CUTANEOUS LESIONS. Common blue nevi are usually solitary, asymptomatic blue, blue–gray, or blue–black papules, usually less than 10 mm in diameter (Fig. 122-13). The blue–gray color of blue nevi is an optical effect of blue light backscatter from the skin over the dermal melanin (Tyndall effect). Hypopigmented, target or targetoid, and combined blue nevi (compound nevomelanocytic nevus and a blue nevus) also exist. Common blue nevi occur anywhere, but about half the reported cases present on the dorsa of hands and feet. Usually, the common blue nevus is singular, but rarely, lesions may be multiple and agminated or arranged in large plaques consisting of multiple solitary papules or nodules with intervening areas of blue discoloration. Common blue nevi also occasionally may have satellite lesions that may be mistaken for melanoma metastasis.[66] Rare giant varieties of congenital blue nevus occur, often with multiple satellite lesions.[9] The large plaque blue nevus (pilar neurocristic hamartoma) may occasionally be associated with a background of lentigo simplex.

The deep penetrating nevus may be considered a unique form of blue nevus, but some would include this lesion in the category of Spitz nevus. Deep penetrating nevi are darkly pigmented, blue–black papules or nodules, mostly on the head and neck or upper extremities, 2–9 mm in diameter, and occurring predominantly in the first four decades of life, including childhood.[67]

Cellular blue nevi are blue–gray or blue–brown nodules or plaques 1–3 cm in diameter, occasionally larger (see Fig. 122-13C). Their surface is usually smooth but may be irregular. Approximately one-half the cases are located on the buttocks or sacrum. Cellular blue nevi may develop in association with CNN, occasionally with target appearance. Cellular blue nevus differs from the common blue nevus in that it is usually larger, more elevated, more aggressive locally, and occasionally associated with lymph node "benign metastasis." Complicating the picture is the fact that melanoma may develop in a cellular blue nevus.

Malignant blue nevus (melanoma) may develop in contiguity with a cellular blue nevus, nevus of Ota, combined congenital blue nevus, or de novo. Malignant blue nevus presents as an expanding dermal nodule with or without ulceration. There is some dispute as to whether malignant blue nevus should be considered a separate entity from melanoma or simply referred to as a *melanoma developing in a blue nevus*.

RELATED PHYSICAL FINDINGS. The presence of epithelioid blue nevi may warrant consideration of Carney complex/myxoma syndrome/LAMB syndrome, with evaluation for related findings, including atrial myxomas and endocrine tumors.

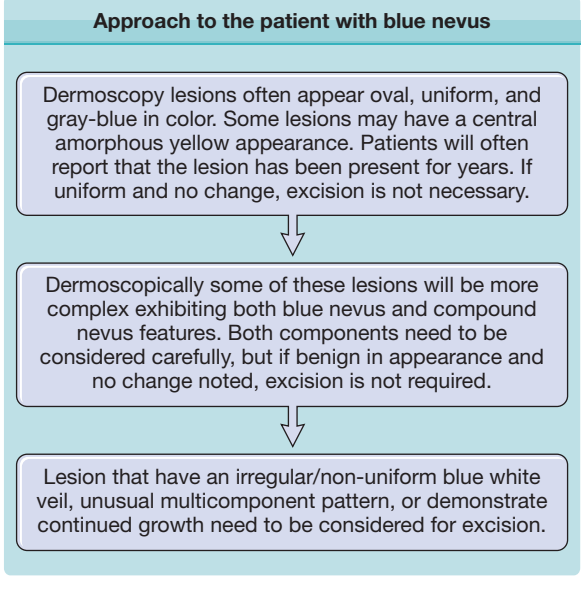

Figure 122-12 Approach to the patient with blue nevus.

LABORATORY TESTS

HISTOPATHOLOGY. In common blue nevi, dermal melanocytes appear as melanin-containing fibroblast-like cells grouped in irregular bundles admixed with melanin-containing macrophages, associated with excessive fibrous tissue in the middle or upper reticular dermis, occasionally extending downward to subcutaneous fat or upward to papillary dermis (Fig. 122-14). Elongated melanin-producing dermal melanocytes in common blue nevi usually lie with their long axis parallel to the epidermis. Except in the case of combined blue nevus (with a compound nevomelanocytic nevus component), the epidermis in common blue nevi appears normal. Combined blue nevi have been noted in 1% of melanocytic nevi excised for histopathologic examination.[68]

Pathology of the plaque-like blue nevus (pilar neurocristic hamartoma) reveals a peripilar grouped arrangement of mostly spindle cells containing varying amounts of melanin, patterns of a common blue nevus and dermal melanocytosis (Mongolian spot), and presence of abnormal (granular) melanosomes. There are other varieties of plaque-like blue nevi with subcutaneous cellular nodules with a range of histologic

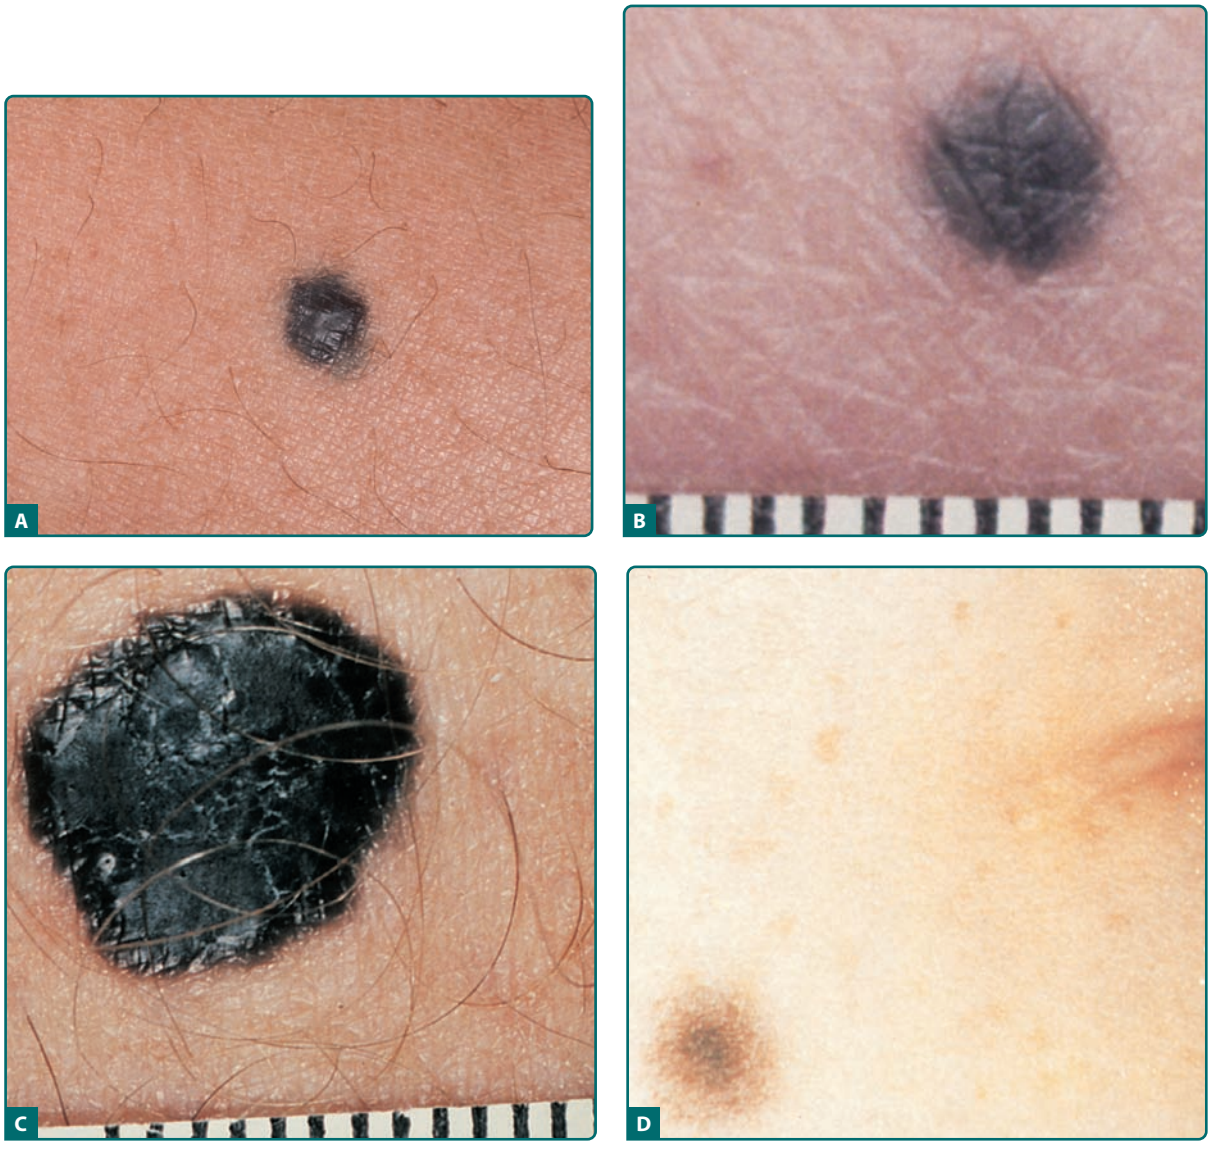

Figure 122-13 Blue nevus. **A.** Common blue nevus appearing as an acquired blue–gray papule on an adult male. Used with permission from Logical Images, Inc. Rochester NY. **B.** Common blue nevus appearing as an acquired blue–gray papule on the buttock of a 62-year-old white man. **C.** Cellular blue nevus appearing as a congenital blue papule on the low back of a 30-year-old white man. **D.** Combined common blue nevus–nevomelanocytic nevus appearing as a brown papule with a blue–gray center on the cheek of a 12-year-old white boy, beginning as a pinpoint dot at age 1 year and enlarging slowly over time. Scale in millimeters. (Part A used with permission from Logical Images, Inc., Rochester, NY.)

appearances from dermal melanocytosis to common blue and cellular blue nevi.[69]

Deep penetrating nevus—identical or similar to plexiform spindle-cell nevus—may have both spindle and epithelioid cell forms and demonstrates deep extension into the dermis or subcutis in a wedge-shaped structure potentially tracking with neurovascular or adnexal structures.[70] These lesions may be related to cellular blue nevi.

In cellular blue nevi, there is usually a component of a common blue nevus plus fascicles of spindle-shaped cells with ovoid nuclei and abundant pale cytoplasm with little or no melanin, and often epithelioid cells, present in the dermis and often in subcutaneous fat in nests, bundles, and neuroid forms with little or no intervening stroma (see Figs. 122-14C and 122-14D). Epithelioid cell and amelanotic varieties of the cellular blue nevus have been described. Epithelioid blue nevi have been reported in association with cardiac myxoma[71] or in isolation.[72] Histopathologic diagnosis may be difficult when the common blue nevus component and melanin production are sparse or inapparent. Differentiation of some cellular blue nevi from melanoma can be difficult. Occasionally, small groups of well-differentiated melanocytes are present in the marginal sinus or parenchyma of lymph nodes draining the anatomic site of the cellular blue nevus, making it difficult to differentiate malignant metastasis from benign "metastasis". It is likely that "inert" deposits of melanocytes in the capsules and peripheral sinuses of

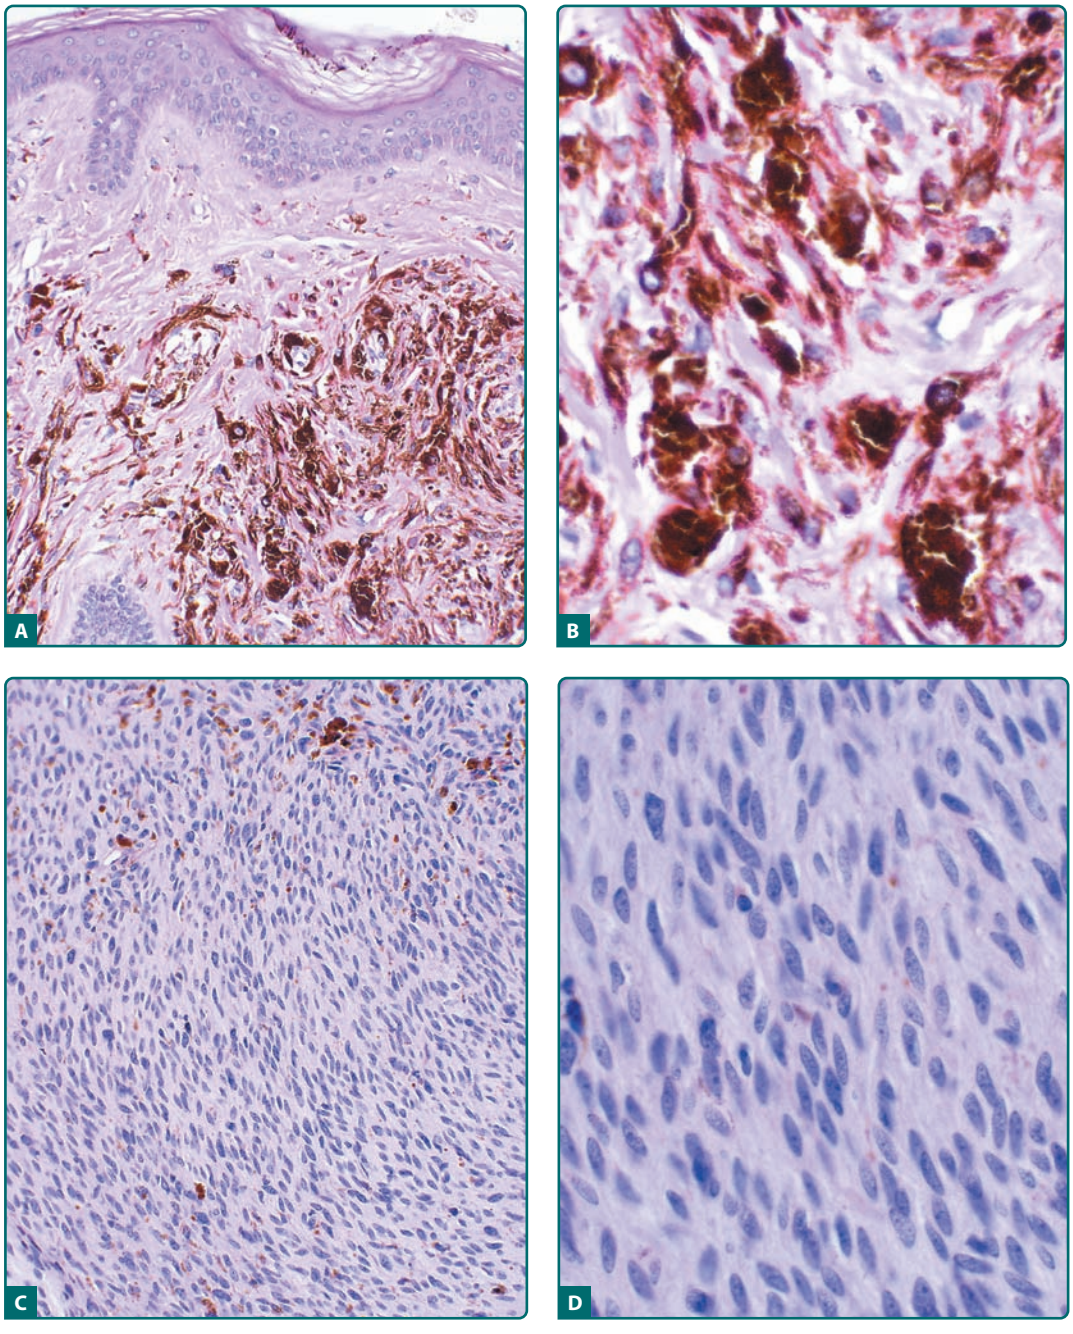

Figure 122-14 Histopathologic features of common and cellular blue nevi. Common blue nevus (**A**) and higher magnification of the dermal component (**B**) revealing heavily pigmented, elongated melanocytes. Cellular blue nevus (**C**) and higher magnification (**D**) revealing sheets of melanocytes with ovoid nuclei.

lymph nodes draining some varieties of cellular blue nevus are transported passively (see Section "Nodal Nevi").

The malignant blue nevus is a variant of melanoma, distinguished from cellular blue nevus by invasiveness, cellular atypia, pleomorphism, atypical mitoses, and areas of necrosis.

SPECIAL TESTS. Imaging tests of the heart may be required if there is concern for Carney complex/myxoma syndrome/LAMB syndrome.

DIFFERENTIAL DIAGNOSIS

(Box 122-4)

COMPLICATIONS

A major complication of blue nevi is the potential risk of melanoma. This risk appears to be highest for cellular blue nevi. Melanoma has been noted to evolve in large blue nevus patches or plaques and in associated with nevus of Ota and Ito.

BOX 122-4 DIFFERENTIAL DIAGNOSIS OF BLUE NEVUS

- Pigmented spindle cell nevus
- Tattoo (traumatic, radiation port marker)
- Primary or metastatic melanoma
- Glomus tumor
- Pyogenic granuloma
- Sclerosing hemangioma
- Dermatofibroma
- Ochronosis

PROGNOSIS AND CLINICAL COURSE

The natural evolution has not been studied for common blue nevi or cellular blue nevi. It is likely that once established, blue nevi remain unchanged or possibly regress over time. "Change" is worrisome for melanoma development.

TREATMENT

A common blue nevus that is stable for many years in an adult usually requires no therapy. Sudden appearance of a blue nodule, expansion of a preexisting blue nodule, a congenital blue nodule, or a relatively large blue nodule or plaque greater than 10 mm in diameter should be considered for histopathologic examination. Excision should include subcutaneous fat to ensure complete removal of deep dermal melanocytes, which are frequently present in the subcutaneous tissue of cellular blue nevus. The large plaque blue nevus (pilar neurocristic hamartoma) requires consideration for excision or periodic evaluation for suspicious change. Cellular blue nevus should be evaluated for excision because of its malignant potential.

PREVENTION

Sun exposure has been implicated as a causative factor in eruptive blue nevi.[73] Thus, as with other nevi, it is reasonable to minimize excessive UVR exposure.

PIGMENTED SPINDLE CELL NEVUS

PIGMENTED SPINDLE CELL NEVUS AT A GLANCE

- Acquired, benign melanocytic tumor comprised of heavily pigmented spindle-shaped melanocytes in nests confined primarily to the epidermis.
- The pigmented spindle cell nevus presents as a jet black lesion often with "starburst" appearance.
- These nevi are thought to develop quickly and then stabilize.
- Malignant degeneration is thought to be rare.
- Synonyms: Reed nevus and pigmented Spitz nevus.

EPIDEMIOLOGY

The mean age of presentation has been reported as 25.3 years, ranging from 2.5 to 56.0 years of age.[74] Similar age ranges have been reported in other studies.[75] The majority of cases occur in the third decade of life. Female patients outnumber male patients with reported ratios of 2:1,[74] 1.4:1.0,[75] and 1.3:1.0.[76] The majority of these lesions are found on the extremities with reported frequencies of 67.0%,[74] 69.6%,[76] and 75.0%.[75] There is a preference for the lower extremity, especially the thigh, with the back being the next most common site.[75]

ETIOLOGY AND PATHOGENESIS

It may be presumed that PSCN are derived from the same progenitor cells giving rise to epidermal melanocytes and nevomelanocytes. No known specific mutation has been identified.

CLINICAL FINDINGS

(Fig. 122-15)

HISTORY. PSCN was first described by Reed in 1975.[77] These lesions are generally detected as acquired lesions, often during the third decade of life. At presentation, patients often note that the lesion has increased in size.[75,76] It is not known how quickly these lesions

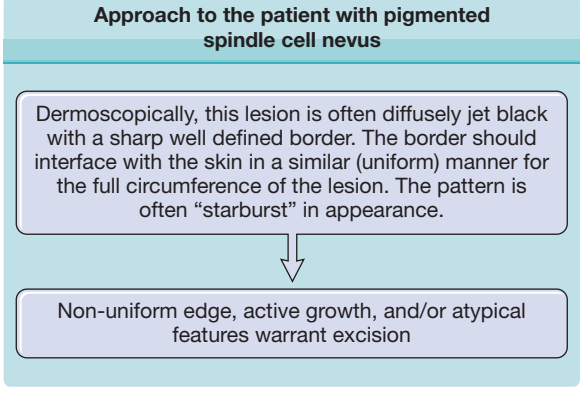

Figure 122-15 Approach to the patient with pigmented spindle cell nevus.

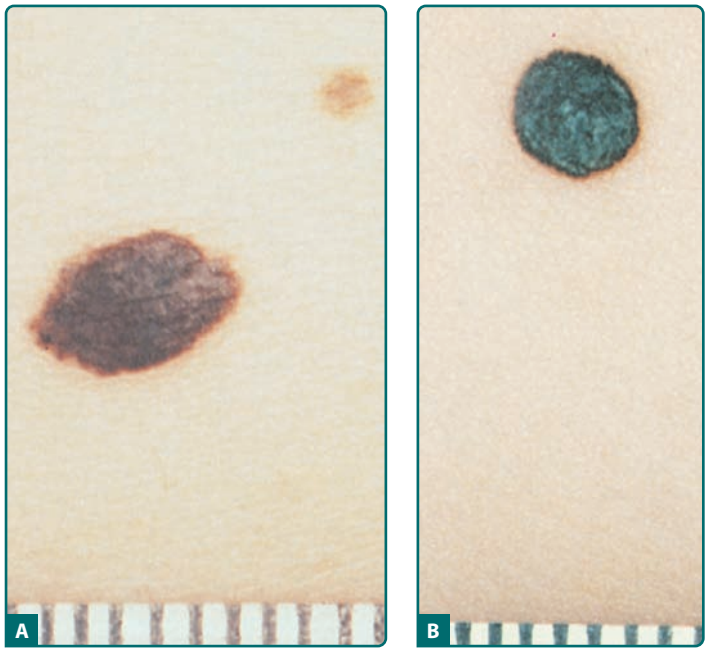

Figure 122-16 Pigmented spindle cell nevus. **A.** Very dark brown plaque appearing over several weeks on the posterior thigh of a 22-year-old white woman. **B.** Very dark-bluish plaque appearing de novo 3 months previously on the back of an 8-month-old white (Hispanic) boy. Scale in millimeters.

grow, but growth may be relatively rapid as one case report of a lesion on a 3-year-old child documented significant growth over a 3 to 6 month period.[78] Once fully developed, it is assumed that these lesions will remain stable, but the full natural history of these lesions is not well characterized.

CUTANEOUS LESIONS. The PSCN is usually a sharply circumscribed, uniformly darkly pigmented papule[74–76] (Fig. 122-16). Dermoscopically, most of the lesions are jet black but may be blue–gray or brown. In the initial growth phase, the lesions may have a globular appearance[78] but the vast majority of these lesions are uniformly dark, with a sharp interface with surrounding skin often exhibiting streaks/pseudopods and giving the lesion a starburst appearance.

RELATED PHYSICAL FINDINGS. No known association.

LABORATORY TESTS

HISTOPATHOLOGY. PSCN consists of vertically oriented fascicles of spindle-shaped, pigment-producing melanocytes (Fig. 122-17); some pagetoid upward migration may be present, but the lesion can be distinguished from melanoma by uniform nuclei, uniform cellular detail, and distinctive pattern of growth. Almost all cases of pigmented spindle cell nevus have a lymphohistiocytic host response. Spindle cells extend down eccrine ducts in 40% and involve hair follicles in 22% of lesions.[74] There is an overlap of these lesions with epithelioid cell and spindle cell nevi (Spitz tumor). In a review of 91 PSCN by Sagebiel et al,[74] cells were predominantly spindle in 74% and mixed spindle cell and epithelioid cell in 26% of patients. There are atypical variants of PSCN in which there are architectural alterations and striking cellular atypia.[76]

SPECIAL TESTS. Although BRAF mutations have been noted, these mutations are also present in other acquired nevi, and thus far there is no specific marker for PSCN.

DIFFERENTIAL DIAGNOSIS

(Box 122-5)

COMPLICATIONS

There are no reported complications, but misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

PROGNOSIS AND CLINICAL COURSE

The PSCN are thought to be benign. No local recurrence or distant spread was noted for 38 patients followed for an average of 14 months.[74] In another study, 57 patients were followed for an average of 6 years and again no local recurrence or metastasis was noted.[75]

BOX 122-5 DIFFERENTIAL DIAGNOSIS OF PIGMENTED SPINDLE CELL NEVUS

- Spitz tumor
- Blue nevus
- Hematoma

- Hypermelanotic nevomelanocytic nevus
- Combined nevomelanocytic/blue nevus
- Melanoma

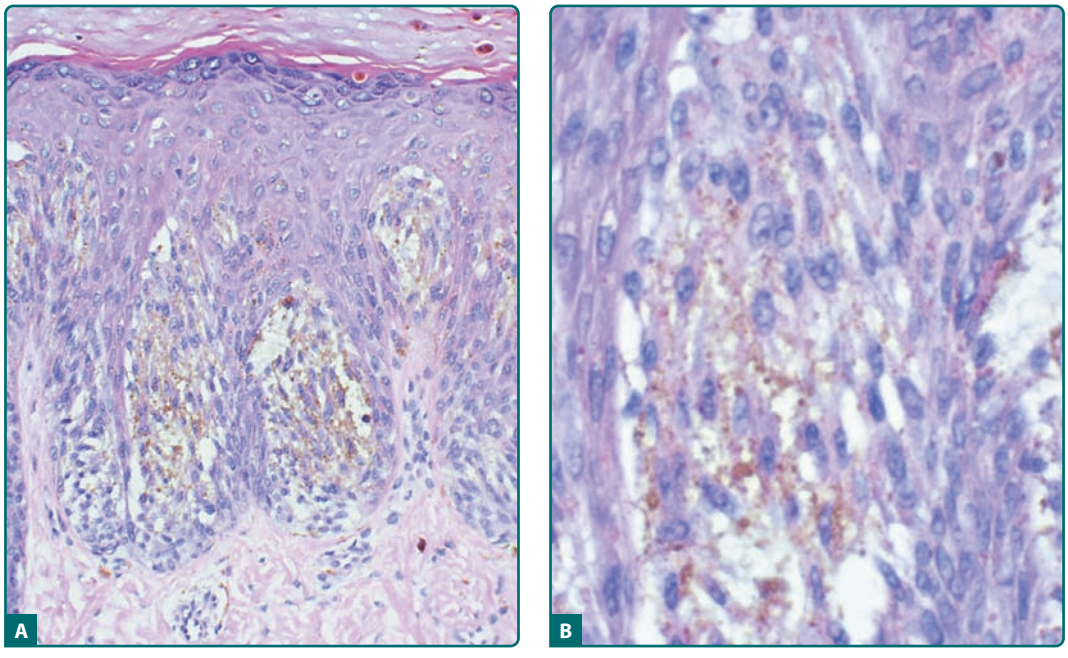

Figure 122-17 Histopathologic features of pigmented spindle cell nevus (**A**) and higher magnification of the intraepidermal component (**B**) revealing pigmented spindle-shaped cells.

TREATMENT

Given the frequent difficulties in the histopathological differentiation from melanoma, these lesions should be excised with 3–5 mm margins of normal skin.

PREVENTION

The role of UVR exposure in the development of PSCN is unknown.

SPITZ NEVUS

EPIDEMIOLOGY

An annual incidence rate of 1.4 cases of Spitz nevus per 100,000 individuals has been estimated in Australia, compared with 25.4 per 100,000 individuals for cutaneous melanoma during the same time interval.[79] Among melanocytic nevi excised in children, 1% to 8% of cases are interpreted as Spitz nevus.[80] In a case series of 308 patients with Spitz nevi reported by Allen,[81] 15% of lesions occurred in adolescents and adults, the oldest patient being 56 years of age. There appears to be no gender predilection for Spitz nevus. Published cases have been described primarily in whites.

ETIOLOGY AND PATHOGENESIS

It may be presumed that Spitz nevi are derived from the same progenitor cells that give rise to epidermal melanocytes and nevomelanocytes. Unlike common acquired nevi and congenital nevi, the *B-RAF* mutation does not appear to be involved. Amplifications of chromosome 11p and H-RAS and activating mutations of H-RAS have been noted in a subset of Spitz nevi.[82] Heritable genetic factors have not been investigated

SPITZ NEVUS AT A GLANCE

- Spitz nevi represent a spectrum of unique, usually acquired lesions, exhibiting epithelioid and often spindle-shaped melanocytic cells with abundant eosinophilic cytoplasm, large nuclei, and often prominent nucleoli. Often develop in the epidermis and dermis, or may be purely intradermal and even desmoplastic. Atypical variants exist.
- Clinically, pure epithelioid nevi are red, dome-shaped papules, while mixed epithelioid cell and spindle cell nevi may have varying degree of pigmentation.
- Spitz nevi are thought to develop quickly and then stabilize. Their clinical presentation and histopathology can cause diagnostic confusion for melanoma.
- Synonyms: Spitz tumor, nevus prominens et pigmentosus, pseudomelanoma, spindle and epithelioid cell nevus, nevus of large spindle and/or epithelioid cells, and compound melanocytoma. The previously used terms *Spitz's juvenile melanoma*, *benign juvenile melanoma*, and *prepubertal melanoma* should not be used to avoid confusion for melanoma.

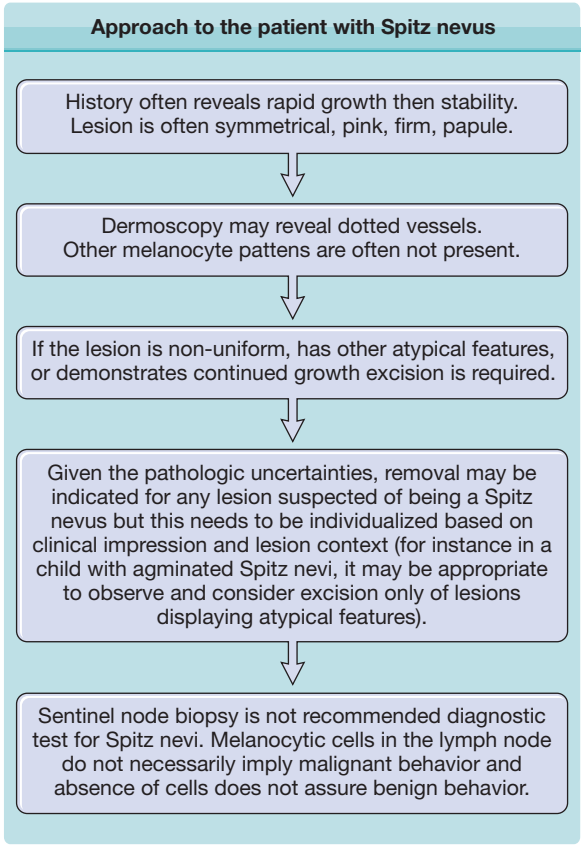

Figure 122-18 Approach to the patient with Spitz nevus.

systematically, but there is a single report of multiple nevi in identical twin boys.[80] The role of trauma in the histogenesis of Spitz nevi is speculative. One case has been reported at the site of Bacille Calmette-Guérin vaccination.[83]

CLINICAL FINDINGS

(Fig. 122-18)

HISTORY. The rate of growth, period of stabilization, and rate of regression of Spitz nevi are not known. The duration of solitary Spitz nevus before presentation is usually less than 9 months. Lesions usually show an increase in radial size over time, some gradual and others rapid.[84] Based on patients with eruptive Spitz nevi, regression has been reported to occur and may even occur in some lesions while new lesions are appearing.[85]

CUTANEOUS LESIONS. The most common variety of Spitz nevus is solitary, asymptomatic, pink or red, hairless, firm, and dome-shaped (Fig. 122-19). Some Spitz nevi may resemble a keloid. The surface is commonly smooth, and the borders may fade into surrounding skin. Verrucous, scaly, stippled, crusted, or (rarely) eroded lesions have been noted. Spitz nevi are usually asymptomatic, but pruritus, tenderness, and/or bleeding may occur.[80] A halo of depigmentation has been associated with several cases of Spitz nevus.[30,86] Spitz nevi are part of a spectrum in which some also include PSCN and deep penetrating nevi.

Spitz nevi can also present as widespread eruptive lesions or in a grouped manner as multiple agminated lesions consisting of red, red–brown, brown, or dark-brown papules or nodules, with a fine stippled surface (see Fig. 122-19C). Agminated Spitz nevi often occur in the early years of life within a background of congenital (sometimes acquired) macular pigmentation (nevus spilus) or occasionally within a hypopigmented plaque. Spitz nevi may also develop as single or multiple lesions in a large CNN.

The diameter of Spitz nevi ranges from several millimeters to several centimeters, the average being 8 mm in one series.[80] In 73% of patients in one series,[79] the nevus diameter was 6 mm or less, and in 94% of patients, the nevus diameter was less than 10 mm. Most cases are described as superficial papules or nodules, although subcutaneous involvement may occur.[85] In one series of 43 patients,[80] the anatomic location included the head or neck in 18, upper extremities in 9, torso in 9, and lower extremities in 7. Spitz nevi tend to spare palms, soles, and mucous membranes.

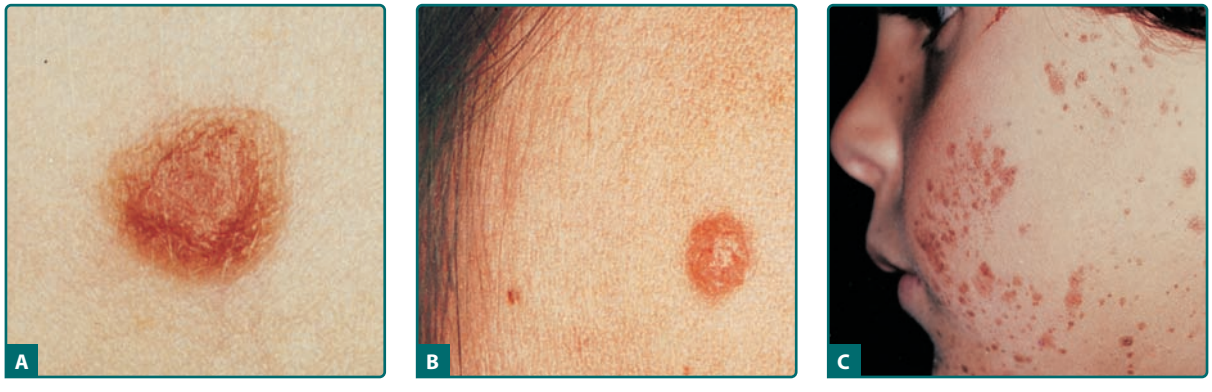

Figure 122-19 Spitz nevi. **A.** Pink plaque, which appeared de novo over an 8-week period, becoming more elevated with time, in the preauricular area of a 4-year-old white boy. **B.** Dome-shaped pink papule, which appeared de novo over a 2-week interval 4 months before, on the forehead of a 5-year-old white boy. **C.** Agminated Spitz tumors. Numerous grouped pink papules and plaques, appearing at age 6 months, on the face of a 4-year-old white boy.

RELATED PHYSICAL FINDINGS. There is no known association with other somatic abnormalities.

LABORATORY TESTS

HISTOPATHOLOGY. Unlike ordinary nevi and melanomas, melanocytic cells in Spitz nevi are large—often twice the size of epidermal basal keratinocytes,[84] with prominent mononuclear or multinucleated giant cells in the epidermis and/or dermis (Fig. 122-20). Mitoses, usually few in number, are detected in one-half the cases,[86] whereas atypical mitoses are uncommon in Spitz nevi. In contrast to melanoma, the melanocytic cells in Spitz nevi show progressive maturation with increasing depth, becoming smaller and more similar to ordinary nevomelanocytes,[84,86] with the overall distribution of cells in the dermis being wedge-shaped, with narrowing of the wedge toward the subcutaneous fat.

Coalescent eosinophilic globules (Kamino bodies), periodic acid-Schiff-positive and diastase-resistant (resembling colloid bodies), have been reported in 60% of Spitz nevi[87] (see Fig. 122-20). Similar globules may be detected in 2% of melanomas and 0.9% of typical acquired nevi, but the globules are smaller in size, more difficult to find, single rather than coalescent, and commonly periodic acid-Schiff-negative.[87]

Melanocytic elements are usually arranged in well-circumscribed nests, although there may be permeation of the epidermis by single cells or small groups of cells. In those cases with epidermal nests, artifactual clefts are usually seen above the nests in half the cases, a finding rarely observed in melanoma.[79] The epidermis is usually hyperplastic, with elongated and bulbous pegs and knobs extending into the dermis, although thinning and even ulceration may occur rarely. The dermal inflammatory cell infiltrate may be slight or marked, band-like, and mainly at the base or patchy around blood vessels and/or intermixing with nevus cells. Although melanin was observed in all 13 patients originally described by Spitz,[84] more recent studies have determined that melanin was moderate in 10% of cases and heavy in 5%.[86]

Although the bizarre histopathologic features and frequent occurrence of dermal inflammation may cause diagnostic confusion, Spitz nevus usually can be differentiated from melanoma. The histologic features of Spitz nevus in children and adults are similar.

SPECIAL TESTS. A subgroup of Spitz nevi have a gain of chromosome 11p and amplification or activation of H-RAS.[82] These markers are not routinely used in the clinical setting but may be helpful in the future for discriminating these nevi from other melanocytic neoplasias. Retention of p16 may also help discriminate Spitz nevi from Spizoid melanomas.[88]

DIFFERENTIAL DIAGNOSIS

(Box 122-6)

COMPLICATIONS

Misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

PROGNOSIS AND CLINICAL COURSE

The natural history of the Spitz nevus is largely unknown. Based on patients with eruptive Spitz nevi, it is clear that spontaneous regression can occur.[85]

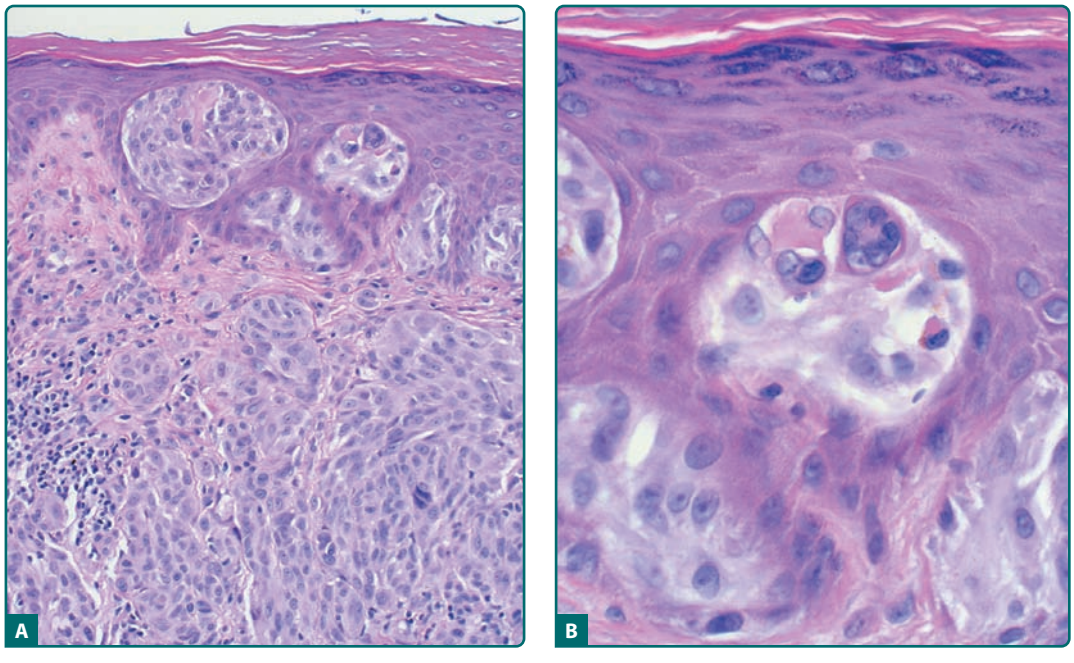

Figure 122-20 Histopathologic features of Spitz tumor (**A**) and higher magnification of the intraepidermal component revealing eosinophilic cytoplasmic changes (Kamino bodies) in several cells (**B**).

WARTY VARIANTS

- Verruca vulgaris
- Seborrheic keratoses
- Epidermal nevus
- Epidermolytic acanthoma

A concern is that some lesions diagnosed as Spitz nevi may progress to melanoma or represent melanoma at the outset.[89]

TREATMENT

Complete excision with a 3–5 mm clear margin of normal skin is generally sufficient treatment for Spitz nevi. Given the difficulty of confidently excluding the possibility of melanoma in certain cases, an even wider margin of normal skin may be prudent for histopathologically worrisome lesions.[89] Incompletely excised lesions may recur in as many as 7% to 16% of patients.[80,90–92] Although some authors have advocated sentinel node biopsies in these lesions, this may only add to the confusion because Spitz nevus cells may be present in the regional lymph nodes but not necessarily indicate malignancy.[93] Management of patients who have numerous Spitz nevi requires individual judgment and periodic surveillance for new or unstable lesions.

PREVENTION

The role of UVR exposure in the development or progression of Spitz nevi is unknown.

NODAL NEVI

NODAL NEVI AT A GLANCE

- Benign melanocytic neoplasia present in a lymph node. Nevomelanocytes are often located in the capsule but may also be present in the nodal parenchyma.
- Generally asymptomatic and found incidentally as a result of lymph node removal.
- Cells may be deposited passively into the node from a cutaneous melanocytic lesion. It is also possible that abnormal migration pathways result in the nevomelanocytes taking up residence in the nodes during embryonic migration of melanocytes.
- The presence of melanocytic cells in nodal tissue creates difficulties for pathologists evaluating sentinel node biopsies in patients with cutaneous melanoma.

EPIDEMIOLOGY

Nevomelanocytes can be identified in lymph nodes with a frequency ranging from 0.3% to 7.3% in lymphadenectomies not related to melanoma and up to 22% in regional nodes removed because of melanoma.[94] When nevomelanocytes are evident in lymphadenectomies due to melanoma, it has been reported that 75% of the primary cutaneous melanomas had an associated nevomelanocytic nevus, often with congenital features.[95] A significant association has also been noted for the presence of cutaneous nevomelanocytic nevi in the zones of skin drained by lymph nodes that were found to include nevomelanocytes.[96] In most cases, the nevomelanocytes appear to be derived from common acquired nevomelanocytic nevi, but CNNs, blue nevi, cellular blue, and Spitz nevi have all also been reported to involve regional lymph nodes.[62]

ETIOLOGY AND PATHOGENESIS

There are two prevailing theories as to the mechanism by which nevomelanocytes appear in regional lymph nodes.

The first theory is that during development, nevomelanocytes get trapped in developing nodal tissues. Some support for this theory could be based on the fact that nodal nevi can be found in association with CNNs. This observation suggests that there is an opportunity for nevomelanocytes to be deposited during development. Further, blue nevus cells can be found in tissues such as prostate, cervix, vagina, spermatic cord, and seminal vesicles.[62] Thus, aberrant migration and differentiation of melanocytic cells does occur.

The second theory suggests that there may be passive transfer from the cutaneous lesion to the lymph node. Substances such as carbon, tattoo ink, and radioactive colloid are readily transferred to the draining lymph node. It is reasonable to assume that loosely adherent nevomelanocytes could also traverse the same path. In fact, nevomelanocytes have been noted in lymph channels.[62] Once in the lymph node, nevomelanocytes are generally identified in the capsule, but they can also be found in the parenchyma.[94] It is not known how nevomelanocytes get into the capsule, but it is reasonable to assume that these cells migrate from the parenchyma into the capsule. It is important to note that melanoma cells can also be found in the capsule,[97] so it is rational to assume that entry into the capsule is not limited to a developmental event. The fact that nevomelanocytes in regional lymph nodes are highly correlated with the presence of nevomelanocytic nevi in the skin supports the concept that these cells may arrive in lymph nodes via dissemination from benign cutaneous lesions.

CLINICAL FINDINGS

(Fig. 122-21)

HISTORY. Generally, nodal nevi are identified in lymph nodes that are removed because of melanoma, but these benign cells are also identified in nodes removed for other reasons. Generally, the patient does not note symptoms related to nodal nevi.

CUTANEOUS LESIONS. Common acquired nevomelanocytic nevi, CNNs, blue nevi, and Spitz nevi have been associated with nodal nevi.[62]

RELATED PHYSICAL FINDINGS. Due to concern for melanoma, patients should be evaluated for findings that might be worrisome for metastatic melanoma.

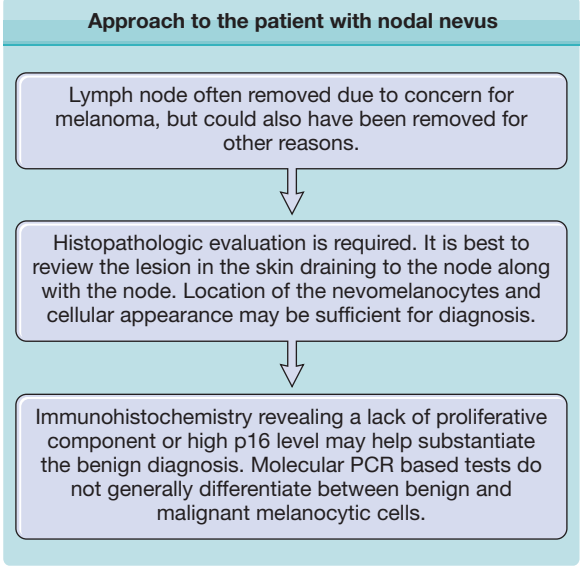

Figure 122-21 Approach to the patient with nodal nevus. PCR = polymerase chain reaction.

