathology (1) the *Diagnostic and Statistical Manual of Mental Disorders/International Statistical Classification of Diseases and Related Health Problems* (DSM/ICD) diagnostic classification, either unmodified or modified to be developmentally appropriate for young children, and (2) the Diagnostic

Classification: 0–3 (DC:0-3, DC:0-3R), an alternative system for classifying mental health disorders in infants and toddlers. These categorical approaches seek to identify clinically significant syndromes, characterized by severity, pervasiveness, persistence, and impairment, that are early-onset "disorders" rather than simply risk factors for later disorders.

Despite its lack of developmental specificity, the DSM has been a useful starting point for examining how psychopathology presents in early childhood, at least in children 2 years old or older. For example, the diagnostic criteria of the fifth edition of the DSM (DSM-5) work quite well as a means of advancing the current understanding of the presentation and course of autism spectrum disorders despite its lack of developmentally specific criteria. The dual approach of testing the applicability of current diagnostic criteria for identifying autism spectrum disorders in young children while exploring the validity and clinical utility of developmentally specific criteria and/or diagnostic algorithms for use with young children provides an exemplary road map for examining the validity of specific behavioral and emotional disorders in young children. Similar approaches are being taken in studies of early-onset attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, depression, posttraumatic stress disorder, and disruptive behavior disorders in young children. In 2003, the Research Diagnostic Criteria–Preschool Age (RDC-PA) was published with the goal of facilitating further research on the diagnostic validity of psychiatric disorders in preschoolers by defining clearly specified, developmentally appropriate criteria for preschool psychopathology.

The RDC-PA explicitly sought to modify the DSM criteria to make them developmentally appropriate rather than to propose a new classification system. The DC:0-3 combines the RDC-PA "top-down" approach with a "bottom-up" approach that seeks to classify disorders in infants and toddlers that are not covered in the DSM. The original DC:0-3 was published in 1994. Despite its title, the DC:0-3 has commonly been used with children through age 5 years. The DC:0-3 classification system included alternative criteria for DSM-5 diagnoses (e.g., many of the Research Diagnostic Criteria [RDC] modifications have been incorporated in the revised edition), new diagnostic categories (e.g., regulation disorders of sensory processing), and a revised multiaxial system that places relationship characteristics and disorders on Axis II and the child's "functional emotional developmental level" on Axis V. The current DSM-5 no longer utilizes the multiaxial system, rather it employs specifiers, making the DC:0-3R even more important for preschool diagnoses. The revised version of DC:0-3 (DC:0-3R) was published in 2005 with a central goal of operationalizing the diagnostic criteria and categories so as to improve diagnostic reliability and facilitate research into the validity of these disorders. Despite its differences from the DSM, DC:0-3R, like the first version, was intended to supplement, not replace, the DSM/ICD

nosologies. The DC:0-3R explicitly provides a place on Axis 1 for coding DSM/ICD diagnoses.

What System Should a Clinician Use?

At this point, it is quite certain that the current diagnostic criteria defining preschool psychopathology are imperfect and will be revised and even supplanted as knowledge grows. For now, however, there is fairly convincing evidence that all these different approaches to classification contribute to identifying clinically significant psychopathology in early childhood. The clinician who seeks to provide mental health care for preschoolers and their families should be familiar with each of these approaches and use one or both of the diagnostic multiaxial nosologies for their assessments. Clinicians who use the DC:0-3 axes commonly may need to make a "cross-walk" to the DSM-5 or because DSM/ICD codes are often needed to obtain insurance reimbursement for services.

COMPREHENSIVE, EVIDENCE-BASED PSYCHIATRIC ASSESSMENTS OF PRESCHOOL CHILDREN

There are five key components of a comprehensive psychiatric assessment of a preschool child: (1) multiple sessions, (2) multiple informants, (3) a multidisciplinary approach, (4) multiple modes of assessment, and (5) a multiaxial diagnostic formulation. These components arise from the multidisciplinary, developmental, relationship-based, family-centered, and prevention-focused orientations that characterize the infant/preschool mental health field's approach to understanding psychopathology in early childhood.

Multiple Sessions

Despite the real reimbursement constraints that clinicians face in conducting multisession evaluations, these constraints cannot dictate the length of an evaluation. It is simply not possible to conduct an adequate psychiatric assessment of a young child in one session. Although it could be argued that this caveat is true for all of pediatric psychiatry, the rapid developmental, cognitive, emotional, and behavioral changes that characterize the preschool period, as well as the young child's physical and emotional dependency on his or her primary caregivers, make it imperative that information be gathered about the child across sessions and across time. For example, a tired 3-year-old child seen after a long day at preschool may look quite different when seen in the morning after he or she has had a good night's sleep. At some preschool clinics the clinicians choose to see the parent(s) without the child for one of the sessions so as to obtain a detailed history about the child's symptoms and the family history and current family structure and functioning. It is essential to obtain

information about current and past parental psychiatric and substance abuse problems and treatments, domestic violence in the home, and marital (or partner) difficulties, but it is not appropriate to discuss these issues in front of the child. Nor is it appropriate for the child to hear negative comments about himself or herself (e.g., "He is a bad kid") or to be privy to a parent's worst fears ("I am afraid that he will end up like my brother who killed himself"). These comments and fears are very important pieces of information about how the parent sees this child. Any parent of a preschooler also knows that it is quite difficult for young children to refrain from interrupting adult conversation long enough for the clinician to obtain the breadth and level of detail needed to understand the child's problems. However, even if the child is seemingly absorbed in play in the corner of the office, he or she will hear the adult conversation. An evaluation should include phone sessions with the child's teacher or child care provider (written consent to contact the teacher or child care provider should be obtained at the first session). A visit to the child's day care or preschool to observe the child's functioning with other adults and peers in an out-of-home setting may also be indicated.

Multiple Informants

The clinician must gather information from multiple informants. First and foremost, the child is an important informant. This is as true of a 2-year-old with limited expressive language as of a 5-year-old about to enter kindergarten. Information can be obtained by speaking with and/or playing with the child (using structured or unstructured approaches) and observing the child interacting with parents, with another clinician, and with teachers or child care providers or peers. It is not possible to assess or diagnose a young child based on parent report alone. Moreover, the clinician should make every effort to spend time alone with the child, without the parents present (severe separation anxiety is an example of a disorder that might make this very difficult).

Of course, an evaluation cannot be conducted without information from the child's parents. These may be the child's biological parents and/or adults who act as parents of the child such as stepparents, grandmothers, or foster parents. An evaluation should include a three-generation genogram identifying the important parental figures and family members (including psychiatric and substance abuse history for each member). Ideally, if there are two parents in the home, both of them will attend the evaluation sessions and fill out all measures and information separately. Often each parent provides a somewhat different description of the child's symptoms. This does not undermine the validity of these reports, but rather reflects the fact that the child shows different aspects of himself or herself within different relationships. This information is diagnostically important and may be useful in guiding treatment planning. The parents

will also provide information about themselves (e.g., current psychiatric symptoms and treatment, parental and marital stress). Information must also be obtained from the child's nonparental caregivers such as teachers or child care providers, nannies, and babysitters who spend a significant amount of time with the child. As described in more detail in the next section, other clinicians, such as the child's pediatrician, are also critical informants.

Multidisciplinary Assessment

A child psychiatrist conducting a preschool psychiatric assessment usually collaborates closely with other clinicians and care providers, including psychologists, primary care and developmental pediatricians, neurologists, occupational therapists, speech and language therapists, early interventionists, case managers, adult psychiatrists and psychotherapists who treat the disorders from which the parents may be suffering, and marital therapists. The child psychiatrist has an opportunity (if not obligation) to assume a leadership role among all of these care providers. At the evaluation stage, the child psychiatrist should integrate the assessments and recommendations made by other providers into his or her assessment and then facilitate treatment planning and coordination of communication among these providers. The child psychiatrist should never provide treatment for a young child, particularly treatment with a psychotropic medication, without having conducted a comprehensive assessment himself or herself.

Multiple Modes of Assessment

Because it is not possible to conduct a standard psychiatric interview with a young child about his or her emotions and behaviors, preschool mental health assessments must draw on information gathered using different approaches, including adult reports, observational assessments, structured or unstructured play/interactions with the child, and standardized cognitive, motor, language, and other developmental assessments. A physical exam (often conducted by the child's pediatrician) is essential. Laboratory measures, including genetic testing, may be indicated.

When possible, empirically tested measures with demonstrated reliability and validity should be used to assess child and family domains. Types of measures include symptom checklists, such as the Child Behavior Checklist 1½–5 or the Infant Toddler Social Emotional Assessment for children 12 to 36 months old, DSM-referenced rating scales such as the Early Childhood Inventory-4 (ages 3 to 6 years), and checklist measures of specific symptom clusters such as the ADHD Rating Scale or the Preschool Anxiety Scale. Teacher/Caregiver measures such as the Caregiver-Teacher Report Form, as well as those assessing social skills and peer relationships,

such as the Social Skills Rating System, are also useful. Similar types of rating scales are available to assess adult domains, such as psychopathology (e.g., Beck Depression Inventory), parental stress (e.g., Parenting Stress Index), or domestic violence (Conflict Tactic Scales).

In the future, structured diagnostic parent interviews for assessing preschool psychopathology will be the best way to obtain comprehensive psychiatric, developmental, and environmental information about the child and the family, but these measures are not yet user-friendly enough for use in clinical settings. The exception is the Autism Diagnostic Interview (ADI). The Preschool Age Psychiatric Assessment (PAPA) is currently the only comprehensive parent psychiatric interview for assessing psychiatric symptoms and disorders in children ages 2 to 5 years with demonstrated test–retest reliability and validity. A version of the PAPA for assessing nonpervasive developmental disorder (PPD) symptoms in children with autism and other PPDs (PAPA-PDD) was scheduled to be completed in 2008. The ePAPA, a web-based version of the PAPA (and PAPA-PDD) to be administered on a tablet personal computer, has recently been developed and will be available for use in clinical settings in the near future.

Direct "interviews" with the young child about his or her feelings and experiences are also an essential component of a comprehensive assessment. In most clinical practices, unstructured play is used to learn about the child's emotions. Structured child interviews, such as the Berkeley Puppet Interview (BPI) and the MacArthur Story-Stem Battery (MSSB), show significant promise for children 4 years old and older.

Observational assessments, particularly of parent–child interactions, play an important role in preschool assessments. Inspired by the success of the Autism Diagnostic Observational Schedule—a structured assessment for autism in which the examiner "presses" for PDD symptoms with specific tasks with the child—researchers have been developing a similar diagnostic observational measure for assessing disruptive behavior disorders in preschoolers (Disruptive Behavior-Diagnostic Observational Schedule [DB-DOS]). The same group is developing a similarly structured observational measure of emotional disorders for use with preschool children.

There are numerous standardized, developmentally specific measures for assessing the preschooler's status in cognitive, language, motor, and preacademic domains. Reviews of specific measures in this and the other areas mentioned in this section can be found in the textbooks listed in the reference section.

Multiaxial Assessment

A comprehensive psychiatric assessment in the preschool age group must be truly multiaxial, with each axis reflecting a developmental framework. Since DSM-5 no longer uses a multiaxial system, coding on DC:0-3 system reflects an understanding of the different presentations of psychiatric

symptoms from ages 2 to 5 years. Familiarity with the current consensus on developmentally appropriate criteria for psychiatric symptoms and disorders during the preschool period is essential. Valuable resources include the *Handbook of Infant Mental Health*, the *Handbook of Preschool Mental Health*, and the *Handbook of Infant, Toddler, and Preschool Mental Health Assessment*.

The child's symptoms across all axes must be understood within the child's current level of functioning across multiple developmental domains (e.g., cognitive functioning, expressive and receptive language, gross and fine motor skills, prekindergarten knowledge, social-emotional skills). These developmental assessments are important for (1) understanding the child's psychiatric symptoms within his or her developmental capacities (not simply the child's chronological age), (2) identifying developmental lags or deficits that can be effectively addressed (e.g., expressive language problems), and (3) ruling out (or ruling in) the presence of a developmental disorder such as autism. Because children 3 years old and younger (and in some states 5-years-old and younger) are eligible for early intervention services for developmental delays, it is critical that child psychiatrists identify these delays and provide appropriate treatment referrals.

Assessment of the context of the child's symptoms, as well as the child's environment within and outside of the family, is also vital. The pervasiveness of the child's symptoms, not only across settings, but also across relationships, will provide important information about the nature of the symptoms. For example, if a child has explosive tantrums that occur when the child is at home and at school and occur with the parent and with the child's day care provider, the child may well be showing a symptom of a behavioral disorder. The child who has similar tantrums only when separating from his or her mother may be experiencing a symptom of an anxiety disorder. The child who only has tantrums when being dropped off for a custody visitation with a divorced parent may be expressing distress that arises from the difficulty of moving back and forth between two parental homes. The child who only has tantrums with his or her mother but shows good emotional and behavioral regulation with all other adults may be showing signs of a relationship disturbance with the mother. The infrequent tantrums that occur only when a child is exhausted (e.g., after a long car trip traveling home from a visit with Grandma) may very well be developmentally normal. These examples highlight the importance of obtaining detailed examples of the child's behaviors with a focus on the characteristics of symptoms. Relevant questions include the following: What does the child do or say? How often does it happen? How long does it last? When did it start? What triggers the symptom? When, where, and with whom does the symptom occur? What helps? This descriptive information is not the same as asking the parent "Why does your child do that?" Often, one does not know "why," but detailed descriptions of specific

symptoms provide the information needed to rule in or rule out specific disorders. An important difference between DSM and DC:0-3R is that the DC:0-3R provides a place (Axis II) to record information about the nature and quality of the child's relationships with his or her primary caregivers and list relationship disorders. The DSM does not provide a place to record any relationship information included in the DC:0-3R text is the Parent–Infant Relationship Global Assessment of Functioning Scale and a relationship problems' checklist that provide a framework for formulating an understanding of the child's relationships with his or her primary caregivers.

Assessment of the child's environment is also essential. In the DC:0-3R systems, stressors and risk factors are listed on Axis IV. DC:0-3R includes a broad (but not exclusive) checklist of known stressors, along with a place to indicate the age of onset, duration, severity, and context of these stressors, which is meant to provide a guide to the assessment of this domain. Axis IV should reflect a careful history of the child's environment, including, to name a few, an understanding of (1) parental/family factors such as a family history of psychiatric and substance abuse disorders and treatment, including types and doses of psychotropic medications and types of psychosocial treatments (a history of postpartum depression should be obtained), family structure and functioning including a careful assessment for physical or emotional abuse or neglect and sexual abuse, parent–partner relationship functioning including an assessment of adult–adult domestic violence and emotional abuse, and sibling relationships; (2) pregnancy and birth factors, including premature birth, low birth weight, maternal smoking or use of other substances during pregnancy, neonatal complications, and maternal depression during or following the child's birth; (3) the child's school or day care experiences, including teacher–child ratios, frequency of changes in child care settings and providers, amount of time the child is away from parent(s), age when the child started out-of-home care, peer relationships, and relationships with nonparental child care providers; (4) community factors, including neighborhood safety and proximity of relatives; and (5) socioeconomic factors, including parental employment status, family's social economic status, and absence of health insurance. Major stressors (e.g., parental divorce, death of a parent, physical abuse, hospitalization, or natural disasters such as a house fire or hurricane) known to be potentially traumatic life events should be included. However, chronic stressors or those that may seem "minor" (e.g., change in day care, moving to a new house) should also be included on Axis IV. There is clear evidence that the accumulation of multiple stressors with varying intensities has as profound an impact as single traumatic events in early childhood, just as they do in later childhood and adolescence. Both acute and cumulative stressors significantly raise the risk that the child will have one or more psychiatric disorders and be impaired.

CLINICAL FORMULATION AND TREATMENT PLANNING

Clinical formulation is an integrative skill that involves the pulling together of multiple observations and sources of information about an individual within a general diagnostic scheme so as to guide decision making. It is worth emphasizing that a psychiatric nosology classifies disorders, not individuals. When a comprehensive psychiatric evaluation has been conducted with a preschool child and his or her family and the DSM and/or DC:0-3R axes have been completed, a clinical formulation about the child and a treatment plan addressing each of the child's problem areas should be developed. Clearly defined symptoms within the child must be identified, ideally using measures that are sensitive to change, so that the clinician will be able to assess the efficacy of the intervention and the outcome of treatment. Of course, the assessment may also identify targets for treatment beyond the child's mental health symptomatology. For example, a treatment plan might include referral of the child for speech or occupational therapy or referral of a parent for treatment of his or her depression.

The evidence is quite clear that approximately 10% of preschoolers have severe impairing psychiatric disorders that cause suffering and put them at risk of ongoing emotional and developmental problems. These children and their families deserve effective and safe treatment. Unfortunately, the evidence base for psychiatric treatments for preschoolers is very thin. Over the next decade there is every reason to hope that there will be major advances in the current understanding of the etiology and course of early-onset mental health problems, as well as the development and dissemination of effective treatments and preventive interventions. However, children and their families cannot wait for the research to catch up with this need. Clinicians who treat preschoolers must (1) know the current state of evidence on the assessment and treatment of preschool psychopathology, (2) know how to decide on and determine the efficacy of treatments that may not have been studied in young children, and (3) be committed to keeping up with and incorporating new findings into their practice. Clinicians and parents should together weigh the risk of the disorder(s) with the risk of treatments so that parents can make fully informed decisions about how to best care for their child. Single-case experimental designs (e.g., *n*-of-one trial) that seek empirically to determine the efficacy of treatments for preschool patients are the best ways to manage these risks. This is particularly vital when use of psychotropic medication is being considered. The guidelines for the psychopharmacological treatment of preschoolers recommend this empirically driven (and cautious) approach to treatment. The infant/preschool mental health field has always had an early intervention and prevention orientation. The hope is that the identification and treatment of preschool children with clinically significant psychiatric

symptoms and disorders will not only ease their suffering during early childhood, but also will contribute to ameliorating or even preventing the onset of new disorders or progression of these disorders into later childhood and adulthood.

▲ 36.3 Neuropsychological and Cognitive Assessment of Children

MARTHA BATES JURA, PH.D., AND LORIE A. HUMPHREY, PH.D.

INTRODUCTION

This section describes cognitive and neuropsychological assessment as ways of understanding the referral issues of children and adolescents, and how the processing of information can affect a wide range of adaptive functions. Although these assessments might overlap, these approaches analyze behavior according to two different paradigms. Cognitive assessment is undertaken without reference to the possible neurobiological underpinnings of overt behavior, and it describes the patient very much as others might observe him or her in the world. Neuropsychological assessment is undertaken in the context of growing knowledge about brain–behavior relationships, and it has the additional possibility of describing the child in terms of unseen neural pathways. These approaches provide ways of conceptualizing how children integrate information (and their thinking, learning, and responding) at different levels. General cognitive assessment focuses on understanding behavior at a cognitive level and in descriptive terms. Focused neuropsychological assessment introduces the additional possibility of understanding behavior at neural levels and in neurobiological terms. However, regardless of the theoretical differences among the psychologists undertaking these evaluations, in a practical way it is the patient's referral issues that shape the assessment process and focus the interpretation of results.

BASICS OF PSYCHOLOGICAL ASSESSMENT

Psychological assessment involves more than testing. Although measurements are useful, testing involves more than scores.

The Testing Process

In addition to testing, assessment procedures include examining past records (medical examinations, prior testing, report cards), interviewing the client and his or her family (in structured and unstructured formats), obtaining information from home and school (and, sometimes, on-site observations), and getting rating scales filled out by the child's parents and teachers (regarding developmental, behavioral, emotional, and diagnostic issues). The diagnostic aspect of the process involves an attempt to determine the psychiatric and educational categories for which the client meets the criteria. Cognitive and neuropsychological testing are only aspects of an attempt to get a broad view of the way a child solves problems in the world, to understand his or her unique interaction with any diagnostic category, and to provide recommendations for interventions.

Psychologists collect information on instruments with a variety of psychometric properties. Behavior forms vary greatly in whether they involve noting the presence or absence of a symptom or include ways of rating and scoring the information. As controlled observations, test instruments involve not only ways of sampling behavior and measuring it, but also ways of noting the way in which the patient goes about solving problems. Although the present discussion about cognitive and neuropsychological assessment focuses on structured (standardized) testing, unstructured testing (such as projective instruments, whether scored or not) also can give a good sense of the cognitive organizing principles that patients bring to bear on a wide range of tasks and life. In fact, when looked at in basic ways, every cognitive test can have a projective aspect if the examiner is willing to analyze the client's response, and every projective test can have a cognitive aspect if the examiner is willing to see the organizing tendencies behind how the client integrates unstructured information.

It needs to be remembered that tests are simply formalized and standardized observations, and useful instruments provide information about both the basic skills and organizing principles that patients bring to understanding and dealing with their life. These principles can be described at neurobiological and/or cognitive levels and as they affect learning and functioning in school, as well as interacting with others.

Measurements in Testing

Although many techniques might be used to help understand a child client and his or her referral question, the emphasis here is on standardized

testing (based on regularized procedures as well as normative data). The point of testing is to create a way of comparing one individual to a population of such individuals, as well as the strengths and weaknesses within one individual. The psychologist will select an instrument that is valid (it measures what is intended) and reliable (it measures it consistently). The testing involves establishing a basal level (the level at which all items are passed) and a ceiling (the level at which no items are passed). The testing process involves converting a raw score to a standard score that can be compared to other scores along what is thought of as a normal distribution with predictable statistical properties. The standard deviation (SD) is a measure of dispersion around the mean; the further scores are from the mean and each other in terms of the SD, the more meaningful is the discrepancy. It is accepted that a measurement is an approximation and not exact. This approximation is recognized by the concept of standard error of measurement (SEM), which is the naturally occurring (random) error that takes place in the real world as one attempts to measure anything. The fact that measurements are not exact is also recognized by the concepts of confidence intervals (the probability that the true score falls within a range of scores) and statistical significance (the probability of finding a result by chance). Test scores are accompanied by confidence intervals; for example, a score of 103 might have a 95 percent chance of falling between 94 and 112. Test discrepancies can be calculated at different confidence levels; for example, a discrepancy might be selected because it has a 1 chance in 100 (0.01) rather than 5 chances in 100 (0.05) of occurring at random.

There are different ways of describing a child's placement in large populations, the most common of which are standard scores and percentiles. It should be noted that there are different kinds of scores and values within the normal distribution, and that they differ by mean and dispersion. (See Fig. 7.4–6 which depicts Z, T, and IQ scores, as well as rounded percentiles under the "bell" curve.) While standard scores (such as those with a mean of 100) can be informative, parents often respond well to the concept of a percentile. For example, a student who falls at the 68th percentile performs as well as or better than 68 percent of the children tested. In addition to percentiles and standard scores, many cognitive tests provide age equivalents or grade equivalents. These measures suggest how the child compares to others of his or her age or grade. Age scores note years and months (e.g., 4–6, for "4 years, 6 months"), whereas grade scores note basically monthly progress within the academic year (e.g., 5.2, for "fifth-grade, 2 months," or 2/10 into the school year).

Beyond Scores and Tests

It should be noted that the testing process involves more than scores. Although scores are important, how the patient goes about solving

cognitive problems also is carefully observed. The examiner is interested not only in test performance, but also in the client's reaction. It is important to the psychologist to note how the client arrives at right as well as wrong answers and to explore the client's cognitive strategies on tasks. In general, it is important to note whether the client responds in a deliberate or impulsive way. It also makes a difference to the examiner whether the child says "This is easy" as he or she fails or laments "Oh this is hard" as he or she succeeds. Both have to been seen and give the examiner a very different sense of how the client will experience school and life.

In addition, the testing process is not separate from the therapeutic process. Well-handled testing can become an extension of the treatment. Feedback about results and their relationship to the presenting problems can be provided as the evaluation unfolds. Often this discussion is among the first opportunities the parents have had to understand the patient's predicament in a sympathetic way and to begin a constructive process. It can be helpful for the family to comprehend the patient's difficulties as a natural outgrowth of problems with understanding and learning, so long as practical interventions and solutions are provided.

COGNITIVE AND NEUROPSYCHOLOGICAL ASSESSMENT

The present discussion describes both general cognitive assessment and focused neuropsychological assessment. Because the purposes of the evaluations tend to differ, so do the instruments and the way in which they are used. The general cognitive assessment tends to be a descriptive and practical event with an eye to the policies and possibilities in the outside world. As a result, the cognitive tests tend to be "comprehensive" instruments. Here they are presented according to the type of instrument administered: intellectual, achievement, and processing. The very factors that make them useful for general assessment limit them when it comes to fine tuning understanding of neurobiological functioning. The neuropsychological instruments tend to be more "precision" tests that attempt to assess very specific behaviors that represent neural constructs in an inner world. Here the instruments are organized according to the domains assessed: Memory, attention, executive functioning, and language, as well as visuoperceptual and sensory/motor functioning. Even when the results are explored at more descriptive levels, functioning within the domains is not seen as separate or independent of their neurobiological underpinnings.

Although the focus here is on the assessment of cognitive functioning and neuropsychological domains, depending on referral issues, the evaluation might also address behavioral, social, and emotional issues using a variety of techniques. In general, psychological assessments/reports might be identified based on the realm of concern—for example, psychoeducational assessment (diagnostic issues involving

academic difficulties) or psychodiagnostic evaluation (referral issues independent of school problems), or based on the professional undertaking the assessment (such as a neuropsychological assessment undertaken by a neuropsychologist). Psychological results might be approached from a descriptive or diagnostic point of view; that is, the clinician might simply try to convey how the patient is functioning and why, or might additionally try to characterize the patient's functioning in categorical terms. The terms might be legal, as in the case of the Individuals with Disabilities Education Act (IDEA) in relation to school systems, or clinical, as in the case of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) in mental health settings. In any event, psychological assessment of all kinds can add texture and detail to the understanding of a patient's referral complaints, especially around the possible effect of processing deficits. Specific information about processing problems (how the child perceives his or her experience and monitors his or her behavior, and therefore responds to his or her situation) can help adults to know better how to interact with the child, as well as plan appropriate educational and interpersonal interventions. Basic information about overall cognitive functioning (based on intellectual, achievement, and processing instruments), as well as neuropsychological functioning (based on assessment of the functional/neurobiological domains), as they are integrated with other assessment data addressing referral issues can help to clarify diagnosis, which in turn can help to clarify issues around medical, school, behavioral, and therapeutic possibilities.

In the context of a focus on general cognitive and neuropsychological assessment, what is of interest is that many of the same processing and learning factors that can affect academic functioning can also affect social/emotional functioning. These factors can include everything from selective attention, memory function, sequential processing, and planning ability to fluid reasoning and self-regulation. These factors can affect the ability to assimilate, track, interpret, and organize experience in school, with others, and in life.

In general psychological practice, the kind of cognitive assessment described here is particularly suited for the evaluation of learning issues as they affect school functioning. In the context of this section, social/emotional issues are seen from a "cognitive point of view" and how processing problems can affect social/emotional functioning. However, cognitive tests in the context of a full psychological evaluation would shed good light on a range of referral issues and provide a rich source of information about the patient's functioning. All the same, there are times when what is needed is a neuropsychological assessment (which uses diverse assessment and testing techniques) provided by a clinical neuropsychologist with advanced training and expertise in neuropsychology. This is true when a known neurological condition, such

as seizure disorder or head injury, is involved. This can also be true when diagnostic issues become particularly complex. Neuropsychological testing might be indicated or helpful when the identification of known neuropsychological circuits might contribute to diagnostic clarity; a systematic assessment of a functional hierarchy might allow for a complex skill to be broken down into its component parts; specific neuropsychological tests might help to clarify strengths and weaknesses in cases at the higher and lower intellectual ranges; or when serial testing is desired while reducing the possibility of practice effect.

In any case, basic neuropsychological concepts have suffused psychological testing, with commonly administered instruments allowing for the assessment of specific processes such as working memory or general constructs such as executive functioning (goal-directed or planned behavior). Furthermore, once the quantitative data are gathered, they mean nothing without a qualitative interpretation, as well as a conceptualization and presentation that helps to make sense of the child client to his or her caretakers.

It should be noted that tests are constantly updated. This is often undertaken to correct perceived shortcomings, to adjust for cohort changes, and to make instruments more relevant. Because of this, instruments are referred to in "generic form" in this text, without any notation that would identify the edition. However, in actual practice, it is important to know that the clinician has used the most up-to-date version of the test, unless there is a good reason not to. For example, some clinicians with specialized practices continue to use old editions (or subtests) of instruments because they find that particular instruments or tasks best meet the needs of their particular population or best answer a type of diagnostic question. (American Psychological Association guidelines require that basically the tests used to make interpretations or recommendations are not outdated or obsolete for the "current purpose.") Clinicians must select from among the available tests the one that seems to best meet the needs of any particular client. Tables 36.3–1 and 36.3–2 note the editions of tests that are current as the present text goes to press.

GENERAL COGNITIVE ASSESSMENT

Cognitive and neuropsychological assessment can be looked at from different perspectives as clinicians attempt to understand referral questions and individual children. Generally, cognitive testing can be addressed in terms of psychoeducational and psychodiagnostic evaluation. However, the combination of intellectual, achievement, and processing testing has commonly been given as part of psychoeducational assessment and to determine the cause of learning problems, as well as, at least in the past, to establish eligibility for services with public schools. The processing instruments may have clinical, as well as educational, applications. As do a

range of psychologists, neuropsychologists commonly administer the intellectual and achievement tests described. They might give some of the processing tests; however, in their exploration of brain–behavior relationships, they usually use more precise instruments.

Description of Cognitive Tests

Although psychologists use diverse tests, three kinds of cognitive testing are described in this subsection: intellectual, achievement, and processing instruments. Whereas some tests are labeled "processing" instruments, all of these tests can be seen in terms of a simple (simplistic) input–output model, with processing mediating the outcome. With various elaborations (the visual input might be text) or exceptions (the task might involve movement), most standardized tests involve the assessment of auditory or visual input and verbal or motor output. Generally, intellectual tests are thought of as measures of overall mental ability and processing tests are thought of as measures of discrete cognitive functions. However, they overlap in that they make varying demands on learning based on past exposure as it interacts with current cognitive strategies in situations that vary in terms of familiarity and novelty. Both kinds of tests can be seen in "processing" terms in that patterns of responding can emerge from the data that reflect not only on school but interpersonal and adaptive functioning. Achievement tests systematically assess past academic learning. Clinicians understand the results are affected by a wide variety of educational opportunities and impacted by a large variety of co-morbid conditions. Once disadvantageous conditions such as sensory disorder and intellectual disability, and, increasingly, lack of appropriate/adequate instruction have been ruled out as primary causes of academic difficulties, academic shortfall has commonly been attributed to processing problems. These can include everything from discrete cognitive functions such as phonological processing to more general mental constructs such as executive functioning. In fact, good basic processing, the ability to successfully use a wide variety of cognitive strategies in a wide variety of tasks, has commonly been thought to support intellectual level and academic success.

When it comes to learning problems, educational research has suggested just how complicated the identification of learning difficulties is, while recognizing the need to define them in order to provide services to children, particularly in school. Descriptions and definitions of learning deficits have recognized disparities in different aspects of functioning, and tried to parse out factors intrinsic to the child and specific to learning from aspects of their environment and experiences. Procedural definitions of learning disorders under DSM in the medical community and of learning disabilities under IDEA in the public schools have tried to grapple with this complexity. As a practical matter, both have generally focused on the concept of "unexpected underachievement."

When it comes to learning disability, what is at stake is the opportunity for a patient to obtain services through school at no cost to the family. Otherwise it falls to the family to obtain private educational therapy in the community. In schools, students might obtain targeted classroom instruction in areas of weakness, or some intervention through a student study team, or accommodations or modifications in class through informal 504 procedures. However, students are apt to receive more extensive and expensive services under IDEA, through more formal IEP (Individualized Education Program) procedures that identify and make recommendations around disabilities, including specific learning disability. (See Table 36.3–3 on education and law.)

Table 36.3–1. Cognitive Tests

Test	Age Range	Description
Intellectual tests		
Omnibus intellectual and ability tests		
Wechsler Preschool and Primary Scale of Intelligence–Fourth Edition (WPPSI-IV) Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V) Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV) Stanford–Binet Intelligence Scales–Fifth Edition (SB5) Kaufman Assessment Battery for Children–Second Edition (KABC-II)	2 years, 6 months–7 years, 7 months 6 years–16 years, 11 months 16 years–90 years, 11 months 2–85+ years 3–18 years	The tests consist of several subtests that can be combined in different ways to understand basic intellectual functioning. The Wechsler tests yield a full-scale intelligence quotient (IQ) score, as well as overall scores within the verbal and nonverbal areas. There are ways of grouping subtests of the Wechsler instruments to distinguish between more verbal versus perceptual reasoning, as well as to measure working memory and processing speed. Because of its age range, the WISC is probably the most familiar of the Wechsler tests to child clinicians. The most recent WISC provides a full scale IQ, and five primary index scales in verbal comprehension, visual spatial, fluid reasoning, working memory, and processing speed. It provides additional ancillary and complementary index scales. The SB also provides full scale as well as verbal and nonverbal IQ scores. In addition, it provides factor indices in fluid reasoning, knowledge, quantitative reasoning, visual–spatial processing, and working memory. The KABC scales and their subtests (which minimize verbal instructions and responses) include measures of sequential and simultaneous processing, fluid reasoning and crystallized ability, and long-term retrieval. Many, if not most, cognitive tests (including intellectual, achievement, and processing) are structured in the same way (mean is 100, standard deviation is 15), and so results can be compared across instruments. This is particularly important in identifying

		learning problems.
Infant and child tests		
Gesell Developmental Observation-Revised (GDO-R) Bayley Scales of Infant and Toddler Development–Third Edition (Bayley III) Mullen Scales of Early Learning (MSEL)	2.5–9 years 1–42 months Birth–68 months	The Gesell is an "old" test that is still administered by medical professionals, as well as psychologists. Along with the Bayley III, the GDO-R is as useful for its opportunities for observations as it is for its scores. Both can be helpful in the identification of children at risk for developmental delay. The MSEL, with its five scales (Gross Motor, Visual Reception, Fine Motor, Expressive, and Receptive Language), is often valued in assessing readiness for school, as well as in identifying specific interventions for children with developmental disabilities.
Nonverbal and language-free tests		
Leiter International Performance Scale–Third Edition (Leiter-3) Test of Nonverbal Intelligence–Fourth Edition (TONI-4) Comprehensive Test of Nonverbal Intelligence, Second Edition (CTONI-2) Wechsler Nonverbal Scale of Ability (WNV) Raven's Progressive Matrices	3–75+ years 6 years–89 years, 11 months 6 years–89 years, 11 months 4 years–21 years, 11 months 5–17+ years	Although the nonverbal tests are often seen as language or culture free, strictly speaking, this is not always true because of representational content or language demands. However, some nonverbal tests (such as the TONI-4) depend more on abstract pattern recognition and can make fewer demands on language systems. The WNV provides batteries for younger (4–7:11) and older clients (8–21:11), and claims to be a general ability measure using nonverbal tests. Tests like Raven's Progressive Matrices (which actually come in several forms) are based on pattern recognition and thought of as "culturally reduced," if not unbiased or unloaded. Nonverbal tests can be useful in assessing individuals whose experience falls outside the "cultural norm."
Quick tests		
Kaufman Brief Intelligence Test–Second Edition (KBIT-2) Wechsler Abbreviated Scale of Intelligence-Second Edition (WASI-II)	4–90 years 6 years–90 years, 11 months	Although the KBIT and WASI include verbal and nonverbal scores, they do not include as much information as more comprehensive intellectual tests. However, they provide an estimate of intellectual level in a fraction of the time.
Achievement tests		
Wechsler Individual Achievement Test–Third Edition (WIAT-III) Woodcock-Johnson Tests of Achievement-Fourth Edition (WJ-IV ACH) Kaufman Test of Educational Achievement–Third Edition (KTEA-3) Wide Range Achievement Test–Fourth Edition (WRAT4) and WRAT-Expanded (WRAT-E)	4 years–50 years, 11 months 2–80+ years 4 years–25 years, 11 months 5–94 years 4–24 years (Indiv.)	The WRAT has traditionally been seen as a screening instrument. The WRAT4 includes subtests on sentence comprehension, word reading, spelling, and math computation. An expanded version (WRAT-E) provides achievement and intellectual information (nonverbal reasoning). The KTEA assesses reading (decoding and comprehension), mathematics, spelling, and written expression. The WIAT and WJ-ACH also systematically address the basic areas that have been identified as relevant for learning disability.

Reading tests		
Gray-Oral Reading Tests–Fifth Edition (GORT-5) Woodcock Reading Mastery Tests–Third Edition (WRMT-III) Comprehensive Test of Phonological Processing-Second Edition (CTOPP-2)	6 years–23 years, 11 months 4 years 6 months–79 years, 11 months 4 years–24 years, 11 months	The WRMT (which includes a measure of listening comprehension) and GORT (which includes a measure of fluency) involve systematic approaches to assessing different aspects of reading skills. Because of the importance of phonological awareness in the development of reading skills, tests of phonological processing (such as the CTOPP) are often included in assessments in which reading problems are identified.
Processing tests		
General processing tests		
Woodcock-Johnson–Fourth Edition Tests of Cognitive Abilities (WJ-IV COG) Differential Ability Scales-Second Edition (DAS-II)	2–80+ years 2 years, 6 months–17 years, 11 months	The WJ-COG scores provide information about intellectual ability, as well as a variety of cognitive and clinical areas. The WJ-COG is co-normed with the WJ-ACH, and the new test of oral language (WJ-OL). The DAS provides a measure of general conceptual ability and a profile of cognitive strengths and weaknesses.
Specialized tests		
A Developmental Neuropsychological Assessment-Second Edition (NEPSY-II)	3 years–16 years, 11 months	Scored across six domains, the NEPSY provides scores in executive functioning/attention, language, sensorimotor, visuospatial, and memory/learning, and social perception.
Delis-Kaplan Executive Function System (D-KEFS)	8 years–89 years, 11 months	As a test of executive functions, nine stand-alone subtests assess cognitive flexibility, response inhibition, problem solving, and concept formation.
Visual–motor tests		
Bender Visual–Motor Gestalt Test–Second Edition (Bender-Gestalt II) Beery Developmental Test of Visual–Motor Integration–Sixth Edition, Revised (VMI-6) Test of Visual Perceptual Skills–Third Edition (TVPS-3)	4–85+ years 2 years–99 years, 11 months 4 years–18 years, 11 months	Both the Bender and VMI involve copying geometric figures. Because the Bender allows the student to organize the items on the page and the VMI asks the student to copy each figure in its own space, the two can be used together to assess organizational issues, as well as visual–motor integration. Both the current versions of the Bender and VMI provide ways of assessing perceptual separate from motor skills. The TVPS is motor free and involves making judgments about visual information—for example, a client might be asked to identify an item from a fragmented presentation.
Auditory–vocal tests		
Test of Auditory Processing Skills–Third Edition (TAPS-3) Test of Auditory Reasoning and Processing Skills (TARPS)	4 years–18 years, 11 months 5–14 years	The TAPS involves making judgments about auditory information. For example, the student might be asked to discriminate sounds or remember words or numbers under different constraints. The TARPS measures the “quality” and “quantity” of the client’s auditory thinking and reasoning.