LABORATORY TESTS

HISTOPATHOLOGY. Pathology often reveals nevomelanocytes largely confined to the nodal capsule. However, cells may also be noted in the parenchyma. These cells should bear resemblance to the cells in the cutaneous lesion. Lack of proliferative markers (Ki67) and possibly high levels of p16 immunohistochemical markers support a benign diagnosis.[98]

SPECIAL TESTS. The use of standard immunohistochemical tests may help identify the location and cellular features of nevomelanocytes in lymph node tissue sections. Reverse transcriptase–polymerase chain reaction tests for tyrosinase mRNA in lymph nodes do not discriminate benign from malignant melanocytic nodal disease.

DIFFERENTIAL DIAGNOSIS

(Box 122-7)

COMPLICATIONS

Complications, such as scarring or lymphedema, may be the consequence of lymphadenectomy. Misinterpretation of benign nodal deposits as malignant could result in unnecessary regional lymph node dissection and treatment with systemic agents. Misinterpretation of malignant melanocytes as benign in lymph nodes may lead to undertreatment.

PROGNOSIS AND CLINICAL COURSE

If the lymph node deposits are determined to be benign, no further treatment is warranted.

TREATMENT

None required for benign nodal nevi.

LENTIGO SIMPLEX

EPIDEMIOLOGY

The frequency of lentigo simplex in children and adults has not been determined. There does not appear to be a racial or gender predilection. Lentigo simplex is the most common histopathologic pattern of darkly

BOX 122-7 DIFFERENTIAL DIAGNOSIS OF NODAL NEVI

- Melanoma
- Cells from another neoplastic source
- Foreign body deposit (tattoo ink, carbon)

LENTIGO SIMPLEX AT A GLANCE

- Includes a spectrum of melanocytic hyperplasias consisting of intraepidermal melanocytic hyperplasia and increased melanin formation. The extent of melanocytic hyperplasia can be quite variable, ranging from lesions in which the increased melanin content is notable but the increase in melanocyte number is marginal, to lesions in which accumulation of melanocytes is marked.
- Lesions consist of hyperpigmented macules and may be isolated, agminated (focal cluster), or multiple and present on skin, nails, and mucous membranes.
- May be congenital or acquired.
- Multiple lentigines may be associated with somatic abnormalities.
- Synonyms: simple lentigo, melanotic macule, lentiginosis. Other names for agminated lentigines include unilateral lentigines, partial unilateral lentiginosis, lentiginous mosaicism, and segmental lentiginosis.
- Other lesions in which epidermal melanocytic hyperplasia may be noted, and some overlap may exist with simple lentigines, include café-au-lait macules, melanoacanthoma, labial melanotic macule, melasma, and inflammatory/cytokine-induced proliferation.

pigmented lesions excised from acral sites of persons who have darkly pigmented skin.[29] Pigmented nail bands, noted in up to 20% of Japanese, may have histopathologic features of lentigo simplex.[99] For agminated lentigines, the population prevalence is unknown but believed to be rare.

ETIOLOGY AND PATHOGENESIS

The increased density of melanocytes in lentigines is presumably due to an underlying developmental or intrinsic defect in melanocyte homeostasis. In some lentigines, the presence of melanin macroglobules in melanocytes and keratinocytes suggests that defects affecting melanization pathways are also involved. The presence of lentigo simplex in association with somatic abnormalities in such diverse conditions as Peutz–Jeghers syndrome, LEOPARD syndrome (*l*entigines; *e*lectrocardiogram conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis; *a*bnormalities of genitalia; *r*etardation of growth, and sensorineural *d*eafness), and LAMB/myxoma syndrome suggests that lentigo development may be influenced by a number of different developmental and genetic factors. For agminated lentigines, it is possible that chromosomal mosaicism plays a role in the development of the localized grouping of lentigines. The cause for delayed appearance of lentigines in the skin, mucosa, and nail matrix in Laugier–Hunziker pigmentation is unknown.

CLINICAL FINDINGS

(Fig. 122-22)

HISTORY. Unlike solar lentigines, lentigo simplex is by definition UVR independent. Lentigo simplex may appear as early as the first decade and may occur anywhere on skin or mucous membranes.

Generalized lentigines may occur as an isolated phenomenon without known familial aggregation and first appear at birth, during infancy, or during adulthood. Familial clustering in an autosomal dominant pattern has been noted. A number of syndromes are recognized (see Chapter 75).

In Moynahan (LEOPARD) syndrome, lentigines are present at birth or shortly thereafter and may increase in number during childhood. In Peutz–Jeghers syndrome, numerous lentigines may be present at birth or appear during early childhood. Oral pigmentation usually persists in Peutz–Jeghers syndrome, whereas cutaneous lentigines usually fade after puberty. In LAMB syndrome, the lentigines on the lips and genital sites appear in early childhood and tend to persist. In Laugier–Hunziker pigmentation, lentigines are acquired during

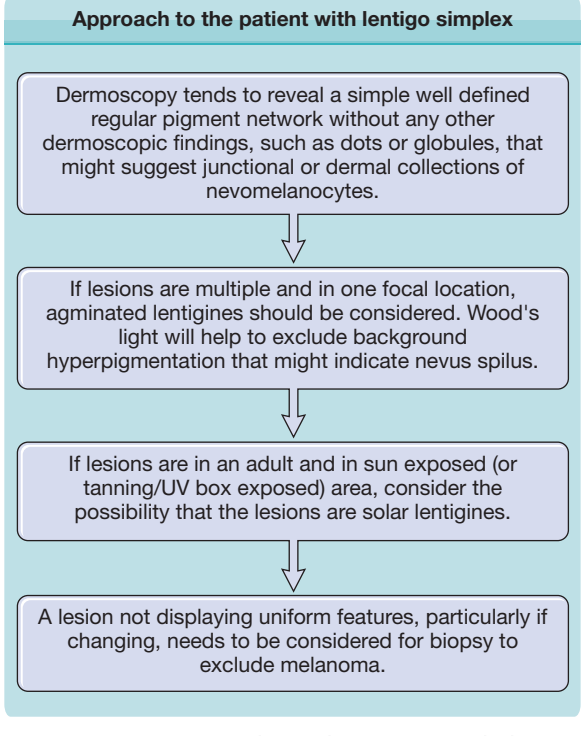

Figure 122-22 Approach to the patient with lentigo simplex. UV = ultraviolet.

adulthood and persist indefinitely, not associated with somatic abnormalities. Agminated lentigines first become manifest at birth or early childhood.

CUTANEOUS LESIONS. Lentigo simplex usually is a sharply circumscribed, light-brown to very dark-brown macule.

In Moynahan (LEOPARD) syndrome, lentigines occur on both sun-exposed and sun-protected sites, including genitalia, conjunctiva, oral mucosa, palms, and soles. In Peutz–Jeghers syndrome, lentigines are almost always present on the oral mucosa. Other common sites of involvement include lips, nose, eyelids, anus, nail bed, and dorsal and ventral surfaces of hands and feet.

Lentigines in the myxoma syndrome (LAMB) occur mainly on the face and genitalia as tan to black macules (Fig. 122-23). In centrofacial lentiginosis, the presence of pigmented macules is restricted to a horizontal band across the central face. Lentigines in Laugier–Hunziker pigmentation occur on the buccal and labial mucosa of the mouth, on fingertips and nail matrix, and occasionally in other sites of the skin and mucous membranes.

Agminated lentigines first become manifest at birth or early childhood as small, circumscribed, light-brown macules, 2–10 mm in diameter, confined to a localized area of the skin, often in a segmental distribution (Fig. 122-24) and frequently in a curvilinear or swirled pattern. Wood's lamp examination may be required to differentiate agminated lentigines from nevus spilus, because the macular background pigmentation is evident in the latter and absent in the former.

RELATED PHYSICAL FINDINGS. If there is concern that the lentigines are part of a syndrome, further evaluation is appropriate, and should be guided by the physical findings and syndrome under consideration.

LABORATORY TESTS

HISTOPATHOLOGY. Lentigo simplex consists of intraepidermal melanocytic hyperplasia in the basal layer of elongated epidermal rete ridges, without nest formation. At one end of the lentigo spectrum, lesions are more similar to café-au-lait lesions, in which the melanocyte number may only be minimally increased but pigmentary differences are marked; at the other end of the spectrum, the number of melanocytes is sufficiently increased to begin forming nests, appearing similar to a junctional nevus. Depending on the degree of keratinocytic hyperplasia, distinct separation from solar lentigo may not be possible based on histopathologic interpretation alone. Giant pigment granules (melanin macroglobules) may occur in lentigo simplex in isolation, and in association with multiple-lentigines (LEOPARD) syndrome.

In agminated lentigines and Laugier–Hunziker pigmentation, histopathologic studies reveal increased numbers of melanocytes in elongated epidermal rete ridges, similar to lentigo simplex, without nests of nevomelanocytes or cellular inflammation.

SPECIAL TESTS. Mart-1, Mel-5, and DOPA histochemistry may be useful to demonstrate increased number of melanocytes confined to the basal layer and lacking junctional nest formation. If a syndrome is under consideration, imaging studies may be required and genetic testing may be considered.

DIFFERENTIAL DIAGNOSIS

(Box 122-8)

COMPLICATIONS

There are no known complications from lentigo simplex. Complications arise from the associated syndromes.

Figure 122-23 Lentigo simplex. **A.** Acquired darkly pigmented lentigines on the vulva of a 13-year-old white girl who has *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi (LAMB, myxoma syndrome, Carney's complex). **B.** Multiple lentigines on the lips of the same patient. This patient died in her mid-20s of a malignant schwannoma.

Figure 122-24 Agminated lentigines. **A.** Grouping of small light brown macules, present since age 14 years, on the right side of the shaft and glans penis of a 17-year-old healthy white male. **B.** Grouping of small, light brown macules, present for at least 6 years, on the right cheek of a healthy 10-year-old African-American male. **C.** Grouping of small, light-brown macules, present since age 2 years, on the right neck and supraclavicular area of a 13-year-old healthy white female.

Atypical varieties of lentigo simplex (in any anatomic site) may be potential precursors or masqueraders of melanoma.

PROGNOSIS AND CLINICAL COURSE

The natural history of isolated lentigo simplex is not known. Once developed, lesions are presumed to be relatively stable. There is no convincing evidence that lentigo simplex evolves to a nevomelanocytic nevus. As with any process in which melanocytes are present (including normal skin), it is possible for melanoma to arise in a lentigo, but an elevated risk has not been demonstrated conclusively for lentigo simplex.

The long-term course and malignant potential of agminated lentigines and the lentigines in Laugier–Hunziker pigmentation are unknown.

BOX 122-8 DIFFERENTIAL DIAGNOSIS OF LENTIGO SIMPLEX

SOLITARY

- Solar lentigo/ephelis
- Junctional nevomelanocytic nevus
- Atypical (dysplastic) melanocytic nevus
- Café-au-lait macule
- Melanoma (lentigo maligna)

GROUPED

- Agminated nevomelanocytic nevi or lentigines
- Nevus spilus

TREATMENT

There is no need to treat benign-appearing lentigo simplex. Cosmetic removal may be achieved with cryotherapy or other destructive approaches such as Q-switched laser. There is a theoretical risk of malignant transformation of any variety of melanocytic hyperplasia or dysplasia using any type of laser. Caution must be exercised to ensure the lesion being treated using destructive therapy is benign. Lesions that are significantly unusual, irregular, asymmetric, or changing in shape should be examined histopathologically to exclude melanoma before destructive therapy is considered. Wood's lamp examination is useful in defining margins of lentigo simplex.

Until the long-term course of agminated lentigines and Laugier–Hunziker pigmentation is known, it may be prudent to recommend periodic examinations to detect the earliest signs of possible malignant evolution.

PREVENTION

UVR is clearly associated with the development of solar lentigines, but its role in the different types of simple lentigines is not known. However, it is rational to limit UVR overexposure.

SOLAR LENTIGO

EPIDEMIOLOGY

The prevalence of solar lentigines is correlated directly with increasing age, and they are present in 90% of white people over 60 years of age.[101] Solar lentigines are common in individuals who sunburn easily and do not tan, whereas they are uncommon among people who have darkly pigmented skin.[102]

Lentigines may be induced by photochemotherapy [psoralen and UVA light (PUVA) lentigo], occurring in 40% to 50% of patients an average of 5.7 years after starting therapy, their frequency and severity directly attributable to the total number of treatments (Fig. 122-25).[102] Darkly pigmented skin is associated with the lowest risk for PUVA-induced or solar-induced lentigines.[102] Lentigines have been associated with UVA tanning bed use.[103]

SOLAR LENTIGO AT A GLANCE

- Solar lentigo is distinguished from lentigo simplex histopathologically on the basis of shape and extent of epidermal hyperplasia. The epidermal hyperplasia is often more prominent in solar lentigines and may include "bud-like" structures at the base of rete ridges.
- Solar lentigines appear as circumscribed pigmented macules occurring singly or as multiple lesions and present on the skin surface exposed to natural or artificial sources of ultraviolet radiation. Distinct subtypes exist and include the ink spot lentigo.
- Solar lentigines occur in children and adults.[100] Children who have xeroderma pigmentosum develop solar lentigines even during the first 6 months of life, after minimal sun exposure.
- Solar lentigines are benign but caution must be taken to discriminate benign lesions from lentigo maligna.
- Synonyms: sun-induced freckle, liver spot (large cell acanthoma) lentigo senilis, and senile lentigo.

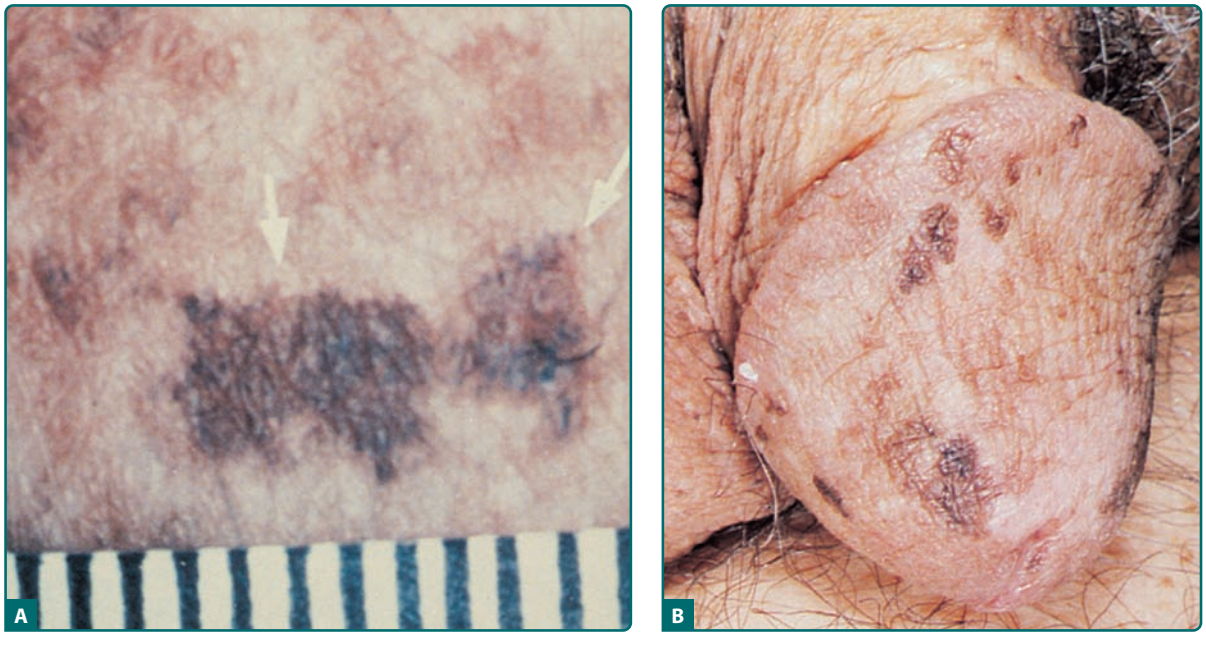

Figure 122-25 Photochemotherapy [psoralen and ultraviolet A light (PUVA)]-induced lentigines on the buttock (**A**) and penis (**B**) of a 57-year-old white man who had received PUVA for psoriasis several times per week for 5 years. The PUVA lentigines appeared between 1 and 2 years after PUVA therapy was begun. The current recommendation is to shield the male genitalia during PUVA therapy to prevent squamous cell carcinoma of the penis and scrotum.

Lesions similar in gross and microscopic appearance to solar lentigo, freckle (ephelis), may occur in children and young adults.[100] They may appear within the first 5 years of life, tend to aggregate in families, and are significantly associated with red hair; their location and density correlate with sun sensitivity and sun exposure. The presence of freckles has been associated with a 2.5-fold increase in the rate of sunburn susceptibility and poor tanning response and a threefold greater likelihood of a lower minimal erythema dose in people who mostly burn and tan minimally or not at all.[104] The presence of dense sun-induced freckling increases the estimated risk for melanoma by three- to fourfold.[105]

ETIOLOGY AND PATHOGENESIS

Solar lentigines are thought to represent a marker of intermittent high-intensity UVR, cumulative UVR, and/or a unique susceptibility to the proliferative, stimulatory, and/or mutagenic effects of UVR. Given the hyperplasia of both the keratinocytes and melanocytes, the primary defect in solar lentigines could be in either cell type eliciting a secondary proliferative response in the other.

There is a pronounced link between UVR exposure and the development of lentigines. Single exposures of experimental UVB radiation (320 mm) that is six to ten times the minimal erythema dose induces "freckling" in susceptible individuals.[106] Phototoxic doses of PUVA may lead to the development of lentigines 6–8 months later.[107] In addition to the total dose of UVR received during photochemotherapy, individual susceptibility factors to lentigo development include degree of skin pigmentation, ethnicity, age, and burning/tanning response to sunlight.[102]

Supportive of the underlying mutation being present in the melanocytes is the finding that epidermal melanocytic cellular atypia persists in lentigines developing in patients receiving chronic photochemotherapy for 1–2 years or longer after therapy is discontinued.[102] In xeroderma pigmentosum (XP), in which patients have an increased sensitivity to UVR, hyperpigmented macules develop on light-exposed skin within the first 5 years of life (see Chapter 139), and these lesions demonstrate hyperplasia of variably atypical epidermal melanocytes (i.e., atypical lentigines). In one series of XP patients from Japan,[108] lentigo maligna melanoma was the predominant melanoma type, suggesting an association between this tumor subtype, sensitivity to UVR, and the presence of UVR-induced atypical solar lentigines, and supportive of the underlying mutation being in the melanocytic lineage.

CLINICAL FINDINGS

(Fig. 122-26)

HISTORY. Solar lentigines appear as acquired lesions, generally in fair-skinned individuals, on sun-exposed skin surfaces. For the majority of solar lentigines, it is assumed that once present, they persist indefinitely.

CUTANEOUS LESIONS. Solar lentigo occurs as a pigmented macule on skin exposed to natural sunlight or artificial sources of UVR, usually in the presence of similar lesions in the same location (Fig. 122-27). Lesions may be tiny (<1 mm in diameter) or large (up to a few centimeters in diameter), with a tendency to confluence in severely sun-damaged skin and with smooth or irregular outlines. Lesions are usually light

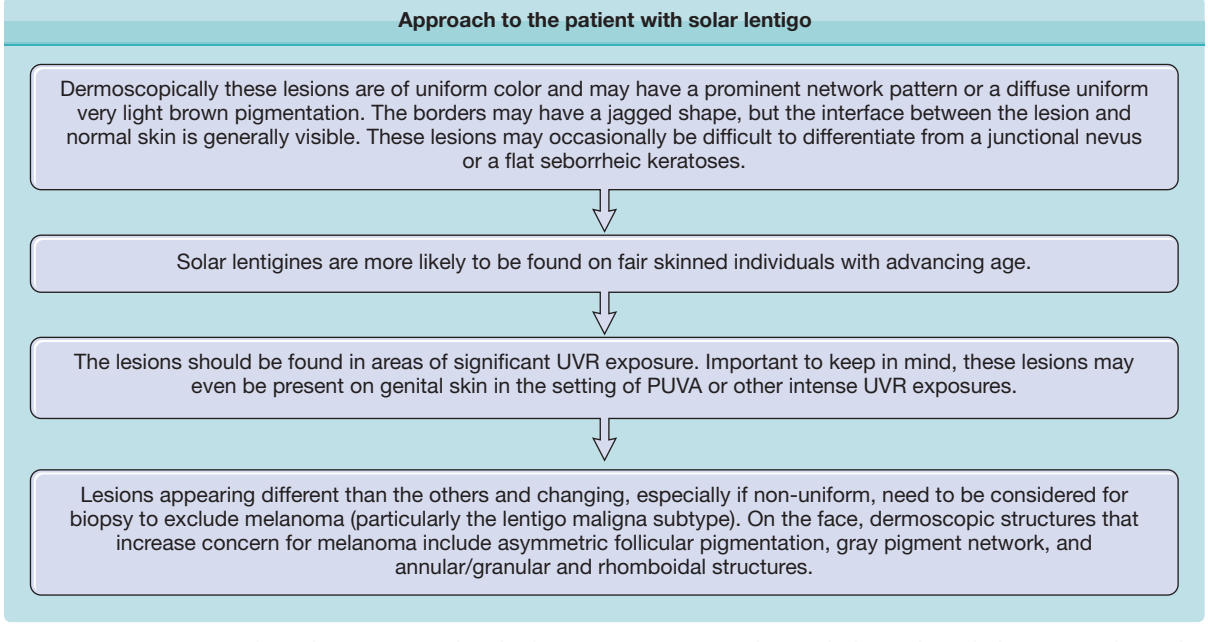

Figure 122-26 Approach to the patient with solar lentigo. PUVA = psoralen and ultraviolet A light; UVR = ultraviolet radiation.

Figure 122-27 Solar lentigo. **A.** Uncountable solar lentigines on the back of a 30-year-old white man, appearing initially during early childhood after multiple sunburns. **B.** High magnification of lentigines in (**A**) showing light-brown macules with markedly irregular outlines. **C.** Solar lentigines on sun-damaged dorsal hand skin (hypopigmentation, wrinkling, and telangiectasia) of an elderly white man.

brown, but varieties of solar lentigo are jet black, similar to an India ink stain (ink spot lentigo). Although solar lentigo usually occurs on sun-exposed skin, identical-appearing lesions may occur on sun-protected sites (including the penis and buttocks) that have been exposed to photochemotherapy (see Fig. 122-25). When examined by dermoscopy, solar lentigines reveal a uniform reticular network.[109] Lentigines in patients receiving PUVA and in individuals who have XP are often darkly and/or irregularly pigmented. Solar lentigines not apparent in visible light may be visualized using Wood's lamp illumination.

The oral–labial melanotic macule has gross morphologic characteristics similar to solar lentigo (Fig. 122-28), but its relation to a sun-sensitive phenotype or excessive sun exposure has not been well documented.

A clinical distinction has been made between a freckle (ephelis) and a solar lentigo. Freckles are common on the central face and often first noted in early childhood, presumably developing after significant sun exposure and are said to fade or even disappear when sun exposure is discontinued. Unfortunately, there are no longitudinal studies of ephelides or solar lentigines that document gross morphologic or time-course differences that would reliably allow a clinical distinction between ephelides and solar lentigines. According to L-3,4-dihydroxyphenylalanine (DOPA) studies on epidermal sheets, ephelides have been reported to show increased melanogenesis but decreased melanocyte number, which implies a different pathologic basis.[106,110] However, counting melanocytes in DOPA-incubated epidermal sheets is unreliable for pigmented lesions, and these early studies must be questioned. Studies in DOPA-incubated tissue vertical sections demonstrate that melanocytes are increased in "ephelides" in children and young adults, similar to solar lentigines.[42,109]

Figure 122-28 Labial melanotic macule, appearing 5 years earlier, on the lower lip of a 26-year-old white woman.

RELATED PHYSICAL FINDINGS. Patients with solar lentigines are more likely to be fair skinned, particularly those with red hair and or lighter eye color. Along with the lentigines, increased solar damage may be noted, and other lesions such as idiopathic guttate hypomelanosis, actinic keratoses, and seborrheic keratoses may be present. The presence of solar lentigines is a risk factor for melanoma, basal cell cancer, and squamous cell cancer.

LABORATORY TESTS

HISTOPATHOLOGY. Solar lentigines reveal elongated epidermal rete ridges with club-shaped or bud-like extensions, frequent branching and fusing of rete ridges, a thinned or atrophic epidermis between rete ridges, and increased numbers of epidermal melanocytes without nesting. The microscopic appearance suggests a concurrent proliferation of keratinocytes and melanocytes.[111] There is a scant to moderate perivascular mononuclear cell infiltrate in the dermis, usually associated with scattered melanin-laden macrophages.

Electron microscopic studies of solar lentigo reveal abundant melanosome complexes in keratinocytes, the complexes being generally larger than complexes in keratinocytes in adjacent skin.[111] Compared with melanocytes in sun-protected skin, melanocytes in solar lentigo reveal increased activity manifested by marked DOPA reactivity (suggesting increased tyrosinase activity), elongated dendrites, large numbers of normal-appearing melanosomes, enlarged perikarya with well-developed rough endoplasmic reticula, numerous mitochondria, and hypertrophic Golgi complexes.[112] Melanin macroglobules have also been noted.[100]

Pathologic features of PUVA-induced lentigo include increased numbers of melanocytes in elongated epidermal rete ridges, with large cell bodies and sometimes atypical cellular morphologic features, dendrites often extending high into the epidermis, and melanocytes frequently residing above the epidermal basal unit.[109] Melanocytes in PUVA lentigo occasionally manifest autophagocytosis, sharply invaginated nuclear contours, nuclear pseudoinclusions, double nuclei, striking melanosomal alterations, and melanin macroglobules; melanosomes in keratinocytes of PUVA lentigines are often large and single instead of small and compound as in solar lentigines.[112] Cosmetic UVA tanning also induces lentigines, and cellular atypia has been reported.

Histopathologic characteristics of the labial melanotic macule (labial lentigo) are similar to those of solar lentigo, showing melanocytic hyperplasia but without cellular atypia. The presence of melanocytic hyperplasia in labial melanotic macule is not a uniform finding in all studies.

SPECIAL TESTS. Mart-1 and DOPA histochemical studies may be useful to demonstrate increased number of melanocytes confined to the basal layer and a lack of junctional nest formation.

DIFFERENTIAL DIAGNOSIS

(Box 122-9)

COMPLICATIONS

A potential complication is the discovery that an atypical solar lentigo is actually melanoma (often of the lentigo maligna variety).

PROGNOSIS AND CLINICAL COURSE

Solar lentigines may appear at any time of life. A solar lentigo may enlarge, darken, and become stable over time, but longitudinal studies of solar lentigines are lacking. It is possible that once formed, solar lentigines may persist indefinitely or fade slightly with time if UVR is avoided. Solar lentigines may be a heterogeneous population that includes lesions that fade and lesions that do not fade after UVR avoidance. The presence of these lesions suggests an increased risk for melanoma and keratinocytic skin cancers.

It has been proposed that some varieties of lichenoid keratosis may be due to an acute inflammatory reaction

BOX 122-9 DIFFERENTIAL DIAGNOSIS OF SOLAR LENTIGO

- "Reticulated" seborrheic keratoses

- Junctional nevomelanocytic nevus
- Pigmented actinic keratoses
- Large cell acanthoma
- Lentigo maligna

targeting the solar lentigo, and that resolution of lichenoid keratosis may cause regression of the associated lentigo.[113] This speculation has not been substantiated.

The long-term course of atypical varieties of PUVA lentigo is unknown, but it is clear that PUVA lentigines (see Fig. 122-25) may persist 1–2 years or longer after therapy is discontinued[102] and that cellular atypia of epidermal melanocytes in these lesions may persist as well. It is also clear that these patients may be at increased risk for melanoma[114] and should be followed periodically for life.

Lentigo maligna (see Chapter 124) may masquerade as a solar lentigo early in its development or, alternatively, may evolve from a preexisting solar lentigo. A solar lentigo not matching the patient's other lentigines and/or enlarging/darkening out of step should be examined histopathologically or followed closely.

TREATMENT

Solar lentigo usually requires no therapy, but importantly, its presence indicates sensitivity and/or excessive exposure to UVR. Bleaching creams containing hydroquinone are usually not effective. Cryotherapy or other superficial destructive techniques (such as Q-switched laser) may be an option if the lesion is clearly benign, but lesions may recur after therapy. There is a theoretical concern about intense light treatment (i.e., laser) of any melanocytic hyperplasia or dysplasia.

PREVENTION

It may be possible to prevent further UVR-induced lentigines by reducing or avoiding UVR exposure. Ideally, protection against overexposure to UVR should be initiated during early childhood and continued throughout life. Vitamin D supplementation needs to be considered for patients practicing UVR protection and avoidance.

Chapter 123 :: Atypical (Dysplastic) Melanocytic Nevi

:: James M. Grichnik & Margaret A. Tucker

ATYPICAL/DYSPLASTIC NEVI AT A GLANCE

- Prevalence among Caucasian young adults roughly 10%; varies by population.
- Flat (totally or partially flat with central elevation), large (>5 mm) lesions with irregular shape, indistinct borders, and variable pigmentation.
- Risk markers for melanoma.
- Most frequent on sun-exposed areas, especially intermittently exposed, such as back.
- Associated with large numbers of common acquired nevi.
- Majority of lesions will involute and disappear over time.
- Histologic features include presence of immature, disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes.

Common atypical/dysplastic nevi were first recognized as distinct melanocytic neoplasias during the clinical assessment of melanoma-prone families.[1] The nomenclature associated with these lesions also includes B–K moles (recognizing the first two families described whose surnames began with B and K),[1] familial atypical multiple mole and melanoma syndrome,[2] atypical mole syndrome,[3] Clark's nevus,[4] atypical moles, and nevus with architectural disorder (with varying degrees of melanocytic atypia).[5] The nomenclature has been contentious. The term *dysplastic nevus* (DN) is frequently used both for clinical and histologic diagnoses,[6,7] and it is the term that will be used in this chapter. Although not covered in this chapter, it is also important to note that the terms *dysplastic* and *atypical* may also be occasionally used as a modifier for other melanocytic neoplasias (i.e., Spitz nevi) or hyperplasias to indicate a distinct histologic variant from a typical pattern or an increased concern for malignancy.

EPIDEMIOLOGY

DN are frequently found in melanoma-prone families in North America, Europe, and Australia.[8–16] One cross-sectional study in a New Zealand cohort (independent of melanoma) revealed DN in 9% of European descent adults.[17] A joint case-control study of nevi and melanoma in Australia and the United Kingdom demonstrated that DN were three times more frequent in the Australian controls (6%) than in the British controls (2%).[18] There are a few case reports of DN in Japanese, primarily in melanoma-prone families.[19]

ETIOLOGY AND PATHOGENESIS

DN occur in a familial pattern; limited segregation analyses suggest an autosomal dominant transmission of the trait.[20] However germ-line susceptibility genes have not yet been identified for DN. Germ-line mutation testing of candidate genes for melanoma (e.g., *PTEN*, *BRAF*, and *CDK4*) did not reveal an association with DN.[21] Germ-line polymorphisms in *BRAF* were also not related to nevi or freckles in another study.[22] Within families having *CDKN2A* germ-line mutations, DN appear to be an independent risk factor for melanoma.[11,23] Earlier, linkage analyses in twin studies found evidence of a gene for increased number of nevi in the region around *CDKN2A*[24,25] and recent genome wide association studies suggest that is close to *MTAP*[26,27]. Areas of modest interest have also been linked to areas on chromosomes 1, 6, and X.[25] Thus, it is likely that DN, like melanoma, is a complex, heterogeneous trait.

Genetic analysis of the cells in DN has revealed activating mutations of *BRAF*,[28,29] or *NRAS*,[30] as well as hemizygous deletions of p16 and p53.[31] However no consistent somatic mutation has been noted that defines the DN pattern.

Several lines of evidence suggest that sun or ultraviolet light (UV) exposure is important in the etiology of DN. First, the lesions occur most frequently in sun-exposed areas, particularly in those intermittently exposed, but DN may also occur in unexposed areas.[8,32–35] The most common area for DN is on the trunk, primarily the back (Fig. 123-1). There is relative sparing of the more sun-protected lateral thoracic regions and the inner aspect of the arms. Fewer DN

Figure 123-1 **A.** A back view showing the distribution of dysplastic nevus (DN) and lesion-to-lesion variability, with an increased number of common acquired nevi also. **B.** A closer view of a cluster of lesions marked as #2 on the back. The lesions are of different sizes, colors, and shapes, with differing amounts of asymmetry, and indistinct borders. Only the largest lesion meets all of the criteria for a clinical DN.

occur in doubly covered areas such as on the buttocks. In a comparison of Australian and British controls from a joint case-control study, the prevalence of DN was three times higher overall in the Australians, but the prevalence of nevi on non–sun-exposed areas was the same.[18] Second, several studies have also demonstrated, to varying degrees, that individuals with DN report more frequent sun exposure and sunburns, especially before age 20, than individuals without DN.[36–38] Individuals who tan well appear to develop fewer DN. Third, based on longitudinal studies of melanoma-prone families, individuals with DN who use sun-protective measures consistently develop fewer new nevi, and the dysplastic and common nevi they have are more likely to involute and disappear.[35] Sun-protected children in these high-risk families also develop fewer nevi.

CLINICAL FINDINGS

(See Fig. 123-2)

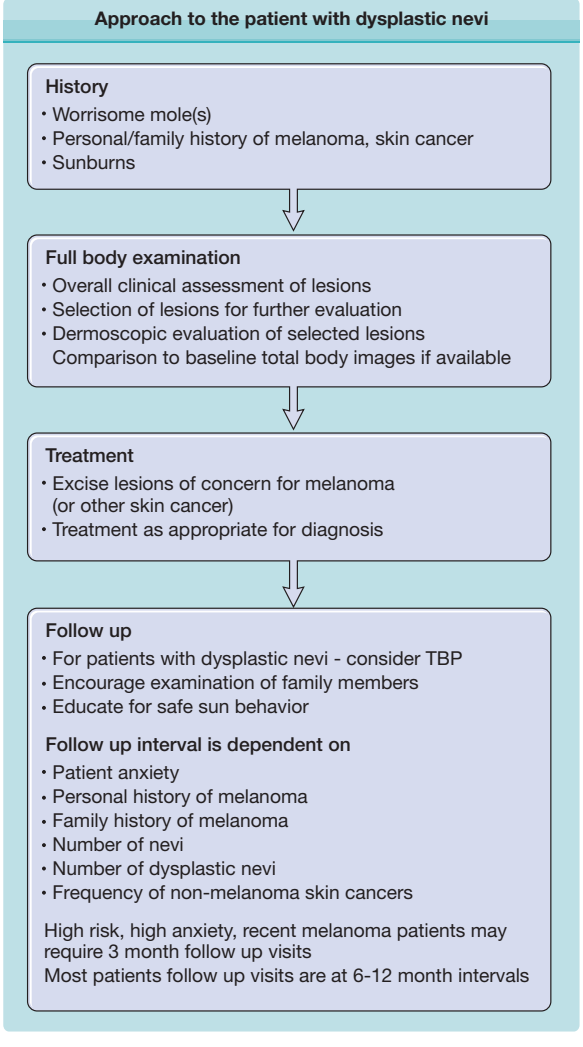

Figure 123-2 Approach to the patient with dysplastic nevi. TBP = total body photography.

CUTANEOUS LESIONS

The usual clinical criteria for the diagnosis of a DN are two obligate features: diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: irregular, asymmetric outline, indistinct borders, and variable pigmentation (Fig. 123-3).[44] The histologic features include the presence of an immature or disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes (Fig. 123-4).[45] Multiple studies have demonstrated that the clinical and histologic criteria are each reproducible across observers.[46–49]

Typically, DN are most frequent on intermittently exposed skin surfaces.[32–35] Epidemiologic studies have demonstrated that the most frequent site is the back (see Fig. 123-1A). DN can, however, occur in minimally sun-exposed areas such as the doubly covered buttocks, breasts, scalp, and pubic regions. Individuals with DN may also develop nevi, not necessarily atypical, on palmar and plantar surfaces and in web spaces of hands and feet. It is uncommon for individuals with DN to have nevi on mucosal surfaces, but they do occur.

Compared to common acquired nevomelanocytic nevi, DN tend to be larger, be entirely flat or have flat shoulders, with a degree of asymmetry and variable coloration (see Fig. 123-3). There may also be a degree of erythema caused by the inflammatory infiltrate in the DN. Within an individual, there is lesion-to-lesion variability, but there tends to be some consistency in the appearance (see Fig. 123-1B). Between individuals, even within the same family, there can be very broad differences in appearance of DN.[35] Any specific lesion needs to be assessed in the context of where it is in its natural life history.

RELATED PHYSICAL FINDINGS

Melanoma is the most important related physical finding in patients with DN. The majority of melanomas develop in normal skin, but may also occur in DN, or in common acquired nevi.[43,50] The challenge is to identify the melanomas as early as possible (see Chapter 124). Compared to DN, melanomas will be found to be (1) unusual (ugly duckling[51]), this is due to the rare combination of mutations giving rise to the melanoma and its growth pattern, they will be (2) growing (this due to defective growth control), and progressively more (3) nonuniform (asymmetry, border, color, dermoscopic structures, ABCDs) this is likely due to genomic instability. Nonuniform characteristics may not be present in early in situ melanomas.[50]

Patients with DN also have elevated numbers of common acquired nevomelanocytic nevi. Other physical findings that may increase melanoma risk in an individual with DN include extent of solar injury and cutaneous phenotype, both of which are independent risk factors for melanoma.[52] Evidence of chronic solar injury is also associated with an increased risk of melanoma in men with DN, especially in older men.[52] Individuals who are heavily freckled and have DN are at higher risk of developing melanoma than those with

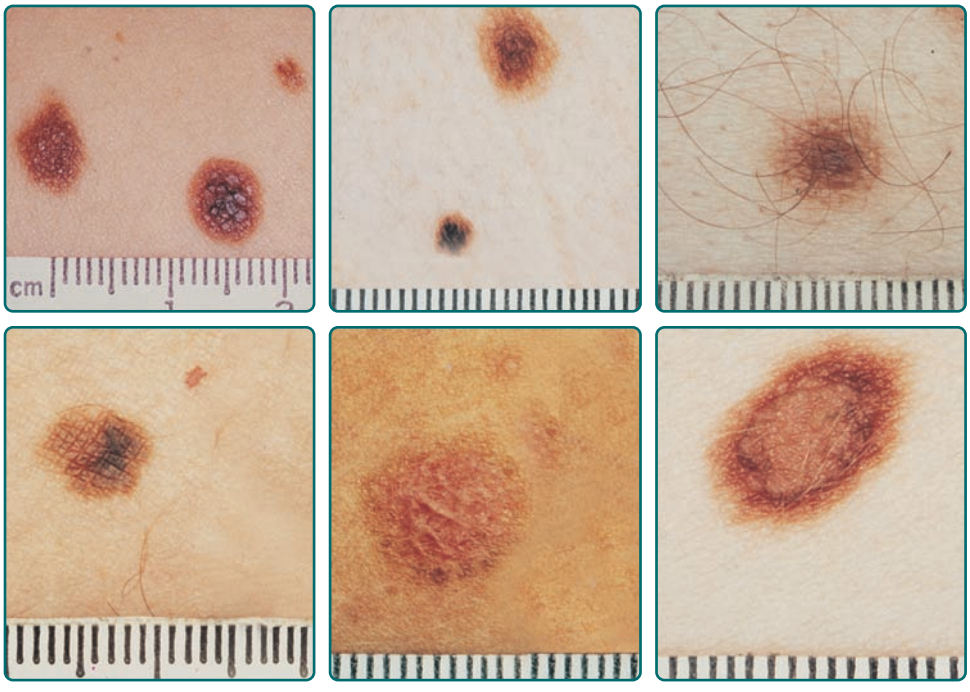

Figure 123-3 Atypical nevi have two obligate features: diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: irregular asymmetric outline, indistinct borders, and variable pigmentation.

DN who are not freckled.[44] DN and variations in *MC1R* both increase the risk of melanoma in *CDKN2A* mutation carriers.[53]

LABORATORY TESTS

HISTOPATHOLOGY. The histologic diagnosis of DN can be based on architectural and cytologic features.[54] Architectural features include a junctional component of scattered atypical melanocytes which may be most of the lesion, or an edge or shoulder extending several retia beyond a dermal component. Rete ridges are elongated, with the nests of melanocytes at the tips or along the side of the retia with occasional bridging of the nests across retia. There is fibroplasia in the dermis, often concentric eosinophilic fibroplasia or lamellar fibroplasia. Lymphocytes tend to be patchy and perivascular. The cytologic features include atypical melanocytes with abundant cytoplasm along the dermal-epidermal junction that are one-third to one-half larger than the melanocytes in the normal surrounding skin.[55] The nuclei may be slightly irregular or folded with hyperchromasia and clumping of chromatin. Some may have prominent nucleoli.

The dermatopathologist should also comment on whether the margins are clear. It is important to communicate with your dermatopathologist on lesions where the clinical and pathologic impressions differ. Marking of worrisome areas on the biopsy or review of dermoscopic images may help insure that particularly troublesome areas have been evaluated to insure that melanoma is not missed. Several groups have proposed criteria for grading histologic dysplasia.[48,56–58] These grading systems may help to define the risk of the lesion actually being a melanoma. Lesions with severe atypia may warrant re-excision or closer follow up after complete excision.

SPECIAL TESTS

Dermoscopy. Dermoscopy (dermatoscopy or epiluminescence microscopy) is also a useful adjunct for examining lesions. Several sets of criteria for differentiating nevi, including DN from melanoma, have been developed, including pattern analysis,[59] ABCD rule,[60] Menzie's method,[61] seven-point checklist,[62] and color, architecture, symmetry, and homogeneity (CASH).[63] The use of dermoscopy has been shown to increase the accuracy of melanoma detection.[64]

Dermoscopic imaging for follow up may also be considered when a lesion is of concern but not sufficiently worrisome to excise. Often these imaged lesions are then followed and excised only if changes are noted.[65,66] In one study with 90-day follow-up identified melanomas, all early, and avoided unnecessary biopsies.[66]

Total Body Photography. For clinical care of individuals with DN, total body photography (TBP, also known as mole mapping) is an essential tool.[35] The photographs serve as a medical record allowing determination to be made as to whether a lesion has changed. Change or lack thereof can then be integrated into the decision-making process as to whether a lesion needs to be excised. Patients with DN should be considered for TBP. Melanomas occurring in patients who are regularly followed using clinical photographs appear to be predominantly in situ or very thin invasive melanomas.[35,41,42,50,67–71] TBP not only allows for the detection of melanomas at earlier stages but it also

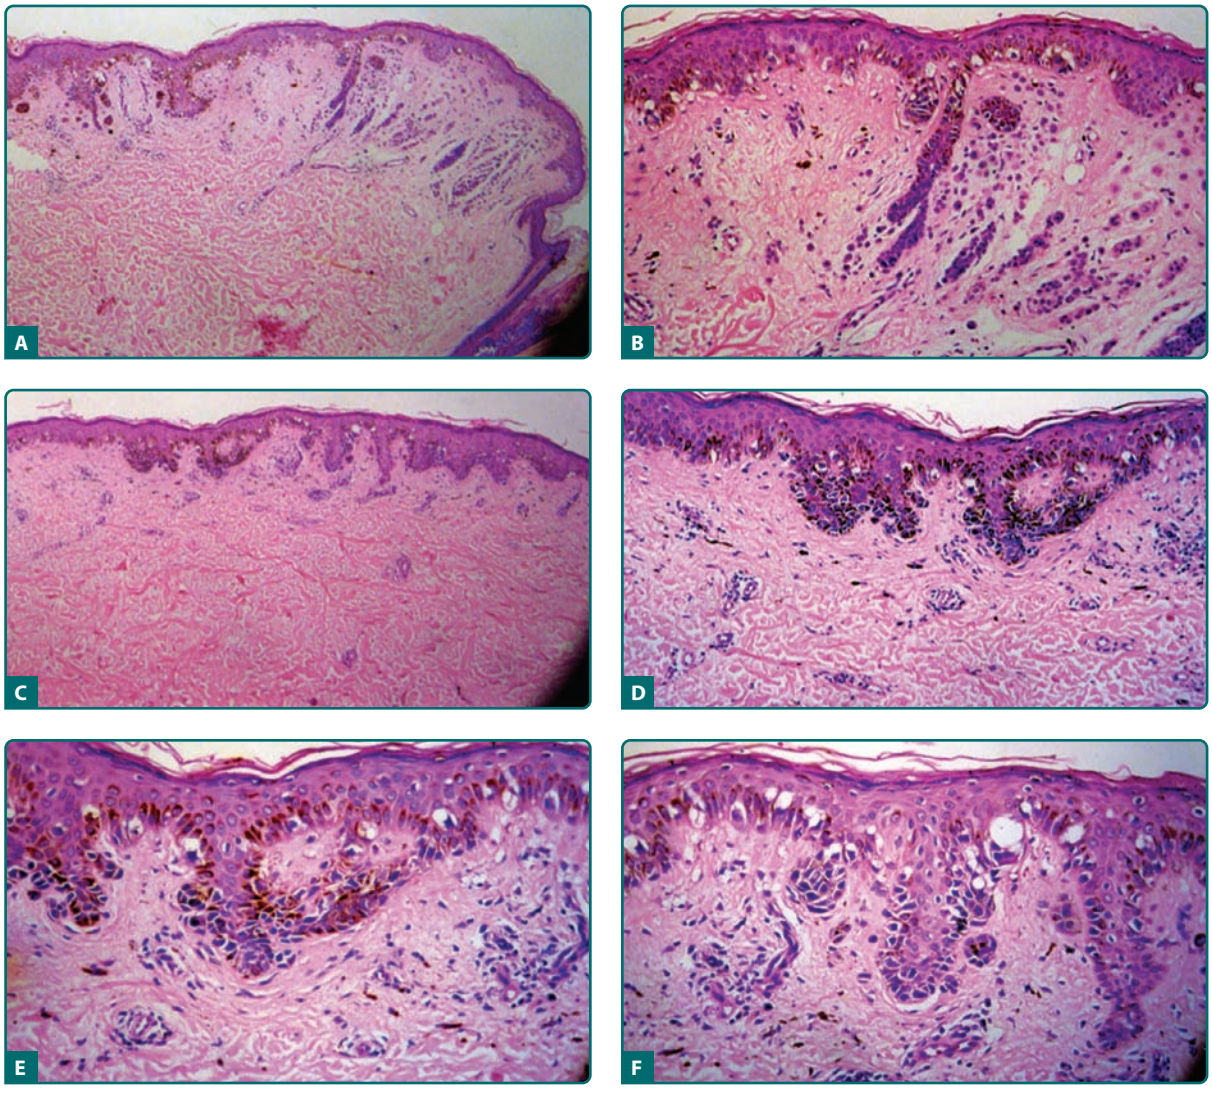

Figure 123-4 The histopathology of a dysplastic nevus (DN). **A.** The low-power view shows a dermal nevus with dysplasia. **B.** A closer view of the dysplasia at the shoulder of the dermal nevus. **C.** Another area of dysplasia. **D.** On closer view, there is an increased number of melanocytes without an apparent increase in keratinocytes, with the melanocytes clustered on the sides and the ends of the retia. The nuclei of the melanocytes are quite atypical. **E.** At higher power, the nuclei of the melanocytes are atypical and enlarged, characteristic of epithelioid melanocytic dysplasia. **F.** Another area of the lesion with melanocytes in linear array, characteristic of lentiginous melanocytic dysplasia. The melanocytes are not as enlarged as in the area of epithelioid dysplasia. With >30 atypical melanocytes and the level of disorganization of the architecture, the lesion is classified as severely dysplastic. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

reduces unnecessary biopsies of benign lesions, and provides an overall cost savings.[43]

NEW IMAGING TECHNIQUES. New imaging techniques are being developed and include confocal microscopy,[72,73] multispectral imaging,[74] optical coherence tomography,[75] ultrasound,[76] Raman spectroscopy,[77] and melanin fluorescence[78] that may all play a role in enhancing our ability to discriminate benign DN from early melanoma.