Memory tests		
Wide Range Assessment of Memory and Learning–Second Edition (WRAML2)	5–90 years	Memory scales attempt systematically to assess memory skills within different spheres. The WRAML core battery consists of Verbal, Visual, and Attention/Concentration subtests. The CMS allows for the assessment of attention and working memory, verbal and visual memory, short-delay and long-delay memory, recall and recognition, and learning characteristics.
Children's Memory Scale (CMS)	5–16 years	
Social cognition		
Test of Problem Solving	6–12 years	Elementary and adolescent clients are asked to answer questions about pictures or scenarios to reveal social reasoning.
TOPS-3 Elementary	12–17 years	
TOPS-2 Adolescent	6 years–18 years, 11 months	
Test of Pragmatic Language-Second Edition (TOPL-2)		A test of language used to achieve goals, with information about six areas (setting, audience, topic, purpose, cues, and abstraction).

Publishers are constantly updating their tests, and these editions will be superseded by newer and better tests. Even now, there may be variations of some instruments that are supplemented, expanded, or newly normed.

Over the years, the basic definition of learning disability as "unexpected underachievement" has remained, but with new understanding and meaning. In this context it should be emphasized that there are two different systems for identifying learning problems: currently Specific Learning Disabilities in school settings and Specific Learning Disorders in clinic settings. For many years, learning disabilities and disorders were essentially interchangeable because of their focus on a severe or substantial (significant) discrepancy (typically one standard deviation or more) between ability and achievement. However, educational and medical definitions of learning deficits under IDEA and DSM, respectively, have changed.

In schools, current IDEA 2004 language forbids states to present a severe discrepancy model to local educational agencies as the only option, and indicates they must allow for other possibilities. Underachievement may be identified in several areas (focusing on reading, mathematics, and written expression). Basically, this can be based on failure to respond to research-based intervention as other students have, or the identification of a pattern of weaknesses in the context of strengths that indicates specific learning disability. Still, under this system, a severe discrepancy between ability and achievement might be identified as evidence of a pattern of strengths and weaknesses indicating the educational diagnosis. However, it can be seen there are potentially several ways of demonstrating learning disability in schools.

In clinics, under DSM-IV (1994) the discrepancy model remained essentially intact until DSM-5 in 2013, when the definition for learning disorder shifted and dropped the discrepancy between achievement and

ability. The new definition focuses on absolute academic deficit, and stipulates two basic requirements. The first requirement is that the learning difficulties have persisted for at least 6 months, "despite the provision of interventions that target those difficulties." The second requirement is that academic skills (in reading, written expression or mathematics) should be "substantially and quantifiably below those expected for the individual's chronological age," and cause significant interference with related activities, "as confirmed by individually administered standard achievement measures and comprehensive clinical assessment." The new definition also requires two additional factors: that the learning difficulties begin in the school-age years although they might not become manifest until later; and that the learning difficulties are not better explained by other issues, such as intellectual disability, other disorders, or inadequate instruction. The exact deficit level associated with the learning disorder might be left to the clinician's judgment, but the threshold is thought to be between 1 to 2.5 SD below the population mean (100), depending on the circumstances of the case. A 1 SD standard would fall at or below 85 (16th percentile); this might be sufficient for diagnosis "with converging evidence." A 1.5 SD standard would fall at or below 78 (7th percentile); this level is thought to provide "more diagnostic certainty." Specific learning disorder is an umbrella term, but impairments can be specified in the three academic areas, and can involve efficiency as well as accuracy. Severity of the disorder can be specified from mild to severe. The clinical standard for learning disorder might be seen as stricter (if not clearer) than the school standard for learning disability.

Table 36.3–2.
Neuropsychological Test List (Selected)

Memory and Learning

Verbal

- California Verbal Learning Test for Children (CVLT-C)
- Children's Auditory Verbal Learning Test
- Children's Memory Scale (CMS): Stories, Word Pairs, Word Lists
- NEPSY: Memory for Names, Narrative Memory, List Learning

Wide Range Assessment of Memory and Learning (WRAML): Story Memory, Sentence Memory, Verbal Learning

Nonverbal/Visual

- Benton Visual Recognition Test
- CMS: Dot Locations, Faces, Family Pictures
- NEPSY: Memory for Faces, Memory for Designs
- Rey-Osterrieth Complex Figure, delayed conditions
- WRAML: Design Memory Picture Memory, Visual Learning

Attention

Sustained Attention/Vigilance

Continuous Performance Tests (CPT): AX Version of the CPT; Connors Continuous Performance Test

(CCPT), Tests of Variables of Attention (TOVA)
NEPSY: Auditory Attention and Response Set, Visual Attention
Paced Auditory Serial Addition Test (PASAT)
Working Memory
Auditory Consonant Trigrams (ACT)
CMS: Numbers, Sequences
Wechsler Intelligence Scale for Children (WISC): Digit Span, Letter-Number Sequencing, Arithmetic, Spatial Span
WRAML: Finger Windows, Number/Letter Memory, Sentence Memory
Inhibition/Impulse Control
Delis-Kaplan Executive Functions System (D-KEFS) Color Word Interference (Inhibition)
Go/No Go Test
NEPSY: Auditory Attention and Response Set, Inhibition (Inhibition), Knock and Tap
Executive Functioning
Organization/problem solving/planning
Children's Category Test
D-KEFS: Sorting, Twenty Questions, Tower
NEPSY: Animal Sorting, Clocks
Rey-Osterrieth Complex Figure, Copy condition
Cognitive flexibility/Set shifting
Children's Color Trails
D-KEFS: Trails (Number-Letter Switching), Verbal Fluency (Category Switching), Design Fluency (Switching), Color-Word Interference (Inhibition/Switching)
Matching Familiar Figures Test
NEPSY: Inhibition (Shifting)
Trail-making Test A and B
Wisconsin Card Sorting Test
Fluency
Controlled Word Association Test
D-KEFS: Verbal Fluency, Design Fluency
NEPSY: Word Generation, Design Fluency
Language
Expressive
Boston Naming Test
Clinical Evaluation of Language Fundamentals (CELF): Word Structure, Recalling Sentences, Formulated Sentences, Word Classes-Expressive, Expressive Vocabulary, Sentence Assembly
Expressive One Word Picture Vocabulary Test
NEPSY: Sentence Repetition, Speeded Naming
Test of Language Competence (TOLC): Ambiguous Sentences, Oral Expression
Woodcock Johnson (WJ): Picture Vocabulary, Rapid Picture Naming
Receptive
CELF: Sentence Structure, Concepts and Following Directions, Word Classes-Receptive, Semantic Relationships, Understanding Spoken Paragraphs

NEPSY: Comprehension of Instructions
Peabody Picture Vocabulary Test
Token Test
TOLC: Listening Comprehension, Figurative Language
WJ: Story Memory, Understanding Directions, Oral Comprehension, Auditory Attention

Visuoperceptual/Visuomotor Functioning

Visuoperceptual

- Benton Facial Recognition
- Benton Judgment of Line Orientation
- Hooper Visual Organization Test
- Motor-Free Test of Visual Perception
- NEPSY: Arrows, Geometric Designs, Picture Puzzles, Route Finding
- Test of Visual Perceptual Skills

Wide Range Assessment of Visual–Motor Abilities (WRAVMA): Matching

Visuomotor functioning

- Beery Developmental Test of Visual–Motor Integration
- NEPSY: Block Construction, Design Copying
- Rey-Osterrieth Complex Figure, Copy
- WRAVMA: Drawing
- WISC: Block Design

Sensorimotor Functions

Sensory perceptual

Dean-Woodcock Sensory Motor Battery (DWSMB) (All sensory subtests)

- NEPSY: Finger Discrimination
- Reitan-Klove Sensory Perceptual Exam

Motor

- DWSMB: All motor subtests
- Grip Strength (Hand Dynamometer)
- Grooved Pegboard

NEPSY: Fingertip Tapping, Imitating Hand Positions, Manual Motor Sequences, Visuomotor Precision

- WRAVMA: Pegboard

The individual intellectual, achievement, and processing tests described in this section have been staples in assessing learning problems in the private as well as public sector over the years. However, their uses may be somewhat different in the present than in the past (and in the future) due to new educational and psychological research, and new legal and medical definitions. Despite recent changes in how specific learning disabilities and disorders are identified, the long legacy of these definitions of learning problems (and learning disability in particular) has impacted the way basic intellectual and academic tests have been developed over the years.

Table 36.3–3. Education and the Law: Students with Disabilities

Students with Disabilities

The federal government has protected the rights of students with disabilities since the 1970s under a series of public laws. In 1990, the 1975 Education for All Handicapped Children Act was renamed the Individuals with Disabilities Education Act (IDEA). Reauthorized in 1997 and in 2004, IDEA establishes the obligation of public school systems to provide a free appropriate public education (FAPE) in the least restrictive environment (LRE) to students with disabilities who “by reason thereof” (because of them) need special education and related services. What constitutes a free appropriate public education is determined on a case-by-case basis by Individualized Education Program (IEP) teams

and, if necessary, by administrative hearing officers and courts. The "least restrictive environment" refers to the right of students to be educated to the maximum extent appropriate in typical settings and alongside nondisabled peers. The issue of eligibility is established through a set of procedures established under IDEA, which involves an evaluation process and a team meeting, which culminates (if the student is found eligible as a student with a disability) in a written IEP. This series of events is sometimes referred to informally as the "IEP" process/team. A number of disabling conditions are specifically identified in IDEA law/regulations, including (in addition to sensory and orthopedic impairments) intellectual disability, speech or language impairments, serious emotional disturbance, autism, traumatic brain injury, other health impairments, and specific learning disability.

In general, three conditions need to be met for a student to be found eligible for special educational services: (1) The student needs to be found to have one of the several disabilities listed in IDEA, (2) the disability must adversely affect educational performance, and (3) the student must require special educational services, that is, "specially designed instruction." At this point, it should be emphasized that assessment is not identical with testing, and that in establishing eligibility for special educational services, schools "must" use a "variety of assessment tools and strategies to gather relevant, functional, developmental and academic information" about the student, including information provided by the parent(s). The evaluation process involves multiple forms of assessment of the disabilities for which the student might need/receive special educational services. However, the assessment process is usually focused on the issues of concern to the parents and school, and parents have an opportunity to approve the procedures to be used, subject to due process rights. School assessment usually involves some kind of testing, but other sources of evaluation (history, observations, ratings) are also important. The purpose of the assessments is to define not only academic but also functional and developmental needs that result from the child's disability. Not only must the school's assessment for disability employ a variety of techniques, but such assessments may be provided for reasons other than academic failure, and schools may not deny services because a disability is not reflected in typical ways (such as failing courses or grade retention).

Specific Learning Disabilities

According to language provided in 1997 and retained in IDEA 2004, a specific learning disability is defined as a disorder in "one or more of the basic psychological processes involved in understanding or in using language, spoken or written," that "may manifest itself in imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations." There are circumstances under which a learning disability cannot be designated—for example, when the academic problem has primarily been due to another problematic condition such as intellectual disability or emotional disturbance.

In the past under IDEA requirements, learning disabilities eligibility has been determined by establishing a severe discrepancy between intellectual ability and academic achievement in one of seven academic areas. The academic shortfall was explained by a processing problem (such as sequential visual memory, attention deficits, or an auditory processing problem), which was established by inclusion or exclusion. There have been a number of changes, and the academic areas now number eight, with slight changes in terminology, but with major changes in procedures.

Prior to 2004, the DSM criteria for learning disorders in mental health centers closely paralleled the IDEA procedures for identifying learning disabilities in schools. Both emphasized the discrepancy between intellectual ability and academic achievement. Interestingly, what have been regarded as exclusionary factors in public schools have been regarded as aggravating factors in medical centers. In research, some have increasingly been understood as co-morbid conditions associated with learning difficulties. All the same, despite differences in meeting criteria between public schools and medical offices, the correspondence between these two systems (learning disorders under DSM and learning disabilities under IDEA) may have made communication between professionals outside and inside of school systems somewhat easier. However, changes to IDEA in 2004 made communication around learning problems more complicated. Then in 2013, the DSM-5 was modified in an attempt to reduce the inconsistency between medical and educational handling of learning disorders and disabilities, respectively. All the same, the situation has remained complex.

While DSM-IV still described learning disorder in terms of discrepancy between ability and achievement, IDEA 2004 changed the way students in public schools might be identified with

learning disability in specific academic areas. The changes under IDEA came about because of the experience of professionals in school systems. In schools the discrepancy model has increasingly been experienced as a "wait-to-fail" approach, because students have often fallen behind, sometimes as much as two years, before being found qualified for services. Instead, based on educational research, policy makers have come to value a "response-to-intervention" (RTI) model, which calls for services to be provided for the student before the student is identified as learning disabled, and as soon as screening indicates they are lagging behind. This approach involves ongoing and systematic assessment (on curriculum-based measures), and intervention occurs in a number of steps (through a series of tiers). This takes place first in the context of general education and curriculum, and only subsequently through more targeted, intensive and individualized instruction, but still within the general education class placement. This approach has been adopted in the context of a general commitment to teaching reading (and with the knowledge of the importance of early intervention), but interest and expertise have been growing in other curricular areas and at higher grade levels. Under federal regulations, this RTI approach has been presented not just as an instructional technique, but potentially as part of the process of determining if a student has a specific learning disability.

As of the reauthorization of IDEA in 2004 (which came into effect in 2005, with regulations following in 2006) the procedures for determining eligibility around learning disability have changed.

When it comes to establishing criteria for specific learning disability, (1) a state must not require a severe discrepancy between academic achievement and intellectual ability in specific academic areas, and (2) the state must permit the use of a process based on scientific, research-based intervention. The IDEA regulations open up a third way of identifying specific learning disability, based on "other research-based procedures." This last option is not well understood, and seems merely to increase the discretion of the IEP team. The chosen options must be adopted in a manner consistent with other regulations/guidelines, including the procedures described below.

According to the current regulatory language (which can change), there are three components to being identified as learning disabled. (Please see http://idea.ed.gov, Part B, as well as www.greatschools.org). First, there are inclusionary criteria: The student shows underachievement (based on age and/or grade) in one of eight academic areas (oral expression, listening comprehension, written expression, basic reading skill, reading fluency skills, reading comprehension, mathematical calculation, and mathematics problem solving) when provided with appropriate learning experience and instruction. The second component contains the procedures for evaluating eligibility. Under the new regulations, two basic factors come into play in considering learning disability eligibility: (1) insufficient progress to meet grade/age standards when using a process based on scientific, research-based intervention, and (2) an option that considers patterns of strengths and weaknesses in performance and achievement relevant to the identification of a specific learning disability using appropriate specific and general assessment. This reference allows for many ways of determining that the student is not meeting expectations according to age or grade standards or intellectual development. The third component involves exclusionary criteria, such that the learning deficit is not primarily the result of visual, hearing, or motor disability, intellectual disability, emotional disturbance, cultural factors, environmental or economic disadvantage, or limited English proficiency. Lack of appropriate instruction in math and reading is also considered in the evaluation process; students who are academically weak because of school failures should not be labeled as having a disability.

Just what the new possibilities mean and how states and school systems will respond are in flux, creating opportunities and challenges in helping families to meet the needs of students.

Impacts on Assessment

Given the ambiguities in several interacting requirement systems, it is difficult to provide definitive information about how professionals should proceed in diagnosing learning problems in order to meet the needs of patients in the schools as well as the community. However, a number of observations can be made that are relevant to interpreting and meeting guidelines for specific learning disabilities in schools and specific learning disorders in clinics, and communicating between the two settings.

Under IDEA regulations pertaining to the identification of specific learning disability that might allow for special educational services, the first identification option (above) is understood as a reference to response-to-intervention (RTI). The evaluation process might involve data about low academic performance as well as monitored progress. Models for this option are not defined by regulation, but are formulated at state and local levels. Whether further testing using norm-referenced and individual instruments is needed as part of the eligibility decision around special education is a matter of debate. The second identification option regarding strengths and weaknesses (S/W) might be seen as framing alternative research-based and severe-discrepancy procedures. In the case of a discrepancy model, it is possible, for example, that professionals will need to demonstrate the diagnostic significance of any discrepancy/weakness and will be encouraged to identify any strengths that might facilitate intervention. While testing is not necessarily implicated, the S/W option would likely involve establishing a pattern of academic strengths and weaknesses between and within tests. There is some debate regarding whether contrasts within a cognitive test (such as high verbal comprehension versus low perceptual reasoning) instead of between or within achievement tests (such as high math and low reading) might be relevant. There are a great many ambiguities and uncertainties about how these regulations might be understood and implemented at state and local levels, and systems often fail to provide clear descriptions of the criteria they employ.

Further, communication between schools and clinics has been complicated not only by previous changes in the definition of learning disabilities under IDEA in 2004, but also by recent changes in the definition of learning disorders under DSM in 2013. Shifts in definition in both schools and clinics will have a variety of impacts on assessment.

Under DSM-5, individuals can be identified with specific learning disorder with impairments in reading, written expression, or math if they show persistent deficits "despite the provision of interventions that target those difficulties," and achievement "substantially and quantifiably below those expected for the individual's chronological age." This definition is very different from the learning disorder designation under the earlier DSM-IV in clinics (which mirrored the schools' ability/achievement discrepancy model) as well as somewhat different from the current IDEA 2004 learning disability definition in schools (which might involve patterns of discrepancies between different areas of achievement and/or between ability and achievement, or which might involve failure to respond to intervention). Currently school settings might offer more options for identifying learning disability than clinic settings do in identifying learning disorders, which seem focused on absolute deficit when looking at achievement and age. The main complications in practice are created by the requirement that deficits persist for 6 months despite targeted interventions. This stipulation introduces a possible ambiguity in the diagnosis, in that it would be commonly be the obligation of public schools to provide services and interventions although the diagnosis of learning disorder is made separately in clinic facilities.

Since the introduction of DSM-5 in 2013, professionals have tried to reconcile it with IDEA 2004, and to gauge the impact of these changes on practice. Tannock (2013) notes that the diagnosis of specific learning disorders in clinics is currently not necessarily synonymous with the designation of specific learning disabilities in schools. She suggests that not all children with the educational diagnosis of specific learning disability would meet criteria for the clinical diagnosis of specific learning disorder, while it is likely that a youngster with a DSM-5 diagnosis of specific learning disorder would meet IDEA/2004 criteria for the educational definition of specific learning disability. She notes two practice shifts as a result of changing definitions around learning difficulties. Some shifts will take place because of the overarching category of specific learning disorder under DSM-5 (with impairments in three academic spheres). Other shifts will take place because of the abandonment of the IQ-Achievement discrepancy criterion, along with the omission of cognitive processing problems in the diagnostic criteria. She notes that in practice, psychologists may shift from what she calls "assessment for diagnosis" to "assessment for intervention." Tannock notes a third and related shift, which calls for evidence of symptoms over time and the use of a wider array of data that might be called upon to characterize low academic achievement.