DIFFERENTIAL DIAGNOSIS

(See Box 123-1)

COMPLICATIONS

The major complication for DN patients is melanoma. In most of the case-control studies evaluating risk of melanoma, melanoma risk increases with increasing DN.[44,79–81] Even one unequivocal DN, increases the risk of melanoma twofold. More than ten DN increased the risk 12-fold [95% confidence interval (CI): 4.4–31]. A meta-analysis of 47 studies revealed the risk of melanoma increased 10-fold (95% CU:5.0-20.3) if DN were present.[81]

The most frequent complication for patients with DN is scarring due to numerous biopsies. Although melanoma may develop within a preexisting nevus

BOX 123-1 DIFFERENTIAL DIAGNOSIS

Most Likely
- Common acquired nevus
- Congenital or congenital-type nevus
- Dermatofibroma
- Seborrheic keratosis

Consider
- Combined nevus
- Spitz nevus/Spitz variant
- Pigmented spindle cell nevus
- Blue nevus
- Pigmented actinic keratosis

Always Rule Out
- Melanoma in situ
- Superficial spreading melanoma
- Pigmented basal cell carcinoma
- Pigmented squamous cell carcinoma

on DN patients, it commonly appears to develop from normal appearing skin. Nevi need only be removed when clinically suspicious for melanoma.

PROGNOSIS AND CLINICAL COURSE

Many individuals with DN come to the attention of a clinician because they are worried about a changing mole or have personal or family history of melanoma/dysplastic nevi and are worried about their risk.

Despite the concern about melanoma in individuals with DN, most will never develop melanoma. Their overall melanoma risk is a composite of a number of factors. These individuals should be asked about their personal and family history of melanoma, nonmelanoma skin cancers, other cancers, nevi, and UV exposure. Individuals who have had one melanoma are at substantially increased risk of developing another primary melanoma (tenfold increased risk of melanoma during the first 5 years).[82] Members of melanoma-prone families with DN are at quite high risk of developing melanoma.[35] Having multiple nevi, especially DN, is one of the risk factors identifying those most likely to develop another primary melanoma.[83] A previous history of nonmelanoma skin cancer approximately doubles the risk for melanoma, especially in older men.[52] Other cancers in the patient or family such as pancreatic cancer in a member of a family where multiple individuals have had melanoma may warrant consideration of genetic testing if it changes clinical care. And finally, UV exposure (peeling sunburns, tanning bed use) have been associated with increased melanoma risk.[84]

Frequency of regular follow-up examinations is based on perceived risk (factors in paragraph above) and competence in self-examinations. While many melanomas appear to grow relatively slowly, some melanomas may grow very quickly and therefore is no defined "safe" period. For very high-risk patients 3-month follow-up may be warranted (especially after recent diagnosis of melanoma or other skin cancer). However, for most patients 6-month and eventually 12-month follow up examinations are appropriate (depending on patient ability and confidence in self examination). Most patients followed in pigmented clinics have their melanomas detected and removed at relatively early stages.[43,50]

Patients should receive copies of their TBP (if taken) and need to be instructed on monthly self-skin examination and the basics of early melanoma detection. Patients may wish to include a partner and the entire skin surface should be viewed. This may require the use of a full-size wall mirror and a hand-held mirror. Patients should look for a lesion that is unusual (not matching other nevi) and growing. This may represent an early melanoma. As these lesions enlarge the may also begin to also display nonuniform features (ABCDs). A lesion that is growing and unusual is worrisome for melanoma, if nonuniform features are also developing this lesion is very concerening for an early invasive melanoma.[50]

Family screening should be encouraged. Although the familiality of DN is not fully understood, it is reasonable to examine the first-degree relatives of individuals with multiple DN. If they are found to have DN, the same approach should be followed for their care.

The patient should be educated about appropriate sun-protection measures. The suggestions for sun protection should be the same as those for the prevention of melanoma: avoidance of midday sun exposure and tanning beds, shade seeking when out of doors, scheduling outdoor activity for early morning or late afternoon, use of protective clothing, and use of sunscreens. These same sun-protection measures behaviors should be encouraged for the patients family members especially their children.

It is also be reasonable to let the patients know that they may want to inform their ophthalmologist, gynecologist, dentist, and hairdresser/barber that they have dysplastic nevi and to be on the lookout for any unusual lesions.

TREATMENT

The treatment for DN is observation. It is not necessary to histologically verify that an individual has DN. Removal of DN does not substantially decrease a patient's risk of developing a melanoma. The challenge is to identify the melanomas as early as possible and excise them to reduce the risk of metastasis. It is important to pay attention to the mole the patient points out as worrisome. Melanomas tend to be growing, unusual, and progressively more nonuniform.

If a lesion is worrisome for melanoma, the entire lesion should be excised (if possible) with visibly clear margins. For DN shave biopsies are discouraged. Repigmentation and regrowth can occur. Histological evaluation of these recurrent lesions can be challenging.

All lesions worrisome for melanoma should be reviewed by a dermatopathologist trained in pigmented lesions and melanoma.

PREVENTION

The major preventive intervention for the development of dysplastic, as well as common acquired nevi, is decreased UV exposure. With the growing body of evidence that childhood sun exposure is important in the number of nevi that develop,[85] it is important to initiate sun-protective behaviors early.

Chapter 124 :: Cutaneous Melanoma

:: Evans C. Bailey, Arthur J. Sober, Hensin Tsao, Martin C. Mihm Jr, & Timothy M. Johnson

MELANOMA AT A GLANCE

- Rising incidence worldwide; United States estimated lifetime risk of developing invasive melanoma is 1:1,500 if born in 1935, 1:600 if born in 1960, 1:62 if born in 2006, and 1:50 if born in 2010 (1:30 with inclusion of in situ melanoma).
- Risk factors include history of sunburns and/or heavy sun exposure, blue or green eyes, blonde or red hair, fair complexion, >100 typical nevi, any atypical nevi, prior personal or family history of melanoma, or *p16* mutation.
- Mean age of diagnosis is 52 years, 10–15 years younger than other more common cancers of the breast, lung, colon, and prostate.
- Most common location is the back for men, and lower extremities followed by trunk for women but can occur anywhere on the skin surface.
- Features used for melanoma recognition: A (*a*symmetry), B (irregular *b*orders), C (*c*olor variegation), D (*d*iameter >6 mm in most common use, but others have changed D to *d*ifference—"ugly duckling" sign or different with respect to change in size, shape, color, or persistent lesional pruritus), and E (*e*volving over time).
- Follows a highly variable course and represents a heterogeneous disorder; surgically curable if diagnosed and treated in early phase, but potentially lethal with increased risk when diagnosed and treated late.

EPIDEMIOLOGY

The incidence of melanoma has increased significantly worldwide over the last several decades. One in 50 born in the United States in 2010 is projected to develop invasive melanoma over their lifetime (1:39 men and 1:58 women), a 2,000% increase from 1930. With the inclusion of melanoma in situ, the lifetime risk increases to >1:30.[1] It is estimated that 121,840 men and women were diagnosed with melanoma of the skin in 2009, of which 68,720 were invasive melanomas and 53,120 were melanoma in situ.[2] Invasive melanoma of the skin is the fifth most frequent site for cancer to occur in men and the sixth most frequent site in women, representing approximately 5% of all newly diagnosed cancers.

Mortality rates for melanoma have recently stabilized for women, but continue to increase for men. The US surveillance, epidemiology, and end results (SEER) data estimates that in 2009, there were 8,650 deaths (5,550 men and 3,100 women) due to melanoma.[2] Melanoma accounts for 75% of all skin cancer deaths. Melanoma is one of the leading cancers in terms of average years of life lost per death from disease.

The mean age of diagnosis is relatively young at 52 years, which is 10–15 years earlier than the mean age of diagnosis in the more common tumors of the breast, lung, colon, and prostate. More than 35% of melanomas occur in persons less than 45 years of age.[1] Melanoma is the most common type of cancer in young adults in the US ages 25–29, second most common cancer in adolescents and young adults 15–29 years old. Incidence rises with age, especially in men. In the United States, women have a slightly higher incidence of melanoma than men before the age of 40 years. After age 40, men have a higher incidence, and the difference becomes remarkably large with increasing age.

Mortality data parallel incidence data, with older men having the highest mortality rates. Although mortality rates in older persons, especially men, are rising, melanoma mortality rates in younger persons and females have been steady or actually declined despite a rising incidence of melanoma in young women.[2–4] Lightly pigmented Caucasians have the highest incidence rates, much higher than Hispanics, Asians, and African-Americans.[1]

ETIOLOGY AND PATHOGENESIS

RISK FACTORS

(Table 124-1)

SUN EXPOSURE. Both genetic and environmental factors are related to melanoma pathogenesis and certainly not all melanomas are sun related. There is, however, clear convincing evidence that sun exposure, and more specifically ultraviolet (UV) exposure, is a major environmental cause of melanoma, especially in high-risk populations. Epidemiologic studies suggest that periodic, intense sun exposure (particularly during the critical time period of childhood and adolescence) rather than long, continued, heavy sun exposure is most important in melanoma causation, termed the *intermittent exposure* hypothesis. Sunburn history, notably blistering and peeling burns, serves as a surrogate measure of intermittent intense sun exposure. In one review of published literature, there was a significant positive association between sunburns during childhood and risk of melanoma development.[5] One blistering sunburn in childhood more than doubles a person's chances of developing melanoma later in life. Sunburns in adulthood have also been shown to contribute to melanoma risk.[6] Data from the behavior risk factor surveillance system of the Centers for Disease Control and Prevention show that nearly 32% of all adults aged ≥18 years, 58% between 18 and 29 years of age, and more than 40% of children report having had at least one annual sunburn defined as red skin for more than 12 hours.[7] Crude sunburn prevalence rates in white adults by state demonstrated higher sunburn rates among Caucasian adults living in the Midwest, possibly a reflection of a population that is more sun sensitive or less likely to practice sun-safe behaviors.

Migration studies generally indicate an increased melanoma risk in individuals who spent childhood in sunny geographic areas or emigrated to sunnier areas.[8] Younger migrants to sunny areas have an increased risk for melanoma as compared with adult immigrants. Lastly, there is an increased melanoma risk with longer duration of residence in the sunny locale.

Melanoma incidence and mortality among Caucasians correlate inversely with latitude of residence and dose of UV radiation, termed the *latitude gradient*. The highest rates are nearest the equator. In areas as geographically diverse as the United States, New Zealand, and Australia, the incidence of melanoma is greater in regions closer to the equator. However, this gradient may be confounded by other risk factors for melanoma. In Italy, for example, more darkly pigmented persons reside in the South whereas more lightly pigmented persons live in the North, so that the latitude gradient is actually reversed.[9] Even in the United States, SEER data from 1992 to 2001 demonstrate that the latitude gradient applies only to non-Hispanic whites; melanoma incidence was not associated with latitude and UV index in African-Americans, Hispanics, Asians, and Native Americans.[10]

The anatomic distribution of melanoma by body site demonstrates that intermittently exposed skin areas have the highest rates of developing melanoma. In men, the trunk, particularly the upper back, is the most common site for melanoma. In women, the lower legs, followed by the trunk, are the most common sites.[11] These intermittently exposed areas are the most common areas to develop melanoma in younger persons. In older persons, there is a greater incidence of melanomas located on chronically exposed areas with maximal cumulative sun exposure. The face is the most common location for melanoma in older persons, with the addition of the neck, scalp, and ears as well, in older men.[12,13]

Several forms of artificial light have been associated with the development of melanoma, particularly psoralen and UVA light (PUVA) and UVB, and tanning booths. The so-called *PUVA Follow-up Study* demonstrated increased rates of melanoma after PUVA exposure, with an incidence rate ratio of 9.3 approximately 20 years after PUVA therapy; these rates increased over time and were higher in patients exposed to high cumulative doses of PUVA.[12–14] However, the role of PUVA in the development of melanoma has been disputed on statistical grounds.[15] Furthermore, an increased incidence of melanoma was not seen in a large follow-up study of PUVA-treated patients in Sweden, although a difference in treatment regimens between the United States and Sweden represented a potential confounding variable. There is also rising concern over tanning beds and melanoma risk, especially as exposure

TABLE 124-1
Risk Factors for Cutaneous Melanoma

- Ultraviolet radiation exposure
  - Blistering sunburns at any time in life; intermittent or sporadic high levels of exposure
  - Excessive chronic exposure to sunlight
- Phenotypic characteristics
  - Fair skin, inability to tan, tendency to sunburn or freckle (SPT I and II)
  - Blue or green eyes
  - Red or blond hair
  - Numerous typical nevi and/or more than one atypical nevus
  - Large congenital nevus
- History of prior melanoma
- Family history of melanoma
- Mutation in p16, BRAF, or MC1R
- Xeroderma pigmentosum
- Immune suppression (debatable)

to the artificial UV radiation is intermittent in nature. Any exposure to artificial tanning devices modestly, but significantly, increases the risk of cutaneous melanoma (odds ratio, 1.25), and longer duration of bed use, younger age at first exposure, and higher frequency of use are associated with a significantly elevated risk (odds ratio, 1.69).[16] Exposure to tanning beds early in life, before age 35, may be the most harmful pattern of tanning bed use, with a summary relative risk of developing a melanoma of 1.75.[17] The evidence does not support a protective effect of tanning bed use before sun exposure.[17]

SKIN PHENOTYPE. Light skin pigmentation, blond or red hair, blue or green eyes, prominent freckling tendency, and tendency to sunburn with Fitzpatrick skin phototype I–II are phenotypic features associated with an increased risk of melanoma.[18–22] Melanoma occurs much less frequently in type V–VI skin, suggesting that skin pigment plays a protective role.

MELANOCYTIC NEVI. There is an increased risk of melanoma associated with nevi, both in a quantitative (i.e., number of nevi) and qualitative (i.e., typical vs. atypical nevi) manner.[23–26] Adults with more than 100 clinically typical-appearing nevi, children with more than 50 typical-appearing nevi, and any patient with atypical nevi are at risk. The presence of a solitary dysplastic nevus may double the risk of melanoma, while having ten or more atypical nevi may be associated with a 12-fold elevation of risk.[26] Nevi more often serve as a genetic marker of increased risk rather than a premalignant lesion, as most melanomas arise de novo. In a study of 1,606 patients with melanoma, only 26% of the melanomas were histologically associated with nevi (43% of these atypical nevi, 57% other nevi).[27]

On the other hand, large congenital nevi are recognized potential precursors of melanoma, although the degree of risk varies depending on the size of the lesion.[28] Many series define large congenital nevi as greater than 20 cm in diameter in adulthood, and lifetime risks for developing melanoma are generally accepted to be in the 5%–10% range. It is estimated that 70% of melanomas in large congenital nevi develop before the age of 10 years old and may occur deep within the nevus or even in the central nervous system, making detection of a thin lesion difficult. Patients with large congenital nevi located on the posterior axis (paraspinal, head, and neck regions) or in conjunction with multiple satellite lesions are at risk for neurocutaneous melanosis, with an increased risk of developing melanoma in the central nervous system. For small- to medium-sized congenital nevi, the melanoma risk is similar to any other area of skin; in this case, melanoma usually occurs later in life (after puberty), and arises at the dermal-epidermal junction, making early detection possible.[28] Thus, prophylactic excision of small- and medium-sized congenital nevi is usually unwarranted.

FAMILY HISTORY. Patients with familial melanoma are estimated to account for 10%–15% of all patients with melanoma. Having one first-degree relative with melanoma doubles the risk of melanoma, whereas having three or more first-degree relatives with melanoma increases the risk 35- to 70-fold.[29] Some of this risk may be attributed to shared risk factors such as skin phenotype, multiple nevi, and excessive sun exposure. The association between familial melanoma and multiple atypical nevi has historically been given various names, including *B-K mole syndrome, familial atypical multiple mole-melanoma syndrome*, and *dysplastic nevus syndrome*. Patients with familial melanoma typically have earlier onset melanoma and multiple primaries as well as atypical nevi. The molecular basis for some familial atypical multiple mole-melanoma syndrome kindreds are discussed under Section "Genetics."

PERSONAL HISTORY. A previous history of melanoma increases the risk for another primary melanoma, with 5%–15% of individuals developing multiple primary melanomas.[30,31] In patients with multiple primary melanomas, roughly one-half develop a second primary tumor in the same region of the body (i.e., trunk, extremity, head, and neck) and roughly one-half develop a second primary melanoma within the first year of initial diagnosis.[30] However, subsequent primary melanomas may develop decades after diagnosis of the initial lesion, stressing the need for long-term surveillance. Subsequent melanomas are thinner compared with the first melanoma in roughly 70%–75% of cases.[30]

An association with an increased incidence of melanoma with immunosuppression remains unclear; ranging from no increased risk to a modest 1.5- to fivefold increased incidence in few studies.[9,32] Several recent large reviews have revealed little to no increased risk of melanoma among HIV patients and no correlation of melanoma risk with declining CD4 count or the diagnosis of AIDS.[32,33] Several studies have provided some evidence for an increased risk of melanoma in patients with a history of non-Hodgkin's lymphoma (NHL), and possibly for melanoma patients having an increased risk of developing NHL, but these findings are not seen in all populations, and the clinical significance of these studies is not clear.[34–36] Outcomes in immunosuppressed transplant recipients are reported as similar to matched nonimmunosuppressed patients, albeit in relatively small series.

Finally, a history of actinic keratosis or nonmelanoma skin cancer also confers a small increased risk of developing melanoma.

GENETICS

CDKN2A-CDK4-TP53 Pathway. Germline mutations in the chromosome 9p21 tumor suppressor gene, cyclin-dependent kinase inhibitor 2A (*CDKN2A*), account for approximately 40% of hereditary melanoma cases (≥3 melanomas in one lineage) and confer a 76% chance of developing melanoma in the United States[37]; concordant with ambient rates, this risk is somewhat higher in Australia and lower in Europe. Individuals with germline *CDKN2A* mutations also exhibit a higher risk of pancreatic cancer; an estimated 15% of individuals with a mutant allele will develop pancreatic cancer in their lifetime.[38] Bonafide deleterious point mutations in *CDKN2A* are relatively uncommon in primary

melanoma tumors although homozygous deletions of this gene may obscure the true rate of somatic loss in melanoma. *CDKN2A* encodes two gene products: p16 (also known as *INK4a*, inhibitor of kinase 4a) and $p14^{ARF}$ (alternative reading frame). p16 is a cell-cycle regulator that binds and inhibits cyclin-dependent kinases Cdk4 or Cdk6, thereby inhibiting progression of cells through the G1 phase of the cell cycle. If p16 function is absent or inactivated by mutation, unrestrained Cdk4 activity phosphorylates the retinoblastoma protein thereby releasing the transcription factor E2-F and inducing S-phase entry. This sequence culminates in enhanced cellular proliferation, which, in the absence of checkpoint regulation, results in unrestrained growth and neoplasia.

The binding partner of the p16 protein is Cdk4. Only a handful of families worldwide thus far have been reported to carry hereditary mutations in *CDK4* while somatic mutations in this gene have also been detected in some melanoma cell lines. Functional studies suggest that mutations in Cdk4 render the cyclin-dependent protein kinase resistant to p16 inhibition, resulting in a phenotype identical to that from p16 loss.

The $p14^{ARF}$ protein from *CDKN2A* inhibits a cellular oncogene Hdm2, which in turn accelerates the destruction of the p53 tumor-suppressor gene.[39] Thus, complete loss of *CDKN2A* also leads to abrogation of $p14^{ARF}$ and loss of p53 function. Thus, this single locus can inactivate both the retinoblastoma protein and p53 pathways and probably explains the low rate of direct *TP53* mutagenesis in melanoma.

RAS Signaling Pathway. Davies et al. first reported in 2002 a somatic mutation in the *BRAF* gene in 66% of melanomas.[40] B-raf is a serine/threonine kinase, which is a major player in the Ras-Raf-Mek-Erk mitogen-activated protein kinase (MAPK) signaling transduction pathway that regulates cell growth, proliferation, and differentiation in response to various growth factors, cytokines, and hormones. The stimuli activate the G-protein Ras by inducing the exchange of guanosine 5′-diphosphate for guanosine 5′-triphosphate, which then binds and activates Raf. Raf phosphorylates and activates Mek, which in turn phosphorylates MAPK (i.e., Erks). This signaling cascade serves to intracellularly amplify the extracellular signals mediated by growth factors. There are three functional Raf proteins in humans, A-raf, B-raf, and C-raf. B-raf has a much higher basal kinase activity than either A-raf or C-raf, and somatic mutations in B-raf occur with moderate to higher frequency in melanoma and colorectal, ovarian, and papillary thyroid carcinomas, implicating activating oncogenic mutations of B-raf as critical promoters of malignancy.[41]

BRAF mutations are significantly more common in melanomas occurring on skin subject to intermittent sun exposure, with 81% of melanomas on skin without chronic sun damage having *BRAF* or *NRAS* mutations.[42] On the other hand, the majority of melanomas from acral sites (palms, soles, and subungual skin), mucosa, or chronically sun-damaged skin do not carry a mutation in either gene. There are also significant differences in the number of copies of genomic DNA in melanomas located in the various regions. Melanomas with wild-type *BRAF* or *RAS* frequently had increases in the number of copies of the genes for *CDK4* and *CCND1* (cyclin D1), two critical G1 cell-cycle proteins and two genes that are transcriptionally induced by activated MAPK signaling.[42]

Mutations in *PTEN/MMAC1* tumor suppressor gene also lead to enhanced Ras pathway signaling.[43] This protein/lipid phosphatase downregulates signaling through the Akt arm of the Ras circuitry. When PTEN is inactivated, there is dysregulated Akt activity along with increased cellular survival. There is both genetic[43] and animal data[44] to support cooperativity between PTEN loss and B-raf activation in driving melanoma formation.

OTHER GENES

Microphthalmia. Recently, somatic amplifications of the microphthalmia (*MITF*) gene in a subset of melanoma tumors were identified, and it was demonstrated that overexpression of *MITF*, in conjunction with ectopic expression of *BRAF*, resulted in melanocyte transformation.[45] The Mitf protein is a transcription factor that appears to be a master regulator of melanocyte differentiation, and amplification of this gene appears to contribute to a novel carcinogenic mechanism known as *lineage addiction*.

KIT. The *KIT* tyrosinse kinase receptor has also been shown to be mutated or amplified in a subset of melanomas predominantly from acral and mucosal sites.[46] These oncogenic lesions occur mostly in the juxtamembrane domain (*KIT* exons 11, 13, and 17)—a region that is frequently targeted in other cancers including gastrointestinal stromal tumors.[47] There is early evidence that imatinib, a tyrosine kinase inhibitor, may be useful in the treatment of c-Kit mutated melanomas.[48]

Melanocortin-1-Receptor. As mentioned above, red hair and sun sensitivity represent epidemiologically demonstrated risk factors for cutaneous melanoma. Recently, mutations in the melanocortin-1-receptor (*MC1R*) were shown to strongly contribute to the red hair/fair skin phenotype.[49] As such, germline mutations in the *MC1R* gene have also been shown to increase melanoma risk by approximately two- to fourfold in the general population[50]; it also confers risk for nonmelanoma skin cancer. Because the prevalence of *MC1R* mutations is quite high in the white population, its attributable risk to melanoma is higher than the rarer high-risk *CDKN2A* mutations.

Xeroderma Pigmentosum Genes. Xeroderma pigmentosum (XP) is a rare autosomal recessive genodermatosis comprised of at least seven complementation groups each defined by a separate gene. The XP genes are involved in excising DNA photoproducts in a reparative program termed *nucleotide excision repair*. Thus, heritable defects in these genes lead to increased mutagenesis and early carcinogenesis. Patients with XP harbor a 600- to 1,000-fold increased risk for skin cancer, including cutaneous melanoma.

Breast Cancer Susceptibility Gene. Carriers of the breast cancer susceptibility gene, *BRCA2*, appear to

harbor an increased risk for melanoma (2.58-fold).[51] Although an interaction between breast cancer and melanoma risk has been suggested on epidemiologic grounds, the genetic interaction between *BRCA2* and melanoma risk remains to be fully determined.

TUMORIGENESIS AND TUMOR PROGRESSION

Five stages of malignant transformation and tumor progression in melanocytes have been suggested, based on clinical, histopathologic, immunopathologic, cytogenetic, and in vitro properties: (1) benign melanocytic nevi; (2) atypical nevi; (3) primary malignant melanoma, radial growth phase; (4) primary malignant melanoma, vertical growth phase; and (5) metastatic malignant melanoma. It is believed that with each successive step of tumorigenesis, a new clone of cells emerges with growth advantages over the surrounding tissue, resulting in "clonal expansion." It has been postulated that a critical step in tumor progression of melanoma may be the transition from radial to vertical growth phases. The radial growth phase consists of primarily intraepidermal proliferation of melanoma cells, but also invasion of the papillary dermis by small numbers of cells that have gained a growth advantage. These cells are thought to have the capacity for autonomous proliferation in this location, but not for aggregative growth. Radial growth phase cells are characterized by the presence of E-cadherin, an adhesion molecule that interacts with keratinocytes and impedes migration of the cells from their intraepidermal location.[55] Melanomas in this phase are less capable of metastasis. The vertical growth phase is signaled by the property of aggregative growth, resulting in the formation of expansile nests or nodules of cells. Because the metastatic cascade comprises a complex range of numerous biochemical events, the vertical growth phase is likely an oversimplified correlate for the metastatic phenotype. Among other characteristics, vertical growth phase cells lose E-cadherin and express N-cadherin, a molecule that interacts with fibroblasts, macrophages, and endothelial cells. This latter interaction may facilitate intravasation of the malignant cells.[55]

A discussion of tumorigenesis of melanoma must take into account several important clinical observations: (1) the association between precursor nevi and melanoma in approximately 30% of cases (an apparent absence of precursor nevi in 70% of melanoma); (2) the role of UV light in the pathogenesis of melanoma; (3) pigmentary phenotype of patients in whom melanoma develops; and (4) family history of melanoma and other genetic factors. When the above observations are considered in light of the multistep process of tumor progression of melanoma, at least two major pathways of tumorigenesis can be envisioned.

In the first pathway, melanomas, particularly superficial spreading melanomas (SSMs), at least in some cases, develop in association with melanocytic nevi. Nevi may represent the first stage of tumor progression of melanoma or an initiated clonal proliferation. The most likely initiating agent would be UV exposure, perhaps at an early age. There is epidemiologic evidence that sun exposure earlier in life may result in larger numbers of nevi. The number of precursor nevi may be important as greater numbers of initiated cells would increase the target population for another mutational event. As UV is believed to be a complete carcinogen, sunlight exposure, perhaps of intermittent nature, could lead to this second mutational event, resulting in tumor progression. A second pathway of melanoma development is exemplified by lentigo maligna melanoma (LMM). This form of melanoma results from cumulative sun exposure and a corresponding cumulative insult to the DNA of melanocytes on sun-exposed skin. The age-incidence rates show a steady increase with age, consistent with continuous exposure (initiation) to a carcinogenic agent such as UV light.

Curtin et al. compared genome-wide alterations in the number of copies of DNA and mutational status of *BRAF* and *NRAS* in melanomas from variable groups in which the degree of exposure to UV light differed.[42] The genetic alterations identified in melanomas at different sites with different levels of sun exposure indicated that there are distinct genetic pathways in the development of melanoma. This supports the hypothesis that the clinical heterogeneity notable for melanoma may be explained by genetically distinct types of melanoma with different susceptibility to UV light.[42] Certainly, other as yet unknown pathways may exist that are independent of UV light.

CLINICAL FINDINGS

SUBTYPES OF MELANOMA

SUPERFICIAL SPREADING MELANOMA. SSM is the most common subtype, accounting for approximately 70% of all cutaneous melanomas. It is diagnosed most commonly on intermittently sun-exposed areas, most frequently the lower extremity of women, and the upper back of men. Its classic clinical appearance best fits into the ABCD criteria (see Section "Making a Diagnosis"), with irregular borders and irregular pigmentation, but it may present subtly as a discrete focal area of darkening within a preexisting nevus. The range of appearance of SSM is broad (Figs. 124-1 and 124-2). Although varying shades of brown typify most melanocytic lesions, striking aspects of dark brown to black, blue-gray, pink, red, and gray-white (which may represent regression) may be found in melanoma. SSM is the subtype of melanoma most commonly associated with preexisting nevi. The history of SSM is often of a lesion slowly changing over months to years. It may be mistaken for an atypical nevus or seborrheic keratosis.

DIFFERENTIAL DIAGNOSIS

(See Box 124-1)

NODULAR MELANOMA. Nodular melanoma (NM) is the second most common melanoma

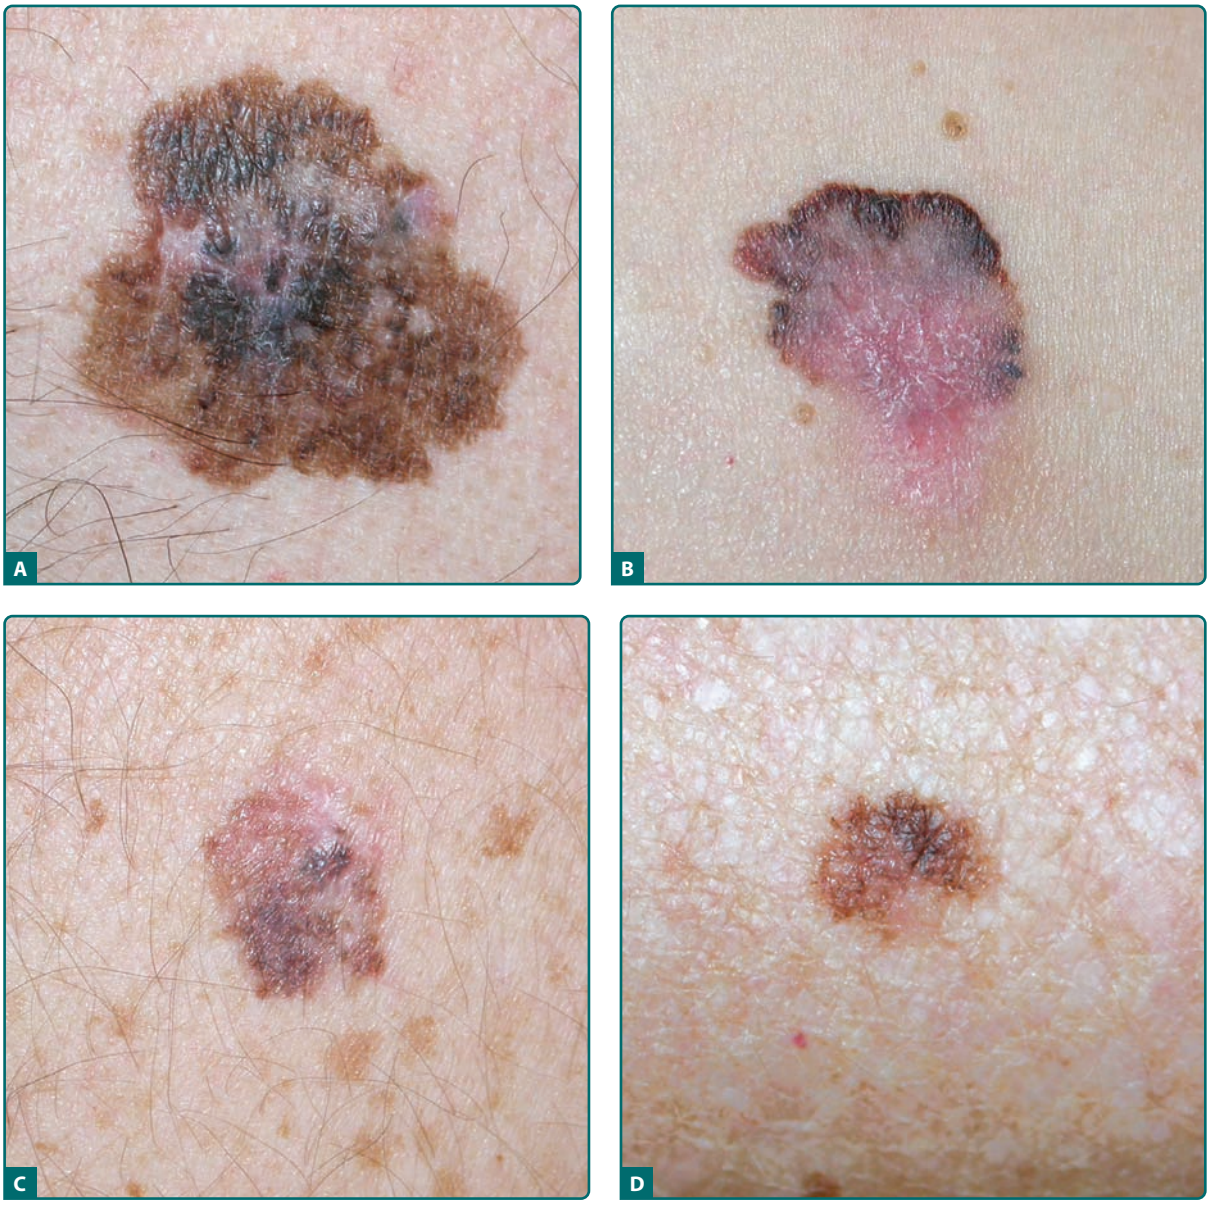

Figure 124-1 Superficial spreading melanoma (SSM). **A.** Classic clinical appearance with cardinal features of SSM: asymmetry, irregular scalloped borders, mottled variegate color, large diameter, and central elevation with surface distortion in a 45-year-old man, left chest, Breslow depth 1.25 mm. **B.** Another SSM with similar features but with pronounced areas of pink, shades of blue and white, with peripheral areas of black and brown in a 54-year-old woman, right lower abdomen, Breslow depth 3.5 mm, 26 mitoses/mm^2, ulceration focally present. **C.** Earlier detection in a 55-year-old man with many atypical nevi, patient unaware of the lesion, lesion noted by primary care physician during a routine physical examination, "different" than other nevi, right upper back, Breslow depth 0.50 mm. The pink/tan upper portion is an atypical nevus, the lower portion SSM arising in an atypical nevus. **D.** Still earlier detection with more subtle asymmetry, border, color, diameter/difference, elevation/evolving (ABCDs), forearm, Breslow depth 0.14 mm. The lesion was 0.8 cm in diameter with a history of a "brown spot," which grew in size, changed shape, and changed to a darker color over several months.

subtype and accounts for approximately 15%–30% of all melanomas. The trunk is the most common site. NM is remarkable for rapid evolution, often arising over several weeks to months. NM more often lacks an apparent radial growth phase. It is more common for NM to begin de novo than to arise in a preexisting nevus. NM typically appears as a uniformly dark blue-black or bluish-red raised lesion, but 5% are amelanotic (Fig. 124-3). A substantial proportion of thick melanomas are of the nodular type.[56] Early lesions often lack asymmetry, have regular borders, and are a uniform color. Amelanotic lesions may be mistaken for basal cell carcinoma, pyogenic granuloma, or hemangioma, whereas pigmented lesions may be mistaken for blue nevi or pigmented basal cell carcinomas.

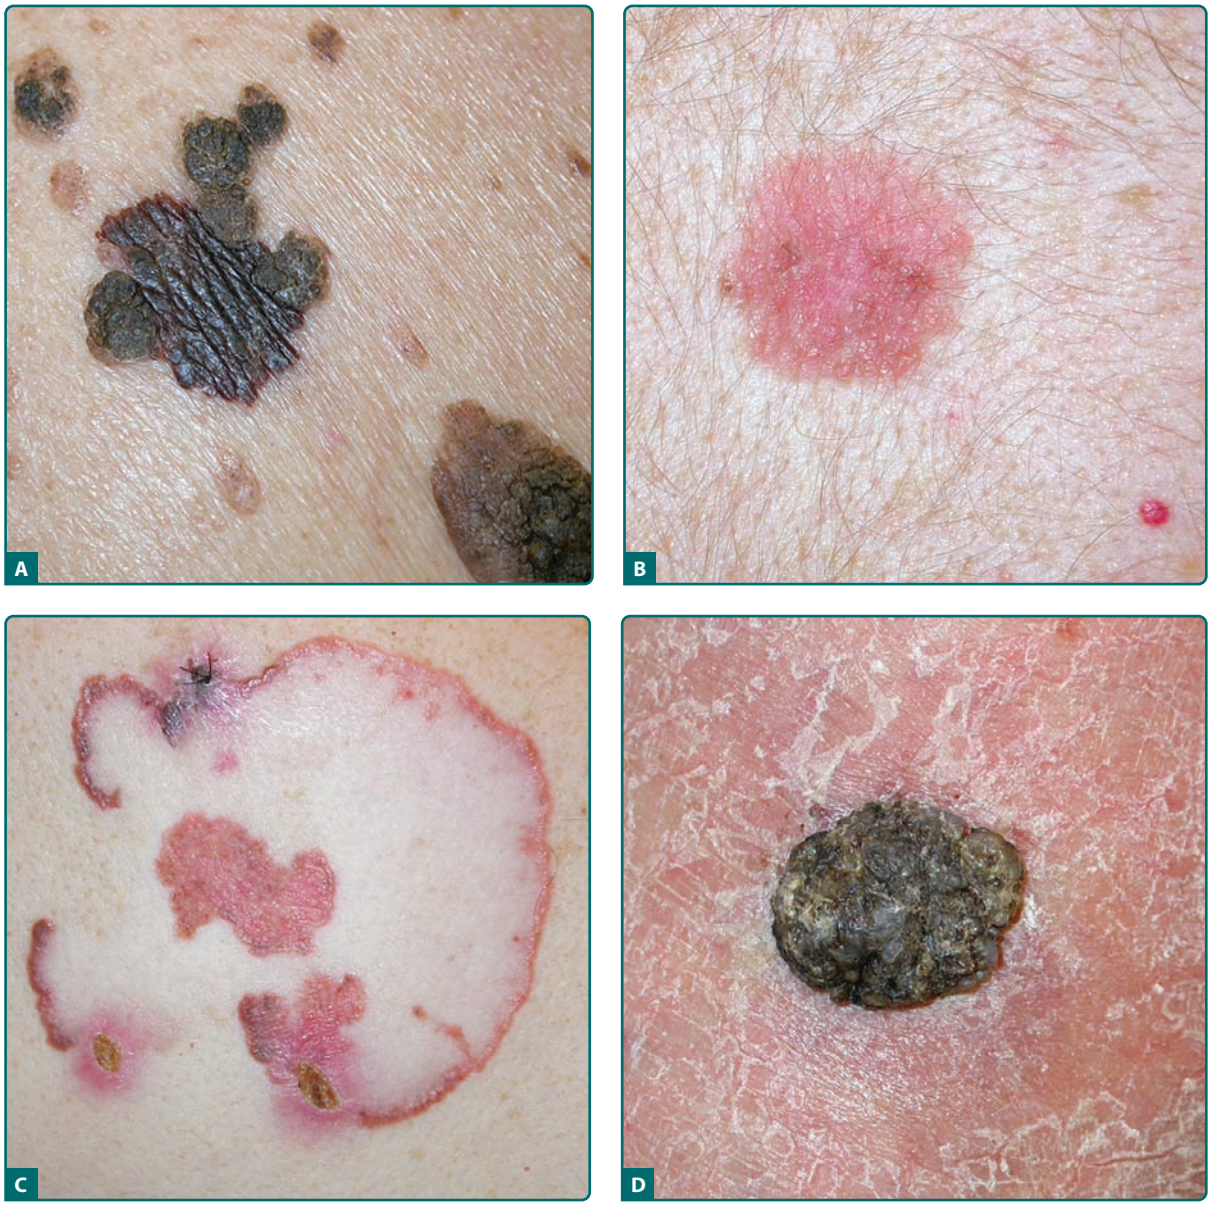

Figure 124-2 Superficial spreading melanoma (SSM) showing a broad range of appearance. **A.** Breslow depth 0.51 mm, central back within a "sea" of seborrheic keratosis but "different" than the surrounding seborrheic keratoses. **B.** Amelanotic SSM, upper back, Breslow depth 0.38 mm. **C.** Unusual presentation, left posterior shoulder, 60-year-old man, 11 cm × 9 cm SSM, slowly growing peripherally for over a decade, large areas of regression, pink amelanotic areas, and a small black component in the superior pole, Breslow depth 1.60 mm, 3 mitoses/mm^2. **D.** Unusual presentation of SSM with papillomatous features, right ankle, Breslow depth 6.3 mm, 3 mitoses/mm^2, vertical growth phase.

the seventh to eighth decades in an older population than other types of melanoma; uncommon before the age 40. The most common location is on the chronically sun-exposed face, on the cheeks and nose in particular; the neck, scalp, and ears in men. Its pathogenesis is thought to be related to cumulative sun exposure rather than intermittent exposure. LM is a flat, slowly enlarging, brown, freckle-like macule with irregular shape and differing shades of brown and tan, usually arising in a background of photodamage (Fig. 124-4). The lifetime risk of LMM developing from LM is estimated to be low but the invasive component is potentially

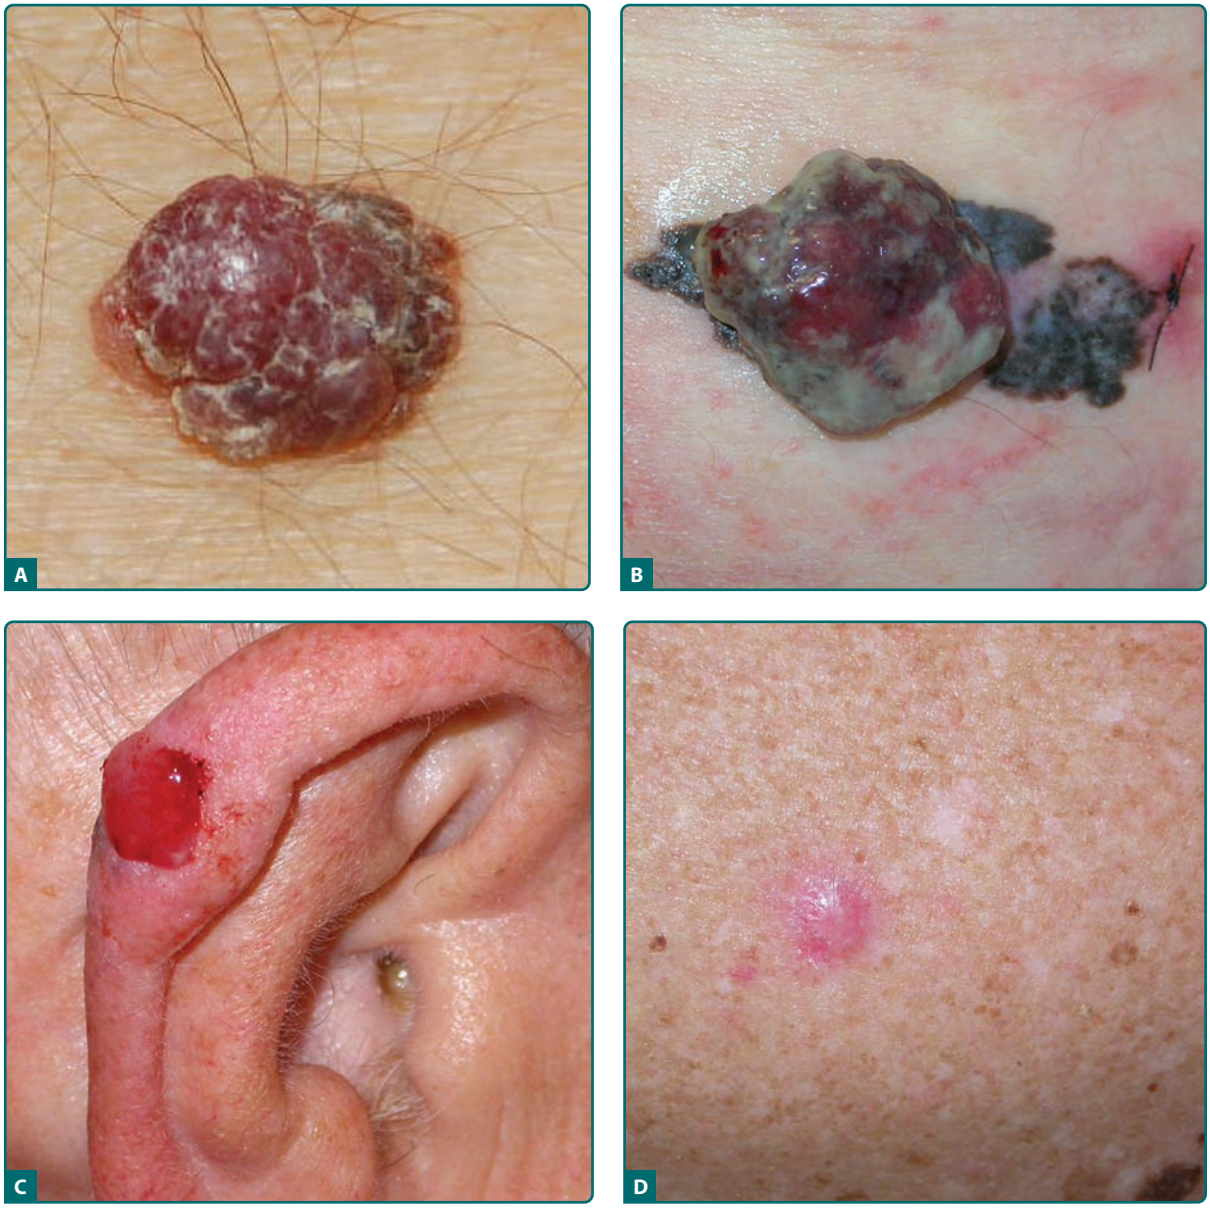

Figure 124-3 Nodular melanoma (NM). **A.** Classic NM, left lower back, Breslow depth 4.3 mm, angiolymphatic spread present. (Used with permission from Walter Barkey, MD.) **B.** Nodular polypoid melanoma, left flank, Breslow depth 16.0 mm, 38 mitoses/mm^2, ulceration and angiolymphatic spread present. **C.** Amelanotic NM, Breslow depth 2.37 mm, 32 mitoses/mm^2, vertical growth phase, ulceration present. **D.** Amelanotic NM with spindle cell features, noted approximately 1–2 months with elevation and bleeding, right posterior shoulder, Breslow depth 3.95 mm, 6 mitoses/mm^2.

Figure 124-4 Lentigo maligna and lentigo maligna melanoma (LMM). **A.** Lentigo maligna (in situ) displays prominent asymmetry, poorly defined irregular borders, and pigment variegation. **B.** Extensive LMM with large nodules. **C.** Amelanotic LMM with nodular component initially suspected to be a basal cell carcinoma, nose, Breslow depth 2.2 mm, 5 mitoses/mm^2, ulceration present. **D.** A pigmented patch of hair was noted after discontinuing practice of hair coloring. Over 6 weeks the area became pruritic and bled once. **E.** Inspection of the skin in the area of pigmented hair revealed the melanoma. Breslow depth 3.4 mm, ulceration present, 6 mitoses/mm^2, two foci of dermal melanoma satellite metastases.

lethal.[57] LMM is frequently larger than LM and may continue to be macular in early lesions, although a nodular portion is often seen within the macule later. Both LM and LMM often have clinically ill-defined borders, which may be obscured by background actinic damage consisting of lentigines, pigmented actinic keratoses, or ephelides. LM and LMM are associated with significantly higher rates of extensive subclinical lateral growth, resulting in higher recurrence rates with standard recommended margins and failure to completely excise the lesion. LM and LMM have the least common association with nevi, at 3% of cases, but the highest rate of association with desmoplastic melanoma (DM, see below).

DIFFERENTIAL DIAGNOSIS

(See Box 124-3)

ACRAL LENTIGINOUS MELANOMA. Acral lentiginous melanoma (ALM) is a subtype of melanoma with distinct differences in frequencies seen between ethnic groups. ALM constitutes only 2%–8% of melanomas in Caucasians but represents the most common form in darker-pigmented individuals (60%–72% African-Americans and 29%–46% Asians). Although the proportion of ALM seen in darker-pigmented individuals is higher, the incidence of ALM is similar for Caucasians and other ethnicities. ALM is diagnosed more often in an older population, with the median age of onset of 65. The most common site for ALM is the sole, with the palm and subungual locations following (Fig. 124-5). Not all palmar or plantar melanomas are ALMs; a minority are SSMs or NMs. The clinical appearance of ALM can be brown, black, tan, or red with variegations in color and irregular borders; however, the most common color is brown-black.

Figure 124-5 Acral lentiginous melanoma (ALM). **A.** Classic ALM demonstrating asymmetry, border, color, diameter/difference, elevation/evolving (ABCDs), left foot, Breslow depth 1.72 mm, ulceration present. **B.** Early detection of lesion followed by the patient, present for many decades, over several months began growing with irregular border and shape, changed in color from brown to black, in situ ALM arising in a dysplastic nevus. **C.** Amelanotic ALM, fourth toe of left foot, Breslow depth 5.0 mm.

BOX 124-3 DIFFERENTIAL DIAGNOSIS OF LENTIGO MALIGNA MELANOMA

- Solar lentigo
- Pigmented actinic keratosis
- Flat seborrheic keratosis
- Superficial pigmented basal cell carcinoma

There is often a delay in the diagnosis of ALM, often misdiagnosed as a plantar wart or hematoma, leading to a more advanced lesion upon diagnosis associated with poorer outcomes.[58] ALM is not thought to be associated with sun exposure.

Subungual melanoma, considered a variant of ALM, generally arises from the nail matrix, most commonly on the great toe or thumb (Fig. 124-6). It appears as a brown to black discoloration or growth in the nail bed. A widening, dark, or irregularly pigmented longitudinal

Figure 124-6 Subungual acral lentiginous melanoma (ALM). **A.** Extensive involvement of periungual skin (Hutchinson sign) with dystrophy and loss of the nail plate secondary to the tumor. **B.** ALM great toe, without notable Hutchinson sign, Breslow depth 3.4 mm, 6 mitoses/mm^2, two positive sentinel nodes identified, disease free at 2 years. **C.** Advanced subungual ALM with proximal periungual macular component and subungual and distal ulcerated nodular component. **D.** Subungual ALM, thumb nail bed streak, Breslow depth 0.5 mm. This was her fourth primary melanoma, other three located on the shoulder, cheek, and neck, the first 14 years prior.

nail streak (melanonychia striata) with or without nail dystrophy and nail plate elevation may be seen. Hutchinson sign, the finding of pigmentation on the proximal nail fold, may be noted with subungual melanoma. Benign lesions that mimic subungual melanoma include: benign longitudinal melanonychia, subungual hematoma, or pyogenic granuloma or even onychomycosis with pigmentation or hemorrhage.

DIFFERENTIAL DIAGNOSIS

(See Box 124-4)

OTHER VARIANTS

DESMOPLASTIC MELANOMA. DM most commonly develops in the sixth or seventh decade on sun-exposed head and neck regions. The lesions typically have a firm, sclerotic, or indurated quality, and one-half are amelanotic. Approximately half of the lesions arise in association with the LM histologic subtype. The DM pattern subtype may be associated with a higher rate of local recurrence due to a propensity to infiltrate perineurally with neurotropism and failure to appreciate occult growth, which may be deeply invasive at diagnosis. Although deeply invasive, DM is associated with lower nodal metastatic rates than other subtypes of melanoma when matched for depth of invasion. A recent study has shown that lesions with fusiform and/or epithelioid melanoma cells had a higher metastatic rate than those with pure DM with only fibrosing component.[59] Results from a small study that involved ten samples that investigated gene expression profiling demonstrated a molecular distinction between DM and nondesmoplastic melanoma.[60]

MUCOSAL MELANOMA. Melanoma can infrequently arise on mucosal surfaces on the head and neck (conjunctival, intranasal, sinus, and oral cavities), vulva, anorectal, or even urethral mucosa (Fig. 124-7). With the exception of the conjunctiva, patients present most often with delayed detection and a deeply pigmented, irregular lesion, but due to its location, may also present with bleeding or a mass lesion.[61] As most of these lesions present with a radial growth phase manifesting a macular pigmentation, any suspicious area in these sites should be biopsied. Lesions of the conjunctiva are visible and appear increased in patients with atypical nevi.[62,63]

NEVOID MELANOMA. Nevoid melanoma describes a heterogeneous group of rare lesions that histologically resemble benign nevi by their symmetry and apparent maturation with descent in the dermis, thus with greater potential for misdiagnosis. Clues to their histologic diagnosis include marked hyperchromasia of the nuclei of the tumor cells, the presence of mitoses, and an expansile growth of the dermal cells with effacement of the adventitia in affected areas. Clinically this may correspond to a tan papule or nodule, more often >1 cm in diameter on a young adult.[64]

SPITZOID MELANOMA. Spitzoid melanoma is a subtype of melanoma that clinically and histologically resembles a Spitz nevus, but tends to be larger and have asymmetry and irregular coloration. Distinction between the two is sometimes extremely difficult, and tumors with overlapping features of Spitz nevi and melanoma are classified as atypical Spitz tumors of uncertain biologic behavior (AST).[65] Features that favor the diagnosis of a Spitzoid melanoma over a benign Spitz nevus are large lesions, greater than 1 cm in diameter; lesions with a thick invasive component, well over 2 mm; lesions with numerous mitoses, many atypical, and lesions that have clinically concerning course such as rapid growth in size or satellitosis. Ambiguous lesions that are not clinically or histologically diagnostic for Spitzoid melanoma nor benign Spitz nevi, but with overlapping features of both, may be classified as AST.[65] Ongoing work with molecular profiling to identify genetic alterations in these tumors may provide markers to stratify AST into high- or low-risk lesions.

OTHER RARE TYPES. Several other rare and unusual types of melanoma are beyond the scope of this chapter, but previously reported in a comprehensive review, which include metaplastic melanoma, balloon cell melanoma, signet-ring cell melanoma, myxoid melanoma, rhabdoid melanoma, minimal-deviation melanoma, and animal-type melanoma, malignant blue nevus.[64,66]

MELANOMA AND PREGNANCY

Melanoma is the second most common cancer in women of child-bearing age, and thus constitutes one of the more common types of cancer diagnosed in pregnancy.[9,67] Historically, controversy existed regarding the effect of pregnancy on the clinical course of melanoma. The basis of potential hormonal effects included hyperpigmentation associated with pregnancy and the elevation of endogenous hormones, including estrogens and melanocyte-stimulating hormone. However, the literature demonstrates that pregnancy does not increase the risk of developing melanoma.[68] Furthermore, pregnancy before, during, or after a woman is

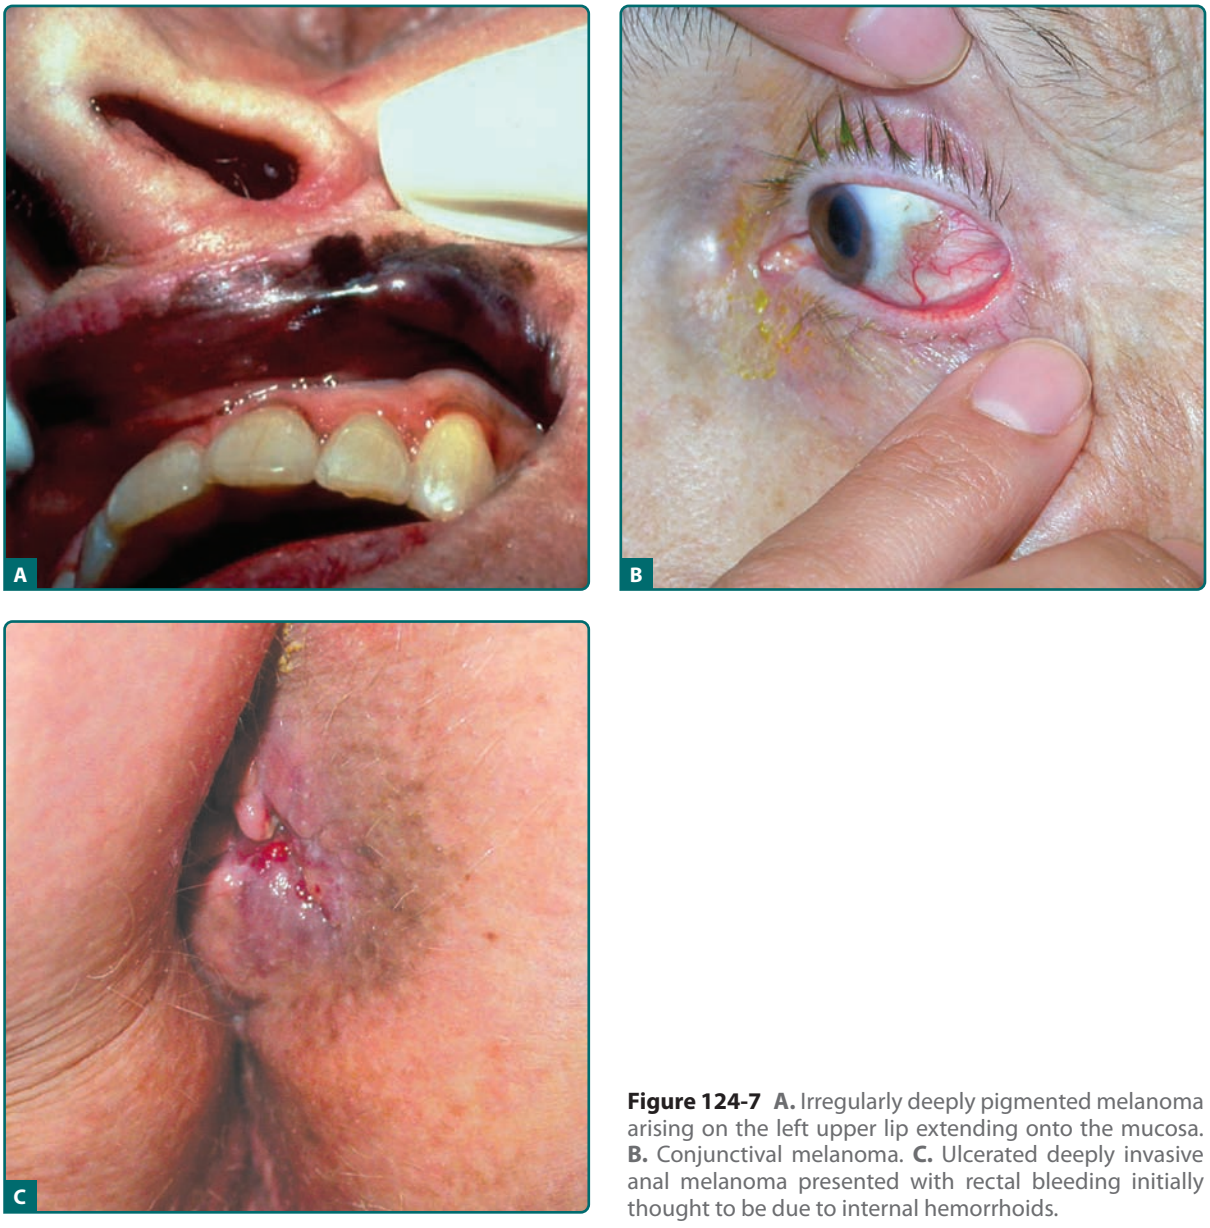

Figure 124-7 **A.** Irregularly deeply pigmented melanoma arising on the left upper lip extending onto the mucosa. **B.** Conjunctival melanoma. **C.** Ulcerated deeply invasive anal melanoma presented with rectal bleeding initially thought to be due to internal hemorrhoids.

diagnosed with melanoma does not appear to influence overall survival, although disease-free survival potentially may be shorted.[69,70,71] There is no reported difference in the distribution or stage of disease, tumor thickness, lymph node positivity, or overall survival for pregnancy-associated melanoma (i.e., melanoma diagnosed during or within 1 year).[72] Pregnant women with melanoma should be offered the same surgical treatments, including sentinel lymph node biopsy (SLNB) (usually with omission of blue dye) as nonpregnant patients; however, certain chemotherapeutic and immunologic regimens used in advanced melanoma may be contraindicated in pregnancy. After the initial diagnosis and treatment of melanoma, there are no standard, defined guidelines for patients who desire to become pregnant. Counseling recommendations should be comprehensive and individualized on a case-by-case basis, depending primarily on the risk of recurrence (related to the stage at diagnosis), patient age, and degree of personal desire to become pregnant relative to risk.

PEDIATRIC MELANOMA

Melanoma in childhood and adolescence is rare. Of all newly diagnosed melanomas, 1%–4% occur in patients younger than 20 years of age, and only 0.3%–0.4% occur in prepubertal children.[73] However, melanoma is being increasingly diagnosed in this age group and being reported to occur more commonly without the classic predisposing risk factors of familial melanoma, congenital nevi, dysplastic nevi, and xeroderma pigmentosum.[74] Based on SEER data of 1,255 melanoma patients less than 20 years of age, a 2.9% increase in the incidence of pediatric melanoma per year from 1973

to 2001 has been noted; the rate of increase was lower (1.4%) in young children less than 10 years.[75] Factors conferring risk of adult melanoma, including increasing age, UV exposure, and Caucasian background, were also found to be important in pediatric melanoma. The classic predisposing factors for adult melanoma are likely to be applicable to some proportion of children. In general, pediatric melanomas tend to have a greater proportion of thicker primaries, possibly related to delayed diagnosis compared with adults.

MAKING A DIAGNOSIS

Early detection is the key to improving prognosis in melanoma. Although melanoma may have a characteristic appearance, there is no single clinical feature that ensures or excludes a diagnosis of melanoma. Even among expert dermatologists, the clinical diagnosis of melanoma can be made in about 80%–90% of cases. The well-known ABCD acronym for melanoma detection continues to be a useful tool for the lay public and physicians.[76] A stands for asymmetry (one half is not identical to the other half); B for border (irregular, notched, scalloped, ragged, or poorly defined borders as opposed to smooth and straight edges); C for color (having varying shades from one area to another); and D for diameter (i.e., greater than 6 mm, approximately the size of a pencil eraser). Lesions having these characteristics may potentially represent melanoma. Studies have found the sensitivity of the ABCD checklist (Box 124-5) to be very high, but the specificity much lower.[77] Another diagnostic aid that is useful in detecting melanoma is the "ugly duckling" sign.[78] A pigmented lesion that is different from other pigmented lesions on a particular individual should be approached with a high index of suspicion. This is based on the premise that within an individual, nevi should globally share a common appearance or family resemblance. Even in an individual with multiple atypical nevi, the nevi should be morphologically similar.

History is very important in the evaluation of a lesion. The old ABCD rule is relatively static and does not account for a critical element of change. For this reason, some have added an E to the ABCD rule, where E stands for evolving.[79] Others have advocated for the D to stand for "difference" (i.e., a change in appearance or symptomatology over time or difference from the other lesions, similar to the "ugly duckling" sign). Change in color and increase in size (or a new lesion) are the two most common early characteristics noticed by patients that may be useful in discriminating between melanoma and other benign lesions.[80] In addition to change in color, size, or shape/elevation, persistent lesional itching is also an earlier (albeit nonspecific) symptom; ulceration, bleeding, and tenderness generally signify a more advanced primary lesion.[81] Therefore, it is important to ask patients if lesions have changed over time, and to pay particular attention to changing or symptomatic lesions. The development of a new pigmented lesion, especially in an individual beyond the age of 40–50 years old and on an anatomic site without similar lesions, is also worthy of suspicion.

[a]Does not apply to nodular melanoma.

PHYSICAL EXAMINATION

The skin examination should be conducted under optimal lighting and encompass the entire skin integument, including the scalp, external ocular/conjunctivae, oral mucosa, groin, buttocks, and palms/soles/web spaces. Melanomas in hidden anatomic sites are associated with thicker tumors at diagnosis, often due to later detection.[82] A global assessment of an individual's skin, including number of nevi, both typical- and atypical-appearing, and distribution of nevi should be noted. Other risk factors, such as a family or personal history of melanoma, skin type, UV history including tanning booths, or previously biopsied atypical nevi, should also be noted. Total body and lesional photography may be useful, especially in high-risk patients with numerous nevi.[83] The use of photography to document the appearance of skin lesions (or the absence of a skin lesion) can allow for better and earlier detection of a changing or new lesion. In high-risk patients, a proportion of melanomas are diagnosed with the aid of photographic surveillance rather than being noted by the patient or even the physician.[84] If a lesion suspicious for melanoma is found on skin examination, palpation of the regional lymph nodes should be performed to evaluate for lymphadenopathy.

DERMOSCOPY

Dermoscopy (also known as *epiluminescence microscopy, dermatoscopy, incident light microscopy*, and *surface microscopy*) is a noninvasive technique in which a handheld device is used to examine a lesion through a film of liquid, usually immersion oil, using nonpolarized light (contact dermoscopy), or the lesion is examined under polarized light without a contact medium (noncontact dermoscopy). In experienced hands, it may improve both the sensitivity and specificity for the clinical diagnosis of melanoma and other pigmented and nonpigmented lesions. Morphologic features that are otherwise not visible to the naked eye are observed using this technique.[85]

Different diagnostic algorithms using dermoscopic findings have been developed for melanoma, including the ABCD rule, the seven-point checklist, pattern analysis, Menzies method, modified ABC-point list, and CASH (color, architechture, symmetry, and homogeneity).[86–91] Several studies have compared these methods

to determine the most effective method for dermoscopic detection of melanoma.[92–94] Pattern analysis, which provides an overall impression of multiple dermoscopic patterns without rigid rules, based primarily on a subjective, simultaneous evaluation of a number of different criteria, is the most widely used method among experienced users of dermoscopy for evaluating pigmented lesions.[85] Lists of the important dermoscopy features with clinical pathologic correlations and significance have been widely published and are easily obtainable through courses, societies, and the Internet.

Digital dermoscopy or digital epiluminescent microscopy permits computerized digital dermoscopic images to be retrieved and examined at a later date so that comparisons can be made and changes detected over time. There are also a number of commercially available automated computer image analysis programs, devices that incorporate image analysis algorithms to digital dermoscopic images, providing objective measurement of changes over time. The use of automated instruments for the diagnosis of melanoma continues to evolve, but no system has demonstrated superior results to date in a clinically useful form. The use of body or lesional photography, professionally obtained or taken by the patient, is also useful to aid physicians and patients for following lesions, particularly in patients with many nevi. Finally, confocal scanning laser microscopy and multispectral digital dermatoscopy are among a number of new imaging techniques being evaluated for early detection of melanomas.[95,96]

HISTOPATHOLOGY

The gold standard for diagnosing melanoma is based on histopathologic evaluation of the biopsy specimen by a dermatopathologist or pathologist experienced with pigmented lesions.[97–99] The histologic diagnosis of melanoma is based on the assessment of a constellation of findings, including both architectural and cytologic features. No single feature is diagnostic. Cytologic atypia, referring to cellular enlargement, nuclear enlargement, nuclear pleomorphism, hyperchromasia of nuclei, nucleolar variability, and the presence of mitoses especially deep in the dermis, is considered necessary for a diagnosis of melanoma. The major architectural features of melanoma include asymmetry, poor circumscription (i.e., cells at the edge of the lesion tend to be small, single, and scattered), and large size (>5–6 mm). Nests of melanocytes in the lower epidermis and dermis tend to vary a good deal in size and shape, and to become confluent. There is a lack of maturation of nests with descent into the dermis. Pagetoid spread of large solitary epidermal melanocytes, usually considered diagnostic of melanoma, should be assessed cautiously in the context of other findings, as pagetoid spread may be seen in benign lesions including Spitz nevi, spindle cell nevi, vulvar nevi, and acral nevi.

The different subtypes of melanoma have histopathologic differences as well. SSM is characterized by a population of melanocytes appearing uniformly atypical (Figs. 124-8 and 124-9). LM and LMM are characterized by atypical melanocytes singly and in nests, predominantly confined to the basal layer of the epidermis, which become confluent without pagetoid spread, occurring in the background of photodamage

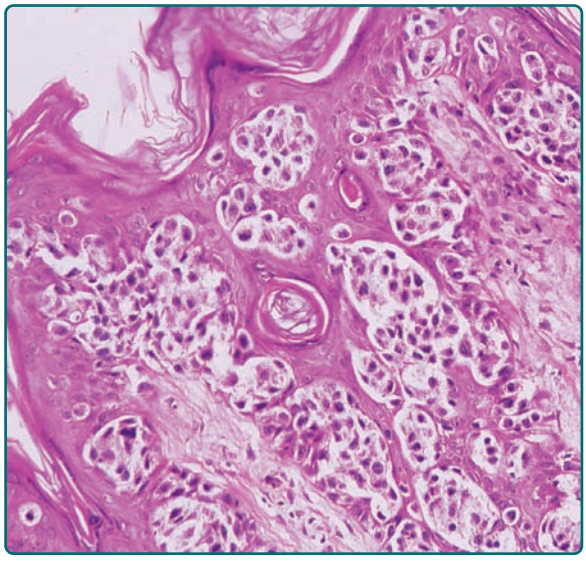

Figure 124-8 Superficial spreading melanoma. This tumor shows intraepidermal growth. In this photomicrograph, the pagetoid distribution is evident in the epidermis. The cells are relatively uniform and have an abundance of dusty, fine pigment. These relatively large melanoma cells are frequently referred to as epithelioid cell type.

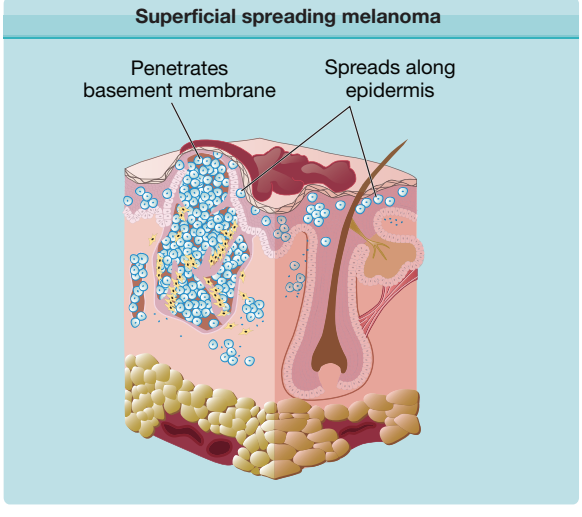

Figure 124-9 Superficial spreading melanoma. The border is irregular and the lesion is elevated throughout its entirety. Biopsy of the area surrounding the large nodule shows a "pagetoid" distribution of large melanocytes that are occurring singly or in nests, and uniformly atypical. On the left is a large nodule, and scattered throughout the surrounding portion of the nodule are smaller papular and nodular areas. The nodule on the left shows malignant melanocytes that are very large, have an abundance of cytoplasm, and often have regularly dispersed fine particles of melanin. The nodules may also show spindle cells or small malignant melanocytes as in lentigo maligna melanoma and nodular melanoma.

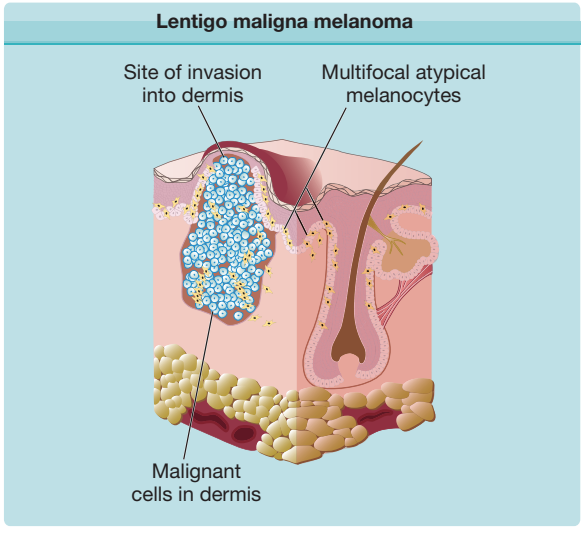

Figure 124-10 Lentigo maligna melanoma. Illustrated on the right is a large, variegated, freckle-like macule (not elevated above the plane of skin) with irregular borders; the tan areas show increased numbers of melanocytes, usually atypical and bizarre, and are distributed single file along the basal layer; at certain places in the dermis, malignant melanocytes have invaded and formed prominent nests. At the left is a large nodule that is composed of epithelioid cells in this illustration; the nodules of all four main subtypes of melanoma are indistinguishable from each other.

(Figs. 124-10–124-12). The cells may extend down hair follicles and appendageal structures. The epidermis is thin and atrophic, with loss of rete ridges. There is variable cytologic atypia. The "lentiginous" in ALM is derived from the characteristic lentiginous pattern of most cells being single and located near the dermal-epidermal junction (Fig. 124-13). ALM differs from LM in that there is irregular acanthosis, and the melanoma cells are uniformly malignant and often dendritic. In LM, the cells are highly pleomorphic in an atrophic

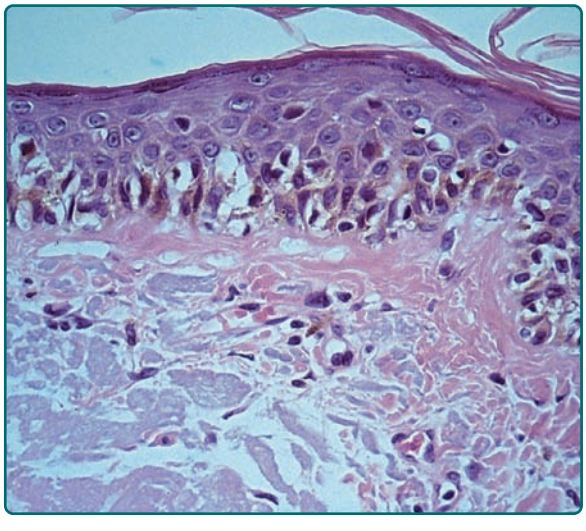

Figure 124-11 Lentigo maligna. This is a proliferation of pleomorphic melanocytes in the basal layer of an atrophic epidermis in sun-damaged skin.

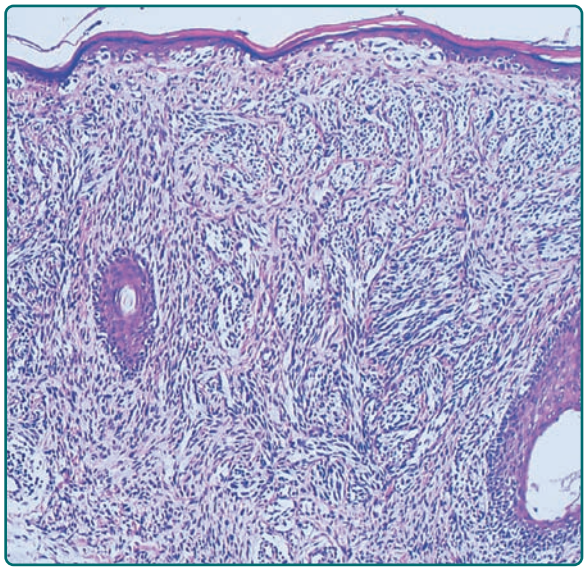

Figure 124-12 Lentigo maligna melanoma (LMM). Extending from the epidermis into the dermis are numerous elongated melanocytes. In LMM, these cells are frequently spindle shaped.

epidermis. NM demonstrates little tendency for intraepidermal growth; instead, there is a dermal mass of atypical melanocytes (Figs. 124-14 and 124-15). DM is composed of strands of elongated, spindle-shaped cells that often infiltrate deeply.

Current National Comprehensive Cancer Center Network (NCCN) guidelines endorse the use of a melanoma histologic profile established by the American Academy of Dermatology.[100] A typical 14-point comprehensive melanoma pathology report is shown in Box 124-6. Use of such a profile ensures that the appropriate histologic features of all melanomas are uniformly analyzed and reported to optimize treatment and future systematic study.

IMMUNOHISTOCHEMISTRY

Immunohistochemistry may be useful for the diagnosis of melanoma, especially in poorly differentiated neoplasms with little or no pigment (i.e., amelanotic melanomas), spindle cell tumors, or tumors with pagetoid spread that are not obviously melanoma. S100 protein is expressed by almost all melanomas; but also by melanocytic nevi, Langerhans cells, and cutaneous neural tumors. HMB-45 is a monoclonal antibody with high specificity for melanoma cells, although it is frequently negative in DM; DMs commonly exhibit vimentin and S100 positivity. Melan-A and MART-1 (melanoma antigen recognized by T cells) are the names given independently to the same gene encoding a melanocytic differentiation antigen expressed in skin and retina but not other normal tissues. Melan-A is broadly expressed in benign and malignant melanocytic lesions but not in most DMs. It is more sensitive than HMB-45 and more specific than S100 for melanoma. Search for the microphthalmia-associated transcription factor (Mitf) may be useful, especially in amelanotic melanomas, as it is a marker in the nucleus, whereas all other markers are intracytoplasmic.[101] It stains most melanomas except for DM where staining is usually negative but variable.

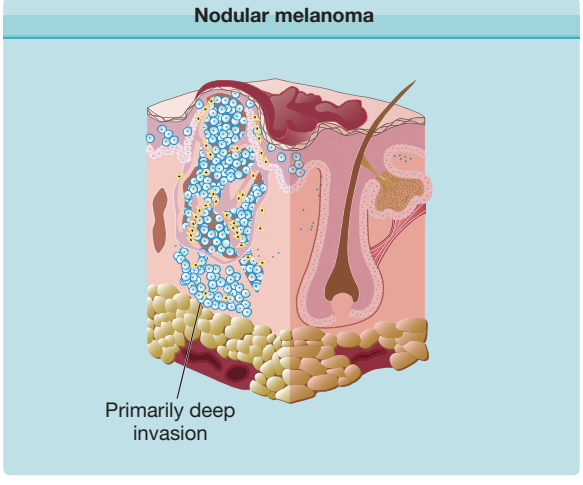

Figure 124-14 Nodular melanoma. This tumor arises at the dermal-epidermal junction and extends vertically into the dermis; intraepidermal growth is present only in a small group of tumor cells that conjointly are also invading the underlying dermis. The epidermis lateral to the areas of this invasion does not demonstrate atypical melanocytes. As with lentigo maligna melanoma and superficial spreading melanoma, the tumor may show large epithelioid cells, spindle cells, small malignant melanocytes, or mixtures of all three.

PROGNOSIS AND CLINICAL COURSE

STAGING AND PROGNOSTIC FACTORS

Accurate staging of melanoma is essential for determining optimal treatment and for assessing prognosis. Accurate staging forms the basis for prognosis and treatment, which is invaluable for the majority of patients in their informed decision-making process. The American Joint Committee on Cancer (AJCC) published a revised staging system for melanoma in 2009.[102,103] Whereas the previous melanoma staging system from 2002 was obtained from data from 17,600 melanoma patients primarily seen in the 1980s and early 90s, the 2009 melanoma staging system was obtained from a more contemporary dataset of 38,918 melanoma patients from 17 institutions/cooperative groups worldwide: 30,946 stage I, II, and III, 7,972 stage IV. This represents

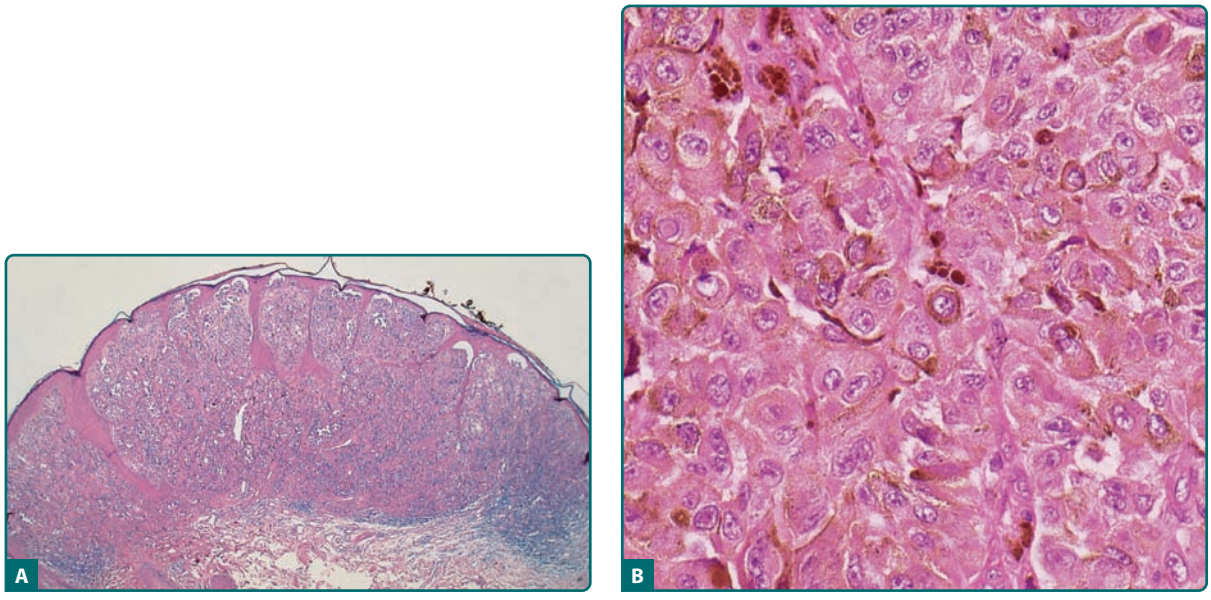

Figure 124-15 Nodular melanoma. **A.** Low-powered photomicrograph demonstrating a dome-shaped expansile tumor located in the upper dermis. **B.** High-powered photomicrograph reveals nests of anaplastic epithelioid cells in the tumor.

the largest body of AJCC melanoma data analyzed in an evidence-based approach and incorporates many patients more accurately staged using SLNB.[102,104,105] The 2009 AJCC melanoma staging system also incorporates mitotic rate, consistent with several previous studies demonstrating this to be an important, independent progonostic variable.[102,106–111] The *t*umor size, *n*ode status, *m*etastasis classification (TNM) system continues to be used, in which T describes the extent or thickness of the primary tumor, N the extent of lymph node metastases, and M the extent of distant metastases.[104] Table 124-2 presents the TNM categories, and Table 124-3 lists the stage groupings. There are five stages based on prognosis: stage 0 (in situ disease), stages I and II (localized disease), stage III (regional disease), and stage IV (distant metastatic disease). In general, prognosis and survival rates worsen with increasing stage (Table 124-4). At initial presentation, approximately 85% of patients have localized disease (stages I and II), 10% have regional metastatic disease, and 5% have distant metastatic disease.[104]

PROGNOSTIC FACTORS IN MICROSTAGING

TUMOR THICKNESS. The single most important prognostic factor for survival and clinical management in localized stage I and II cutaneous melanoma is tumor thickness.[102,105] As originally described by Breslow, thickness is measured from the top of the granular layer of the epidermis to the greatest depth of tumor invasion using an ocular micrometer measured in millimeters. Survival decreases with increasing Breslow depth. Clark level is an alternate, less accurate method of measuring tumor thickness by the anatomic level of invasion. Clark level of invasion is no longer used in routine staging of melanoma.[102]

ULCERATION. Ulceration is an independent prognostic factor for localized melanoma.[102,105] The presence of ulceration in the primary confers a higher risk of developing advanced disease and lower survival rate. The presence of ulceration upstages all patients with localized and regional disease [i.e., stages I to III (see Table 124-2)]. Ulceration correlates with tumor thickness; it occurs infrequently in thin melanomas (6% for melanomas <1 mm) and frequently in thick melanomas (63% for melanomas >4 mm).[105] One potential shortcoming of ulceration as a variable is that ulceration is not always a homogeneous phenomenon and may result from trauma, which is prognostically insignificant. For this reason, ulceration should be reported when there is evidence of host response at the site, including fibrin and nuclear debris. Their presence indicates a preoperative event not possibly associated with artifactual causes due to surgery or processing.

MITOTIC RATE. Several studies reported the importance of tumor mitotic rate as an independent predictor of survival, with an increasing mitotic rate correlating with a decreasing survival.[106–112] Among patients with clinically localized melanoma, a mitotic rate of 1/mm^2 or greater may be the second most powerful predictor of survival, after tumor thickness.[102] In the 2009 revised AJCC staging system, mitotic rate has replaced Clark level of invasion in defining T1b melanomas because. When ulceration, tumor thickness and mitotic rate are accounted for, Clark level is no longer an independent predictor of survival.[102,103] Clark level IV or V of invasion should only be used to define T1b melanoma in the rare cases of T1melanomas for which the mitotic rate cannot be determined. Mitotic rate, measured as the number of mitoses per square millimeter, is usually counted as the number of mitoses seen in four to five high-power (×40) microscope fields (the equivalent

TABLE 124-2
Melanoma TNM Classifications[a]

T Classification	Thickness (mm)	Ulceration Status
T1	≤1.0	a: without ulceration and mitosis <1/mm^2 b: with ulceration or mitosis ≥1/mm^2
T2	1.01–2.0	a: without ulceration b: with ulceration
T3	2.01–4.0	a: without ulceration b: with ulceration
T4	>4.0	a: without ulceration b: with ulceration
N Classification	**Number of Metastatic Nodes**	**Nodal Metastatic Mass**
N1	1	a: micrometastasis[b] b: macrometastasis[c]
N2	2–3	a: micrometastasis[b] b: macrometastasis[c]
N3	Four or more nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic node(s)	c: in-transit met(s)/satellite(s) without metastatic nodes
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

TNM = tumor size, node status, metastasis classification.

[a]Four major changes are included in the 2009 version of American Joint Committee on Cancer melanoma staging system:

1. Anatomic level is no longer in the routine staging of thin tumors. Thickness and ulceration are primarily used to define the T category. For T1 melanomas, the anatomic level of invasion (Clark levels) has been replaced by mitotic rate as a prognostic feature for defining T1b melanomas. Clark level is only used for defining T1b melanomas if a mitotic rate cannot be determined for a nonulcerated T1 melanoma. Any mitosis rate ≥1 mitosis/mm^2 in a melanoma ≤1.0 mm in thickness upstages that tumor to T1b.
2. Mitotic rate has been included for categorizing T1 melanomas (see above).
3. The presence of nodal micrometastases can be determined using either hematoxylin and eosin (H&E) or immunohistochemical stains using melanoma specific markers.
4. Any amount of micrometastatic disease in a lymph node is considered to be positive and clinically significant.

[b]Micrometastases are diagnosed after sentinel or elective lymphadenectomy.

[c]Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

of a 1-mm^2 area), starting in the fields with the most mitoses. Patients with a mitotic rate of <1 mitoses/mm^2 have a significantly better survival than those with ≥1 mitosis/mm^2. Mitotic rate may also correlate with SLNB positivity, especially in younger patients.[111] There minimizevariability in reporting of mitotic rate, each microscopist is advised to seek technical assistance if necessary to determine the number of fields equal to 1 mm^2 in each microscope.

ANGIOLYMPHATIC INVASION. Vascular involvement denotes the invasion of tumor cells into the microvasculature in the dermis. Some reports note that vascular invasion significantly increases the risk of relapse, lymph node involvement, distant metastases, and death.[111–114]

MICROSCOPIC SATELLITES. The presence of microscopic satellitosis, in particular, has been consistently reported to correlate with a poorer outcome, and this has been retained in the current AJCC melanoma staging system.[102,104] Patients with any satellite metastases, including microsatellite metastases, are considered to have stage III disease even in the absence of nodal metastases (N2c, satellite metastases without nodal metastases).[102]

OTHER HISTOLOGIC FACTORS. Other factors have been variably reported as predictive of prognosis in melanoma including the presence of tumor-infiltrating lymphocytes, regression, tumor lymphangiogenesis (i.e., formation of new vessels), and radial versus vertical growth phase. None of these have been demonstrated to be strong independent predictors of melanoma outcome. Sentinel lymph node status, however, is a predictor of melanoma outcome, and the evaluation and histologic classification of nodal metastases in sentinel lymph node biopsies has been revised in the

[a]Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.
[b]Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.
[c]There are no stage III subgroups for clinical staging.

most recent AJCC staging system for melanoma (see Section "Sentinel Lymph Node Biopsy" under "Microscopic Metastases").

CLINICAL PROGNOSTIC FACTORS

Age. Many studies have reported that increasing patient age portends a worse prognosis with respect to overall survival rates. Males more than 60 years of age have the highest mortality rates from melanoma. Older patients have thicker primaries and a higher proportion of ulcerated melanomas, but even after adjusting for these factors, age appears to be an independent prognostic factor.[3,9,81,113] It has been postulated that age may serve as a surrogate for declining host immune defense mechanisms.