In assessing learning problems and seeking services through school systems, clinicians need to be aware of the different vocabularies and criteria that school and clinics use for identifying learning problems. In this context, it should be noted it is always possible that if the student is not found eligible for

special educational services under specific learning disability, they might be found eligible under one of the other designations, for example other health impairment (which can cover attention-deficit/hyperactivity disorder), speech and language impairment (which can impact aspects of academic learning), or autism (where learning problems can be associated with the diagnosis). Further, if the child does not qualify for special educational services under IDEA, they may qualify for support under Section 504 of the Rehabilitation Act of 1973.

If professionals wish to receive services for their child patients through schools, they should be aware of their instructional environment and how this might be related to assessment, as well as current state and local policies and procedures around disability eligibility in general, and learning disability in particular. In the past under the traditional discrepancy model, clinicians were advised to identify a processing problem associated with academic shortfall, in case it was a local requirement for specific learning disability. In the present given the various possible models that might be relevant, it might be wise to make it clear how diagnoses are impediments to progress in instruction, or shortfall is part of a pattern of strengths and weaknesses suggesting specific learning disability. It should be noted that IDEA is subject to re-authorization. At that time, the definition of learning disabilities and the procedures for identifying them can change. In fact, given the rhetoric around the last re-authorization, there may be some debate this next time about basic educational, definitional, and procedural issues. Up-to-date information can be obtained from http://www.copaa.org. It should also be noted that regardless of the model being used, it is ultimately up to the discretion of the IEP process/team to make findings around eligibility based on disability, and to recommend special educational services and placements. Any outside evaluation can be submitted to the IEP team; it must consider the results, but is not obligated to follow the recommendations. Once the special educational evaluation is underway, the opinion of outside professionals regarding learning issues becomes one data point among many in helping the IEP team decide whether the student is learning disabled and in need of special educational services.

It can be seen that changes within the school in providing instruction and evaluating learning disability will impact the way professionals see cognitive assessment that might be relevant to both community and school interventions. Regardless of the changes taking place, learning disability will still be understood in terms of “unexpected underachievement,” and this knowledge will guide the exploration of learning problems.

Provision of Services

At the end of the evaluation process, a decision about eligibility and services is made by the team that writes the IEP. The services might include special educational placements (such as resource support or special class assignment). The provisions might include classroom accommodations (adjustments in the way a student is taught and/or tested) or curricular modifications (adjustments in what the student is expected to learn). The IEP can also include referral to “related services,” such as counseling or language therapy to make it possible for the student to benefit from special education, or promote access to general education (curricula or peers). Furthermore, the IEP might include funding of services through an agency in the community (a non-public agency) or placement in a private special education school (a non-public school) to achieve FAPE.

In addition to IDEA and the IEP, there are also Section 504 protections and procedures established under the Rehabilitation Act of 1973, which is a philosophical spin-off of civil rights legislation of 1964 focused on issues of access. The Section 504 provisions cover individuals with a disability that “substantially limits” their ability to learn or to engage in another “major life activity.”

Although there is potentially some overlap and variability, the Section 504 procedures are potentially less formal than the IDEA and IEP process. The IEP involves an administrative meeting and is regarded as the most typical avenue for receiving special educational services such as resource teacher help, special class placement, and specialized interventions. In contrast, the Section 504 assessment can be very descriptive, and the evaluation process is less complicated and the meeting less formal than the IEP evaluation. However, the Section 504 process is designed basically to parallel the IEP process in terms of requirements for evaluation and placement, as well as a system of safeguards, for school children. Although it may be unclear that the Section 504 plan needs to be written, it would be prudent to do so to keep expectations clear. The interventions specified tend to

be accommodations/modifications that might benefit the student, such as seating toward the front of the room, extra time on tests, or adjustments in homework. However, services can also be required, depending on what is necessary in order to meet the student's needs as adequately as the needs of students without disabilities are met. The Section 504 procedure is a way of intervening with students with learning differences or problems who do not necessarily meet the strict criteria for disability under IDEA and its related regulations. Although some parents and schools prefer the Section 504 procedures because they can streamline getting help to a student, clinicians often prefer the IEP process because it includes more procedural protections than Section 504, and students found to be disabled through the IEP process are almost always covered under Section 504. As a result, clinicians have incentives for evaluating students to determine whether they have a learning disability and to pursue interventions (special services in addition to accommodations/modifications) through the IEP process. Although Section 504 procedures are thought of as less formal and interventions as less inclusive, like IDEA, Section 504's implementing regulations guarantee a free appropriate public education in the least restrictive environment—education that is provided to the maximum extent appropriate with nondisabled students. Affirmative services (such as speech-language therapy or even special educational placement) are also technically available through Section 504 procedures. In requesting school services, clinicians will need to consider whether pursuing interventions through 504 or IEP procedures would be "better" for their client.

How to Proceed

Whatever the disability in question, the starting point in receiving services for any student with school problems is to request an evaluation in writing from his or her home school. If the parent or guardian does not feel the evaluation team's recommendations will meet their student's needs, they can appeal the findings through a fair hearing (and opportunity for mediation) process. If they disagree with the district's assessment and the IEP team's findings, they may obtain an independent evaluation (before or after filing for fair hearing), which the district is required to consider and for which the district may be required to pay under certain circumstances. Independent evaluators generally have a right to observe students at school, and are most persuasive if they do so. Independent evaluators should seek teacher and school staff input orally and in writing. Practitioners who want their clients to receive services through the public school system should know the current state and local procedures that might apply to their assessment, eligibility, and services.

This discussion about educational law was prepared with the help of Maureen Graves, Attorney at Law. A practitioner with a client for whom legal issues will probably be important in obtaining special education services through the school district should consult an attorney or advocate (perhaps identified through the Council of Parent Attorneys and Advocates website, http://www.copaa.net). This discussion in no way constitutes legal advice.

Under the influence of definitions of learning disability that have emphasized the discrepancy between ability and achievement, it will be seen that many intellectual and academic instruments described here have been developed (perhaps co-normed) so as to facilitate this comparison. The tests assessing cognitive processing are quite varied, offering different ways of identifying and conceptualizing processing problems. Combined in different ways, the instruments described here can be useful in psychodiagnostic as well as psychoeducational evaluations. Because the focus of this subsection is not on learning disabilities or disorders but on cognitive assessment, a range of intellectual, achievement, and processing instruments and their uses are reviewed.

While intellectual and processing tests/subtests can be interpreted at "face value" they can also be assessed for "cognitive patterns" (perhaps in connection with projective tests) that might be relevant for social as well as

academic functioning. This enterprise depends on the same clinical judgment and skill (informed by research) that professionals bring to interpreting behavior in the history or observing the patient in the office. As a result, these intellectual, achievement, and processing tests are useful in the assessment of learning problems (such as SLD) as well as other complaints associated with disruptions in cognitive functioning and integration, such as Autism Spectrum Disorder (ASD) or Attention Deficit/Hyperactivity Disorder (ADHD).

Description of the General Applications of Cognitive Testing

Intellectual, achievement, and processing assessments are important in understanding learning and functional problems from a clinician's point of view. The instruments can provide useful information in exploring a wide range of referral issues, including psychoeducational and psychodiagnostic assessment, as well as neuropsychological assessment. However, each psychologist will select those instruments that meet the particular needs in any particular case. A full range of cognitive instruments and their uses are described in this section.

Intellectual Testing. Because of the importance of intellectual functioning as it affects the ability to learn and adapt in social and academic situations, intellectual testing is often part of a variety of psychological assessment batteries, including psychoeducational and neuropsychological evaluation, along with more general developmental and clinical evaluations.

BACKGROUND. Intellectual testing is usually undertaken to determine the patient's general intellectual level of functioning. The intelligence quotient (IQ) is valued because of its stability over time in the general population, as well as for the protective aspect of intelligence in a range of potentially disabling situations. It should be noted that, although intellectual level can be measured, it is hard actually to define intelligence.

Definition. Different theorists have had their own take on intelligence. Although, theoretically, Sattler saw intelligence as "multifaceted and hierarchically organized," practically, there is no agreement about what intelligence is, and this is reflected in the different ways in which it is measured. However, a commonsense definition of intelligence would include the ability to learn from and adapt to the environment. It would also include the ability to think abstractly (to use symbols and higher-level concepts) and to recognize patterns in diverse situations (on tests and in life). Although intelligence tests yield one IQ score (or several IQ or index scores), they are, in fact, devices for "sampling" many tasks in a variety of verbal and nonverbal areas. Intelligence tests differ from achievement tests

in that they are more process than content oriented. That is, for the most part, they put the student in a position in which he or she has to solve verbal or nonverbal problems in the present rather than use specific reading, mathematics, or writing skills learned in the past.

Stability. Although there is some disagreement, IQ scores tend to be relatively stable starting as young as 5 to 7 years of age. In general, the older the child is when tested and the smaller the interval between test administrations, the greater is the correlation between two IQ scores. Although using an IQ score can be useful as a way of assessing the client's basic trajectory through life, the prudent practitioner must be aware that there are a number of factors that can affect intellectual functioning and, thus, IQ scores. Factors associated with disorder and illness can suppress scores, particularly in psychiatric practice. These can include situational factors, such as lack of motivation, as well as transient factors, including inattention, depression, and psychosis. Some ongoing conditions (e.g., those that involve problems with relating, involvement, or cognition) can negatively affect learning and performance and potentially affect intellectual levels as well. In some cases, treatments and interventions implemented to improve cognition and development can improve functioning and, thus, IQ scores.

Protection. Despite conceptual and practical complications, high intelligence is associated with better prognosis in a wide range of psychiatric conditions; lower rates for behavior, conduct, and emotional problems in children; and lower rates of referral for psychiatric problems in adults. In the case of any kind of brain damage (neuronal death), intellectual level accounts for a great deal of variance in predicting outcome, with lower IQs associated with poorer outcomes and higher IQs associated with better outcomes.

ASSESSMENT. Although IQ is what is obtained with an IQ test, there are a variety of intellectual tests, as well as other ways of calculating intellectual level. There are a number of instruments from which to choose, and the psychologist must make his or her selection based on the specific characteristics of each test (e.g., normative sample and construction of the instrument) as they relate to the characteristics of the client (e.g., age and referral question). Once the test has been administered, the clinician must make interpretations based on the analysis of overall and subtest scores and their pattern in the context of the diagnostic process.

Sometimes, there are misinterpretations of scores at the bottom of the intellectual range. Distinctions must be made between level designations and diagnostic categories. Over the years professionals may have seen results from testing that suggest findings in the "intellectually deficient" or "mentally retarded" range. Over this period, even the description of

functioning within the mentally retarded range has not necessarily meant the client was diagnosed as mentally retarded. The diagnosis depended on other features of the case, including developmental course and adaptive functioning. The clinical terrain has shifted yet again with the change in DSM-5 diagnoses and language. The designation mental retardation has been replaced with intellectual disability, with less emphasis on IQ score alone. However, while intellectual level (IQ score) has been removed from the diagnostic criteria, they are still referred to in the text description. The term intellectual disability involves impairments in mental abilities that impact adaptive functioning in three domains (conceptual, social, practical). Severity of the disability is determined by adaptive level not intellectual score, because it is those impairments that determine the level of supports needed. It is hoped that the diagnostic change will encourage more comprehensive and complete assessment. However, it is important that measurement of intellectual level still be part of any individual's assessment, along with developmental course and adaptive deficits. Under DSM-5, intellectual disability is associated with intellectual levels two SD or more below the population mean, or an IQ score of about 70 or below. While in the past some agencies or regulations have referred to mental retardation as a population served or referenced, since Rosa's Law (2010) this designation has been changed to intellectual disability. In making determinations about low intellectual level, the psychologist must look at the pattern of strengths and weaknesses not only within the instrument, but also within the overall case presentation. For example, some IQ scores can be brought down by specific language disorders or perceptual–motor difficulties. One of the many reasons for looking for alternatives to the discrepancy model around specific learning deficits is that IQ can be seen as an outcome measure of the very same processes that are associated with academic shortfall.

Although the emphasis with intellectual testing has often been on overall intellectual "level," actually, IQ tests are very good for assessing processing, and contrasts can be made between not only composite scores but also subtest scores. The psychologist is very sensitive to the pattern of responding, with an eye to identifying strengths as well as weaknesses. For example, the psychologist might look at not only auditory–verbal versus visual–motor functioning, but also the complexity of demand for comprehension and expression on verbal tasks or the nature of any integrative problems within the perceptual sphere. There are many different ways of looking at processing issues within intellectual tests. Perhaps in part because of the way intelligence was initially understood and intellectual tests were historically constructed (particularly the Wechsler), there may have been a tendency to contrast two spheres of functioning. This might have involved comparing verbal versus nonverbal tasks or crystallized versus fluid reasoning. Or it might have involved

identifying language-based in contrast to nonverbal learning disorders. While these traditional ways of understanding intellectual functioning continue to be valid and useful, the understanding of "intelligence" itself has evolved, as have the instruments designed to detect it. For example, there has been an ongoing interest in concepts like crystallized versus fluid reasoning or intelligence. Crystallized intelligence has been associated with previously-learned information and fluid reasoning with on-the-spot problem solving. Traditionally these cognitive modes have been associated with verbal versus nonverbal functioning. However, over time, as the understanding of both intelligence and processing have evolved so have IQ tests. The changes in the Stanford–Binet and the Wechsler tests reflect developments in the understanding of intelligence in general, and crystallized and fluid reasoning in particular. As an example, the SB5 and the WISC-V both include verbal items in fluid reasoning options (e.g., verbal analogies or mental arithmetic, respectively). As a further example, on the SB5, the knowledge factor can be regarded as a measure of crystallized intelligence, and includes both verbal (e.g., vocabulary) and nonverbal tasks (e.g., procedural information and picture absurdities). In general, as understanding of these and other intellectual concepts has shifted, so have the ways instruments are designed to characterize intellectual functioning. As publishers have revised their intellectual instruments, there has been a tendency to produce more elaborate scoring systems and reporting options. While there are still ways of comparing things like basic verbal and nonverbal functioning, or crystallized versus fluid intelligence, how this might be done on both the Wechsler and the Stanford–Binet has changed. The scoring developments have served to give the clinician more flexibility in exploring basic processing and intellectual issues. Both the SB5 and WISC-V provide a full scale IQ, and additional scoring. The SB5 provides five factor scores that are comprised of both verbal and nonverbal subtests. The instrument also provides overall verbal and nonverbal IQ scores. The WISC-V provides five primary index scales, as well as eight ancillary and complementary scales. On both instruments there are ways for the clinician to assess things like verbal and nonverbal functioning, fluid and quantitative reasoning, visual–spatial processing, and working memory, but how this might be done is different on the two tests. Psychologists are sensitive to the pattern of responding within and among tasks and spheres, and the meaning of that pattern of strengths and weaknesses for functioning. Intellectual tests can be supplemented by a variety of instruments to further characterize any patient's presentation, in order to contribute to their understanding and diagnosis, and to help identify appropriate interventions. Going forward, "traditional" concepts (often dichotomies) will continue to be useful, but with "contemporary" understanding.

Comprehensive Intellectual Tests. The two best-known intellectual tests are probably the Wechsler Intelligence Scales and the Stanford–Binet Intelligence Scales (SB). The current editions of both are divided into separate subtests, and the data are analyzed in separate spheres. Each test has an overall mean of 100 (50th percentile) and a standard deviation of 15. Subtests have a mean of 10 and a standard deviation of 3. In the case of the Wechsler tests, three separate instruments (Wechsler Preschool and Primary Scale of Intelligence [WPPSI], Wechsler Intelligence Scale for Children [WISC], and Wechsler Adult Intelligence Scale [WAIS]) are designed for three different age groups over the lifespan. In the case of the SB, one instrument covers a lifetime. All instruments include full-scale IQ scores, as well as (broadly speaking) verbal and nonverbal composite scores. Both instruments have made attempts to assist in decision making regarding attentional problems. The SB provides an extended score range (at the top and bottom of the scale) that may make it more useful for individuals within the "gifted" and "impaired" ranges. The WISC anticipates providing a technical report with extended norms to differentiate highly gifted children. Both the SB and the Wechsler tests have been the "standard" individual intellectual tests for the school-age population. They allow for the assessment of overall functioning and verbal and nonverbal reasoning, as well as of some processing. Both instruments have taken care to relate to achievement tests to facilitate the recognition of learning disabilities according to a "traditional discrepancy model" in which estimated ability is compared to academic achievement. Such comparisons are still relevant to the identification of learning disabilities, where a discrepancy between ability and achievement might be evidence of a pattern of strengths and weaknesses suggesting learning disability (where another might be a pattern of academic strengths in one area in contrast to academic weaknesses in another). The new definition of learning disorder makes intellectual testing less immediately relevant, in that the emphasis is on absolute deficits in academic subjects (although intellectual level and processing may help to understand academic differences or difficulties). Intellectual testing is commonly a part of psychological evaluation as it provides a way of understanding a patient's overall level of functioning in school and in life.

Other Intellectual Tests. Sometimes, specific characteristics of clients, such as age, suggest the use of specific instruments.

1. *Infant and child tests*. Although very young clients can be "tested," these administrations are often as useful for their observations as their scores. Because of the emphasis on sensorimotor functioning and development of language skills of very young clients, the instruments (such as the Bayley Scales of Infant and Toddler Development) are not as useful

for predicting later IQ scores as they are for identifying individuals who are, or are not, at risk. The instruments do not become predictive in a more specific way until children are of school age.

2. *Nonverbal and language-free tests.* Although some tests seem especially suited for individuals who have difficulty in hearing or have language issues (such as the Leiter International Performance Scale), the nonverbal tests can have broader applications. Their emphasis is on cognitive problem solving based on visual information. Naglieri suggests that nonverbal tests can measure the same constructs as broader intellectual tests. In fact, the Wechsler Nonverbal Scale of Ability claims to be a test of general ability using nonverbal tasks, not a measure of "nonverbal intelligence." (It includes an Object Assembly subtest for younger and a Picture Arrangement subtest for older clients.) Although these nonverbal tests are useful, it is important to remember that they may not provide the whole picture, and the significance of these tests for the client's ability and functioning must be carefully assessed.

3. *Quick tests.* The commonly used tests in research and clinical practice are the Kaufman Brief Intelligence Test (KBIT) and the Wechsler Abbreviated Scale of Intelligence (WASI). Both the KBIT and the WASI include verbal and nonverbal tasks to assess crystallized and fluid thinking. The WASI and KBIT2 have been able to provide evidence of good correlations with established Wechsler tests. The available data suggest that the quick tests, in fact, yield very representative overall IQ scores. Although a clinician might not get all of the processing information made available by a full intellectual test, these correlation coefficients suggest that the quick tests can provide a very good estimate of the client's general level of functioning.