GENDER. A large number of studies have reported that women have better survival rates than men, even after adjustment for tumor thickness and anatomic site.

ANATOMIC SITE. The anatomic location of primary cutaneous melanomas has been variably reported to affect survival. In the 2002 AJCC study, melanomas located on the trunk and head and neck were correlated with worse prognosis than melanomas on the extremities, but the recorded locations were only (1) extremities or (2) trunk, head, or neck.[105] In another large study of 5,093 patients, melanomas on the back and thorax, upper neck, and scalp (BANS regions) were associated with significantly lower survival rates than melanomas on the lower trunk, thigh, lower leg, feet, lower arms, hands, and face.[115] Finally, review of 1,130 patients from a single institution showed a greater likelihood of SLNB positivity for melanomas located on the trunk and lower extremity.[111] Given the

conflicting data, it is likely that anatomic site is not a strong independent prognostic factor in melanoma.

PROGNOSTIC FACTORS IN REGIONAL METASTASIS

The status of the regional lymph nodes is the most powerful prognostic factor for survival in melanoma. The presence of regional lymph node metastasis portends a worse prognosis. The number of lymph nodes involved, independent of size, is the most significant risk factor in patients with stage III melanoma.[102,105] The second most important risk factor is tumor burden, stratified into micrometastatic disease as determined by SLNB, or macrometastatic disease (i.e., clinically palpable nodes). In clinically node-negative stage I or II patients, SLN status is the most significant prognostic factor with respect to disease-free and disease-specific survival.[116,117] As such, consideration of SLNB to search for micrometastatic disease has become the standard of care for most clinically node-negative patients with melanomas 1 mm and greater in thickness, and for a subset of T1b melanomas 0.76 mm and greater in thickness.[118] SNLB is a powerful tool for accurately staging clinically node-negative patients and as such, use of this technique continues play a central role in the AJCC staging classification system for melanoma.[102] SLNB is far more sensitive and accurate at detecting microscopic metastases than positron emission tomography (PET) scan, computed tomography (CT) scans, or ultrasound imaging combined with lymph node fine needle aspiration (reviewed in Sabel and Wong, 2009).[119] Ulceration of the primary lesion signifies a worse prognosis in regional stage III disease. Mitotic rate of the primary lesion strongly correlates with a worse prognosis for microscopic regional stage III disease. Satellite, both clinical and microscopic, metastases around a primary melanoma and in-transit metastases between the primary and its nodal basin represent intralymphatic metastases (N2c or N3) and portend the worst prognosis for regional metastases (stage IIIC disease) with a 5-year survival rate less than 50%.[102] Other changes in the AJCC melanoma staging system from the sixth Edition (2002) to the seventh Edition (2009) include: (1) the inclusion and use of immunohistochemistry markers for SLNB diagnosis and (2) no lower N+ size threshold, previously implied at 0.2 mm. Any tumor deposits, regardless of size, are now scored N+.

PROGNOSTIC FACTORS IN DISTANT METASTASIS

The presence of distant metastases portends the worst prognosis, with mean survival rates measured in months rather than years. Site of metastasis continues to be an important prognostic factor in the AJCC melanoma staging; with visceral metastases having a relatively poorer prognosis than nonvisceral (skin, subcutaneous tissue, and distant lymph nodes) sites.[102,105] Other variables of prognostic significance are the number of metastatic sites and surgical resectability. Solitary metastases resected after radiologic demonstration of stability over 3–6 months have been associated

with prolonged survival in some, but no strong evidence exists that asymptomatic detection is associated with significant overall survival to date.[120] Elevated serum lactate dehydrogenase (LDH) levels are associated with a worse prognosis, regardless of the site of metastatic disease. Patients with elevated LDH at the time of diagnosis of stage IV melanoma are assigned to M1c regardless of the location of the stage IV disease.[102]

CLINICAL COURSE

STAGES I AND II MELANOMA. In general, the 5–10-year survival for patients with localized thin primary melanoma <1 mm in Breslow depth is more than 90%. Melanoma typically recurs in a predictable fashion, first in a local and regional distribution, then to distant sites. It is also recognized that melanoma may bypass the regional nodes with direct hematogenous dissemination. The majority of recurrences manifest in the first 5 years after diagnosis and treatment, depending on tumor thickness and other prognostic features of the primary lesion (see Section "Prognostic Factors in Microstaging"). However, melanoma can recur at any time, and the incidence of late recurrence 10 or more years after initial diagnosis is approximately 1%–5%.[121] "Ultralate" recurrences more than 15 years after diagnosis are rare but do occur.[122]

STAGE III MELANOMA. Stage III melanoma represents a broad range of patients with a diverse clinical outcome, from patients with microscopic nodal disease (IIIA) to patients with bulky clinical nodes or in-transit metastases (IIIC) (Fig. 124-16). The general overall 5-year survival range of 38%–78% is wide, primarily related to several variables such as: the number of positive lymph nodes (most important), tumor burden within a lymph node (microscopic vs. macroscopic), age, and ulceration status, Breslow thickness, and mitotic rate of the primary melanoma (Table 124-4).[102]

Figure 124-16 Uncontrollable bulky metastatic melanoma to the regional lymph nodes.

There is a significant decline in survival in melanoma patients who present with clinically evident macroscopic nodal disease versus those with microscopic nodal disease identified via SLNB.[102,117] SLNB is a powerful staging technique (see Section "Sentinel Lymph Node Biopsy").

STAGE IV MELANOMA. Melanoma is known for its propensity to metastasize to virtually any organ and also for its highly variable clinical course. Melanoma metastasizes to nonvisceral sites: distant skin/subcutaneous tissue and distant lymph nodes in approximately half of the stage IV cases (42%–57%) (Fig. 124-17). The most common visceral sites are the lungs (18%–36%), liver (14%–20%), brain (12%–20%), bone (11%–17%), and gastrointestinal tract (1%–7%). Once metastases to distant sites have been detected, median survival is approximately 6–8 months, but rare longer term and even durable remissions do occur.[105]

METASTATIC MELANOMA OF UNKNOWN PRIMARY. Metastatic melanoma of unknown primary is defined as the presence of histologically confirmed melanoma in a lymph node, visceral site, or distant skin/subcutaneous tissues without a history or evidence of a primary cutaneous, mucosal, or ocular melanoma. This situation occurs in approximately 2%–5% of all cases of melanoma. Approximately 60% of these involve the lymph nodes, the remaining involve distant sites typically the skin/subcutaneous tissue, and less commonly lung, brain, or gastrointestinal tract.[122] Melanoma of unknown primary has similar survival rates compared to equivalently staged melanomas of known primary origin. In the largest study to date, melanoma of unknown primary metastatic to lymph nodes had 5- and 10-year survival rates of 46% and 41%, which is comparable to the equivalent stage III melanoma of known primary.[124] Melanoma of unknown primary metastatic to viscera had a median survival of 6 months.[125]

Although rare, a handful of cases have been reported in which a solitary melanoma of the skin confined to the dermis or subcutaneous tissue presumed to be metastatic melanoma of unknown primary has unexpectedly high survival rates.[126,127] *Primary dermal melanoma* is the term used to describe these solitary lesions with 5-year survival rates reported over 80%. It may represent a distinct subtype of primary melanoma actually originating in the dermal and/or subcutaneous tissue.

Evaluation of melanoma of unknown primary or dermal melanoma should involve a complete skin examination looking for a primary site. Wood's lamp may be used to identify subclinical hypopigmented areas, which may suggest a regressed primary lesion. In melanoma of unknown primary metastatic to a lymph node, particular attention should be focused on the skin areas that drain to the nodal basin involved. A complete history of previously excised skin lesions should be reviewed. The patient should be referred for proctoscopic, gynecologic, ocular, and nasal mucosal examinations, when warranted. Staging workup and treatment should be performed as for the equivalent clinical stage of known primary.

Figure 124-17 **A.** Zosteriform pattern metastases on the back. The primary melanoma was also on the back, Breslow depth 3.9 mm with ulceration and satellitosis. **B.** Epidermotropic and dermal metastatic melanoma on the scalp (also present on the face and neck) occurring 1 year following diagnosis of nodular primary mid-back melanoma, Breslow depth 3.75 mm, SLNB positive left and right axilla.

TREATMENT

STAGING WORKUP

(See Fig. 124-18)

BIOPSY. Patients with lesions clinically suspicious for melanoma should, whenever possible, undergo prompt excisional biopsy with narrow margins. A wider margin should be avoided to permit the most accurate subsequent SLNB if indicated. Most melanomas undergo initial biopsy in their clinical entirety, but if the lesion is large and/or located on anatomic areas such as the palm/sole, digit, face, or ear, an incisional full-thickness to adipose skin biopsy may be performed. Another common reason for incomplete incisional biopsy is lack of initial suspicion for rarer subtypes such as small amelanotic lesions that may resemble a small basal cell carcinoma or even eczema. An incisional biopsy should be obtained in the most elevated or darkest area of the lesion, with a strong appreciation that the clinically most suspicious area may not always correlate with the thickest portion of the lesion. There is no evidence that biopsy or incision of a primary melanoma leads to "seeding" of tissue and adversely affects survival. If subtotal incisional biopsy confirms melanoma <1-mm thickness, and significant residual clinical lesion remains, a narrow margin excisional biopsy should be considered first for accurate microstaging if the patient is a candidate for SLNB, or treatment would be altered with upstaging. Excisional biopsy performed after incisional biopsy of melanoma with ≥50% of the lesion remaining resulted in significant upstaging in 21% of patients, and change in SLNB consideration in 10% of patients in one large study.[128]

EVALUATION FOR REGIONAL METASTASIS

MACROSCOPIC METASTASES. The foundation of the initial workup following diagnosis of primary cutaneous melanoma is thorough history taking and physical examination. The findings on a good history and physical examination will, to a great extent, drive any further workup. Patients should be evaluated for regional spread by careful palpation of lymph nodes, particularly the primary echelon nodal basin(s). The concepts of aberrant lymphatic drainage pathways to unexpected nodal basins and interval nodes located between the primary site and the expected regional nodal basin have taught physicians to search for clinically detectable nodal disease in unexpected locations.[129,130] If a palpable lymph node or a dermal/subcutaneous nodule in the regional area of the primary is found, fine needle aspiration may be utilized to make a histological diagnosis.[118] An excisional biopsy of the lymph node should be performed if fine needle aspiration is inconclusive or not feasible.[131] Noninvasive imaging, most commonly with ultrasound or computerized or PET, is perhaps the most sensitive noninvasive method to detect small nodal metastases. However, the sensitivity and specificity of these tests are far inferior to tissue diagnosis obtained with SLNB, and not to be utilized for routine work up in the asymptomatic patient.[119,132–134]

MICROSCOPIC METASTASES

Sentinel Lymph Node Biopsy. SLNB is a powerful staging and prognostic tool used to detect occult micrometastases in regional lymph nodes for a subset of patients with melanoma.[135] SLNB represents

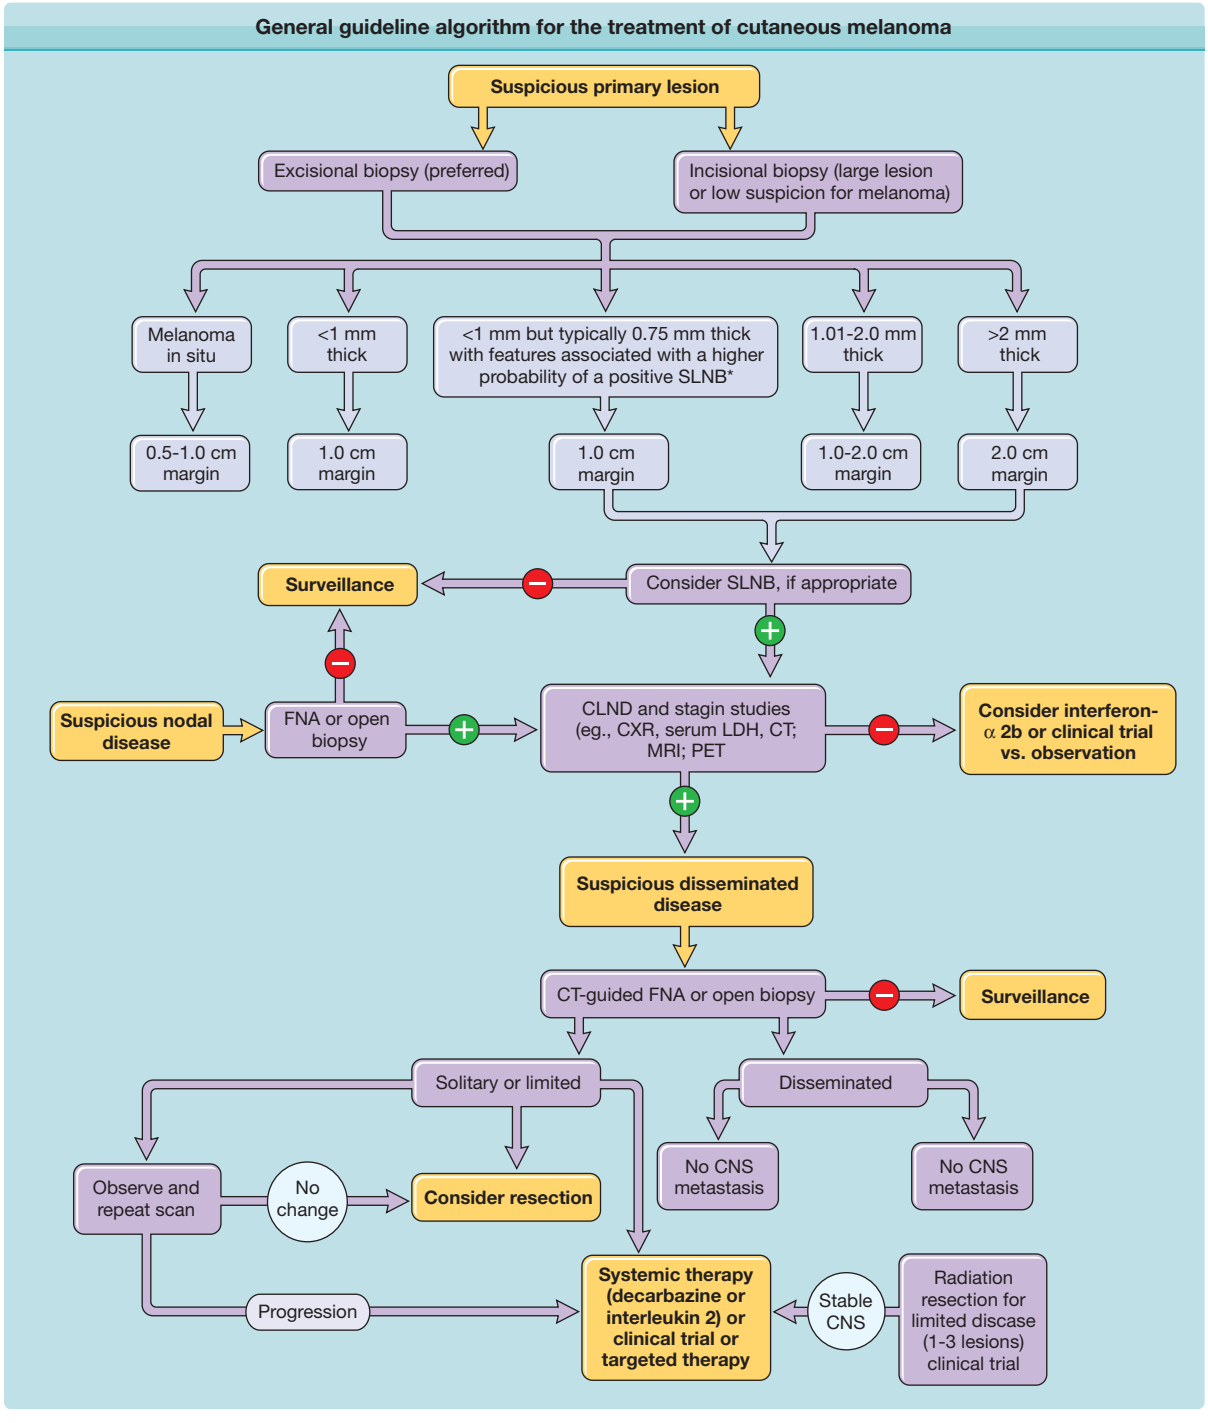

Figure 124-18 General guideline algorithm for the treatment of cutaneous melanoma. *Ulceration, extensive vertical regression to at least 1-mm thick, young patient age, high mitotic rate, especially in younger persons, shave biopsy with positive deep margin, presence of angiolymphatic invasion, and Clark level IV. CLND = completion lymph-node dissection; CNS = central nervous system; CT = computed tomography; CXR = chest X-ray; FNA = fine-needle aspiration; LDH = serum lactate dehydrogenase; MRI = magnetic resonance imaging; PET = positron emission tomography; and SLNB = sentinel-lymph-node biopsy. A minus sign indicates no evidence of disease, and a plus sign evidence of metastasis. Patients who are candidates for SLNB should be referred to a surgeon experienced in performing the procedure so that the benefits and complications can be fully discussed. (Used with permission from Tsao H, Atkins MB, Sober AJ: Management of cutaneous melanoma. *N Engl J Med* **351**:998, 2004)

the best baseline staging test for detection of occult nodal metastasis in the subset of melanoma patients where it is indicated, and is the only staging test with both relatively high sensitivity and specificity. There is a small likelihood of identifiable distant disease if the SLN is negative.[136] In the early 1990s, Morton et al initially reported the technique to selectively sample the first draining regional lymph node(s), or SLN(s) for melanoma; this SLN is most likely to contain any tumor cells that may have metastasized from the primary.[137,138] In current practice, technetium-99-labeled radio-colloid solution, often with vital blue dye, allows for detection of the SLN >95% of the time in skilled hands. Ideally, the procedure should be performed at the same time as wide local excision (WLE) of the primary melanoma for greatest accuracy. SLNB may not be accurate if performed after WLE in areas of ambiguous lymphatic drainage or following a local skin flap due to radiocolloid and dye injection location away from the true primary site. Once removed, the SLN(s) must be assessed with serial sectioning, using standard hematoxylin and eosin (H&E) techniques combined with immunohistochemical stains such as S100, HMB-45, and/or Melan-A if H&E is negative or inconclusive. This increases sensitivity for melanoma and has resulted in the upstaging of up to 10%–20% of patients.[139] The SLNB procedure requires the expertise and experience of three disciplines: surgery, nuclear medicine, and pathology.

In the new seventh edition of the AJCC melanoma staging system, an important revision concerns the definition of nodal positivity for sentinel lymph nodes. Previously, in the sixth edition of the AJCC melanoma staging system, metastatic melanoma foci in sentinel lymph nodes could only be identified by routine (H&E) stains. The seventh edition of the AJCC melanoma staging system now accepts as positive any sentinel lymph node containing metastatic foci that are clearly visualized by immunohistochemistry with melanoma markers, even if these metastatic deposits are not visible on H&E staining.

In 2006, Morton et al published the third interim analysis of the multicenter sentinel lymphadenectomy trial (MSLT)-I, the first prospective randomized controlled clinical trial of SLNB in melanoma.[117] In this analysis, 1,269 clinically node-negative patients with newly diagnosed melanoma 1.2–3.5 mm in depth were randomized to wide excision and nodal basin observation versus wide excision and SLNB. Patients with a positive SLN received an immediate node dissection, and patients in the observation arm also received node dissection if they developed regional lymph node metastasis. Sentinel lymph node status was demonstrated to be a powerful predictor of survival as those with a negative SLN had a 5-year survival of 90.2%, versus 72.3% 5-year survival for those with a positive SLN.

Current NCCN guidelines recommend consideration of SLNB for relatively healthy patients with primary localized melanoma ≥1 mm in Breslow depth (see Fig. 124-18).[118] The most important and consistently reported predictor of SLN positivity is Breslow depth. The likelihood of regional nodal involvement rises with increasing tumor thickness. For melanoma <1 mm Breslow depth, the probability of a positive SLN in general ranges from 5% to 10%; for 1–2 mm 15% to 20%; 2–4 mm, 25% to 35%; and >4 mm 40% to 50%.[116,135,140–143] Prognosis for thick melanoma >4 mm does correlate with SLNB status, while lesions <0.75-mm thick do not. However, SLNB may be considered for thinner lesions 0.76 to 0.99 mm in Breslow depth in the presence of certain adverse features that increase SLN positivity in thin lesions: ulceration, young patient age, mitotic rate ≥1 mm especially in younger persons, shave biopsy with positive deep margin, and the presence of angiolymphatic invasion.[110,116,141,142,144] Clark level IV is no longer used as an indication for consideration of SLNB for most melanomas, while extensive vertical regression to at least 1 mm is used in some centers.

EVALUATION FOR DISTANT METASTASIS

A thorough melanoma-focused review of systems constitutes the foundation of the evaluation for distant metastases with particular attention to the general/constitutional, neurologic, psychiatric, gastrointestinal, musculoskeletal, skin, lymphatic, endocrine, cardiovascular, and respiratory systems.[144] Routine imaging and hematologic tests in asymptomatic patients rarely identifies occult systemic disease that is associated with improved survival based on asymptomatic detection.[119,136] The presently available imaging modalities including CT, magnetic resonance imaging (MRI), PET, chest X-ray (CXR), and hematologic tests such as LDH lack both high sensitivity and specificity to make them routinely indicated. The reported true-positive rate of routine baseline CXR in asymptomatic patients is exceptionally low ranging from 0% to 0.5% [145]; with similar ranges for CT of the chest, abdomen, pelvis, and brain CT or MRI.[136] Specificity is also low, and false-positive rates with these modalities range from 8% to 15%[144]; which leads to additional cost of studies and possibly invasive procedures, as well as increased patient anxiety. Unfortunately, there are no data demonstrating improved survival rates if metastases are detected when clinically asymptomatic versus early symptomatic stage IV disease.[104,120,144] Current NCCN guidelines recommend no additional workup in Stage 0 and 1A, optional CXR in stage 1B and II, optional CXR and LDH for stage III, and CXR and/or chest CT plus LDH for stage IV.[118] Even for stage III and IV, further imaging with CT, MRI, or PET is recommended to be performed as clinically indicated, which emphasizes the importance of a thorough melanoma-focused review of systems and physical examination.

TREATMENT OF PRIMARY MELANOMA

SURGERY. A general guideline algorithm for the management of cutaneous melanoma in 2010 is noted in Fig. 124-18. The standard of therapy for primary cutaneous melanoma is WLE. The purpose of the wider excision is to prevent local recurrence due to persistent disease by complete excision with histopathologically

Figure 124-19 Potentially preventable deep local recurrence at both poles of previous local excision scar with satellite lesions, occurring approximately 4 years after narrow excision of a thin melanoma with 0.5-cm margins.

confirmed tumor-free margins. True local recurrence from inadequate excision is clinically significant in a small subset with the potential lethal consequence of preventable recurrence (Fig. 124-19). Current recommended clinical margins around the residual lesion or biopsy scar for melanoma in situ, non-LM pattern, is 0.5–1 cm, for melanoma <1 mm Breslow depth 1-cm margin, for melanoma 1–2-mm thick 1–2 cm as anatomically possible, and for melanoma >2-mm thick 2 cm (with pathologic confirmation of clear peripheral margins for all). Several large randomized controlled trials have failed to demonstrate a difference in survival rates or local recurrence rates between narrow (1–2 cm) versus wide (3–5 cm) margins.[146–152] Ultimately, each patient should be evaluated individually, taking into account current surgical guidelines as well as anatomic site (i.e., location near a vital structure), the possibility of primary closure versus need for skin graft, and the presence or lack of adverse prognostic factors from microstaging. Melanoma excision at special sites, such as the digits, soles, ears, vagina, or anus, also requires separate surgical and functional considerations. Still, the fundamental oncologic principle should always be: tumor clearance first, reconstruction second. A partial or complete amputation of the digit is still the preferred surgical treatment for subungual invasive melanoma.

LENTIGO MALIGNA AND LENTIGO MALIGNA MELANOMA. Histologic confirmation of negative margins is especially important for LM and LMM subtypes, which are characterized by a propensity for extensive subclinical peripheral extension. The risk of an invasive desmoplastic component is increased in the setting of LMM. Standard surgical recommendations of 0.5-cm margins for LM and 1-cm margin for LMM <1-mm thick are often insufficient. One study found the average margin required to clear LM was 0.8 cm, 1.5 cm needed to clear 96% of LM lesions. The mean margin to clear LMM was 1.1 cm, 2.6 cm to clear 95% of LMM lesions.[153] Another reported that 97% of melanomas <1.5 cm in diameter required 1.5-cm margin for complete excision with 95% of melanomas >3 cm in diameter required 2.5-cm margin for complete excision.[154] Another study of periocular LM/LMM melanoma revealed tumor-free margins were reached within a mean margin of 1.3 cm for LM melanoma in situ and of 1.6 cm for invasive LMM, associated with a 2% 8-year local recurrence rate.[155]

Recurrence rates for standard breadloaf processing following narrow excision of LM is unacceptably high, up to 20% or higher.[156] A variety of surgical techniques and methods of more comprehensive histologic evaluation have been advocated: standard excision with more comprehensive vertical sectioning (i.e., "breadloafing"); Mohs micrographic surgery with frozen horizontal sectioning with or without immunostains; Mohs micrographic surgery with permanent horizontal sectioning; and mapped (i.e., "slow Mohs"), and staged mapped excisions with vertical sectioning (i.e., "square" technique).[157] The Mohs technique is problematic with the use of frozen sections that are difficult to accurately interpret even with the use of immunostains. Despite debate, favorable studies with minimally acceptable methodological design and analyses are lacking. Formalin fixed permanent section histology remains the "gold standard" for histologic evaluation of surgical margin assessment of melanocytic lesions and are, in general, far superior to frozen sections.[158] Even with "slow Mohs," permanent processing and interpretation of horizontal sections is problematic in laboratories and for pathologists unaccustomed to this technique. Histologic margins require significant experience to evaluate, as there is a spectrum ranging from background benign junctional melanocytic hyperplasia to lesional trailing edge atypical junctional melanocytic hyperplasia.[159] One of the most frequently overdiagnosed proliferations are ones in which there are activated melanocytes. These cells are present in sun-damaged skin and exhibit a uniformity of appearance with either small round nuclei surrounded by a pale cytoplasm lying in the center of the "clear space" of a semilunar-shaped hyperchromatic nucleus with minimal cytoplasm lying along the basement membrane zone. This type of change can be found overlying most dermal nevi and angiofibromas in sun-exposed areas. The involvement of an experienced pathologist is crucial for all of the techniques described above and used today.

TREATMENT OF REGIONAL METASTASIS

MACROMETASTATIC NODAL DISEASE

Complete Lymph Node Dissection. The current standard of therapy for microscopic or macroscopic melanoma in lymph nodes is complete lymph node dissection (CLND) of the involved regional

basin. Uncontrolled nodal disease is a cause of melanoma-related morbidity with a significant high negative impact on quality of life (see Fig. 124-16). Current NCCN guidelines no longer specify the number of lymph nodes that constitute an adequate lymphadenectomy. Current guidelines state that the operative report from a completion dissection should fully describe the anatomic boundaries of the lymph node dissection.[118] CLND for regional metastatic melanoma is associated with long-term survival in a proportion of patients.[160]

MICROMETASTATIC NODAL DISEASE. Elective lymph node dissection (ELND) is the removal of regional lymph nodes draining the site of a primary cutaneous melanoma in the absence of any palpable or clinically evident metastatic disease. Historically, before the advent of SLNB, ELND was advocated for melanomas at higher risk of regional spread to eradicate occult micrometastases in a potentially curative manner. Multiple prospective randomized-controlled trials failed to demonstrate a significant benefit from ELND for melanoma.[161,162] Thus, there is no role for ELND today, especially in light of the development and availability of SLNB.[163]

As mentioned previously, the SLNB procedure is a powerful staging tool that identifies micrometastatic nodal disease E[164] SLNB cannot be classified as therapeutic to date based on interim data, and for the entire group, patients in the randomized MSLT-I trial who received a SLNB did not have an improved melanoma specific survival when compared to patients who did not receive a SLNB. This is not surprising since the study is underpowered to answer that question with approximately 80% of subjects not harboring nodal deposits. However, in the group of patients with melanoma metastatic to the lymph nodes, the 5-year survival was significantly higher among patients with a positive SLNB and immediate lymphadenectomy compared to patients in the observation followed by lymphadenectomy for clinical nodal disease arm (72% vs. 52%).[117] Critics accurately point to the fact that this trial component was not randomized and data is not mature. Still this data suggests a potential outcome benefit that needs mature data analysis.

After positive SLNB, up to 15%–20% of patients have evidence of non-SLN metastases found during CLND.[165] Therefore a positive SLNB should be followed by a CLND for both prognostic and therapeutic benefit. From a prognostic standpoint, among node-positive patients with melanoma, the presence of a positive non-SLN is a significant poor prognostic sign.[166] In addition, reports support improved regional control with less morbidity with patients undergoing a CLND for a positive SLN have a significantly lower risk of postoperative complication or lymphedema than patients undergoing CLND for clinically palpable disease.[167]

The MSLT-II is currently underway to determine if an identifiable subset of patients with a positive SLNB exist who may safely avoid CLND after a positive SLNB. In the absence of further data, patients with a positive SLNB should undergo completion lymph node dissection, or enroll in MSLT-II for several reasons above.

ADJUVANT THERAPY

Interferon-α 2b. Adjuvant therapy is additional treatment for patients surgically resected of clinical disease but at high risk for relapse such as thick primary melanoma >4 mm with ulceration or nodal disease. High-dose interferon-α 2b (IFN-α 2b) is the only adjuvant therapy approved by the U.S. Food and Drug Administration (FDA) that has been shown to improve disease-free survival for stage IIB–III melanoma.[168–170] Low-dose regimens failed to demonstrated an accepted benefit. The high-dose regimen consists of 20 million units per square meter of body surface area per day given intravenously 5 days a week for 4 weeks (induction phase), followed by 10 million units per square meter per day given subcutaneously three times a week for 48 weeks (maintenance phase). Interestingly, the appearance of autoantibodies or clinical manifestations of autoimmunity (vitiligo) during treatment with IFN may be associated with a significant improvement in relapse-free survival and overall survival in melanoma patients undergoing adjuvant IFN.[171,172]

There are significant toxicities associated with the high-dose IFN regimen, the most frequent being flu-like symptoms in almost all patients (i.e., fatigue, anorexia, weight loss, myalgias, fever, nausea, and headache). Other side effects include depression, hepatotoxicity (elevated transaminases), and myelosuppression. The toxicities may require dose modification and if the patient makes it through the first 3 months of therapy, most are able to complete at least 80% of the scheduled dosing and are able to finish treatment.[168] In addition, in this biased group, quality of life is improved and patients seem to prefer IFN therapy to no treatment.[173,174] Counseling and consideration of potential benefits and risks of toxicities is done on an individual basis.

Melanoma Vaccines. A number of autologous, allogeneic, and peptide vaccines have been studied in the management of melanoma but none are currently available as approved therapy. Vaccines are attractive, given antigen-directed approaches and low toxicities as they attempt to stimulate a specific immune response against melanoma-associated antigens. A number of promising approaches to developing melanoma vaccines are being explored.[175]

SATELLITE OR IN-TRANSIT METASTASES

Isolated Limb Perfusion. In general, regional in-transit or satellite disease should be surgically excised with clear margins whenever possible. However, if multiple lesions make surgery unreasonable, isolated limb perfusion (ILP) may be considered for locoregional disease control limited to an extremity. ILP is a form of regional chemotherapy that delivers higher doses of chemotherapeutic agents to the limb with less systemic toxicities. The technique involves perfusing an isolated extremity under hyperthermic conditions

with cytotoxic agents, conventionally melphalan. ILP with melphalan is an effective form of regional therapy in some cases with an associated considerable morbidity, producing partial or complete regional responses rate as high as 80%.[176] The benefit is aimed at locoregional control, not overall survival.

The ILP procedure may be associated with serious local morbidities, including significant tissue damage or compartment syndrome. Elderly age and serious medical comorbidities are generally considered exclusion criteria. Isolated limb infusion (ILI) is a, simpler, less-invasive technique. Early studies of ILI with melphalan and actinomycin D demonstrate comparable efficacy to ILP with melphalan.[177] ILI may be considered for patients ineligible for ILP.

TREATMENT OF DISTANT AND/OR DISSEMINATED METASTASIS

The treatment of stage IV melanoma must take into account that the average survival is 6–8 months and that no systemic therapies have been shown to significantly increase survival in randomized controlled trials.[135] Goals of treatment should be increasing length of survival and palliation of symptoms. The option of observation and conservative treatment is reasonable, especially in the asymptomatic, elderly, or those with serious comorbidities. Surgical excision of isolated visceral metastases (i.e., metastasectomy) demonstrated to be stable over a 3- to 6-month period may be performed with long-term disease free intervals in some. Surgical excision of skin/subcutis or distant lymph node metastases may result in improved locoregional control and decreased morbidity.[178] Surgery may also be palliative, for example, to relieve obstruction from gastrointestinal metastases. Melanoma is not known to be highly radiosensitive, but radiotherapy is an option and preferred used for brain metastases of more than three lesions, and following surgical removal with steriotactic radiosurgery or standard cold-knife surgery for focal disease. Palliative radiation may be indicated for spinal cord compression and painful bone metastases.

SYSTEMIC THERAPIES

Chemotherapy and Immunotherapies. The alkylating agent dacarbazine (DTIC) is the only FDA-approved chemotherapy for metastatic melanoma. Response rates are in the 10%–20% range, with median response duration 4 to 6 months.[179] There is no difference in terms of response rates and duration of response between the various dosing schedules used. The major side effects are nausea and vomiting. Temozolomide (TMZ) is an alkylating agent with the same active metabolite as DTIC, but it is able to cross the blood-brain barrier and can be absorbed orally. TMZ has been shown in a randomized phase III study to have efficacy equal to DTIC.[180] Other single agent regimens include paclitaxel or high-dose interleukin-2 (IL-2).[118] High-dose bolus IL-2 is the only FDA-approved immunologic treatment of metastatic melanoma that may produce rare but durable complete responses. It has been shown as a single agent to produce a 16% overall response rate but with a durable response in up to 5%–8% of patients, highest in those with lung, node, and/or skin metastases.[181] High-dose IL-2 is associated with significant toxicity and its use is limited to specialized programs with experienced clinicians and select patients.

Combination chemotherapies have been increasingly used for melanoma including regimens such as CVD (cisplatin, vinblastine and dacarbazine). The combination of CVD with interferon-α and IL-2 is known as biochemotherapy and may produce a higher response rate compared to CVD alone.[182] However, biochemotherapy is more toxic than CVD and may not improve overall survival.

Novel Therapies. B-raf mutations have been found in two-thirds of melanomas.[40] Sorafenib is an orally available RAF inhibitor that inhibits B-raf and C-raf but in a phase III trial this agent demonstrated little activity in patients with unresectable stage III or stage IV melanoma.[183] Recently, a phase I trial of a novel oral BRAF inhibitor, PLX4032 (also known as R05185426) demonstrated a 70% response rate in patients with metastatic melanoma.[185–186] This agent was approved in 2011 for targeted therapy in BRAF V600 positive tumors for stage IV disease.[187]

Melanomas from acral and mucosal sites are genetically distinct from other melanomas.[42] Most melanomas from acral and mucosal sites do not demonstrate mutations in *BRAF*, but a subset have activating mutations or amplification of the tyrosine kinase receptor *KIT*.[42,46] Early studies with the tyrosine kinase inhibitor imatinib have demonstrated significant responses in patients with metastatic melanoma harboring activating mutations in c-KIT.[48,188] Further studies are being conducted to evaluate approved and novel tyrosine kinase inhibitors in melanoma harboring mutations in c-KIT.

FOLLOW-UP

Patients with melanoma are at risk for local, regional, and distant recurrence, with the level of risk dependent on the stage at initial diagnosis and workup. Follow-up visits are an opportunity to review how to perform monthly self-skin and lymph node examinations, address any psychosocial emotional distress issues, obtain a melanoma-focused review of systems, and provide continuing patient education regarding early detection signs and symptoms and sun-protection/prevention strategies. Regular follow-up is indicated for all patients with melanoma. Current NCCN and national melanoma center guidelines call for at least annual follow-up visits for life, with follow-up intervals generally ranging from every 3 to 6 months for 1–3 years after diagnosis and annually thereafter, depending primarily on stage of disease.[118] Patients with other risk factors, such as a positive family history of melanoma, numerous nevi, a mutation in *p16* or *BRAF*, or difficulty with self-examination, may require more

frequent follow-up. A referral to a genetics counselor is warranted if there is a strong family history of melanoma, or a family history of pancreatic cancer.

The follow-up visit should consist of a thorough complete skin examination for additional primary lesions and cutaneous/subcutaneous metastases, particularly in the regional distribution of the primary, palpation of lymph nodes with particular attention to the regional nodal basin, and thorough history taking. The review of systems is the foundation for detecting symptomatology possibly attributable to melanoma, and directs additional testing or imaging. The yield and value of routine imaging to restage asymptomatic patients as part of standard melanoma follow-up are low and, thus, imaging and hematologic tests are based on any suspicious findings from a good history and physical examination.

PREVENTION

Public awareness and knowledge of melanoma and UV exposure is improving, but still a substantial gap exists between knowledge and behavior. Primary prevention strategy should focus on safe sun exposure, including limited UV exposure and sunburn prevention, especially in childhood and adolescence when the risk is greatest. Avoidance of peak sunlight hours and use of wide-brimmed hats, clothing, and sunscreen are recommended. In addition, early detection by regular self-skin examinations, skin awareness, and knowledge of the early signs and symptoms of melanomas should also be emphasized to patient, partners, and family members. The goal of secondary prevention is early diagnosis, which greatly reduces melanoma-related morbidity and mortality.

SECTION 23

Tumors and Hyperplasias of the Dermis and Subcutaneous Fat

Chapter 125 :: Malignant Fibrous, Fibrohistiocytic, and Histiocytic Tumors of the Dermis

:: Jürgen C. Becker, Bernadette Liegl-Atzwanger, & Selma Ugurel

MALIGNANT FIBROUS DERMAL TUMORS AT A GLANCE

- A group of uncommon and rare cutaneous tumors with varying degrees of malignant potential.
- Includes dermatofibrosarcoma protuberans (DFSP), atypical fibroxanthoma (AFX), desmoids tumor, myxofibrosarcoma (MFS), undifferentiated pleomorphic sarcomas (UPS), and epithelioid sarcoma (ES).
- Diagnosis is made by biopsy.
- DFSP is a locally aggressive tumor with a high rate of local recurrence with rare metastases.
- AFX is an intermediate-grade neoplasm that usually arises on sun-damaged skin in the eighth decade.
- Desmoid tumors are slowly growing tumors arising from the muscular aponeurosis that have been associated with a history of trauma or an operation; thus, women undergoing cesarean sections are at greater risk.
- MFS represent a spectrum of malignant myxoid tumors of fibroblastic origin that exhibit a range of clinical and histopathologic features.
- UPS is almost never a cutaneous tumor.
- ES is a rare, highly aggressive tumor that classically presents on the hands and fingers of young males, which can mimic nonneoplastic inflammatory lesions.

Malignant fibrohistiocytic tumors are a heterogeneous group of mesenchymal neoplasms. These neoplasms occur in the dermis and subcutaneous tissue and may cause diagnostic difficulties. This is at least in part due to the fact that these tumors are relatively rare while at the same time there is a perplexing variety of morphological types and subtypes; thus, the individual physician usually has limited experience in these tumors. By light-microscopic examination cells constituting fibrohistiocytic tumors are characterized by morphologic similarities to fibroblasts and histiocytes. Notably, the term "fibrohistiocytic" only denotes this morphologic appearance, it does not necessarily account for the histogenesis of the respective neoplasm.

The initial descriptions of these tumors were based entirely on hematoxylin and eosin (H&E) morphology and the term "fibrohistiocytic" was chosen in an attempt to provide an organizing principle and nomenclature for this group of soft tissue tumors, composed of cells resembling fibroblasts and histiocytes.

Over the last decades all scientific attempts to demonstrate true histiocytic differentiation in these tumors failed. By means of electron microscopy, immunohistochemistry (IHC), and cytogenetics, it became increasingly obvious that the term "fibrohistiocytic" is a misnomer and falsely unite a heterogeneous group of tumors, many of them are probably unrelated. This notion has been also recently endorsed by the World Health Organization by the use of the terminology "**So-called Fibrohistiocytic Tumors**" indicating that this term is only used descriptively.[1]

The symptoms that call attention to a fibrohistiocytic tumor are usually those caused by its presence and growth at its site of origin. In most cases the patient may present with an asymptomatic mass. Thus, a biopsy (either open or large-gauge core needle) is needed to obtain adequate tissue for diagnosis. Care should be taken to ensure that the biopsy does not interfere with subsequent optimal definitive surgery. Moreover, it should be kept in mind that fibrohistiocytic tumors can be very heterogeneous: the smaller the biopsy sample, the more likely it is that only a temporary, working diagnosis becomes possible. This is of course particularly

true for a purely cytological examination, since this can only evaluate individual cells. Nevertheless, in the hands of an experienced investigator, the cytological findings in most cases provide enough information to plan the subsequent therapeutic strategy.

The diagnosis of fibrohistiocytic tumors is done principally on the basis of the H&E-stained section. Despite the enormous increase in additional methods available, the H&E section remains the gold standard of morphological diagnosis. When necessary, IHC can be employed; this can reveal cell-line differentiation or antigen expression patterns typical for a particular tumor entity. Likewise, methods of genetic analysis allow the detection of chromosomal translocations, as well as gene deletions or amplifications. These methods are usually exercised when no tumor classification is possible on the basis of the H&E section even in combination with IHC. Chromosomal translocations can be detected in formalin-fixed paraffin-embedded (FFPE) tissue by fluorescence in situ hybridization (FISH) or by reverse transcription polymerase chain reaction (RT-PCR) for the product generated by gene fusion (hybrid RNA). The latter has the advantage of demonstrating not only the translocation, but also the sites of the breakpoints in the genes. Unfortunately, chromosomal translocations are not always diagnostically unambiguous.

Malignant fibrohistiocytic tumors of the dermis represent the malignant end of a spectrum that begins with fibroplasias and benign fibrous tumors. Fibrous lesions are often composed predominantly of stroma, and only in certain high-grade sarcomas the neoplastic nature of the lesion is immediately obvious. However, it should be noted that the identification of defined chromosomal abnormalities in some fibrohistiocytic lesions traditionally regarded as reactive suggests their neoplastic status. Thus, the classification of fibrohistiocytic tumors, like that for other tumor entities, is not static. New aspects or interpretations have to be taken into account and incorporated into clinical practice, i.e., it becomes necessary to update the tumor classification, modify it, or even alter major parts of it.[1]

A prominent example for such an evolution is malignant fibrous histiocytoma (MFH). MFH as a tumor entity has already been a subject of debate for sometime. Tumors were originally classified as MFH based on the assumption that the histiocytic tumor cells possess the ability to modulate into facultative fibroblasts. Indeed, MFH was regarded as the most common soft-tissue tumor of advanced adulthood, with pleomorphic MFH being the prevalent subtype. Subsequently, however, it was demonstrated that the phenotype of pleomorphic MFH can be adopted by various soft tissue malignancies by loss of differentiation; thus, in the majority of cases there is no independent tumor entity and the cells of pleomorphic MFH are basically dedifferentiated or undifferentiated cells of different origin. By means of more advanced techniques it was possible to demonstrate markers of residual differentiation for the majority of these tumors and thereby to remove such defined soft-tissue tumors from the group of pleomorphic MFH. According to the recommendations of the WHO, the remaining tumors that cannot be further subtyped, i.e., pleomorphic MFH in the narrower sense, should be described as undifferentiated pleomorphic sarcomas (UPS); notably, these very rare tumors are almost never cutaneous lesions. The tumor cells of the second prominent MFH subtype—the myxoid variant—are now understood as fibroblastic cells; thus, the preferred designation today is myxofibrosarcoma (MFS).

With regard to the treatment of "so-called malignant fibrohistiocytic tumors" surgery is the primary treatment of choice. In cases where surgery is not feasible, i.e., large primary tumors or inoperable metastatic disease, beneath chemotherapy and radiation the search for suitable molecularly targeted agents is strongly pursued.[2] To achieve this goal, however, a pathogenetically essential molecular target is needed. This strategy up to now was successful in one tumor entity only, dermatofibrosarcoma protuberans (DFSP), which can be effectively treated with tyrosine kinase inhibitors (TKI) targeting the platelet-derived growth factor receptor (PDGFR), for example, imatinib. For all other entities of malignant fibrohistiocytic tumors, clinical studies investigating different targeted agents in an unselective manner did not show any promising results. Here, the key molecular pathways for pathogenesis and maintenance of the different tumor entities first have to be elucidated in more detail to subsequently serve as targets for a molecularly driven therapy.

DERMATOFIBROSARCOMA PROTUBERANS

EPIDEMIOLOGY

The incidence of DFSP ranges between 0.5 and 1:100,000, thus it is the most common cutaneous sarcoma. Although DFSP can present at birth or in children, most patients are middle-aged adults. There does not seem to be a gender or racial predilection for the tumor, however, the pigmented variant (Bednar's tumor) is more common in black patients.