General Comment. In discussing intellectual testing, it is important to note what IQ tests are and what they are not. Although IQ scores are commonly used as estimates of ability, they are not measures of "native" or "raw" intelligence. Every client brings a long learning history, including opportunities, to the testing situation. The debate over whether tests are culture free or culture fair has raged over the years. Although some instruments (such as those that emphasize nonverbal functioning) may seem less biased or loaded, it must be acknowledged that probably no intellectual test is either culture free or fair. However, because IQ tests have, in large part, been designed to predict school success, they can be useful in the context of assessing learning capacity. Nonetheless, because of the way in which tests have been constructed and normed, caution has to be exercised in making conclusions in any case involving an unusual cultural or medical situation. Although IQ scores are useful as estimates of ability, they are, in fact, measures of functioning. There are a variety of transient factors that can be associated with alterations in IQ scores,

including problems with involvement, attention, and disorganization. As a result, the clinician has to be prepared for changes in intellectual level based on changes in medical status. For example, in some cases, clinicians have observed increases in IQ scores subsequent to medical treatment for attention-deficit/hyperactivity disorder (ADHD), partly due to increased efficiency on the instrument itself and partly due to increased learning over time in the environment and in school. Further, clinicians need to be aware of what IQ scores do and do not measure. They do not measure social intelligence or "street smarts"—the kind of savvy large portions of the population use every day to keep jobs and raise families. Nor do they reflect the creativity that artists of different kinds bring to their art and that entertains and informs people daily.

Considerations. Here are a number of factors professionals should keep in mind when they deal with intellectual test results.

1. The intellectual instruments have developed classification systems according to intellectual level. The Wechsler system, based on scores with a mean of 100 and a standard deviation of 15, has become widely recognized, although the labels have recently been adjusted for the WISC-V. Average scores fall between 80 and 89 (Low Average), 90 and 109 (Average), and 110 and 119 (High Average). New labels for the WISC-V levels appear hereafter in parentheses. Those scores above the average range between 120 and 129 have been seen as Superior (Very high) and those ≥130 have been seen as Very superior (Extremely high). Those scores below the average range between 70 and 79 have been labeled as "Borderline" (Very low). The scores ≤69 remain Extremely low. The Stanford–Binet test uses the same classification system for low average to high average scores (80 to 119). However the classification system has a wider range including scores from 40 to 160, from Moderately impaired or delayed to Very gifted or highly advanced. While the Wechsler system has been widely applied to a variety of instruments with a mean of 100 and standard deviation of 15, each instrument is free to specify their own classification system. Recently there has been some discussion about providing levels with more "neutral" and less "laden" labels.
2. The more variability seen on intellectual testing, the less do composite or summary scores mean. For example, on the WISC or SB, when the verbal and nonverbal scores (or other contributing indices or composites) differ significantly, the full-scale IQ is not informative. Similarly, when subtest scores differ significantly within a sphere, the emphasis should be on specific processing issues rather than overall functioning.
3. Sometimes a practitioner will ask what a patient's IQ is. It is clear from the multiplicity of the tests and scores available that there is no one IQ. Although IQ is what the client gets on an IQ test, it is prudent to be well

aware of which test was administered and which IQ is being quoted. The practitioner should be aware of disparities on different tests or in different areas; this pattern is often important in making decisions for a client.

4. In the context of a psychoeducational assessment, when scores differ significantly on intellectual testing, the full-scale IQ may not be the best estimate of "ability," and the clinician will make attempts to choose among the possible summary scores on a range of instruments to identify the one that best represents the student's learning potential.
5. What can be most helpful about the IQ score is the way in which it helps the practitioner to be aware of the client's general level of functioning. Each intellectual test uses its own language to indicate relatively low or high functioning. In school or practice, the designations at the higher end of the scale might include mildly gifted (starting at 115), moderately gifted (at 130), highly gifted (at 145), exceptionally gifted (at 160), and profoundly gifted (at 175 or 180). However, because of a ceiling effect on most newer intellectual test scores, there is some question about the utility of these traditional ranges. Furthermore, there is really no agreement about how to characterize or segment giftedness. In the context of this discussion, it is worth noting that the "old" Stanford–Binet L-M is useful in detecting these very high IQ scores. However, the SB5 has provided and the WISC-V anticipates providing methods of detecting and refining high scores in the gifted range.

FURTHER ASSESSMENT. The following is a list of patterns that suggest the need for further evaluation.

1. *There are significant discrepancies between verbal and nonverbal scores*. When verbal scores are significantly lower than the nonverbal scores, the possibility of a language disorder should be considered. In the case of low verbal scores, a speech and language assessment, to include measures of receptive and expressive language, as well as pragmatics (the factors affecting successful communication), might be indicated. It is particularly important to identify language-based learning disorders because of their potential effect on school (and relating), and because there are some very specific treatments that might be helpful. When nonverbal scores are significantly lower than verbal scores, further assessment regarding a variety of possibilities must be considered. More than the verbal tasks, the performance tasks (which might be timed) are vulnerable to ongoing and transient factors mediated by attention. In the case of particularly large discrepancies, the possibility of nonverbal learning disorder should also be considered. This is a pattern of cognitive assets and deficits that can be associated with peer, as well as academic, problems. The identification of a nonverbal learning disorder can be very helpful because it can lead to a wide variety of interventions, including those

around social skills.

2. *The full or composite score is above the 98th or below the 2nd percentile (130 or 70).* At the intellectual extremes, the examiner may consider whether further assessment regarding educational or adaptive needs might be in order. When a client has a very high intellectual level (e.g., moderately to profoundly gifted), the professional might refer the family to a psychologist specializing in very bright children or consult the website of the Davidson Institute for Talent Development, http://www.davidsongifted.org, for information about how to meet the needs of his or her client. In the case of individuals with very low intellectual level, further assessment can be obtained through the school system or the local public agency serving developmentally delayed clients. Professionals and parents may access the websites http://www.aaidd.org, http://www.thearc.org, http://www.autism-society.org, and http://www.eparent.com for information about services and products associated with intellectual and developmental disabilities.

3. *The intellectual score shifts downward in a significant way.* Because it is anticipated that intellectual scores will remain relatively stable over time, the mental health professional is advised to look for an explanation, either psychological or medical, for dramatic score changes. This is a time when the psychologist should look at raw, as well as standard, scores; a drop in a raw score is the test equivalent of losing functioning in everyday life. After some exploration, consideration of medical issues, as well as consultation with further medical personnel such as the pediatrician or neurologist, or further psychological professionals, such as a neuropsychologist, might be in order.

Achievement Testing. When achievement testing is undertaken along with intellectual and processing testing, the overall evaluation is commonly referred to as a psychoeducational assessment. The purpose of the assessment is to identify learning problems and usually to rule out other psychological factors that might be complicating learning. In addition, its purpose has been to establish eligibility for services through the public school system under learning disability. Clinicians communicating with school systems will need to be aware of the state and local guidelines for establishing learning disability, and, for example, how/whether/when the kinds of standard testing described here might be relevant under new identification models. However, practitioners will still value standardized (individual) achievement testing as an objective (normative) view of how the child stands nationally and for the ability to identify academic strengths and weaknesses. Of course, other information will be important—for example, the child's grades, academic interventions, and behavioral information.

BACKGROUND. Achievement testing is administered to determine a student's level of functioning in basic academic areas, including reading, mathematics, and writing. The factors assessed are more transient and circumscribed than those assessed in intellectual testing. Unlike intellectual testing, achievement testing is not necessarily expected to be stable over time because it measures the child's success in formal learning and is highly dependent on the home environment and the school curriculum.

Learning disability is commonly defined in terms of "unexpected underachievement"—that is, the child has the potential and opportunities to have learned more. The term learning disability is described in IDEA, which was reauthorized in 2004, with changes coming into effect in 2005 and regulations following in 2006. Since then, states and schools have been determining how they will respond to new regulations and procedures, and the role of achievement testing in schools is being seen in new ways. Table 36.3–3 provides further discussion of the federal laws that affect access to special services at the local level for students with disability.

ASSESSMENT. Psychologists commonly begin an assessment of academic achievement by giving a comprehensive test in order to get a sense of a client's areas of weakness in contrast to their strengths in reading, math, and writing. These findings are compared to school records. Because reading problems are a relatively common reason for referral and their causes are increasingly understood, where indicated, this comprehensive test is commonly followed by other tests of reading skills that separate out accuracy, fluency, and comprehension.

It needs to be noted that while specific learning disabilities (in schools) and specific learning disorders (in clinics) are commonly thought of in terms of underachievement in a specific academic area, learning difficulties can be more diffuse. They might not impact a particular subject in a significant way, but might impact a range of subjects in a moderate way. Or they might impact overall school performance in a drastic way. DSM-IV provided a way of recognizing this. Not only could learning problems be identified as a Learning Disorder in reading, mathematics, or written expression, but as learning disorder NOS. This allowed for the identification of a learning disorder across academic spheres and, arguably, in processing terms. For example, Learning Disorder, NOS might have been associated with executive dysfunction or nonverbal learning disorder. Under DSM-5, Specific Learning Disorder might be identified with impairments in reading, written expression, or mathematics. As part of the reconceptualization and reorganization of the diagnostic manual around neurodevelopmental disorders, learning problems associated with processing problems impacting general adaptive and social functioning rather than subject areas might be identified as Other Specified (or

Unspecified) Neurodevelopmental Disorder.

Comprehensive Achievement Tests. Each of the tests assesses a range of academic areas, so that they can be compared to each other within any individual or to academic achievement according to more external standards (age/grade expectations). The WIAT and the WJ-ACH allow for the systematic assessment of reading (basic skills, fluency, and comprehension), mathematics (calculation, fluency, and reasoning), and writing (spelling and brief to extensive composition), as well as other academic spheres. Each test has its strengths and weaknesses, and, often, most of one and portions of the other are included in an educational assessment. Both instruments are relevant for identifying specific learning disabilities whether under the (old) discrepancy model or the (new) patterns of strengths or weaknesses. They are also relevant in identifying specific learning disorders in reading, written expression, or mathematics. The WIAT is a companion test to the WISC. The WJ-ACH is a companion instrument to the Woodcock–Johnson Tests of Cognitive Abilities (WJ-COG), which evaluates processing skills and includes measures of intellectual ability, and the Woodcock–Johnson Tests of Oral Language (WJ-OL) which assesses specific oral language functions. As individual achievement tests, both the WIAT and WJ-ACH are widely used in the community and schools. An additional comprehensive test is the Kaufman Test of Educational Achievement (KTEA), which is co-normed with the Kaufman Assessment Battery for Children (KABC).

Other Achievement Tests. These and additional achievement tests are also available and can involve general or specific assessment.

1. *General achievement tests.* Some instruments focus on screening, such as the basic Wide Range Achievement Test. However, the fourth edition allows for the assessment of sentence comprehension, as well as reading, spelling, and math calculations. An expanded version provides even more information. There are other tests that may assess a range of academic areas in more depth. Some instruments focus on one area of achievement, usually reading.

2. *Specific reading tests.* Because of the importance of reading in school and in life, particular effort has gone into systematically assessing reading skills and the ability to make symbolic associations between sights and sounds, as well as the ability to decode words and understand text. In addition to reading subtests on major achievement instruments, there are specific reading tests, such as the Gray Oral Reading Tests (GORT) and the Woodcock Reading Mastery Tests (WRMT). Some instruments facilitate the pinpointing of the level and nature of the reading problems—for example, by presenting not only common words, but also nonsense words to assess decoding ability. In addition, because of the importance of

phonological awareness in reading, tests of phonological strengths and weaknesses, such as the Comprehensive Test of Phonological Processing (CTOPP), are also often given. It is up to the psychologist to select the battery of instruments that best meets the needs of a particular student in any particular situation. It should be noted that, because achievement tests assess academic functioning in slightly different ways, psychologists often administer a combination of achievement tests to any one client. For example, reading comprehension might be assessed by asking a student to read a passage and supply a missing word or by asking a student to answer questions about a paragraph. The format of the test can influence how well a student does. How the student does in different contexts may help to explain the nature of his or her academic problems.

General Comment. Under the response-to-intervention (RTI) approach as it unfolds, whether standardized/individual achievement testing undertaken within or outside the school will be useful or relevant may depend on whether the tests can fit into assessment protocols (usually involving repeated testing) and whether the results can be directly related to instructional models within the school (which need to be research based). The response-to-intervention model involves data-based decision making and includes screening, benchmarking, and progress monitoring. The assessment procedures might be called "curriculum-based measurement" (CBM) and tend to look like classroom activities but are undertaken in formal ways. CBM commonly involves criterion-referenced measures in contrast to the kind of norm-referenced measures described in this section.

Considerations. Here are a number of issues that mental health professionals should keep in mind in assessing achievement results:

1. Although estimates vary greatly, it can be realistically to conservatively estimated that between 15 and 30 percent of children with attention-deficit/hyperactivity disorder (ADHD) have a learning disability, and between 20 and 30 percent of children with a learning disability also have ADHD. As a result, when a clinician finds one condition, he or she should look for the other. Although they can co-occur, ADHD and learning disabilities are separate conditions requiring separate and specific recommendations—one potentially medical treatment, and the other educational intervention.
2. The vast majority of individuals with a learning disability have problems with reading (between 70 and 85 percent). Students who have learning issues in other academic areas commonly also have reading problems. Isolated learning disabilities in mathematics are much less frequent (perhaps 10 to 15 percent).
3. There are a variety of reasons why there have been objections to using a discrepancy formula (between ability and achievement) in assessing

learning disabilities. An important one is that it has been common for the identification of students with learning disabilities to be delayed into mid-elementary school, when earlier identification might have allowed for more preventive or effective work. In addition, there are other issues. One is whether it makes sense to identify a child with superior intelligence but average achievement as learning disabled, even when there is a processing problem. Another is whether it makes sense to exclude slow learners who might need special supports. It is hoped that the response-to-intervention model will avoid or sidestep some of these issues.

4. Although achievement tests commonly note grade- and age-equivalent scores, as well as standard scores, for a variety of reasons, the standard scores are more reliable than the age or grade equivalents. The concept of grade equivalent can be misleading. For example, it does not mean that a student functioning at the 6.5 level while in the fourth grade could perform sixth-grade work. The student has not been exposed to the same content as sixth-graders, nor would the fourth-grade test have included sixth-grade content. The score merely indicates that the typical sixth-grader would have received the same score, had sixth-graders taken the fourth-grade test. This same statement would also be true of age-equivalent scores. That is, it reflects performance in terms of the age level in the normative sample at which the average score is the same as the client's score.
5. Although all schools must provide services to individuals identified as disabled, there are other populations who, despite being at an advantage, may still need help but are not protected by federal laws and regulations. Because giftedness is not a disability, it is not defined and covered under IDEA. There is, however, a federal definition of "gifted and talented" referring to high-performance/achievement capability students who need services or activities "not ordinarily provided," and the federal government encourages their provision through state enrichment (Gifted and Talented Education [GATE]) programs.

Further Assessment. In practice, when any academic problem is extreme or does not respond to appropriate intervention, further evaluation of the problem is in order. Reading problems in particular may need very careful evaluation regarding the basic processes that might underlie the difficulty. A language specialist who deals with reading issues or a neuropsychologist who might shed light on the pathways available or impaired in a student can perform this assessment.

Processing Assessment. Processing problems can be addressed in a variety of situations and evaluations. One important one is in the context of more specific psychoeducational assessment in which processing problems

are identified in order to understand academic shortfall in basic reading, math, or writing skills. However, another important one is in the context of a more general psychodiagnostic evaluation in which processing issues are thought to be potentially relevant to more general social or diagnostic problems.

In the context of academic assessment, processing problems are identified to help explain academic problems or to help identify a student's learning style. In some cases the identification of processing problems has been necessary to meet criteria for learning disability. In the context of more clinical assessment, processing problems are identified to help explain problems with behavior regulation, cognitive confusion, and social judgment. In these cases the processing problems are handled in a functional and descriptive way.

Processing problems can also be assessed from a neuropsychological point of view (see the later discussion in the subsection Focused Neuropsychological Assessment) in which the processing issues are explored in an attempt to evaluate neurological integrity or to fine tune understanding of specific domains of cognitive functioning with the goal of understanding the child's referral problems and making appropriate recommendations. In this type of evaluation, instruments are chosen and administered in a systematic way so as to evaluate different systems in the brain and describe cognitive functioning in specific ways.

BACKGROUND. In the current psychological climate, it is understood that a child can have social learning as well as academic learning problems. Furthermore, it is understood that the same organizing principles that affect academic behavior can affect interpersonal interactions.

Educational Focus. The purpose of a psychoeducational assessment is to identify and explain learning disabilities and potentially rule out significant psychological factors as causes of school problems. In this context, processing issues are often evaluated as a supplement to achievement and intellectual testing in an attempt to find processing strengths and weaknesses, and to identify the processing factors associated with learning problems. The processing problems that might be evaluated as part of a psychoeducational assessment are diverse and not well defined. Even when schools have required the specification of a processing problem when finding a learning disability according to the discrepancy model, they have tended to include a wide range of processing possibilities (everything from attention to visual sequential memory), often without adequately determining what is in fact contributing to the immediate learning problem. New, more practical, and less theoretical approaches to identifying learning problems (such as RTI) seek to bypass definition and debate in order to provide service and supports to struggling students.

In educational evaluation, "processing disorders" is the term often used

by professionals to designate spheres of difficulty, such as specific perceptual inputs (visual, auditory) and expressive outputs (motor, vocal). The term "processing disorder" also includes difficulties in integrating information between two or more of these areas—for example, visual–motor dysfunction or sensory integration difficulties. The term may also refer to particular functions, such as memory or attention, or other factors, such as organizational issues. Such processing problems can interfere with academic learning and even social interaction.

Clinical Focus. The purpose of a psychodiagnostic assessment is to identify and explain the psychological factors associated with broad referral issues. When processing is explored in this context, tests are deployed to shed light on problematic psychological functioning and referral concerns. The emphasis is on the more integrative functions and control factors that might affect a diverse set of competencies, including general modulation and interpersonal interaction. In addition to standard processing instruments, tests of executive functioning and social cognition might be used, along with relevant rating scales in the context of history, in addition to projective tests interpreted from a variety of cognitive, social, and emotional vantage points. For example, tests or subtests might be selected to understand the interplay between "lower-level" and "higher-level" processing as a way of understanding problems with impulsivity in attention-deficit/hyperactivity disorder (ADHD) or social judgment in autism spectrum disorder (ASD). In this context, although a neuropsychologist might explore the neurological underpinnings of these behaviors and conditions, the more general clinician might "stand mute" regarding the neurological implications of the findings but try to apply research information and clinical understanding to relating test results to diagnostic issues. The practitioner is apt to recruit broad concepts of cognitive integration and functioning, as well as a range of cognitive and projective tests, to understand problematic behavior. In fact, in this context, every cognitive test is potentially seen as a projective test, and every projective test is seen as a cognitive test. Test scores in addition to observational data are enlisted to understand how the client makes sense (or does not) of his or her experience. These and other organizational issues might in turn affect how the client resolves everyday problems.

In the context of clinical assessment, processing issues might be identified in diverse testing, including general intellectual tests, as well as processing tests obviously designed for the specific purpose of assessing cognitive functioning in systematic ways. More important in this context, however, are the tests (and other instruments) that are designed to assess more integrative functions, particularly those structured and unstructured tests that might reveal the ability to make sense of things in general and executive functioning or social cognition in particular. For example, in this

context puzzle-like tasks from previous editions of intellectual instruments (such as the Object Assembly and Picture Arrangement from the "old" WISC-III and WAIS-III) might suggest that the same sequential/narrative problems that affect the ability to arrange cartoon pictures to tell a story that makes sense might also affect the ability to tell a Thematic Apperception Test (TAT) story, or the same holistic/simultaneous problems that affect the capacity to assemble a schematic drawing might also affect the capacity to make sense of Rorschach blots. In turn, these difficulties in making meaning on testing might be associated with "knowing what's going on" in life. For example, the child might not be able to understand social situations as they unfold, or to write a coherent story in school, or to process context in an academic or social situation.

ASSESSMENT. The assessment of processing variables can be conceptualized in terms of different models using omnibus or specialized tests.

Comprehensive Processing Tests. Comprehensive processing tests allow for the identification of areas of strength and weakness when it comes to processing issues. The WJ-COG allows for the extensive assessment of processing across a diverse range of areas and ages. Although it includes composite scores referring to intellectual ability, it is most often thought of as a processing test and is often administered in addition to a comprehensive intellectual test. The WJ-COG data are provided for individual subtests, as well as for informative composite scores. The Differential Ability Scales (DAS) provide a measure of general conceptual ability, as well as cluster scores in cognitive areas. It allows for the analysis of children's learning abilities and their strengths and weaknesses in cognitive processing. It has links with the WIAT that allow comparison of cognitive and achievement scores.

More-Specialized Tests. The NEPSY (a developmental neuropsychological assessment) is particularly useful as an instrument that allows for the systematic assessment of cognitive processing across a range of specific areas of functioning, including executive and attention, language, memory and learning, sensorimotor, visuospatial, and social perception (a relatively new domain). These areas of functioning are derived from neuropsychological constructs, and in the context of general psychoeducational or psychodiagnostic assessment they provide descriptive analyses and comparisons across domains. The NEPSY is only relevant to children and adolescents. The Delis-Kaplan Executive Function System (D-KEFS) is a systematic assessment of executive functioning across a wide range of ages into adulthood. The nine subtests allow for the evaluation of executive functioning at different cognitive levels (e.g., shifting set and verbal fluency, up to abstract thinking and deductive

reasoning). Analysis is made not only of the subtest scores, but also of the strategies the client uses for solving diverse problems. The data can be handled descriptively in terms of cognitive functioning, without comment on frontal lobe integrity.

Other Processing Tests. In addition to these more general tests, there are other instruments designed to provide more specific assessments according to different ways of understanding processing. Because they are comprised of subtests, separate tasks are often undertaken to illuminate different issues.

1. *Functions*. Processing understood in terms of functions refers to an input–output model dealing primarily with visual–motor or auditory–vocal systems. Testing involves the systematic presentation of auditory or visual stimuli, along with vocal or motor output. Such tests include the Test of Auditory Processing Skills (TAPS) and the Test of Visual Perceptual Skills (TVPS), as well as the Beery Developmental Test of Visual–Motor Integration (VMI). In addition, there may be other processing problems, perhaps having to do less with input–output models than pervasive functions, such as attention or memory. The NEPSY includes measures of attention. The Wide Range Assessment of Memory and Learning (WRAML) is helpful in the systematic assessment of what children recollect.
2. *Pragmatics*. As psychologists look at higher and higher levels of functioning, the application to more social spheres becomes apparent. The NEPSY's relatively new subtests (Theory of Mind and Affect Recognition) illuminate social perception. The same interest in "goal-directed behavior" that has informed the exploration of executive functioning has informed the study of social cognition as well. The Test of Problem Solving (TOPS) allows for the assessment of social judgment. Clients are asked questions about social situations presented in pictures or stories. The Test of Pragmatic Language (TOPL) allows for the assessment of pragmatic language—that is, language that is undertaken with a goal in mind.

General Comment. A wide variety of constructs at different cognitive levels have been used to understand processing patterns. Some have been alluded to, including visual versus auditory input and crystallized versus fluid intelligence, as well as nonverbal learning disorder and language-based learning disorder. However, there has been an increasing interest in the concepts of executive function (particularly around ADHD) and social cognition (especially around ASD). As has been noted, although there are tests specifically designed for their detection and description, information about integrative functions can be found in unexpected places, including everything from cognitive testing (puzzle-like tasks) to projective

instruments (with different demand characteristics).

It should be noted that, although assessing processing is commonly part of a psychoeducational assessment, the extent to which the direct remediation of processing problems can benefit learning disabilities varies, and such interventions should be viewed with caution. Some research cited by Kavale and Forness has been very disappointing. Actual treatment (if it does not involve medication for attention) is apt to be linked to the academic area affected by the processing difficulty. However, in contrast, recent studies linking the teaching of basic auditory processing and phonological skills in the context of reading programs are promising and leading to research-based intervention. In addition, simply describing a student's processing issues and how to work around them often helps teachers to instruct students and parents to manage and interact with their children.

There is also increasing information about interventions targeted toward executive functions and social cognition. Although there has been some success with the treatment of some executive functions, the identification of specific remediations for executive functioning, outside of interventions that look like organizational strategies and study skills, has remained problematic. Although there are some interventions targeting specific aspects of social cognition (such as recognition of facial expressions), again treatments for social cognition have often been an aspect of a larger event, such as social skills group. However, executive functioning and social cognition continue to be areas of interest, research and application, and, their identification can be crucial to the diagnostic process, and therefore ultimately to the intervention plan.

Considerations. These are some factors mental health professionals should keep in mind when considering processing problems:

1. The issue of the relationship between processing problems and academic difficulties has become controversial, especially around response-to-intervention, which so far has focused on reading. Some educators have maintained that the identification of a processing problem associated with academic shortfall is necessary to identify the core cognitive deficit predictive of learning disability. Other educators have maintained that even if present, it is not necessary to identify the actual processing deficit in order to prescribe educational remediation, and that the identification of learning disability cannot be separated from instruction.
2. Although it is always tempting to think in terms of organic versus functional, it needs to be remembered that these are interacting systems, and learning new skills can alter brain structure. This has been found in the case of taxi drivers in a major European city, as well as in individuals being taught to juggle.
3. It should be noted that the term "attentional problems" can be used

diagnostically or descriptively. The fact that clinicians detect problems with attention on a student's individual intellectual or processing tests (including computerized instruments) does not mean that the student has ADHD. Under DSM-5 this is a clinical diagnosis that involves specific criteria, is described behaviorally (inattention, hyperactivity, and impulsivity), and is determined by history (several symptoms by age 12 years) and current functioning (several symptoms seen in two settings). Systematic assessment can help to clarify issues around ADHD (and medication), but this will not be done with a single instrument and will require a pattern of responding on a selected group of tools along with interviews, observations, and, usually, rating scales from home and school.

4. It should be noted that learning (and emotional) problems can mimic attention deficit. In assessing ADHD, the clinician will need to rule out artifacts and to consider whether a child stops paying attention because he or she stops understanding (e.g., what he or she is reading or hearing) or has primary ADHD. In addition, the clinician will need to consider whether something like ongoing depression or situational anxiety is making it hard for the child to attend.
5. Broad constructs such as executive function can have relevance for a wide variety of diagnostic categories, such as ADHD and ASD. It is possible that about one third of the adults and children who have ADHD also have executive dysfunction (EDF), which can increase the difficulties facing these clients. As a result, as with ADHD and learning disorder, where there is a large overlap, when one sees ADHD one might look for EDF. The statistical overlap between ASD and EDF is harder to determine because of issues of definition, as well as of research results. Depending on how it is measured, EDF might be seen as ubiquitous in ASD. Research and clinical observations suggest that it would be useful to understand executive functioning in autism because of the usefulness of this information when interacting with affected individuals and making recommendations for them.

FURTHER ASSESSMENT. When processing problems are particularly severe or present a complicated pattern, further assessment may be in order. Neuropsychologists can fine tune information about processing in a variety of spheres.

Conclusions. A wide variety of intellectual, achievement, and processing tests have been explored as they apply to clarifying cognitive functioning in general and describing competencies in the academic and social spheres. There has been some discussion of learning disabilities and disorders, and some attempt to provide information so that psychiatrists might help patients receive services through the school as well as in the

community. However, the same processing issues that affect academic skills acquisition can affect behavioral control and social appropriateness. In addition to cognitive and neuropsychological testing, more projective testing might be undertaken to help identify the organizational issues that contribute to school or social problems, along with the more emotional factors that might interact with them. A battery of psychological tests provides a fairly systematic assessment of different kinds of input and output as they are affected by more and less structure.

COGNITIVE CONCLUSION

In general, when a systematic assessment of brain–behavior relationships is important to understanding referral issues, focused neuropsychological evaluation is indicated. When the clinical focus is served by a careful description of how cognitive functioning and processing issues are related to referral questions, the more general psychological assessment would be relevant and useful. However, every situation should be decided on a case-by-case basis, in consultation with the parents and involved professionals. It should be noted that general cognitive or psychological evaluation and focused neuropsychological assessment are complementary rather than competing approaches. They can be used as alternatives, depending on the needs of the case, or to supplement each other in complicated situations involving testing by one or more professional psychologists.

This subsection has focused on cognitive approaches to testing and psychological assessment in some general way, recognizing the complexity of the enterprise. The next subsection focuses on neuropsychological assessment, with a view to exploring brain as well as behavioral functioning. In this context, processing is seen in neurobiological and not just cognitive terms.

FOCUSED NEUROPSYCHOLOGICAL ASSESSMENT

Neuropsychology is dedicated to the study of brain–behavior relations and has matured into a clinical discipline for the diagnosis and characterization of brain function and dysfunction.

Assessment of Functioning. Neuropsychological assessment was originally developed for the assessment of *adult* patients and was not generally applied to child assessment until later. When it was used it was typically to assess children's *functioning* subsequent to acquired injuries or diseases affecting the brain. This functional assessment was important because the effect of trauma to the brain is highly variable across individuals, even when the precise location and size of the lesion is known. In these situations neuropsychological tests could provide specific functional information that took the child's age and developmental status

into account. This continues to be a prominent point of referral for pediatric neuropsychology because it discusses, not just the existence of the brain disruption, but its *meaning* in terms of the child's ability to function. This discussion of function is important both immediately after the injury and later on when intervention and development have had a chance to have their effect. This use of neuropsychological assessment is important with gross injury to the brain, but it is also valuable in situations in which sequelae are subtle and at risk of being attributed to psychological factors such as grief or poor motivation.

Technical Advances. Recent advances in neuroimaging have added to the use of neuropsychology in child assessment. One reason that neuropsychology was later in being applied to children was that technology for learning about *children's normal brain development* was not available. Given that neuropsychology studies the relationship between behavior *and the brain*, this gap in knowledge meant that inferences about brain function could not be applied to children. In contrast, neuropsychology *was* applied to adult populations based on the impression then held that brain development was finished by adulthood (thereby allowing for generalizations to be made regarding normal brain states and behavior). Because techniques such as positron emission tomography were prohibited in research with children, it was not until the introduction of functional magnetic resonance imaging (fMRI) in the early 1990s that full-scale research of child brain development could begin. Since that time there has been an unprecedented explosion of knowledge that has expanded the scientific understanding of child brain development exponentially every year up to the present.

Developments in Test Instruments. Other advances in pediatric neuropsychology include the introduction of tests specifically designed for use with children. These instruments assess similar behaviors as do their adult counterparts but use paradigms that are more engaging to children and better measure developmental transitions throughout childhood. These instruments are used in clinical assessments but are now also part of many research protocols examining childhood diseases and genetic conditions. Given its precision in measuring behavior, neuropsychological assessment is now involved, not just in the assessment of function after an injury, but also in the initial *diagnostic* processes. Another example of this specificity is the now-routine use of neuropsychological testing in genetic research of developmental disorders of childhood, given the precision that it adds to questions of endophenotype expression.

Neuropsychology's Application to Diagnosis and Treatment Planning. These new technologies have greatly enlarged the current understanding of

both normal and atypical brain development in children, affecting the current knowledge of childhood brain–behavior relationships, as well as diagnosis and treatment planning in pediatric groups. This increased understanding of typical as well as atypical brain development has made neuropsychological assessment useful, not just for children with acquired disorders, but also in cases of developmental disorders. In this context, the term “developmental disorders” is used in reference to a child who is not developing in step with peers but who for unknown reasons struggles greatly or fails to develop specific abilities. Examples are difficulty in learning to read in an otherwise intact child (referred to as the developmental disorder of dyslexia) and problems with developing social or self-regulatory skills (seen in, respectively, autism spectrum and attention-deficit disorders). These disorders stand in contrast to “acquired” disorders, in which a known event, such as injury or illness, has affected the child’s developmental trajectory.

EXECUTIVE FUNCTIONING AND THE PREFRONTAL CORTEX

The term "executive functioning" (EF) has become increasingly popular in the last few years, although many professionals remain unclear about its meaning. Despite the increasing familiarity of this term, many psychiatrists report gaps in their understanding, especially as the concept applies to the lives of their patients. This subsection reviews the history of the construct of EF, explains the factors it is thought to include, and then applies this information to an appreciation of its role in successful adult living.

Broadly described, EF refers to people's ability to coordinate behaviors so as to accomplish what they have set out to do (in other words, to reach their goals). Many of the abilities now included under the umbrella term of EF were recognized and researched before they were organized as part of this larger construct. For example attention, impulse control, and working memory are just three domains included in "executive functioning," but each of these preceded EF in the brain–behavior literature. It was not until later in the development of cognitive science that researchers and clinicians began to write of a larger, unified capacity to which many already-conceived abilities belonged. Furthermore, although many clinicians now recognize the multifactorial nature of EF, confusion continues to exist regarding how the specific abilities it includes were chosen, what they share in common, and why other behaviors (also seemingly important to goal attainment) are not part of this overarching concept. To answer these questions, it is helpful to understand some of the history that contributed to our current understanding of EF as well as the neurological underpinnings of the term and the specific behaviors included in it.

Although constructs included in the EF paradigm had been studied individually for some time, it was not until clinicians and researchers observed injured people who had *lost* this ability that they began to conceptualize it more specifically. The clinicians saw that although their patients (often the victims of severe head injuries) were still able to perform many basic acts independently, they now struggled to organize and calibrate their actions toward higher-level goals. Ultimately these observing physicians realized that the loss of this unnamed overarching ability was equally if not more handicapping than the absence of any of the individual functions making it up would have been.

One of the first and most celebrated of such cases was the story of Phineas Gage. Gage sustained a traumatic brain injury to his frontal lobes after an explosion sent a railroad tie through his head in 1842. He was immediately thrown onto his back convulsing, but after a brief period was reportedly "stunned . . . silent, but awake." Within a few minutes he was speaking and able to ride, sitting erect, in an ox car for the three-quarter-mile journey to the town hotel. An hour following the injury Gage was coherent, walking and talking, and telling the doctor and bystanders how he had been hurt. He survived an ensuing infection, and within 2 months, given the apparent preservation of so many necessary behaviors, was pronounced cured. Shortly thereafter, however, despite his intact hearing, sight in his right eye, and ongoing ability to speak, it became clear that he had changed a great deal. In contrast to his clear thinking and responsible personality prior to the injury, his behavior was now marked by profanity and impatience, as well as disrespect for others, and, most concerning and interesting, abandonment of his plans soon after he had created them. Ultimately, unable to maintain the consistent employment as a foreman at which he had earlier excelled, he worked at odd jobs and then as a circus attraction before his death in 1861.

This incident and subsequent clinical observations and research led to increasing understanding of the characteristics of executive functioning and its development. Three basic aspects of EF have been noted, including its association with the prefrontal cortex, its tendency to be late developing, and its involvement in mental planning.

1. *Prefrontal cortex*. The story of Phineas Gage, as well as that of many other survivors of brain injury or disease, illustrates one of the first characteristics of EF. The functions that are included in the EF construct are those subserved, at least in part, by the frontal (specifically *prefrontal*) cortices. In fact, the prefrontal cortex alone does not subserve executive functioning, but, rather, it works together with the basal ganglia and thalamus as part of several larger circuits that are now known to support this higher-level ability. These circuits include frontostriatal, frontoparietal, and frontocerebellar pathways. Because the extent of these neural connections were not well understood at the time that the concept of executive functioning was developed, in common parlance the prefrontal cortex is often cited as the "focus" of EF abilities. This abbreviation is helpful for people who are just learning about the EF construct and who may be confused as to why some behaviors are included and others are not, especially if they can all be logically described as being helpful in goal attainment. For example, why are set shifting and cognitive flexibility part of the EF paradigm whereas reading is not, especially given that, for some goals, reading seems like a more necessary skill? When facing these questions, it is helpful to stop and remember this first characteristic—namely, that unless a behavior can be mapped onto prefrontal cortex, it is not included in the EF construct.

2. *Later developing*. A second characteristic of EF follows from the first. The prefrontal cortex is one of the last cortical regions to develop, with full maturation peaking in adolescence and continuing into young adulthood. Because of the late development of this brain system, it would also be expected that EF will not be fully expressed until people have reached early adulthood. Thus, it is the later-developing cognitive functions—those arising in earnest in adolescence and reaching maturity in adulthood—that are part of the EF construct. One way of conceptualizing this point is to think about the abilities of a typical 10-year-old child versus those of a 25-year-old adult. One would notice no appreciable difference in their gait if one asked them to walk across the room, but one would likely see remarkable differences if the tasks suggested were those that reached maturity in late adolescence and early adulthood and that relied on mature executive functioning. For example, imagine these two if they were asked to sit through a 1-hour lecture, take out a mortgage, start a small business, or organize a family reunion. Although most 25-year-olds could competently manage these challenges (and thereby reach these higher-level "goals"), it is the rare 10-year-old who could anticipate and handle the multiple requirements of these "executive" tasks.

At this point it may be helpful to demonstrate which of the components of the examples described in the preceding paragraph are parts of the EF paradigm. The first request—sitting through a 1-hour lecture—obviously involves sustained attention, but, beyond that, also requires the *inhibition of distracters*. These two behaviors (attending to this, ignoring that) work together to allow us to *continue to focus* despite waning enthusiasm for the topic and competition for our attention such as a hungry stomach or tonight's football championship. The rest of the examples go beyond just sustained attention and include the need for insight to identify goals, imagination to create steps for reaching those goals, and anticipation of challenges that may arise and will need to be addressed, and then, of course, actually to get started on the work. Once the project has begun, one must be able to self-monitor using both verbal and visual reminders to stay on track, to identify unforeseen roadblocks and generate alternate plans for dealing with them, and then to efficiently switch to those new plans and not cling too long to the former blueprint.

3. *Mental planning*. The EF components necessary for the "25-year-old tasks" just listed almost all involve *thinking first*, followed by taking the appropriate action. Thus, a third aspect of executive functioning is that a great deal of it is accomplished mentally through planning, anticipating, generating solutions, evaluating them, and then making a choice of how to proceed before any actual action is taken. The ability to process ideas and actions mentally is crucial for mature executive functioning because it eliminates the time it would take actually to act out each potential step, making the process faster and more effective. Of course this mental planning must be followed by *action* if the goal is to be reached. But even after the action has begun, to remain effective executive functioning is necessary for monitoring the process mentally, thereby managing

challenges and interruptions that must be successfully overcome if work is to continue.

The characteristic of mental planning as part of executive functioning has its basis in the development of the EF system in general and the frontal lobes in particular. In this way further clarification is added to the understanding of the construct. Although *prefrontal* cortex does not fully mature until late adolescence and early adulthood, some regions of the frontal lobes are developed even at birth and show fast ascendance during childhood. These early-developing regions are predominantly involved in attainment of *goal-directed (motor) actions*. One of the earliest expressions of "goal-directed behavior" might be *seeing* the toy, *wanting* the toy, and then, finally, after weeks of practice and stretching of the body and hands, *actually being able to reach out for the toy and—joy—grab it!* Thus, development of deliberate and goal-directed movement can be seen as a first, concrete step toward the mental functions that serve goal attainment when the person is older. With maturation we become able, not just to move, but to *imagine* our movements. Alongside this development of foresight is the growing capacity to inhibit our movements until we decide whether we actually want to make them. The interaction of these two processes (thinking about doing it, then either doing it or choosing *not* to do it) creates an expertise for planning that stretches into adulthood and beyond.