ETIOLOGY AND PATHOGENESIS

The histogenesis of DFSP is uncertain: fibrohistiocytic, purely fibroblastic, and neural-related differentiation have all been hypothesized. At the molecular level, DFSP is characterized cytogenetically by a reciprocal translocation t(17;22) (q22;q13), or more frequently, a supernumerary ring chromosome composed of hybrid material derived from t(17;22).[2] The translocated chromosome and the supernumerary rings contain the same molecular genetic rearrangements. The t(17;22) translocation fuses the gene *PDGFB* on chromosome 22 with the strongly expressed collagen 1 alpha 1 (*COL1A1*) gene on chromosome 17. The *PDFGB* gene encodes the β chain of the PDGF, a ligand for the cell-surface receptor tyrosine kinase PDGFR (both PDGFRβ and PDFRα). PDGFβ is a growth factor that acts as a potent mitogen for a variety of connective tissue cells.

The formation of the *COL1A1-PFGFB* fusion gene results in constitutive production of COL1A1-PDGFβ protein. After translation the COL1A1-PDGFβ fusion undergoes posttranslational processing to form functional PDGFβ. Thus, the production of PDGFβ can lead to autocrine stimulation of the tumor's own PDGFR, promoting tumor growth and survival. These observations suggest that deregulated expression of PDGFβ, with concomitant autocrine stimulation of PDGFR, is the critical molecular event in the pathogenesis of DFSP. Notably, both fibrosarcomatous transformation of DFSP and some cases of superficial fibrosarcoma (which actually may represent fibrosarcomatous transformed DFSP) have been shown to harbor these fusion transcripts, suggesting a close affinity between DFSP and fibrosarcoma.

In some patients, there is a history of previous trauma; in this regard it should be noted that DFSP has also been described as arising in scars, including surgical, burn, and vaccination sites.

CLINICAL FINDINGS

DFSP is a slow-growing lesion that often presents on the trunk and proximal extremities, less frequently on the head and neck of patients. Due to its indolent onset, the patient may present rather late when the tumor is already several centimeters in size. The tumor is often misdiagnosed as a simple scar, keloid, or cyst (Box 125-1). Even when allowed to grow for many years, the tumor usually remains asymptomatic.

The clinical presentation of DFSP is variable. The most common presentation is a firm, indurated plaque, often skin-colored with red–brown exophytic nodules (Fig. 125-1A). Purely plaque-like DFSP never developing nodules or tumors consisting of only a single nodule are rare. Initially the tumor is freely moveable; subsequently, however, larger adherent tumors evolve. At this stage the overlying epidermis may be thinned and telangiectases appear. Bleeding and ulceration are uncommon. DFSP may less frequently present as a nonprotuberant, atrophic (Fig. 125-1B), violaceous lesion resembling morphea or a sclerosing basal cell carcinoma; this form is more common in childhood.

BOX 125-1 DIFFERENTIAL DIAGNOSES OF DFSP, AFX, AND ES

DERMATOFIBROSARCOMA PROTUBERANS

- Classic presentation
  - Keloid/hypertrophic scar
  - Dermatofibroma
  - Fibrous histiocytoma
  - Nodular melanoma (Bednar variant)
- Atrophic presentation
  - Morphea
  - Lichen sclerosis
  - Morpheaform basal cell carcinoma

ATYPICAL FIBROXANTHOMA

- Squamous cell carcinoma
- Basal cell carcinoma
- Amelanotic malignant melanoma

EPITHELIOID SARCOMA

- Granuloma annulare
- Rheumatoid nodule
- Dupuytren contracture
- Infectious ulcer

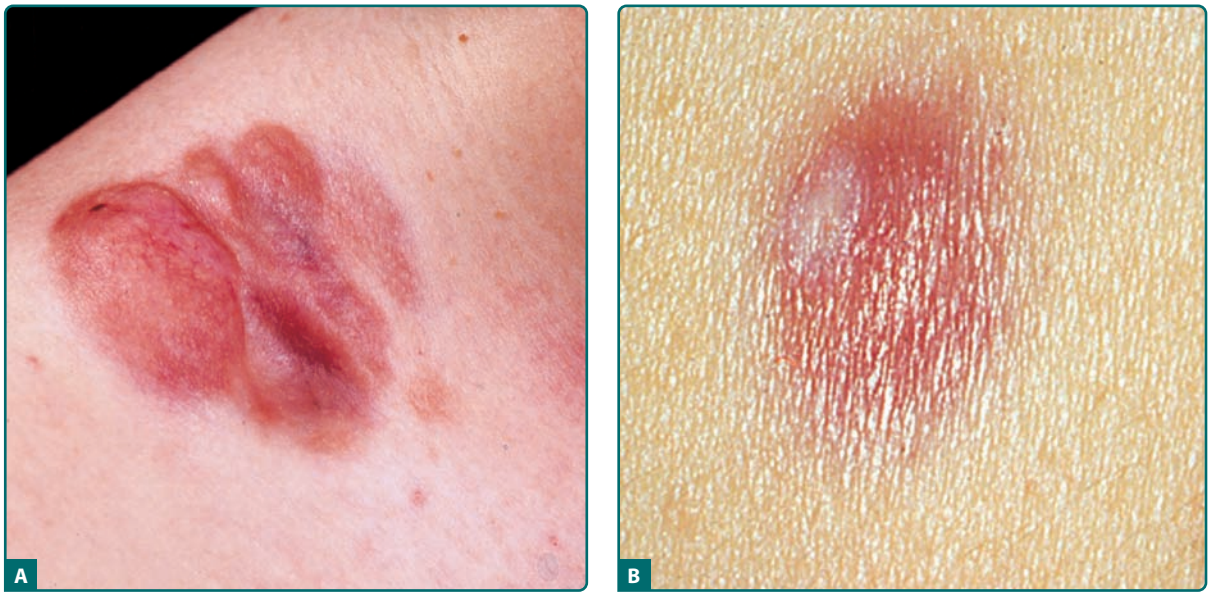

Figure 125-1 **A.** Dermatofibrosarcoma protuberans (DFSP) presenting as reddish brown confluent flat nodules. **B.** Atrophic variant of DFSP.

The pigmented variant of DFSP is termed **Bednar tumor**.

Giant cell fibroblastoma is considered a variant of DSFP, i.e., the juvenile variant of DFSP. Giant cell fibroblastoma typically presents as a dermal or subcutaneous mass, which most frequently involves the trunk, thigh, or inguinal region. It presents much earlier in life than the typical DFSP, often within the first decade, although occurrences in adults have been reported.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

DFSP is a dermal proliferation of monomorphous, slender, or slightly plump spindle cells with little pleomorphism arranged in a storiform pattern (Figs. 125-2A and 125-2B). The epidermis is usually uninvolved. The proliferation commonly infiltrates the subcutaneous fat along the fibrous septa, isolating adipocytes to form lucencies ("honeycomb" pattern). The periphery of the tumor is poorly defined, rendering histological control of the surgical margins difficult. In contrast to dermatofibroma, the tumor is much more cellular and usually does not have mature collagen interspersed between fascicles of spindle cells. Mitoses are present; a high mitotic rate may correlate with an impaired prognosis.

Variable histologic patterns described include myxoid, neuroid, fibrosarcomatous, and granular cell types. The tumor may be relatively monomorphous or may show combinations of various patterns within the original tumor or in the recurrences. The Bednar tumor is rich in melanocytes. Giant cell fibroblastoma is characterized by giant cells, irregular vascular-like space partially ligned by giant cells as well as myxoid to collagenous areas with elongated to stellated cells. Some lesions show overlap between giant cell fibroblastoma and DFSP. The fibrosarcomatous dedifferentiation appears histologically as cellular tumor zones with a fascicular growth pattern, cellular atypia, and numerous mitoses. These atypical cells are arranged in long fascicles in a herringbone (fibrosarcoma-like) pattern; this transformation appears to be related to mutations in the p53 pathway.

A very sensitive, although nonspecific, marker for DFSP is CD34.[3] DFSP cells label diffusely and strongly with antibodies to CD34 (Figs. 125-2C and 125-2D) and vimentin; however, CD34 positivity may be lost

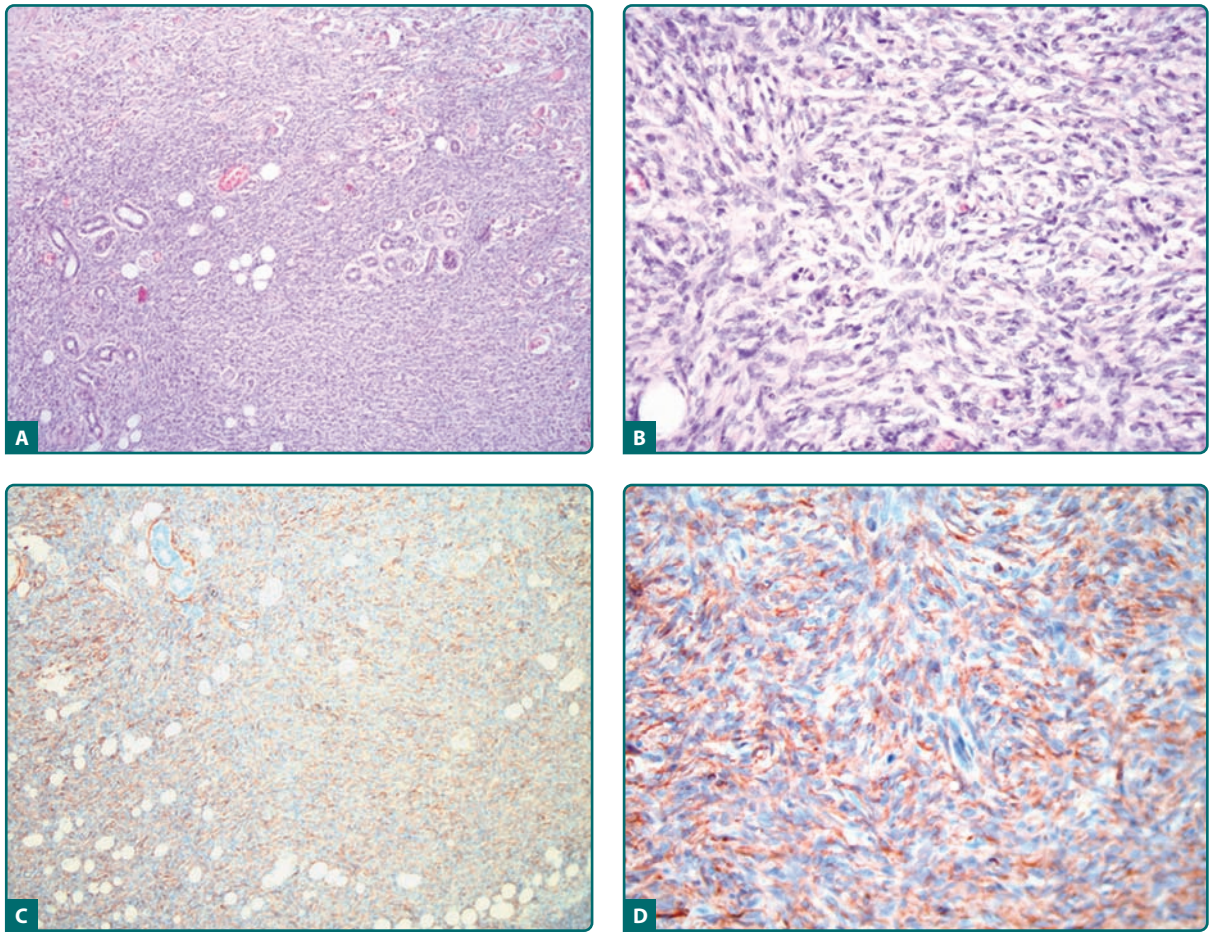

Figure 125-2 **A** and **B.** Dermatofibrosarcoma protuberans showing fibroblastic spindle cells that are arranged in interlacing fascicles. These intersect and bend at acute angles, producing a starburst (storiform) pattern. **C** and **D.** Strong expression of CD34 of the tumor cells. Magnification: **A** and **C,** 10×; **B** and **D,** 20×.

in nodular regions; particularly the fibrosarcomatous dedifferentiated cellular zones can be negative for CD34. The low-affinity nerve growth factor receptor p75 has been reported positive in DFSP cells. Scattered Factor XIIIa positive cells may be present. Tenascin is negative at the dermoepidermal zone in DFSP. DFSP cells are negative for S100 protein, smooth muscle actin (SMA), desmin, keratins, and epithelial membrane antigen (EMA). In contrast to dermatofibroma, stromelysin 3 is not expressed in DFSP.

CLINICAL COURSE, PROGNOSIS AND TREATMENT

DFSP is a low-grade malignant tumor, often infiltrating diffusely through the dermis and into the subcutaneous fat but seldom metastasizing. Increased age, high mitotic index, and increased cellularity are predictors of poor clinical outcome. Approximately 30%–50% of DFSPs recur locally after simple excision. Local recurrences even after wide excision with 1–3-cm margins to the fascia or periosteum are common. Best results can be achieved by means of micrographic controlled surgery (Mohs micrographic surgery) for tumor extirpation. However, it should be kept in mind that by use of frozen sections the histomorphology is not as good as by use of formalin-fixed paraffin embedded sections—in some cases impede correct diagnosis. Metastases of DFSP are extremely rare, usually occurring in the setting of multiply recurrent tumors and tumor progression to fibrosarcoma. Metastases to the lung are most common, with nodal disease the next most common site of spread. Metastatic disease portends a poor prognosis. It has been suggested that tumors with fibrosarcomatous change may have a higher risk of recurrence or metastases. It is estimated that there is a 5% transformation rate from DFSP to conventional fibrosarcoma. The true impact of fibrosarcomatous changes seen within a DFSP remains uncertain.

Standard management of localized disease is complete local surgical resection. With standard excision, margins of 1–3 cm may be necessary to achieve clear margins. However, local recurrence rates are high (13%–52%), especially in fibrosarcomatous DFSP. Risk of local recurrence decreases with increasing surgical margins. Pathologic examination of margins during surgery is helpful in delineating the extent of the tumor. Multiple case series have shown Mohs micrographic surgery to be an extremely effective method of resection of DFSP, with an extremely low rate of local recurrence. As a result, Mohs micrographic surgery represents the preferred surgical approach of many practitioners.

The role of radiotherapy remains unclear. Radiotherapy in the adjuvant setting following surgery is a treatment option particularly when margins are positive or close after maximal resection, if there is concern about the adequacy of negative margins, or if the achievement of wide margins would result in a functional or cosmetic defect.

Targeting the PDGF receptor signaling by receptor TKI, such imatinib or nilotinib, has demonstrated remarkable clinical success in the setting of advanced, unresectable primary tumors or metastatic disease.[4] These TKI are competitive antagonists of the adenosine triphosphate (ATP)-binding site, blocking the transfer of phosphate groups from ATP to tyrosine kinase residues of the substrates. This causes interruption of the downstream signaling process that leads to cell proliferation. The clinical activity of imatinib in patients with metastatic or locally advanced, unresectable DFSP was initially documented in case reports. The first published larger series of DFSP patients treated with imatinib confirmed the clinical activity with eight of eight patients with locally advanced disease obtained a clinical response. Four of these had a complete response; the other four patients were rendered free of disease after surgery following a partial response. Since 2007, imatinib has been approved in the United States and in the European Union for use in adult patients who have unresectable, recurrent, and/or metastatic DFSP and are no primary candidates for surgery. However, these observations raise the possibility of using PDGFR-specific TKI in the neoadjuvant setting in cases where surgery is associated with significant morbidity.[2] Clinical trials are needed to determine whether neoadjuvant use of such TKI to reduce tumor burden and facilitate resection, as well as adjuvant use following complete surgery, particularly in fibrosarcomatous DFSP, can improve patient outcome. Several studies in the United States and in Europe are ongoing in these clinical settings.

DESMOID TUMOR

EPIDEMIOLOGY

Desmoid tumors, or aggressive fibromatosis, are rare, with an estimated incidence rate of two to four cases per million per year. Desmoid tumors occur in a wide age range, between 16 and 79 years with a median age of 35, the majority being diagnosed before the age of 40.[5] Desmoids are slightly more common in women than men, but there are no apparent differences by race.

Desmoid tumors usually occur sporadically, but can be associated with familial adenomatous polyposis (FAP). Indeed, their incidence is 1,000-fold more frequently in patients with FAP; approximately 2% of desmoid cases occur in the setting of FAP. FAP, characterized by a mutation in the adenomatous polyposis coli (APC) tumor suppressor gene, has a clinical manifestation of hundreds, if not thousands, of adenomatous polyps in the colon and rectum. Although the association of desmoid tumor with FAP has been noted earlier, Gardner described a familial syndrome characterized by intestinal polyposis, fibromas, and sebaceous and epidermal cysts. Gardner syndrome is viewed as a variant of FAP. Notably, intra-abdominal and extremity desmoids tumors represent common extracolonic manifestations of disease in Gardner's syndrome.

ETIOLOGY AND PATHOGENESIS

The genetic predisposition to desmoid tumors in FAP patients prompted mutation analyses of the APC gene

to elucidate the pathogenesis of fibromatosis. However, current evidence demonstrates that there are likely undefined genetic or clinical factors independent of APC that are responsible for the pathogenesis of fibromatosis.[5]

Because APC and CTNNB1 are both part of the Wnt signaling pathway, mutations in either gene result in β-catenin protein stabilization and subsequent downstream activation of the T-cell factor/lymphoid enhancer factor (TCF/Lef) family of transcription factors. In a transgenic mouse model, induction of stabilized β-catenin leads to the development of desmoid tumors and hyperplastic cutaneous wounds, suggesting that β-catenin plays a role in these fibroproliferative disorders. Indeed, in a study of sporadic desmoid tumors, 3 of 12 cases had a mutation in β-catenin. In another study, 16 of 19 cases of desmoid tumors had a mutation of the Wnt pathway (APC or CTNNB1). The resulting activation of this pathway may be a potential target for future studies and the development of tailored therapies.

Recently the differential expression of estrogen receptors in desmoid tumors has been reported. There appears to be an increased estrogen receptor-β expression in 80% of desmoid specimens. Increased expression of PDGF receptors and their ligands in desmoid tumors have been reported.

CLINICAL FINDINGS

Desmoids are slowly growing tumors that may arise from the muscular aponeuroses at any site of the body, but are most commonly found on the trunk and extremities. In these locations, these solitary tumors tend to be located deep in the muscles or along fascial planes, such as at a point of muscular insertion. They may become quite large, displacing normal structures and hampering function. Patients will usually present with a greater than 5 cm, localized, firm mass with an indolent pattern of growth, which can be painless or minimally painful. The tumors of the abdominal wall occur along the anterior abdominal wall, most commonly in young women during or immediately after pregnancy. Desmoid tumors have been associated with a history of trauma or an operation. Thus, women undergoing cesarean sections are at higher risk.[5]

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

Desmoid tumors are characterized by a monoclonal fibroblastic proliferation typically arising from muscular or aponeurotic structures. They may resemble low-grade fibrosarcoma, but their histologic appearance lacks nuclear and cytoplasmic features of malignancy. Desmoid tumors consist of spindle-shaped cells, separated by collagen fibers. The tumor cells have regular nuclei and show few mitoses. The tumor cells are arranged in long fascicles. Variable prominent elongated and compressed vessely can be seen. An infiltration of tumor cells into surrounding tissue frequently observed. By IHC, these spindle cells usually stain for vimentin and SMA, but are generally negative for desmin, cytokeratins, and S100. 70% of these tumors show a nuclear staining with antibodies against β-catenin.

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

Desmoid tumors are notoriously infiltrative and persistent. Moreover, trauma, including surgery, can stimulate desmoid tumor growth. Thus, recurrence after surgery is common. Albeit to date no agreement has been reached on the optimal treatment of desmoid tumors, complete resection is generally considered the best choice of initial treatment and is potentially curative. Ability to accomplish complete resection at the first attempt defines likelihood of recurrence. Preoperative diagnosis with core needle biopsy may be helpful in planning a radical resection. Due to the locally aggressive nature of desmoid tumors and the therefore needed safety margins the localization of the tumor is important for treatment planning. Thus, clinical evaluation should include radiologic studies by MRI to determine proximity to adjacent structures.

There are no strong data to support the use of radiation therapy in the adjuvant setting following complete surgical resection. Thus, its use may be deferred until recurrence is seen and not amenable to repeat resection. Because palliative resection in most cases neither improves symptoms nor lengthens survival, there should be a consideration of radiation therapy in truncal or extremity desmoid tumors when a complete resection is not feasible.

Systemic therapy is indicated for patients with unresectable lesions. A number of treatment regimens have been reported in single case studies. Given the slow natural course of the disease, a low-toxicity regimen of chemotherapy is preferred; the combination of methotrexate and vinblastine is one of the most studied regimens. Chemotherapy, however, is met with scepticism since oncologic dogma dictates that cytotoxic treatments are not particularly effective in indolent tumors without metastatic potential.

Noncytotoxic agents that have been used for systemic treatment of desmoid tumors include antihormonal, nonsteroidal anti-inflammatory, and molecularly targeted agents. Because of clinical and experimental evidence linking hormonal surges to desmoid growth, antiestrogen agents (tamoxifen, toremifene, and raloxifene) have been commonly used over the years. Control of disease (either tumor shrinkage or stabilization) has been observed in up to 50% of patients; notably, responses are sometimes seen after the medication is discontinued. Recently, preliminary reports on the clinical activity of imatinib in desmoid tumors have generated some enthusiasm, though the mechanism of its action remains unclear. Nevertheless, several case reports have described meaningful responses to imatinib and in a series of 19 patients with desmoid tumors control of disease was achieved in almost 40% of the patients. The notion that the Wnt/β-catenin signaling pathway is involved in the pathogenesis of desmoid

tumors, opens new avenues for novel molecularly targeted agents.

ATYPICAL FIBROXANTHOMA

EPIDEMIOLOGY

AFX is a rare, rapidly growing neoplasm of intermediate malignant potential. It occurs mainly on sun-exposed skin (face, neck, and hands) of elderly individuals, mostly in the eighth decade of life, and shows male predominance.[6] However, in xeroderma pigmentosum (XP) patients, a rare, usually autosomal recessive disorder related to DNA repair defects, AFX does not only have a higher incidence but also occurs earlier in life, even in children.[7] Moreover, several lines of evidence indicate that the incidence of AFX is dramatically higher in transplant patients receiving immune suppression.

ETIOLOGY AND PATHOGENESIS

The nosologic nature of AFX has been the subject of much debate. Given its histologic appearance as well as its immunoperoxidase staining profile, AFX has traditionally been considered mesenchymal in origin. Because its histological appearance is similar to pleomorphic MFH, AFX is often regarded as a superficial version of this tumor. However, since the phenotype of "pleomorphic MFH" can be adopted by various soft-tissue tumors by loss of differentiation, AFX may also represent a tumor of dedifferentiated or undifferentiated cells of different origin. Thus, recently, some authors argue that AFX is an undifferentiated form of a spindle cell squamous cell carcinoma (SCC) or spindle cell melanoma. Indeed, one study has shown that depth-matched SCC and AFX behave similarly (Box 125-1).

Solar radiation probably represents a predisposing factor in the pathogenesis of AFX. This is supported by the common occurrence of the tumor on actinically damaged skin and its frequent association with other actinic-related lesions. The presence of cyclobutane pyrimidine dimers further supports a pathogenic role for ultraviolet radiation in the development of AFX.

Moreover, the majority of AFX cases are characterized by p53 immunoreactivity independent of acute stimuli for it expression; indeed, molecular analysis of the *p53* gene in a case series revealed that there were abnormal single strand conformational polymorphism patterns in all p53-immune reactive cases.[6] The increased incidence of AFX in XP patients also strongly suggests that UV-induced damage in the pathogenesis of the tumor.

CLINICAL FINDINGS

The patient may report a lesion on sun-damaged skin of relatively rapid onset. The predominant locations are ears, cheeks, nose, and scalp. The background skin is often sun damaged. The lesion usually presents as an asymptomatic, solitary, often dome-shaped nodule, which may be eroded or ulcerated (Fig. 125-3A). The size of presentation is usually less than 2 cm in diameter. AFX may resemble an SCC, basal cell carcinoma, or even a necrotic pyogenic granuloma.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

AFX is a poorly circumscribed hypercellular tumor that may extend deeply into the reticular dermis. It consists of an admixture of highly pleomorphic spindle, epithelioid (histiocyte-like), and multinucleated giant cells in the dermis (Figs. 125-3B and 125-3C). The proportion of individual cell types within individual lesions may vary, from predominantly spindle to predominantly epithelioid lesions. The neoplastic cells display pronounced atypia, with bizarre, large, round, or ovoid hyperchromatic nuclei with numerous mitotic figures (some of them atypical); large, prominent eosinophilic nucleoli; and abundant, occasionally vacuolated cytoplasm. An epidermal collarette at the periphery of the lesion is frequently observed and may extend along the base of the lesion. Skin adnexa are generally surrounded but not destroyed by the tumor. The deep margin is generally pushing rather than infiltrative. Surface ulceration precludes adequate evaluation of epidermal changes, for example, the presence of epidermal dysplasia or melanocytic proliferation.

At present, no single reliable immunohistochemical marker has been detected to confirm the diagnosis of AFX, which still remains a diagnosis of exclusion.[6] A panel of antibodies is therefore mandatory to exclude its potential mimics. Immunohistochemically, AFX has variable profiles, but cells usually express vimentin and histiocytic markers such as α_1-antitrypsin, α_1-antichymotrypsin, and CD68. Focal smooth muscle positivity can be detected in as many as 45% of AFXs. Although diffuse and strong CD10 and CD99 positivity has been described in AFXs, these markers are nonspecific and noncontributory in the diagnosis of AFX. MIB-1 and Ki-67 are useful markers in this highly proliferative tumor (Fig. 125-3D). CD74 expression has been suggested to represent a marker of more aggressive behavior in this tumor. By definition, AFXs are consistently negative for various low- and high-molecular-weight cytokeratins, S100 and desmin. Reactive S100+ dendritic cells are frequently seen dispersed among the lesional cells.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT

The growth pattern of AFX has a propensity of local invasion beyond the obviously involved skin, there by inflicting the risk of local recurrence after surgical excision. In the literature, the recurrence rate of AFX is estimated to be 5%. Large case series from the 1960s and 1970s showed recurrence rates ranging from 2% to 21%, whereas more recently reported recurrence rates, particular if micrographic controlled surgery

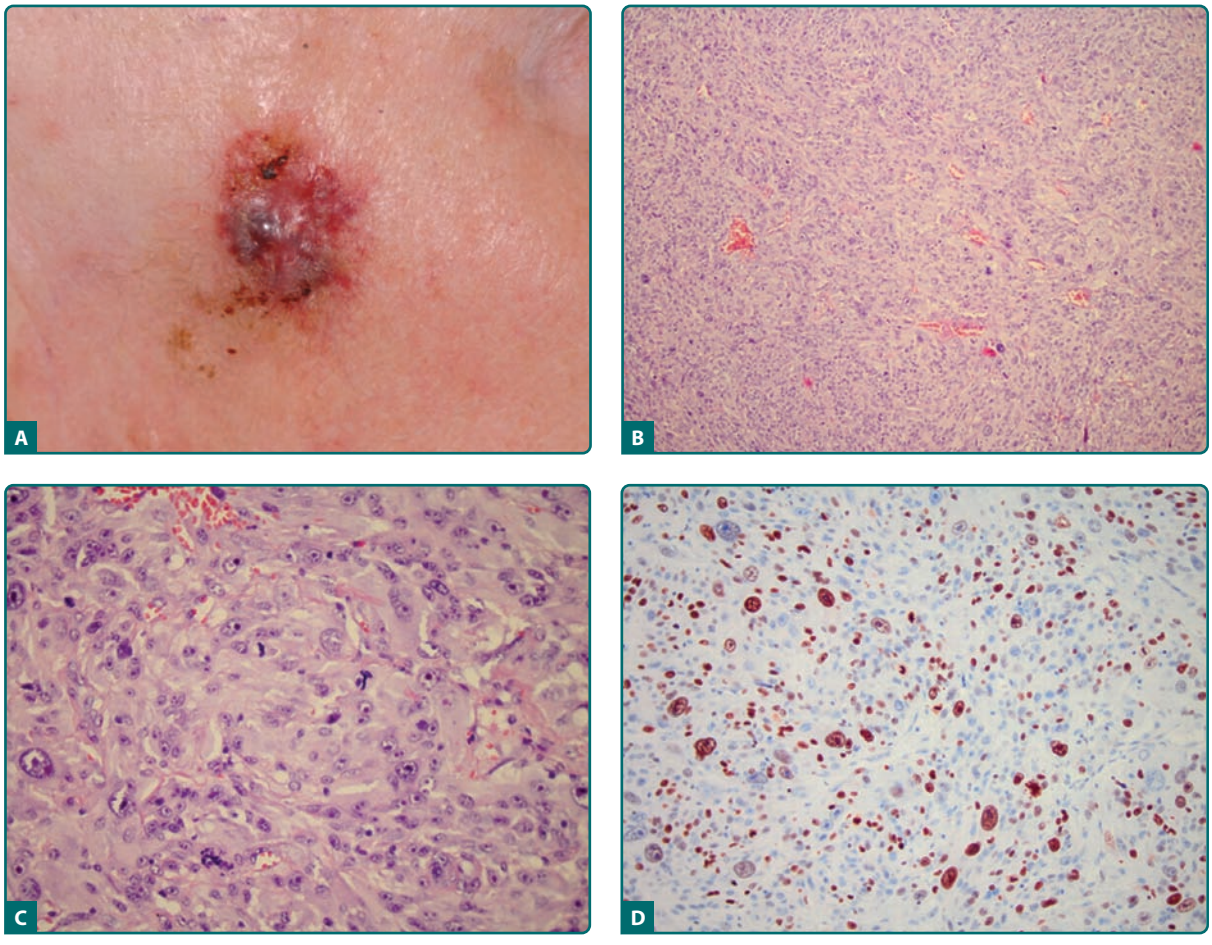

Figure 125-3 **A.** Atypical fibroxanthoma (AFX) presenting as a flat, ulcerated tumor on the temple of an elderly man. **B** and **C.** AFX showing atypical plump spindle cells and multinucleated giant cells. **D.** Tumor cells are characterized by a high proliferative rate revealed by MIB1 expression. Magnification: **B**, 10×; **C** and **D**, 20×.

(Mohs micrographic surgery) is used, are much lower. Thus, recurrent tumors may be better regarded as residual tumors.

AFX is a neoplasm with extremely low metastatic potential. In the largest case series reported to date by Ang et al, 3 out of 89 patients developed loco-regional or systemic metastases.[6] In 2005, Cooper et al described five cases of what they termed "metastasizing atypical fibroxanthoma"[8]; in their comprehensive review of the literature they identified additional 16 published cases of metastasized AFX since 1961. Thus, with respect to the management of patients, it is important to recognize that any tumor diagnosed as AFX has the potential for regional or even distant spread, whether it is an aggressive form of AFX or histologically misinterpreted as AFX instead of SCC. AFX is often found in the setting of diffuse actinic damage and other nonmelanoma skin cancer, so close follow-up after complete tumor exstirpation is prudent.

Treatment of AFX is surgical. Studies have suggested that Mohs micrographic surgery provides a lower rate of recurrence than wide local excision. Mohs micrographic surgery was found to be tissue sparing. Notably, even for larger tumors, the margins needed in Mohs micrographic surgery to clear the tumor effectively were smaller than that needed in wide local excision. In the series of 91 patients reported by Ang et al analysis of the Mohs micrographic surgery margins showed that in cases in which Mohs micrographic surgery cannot be employed a 2-cm margin is needed to ensure clearance of 96.6% of tumors by wide local excision. Excision should be to the level of the deep subcutaneous tissue.

In addition, follow-up examinations including inspection and palpation of the surgical site and the regional lymph nodes, should be performed for at least 2 years, because this is the time during which nearly all of recurrences reported in the literature occurred.

MYXOFIBROSARCOMA

EPIDEMIOLOGY

MFS represents a spectrum of malignant myxoid tumors of fibroblastic origin that exhibit a range of clinical and histopathologic features. For many years, this entity was generally known as myxoid MFH. However, several studies showed that MFS has reproducible cytoarchitectural features and consistent clinicopathologic characteristics and, therefore, these

tumors appear to constitute a defined entity and are better referred to as MFS.[1]

MFS is the most common malignant mesenchymal neoplasm of the extremities/limb girdles of older adults.[9] It shows marked predilection for subcutaneous tissue of the limbs and limb girdles; approximately more than two thirds of cases develop within the dermis or subcutis. MFS has no significant gender predilection and tend to affect patients in their sixth to eighth decades. However, the overall age range is wide, and cases in teenagers have been reported.

ETIOLOGY AND PATHOGENESIS

Cytogenetics demonstrated variable complex chromosomal abnormalities with translocations, for example, t(2;15)(p23;q21.2) or t(13;17)(q10;q10), or ring chromosomes as a consistent feature. To date, the constituents of these chromosomes remain unknown. Thus, there seems to be a number of different chromosomal alterations that contribute to the histogenesis of MFS.

CLINICAL FINDINGS

MFS is most frequently encountered on the extremities and limb girdles, but may also arise within the head and neck region, the trunk, hands, and feet. A gradually enlarging painless dermal or subcutaneous mass is the most frequent clinical presentation. The tumors are usually attached to a tendon or muscle but may also be superficially localized, presenting as multiple adherent cutaneous nodules, often with satellites. The most common clinical differential diagnosis is a benign dermal neoplasm such as lipoma, neurofibroma, or follicular cysts.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

MFS typically presents as a multinodular tumor characterized by variable amounts of hyaluronic acid-rich myxoid stroma, delicate blood vessels, and spindle-shaped or stellate fibroblasts. MFS exhibits a remarkably broad spectrum of histopathologic features ranging from banal to high grade. MFS grading is somewhat controversial and can be performed using a 3- or 4-tier grading system, which will grade these tumors in high, intermediate, and low-grade, or grades I to IV, respectively.[10] Both systems are based on the extent of the cellular components, nuclear pleomorphism, mitotic rate, and presence or absence of necrosis.

Low-grade MFS are hypocellular tumors comprised of relatively uniformly appearing spindle or stellate cells dispersed within a myxoid matrix; while nuclear pleomorphism and hyperchromasia may be present, mitotic figures and other overtly malignant features are absent. With increasing histological grade, MFS displays increasing cellularity, nuclear atypia, and mitotic activity. High-grade MFS is characterized by hypercellularity, marked nuclear atypia, hemorrhage and necrosis, and a high mitotic rate. It should be noted, however, that superficial portions of MFS tend to be morphologically low grade, regardless of the grade seen within the remainder of the tumor. Moreover, irrespective of the grade of MFS, the periphery is usually poorly defined, with finger-like extensions that account for satellites and a high recurrence rate.

At present, no single reliable IHC marker has been detected to confirm the diagnosis of MFS. The characteristic tumor cells in myxoid areas stain positively for vimentin, but are generally negative for CD68 or Factor XIIIa.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT

The primary therapy for MFS is complete local surgical resection. Wide and deep local excision is required. The first excision offers the best chance for cure. Three-centimeter margins are usually suggested, but the deep extensions are hard to identify, even when one excises to the fascia; particularly as MFS is deceptively infiltrative, making clinical assessment of margins difficult. Thus, MFS has a high rate of local recurrence of almost 50%. The potential of MFS to recur and to spread seems to be related to the anatomic depth of the primary tumor and histologic grade; however, even histological bland lesions carry a significant risk of recurrence. Importantly, recurrent low-grade lesions may undergo progression to more malignant histopathology and this transition may be accompanied by increasing metastatic potential. Metastasis occurs in a significant number of high-grade tumors with an overall risk of approximately 20%–25%.[10] Lung and bone are the most common metastatic sites, but spread to regional lymph nodes may also occur. The overall 5-year survival rate is 60%–70%.

UNDIFFERENTIATED PLEOMORPHIC SARCOMA

EPIDEMIOLOGY

In the past, MFH has been considered to be the most common malignant soft-tissue tumor, with pleomorphic MFH being the prevalent subtype. However, the availability of more advanced techniques revealed markers of residual differentiation for the majority of these tumors; thus, MFH is not a distinct entity but rather a common histopathologic endpoint for several high-grade undifferentiated sarcomas and only such tumors that cannot be further subtyped, i.e., the pleomorphic MFH in the narrower sense, should be described as UPS[1]; notably, these very rare tumors are almost never cutaneous lesions.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of soft-tissue sarcomas in general and UPS, in particular, has not been well defined. Depending

on the cells of origin, various genetic, physical, chemical, and viral etiologies have been suggested.

UPS may arise as a result of arrested maturation of tissue stem cells along the recently proposed differentiation spectrum from the fibroblastic mesenchymal stem-like cell to the fibroblast-myofibroblast-pericyte. It is possible that residual tumor stem cells that persist after treatment could have a role in progression or relapse, with implications for new therapeutic strategies.

CLINICAL FINDINGS

UPS is almost never a cutaneous tumor. The skin may be involved as a result of direct extension or metastasis. About 15% of UPS cases are found in the subcutaneous tissue, the remaining majority of cases arise from the deeper soft tissues.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

The most common appearance of tumor cells in UPS is that of spindle cells in a storiform pattern. The stroma may be finely fibrillary, myxoid, or densely collagenous. Bizarre epithelioid and giant cells may be present and may contain small amounts of lipid. Many mitotic figures, bizarre giant cells, and necroses are common. Ultrastructurally, the neoplastic cells have features consistent with fibroblastic, myofibroblastic, and histiocytic differentiation.

IHC using a broad antibody panel is required to rule out metastatic carcinoma, lymphoma, pleomorphic rhabdomyosarcoma, pleomorphic liposarcoma, high-grade leiomyosarcoma, defifferentiated liposarcoma, melanoma, and similar lesions. UPS is characterized by negative immunostains for EMA, cytokeratins, CD34, SMA, desmin, and HMB45. Among stem cell markers, CD117 and occasionally nestin may be expressed.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT

Up to 50% of patients presenting with an UPS may have distant metastases (lung most likely). UPS should be treated in analogy to other poorly differentiated sarcomas. When the disease appears localized, treatment is based on the prognosis. In general, small low-grade tumors with wide pathologically negative margins can be treated with surgery alone. Large or high-grade lesions may benefit from radiotherapy with a reduction in the incidence of local recurrence but with no benefit in overall survival (OS). Chemotherapy may be used before surgery to try to shrink the lesion, and after surgery to try to prevent its recurrence.

Although with rare exceptions metastatic UPS is incurable, substantial benefit can be derived from the appropriate use of chemotherapy or local control measures including surgery, radiotherapy, and other interventional techniques.

EPITHELIOID SARCOMA

EPIDEMIOLOGY

ES is a relatively rare soft-tissue sarcoma of unknown histogenesis accounting for <1% of all soft-tissue sarcomas. ES is a slow-growing tumor with a seemingly benign pathomorphologic appearance due to which it is often misdiagnosed. The tumor may develop at any age with a peak in young adults and more frequently in males. A higher than usual proportion (i.e., one-fourth) of cases has been associated with prior trauma, including origin in scar tissue.

ETIOLOGY AND PATHOGENESIS

The etiology and histogenesis of ES is obscure; in the current World Health Organization classification, ES is categorized as a tumor of uncertain differentiation and described as being of unknown lineage. The reported histomorphology and immunophenotype, however, suggest a mesenchymal neoplasm with multidirectional differentiation, including epithelial, histiocytic, fibroblastic, myofibroblastic, endothelial, and perineural differentiation.

There are no consistent or specific cytogenetic findings in ES. Some tumors are diploid and others polyploid. Abnormalities involving 18q11 and 22q11 (including 22q deletions) have been observed. Furthermore, chromosomal rearrangements t(8;22)(q22;q11) in classic ES and t(10;22) in two cases of proximal ES have been described. Additionally, inactivation of a tumor-suppressor gene *Smarcb1*, located at band 22q11, has been found in a subgroup of ES, i.e., the proximal type. Inactivating mutations in the *Smarcb1* gene are a hallmark of rhabdoid tumors, i.e., especially lethal cancers that predominantly strike young children. SMARCB1 was the first member of an ATPase chromatin-remodeling complex to be implicated in the genesis of cancer. SMARCB1 loss causes cell-cycle progression in part via downregulation of $p16^{INK4a}$ and upregulation of E2F and Cyclin D. Heterozygous *Smarcb1* knockout mice are born at the expected frequency and appear normal, but are predisposed to cancer with approximately 20% developing sarcomas at a median age of 12 months.

CLINICAL FINDINGS

Clinically, ES usually presents as a painless, slow-growing, firm tumor. While most tumors are situated in the subcutaneous fat and fascia, some may arise in the dermis.[11] When the skin is involved, one or more slowly growing nodules are seen, often accompanied by superficial ulceration, hemorrhage, necrosis, and plaques. Ulcerating ES lesions have raised margins and are nonhealing (Fig. 125-4). Deeper ES lesions can extend along tendon sheaths or aponeuroses. In any case the tumor may grow to a large size, up to 20 cm in diameter. The usual presentation is with symptoms of an infiltrative mass. Often, there is a delay in diagnosis

Figure 125-4 Epithelioid sarcoma typically occurring over the wrist. Note ulceration and granuloma-like border.

due to the rare nature of this tumor and the resemblance to more common inflammatory skin lesions, such as granuloma anulare (Box 125-1).

ES can be differentiated by histology into two subtypes: classical and proximal ES (see below for details). Classic ES usually involves the extremities of young adults most often localized on the hands and fingers; whereas the proximal subtype occurs mainly in axial or proximal regions, including limb girdles, pelvis, perineum, or genitalia, mediastinum, and trunk. However, the classic and proximal types can each occur in either proximal or distal locations.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

The histopathological diagnosis of ES can be quite difficult, as a superficial biopsy may only show necrobiosis or granulomatous inflammation, thereby mimicking infectious processes or granuloma anulare.

The tumor forms nodules composed of relatively uniform polygonal cells, often with loss of cohesion, which merge in the periphery into spindle cells without demarcation. The cells have relatively abundant deeply eosinophilic cytoplasm; mitotic figures are rare and only minimal pleomorphism is evident. Stromal changes include desmoplasia with cords of bland spindle cells sometimes with storiform pattern. The nodules frequently have central necrosis; hemorrhage is frequently observed.[11]

The proximal variant is characterized by marked cytologic atypia, frequent mitosis, vascular invasion, and absence of a granulomatous appearance. The tumor cells are large epithelioid and may mimic a carcinoma, furthermore, cells with a rhabdoid morphology can be seen. Rarely, tumors have features of both the classic and proximal variants. Notably, both variants can each occur in either proximal or distal locations.

Although there are several reported immunohistochemical studies on ES, a specific tumor marker for the diagnosis of this tumor has not yet been established. Most cases coexpress cytokeratins (particularly CK8, 14, and 19), EMA, and vimentin, but a few cases are vimentin-negative. CD34 staining is positive in more than half of ES; other endothelial markers such as CD31, however, are usually negative. SMA and neurofilament are often positive, especially in the spindle cells. Most cases are negative for S100. Recently, loss of INI-1 expression has been proposed to be of diagnostic benefit.[12]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT

Because the classic location of ES on distal extremities often discourages early deep biopsy, and because ES may closely mimic various nonneoplastic lesions histologically such as granuloma anulare, it often evades diagnosis at an early, localized stage.

ES is an aggressive neoplasm, and the rate of local recurrence is very high, often with successive lesions appearing more proximally; distant metastases of ES are frequent. In the large series of Chase and Enzinger assessing 202 cases with follow-up, 77% recurred, and 45% metastasized, predominantly to the lungs (51%), local lymph nodes (34%), skin, bone, brain, liver, and pleura. Metastases developed in 36% of patients without local recurrence.[11] The median OS of about 7 years for patients with localized disease, but only just months for patients with distant metastases. Adverse prognostic factors include proximal subtype, amount of necrosis and vascular invasion, and inadequate excision. Favorable factors are young age at first diagnosis, female sex, and small size of tumor.

Radical excision traditionally with clear margins has been the treatment of choice, but recurrences occur even with amputation. Conservative (limb-sparing) surgery combined with preoperative or postoperative radiation therapy has been tried, with results comparable with those reported for radical amputation.

For metastatic disease systemic chemotherapy is indicated. Of the chemotherapeutic agents that have been used to treat ES, the two currently most often used are doxorubicin and ifosfamide; the use of gemcitabine is also increasing. These drugs alone or in combinations were shown to elicit limited but distinct response rates ranging from <10% to >30%.

Chapter 126 :: Vascular Tumors

:: Erin F. Mathes & Ilona J. Frieden

Vascular anomalies are common birthmarks.[1] Their classification has often been problematic, with contradictory and confusing descriptive nomenclature. A classification system first proposed by Mulliken and Glowacki was revised in 1996 by the International Society for the Study of Vascular Anomalies based on clinical, radiologic, and hemodynamic characteristics, into vascular malformations and vascular tumors.[2] Vascular malformations (see Chapter 172) are errors of morphogenesis whereas hemangiomas and other vascular tumors grow by cellular proliferation.

There are several types of vascular tumors, many of which occur in childhood. These tumors have also had confusing nosology,[3] with descriptive but imprecise terminology such as *strawberry*, *capillary*, and *cavernous*. Several types of hemangiomas have been described (infantile, rapidly involuting congenital, lobular capillary, etc.), so whenever possible, *hemangioma* should not be used as a stand-alone noun but rather qualified by an adjective based on the specific condition.