This internalization of response represents another phase of prefrontal cortical development and another foundational step toward mature executive functioning. In other words, another way of understanding executive functioning is that it is our later-developing capacity to imagine, ponder, consider, and plan *eventual* movements that serve our *now-anticipated* goals. The anterior cortex is all about movement, motor development, and the translation of these skills into "doing." In this regard, executive functioning (also known as goal attainment) can ultimately be thought of as the ability to "do something mentally." By adulthood much of our "doing" occurs *only in our minds* as we imagine, anticipate, rehearse, and analyze potential movements (or actions). This *imagined doing,* however, has its roots in our *actual doing*—the movements we practiced and perfected when we were very young.

Thus, executive functioning is a multifactorial construct reflecting the behaviors that come increasingly "online" during adolescence and combine to address the challenges of adulthood. Although researchers do not fully agree regarding the specific list of behaviors that the EF construct should include, there is largely agreement regarding most of the neuropsychological domains, as identified through the guidelines described earlier, as well as factor analyses of competing potential properties of executive functioning. Typically, factors of response inhibition and execution, cognitive flexibility/set shifting, and planning and organization are included in models, as well as, less frequently, fluency and attention. Some professionals see these cognitive behaviors as providing the scaffolding for higher-level thinking (including abstraction).

FIGURE 36.3–1.

Previously, developmental disorders such as those mentioned earlier were often explained from psychological or educational perspectives, but they can now be reinterpreted from the standpoint of neurology (consistent with long-recognized similarities between symptoms shared by developmental and acquired learning disorders). Clarification of the neurological bases of these relatively common childhood disorders has demystified them and increased public awareness of their validity as diagnosable *and treatable* entities. With these discoveries has come increased funding for research on their treatment, yielding highly successful results and clear evidence regarding which interventions are most efficacious and appropriate for children struggling with these conditions.

Integration of Neuropsychological, Educational, and Psychological Paradigms in Testing. The effect on testing that these breakthroughs have made has also been significant. Most of this subsection has focused on test instruments that are foundational when assessing developmental differences in children. These measures (including, e.g., tests of IQ or academic achievement) are central when youngsters are not keeping up with their peers in one regard or another and are the backbone of testing regardless of whether the assessor is trained as a psychologist or a neuropsychologist or has a background in education. These instruments are pivotal because they measure the major paradigms of both education and psychology, paradigms that govern both diagnosis and the provision of services. These paradigms have been important, not just for the practical purpose of helping young patients receive support, but also because of the quality of the theories they represent and the background of extensive empirical research that has shaped them.

More recently, however, these established paradigms have been joined and affected by new information emerging from cognitive and

neuropsychology in concert with the aforementioned breakthroughs in neuroimaging. The integration of these findings has led to relatively rapid changes in educational law and in the instruments used to test children for learning disabilities. Earlier subsections went into detail about recent legal changes for how learning disabilities are identified. These changes are in large part the result of neuropsychological and cognitive research, including both testing and use of functional neuroimaging to clarify the neurological underpinnings of learning problems and the efficacy of early identification and specific interventions in treating them.

In addition to changes regarding the conceptualization of learning problems are actual changes in the tests used to assess children with unexpected delays. For example, in 2003 the Wechsler Intelligence Scale for Children (4th Edition) included changes in terminology to reflect cognitive and neuropsychological theory (e.g., the Freedom from Distractibility Index was changed to the Working Memory Index), as well as modifications of the subtests themselves, so as to allow for direct comparison between abilities known to reflect typical neural organization (e.g., the WISC-IV provided analogue tests of categorization, one mediated verbally, and the other nonverbally).

Applications of Neuropsychological Assessment. The functional and diagnostic assessment of children and adolescents often begins (and ends) with the kinds of evaluations described in the General Cognitive Assessment subsection. There are situations, however, in which the use of educational or psychological/cognitive testing alone is not able to clarify the diagnosis and determine the most appropriate treatment plan. In those cases the psychiatrist should consider additional neuropsychological testing. To help treating psychiatrists to know more about when to refer a patient for neuropsychological testing, the following list offers specific information about this approach to testing.

1. Neuropsychological tests are designed with the expressed intent of assessing brain function. Thus, if patients present with ADHD-like symptoms but have a history of brain damage (such as a traumatic brain injury or medical history including epilepsy or resection of brain tumor), neuropsychological assessment would be the testing of choice.

2. Children presenting with complexes of behaviors that could indicate more than one DSM diagnosis (e.g., ADHD *and/or* ASD) may benefit from the additional diagnostic clarity that neuropsychological assessment can bring. Because of the known correlations between specific neuropsychological tests and functioning in particular brain regions/circuits, neuropsychology can provide the psychiatrist with an indirect measure of brain function that can add clarity to diagnostic questions. For example, executive functioning profiles vary between

children with ADHD and autism spectrum disorders in some key respects, and so full assessment of executive functioning can add clarifying details when behavioral analysis alone has not been discriminating enough. Specifically, although executive functioning is typically impaired in both ADHD and people on the autism spectrum, those with ADHD tend to have more problems with impulse control and working memory, whereas core deficits in set shifting, cognitive flexibility, and planning are more representative in people with autism.

3. Neuropsychological tests are valuable when one aspect of a child's profile lowers a score that is being given to assess another function. For example, if a child works slowly on a reading fluency task, is the cause his or her reading problems or slow processing speed? Many neuropsychological tests employ a functional hierarchy of demands that allow several basic aspects of a complex skill to be measured independently to reduce confounding variables and more confidently examine the specific behavior initially intended.

For example, the Delis-Kaplan Executive Function System (D-KEFS) includes a version of a common neuropsychological instrument called the "Trailmaking Test" that measures set shifting and cognitive flexibility. On this test the child is shown a page with many circles, each of which contains either a number or a letter. The child must connect the dots as quickly as he or she can, alternating from a number to a letter to a number, in order (e.g., the child would connect "1" to "A" to "2" to B" and so on). The problem with this test as it was originally created was that, although it certainly *did* measure set shifting, it also measured many other abilities that could also lower the score. The D-KEFS version, however, provides four "control" conditions that provide information about other weaknesses that might also affect the set-shifting score. These additional subtests include a visual scanning subtest (showing a page of circles with numbers and letters and the demand to cross out all that contain the number "3"), two subtests that verify that the child can sequence numbers and letters separately (showing stimuli containing circles with numbers and letters and the demand to connect only the numbers and then only the letters), and a subtest assessing motor speed that requires the child to quickly draw a line over a dotted line to connect empty circles. If any of these conditions yields a very low score, the validity of interpreting a poor score on the final "switching" condition is in question, and interpretation is adjusted accordingly.

In addition, the neuropsychological battery contains many tests that appear to be very simple but are included because of the narrow range of abilities that are required for them to be done well. Examples of these are examination of sensory skills such as auditory processing in the right versus left ear, lateralized tests of motor development such as grip strength or pegboard placing, and the administration of timed, simple tests across several skills to highlight selected low scores that fit into known patterns

(such as the language-based weaknesses suggested by compromised rapid color naming alongside weak math automaticity).

4. Another application of neuropsychological testing occurs in instances in which cognitive testing does not demonstrate a clear score profile, not because of the diagnostic complexities addressed in the foregoing, but because of subtleties in score differences that are a result of the examinee's intelligence. These less-profound score distributions can occur when the examinee is very bright or when intelligence is very low.

A very bright examinee can "outsmart" tests that measure multiple abilities, making him or her a poor match for the normative sample to which he or she is being compared. Bright students with learning disorders have many unaffected domains of strength that can be applied to "multiple construct" tests to support the more discrete impairment. Although this will usually result in relatively lower-than-expected scores, in very gifted students the bottom of the range of such scores may be average to high average, making interpretation difficult. It is important to note, however, that the ability to apply a clever strategy to a test does not mean that the student can likewise use intellect to manage his or her symptoms in the larger contexts of life (which is the reason the child presented for assessment in the first place). Rather, the child's clever approach to testing means that there is a greater risk that all scores will cluster together at an above-average point and not demonstrate discrepancies that suggest learning problems. In these cases students are often not diagnosed at all or until much later, after life's demands have caused considerable disruption to their academic, social, and/or emotional success.

Conversely, when a student's intellectual functioning is very compromised, tests that do not include the functional hierarchies discussed earlier make it more likely that all scores will be low. This is a concern, given the importance of identifying relative cognitive strengths in these children because these islands of ability can be quite amenable to intervention and so will demonstrate more improvement with treatment than the other, very impaired skills. When these children are young they should receive intervention for both their areas of profound weakness and their relative strengths, but in adulthood it will likely be the isolated strengths (which, with specific early intervention, will develop on a higher trajectory than those that are more impaired) that provide the foundations for future participation in aspects of adult life.

5. A last benefit of neuropsychological tests that may be important to a psychiatrist is that many of these instruments have been constructed so as to control for "practice effects" (artificial increase of a score resulting because a test was given twice with too little time between the administrations). When practice effects are controlled tests can be readministered at short intervals, providing an effective way of assessing treatments such as medication that should show rapid improvement.

Although this approach needs to be undertaken cautiously (and results interpreted in light of slight improvements seen in nonclinical populations, as are known to occur with some medications), significant changes measured with retesting can add confidence to clinical observations obtained informally or with questionnaires.

One way of managing practice effects is to have two alternate forms of the same test, which allows them to be readministered after only short intervals. Many subtests from the D-KEFS provide these alternate forms, making them a good choice when disorders characterized by executive functioning deficits are part of the referral question. A second way of managing practice effects is with tests that are intentionally boring such as those measuring sustained attention (e.g., the Connors Continuous Performance Test [CCPT]). When, after a short interval, children with normal attention retake the CCPT they typically perform *worse* than they did the first time (contrary to what practice effects would suggest). The decrease in scores is attributed to the boring nature of this long, computerized test; the first time the child takes it there is some excitement about its novelty, but by the second time the child knows what he or she in for from the start, which affects the child's motivation. If a child does significantly better on the second administration, the change is attributed to something other than practice; if done in the course of a medication trial for ADHD, the assumption is that the medicine is helping performance more than the practice is hurting it.

There are several ways that retesting can be used to aid a psychiatrist in quantifying medication effects. For example, when a child who is already on medication for ADHD presents for testing, a 45-minute battery that measures behaviors that are sensitive to the medicine can be administered one morning without medication and a second morning with it. Alternatively, if at the close of testing ADHD is a diagnostic impression and the treating physician thinks a medication trial is appropriate, the child can return for brief reassessment with sensitive tests once the medicine is thought to be at therapeutic levels. Information obtained from retesting can provide data about the benefit of the medication and the appropriateness of the dosing, as well as increasing parents' and patients' confidence about the intervention.

Descriptions and Assessment of Typical Neuropsychological Domains. Typically, in addition to assessing IQ, academic achievement, and social and emotional functioning, neuropsychologists assess domains of memory, attention, executive functioning, language, visual perception, and sensory-motor development. Tests have been developed to examine specific aspects of these domains in isolation so as to increase diagnostic clarity. Although these domains are discussed as different constructs in this subsection, in

truth, they overlap with one another in many different ways. For example, the term *working memory* is often conceptualized as being an aspect of attention, as well as a necessary component of good planning (which is part of executive functioning). It is also a component of memory in that, when it is not well developed, it leads to the phenomenon of "forgetfulness." Many of the measures used to discuss one of these constructs will also be used to discuss others. In addition, neural substrates and pathways supporting their functions are often overlapping or, at least, parallel systems.

Thus, the interdependence of these domains is an assumption of this portion of this section. Each subsection provides an overview of the theory supporting the conceptualization of the domains, followed by a description of the ways in which a neuropsychologist might assess them.

MEMORY

Overview. To memorize something, a person must first pay attention to it. Assuming that this attention is intact, the next step is to "make" the memory, or *encode* it. Once the memory has been made, however, it must be available on demand to be of use. Knowing the name of France's first president is of no benefit if you cannot *retrieve* it during the history examination.

One metaphor for this two-step memory process is a filing cabinet. *Encoding*, then, is when a person puts information into the "filing drawer." Someone with a true amnesic disorder (such as Alzheimer disease) never gets the information into the drawer. No amount of cueing or reminders later on will help the person to recall the information because it never "got into the drawer" in the first place. This type of impairment can be seen in some children, most often those with seizure disorders that adversely affect the temporal lobes. For most children, however, the problem described as "poor memory" is actually a difficulty with retrieval. *Retrieval* is the ability to get information out of the "file drawer" once it has been put in. Poor retrieval is associated with problems of organization (the folders are missing labels) and is more often the issue when children are described as being "forgetful."

To differentiate between encoding and retrieval, children are asked to memorize material and then, 20 to 30 minutes later, to recall it. If they are unable to remember it spontaneously, the examiner does not know whether they have not encoded it or are having problems with retrieval. If the child can remember the material with cueing (e.g., "In the story I read you, was the boy's name Johnny or Sam?"), retrieval is implicated. For the child who cannot encode, however, cueing will not help.

Assessment. In assessing memory, several guidelines should be followed. Both visual and verbal memory tasks should be given. Visual memory tasks (such as learning the location of dots or memorizing faces) are usually

aided by the right hemisphere. In most people, verbal memory tasks (such as memorizing a shopping list or a story) are supported by the left hemisphere. In addition, material to be memorized should include rote tasks (such as word lists), as well as material that is presented in context (such as stories). Some memory tasks assess learning, or the child's ability to benefit from several presentations of the material. It is expected that, after three exposures to a picture of dots, the child's memory of it will be stronger than it was after the first exposure. If not, encoding may be implicated. A 20- to 30-minute delay should also be part of the memory assessment, and cues should be available to differentiate between encoding and retrieval difficulties.

Other terms in the neuropsychological literature appear to describe memory but are actually probably better classified as part of the attention system. These include *short-term memory* and *working memory*. These terms are discussed in the following subsection on attention.

ATTENTION

Overview. The attention literature is large and includes many different conceptualizations. The following illustration demonstrates some elements of good attention.

Suppose you arrive at a lecture hall, open your notebook, and rather than scanning the room indiscriminately, turn your attention to the instructor, who is just beginning to speak (*selective attention*). The lecture is mildly interesting, and you are able to pay attention for the full 20-minute presentation (*sustained attention* or *vigilance*). At the same time that you are listening to the instructor, you are taking handwritten notes incorporating headings and subheadings. It appears that you are able simultaneously to listen, write, and organize rather effortlessly, although you are probably shifting your attention among these competing tasks (*divided attention*). A fire engine goes by the lecture hall and you look up (*distraction*) but are then able to ignore the dimming noise of the siren (*inhibition*) and continue to listen to the lecture (again, *sustained attention*). Suddenly, the fire alarm rings, and you smell smoke. These distracters capture your full attention (*disengagement* from lecture), and their importance causes you to change your attention and behavior (*set shifting*) as you hurriedly head for the door.

A breakdown in any one of these areas can lead to a breakdown in attention. Some children are so caught up in their private thoughts that they have difficulty disengaging from their inner musings, not realizing, for instance, that their babysitter is asking them a question. Or, once they are involved in a task, they have trouble switching to something new, causing them to "get stuck" or perseverate.

The attention literature also discusses divided attention. This is the ability to pay attention to two things at the same time, although, in fact, a

shifting of attention between two things is probably occurring. Good divided attention is important in multitasking. Some authors use the terms *divided attention* and *working memory* synonymously.

Assessment. Assessment of attention requires a number of approaches. Children with attention problems exhibit them at home and at school whenever a task becomes less interesting to them. They function better when working one-on-one with a person or when working on a new activity because it is more stimulating. For this reason, the testing environment may not elicit the inattentive behavior (especially on the first day). To assess the child's attention "in real life" and across settings, attention questionnaires should be completed by both parents and teachers. Many researchers consider this aspect of the assessment of attention to be the most important. Some neuropsychological measures have been found to be sensitive to attention as well. Computerized measures of sustained attention that are designed to be long and boring can capture the loss of attention described here. In addition, specific kinds of performance patterns on these measures have been shown to differentiate different types of attention problems.

Assessment of *verbal* short-term memory might include the repetition of digits or of short sentences. Assessment of *visual* short-term memory can be achieved by having the child point to dots or circles on the page in the same order in which the examiner has just pointed to them. Working memory is usually assessed as the second part of a short-term memory test. It requires that the material that has been stored in short-term memory be manipulated in some way. Verbal working memory can be assessed by having the child repeat digits backward or by doing mathematics in his or her head. Saying the months of the year backward can also assess verbal working memory (as long as the child is able to give them in their usual order without difficulty). Having the child point to the dots on the page in the reverse order in which they are shown can assess visual–spatial working memory.

EXECUTIVE FUNCTIONING

Overview. Executive functioning could be considered to be the mature product of good attention. Although not developed in earnest until children reach adolescence, many aspects of executive functioning begin to appear when children are younger and, thus, can be measured. *Executive functioning* refers to the person's ability to organize his or her behaviors to perform a specific goal. Good executive functioning allows a person to identify problems, generate solutions, choose among them, follow through on the chosen strategy, and evaluate its effectiveness as the work progresses. Without good executive functioning, children who are bright have difficulty demonstrating their abilities. Their parents often report

school underachievement that cannot be explained by learning problems. The issue is not about "knowledge," but rather the application of that knowledge to everyday functioning.

Assessment. Assessment of executive functioning requires several tests, given its many facets. Good attention and working memory, already discussed, are crucial to goal-directed behavior. Inhibition can be tested by giving the child a task in which he or she must control an automatic response. For example, on tests using the Stroop paradigm, the child is shown a color word printed in ink of a different color (e.g., the word "BLUE" written in red ink). The automatic response is to just read the word "BLUE," but this task requires that the child, instead, name the color of the ink. After several items, inhibition appears to tire, and children with poor impulse control perform worse than their peers.

Fluency can be assessed by having the child generate category words under a time limit. For example, a child might be asked to name as many kinds of toys as he or she can in 1 minute. A variant of this task requires the child to create as many designs as he or she can in a 1-minute period, according to strict guidelines.

Cognitive flexibility is often tested with the Wisconsin Card Sorting Test (WCST), a measure of problem solving. On this test, the child is not told how to solve the puzzles; rather, he or she must use feedback that his or her attempts are "right" or "wrong" and is then expected to use this information to generate strategies. During the course of this test, the rules often change without warning, requiring that the child "regroup" and develop a new strategy. This measure generates information about the child's ability to initially figure out the task, his or her tendency to perseverate on wrong responses, and his or her ability to use feedback to generate new responses.

Planning is another aspect of executive functioning. Variants of a "tower" test are often used to assess this ability. On a tower test, the child is shown a picture with colored balls or disks stacked on top of one another on wooden pegs in a specific configuration. The child is told to move the balls or disks on the pegs on an actual model on the table to match the configuration shown in the picture. The child is instructed to move only one ball or disk at a time and to use as few moves as possible. To perform the task well, the child must first "hold back" and not make impulsive moves that may get him or her "cornered." The child must also visualize the first few steps of the problem. Thus, both impulse control and visual working memory are required to exhibit good planning on this rather entertaining test.