INFANTILE HEMANGIOMAS

INFANTILE HEMANGIOMAS AT A GLANCE

- Infantile hemangiomas are the most common tumor of infancy.
- Hemangiomas in high-risk anatomic sites are likely to require further work-up and, often, intervention.
- Segmental hemangiomas have a greater risk for morbidity than localized hemangiomas.
- Kasabach-Merritt syndrome is not due to infantile hemangioma.

EPIDEMIOLOGY

Infantile hemangiomas (IH) are the most common benign tumors of childhood, occurring in approximately 4% of children by 1 year of age.[4,5] In contrast to other types of hemangiomas and vascular malformations, IH have a characteristic proliferative phase followed by a slower involution phase. They are more common in females (2–5:1 ratio) and in premature infants, especially those weighing less than 2,500 g.[6,7] Other risk factors are Caucasian race, multiple gestation pregnancy, and maternal age greater than 30 years. Preterm infants are more likely to have multiple tumors, and the sex ratio is less skewed toward females.[8] Contrary to prior observations, newer prospective studies do not support chorionic villus sampling as a risk factor.[7,8]

ETIOLOGY AND PATHOGENESIS

IH are primarily composed of endothelial cells but also contain fibroblasts, pericytes, interstitial cells, and mast cells. Although the precise pathophysiologic mechanisms of the growth and involution of endothelial cells remains unknown, several recent discoveries have advanced our understanding of IH.[9–13] The patterns found in segmental hemangiomas suggest at least some hemangiomas occur via developmental error as early as 4–6 weeks of gestation.[14] IH only occur in humans, and adequate animal or laboratory models have been difficult to develop.

The recognition that a glucose transporter protein, GLUT1, is expressed in all stages of hemangioma maturation spurred new hypotheses on the pathogenesis of IH.[15,16] GLUT1 expression in absent in the normal cutaneous vasculature but is found in placental blood vessels as well as in other so-called barrier tissues such as the blood–brain barrier. This, together with other immunohistochemical markers shared by IH and human placenta (FcγRII, merosin, and LeY), and the similar gene expression profiles found on DNA-based microarrays led to speculation that these tumors are of placental origin from either embolized placental cells or invading angioblasts that have differentiated toward a placental phenotype.[16,17] IH lack a villous architecture and do not express known placental trophoblastic markers suggesting that they are not placental emboli.[18] In addition, a recent study determined that hemangioma endothelial cells are of fetal, not maternal origin.[19] Further investigations into the cellular origin of hemangioma endothelial cells have demonstrated that these cells have features of immature mesenchymal cells. They have features similar to an early embryologic vessel, the cardinal vein[20] and express CD133, a primitive cell marker, during proliferation.[21,22] Implantation into immunodeficient mice of $CD133^+$ cells isolated from IH gives rise to $GLUT1^+$ vessels that later diminish and are replaced by adipocytes.[23] While not a perfect replica of IH growth, this model merits attention and additional study.

Additionally, while previous work suggested that IH arise because of aberrations in angiogenesis, recent investigations show that IH are *not* simply cutaneous capillaries with excessive growth, but more likely represent de novo vasculogenesis in the skin and other sites. Alterations in pathways that negatively control vascular endothelial growth factor receptor 2 (VEGFR2) signaling in vascular endothelial cells appear to play an important role in IH development and their rapid growth. In some patients germline mutations in VEGFR2 or tumor

endothelial marker 8 (TEM8) lead to these signaling abnormalities.[24,25] In vitro studies indicate that hypoxia and estrogen synergistically enhance hemangioma proliferation.[21] Some studies have demonstrated evidence of clonality in hemangiomas, but further research is needed to demonstrate whether these tumors, particularly when in segmental patterns, are truly clonal.[26,27]

CLINICAL FINDINGS

HISTORY. The clinical history is one of the most important keys to diagnosing an IH (Box 126-1).[28] Absence at birth or presence as a premonitory mark, usually an area of pallor, telangiectasias, or duskiness is characteristic, whereas a fully formed soft-tissue mass at the time of birth is most likely not an IH, but another vascular anomaly or other disease process.

BOX 126-1 HISTORY

- Birth history
  - Was the child premature?
  - Part of a multiple gestational birth?
  - Complications during the pregnancy or delivery?
- Overall health and past medical history
  - Is the child feeding well and gaining weight appropriately?
  - Have there been any hospitalizations or major illnesses?
- History of "birthmark"
  - Was it visible at the time of birth?
  - Has it changed since birth?
  - Growth: Is it growing proportionately or disproportionately with child's somatic growth? Is it still growing, stable, or shrinking in size? (Serial photographs are often helpful.)
  - Any complications such as pain, bleeding, or ulceration?
  - Any prior treatments?
- Family history
  - Is there a family history of hemangiomas or other vascular birthmarks?

CUTANEOUS LESIONS

Growth Characteristics. Though IH are not present at birth as fully formed tumors, superficial IH almost always become apparent within the first month of life. The period of most rapid growth typically occurs within the first 5 months of life, with 80% of growth being completed by 5 months of age.[29] Deep hemangiomas may be noted at a somewhat later age, on average 1 month later than superficial IH and uncommonly are not appreciated until a few months of life. Large, segmental, deep, and parotid gland hemangiomas may continue to enlarge slowly for months to years longer.[30] This growth phase is followed by a slower involution phase which is more variable in length, lasting for months to years (Fig. 126-1). Evidence of involution (change to a dull red, then gray or milky-white color, followed by flattening and softening) is usually apparent by 1 year of age.[29] Smaller hemangiomas typically involute sooner than very large ones, but there are exceptions. Most IH complete their course by the age of 7–10 years. Some children have normal skin after involution whereas the remainder has telangiectasias, atrophy, fibrofatty residuum, or scarring.

Figure 126-1 Natural history of segmental infantile hemangioma. Note the plaque-like, geographic configuration. **A.** Age 11 months, peak of proliferating phase. **B.** Age 2 years, involuting phase, apoptosis is maximal. **C.** Age 4 years, some further involution expected.

Figure 126-2 Localized infantile hemangioma, cheek of an infant.

Figure 126-3 Indeterminate infantile hemangioma, cheek, age 14 months.

Classification.[14] Hemangiomas which involve the upper dermis (so-called *superficial hemangiomas*) have a bright strawberry red color; whereas those with deep dermal and subcutaneous location are skin color to blue in color. Those involving both superficial and deeper skin structures, so-called *mixed* hemangiomas, have both features. In addition to this clinical appearance, IH can be classified as localized, segmental, or indeterminate.[31,32] Localized hemangiomas exhibit clear spatial containment as if arising from one central focus (Fig. 126-2). Segmental hemangiomas (similar to other segmental dermatologic disease such as vitiligo and neurofibromatosis) correspond to a portion of a developmental segment or broad anatomic territory (Fig. 126-3).[33] They are often plaque-like in nature with a linear or geographic configuration. Those hemangiomas not clearly identifiable as localized or segmental are termed *indeterminate* (see Fig. 126-3). The patterns of facial segmental IH have been found to correspond to neural-crest-derived facial prominences, and a new map for them has recently been proposed.[14] Multifocal hemangiomas are usually multiple localized hemangiomas. Though the exact number is somewhat arbitrary, the presence of more than five hemangiomas confers a risk of extracutaneous hemangiomas.

Classification of hemangiomas by subtype not only facilitates communication but also helps predict risk of complications and need for treatment. A prospective study of 1,058 children with IH showed that segmental hemangiomas are 11 times more likely to experience complications and eight times more likely to receive treatment than localized hemangiomas even when controlled for size.[34]

Atypical Presentations. Atypical presentations of IH include deep hemangiomas and those with minimal to no proliferation. Deep IH proliferate in the lower dermis and subcutaneous tissue without penetration of the papillary dermis (Fig. 126-4). They present as a localized, firm, rubbery subcutaneous mass that can be slightly raised with a bluish color or with telangiectasias involving the overlying skin, or they may be deep enough that the overlying skin is completely flat and of normal hue. If there is involvement of the papillary dermis, the cutaneous surface is often bright red and thus classified as a superficial and deep IH. IH with minimal to absent proliferation often have fine telangiectasias with a minimal to absent proliferative component thus resembling persistent premonitory IH (Fig. 126-5). They have recently been shown to be GLUT-1 positive indicating that they are indeed IH, but for unknown reasons, have not had a rapid proliferative phase. For unknown reasons, they are more common in the lower body.[35,36]

Medical and Extracutaneous Risks. Certain hemangiomas have known associated risks. Anatomic location is one of the most important factors affecting risk. Hemangiomas involving the central face (including the nose and perioral skin), periocular area, neck, mandibular region, and perineum should alert clinicians to possible increased risk of complications. In addition, the presence of multiple or segmental hemangiomas is associated with greater risk of extracutaneous disease.[28]

PHACE. Facial segmental IH are associated with PHACE (Online Mendelian Inheritance in Man #606519), a neurocutaneous syndrome that consists of the following features: posterior fossa brain malformations, segmental cervicofacial hemangioma, arterial anomalies, cardiac defects or coarctation of the aorta, eye anomalies, and sternal defects, such as sternal clefting or supraumbilical raphe.[37] A recent workshop reviewed knowledge about PHACE and consensus criteria for

Figure 126-4 Natural history of a deep infantile hemangioma, right cheek/parotid. **A.** Age 1 year, peak of proliferation. **B.** Age 3 years, involuting phase.

diagnosis have been proposed (see Table 126-1).[38,39] Up to one third of patients with large facial hemangiomas will be found to have PHACE when studied thoroughly.[38] While initial reports emphasized structural brain abnormalities, particularly Dandy–Walker malformation, recent reports have found that arterial anomalies of the head and neck are more common than structural brain abnormalities.[37–40] These intracranial arterial defects can lead to a Moyamoya phenomenon, ischemia, and stroke.[41,42] Other complications including seizure disorders and developmental delay are sometimes present in the setting of these CNS abnormalities.[40] The most common cardiac anomaly is coarctation of the aorta, most often involving the transverse aorta. Brain imaging [magnetic resonance imaging (MRI) and magnetic resonance angiography] should

Figure 126-5 Telangiectatic infantile hemangioma, left foot. This lesion could be confused with a port-wine stain. **A.** Reticulated stain and minor soft-tissue hypertrophy. **B.** Age 11 years, only fine telangiectasias remain (involuted phase).

TABLE 126-1
Diagnostic Criteria: PHACE Syndrome[38]

PHACE Syndrome		
Facial hemangioma >5 cm in diameter PLUS 1 major criterion OR 2 minor criteria		
Possible PHACE Syndrome		
Facial hemangioma >5 cm in diameter PLUS 1 minor criterion	Hemangioma of the neck or upper torso PLUS 1 major criterion OR 2 minor criteria	No hemangioma PLUS 2 major criteria
Organ System	**Major Criteria**	**Minor Criteria**
Cerebrovascular	Anomaly of major cerebral arteries Dysplasia[a] of the large cerebral arteries[b] Arterial stenosis or occlusion with or without moyamoya collaterals Absence or moderate to severe hypoplasia of the large cerebral arteries Aberrant origin or course of the large cerebral arteries[b] Persistent trigeminal artery Saccular aneurysms of any cerebral arteries	Persistent embryonic artery other than trigeminal artery Proatlantal intersegmental artery (types 1 and 2) Primitive hypoglossal artery Primitive otic artery
Structural brain	Posterior fossa anomaly Dandy-Walker complex or unilateral/bilateral cerebellar hypoplasia/dysplasia	Enhancing extra-axial lesion with features consistent with intracranial hemangioma Midline anomaly[c] Neuronal migration disorder[d]
Cardiovascular	Aortic arch anomaly Coarctation of aorta dysplasia[a] Aneurysm	Ventricular septal defect Right aortic arch (double aortic arch) Aberrant origin of the subclavian artery with or without a vascular ring
Ocular	Posterior segment abnormality Persistent fetal vasculature (persistent hyperplastic primary vitreous) Retinal vascular anomalies Morning glory disc anomaly optic nerve hypoplasia Peripapillary staphyloma Coloboma	Anterior segment abnormality Sclerocornea Cataract Coloboma Microphthalmia
Ventral or midline	Sternal defect Sternal cleft Supraumbilical raphe Sternal defects	Hypopituitarism Ectopic thyroid

[a]Includes kinking, looping, tortuosity, and/or dolichoectasia.
[b]Internal carotid artery, middle cerebral artery, anterior cerebral artery, posterior cerebral artery, or vertebrobasilar system.
[c]Callosal agenesis or dysgenesis, septum pellucidum agenesis, pituitary malformation, or pituitary ectopia.
[d]Polymicrogyria, cortical dysplasia, or gray matter heterotopia.

be considered in all infants with a large segmental hemangioma of the face.[43] In addition, formal ophthalmologic examination and echocardiogram may be performed, given the relative frequency of anomalies in these sites. Periodic developmental and neurologic assessments should be performed.

Periocular Hemangiomas. Infants with periocular hemangiomas are at risk for anisometropia and amblyopia, which if untreated, can lead to permanent visual loss (Fig. 126-6).[44,45] Direct pressure on the cornea can produce astigmatism or myopia, and the mass effect of the tumor itself can cause ptosis, proptosis, visual axis occlusion, or strabismus. Any patient with a hemangioma in the periocular area should have a prompt formal ophthalmologic evaluation with repeat visits during the proliferative phase (typically the first 3–4 months of life). Imaging studies may be needed to assess whether retrobulbar involvement is present.

"Beard Area" Hemangiomas. Segmental hemangiomas involving the preauricular, mandibular, chin, and neck skin (or so-called *beard area*) have a 60% risk of having symptomatic airway disease.[46] Airway hemangiomas often present with the insidious onset of

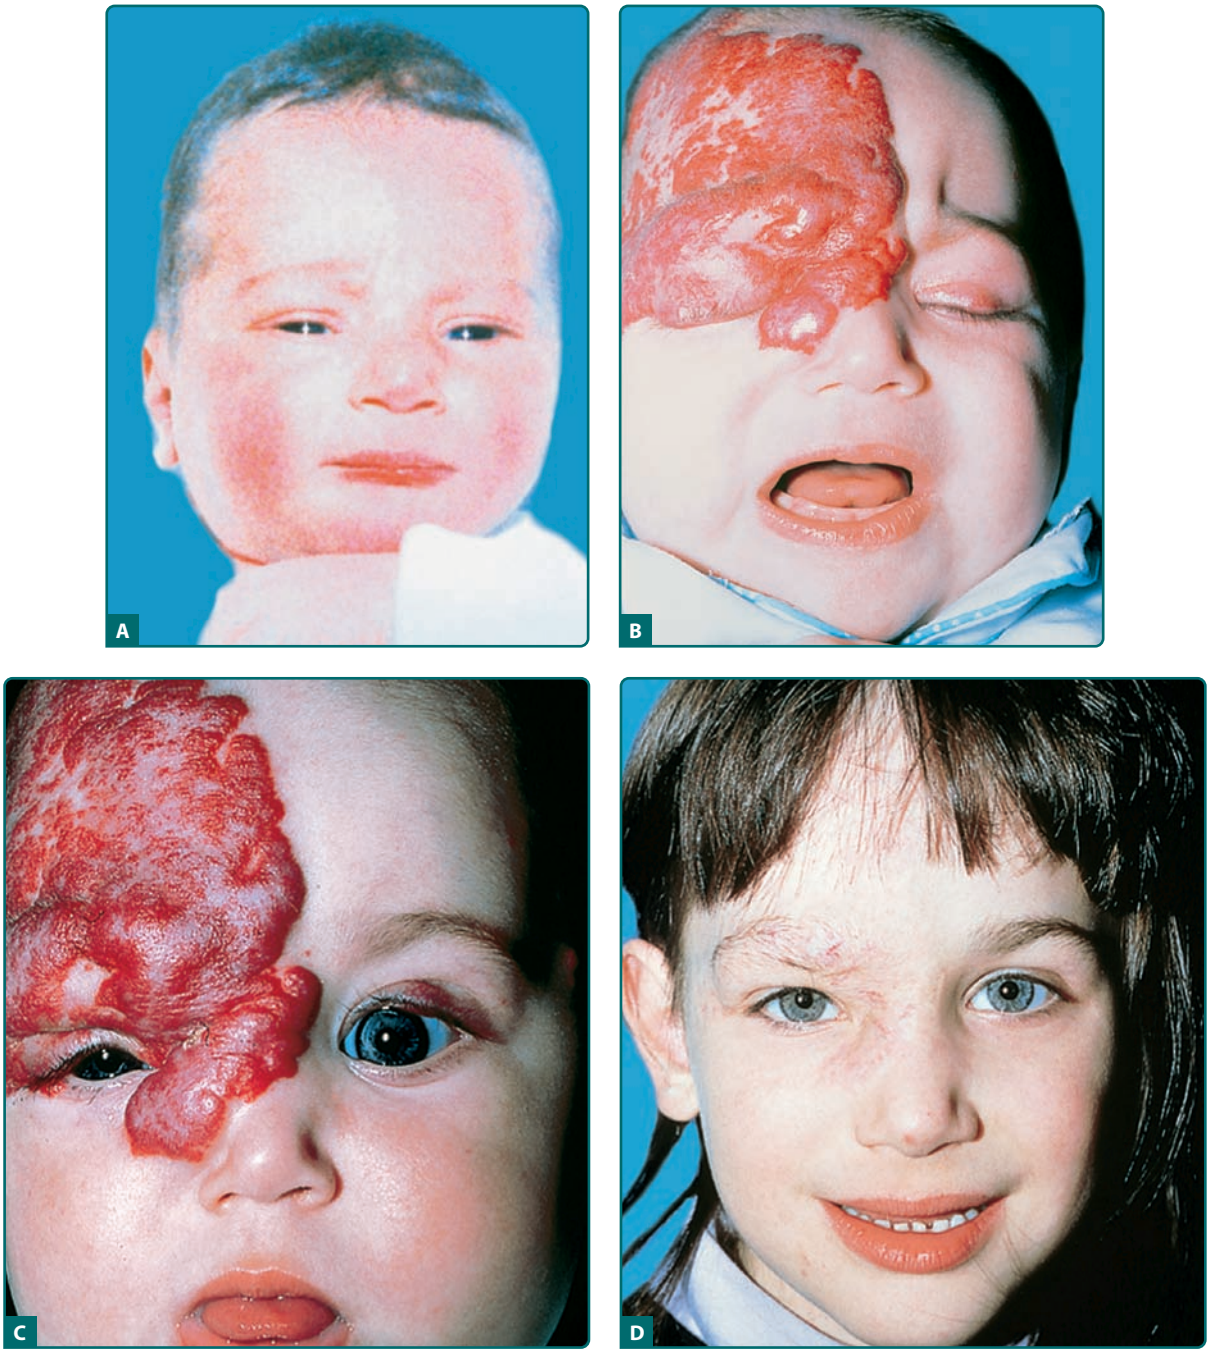

Figure 126-6 Vision-endangering segmental infantile hemangioma treated with systemic glucocorticoids. **A.** No premonitory signs of tumor seen on infant's photograph. **B.** By age 3 months, extensive infantile hemangioma infiltrating the upper lid and surrounding tissue, causing blocked vision. **C.** Eyelid opened within 2 weeks of glucocorticoid therapy. **D.** Involuted tumor, age 6 years.

biphasic stridor between weeks 4 and 12 of life and are often mistakenly diagnosed as tracheomalacia, upper respiratory infection, or croup. If the hemangioma continues to enlarge, respiratory distress can ensue and become life-threatening. Prompt evaluation by a pediatric otolaryngologist and treatment is essential.[47] Hemangiomas can also involve the parotid gland, and may require treatment due to massive growth, deformity of adjacent structures, and, in rare cases, high-output congestive heart failure.[48,49]

Lumbosacral and Perineal Hemangiomas. Segmental hemangiomas overlying the lumbosacral or perineal area can have associated spinal, bony, and genitourinary anomalies. Two acronyms have been proposed for this constellation of findings: PELVIS syndrome for perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag, and SACRAL syndrome, denoting spinal dysraphism, anogenital anomalies, cutaneous anomalies, renal and

Figure 126-7 Multifocal infantile hemangiomas in a 6-month-old infant. There are multiple, dome-shaped, erythematous papules on the left arm, flank, and back.

urologic anomalies, associated with angioma of lumbosacral localization.[50,51] Segmental hemangiomas overlying the lumbosacral spine have a significant risk of spinal dysraphism and tethered spinal cord. MRI is strongly recommended in this setting.[52] Other evaluations such as renal ultrasound should be based on clinical findings.

Multifocal Hemangiomas. Approximately 15% of infants will have more than one hemangioma, and premature infants have an even higher risk of multiple lesions (Fig. 126-7). In rare cases, infants can have hundreds of lesions. Until Glut-1 staining was recognized as a specific marker for IH, many infants with multifocal vascular tumors and extracutaneous disease were described as having *diffuse neonatal hemangiomatosis.* Many of these infants however actually have other vascular tumors. Infants with 5 or more IH are known to have an increased risk of having hepatic hemangiomas. Other sites of visceral involvement are exceeding rare in true IH. Visceral hemangiomas including those affecting the liver, gastrointestinal tract, and brain, have also been reported with solitary segmental hemangiomas.[53]

Hepatic Hemangiomas. The liver is the most common extracutaneous site of IH, Infants with >5 IH should be evaluated for the possibility of liver hemangiomas with liver ultrasound.[54] Even if present, hepatic hemangiomas are often asymptomatic, however a minority cause morbidity, and in rare cases are life threatening. A classification for liver hemangiomas has been proposed by Christison-Lagay et al including three types of hepatic hemangiomas, two of which are true IH.[55] The most common type (the presence of a few or multifocal liver hemangiomas) is often asymptomatic but can cause high-output congestive heart failure. A much rarer condition where the liver is virtually replaced by hemangiomas is termed "diffuse" disease. This life-threatening condition can result in abdominal compartment syndrome and a severe form of hypothyroidism due to tumor-related deiodination of thyroid hormone (see Section "Laboratory Tests"). A third type of hepatic hemangioma, wherein large solitary vascular tumors are typically present at birth is associated with arteriovenous shunting. In most cases these are not true infantile hemangioma but more likely analogous to rapidly involuting congenital hemangioma (RICH) occurring in the liver.

When cardiac compromise or severe hypothyroidism is a complication of hepatic hemangioma, systemic intervention is necessary. Embolization may be helpful if high-output congestive heart failure is present.[56,57] Aggressive thyroid hormone replacement is needed in cases with hypothyroidism.[58] In life-threatening cases liver transplant may be considered as a therapeutic option.

LABORATORY TESTS

Thyroid Function Tests. Hypothyroidism is a rare complication in infants with massive hemangiomas of the liver.[59,60] First reported by Huang et al, hemangioma tissue demonstrates high levels of type 3 iodothyronine deiodinase activity, which accelerates the degradation of thyroid hormone.[58,61] Infants with significant hepatic hemangiomas should have thyroid function evaluated, including T3 (the hormone consumed) and thyroid-stimulating hormone, because T4 levels may initially remain normal. Conversely, screening liver ultrasound looking for hemangiomas should be performed in infants with hypothyroidism of unknown etiology even in the absence of cutaneous hemangiomas. Hypothyroidism and other endocrine abnormalities have also been reported with PHACE syndrome. Infants with PHACE syndrome, large cutaneous hemangiomas, or extensive hepatic haemangiomas should have thyroid function [specifically thyroid-stimulating hormone, triiodothyronine (T3), and thyroxine (T4)] checked routinely.[62]

Platelet Studies. Platelet studies are not indicated in IH as the Kasabach-Merritt phenomenon (KMP) is not associated with IH but rather with kaposiform hemangioendothelioma (KHE) and tufted angioma (TA) (see Section "Pharmacologic Therapy").

Recommended tests and imaging studies are included in Section "Cutaneous Lesions" with discussion on specific IH and their related physical findings.

COMPLICATIONS

Ulceration is the most common complication of IH, occurring in approximately 15% of patients usually during the proliferative phase with a median age of onset of 4 months.[63] It occurs most frequently with segmental IH and at sites that are exposed to moisture and friction such as the perioral, perianal, and other intertriginous sites.[64] Secondary infection can occur but its frequency is debatable. Cultures usually show polymicrobial growth and are likely the result of colonization.[65] Localized infection will often improve with the use of topical mupirocin or metronidazole. However, if deeper or persistent infection is suspected, systemic antibiotics should be prescribed.

Local wound care, barrier protection, and pain control are essential for treatment. Bio-occlusive dressings may be helpful but those intended to stick to the skin may be limited by location because they do not adhere well near orifices.[66,67] In these areas, thick applications of petrolatum-based ointments can be helpful. Pain can be a major issue in management. It can be minimized with an occlusive dressing, oral acetaminophen with or without codeine, and the use of very small amounts of topical lidocaine ointment no more than a few times a day.[64] Ulcerations generally heal with scarring within 2–3 weeks with topical care. For refractory cases, other treatment modalities including pulsed dye laser (PDL) or Becaplermin 0.01% gel, a synthetic platelet-derived growth factor, have anecdotally been reported to be effective.[68,69] Therapies aimed at halting hemangioma growth, such as intralesional and systemic steroids or excision, may be useful in some cases.

Other serious complications such as hypothyroidism, internal organ involvement, or vital structure compromise due to the location of IH in certain anatomic sites have been discussed in Section "Cutaneous Lesions."

PROGNOSIS AND CLINICAL COURSE

The prognosis of most IH is excellent, with spontaneous involution and little to no sequelae, but a significant minority of IH result in permanent disfigurement or medical sequelae. Certain characteristics are associated with an increased risk of complications and need for treatment (Table 126-2).[29,70] Consideration of early treatment should be given to hemangiomas with these characteristics, depending on the specific clinical setting.

TREATMENT

The decision to initiate treatment is based on many factors, including size and location, psychosocial implications, and risks and benefits of the proposed therapy. For the majority of small hemangiomas, close observation and follow up is the most appropriate approach. This does not mean doing nothing. The infant should be seen frequently, especially during the first few months (corresponding to the proliferative phase). During these visits, education about the natural course of IH and discussions about the psychosocial impact on the child and/or the family should occur.[71] Photographs of the likely outcome for a similar lesion are often helpful. Many parents experience anxiety and may find themselves subject to comments from complete strangers about their child's hemangioma.[72] Most parents of young children do not think their child is deeply affected by these reactions, but facial hemangiomas, in particular, can cause psychological suffering once the child reaches school age.[73,74] Potential treatment options should be discussed well ahead of entrance to elementary school.

If it is decided that treatment is necessary, options include pharmacologic, laser, or surgical interventions (see Table 126-3). However, management remains controversial with few double-blind controlled studies and no Food and Drug Administration-approved labeled indications for medical treatments.

PHARMACOLOGIC THERAPY

Corticosteroids. Until recently systemic corticosteroids were the first-line treatment for deforming, endangering, or life-threatening IH (see Fig. 126-6).[75] They work best during the growth phase, causing slowing or cessation of growth in up to 90% of cases, with actual shrinkage in approximately one third. Although the mechanism of action is not well understood, recent studies suggest the upregulation of mitochondrial cytochrome b, clusterin/ApoJ (possible apoptotic markers), and/or interleukin-6 as markers of corticosteroid-induced cessation of hemangioma growth.[76–78] Prednisone or prednisolone is given at a dose of 2–3 mg/kg/day, typically for 4–8 weeks

TABLE 126-2
Features of IHs with Highest Risk for Morbidity According to Anatomic Location and/or Morphology of the Hemangioma

Anatomic Location/Morphology	Associated Risk
Facial, large segmental	PHACE syndrome (posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects, eye abnormalities, sternal clefting)
Nasal tip, ear, large facial (especially with prominent dermal component)	Permanent scarring, disfigurement
Periorbital and retrobulbar	Ocular axis occlusion, astigmatism, amblyopia, tear-duct occlusion
Segmental "beard area," central neck	Airway hemangioma
Perioral	Ulceration, disfigurement, feeding difficulties
Segmental overlying lumbosacral spine	Tethered spinal cord, genitourinary anomalies
Perineal, axilla, neck, perioral	Ulceration
Multiple hemangiomas	Visceral involvement (especially liver, gastrointestinal tract)

TABLE 126-3
Major Side Effects of Common Infantile Hemangioma Treatments

Treatment	Major Side Effects
Systemic corticosteroids	Diminished gain of height and weight, cushingoid facies, personality changes, gastric irritation, hypertension, immunosuppression
Intralesional corticosteroids	Arterial embolization/injection, atrophy, systemic absorption
Topical corticosteroids	Local atrophy, systemic absorption
Propranolol	Hypotension, symptomatic bradycardia, hypoglycemia, agitation, sleep alteration, sweating, cold hands, wheezing
Interferon-α	Spastic diplegia (neurotoxicity), fever, hepatotoxicity, neutropenia, anemia
Vincristine	Central line placement, neuropathy, abdominal pain, constipation
Laser	Pain, scarring, hypopigmentation, textural change, ulceration
Surgery	General anesthesia, scarring

followed by a tapering of varying length, depending on the age of the child and indication for treatment. A meta-analysis showed an 84% response rate with an average dose of 2.9 mg/kg for a mean of 1.8 months before tapering. Although 3 mg/kg/day is more effective (94% response) than 2 mg/kg/day (75% response), greater adverse events are found with the higher dose.[79]

Short-term complications of systemic corticosteroids include: cushingoid faces (71%), personality changes (29%), gastric irritation (21%), fungal infection (oral or perineal, 6%), and diminished gain of height (35%) and weight (42%) during treatment. More than 90% of children with diminished gain of height return to their pretreatment growth curve by 24 months of age (Table 126-3).[80,81] Other complications include hypertension, steroid-induced myopathy, immunosuppression, and transient adrenal insufficiency.[81,82] Blood pressure should be monitored with each visit to the dermatologist or pediatrician.[83] Children taking more than 2 mg/kg/day of prednisone for longer than 14 days are considered to have a deficit in cell-mediated immunity. Live viral vaccinations should be deferred in infants receiving high-dose corticosteroids. Rare cases of *Pneumocystis carinii* pneumonia have been reported in this setting, leading some physicians to use trimethoprim-sulfamethoxazole prophylaxis during treatment.[84,85]

Intralesional corticosteroids can be an effective treatment for relatively small localized hemangiomas located in high-risk sites such as the lip, nasal tip, cheek, and ear. Injections for periocular hemangiomas are usually performed by ophthalmologists, but reports of retinal artery embolization and blindness have resulted in a reduced use of this modality.[86–87] The largest published case series of intralesional steroids found that the majority showed greater than 50% reduction in volume with the best results occurring in relatively superficial hemangiomas. Adverse events occurred in 6.4% of patients and included cushingoid appearance, cutaneous atrophy, and anaphylactic shock (see Table 126-3).[88]

A few case series have reported on the efficacy of class 1 topical corticosteroids, especially for small, superficial hemangiomas.[89–91]

Propranolol. Recently, propranolol has been found to cause cessation of growth and shrinkage of IH and has replaced corticosteroids as the first line treatment for most deforming, endangering, or life-threatening IH.[91] In the 3 years since 2008 when the initial series of 11 infants reported by Leaute-Labreze and colleagues, more than 150 articles have been published, most of them enthusiastically attesting to the efficacy of this treatment modality. This includes a randomized controlled trial comparing placebo to propranolol and retrospective studies comparing the effects of corticosteroids and propranolol.[92,93] Most studies have used a dose range from 1.5 to 3 mg/kg/day given either 2 or 3 times per day. In most reports, patients are treated for at least 6 months with an acceptable side-effect profile. Unlike steroids which usually stabilize hemangioma growth, but do not cause involution, propranolol causes actual regression in the majority of cases. Rebound growth after cessation of therapy can occur, but usually responds well to retreatment.[92,93] Side effects of propranolol include asymptomatic transient decrease in blood pressure, agitation, sleep alteration, sweating, wheezing, and cold hands (See Table 125-4). However the most concerning side effect which has emerged is hypoglycemia, which while rare, can be potentially life-threatening. Anticipatory guidance to minimize hypoglycemia in young infants includes frequent feeding and stopping the medication if oral intake is poor.[94,95] Impressive results have been reported in other settings including fully proliferated cutaneous hemangiomas, airway, liver and orbital hemangiomas.[92,96–98] Patients with PHACE syndrome who have central nervous system vascular anomalies may be at risk for stroke or other sequellae due to impaired arterial blood flow related to a drop in blood pressure or heart rate. Uniformly accepted standard monitoring procedures for patients on propranolol for IH have not yet been established. The mechanism of action of propranolol for hemangiomas is unknown, but it has been postulated to its effects by three different molecular mechanisms: vasoconstriction, inhibition of angiogenesis and induction of apoptosis.[95,99]

Topical β Blockers. Preliminary reports have demonstrated good responses with timolol 0.5% administered twice a day for superficial hemangiomas. Timolol is much more potent than propranolol, and data regarding percutaneous absorption are lacking, so using only a small amount (i.e., 1 drop BID) is currently recommended. More studies are needed to assess the results of this modality to determine its place in therapy.[100,101,102]

Interferon-α. Interferon-α therapy is reserved for hemangiomas causing morbidity that are unresponsive to oral corticosteroids, or where such therapy is contraindicated. It is quite effective, but potential neurotoxicity, specifically spastic diplegia, has limited its use (see Table 126-3). A meta-analysis of 441 patients showed 11 developed irreversible spastic diplegia and 16 developed motor disturbances that were reversible on discontinuation of the drug.[103] All affected patients were younger than 1 year of age at initiation of therapy, suggesting that the drug may be safer after 1 year of age. Neurologic evaluations should also be performed monthly in treated children.

Chemotherapy. Vincristine is often used in the treatment of the KMP and its associated tumors, KHE and TA.[104–106] Given the potential neurotoxicity of interferon (see Section "Interferon-α"), vincristine is considered by some to be a second-line treatment for aggressive, complicated IH that do not respond to corticosteroids. However, further evaluation through prospective clinical trials is needed (see Table 126-3).

Cyclophosphamide has been reported in the pediatric hematology-oncology literature to be effective in the treatment of life-threatening diffuse neonatal hemangiomatosis.[78,107]

Imiquimod. A recent phase II open-label, uncontrolled study found that topical imiquimod 5% cream improved IH color, but not size, confirming that imiquimod's utility is limited superficial hemangiomas.[108] Crusting and ulceration are potential side effects.[109]

LASER THERAPY. The PDL, originally designed to treat portwine stains, has been used to treat IH with varying results.[110] Several reports have shown improvement in treating hemangioma ulceration,[111,112] and its use in diminishing residual telangiectasias and erythema after involution is well accepted. Its use in the treatment of proliferating hemangiomas is controversial.[113] Batta et al performed the only prospective, randomized, controlled study to date regarding the treatment of IH in 121 patients aged 1–14 weeks, using 585-nm PDL without cooling compared to observation alone.[110] Their results showed no difference between complete and nearly complete clearance with laser compared to observation alone at age 1 year, with a trend toward increased hypopigmentation and textural change in the laser-treated group. Other studies have shown good results with either the 585-nm PDL or 595-nm PDL, with varying fluences (total energy per unit area), but several have emphasized that treatments work best for more superficial hemangiomas and are unable to halt growth of deeper components.[114–117] Severe ulceration and scarring, particularly in treating segmental hemangiomas during the proliferative phase, have been reported (see Table 126-3).[118] A conservative approach is to reserve PDL primarily for treating ulceration and for hastening resolution of erythema in IH after the proliferative phase is completed.[119]

SURGICAL THERAPY. Surgical excision may be indicated at any time during the life cycle of an IH (Fig. 126-8).[1] In most instances, it is best to wait until regression is well under way and a more accurate assessment can be made regarding whether scarring and textural changes have occurred. Decisions regarding this can often be made at age 3–5 years, even if involution is not complete.[120] Certain anatomic locations such as the nasal tip and lip often require surgery.[121–126] Even earlier excision may be indicated in cases where clinical characteristics, such as pedunculated, very ulcerated, or extremely thick dermal involvement dictate that scarring will inevitably occur. A standard elliptical excision is often performed; however, circular excision followed by a purse-string closure may leave a smaller scar.[127]

OTHER VASCULAR TUMORS

OTHER VASCULAR TUMORS AT A GLANCE

- Congenital hemangiomas are fully formed at birth. Rapidly involuting congenital hemangiomas and noninvoluting congenital hemangiomas are recognized subtypes.
- Tufted angiomas represent subtle pink or dusky-red patches and may evolve into plaques or nodules and have a characteristic histology.
- Kaposiform hemangioendothelioma is morphologically similar to but etiologically distinct from Kaposi sarcoma and can be associated with Kasabach-Merritt phenomenon.
- Multifocal lymphangiomatosis with thrombocytopenia consists of cutaneous vascular papules and plaques associated with intermittent thrombocytopenia, often with gastrointestinal bleeding.
- Spindle cell hemangioendothelioma usually occurs in the extremities most often associated with Maffucci syndrome.
- Congenital eccrine angiomatous hamartoma is a rare ill-defined plaque associated with increased lanugo hair and sweating.
- Pyogenic granuloma is very common; a rapidly growing papule or nodule with a collarette of scale or eroded surface. Treatment is excision or electrocautery.

Figure 126-8 Surgical correction of involuting-phase infantile hemangioma. **A.** Age 3 years, infantile hemangioma on upper eyelid. **B.** Age 9 years, after staged surgical resection, including vertical shortening of eyelid, repair of blepharoptosis, and formation of tarsal crease.

Many other benign vascular neoplasms occur in both children and adults.[128] This chapter highlights selected important vascular tumors. More comprehensive reviews of this subject can be found elsewhere.[128–130]

CONGENITAL HEMANGIOMAS

Hemangiomas that are fully formed tumors at the time of birth and do not proliferate in postnatal life are referred to as *congenital hemangioma* or *congenital nonprogressive hemangioma*. There are two major subtypes recognized on the basis of their natural history: the RICH and noninvoluting congenital hemangioma (NICH).[131] Collectively, both are sometimes referred to as *congenital nonprogressive hemangioma*. The distinguishing pathologic features of these tumors are lobules of capillaries set within densely fibrotic stroma containing hemosiderin deposits, focal lobular thrombosis, and sclerosis.[132] They are GLUT-1 negative.[133] Both have similar anatomic sites of predilection, such as the extremities or postauricular skin, but they can occur elsewhere. RICH often appears as a raised, violaceous tumor with large, radiating veins or with overlying telangiectasia and a halo of pallor (Fig. 126-9). Central ulceration may be present. Most RICH involute spontaneously by age 14 months, often sooner, and usually leave residual atrophic inelastic skin in their wake.[134] In one report a presumed RICH was noted on prenatal ultrasound and involuted before birth, leaving

Figure 126-9 Rapidly involuting congenital hemangioma on left thigh. **A.** Note central ulceration, violaceous color, and pale periphery. Fast-flow vessels were detected on Doppler examination. **B.** Rapid regression at age 2 months.

Figure 126-10 Noninvoluting congenital hemangioma on right mandible. Note the overlying telangiectasias and rim of pallor.

Figure 126-11 Age 18 months. Tufted angioma (confirmed by biopsy) of the left leg, buttocks, lower abdomen. Laboratory evaluation revealed elevated D-dimers.

a scar tissue at the site of the lesion.[135] NICH are also present at birth, but usually flatter than RICH, presenting as a well-circumscribed round to oval, slightly indurated, or raised soft-tissue mass with overlying telangiectasias and a rim of pallor (Fig. 126-10).

Both NICH and RICH are high-flow vascular anomalies, often showing arteriovenous microfistulas on Doppler interrogation. Some cases of RICH involute only partially, and the residual tumor resembles NICH, supporting the concept that RICH and NICH may be variants of each other.

Indications for treatment of NICH or RICH are similar to those for IH, including impairment of visual function and congestive heart failure. Excision should definitely be considered for ulceration, which can lead to severe hemorrhage, and for postinvolutional skin changes if disfiguring. NICH do not go away but are often asymptomatic; decisions regarding their removal must weigh risks and benefits of the proposed treatment.

TUFTED ANGIOMA

ETIOLOGY. TA is a benign vascular tumor that has also been called *angioblastoma of Nakagawa*. Its etiology and pathogenesis are uncertain. Unlike IH, there are no known gender or gestational age correlates.

CLINICAL FINDINGS. Most cases are acquired early in childhood and have a protracted course. Rare congenital forms also exist. TAs display various clinical patterns. They may present as a subtle stain-like area that later thickens, as a large, plaque-like, infiltrated, red or dusky blue-purple lesion, or as an exophytic, firm, violaceous, cutaneous nodule (Fig. 126-11). TA are usually solitary, but multifocal cases have been reported.[136] TA must be differentiated from IH as well as other vascular tumors. They are often somewhat firmer and may be tender. Histologically, both acquired and congenital TAs demonstrate vascular tufts of tightly packed capillaries, randomly dispersed throughout the dermis in a typical "cannonball distribution" with crescentic spaces surrounding the vascular tufts, and lymphatic-like spaces within the tumor stroma.[137,138] Unlike IH, TA does not stain with GLUT1,[15] and D2–40, a lymphatic marker, is only partially positive in surrounding vessels, helping distinguish TA from KHE.[139]

COMPLICATIONS. KMP may develop in TA but this is more common with KHE (see Section "Kaposiform Hemangioendothelioma").

PROGNOSIS AND CLINICAL COURSE. TA may persist unchanged or regress completely within a few years.[140]

TREATMENT. No single treatment is effective. Interferon-α and PDL have anecdotally been reported to be effective.

KAPOSIFORM HEMANGIOENDOTHELIOMA

KHE is a rare vascular tumor that has usually been reported in association with KMP. It may be present at birth or develop in early childhood. Rare adult cases have been reported. It may present as a brown-red stain at birth which begins to thicken and become purpuric, or as a plaque or nodule similar to TA. Regional lymph node involvement may occur, but not distant metastases. Mediastinal or retroperitoneal disease may present with hemothorax and ascites.[141] Spontaneous involution is rare. Most reported cases have had associated KMP, but the KHE can occur in the absence of a coagulopathy.[142,143]

The histology of KHE is characterized by spindled cells with minimal atypia and infrequent mitoses lining slit-like or crescentic vessels containing hemosiderin. The tumor is GLUT-1 negative. The overlap of both clinical and histologic features has led some to suggest that TA and KHE are part of a spectrum of disease. Increased lymphatic spaces reactive with the lymphatic markers vascular endothelial growth factor receptor-3 and D2–40 suggest a lymphatic origin, similar to that of Kaposi sarcoma.[144,145]

The prognosis and management of KHE varies with extent and location of the tumor, in addition to the presence of KMP. Therapies for KMP are discussed below.

KASABACH-MERRITT PHENOMENON

The KMP refers to the presence of platelet trapping in the setting of vascular tumors (Fig. 126-12). It was long considered to be a complication of "hemangioma," but it is now recognized to be a complication of TA and KHE, not IH.[146,147]

KMP must be differentiated from the coagulopathy which can arise in association with venous and mixed venous-lymphatic malformations (sometimes erroneously called *KMP*) due to chronic clotting and consumption of clotting factors, but not primarily by platelet trapping.[148] The hallmark of KMP is a tender, expanding vascular tumor with thrombocytopenia, usually severe. Consumption of fibrinogen, elevated D-dimers, and decreased coagulation factors occurs to varying degrees. Most cases involve the skin and musculature, but deeper viscera including cervicothoracic, abdominal, and pelvic regions can be affected. Although the tumors causing KMP can persist, the coagulopathy usually abates by 1 year of age or sooner with treatment. KMP may resolve with atrophic or stain-like areas, infiltrated plaques and papules, or nodules. Residual fibrosis is not rare and can result in considerable morbidity.[149]

No one treatment is uniformly effective. Options include corticosteroids, vincristine, cyclophosphamide, actinomycin-D, methotrexate, interferon-α, ticlopidine plus aspirin, surgical excision, arterial embolization, and radiotherapy. Platelet transfusions should be avoided unless active bleeding occurs or before surgical procedures.[150–154]

Figure 126-12 Kasabach–Merritt phenomenon secondary to kaposiform hemangioendothelioma (KHE). An indurated, purpuric tumor appeared at age 3 months and is seen here at age 8 months. KHE confirmed by magnetic resonance imaging and biopsy. Platelet count <5,000/mm^3.

MULTIFOCAL LYMPHANGIOENDOTHELIOMATOSIS WITH THROMBOCYTOPENIA

Multifocal lymphangioendotheliomatosis with thrombocytopenia (MLT)—also known as *cutaneovisceral angiomatosis with thrombocytopenia*—is a rare condition, characterized by multiple cutaneous vascular papules and plaques that are usually present at birth with more developing over time. The use of GLUT1 as a specific histopathologic marker for IH has led to the recognition that these vascular growths are not a widespread variant of IH. The clinical spectrum of the disease is expanding. Some patients have prominent exophytic cutaneous vascular tumors, whereas others have subtle blueberry muffin-like papules.[155] Most affected infants have intermittent thrombocytopenia and lesions in the gastrointestinal tract, leading to gastrointestinal bleeding. Other reported sites of involvement include bones, synovium, lungs, liver, spleen, and brain. Undoubtedly, many patients previously diagnosed with "diffuse neonatal hemangiomatosis" actually had MLT. Skin biopsy specimens demonstrate thin-walled vessels, some hobnailed endothelial cells, and intraluminal papillary projections similar to Dabska tumor.[156,157] Some of the vessels stain with lymphatic markers such as LYVE-1 or D2–40.[155] No single treatment has been effective; patients have been treated with a variety of systemic medications including corticosteroids, interferon, vincristine, and most recently bevacizumab and thalidomide.[155,158] Prognosis varies based on extent of disease and bleeding complications.