LANGUAGE

Overview. Human language organizes, supports, and communicates

knowledge, memories, and ideas. Beyond just allowing people to communicate with others, language organizes both thoughts and emotions, as well as helping people sequence their actions. Although traditionally discussed in terms of left hemisphere functioning, much of the human cortex is involved in various aspects of language. Communication includes both *speech*, the rapid and complex motor movements involved in talking, and *language*, the code used to express thoughts and ideas.

Linguists conceptualize language as being composed of four separate parts: *Phonemes*, defined as the smallest units of sound in a language; *morphemes*, the smallest units of meaning; *syntax* at the level of the sentence (e.g., use of direct or indirect pronouns); and *discourse*, the stringing together of sentences to create a narrative.

In considering language, perhaps the most common distinction made is between *expressive* and *receptive* language. Expressive language requires the production of language, including articulating clearly, finding the right word, and applying grammar and syntax to one's ideas, in addition to vocal fluency and voice tone (prosody). Receptive language involves the ability to comprehend and remember what is said.

Children with expressive language problems may appear to have little to say and considered to be shy. In fact, however, their difficulty may be with self-expression. Some children who are very talkative ("fluent") may also have difficulty with finding the word they want or organizing their sentences to make them clear. The paradox of a fluent child with an expressive language disorder may cause his or her problems to be overlooked.

Receptive language, or the ability to understand what is being said, represents another aspect of the language system. Children with poor receptive language have difficulty in processing information that is spoken to them and may have difficulty learning in the classroom or appear to be inattentive. Sometimes they appear to be oppositional because of their difficulty with understanding (and therefore *doing*) what they are told.

Secondary problems of children with language disorders include difficulties with social interactions and processing of emotions. Language is what humans use to interact and communicate their ideas to one another. When this ability is compromised, children may isolate or try to find less language-intense activities to occupy their time. Emotional problems may ensue from the child's difficulty with using language to express and, therefore, process his or her inner world.

Assessment. Assessment of language should include several measures meant to identify the child's specific language profile. Tests should assess all levels of language, including phonemes, single words, simple phrases, complex sentences, and conversation. Measures of both expressive and receptive language should be included. In the assessment of receptive

language, children are asked to distinguish between similar sounds and words, remember and repeat word lists and related strings of words, point to a picture that depicts a vocabulary word, and follow increasingly complex directions presented only once. In the assessment of expressive language, children are asked to perform tasks such as listing as many round objects as they can within a time limit, naming a depicted or described item, defining words or concepts, or creating a syntactically complex sentence according to strict guidelines.

In addition, the psychologist might explore *pragmatics*, which is the child's ability to participate in conversation and use social language. This involves interpreting nonverbal aspects of communication, as well as observing basic social rules, such as turn taking in conversation. Although neuropsychologists often evaluate pragmatics in addition to receptive and expressive language, they also work in concert with speech and language specialists when additional assessment is indicated.

VISUOPERCEPTUAL FUNCTIONING

Overview. There are several associated constructs in neuropsychology that reflect people's ability to make sense of what they see, to organize it, or to copy it. These abilities are referred to as *visuoperceptual–visuoconstructive abilities*.

Problems with *visuoperception* are distinct from problems with vision. A person with acute eyesight can struggle with perceptual difficulties, such as identifying which of several figures are exactly alike. Some children have difficulty seeing exactly where something is, and these children may have trouble localizing a point in space or judging the direction of a line. *Visuoconstruction* abilities allow a child to join parts to make a whole. These skills require the integration of the motor system with the visual system. Examples include the ability to put together blocks to form a design or to draw three lines to form a triangle.

Problems with visuoperceptual development have academic, as well as social, ramifications. Academic areas, such as mathematics, that are less reliant on verbal support are at risk. In addition, concepts such as time and monetary values may not be clearly understood. Students with these difficulties often exhibit a poor sense of direction, and problems with integrating complex visual arrays may lead to feelings of being overwhelmed. They may also have difficulty "reading between the lines," thereby making comprehension of less tangible reading concepts (such as theme) more elusive.

Social problems are also often seen in students with these delays. Many elements of good social interactions are nonverbal, including the ability to notice and interpret gestures, facial expression, body posture, and tone of voice. Students with visuoperceptual delays may be overreliant on verbal information and may not understand when people are being sarcastic or

when something is said in jest.

Assessment. Assessment of visual processing must address each of the specific elements of this system. The visuoperceptual abilities should be tested using tasks that do not require the child to use his or her hands to produce the response—for example, activities that require the child to identify designs that match or differ from the target, as well as measures of mental rotation (finding which design one is the same as the target, only rotated). Visuoconstruction tasks add the demand of integrating the hands and eyes in producing the response—for example, having the child draw copies of designs or use blocks to create a replica of a model.

SENSORY/MOTOR FUNCTIONING

Overview. The sensory/motor system is also assessed as part of the neuropsychological examination. Lateralized sensory or motor problems suggest neurological problems on the opposite side of the brain and are often correlated with cognitive processes localized to the right or left hemisphere. Tasks requiring the perception of visual/auditory fields or specific actions with right and/or left sides of the body are part of this domain. In addition, integration of perceptions or movements is also assessed.

Motor assessment is further broken down into the assessment of handedness and tests of large versus fine motor development, as well as the ability to plan motor responses (praxis).

Assessment. The sensory examination usually includes assessment of visual fields using clinical methods such as having the child look at the examiner's nose and then determine whether the assessor is moving the right or left extended hand. Similarly, assessment of bilateral auditory perception might include the assessor standing behind the child and rubbing his or her fingers near the child's right or left ear. Other perceptual tests might assess the ability to name unseen objects placed in the child's right or left hands. Finger agnosia is tested by touching a finger when the child's hand is hidden behind a screen and then having him or her indicate which finger was touched. Integration of perception might include having the child follow directions involving a picture that is shown. Age-based normative data are available for all of these tasks.

Both fine and large motor tests are usually assessed on both the right and left sides of the body. Lateralized fine motor tasks include quickly placing pegs in holes with each hand or squeezing a hand dynamometer with each hand to assess grip strength. Fingertip tapping is one way of testing motor sequencing, as do activities requiring the child to repeat sequences of movements from memory. Handedness is best assessed by having the child do a number of tasks with one hand (e.g., "Show me how you use this spoon," "Hand me the dime," and "Throw me the ball.") in

random order. Assessment of difficulties with motor planning can be done using pantomime.

Large motor testing involves having the child demonstrate gait while walking forward and backward, running, skipping, walking a straight line, and balancing on one foot. In cases in which the findings of motor screening are significant, the neuropsychologist might refer the child to an occupational or physical therapist for further, more specific, evaluation.

NEUROPSYCHOLOGICAL CONCLUSION

Neuropsychological testing is commonly undertaken according to several discrete domains that reflect areas of brain functioning. Typically, these include attention and executive functioning, memory, and language, as well as visuoperceptual and sensory/motor functioning.

Considerations. In considering neuropsychological issues, the following factors should be kept in mind:

1. After early brain injury, language and motor functioning are the most likely to benefit from "plasticity." Some research suggests that, with this process of reorganization, other functions (most notably, visuoperceptual abilities) may be "crowded out," yielding scores that are lower than expected.
2. Interventions for neurologically driven developmental delays have their most profound effect on younger children. Recent studies have shown that, in children with reading disabilities, bilateral representation of language identified with fMRI before intervention shifted to the left hemisphere by several orders of magnitude in every subject after only 80 hours of reading intervention. These changes in the brain were accompanied by improved reading skills. Thus, the philosophy of delaying intervention until a deficit is fully expressed may keep children from receiving the full benefit that early intervention provides.
3. Risk factors for reading disabilities include family history, early language delays, poor articulation, chronic ear infections, poor early rhyming abilities, inability to recite (not sing) the alphabet by the end of kindergarten, and early brain injury.
4. "Ambidexterity" (consistently using the right hand for some specific tasks and the left hand for other specific tasks) often runs in families in which several members are left-handed. In contrast, "ambiguous handedness" (or the use of either hand for the same task; sometimes writing with the right hand, sometimes writing with the left hand) can be a pathognomonic sign suggesting poor cerebral organization for specific behaviors.
5. ADHD more adversely affects abilities typically associated with right hemisphere functioning (such as fine motor skills and visuoperceptual abilities) and affects attention and executive functioning.

Psychostimulant medication has been shown to improve functioning in all of these domains in children with ADHD.

DIFFERENT APPROACHES

General cognitive assessment and focused neuropsychological assessment represent different paradigms: One assesses referral issues in a descriptive way without reference to brain-behavior relationships, and the other assesses them in a functional way from a brain-behavior point of view. When these two approaches are seen together, psychological assessment undertaken from a more processing standpoint allows opportunities to "zoom in" (to the neurobiological level) or "zoom out" (to the observational level). However, regardless of whether the psychologist is working from a more "macro" or "micro" level, ultimately it is his or her ability to integrate these and other test data with clinical observations, referral issues, and diagnostic possibilities that benefits the patient in a practical way in terms of understanding what is going wrong and making appropriate interventions.

▲ 36.4 Psychiatric Emergencies in Children and Adolescents

RUTH S. GERSON, M.D., AND FADI HADDAD, M.D.

INTRODUCTION

The past 20 years have seen a dramatic increase in the number of visits to emergency rooms by children and adolescents in psychiatric crisis, with estimates now reaching 2 to 5 percent of all visits, or over 800,000 visits per year. Unfortunately, appropriate assessment and treatment are not available to many youth presenting to the emergency department (ED) in psychiatric crisis. As an example, nationwide fewer than 50 percent of youth presenting to the ED with suicidal behavior receive a mental health evaluation, even though those who do not are at increased risk of a future suicide attempt. As the ED is the entry point to psychiatric care for an increasing number of youth, improving the care provided to these patients is imperative. This section will underscore the key components of the emergency evaluation of a child or adolescent in psychiatric crisis and will emphasize:

- Understanding the role of developmental, academic, and social context in assessing children in psychiatric crisis.
- Differential diagnosis of behavioral disturbances.
- Assessment of suicidality, aggression, new-onset psychotic symptoms, and risk-taking behaviors.
- Assessment of nonverbal children (including young children and those with autism or intellectual disability).
- Management of agitation in the ED.
- Legal issues in emergency child psychiatry, including assessing for child abuse.

EPIDEMIOLOGY

The emergency care system has unfortunately been slow to adapt to the increasing demand for child and adolescent psychiatric emergency care. Youth in psychiatric crisis are difficult for EDs to manage. Most children presenting to EDs in psychiatric crisis are seen in general medical or pediatric emergency rooms, or more rarely in adult psychiatric emergency services (PES). Most EDs lack the specialized staff (psychiatrists, child psychiatrists, social work, and nursing staff) necessary to effectively care for youth in psychiatric crisis, who also have longer length of stay and increased need for inpatient admission or transfer than other young patients. EDs also typically lack the physical resources to manage the high volume of child psychiatric patients safely. Agitated or suicidal youth are

often placed together in medical exam rooms full of potentially dangerous objects, in busy and noisy holding areas, or on stretchers in trauma bays with security or police watching over them. Youth that are seen in the adult PES instead are exposed to adult patients who are severely mentally ill, homeless, or intoxicated. This can be frightening and reinforces the stigma surrounding mental illness and psychiatric treatment. The PES also lack appropriate staff, as adult psychiatrists and nursing staff trained to work with adults may not know how to approach youth in a developmentally appropriate way. These factors can exacerbate a youth's anxiety or agitation, such that 15 percent of youth in the ED for psychiatric complaints end up restrained during their ED stay, putting themselves and others in danger.

Youth accessing emergency psychiatric care are increasingly presenting with severe symptoms including suicidality, severe aggression, mania, or psychosis, and many of these youth require inpatient hospitalization for safety and stabilization. But with the steady decline in access to inpatient child and adolescent psychiatry beds, young people are often left boarding in EDs for days, without meaningful treatment, awaiting inpatient admission.

Adding to the structural challenges of treating youth in psychiatric crisis in the ED, these patients are often clinically very complicated. ED clinicians are not only treating youth with known psychiatric illness presenting in behavioral crisis, they often also are treating youth with previously undiagnosed or undetected psychiatric illness including depression, anxiety, psychosis, posttraumatic stress disorder, substance use, autism, and attention-deficit hyperactivity disorder. Because of the shortage of outpatient clinic services to diagnose and treat these youth, psychiatric illness often goes undetected and untreated. It is not until symptoms have reached a breaking point that the child accesses care. Thus, by the time a youth presents to the ED, their untreated psychiatric symptoms may also have disrupted their school performance, social interactions, and family relationships. These secondary effects often prompt the ED visit, as in youth sent from school for aggressive outbursts or brought in by a foster family no longer willing to care for them due to difficult behaviors. These systems complexities make these youth even more difficult for ED clinicians to assess and treat.

Suicidal thoughts and severe aggression are also common precipitants for an ED visit, again often subsequent to a lengthy period of unrecognized or untreated psychiatric symptoms. Suicide is currently the fourth leading cause of death for 10- to 14-year olds and the third leading cause of death for 15- to 19-year olds, and as many as 10 percent of children attempt suicide sometime during their young lives. Studies indicate that 40 percent of youth who attempt suicide had been seen in the ED in the year before their death, suggesting that an opportunity for life-saving intervention at

that ED visit was missed. EDs are also increasingly seeing violent youth, who are often "frequent fliers" in the ED. Youth who frequently use the ED for mental health complaints are often there for threatening others or other criminal behaviors. They frequently have diagnoses of conduct disorder or other disruptive behavior disorders; are involved with the juvenile justice or child welfare systems; and have cognitive impairments that make it difficult for them to function in the community.

Though youth in psychiatric crisis are presenting to EDs in greater numbers with increasingly severe symptoms and complex systems involvement, clinicians in the ED lack training in how to evaluate and treat these youth. Pediatricians and emergency medicine physicians evaluating youth in psychiatric crisis are uncomfortable assessing suicidal versus nonsuicidal self-harm, violence risk, and complex presentations of psychiatric illness such as new-onset hallucinations or complex trauma reactions. Adult psychiatrists often lack the developmental perspective and understanding of psychosocial context necessary to inform a comprehensive assessment. This chapter will outline the key priorities, principles, and components of a comprehensive evaluation and risk assessment for a child or adolescent in psychiatric crisis.

PRIORITIES OF EMERGENCY PSYCHIATRIC EVALUATION FOR CHILDREN AND ADOLESCENTS

Safety

The psychiatric evaluation of a child or adolescent in the ED should have two main priorities. First, safety, which in the ED includes both safety of patients and staff while the patient is in the ED, and effective risk assessment to determine whether the child is safe to leave the emergency room or requires inpatient treatment. Ensuring safety in the ED starts with appropriate physical space. Children and teens presenting to the ED with suicidal ideation, aggressive agitation, or other acute psychiatric manifestations are unlikely to be safe in a standard medical exam room. The ED environment, whenever possible, should be modified for safety including: removing potentially dangerous items (sharps, cords, IV poles, and other objects that could be used for self-harm or as a weapon to harm others), decreasing overstimulation by avoiding bright lights and unnecessary noise, providing privacy while allowing the patient to be observed continuously, and enhancing patient comfort by giving the patient a comfortable place to lie or sit down as well as food or drink. The child and family should be given clear expectations as to the components of the evaluation, the waiting time, and the interventions and consequences that will be given should the patient become agitated or violent. Adequate trained personnel should be available to help if the patient becomes agitated, and staff should have a clear response plan for calming an

agitated or aggressive patient including with medication or restraint if needed (this is discussed further below). These modifications reduce the likelihood of aggression to self or others, and if such aggression does occur, mitigate the risk of serious injury to patient or staff. The second aspect of safety is a comprehensive and effective risk assessment to determine the child's safety to leave the ED or need for inpatient treatment. Such an assessment is difficult and often puts the ED team at odds with the parent, who may wish to take the patient home against medical advice or who may wish to hospitalize the patient when this is not clinically indicated. Assessing and managing risk of harm to self or others is discussed more at length below.

Evaluating Medical and Psychosocial Causes of Behavioral Disturbance

The second priority of the ED evaluation is ruling out and treating medical and social/systemic causes of behavioral disturbance. While children and adolescents generally lack the complex and chronic medical conditions of adult psychiatric patients, medical illness can nonetheless masquerade as psychiatric illness in subtle and confusing ways. Seizures (particularly temporal lobe seizures and absence seizures), infectious and autoimmune encephalitis, brain tumors, head trauma, and tropical diseases can manifest with hallucinations, mental status change, and behavioral dysregulation. Children may also present with behavioral changes related to undiagnosed chronic diseases such as porphyria, sickle cell anemia, metabolic disorders and other genetic syndromes. Drug intoxication and other self-poisoning (due to accidental ingestion or intentional acts meant as a suicide attempt or to get high) can also present with psychiatric symptoms. Red flags that are suggestive of a possible medical etiology include:

- Clouding of consciousness
- Waxing and waning mental status
- Disorientation
- Memory impairment
- Acute onset of psychosis in a child with no previous psychiatric history
- Abnormal vital signs

When a medical etiology is suspected, even if it is unlikely, an appropriate workup should be completed to ensure that a medical illness is not missed. Initial workup should include a full physical examination; diagnostic studies including a complete blood count with differential, liver function tests, chemistries including glucose and electrolytes, an electrocardiogram, urine drug screen, blood alcohol level, medication blood levels if applicable, neuroimaging when indicated, and in certain cases cerebrospinal fluid studies if encephalitis is a potential concern. Children with acute medical illness, who are severely intoxicated, or who have made

a suicide attempt by overdose or other method that has caused significant injury, will likely require medical admission prior to psychiatric hospitalization, and should be followed by the psychiatric consult–liason service during their medical care to avoid unnecessary delay in their psychiatric treatment.

Clinicians should also remember that normal developmental changes, such as puberty, and minor physical ailments such as ear infections, tooth pain, hunger, or fatigue can manifest with or trigger psychiatric or behavioral symptoms, particularly in young children and youth with intellectual or developmental disabilities (Table 36-4–1).

Table 36.4–1.
Common Medical Causes of Psychiatric Disturbance in Children and Adolescents

Fever
Nonconvulsive status epilepticus
Temporal lobe seizures
Absence seizure
Encephalitis
Central nervous system neoplasm or other occult malignancy
Cerebral systemic lupus erythematosus
Childhood confusional migraine
Head trauma or postconcussive syndrome
Porphyria
Sickle cell disease
Substance intoxication
Withdrawal from illicit substances
Anticholinergic delirium
Steroid psychosis or steroid-induced mania
Medication adverse effects such as akathisia from risperidone or irritability from levetiracetam

While medical illness can and does masquerade as psychiatric illness, what is even more common in children is psychosocial crisis manifesting as psychiatric disturbance. It is crucial to consider when a child presents with behavioral disturbance or even more classically psychiatric symptoms such as hallucinations or anxiety, that the child may be the “identified patient” in a distressed or pathological family or social system. Domestic violence and family conflict often manifests with aggressive behavior in a child; reports of auditory hallucinations may be a child’s mimicking the symptoms of a mentally ill parent; or the child may be a victim of physical or sexual abuse or of fabricated or exaggerated symptoms in cases of medical child abuse. Treating the child alone when the source of the symptoms are in the family or social environment not only puts the child at risk for adverse effects from unnecessary medication, but is also psychologically damaging as it teaches the child that the problem is him, not the toxic context in which he