SPINDLE CELL HEMANGIOENDOTHELIOMA

Spindle cell hemangioendothelioma is a rare vascular tumor most often seen with Maffucci syndrome. It can occur at any age and site but the extremities are the most commonly affected. The histology is of a nodular, dense, spindle cell proliferation in association with dilated dysplastic veins. Lesions can be locally aggressive and may recur even after excision.[159]

CONGENITAL ECCRINE ANGIOMATOUS HAMARTOMA (SUDORIPAROUS ANGIOMA)

Congenital eccrine angiomatous hamartoma is a rare condition characterized by ill-defined plaques with

Figure 126-13 Large pyogenic granuloma on chest, age 2 years.

increased lanugo hair and sweating at the site of the lesion. They are usually located on the extremities or abdomen. Diagnosis is established on the basis of characteristic histologic findings: closely packed eccrine sweat glands associated with dilated capillaries, a few dysplastic venous channels, and a dense collagenous matrix.[160]

PYOGENIC GRANULOMA (LOBULAR CAPILLARY HEMANGIOMA)

Pyogenic granuloma (PG) is also known by its correct histopathologic description *lobular capillary hemangioma.* It is one of the most common vascular tumors of infants and children and can also occur in adults, particularly in pregnant women. PG usually presents as a solitary, red, rapidly growing papule or nodule, often with a subtle collarette of scale (Fig. 126-13). Typical locations include the cheek or forehead but virtually any body site including the mucous membranes may be affected. They often develop an eroded surface, with subsequent bleeding which can be profuse, resulting in the moniker *the band-aid disease*. In very young infants, PG is often mistaken for an infantile hemangioma.[161]

PG does not involute spontaneously, but simple curettage with electrocautery is usually curative. Other options include excision, laser surgery (carbon dioxide or pulsed dye), and cryotherapy. Topical imiquimod has recently been shown to be an effective treatment.[162] Recurrence and even satellite lesions surrounding the original PG have been reported.[163,164]

OTHER VASCULAR TUMORS

Targetoid hemosiderotic hemangioma is a benign lesion presenting as a violaceous papule, often surrounded by a pale rim and peripheral ecchymotic halo, which fades with time. Lesions usually present on the trunk or extremities and histologically consist of dilated vascular channels within intraluminal papillary projections dissecting into collagen bundles in the subcutis. Extravasated erythrocytes and hemosiderin are present, hence the designation.

Endovascular papillary angioendothelioma (Dabska tumor) is a dermal nodule or a diffuse swelling on the head, neck, or extremities. Dabska tumor is a low-grade angiosarcoma. Epithelioid hemangioendothelioma and retiform hemangioendothelioma are other examples of low-grade angiosarcomas. These tumors, Kaposi sarcoma, and angiosarcoma are discussed in Chapter 128. Vascular malformations are discussed in Chapter 172.

Chapter 127 :: Neoplasias and Hyperplasias of Muscular and Neural Origin

:: Lucile E. White, Ross M. Levy, & Murad Alam

TUMORS OF SMOOTH MUSCLE

The dermis contains smooth muscle fibers in the arrector pili muscles, in the walls of dermal blood vessels, and in the dartos muscle of the scrotum, vulva, nipple, and areola. There are three types of cutaneous smooth muscle lesions: (1) leiomyomas, (2) leiomyosarcomas, and (3) hamartomas. Smooth muscle is recognized histologically by spindle cell shape, eosinophilic, fibrillary cytoplasm, and blunt-ended, oval, "cigar-shaped" nuclei. On immunohistochemical staining, cells express smooth muscle actin and the muscle-specific intermediate filament desmin, but are negative for S100 protein and epithelial membrane antigen (EMA).

LEIOMYOMA

LEIOMYOMA AT A GLANCE

- Benign cutaneous neoplasm derived from arrector pili muscle (piloleiomyoma), mammillary, dartoic or labial/vulvar muscle (genital leiomyoma), or the walls of blood vessels (angioleiomyoma).
- Present as solitary or multiple flesh-colored, occasionally painful papules; rarely associated with uterine leiomyomas and renal cell cancer.
- Treatment: surgical; recurrence is common.

EPIDEMIOLOGY. The exact incidence of leiomyomas is unknown. In one study, the 10-year incidence was 0.04% with the majority of lesions occurring in women.[1] Although leiomyomas are thought to be relatively uncommon neoplasms, the actual incidence may be higher than previously believed due to failure to recognize and biopsy the lesion.

ETIOLOGY AND PATHOGENESIS. Cutaneous leiomyomas are divided into three subsets: (1) solitary or multiple piloleiomyomas originating from the arrector pili muscles; (2) genital leiomyomas originating from the mammillary, dartoic, or labial/vulvar muscles; and (3) angioleiomyomas, originating from vascular smooth muscle. Most leiomyomas are acquired; however, familial inheritance patterns have been described. Especially noteworthy are patients with multiple piloleiomyomas. Starting in early adulthood, these patients present with increasing numbers of tumors, developing as many as 100–1,000 lesions. Transmission appears to be autosomal dominant with variable penetrance.[2] Women with multiple piloleiomyomas may also develop uterine leiomyomas, an entity termed *multiple cutaneous and uterine leiomyomatosis* (also known as *familial leiomyomatosis cutis et uteri* or *Reed syndrome*).[2] In addition, some families with multiple cutaneous and uterine leiomyomatosis have been shown to cluster renal cell cancer, and this has been termed *hereditary leiomyomatosis and renal cell cancer*. Recently, a loss of function mutation in the gene encoding fumarate hydratase on chromosome 1q42.3–43 has been shown to predispose individuals to these conditions. Fumarate hydratase catalyses the conversion of fumarate to malate in the Krebs cycle but is also considered to be a tumor-suppressor gene.[3,4]

CLINICAL FINDINGS. The most common presentation is that of multiple piloleiomyomas.[5] Individual lesions range in size from several millimeters to 1 cm and are usually reddish-brown firm papulonodules that are fixed to the skin but freely moveable over underling deeper structures (Fig. 127-1). They can coalesce to form plaques or linear, grouped, or dermatomal patterns.[5] The extensor extremities, trunk, and sides of the face and neck are the most common locations. Patients with piloleiomyomas often have pain

Figure 127-1 Clinical photograph showing multiple leiomyomas involving the back.

that may be spontaneous or secondary to cold, pressure, or emotion.[2,5–7] Possible explanations for this phenomenon include pressure of the tumor on local nerve fibers and contraction of the smooth muscle fibers.[5] Genital leiomyomas are clinically similar to pilolеiomyomas except that they are usually asymptomatic.[5] They commonly present as solitary, deep papulonodules or occasionally, pedunculated papules on the scrotum, vulva, penis, or areolar region. Angioleiomyomas present most commonly as solitary, painful subcutaneous nodules on the legs in women that can grow to several centimeters in diameter.[8]

HISTOPATHOLOGY. Pilar leiomyomas are composed of a poorly circumscribed proliferation of haphazardly arranged, bland-appearing smooth muscle cells with characteristic eosinophilic cytoplasm, blunt-ended nuclei, and perinuclear halos in cross section. They are located in the dermis and can infiltrate the surrounding tissue with extension into the subcutis. Genital leiomyomas usually resemble pilar leiomyomas. Angioleiomyomas are well-circumscribed, richly vascularized dermal or subcutaneous nodules composed of well-differentiated smooth muscle fibers (Fig. 127-2). Occasionally, the vessel of origin can be identified. Leiomyomas stain positive with smooth-muscle actin and desmin.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of leiomyoma includes any flesh-colored or reddish-brown superficial or deep-seated papule or nodule: angiolipoma, glomus tumor, eccrine spiradenoma, neurofibroma, nevus, or lipoma.

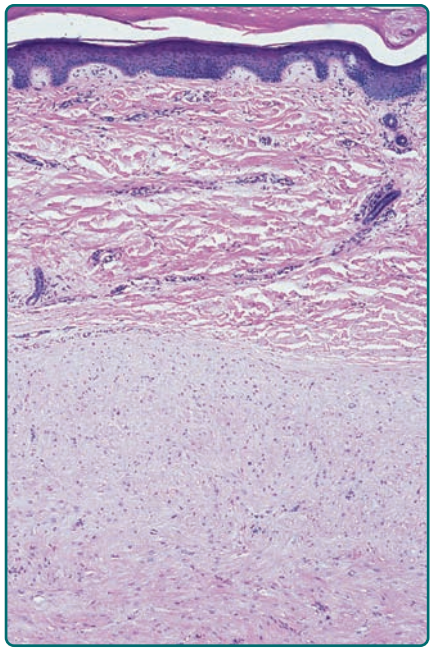

Figure 127-2 Histologic appearance of an angioleiomyoma. Compared with the pilar leiomyoma, this tumor is more sharply circumscribed (but not encapsulated). Furthermore, the smooth muscle fibers form a solid nodule with little, if any, intervening collagen. (Hematoxylin and eosin, ×40.)

PROGNOSIS AND CLINICAL COURSE. Cutaneous leiomyomas do not regress spontaneously, and there does not appear to be risk of malignant degeneration into leiomyosarcoma. A minority of patients may also develop uterine leiomyomas and, in some families, association with renal cell carcinoma has been described. Occasionally, leiomyomas are associated with polycythemia. This may be due to erythropoietin-like activity of leiomyomas, which has been demonstrated in tumor extracts.[9]

TREATMENT. Excision is the treatment of choice for leiomyomas that cause pain or cosmetic concern; however, recurrence is common. In patients with numerous lesions, this method is impractical. Carbon dioxide laser ablation was reported as an effective modality[10] whereas cryotherapy and electrosurgery have been used with disappointing results.[11] Pain may be a significant source of morbidity and, when surgical intervention is not possible, potential treatment options include nitroglycerin, phenoxybenzamine, nifedipine, gabapentin, intralesional botulinum toxin, or topical analgesics.[2,12–15]

LEIOMYOSARCOMA

LEIOMYOSARCOMA AT A GLANCE

- Rare malignant tumor of smooth muscle: cutaneous and subcutaneous types based on location of origin.
- Presentation: enlarging cutaneous or subcutaneous tumor most commonly on hair-bearing areas of the lower extremities.
- Recurrence rate: high, with significant risk of metastases in case of subcutaneous leiomyosarcoma.

EPIDEMIOLOGY. Exact incidence is unknown, but older studies suggest that leiomyosarcomas comprise approximately 3% of soft-tissue sarcomas.[16] Superficial leiomyosarcoma occurs in all age groups, and there appears to be no gender predilection.

ETIOLOGY AND PATHOGENESIS. Leiomyosarcoma is a rare, malignant mesenchymal tumor of smooth muscle origin usually found in the uterus, the retroperitoneum, gastrointestinal tract, or deep soft tissue. The term *superficial leiomyosarcomas* refers to those tumors whose primary site of origin is the skin. Those derived from arrector pili or genital smooth muscles are termed *cutaneous leiomyosarcomas*, and those derived from blood vessel smooth muscle are termed *subcutaneous leiomyosarcomas*. In some cases, tumors have arisen in sites of earlier radiotherapy or trauma.[5] Leiomyosarcomas typically arise de novo rather than from preexisting leiomyomas.

CLINICAL FINDINGS. Leiomyosarcomas present as solitary, enlarging lesions most commonly on the hair-bearing areas of lower extremities.[17] They can exhibit a variety of colors and may be painful, pruritic, or paresthetic. Cutaneous leiomyosarcoma usually presents as small (<2 cm), sometimes ulcerated nodules that are fixed to the epidermis. Subcutaneous leiomyosarcomas tend to be larger and are usually not associated with epidermal change. Some patients have multiple grouped lesions; in one series, four of seven such patients had a previous retroperitoneal leiomyosarcoma,[18] highlighting the importance of ruling out metastases in patients with numerous superficial leiomyosarcomas.

HISTOPATHOLOGY. Leiomyosarcomas are large tumors consisting of smooth muscle fibers arranged in irregular, intersecting bundles and fascicles in the dermis and subcutis, often with infiltrating borders. Tumor cells exhibit smooth muscle differentiation with atypical cytologic features such as nuclear hyperchromasia, prominent nucleoli, mitosis, and necrosis (Fig. 127-3). In less well-differentiated areas, highly pleomorphic and multinucleated cells may be found.[5] Granular cell, epithelioid cell, myxoid, and sclerosing (or desmoplastic) variants have been described.[19] Leiomyosarcomas must be histopathologically distinguished from other malignant cutaneous spindle cell tumors, such as spindle cell melanoma, spindle cell squamous cell carcinoma, or atypical fibroxanthoma. Leiomyosarcomas stain positive with smooth-muscle actin, desmin, and vimentin and occasionally with S100 and cytokeratin, which makes distinguishing them from melanoma and squamous cell carcinoma difficult in certain cases.[5,20,21]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of leiomyosarcoma includes any solitary, enlarging dermal or subcutaneous nodule: lipoma, dermatofibroma, dermatofibrosarcoma, neurofibroma, spindle cell melanoma, spindle cell squamous cell carcinoma, and atypical fibroxanthoma.

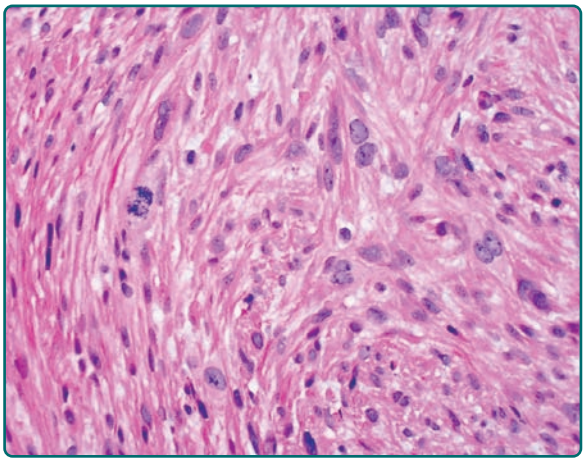

Figure 127-3 Histologic examination of a leiomyosarcoma. This tumor exhibits smooth muscle differentiation with atypical cytologic features such as nuclear hyperchromasia, prominent nucleoli, and mitoses. (Hematoxylin and eosin, ×400.)

PROGNOSIS AND CLINICAL COURSE. The most important prognostic factor depends on whether the leiomyosarcoma is of cutaneous or subcutaneous origin. Although both cutaneous and subcutaneous lesions may recur locally in up to one-third to one-half of cases, the risk of metastasis is 5%–10% for cutaneous leiomyosarcomas compared with 30%–60% for subcutaneous leiomyosarcomas.[5,9,16,17,22–25] The lung is the most common location of metastasis.

TREATMENT. Therapy for superficial leiomyosarcoma is wide local excision with 3- to 5-cm margins and re-excision for recurrent lesions.[17] On acral locations, complete excision may require amputation.[17] Patients with subcutaneous leiomyosarcomas should undergo a chest X-ray for metastases. Adjuvant radiation and/or chemotherapy have unclear benefit. Alternative local treatment modalities in selected patients include Mohs micrographic surgery, cryosurgery, and isolated limb perfusion with chemotherapeutic agents.[17,26]

SMOOTH MUSCLE HAMARTOMA

SMOOTH MUSCLE HAMARTOMA AT A GLANCE

- Benign hamartomatous proliferation of smooth muscle.
- Presenting as a solitary patch or plaque on the trunk.
- Associated with variable pigmentation, hypertrichosis, and follicular prominence.
- Clinical and histologic features similar to Becker's nevus.

EPIDEMIOLOGY. First described by Stokes in 1923,[27] smooth muscle hamartoma has become increasingly recognized during the last two decades. Most cases are congenital but some are acquired,[28,29] and prevalence estimates of up to 0.2% in children have been reported.[29]

ETIOLOGY AND PATHOGENESIS. Smooth muscle hamartoma is a benign proliferation of mature smooth muscle. The cause is unknown, and the majority of cases are present from birth.

CLINICAL FINDINGS. Smooth muscle hamartoma is usually found on the trunk or extremity (Fig. 127-4) and may take one of several forms: a single patch or plaque with or without follicular prominence, grouped solitary lesions (rarely with a linear distribution), and diffuse skin involvement as seen in the Michelin tire baby syndrome.[30,31] Lesions can exhibit variable hyperpigmentation and hypertrichosis. Vellus hairs may be prominent. Some can produce worm-like movements

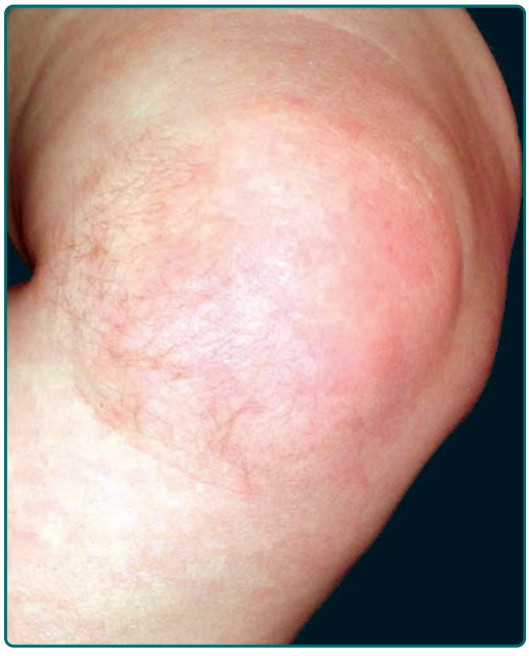

Figure 127-4 Smooth muscle hamartoma. This tumor presented with a focal area of hypertrichosis on the leg. (Photo from the collection of Dr. Amy Paller, MD, Children's Memorial Hospital, Chicago, IL.)

(vermiculation), and stroking may induce transient induration with piloerection (pseudo-Darier sign). Smooth muscle hamartoma shares some clinical and histologic features with Becker's nevus. Some authors consider these lesions a spectrum,[29] whereas others prefer to keep them separate.[28,32]

HISTOPATHOLOGY. There is a marked increase of sharply circumscribed bundles of smooth muscle fibers that are haphazardly arranged in the reticular dermis. These fibers are sometimes associated with follicular units. There may be basal layer hyperpigmentation, as well as acanthosis and papillomatosis of the overlying epidermis. Factors that help to distinguish smooth muscle hamartomas from pilar leiomyomas include the grouping of smooth muscle fibers into discrete bundles and the lack of intermingling of these bundles with dermal collagen fibers.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of hamartoma includes congenital nevus, Becker's nevus, café-au-lait macule, leiomyoma, neurofibroma, and solitary mastocytoma.

PROGNOSIS AND CLINICAL COURSE. Malignant degeneration has not been reported. Although the localized form is usually not associated with other congenital anomalies,[29] patients with the generalized form have been reported to have multiple associated congenital malformations[33] and psychomotor retardation.[33,34]

TREATMENT. No specific treatment is indicated. Surgical excision can be performed if the lesions are of cosmetic concern.

TUMORS OF STRIATED MUSCLE

Tumors of striated muscle include true neoplasms of striated muscle differentiation (rhabdomyomas and rhabdomyosarcomas) as well as non-neoplastic neuromuscular and rhabdomyomatous mesenchymal hamartomas (RMHs).

RHABDOMYOMA

RHABDOMYOMA AT A GLANCE

- Benign neoplasms of striated muscle.
- Most common on the head and neck of young males.
- Noncardiac rhabdomyomas usually asymptomatic.
- Surgical excision is treatment of choice.

EPIDEMIOLOGY. Extracardiac rhabdomyomas are extremely rare and comprise fewer than 2% of striated muscle neoplasms.[35] The adult and fetal types of rhabdomyomas occur predominantly in male patients. Cardiac rhabdomyomas occur in approximately 30%–50% of patients with tuberous sclerosis (TS; see Chapter 140).[36]

ETIOLOGY AND PATHOGENESIS. Rhabdomyomas are benign tumors of striated muscle. Extracardiac rhabdomyomas are not associated with TS, whereas significant portion of patients with cardiac rhabdomyomas are ultimately diagnosed with TS.

CLINICAL FINDINGS. Extracardiac rhabdomyomas are subdivided into three types: (1) adult, (2) fetal, and (3) genital.[35,37] The designation as *adult* or *fetal* refers to the tumor's resemblance to adult or fetal skeletal muscle, not to the age of the patient.[37] Adult and fetal types usually arise in the soft tissues or mucosal surfaces of the head and neck region soon after birth. They are usually asymptomatic. The fetal type has been repeatedly associated with basal cell nevus syndrome.[37] Genital rhabdomyomas usually occur as small polypoid vaginal or vulvar lesions in middle-aged women.[37]

HISTOPATHOLOGY. Rhabdomyomas are composed of fascicles of oval and polygonal-shaped cells with eosinophilic, often vacuolar cytoplasm and eccentrically placed nuclei.[35] Atypia, mitosis, and pleomorphism are absent.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of rhabdomyomas includes granular cell tumor (GCT), hibernoma, and reticulohistiocytoma.

PROGNOSIS AND CLINICAL COURSE. Extracardiac and cardiac rhabdomyomas have a very low

risk of malignant degeneration. Many cardiac rhabdomyomas regress spontaneously with age.

TREATMENT. The treatment of choice for symptomatic extracardiac rhabdomyomas is surgical excision.

RHABDOMYOSARCOMA

RHABDOMYOSARCOMA AT A GLANCE

- Malignant neoplasm of striated muscle.
- Most common soft-tissue sarcoma in children.
- Presentation: subcutaneous or ulcerated tumor on extremities or head and neck; rare cause of "blueberry muffin baby."
- Treatment: surgical excision, chemotherapy, and/or radiotherapy.
- Prognosis: poor.

EPIDEMIOLOGY. Rhabdomyosarcoma is the most frequent soft-tissue sarcoma of childhood with annual incidence of 4.3/million, accounting for approximately 50% of soft-tissue sarcomas in children younger than age 15 years and 5%–8% of all childhood cancers.[38–40] Only approximately 0.7% occur as primary skin lesions.[40] Males are more commonly affected than females.[38]

ETIOLOGY AND PATHOGENESIS. Rhabdomyosarcomas are malignant neoplasms derived from skeletal muscle precursors. Primary cutaneous disease is rare, and skin involvement is more commonly a result of either direct extension from underlying soft tissues or metastases.[41] Four subtypes have been described based on histologic appearance: (1) embryonal, (2) alveolar, (3) botryoid, and (4) pleomorphic. The embryonal type is most common, followed by alveolar. Alveolar rhabdomyosarcoma is characterized at the molecular level by novel fusion genes combining the forkhead (*FKHR*) gene with either the *PAX3* or the *PAX7* gene, producing a t(2;13)(q35;q14) or t(1;13)(p36;q14), respectively.[38]

CLINICAL FINDINGS. Cutaneous rhabdomyosarcoma typically presents as an enlarging subcutaneous or ulcerated tumor involving the head and neck, the genitourinary tract, or the extremities. A deep soft-tissue rhabdomyosarcoma can also extend into the overlying skin and present as a cutaneous nodule.[40] In neonates, congenital alveolar rhabdomyosarcoma is a very rare cause of "blueberry muffin baby" in which multiple cutaneous and subcutaneous metastases present as scattered blue nodules.

HISTOPATHOLOGY. Rhabdomyosarcoma is composed of sheets of pleomorphic, small blue cells infiltrating the dermis and subcutaneous tissue. High mitotic index is present, and focal areas of necrosis can often be identified.[41] The embryonic type is composed of interlocking bands of spindle cells and sheets of small round cells whereas the alveolar type exhibits loss of cellular cohesion leading to spaces resembling alveoli. Immunohistochemistry can be helpful in differentiating rhabdomyosarcoma from other "small blue cell tumors." Rhabdomyosarcomas express positivity for muscle-specific actin, desmin, myoD1, and myogenin. Reverse transcription polymerase chain reaction and fluorescence in situ hybridization analysis can used to detect the t(2;13)(q35;q14) and t(1;13)(p36;q14) chromosomal translocations.[38,41]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of rhabdomyosarcoma includes hemangioma, hematoma, neuroblastoma, and other soft-tissue sarcomas.

PROGNOSIS AND CLINICAL COURSE. Prognosis is poor, with many patients succumbing to their disease. Even with appropriate treatment, rhabdomyosarcomas can recur and metastasize to regional lymph nodes, lung, bone, and heart. Congenital alveolar rhabdomyosarcoma has an especially poor prognosis; there are no reports in the literature of survivors.[38]

TREATMENT. Treatment of rhabdomyosarcoma consists of a combination of surgical excision, chemotherapy, and radiotherapy.

BENIGN PROLIFERATIONS OF NERVES: NEUROMAS

NEUROMAS AT A GLANCE

- Nonneoplastic overgrowths of nerves; benign.
- Consist of both Schwann cells and axons.
- Presentation: flesh-colored papules or nodules.
- Treatment: excision.

TRAUMATIC (AMPUTATION) NEUROMA

EPIDEMIOLOGY. The exact incidence of traumatic neuromas is not known. Several small studies suggest that up to 30% of amputations result in neuromas.[44,45]

ETIOLOGY AND PATHOGENESIS. When a nerve is partially or completely severed, axons and Schwann cells can proliferate from the proximal stump and form a disorganized tangle of nerves and fibroblasts, called a *traumatic neuroma*. Within the bundle

of nerves and fibroblasts, the axons can begin to synapse and send pain signals. These signals occur spontaneously or after mechanical thresholds lower than in normal nerves. The nerve proliferation typical of accessory digits may also represent an example of traumatic neuroma.

CLINICAL FINDINGS. Traumatic neuromas are flesh-colored papules or nodules occurring at the sites of previous trauma or surgery. They often occur within suture lines and can be very painful.

HISTOPATHOLOGY. Histologically, a neuroma appears as a collection of nerve fascicles that are haphazardly arranged. A fibrous or collagen sheath may surround neuromas, but these neuromas are not encapsulated by perineurium. The neuromas stain for EMA. Staining of the neural lesions is reviewed in Table 127-1.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of neuromas includes hypertrophic scar, dermatofibroma, digital fibrokeratoma, and verruca vulgaris.

TREATMENT. Temporary pain relief can be achieved with a local anesthetic nerve block. For more permanent pain relief, surgical treatment aims either at isolating the nerve from injury or excising the neuroma.[46]

PALISADED ENCAPSULATED NEUROMA

EPIDEMIOLOGY. Palisaded encapsulated neuromas (PENs) present in adults, mostly in their third to fifth decade. There appears to be no gender predilection. PENs make up approximately one-fourth of benign cutaneous neural lesions.[47]

ETIOLOGY AND PATHOGENESIS. PENs consist of a hamartomatous overgrowth of Schwann cells.[48] The etiology is unknown.

CLINICAL FINDINGS. PENs often present as asymptomatic, flesh-colored papules or nodules that are smaller than 1 cm in diameter. PENs are located on the face in approximately 80% of cases.[47] PEN is almost never diagnosed clinically; the most common misdiagnoses are dermal melanocytic nevus, basal cell carcinoma, and adnexal tumor.

HISTOPATHOLOGY. PENs are well-demarcated dermal nodules composed of fascicles of Schwann cells (Fig. 127-5). Contrary to what the name implies, the capsule is rarely complete and the palisading typical of schwannomas is often indistinct. Special stains demonstrate variable numbers of axons within the lesion. The capsule often stains with EMA, suggesting

TABLE 127-1
Staining of Neural Hyperplasias and Neoplasms

Neural Proliferation	S100	Neurofilament	Epithelial Membrane Antigen (EMA)	Other
Traumatic neuroma	+	+	+	Neuron-specific enolase positive
Palisaded encapsulated neuroma	+	+	+ for the capsule	
Schwannoma	+	–	+ for the capsule only	Vimentin positive
Neurofibroma	+	Variable	–	
Plexiform neurofibroma	+	+		
Neurothekeoma	+/–	–	Variable	Vimentin variable; usually EMA negative
Cellular neurothekeoma	–		–	CD57 positive; Ki-Mip positive
Perineurioma	–	–	+	Vimentin positive; neuron-specific enolase negative
Malignant peripheral nerve sheath tumor	+	+	Variable	Vimentin variable; cytokeratin negative; neuron-specific enolase positive
Primitive neuroectodermal tumor	+ if differentiated			Neuron-specific enolase positive; CD99 positive
Granular cell tumor	+			Neuron-specific enolase positive

+ = positive; – = negative.

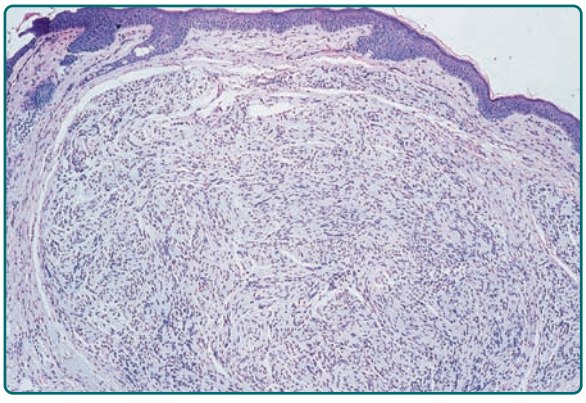

Figure 127-5 Histologic appearance of a typical palisaded encapsulated neuroma. The tumor is composed of fascicles of Schwann cells and surrounded by a delicate capsule best seen on the left. There is a suggestion of nuclear palisading, but this is not as pronounced as that seen in a schwannoma. (The axons that are normally also present cannot be seen on this stain; hematoxylin and eosin, ×40.)

a perineural origin, and the tumor body stains for S100, suggesting a Schwann cell origin (see Table 127-1).[49,50] Some PENs may actually be small dermal schwannomas that contain a few residual entrapped axons.[51]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of PEN includes dermal melanocytic nevus, basal cell carcinoma, adnexal tumor, and neurofibroma.

TREATMENT. Excision is the treatment of choice. There is no evidence of an association between PEN and neurofibromatosis (NF; see Chapter 141) or multiple endocrine neoplasia syndrome type 2B (MEN2B; see Section "Mucosal Neuromas and Multiple Endocrine Neoplasia Syndrome Type 2B").

MUCOSAL NEUROMAS AND MULTIPLE ENDOCRINE NEOPLASIA SYNDROME TYPE 2B

EPIDEMIOLOGY. Due to inconsistent nomenclature, the incidence of mucosal neuromas is not known.[52]

ETIOLOGY AND PATHOGENESIS. MEN2B is an autosomal dominant condition. MEN2B is caused by germ-line mutations of the *RET* proto-oncogene located on chromosome 10q11.2.[53] The mutation is a result of substituting a threonine for a methionine in the tyrosine kinase domain of the RET protein.[51]

CLINICAL FINDINGS. MEN2A is characterized by the triad of medullary carcinoma of the thyroid gland, pheochromocytoma, and parathyroid hyperplasia. The neoplastic spectrum of MEN2B is similar, but in addition, these patients have malformations (Marfanoid habitus, facial dysmorphism) and overgrowth of mucosal nerves leading to the mucosal neuromas.[54,55]

The neuromas appear by 2 years of age and thus serve as an important clinical marker for identifying affected individuals in MEN2B families.[53] The neuromas involve all mucosal surfaces (oral mucosa, lips, tongue, and conjunctivae) and appear as pink, pedunculated papules or nodules. The lips become enlarged and bulging, and the eyelids may be everted. Other cutaneous lesions include café-au-lait spots, facial lentigines, and hyperpigmentation of the hands and feet.

HISTOPATHOLOGY. Histologically, there is hypertrophy of the mucosal nerves; some lesions may resemble PENs.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of mucosal neuromas and MEN2B includes PEN and mucocele.

TREATMENT. The main threat to these patients is the development of related cancers. Virtually all patients have a medullary carcinoma of the thyroid by early adulthood, and approximately one-half develop pheochromocytomas. The thyroid carcinoma is highly aggressive. Early detection and prophylactic thyroidectomy by 5 years of age are essential.[53]

BENIGN NERVE SHEATH NEOPLASMS

BENIGN NERVE SHEATH NEOPLASMS AT A GLANCE

- Schwann cells and the endo- and perineurial fibroblasts make up the nerve sheath.
- Schwannomas: benign encapsulated tumors originating from the Schwann cells.
- Neurofibromas: benign nerve sheath tumors that are proliferations of all the nerve's elements.
- Presentation: usually isolated lesions, but multiple neurofibromas found in neurofibromatosis type 1 and bilateral vestibular schwannomas found in neurofibromatosis type 2.
- Treatment: if solitary, excision. Schwannomas can often be resected without sacrificing the nerve of origin, whereas resection of a neurofibroma usually requires transection of the nerve.

SCHWANNOMA

EPIDEMIOLOGY. The peak incidence of schwannomas is in the third to sixth decades. Men and women are affected similarly. Schwannomas occur sporadically or in association with neurofibromatosis type 2 (NF2), which is discussed in greater detail in Chapter 141).

ETIOLOGY AND PATHOGENESIS. Schwannomas are also called *neurinomas*, *neurolem(m)omas*, or *neurilem(m)omas*. Mutations in the NF2 gene are the

underlying cause of the schwannomas of both the sporadic type and NF2. They usually arise in cranial nerves, especially the vestibular nerve (the so-called *acoustic neuromas* are actually schwannomas of the vestibular division of the eighth cranial nerve); they also occur in other peripheral nerves and spinal roots.

CLINICAL FINDINGS

Cutaneous Lesions. The classic schwannomas often involve the head and neck. Most schwannomas are intracranial, intraspinal, or deep soft-tissue lesions. In the skin, schwannomas present as soft, asymptomatic, dermal, or subcutaneous papules or nodules. They are usually solitary.

Multiple Schwannomas. Neurilemmomatosis or schwannomatosis presents with multiple cutaneous, soft-tissue, or spinal schwannomas, but without vestibular schwannomas or other central nervous system tumors typical of NF2 (such as meningiomas or ependymomas). This entity is usually sporadic but can rarely be familial. Some of these patients may have unrecognized NF2, either because they have had insufficient cranial imaging or because they are still too young to exclude the eventual growth of the tumors.[58] Among those in whom vestibular schwannomas have been definitively excluded, a minority carry germ-line mutations of the NF2 gene.[58,59] Some patients are in fact somatic mosaics, which could explain the limited extent of their disease.[60] However, the majority of schwannomatosis patients (including those with the familial form) do not have germ-line mutations of NF2, even though their schwannomas do harbor the typical somatic mutations seen in NF2-associated schwannomas. It has been surmised that this type of schwannomatosis is due to an inheritable predisposition to somatic NF2 mutations.[60] Finally, a last group of patients has neither germ-line nor somatic NF2 mutations; in these individuals, an as yet unknown gene may be involved.[57]

HISTOPATHOLOGY. Because a schwannoma is a neoplastic proliferation composed only of Schwann cells and devoid of axons, it grows as an eccentric nodule, displacing its nerve of origin. This growth pattern and its cellular composition distinguish schwannoma from neurofibroma (Fig. 127-6).

Schwannomas are well encapsulated. The capsule is derived from the epineurium of the schwannoma's nerve of origin. The tumor cells are typically slender, spindled, elongated, and "wavy" in appearance. Areas of high cellularity (called *Antoni A*) alternate with areas of hypocellularity (*Antoni B*), which can have a myxoid quality. In the cellular Antoni A areas, adjacent cells have a tendency to align, creating stacks of nuclei known as *palisades*. These palisades are separated by an anuclear area made up of stacked cytoplasmic extensions; these stacks of nuclei and cell processes form the so-called *Verocay bodies* (see Fig. 127-6). Tumor blood vessels are characteristically thick and hyalinized.

By immunohistochemistry, schwannomas are strongly positive for S100 protein and negative for EMA and smooth muscle markers (desmin, α-actin),

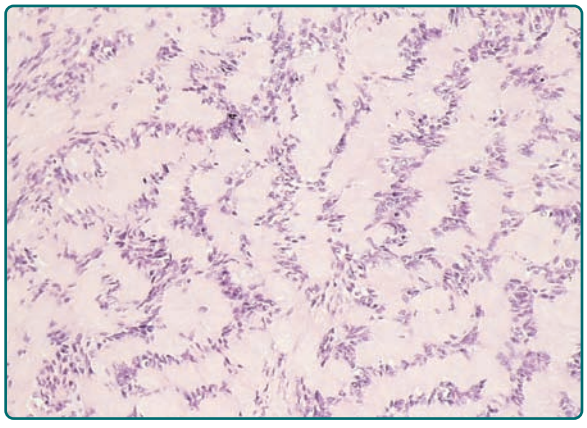

Figure 127-6 Photomicrograph of a schwannoma showing orderly arrangement of tumor cells into palisades and Verocay bodies. (Hematoxylin and eosin, ×100.)

which distinguishes them from perineuromas (S100 negative, EMA positive, desmin and α-actin negative) and leiomyomas (S100 and EMA negative, desmin and α-actin positive) (see Table 127-1).

Several histologic variants of schwannoma are recognized.[61] Some tumors have extensive degeneration with cyst formation, old hemorrhage, and marked hyalinization (ancient schwannoma). This may be accompanied by bizarre nuclear morphology that does not imply malignancy. Other schwannomas are cellular with few hypocellular areas and few palisades or Verocay bodies. These tumors have been called *cellular schwannomas*.[62] They may have significant mitotic activity but behave in a benign fashion. A rare and unusual variant is the melanotic schwannoma and contains concentrically lamellated microcalcifications called *psammoma bodies*. Although this psammomatous melanotic schwannoma only rarely involves the skin, it is noteworthy that roughly one-half the affected patients have Carney syndrome (myxomas, spotty hyperpigmentation, endocrine overactivities, and schwannomas)[52] and approximately 10% of cases metastasize.[63]

The plexiform schwannoma is a tumor that grows within a nerve, forming an agglomeration of small nodules and interconnected cords. Plexiform schwannomas have a distinct predilection for the dermis and subcutaneous tissue. The relationship between plexiform schwannoma and NF is somewhat ill defined, because of confusing nomenclature and because some authors do not distinguish between NF1 and NF2. Some solitary, and, especially, multiple plexiform schwannomas can be associated with NF2.[64,65]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of schwannomas includes lipoma, cyst, leiomyoma, and malignant peripheral nerve sheath tumor (MPNST).

TREATMENT. Malignant transformation of classic schwannomas is exceedingly rare but has been reported. Excision is the treatment of choice. Plexiform schwannomas may recur, but this probably reflects incomplete excision due to their multifocal nature rather than true recurrence. Pregnancy does not alter the natural history of schwannomas.[66]

NEUROFIBROMA

EPIDEMIOLOGY. Neurofibromas often occur as solitary lesions and are common in the general population. NF1 has a prevalence of 1 in 4,000.[67]

ETIOLOGY AND PATHOGENESIS. Neurofibromas are hyperplasias of all the nerves elements.[68] Neurofibromas can be seen as sporadic lesions or in the context of NF1, which is covered in detail in Chapter 141. The gene for NF1 is located on the long arm of chromosome 17 (17q11.2). At least one of the functions of the NF1 protein, neurofibromin, is regulation of the *ras* oncogene.[69–71] Although it has been shown that ablating NF1 in mice can lead to the development of neurofibromas,[72] the effects on the levels of *ras* are not consistent and, thus, other stromal or genetic effects must contribute to the development of neurofibromas.

CLINICAL FINDINGS. Cutaneous neurofibromas present as protuberant to pedunculated, flesh-colored, soft papules or nodules. They are usually asymptomatic, but they can be pruritic. Subcutaneous neurofibromas are usually larger than dermal lesions and consist of a fusiform swelling involving a larger nerve. In patients with NF1, the tumors start appearing in early childhood and may be quite variable in size. NF1 has a highly variable expressivity, even among patients from the same kindred who have identical germ-line mutations.[73] Another type of neurofibroma is the plexiform variant (Fig. 127-7), which involves an entire large nerve and its branches, forming a mass of tangled, rope-like structures that feel similar to a "bag of worms" on palpation and can be associated with massive soft-tissue overgrowth, leading to functional impairment.

Figure 127-7 Plexiform neurofibroma on the arm. The excoriations show the pruritus associated with these lesions. (Photo from the collection of Dr. Amy Paller, MD, Children's Memorial Hospital, Chicago, IL.)

HISTOPATHOLOGY. Histologically, a neurofibroma is composed of Schwann cells, fibroblasts, endothelial cells, perineurial fibroblasts, mast cells, and axons, all arranged haphazardly in a matrix that contains collagen and myxoid ground substance in various proportions. Dermal neurofibromas are circumscribed but unencapsulated nodules. A rare subtype of neurofibroma is the diffuse variant that involves the skin and subcutaneous tissue in a plaque-like fashion, surrounding rather than displacing preexisting structures such as skin appendages. Plexiform neurofibromas have the same histologic appearance as ordinary neurofibromas but involve an entire nerve and its branches; they also infiltrate the surrounding soft tissue. A variant with a very unusual histologic appearance has been described as *dendritic cell neurofibroma with pseudorosettes*.[74] Finally, some neurofibromas are melanotic.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of neurofibroma includes fibrolipoma, lipoma, and MPNST.

TREATMENT. Solitary dermal neurofibromas can be excised. Management of patients with NF1[75] is discussed in Chapter 141. Resection is currently the best treatment option for plexiform neurofibromas; however, the lesions frequently recur after resection. Recurrence is more commonly associated with a young patient age, incomplete tumor resection, or nonextremity tumor location.[76]

MALIGNANT TUMORS OF NERVE

MALIGNANT NERVE SHEATH TUMORS

MALIGNANT NERVE SHEATH TUMORS AT A GLANCE

- Malignant nerve sheath tumors are also known as neurofibrosarcoma, neurogenic sarcoma, neurosarcoma or malignant schwannoma.
- Two percent of nerve sheath tumors are malignant peripheral nerve sheath tumors (MPNSTs).
- Twenty percent to 70% of MPNSTs occur in neurofibromatosis type 1.
- Clinical presentation: nodules in the deep soft tissues.
- Treatment: surgical.
- Outcome: guarded, with 5-year survival rates of not more than 50%.

EPIDEMIOLOGY. Only 2% of nerve sheath tumors are MPNSTs.[91] Depending on the series, approximately 20%–70% of MPNSTs occur in patients with NF1.[71] Young and middle-aged adults are most commonly affected.

ETIOLOGY AND PATHOGENESIS. MPNST is also known as *neurofibrosarcoma*, *neurogenic sarcoma*, *neurosarcoma*, and *malignant schwannoma*, but because its histogenesis is uncertain, the noncommittal term *MPNST* is preferred. Plexiform neurofibromas and neurofibromas involving medium-sized to large nerves can undergo malignant degeneration into MPNSTs. Benign schwannomas and cutaneous neurofibromas, on the other hand, almost never undergo malignant transformation. There have been very few cases reported.[92]

CLINICAL FINDINGS. These neoplasms arise mostly in the deep, soft tissues as nodules. Primary cutaneous MPNSTs are rare.[93,94]

HISTOPATHOLOGY. MPNSTs often have a relatively nonspecific presentation of interlacing bundles of spindle cells. Most tumors consist of perineural or endoneural fibroblasts.[95] Often, the major reason for calling such a tumor MPNST is that it arises within a nerve or a neurofibroma and shows some immunoreactivity for S100 protein.[96] In addition to S100 staining, MPNSTs can also stain for neuron-specific enolase, neurofilament protein, and myelin basic protein, although staining can be very weak (see Table 127-1). Cytokeratin stains are negative. MPNSTs can contain heterologous components such as bone, cartilage, glandular or squamous epithelium, and skeletal muscle. An MPNST with a rhabdomyosarcomatous component is called a *malignant triton tumor* and stain positive for myoglobin. In some MPNSTs, the tumor cells have an epithelioid appearance, and this variant must be distinguished from melanoma.[97]

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of MPNSTs includes neurofibroma, lipoma, and cyst.

TREATMENT. MPNSTs in patients with NF are aggressive tumors with a tendency to recur and metastasize. Treatment is surgical. Outcome is guarded with reported 5-year survival rates of no more than 50% in spite of aggressive therapy.[71] Primary cutaneous MPNSTs may have a better prognosis.[93,94]

MISCELLANEOUS TUMORS

GRANULAR CELL TUMOR

GRANULAR CELL TUMOR AT A GLANCE

- S100 positive; suspected to be of neural crest origin.
- Most common single anatomic site: tongue.
- Forty-four percent occur in skin.
- Treatment: excision.

EPIDEMIOLOGY. GCTs are rare. The age range at presentation is usually from the second through the sixth decades.[103]

ETIOLOGY AND PATHOGENESIS. GCTs may also be referred to as *Abrikossoff tumors*. GCTs are neoplasms of uncertain histogenesis, but due to the S100 staining, current opinion favors neural crest origin.[104] The etiology is unknown, but they have been attributed to chronic trauma.[103]

CLINICAL FINDINGS. GCTs have been reported in many anatomic sites but are most often seen in the tongue and skin. The tongue is the most common single anatomic site reported; however, 44% of GCTs occurred in skin or subcutaneous tissue. GCTs have also been reported in the breast, genitalia, esophagus, and larynx.[103] Multiple GCTs are seen in approximately 10%–25% of affected patients.[104] Most cutaneous GCTs are asymptomatic papules or nodules smaller than 3 cm in diameter.

HISTOPATHOLOGY. The classical histologic picture is that of an ill-defined, dermal, nonencapsulated nodule composed of large, polyhedral cells that grow in a sheet-like fashion. The cells have distinct cell borders, small, round, central nuclei, and abundant granular cytoplasm (Fig. 127-8). The cytoplasmic granules stain strongly with the periodic acid-Schiff stain and retain this characteristic after diastase digestion. By immunohistochemistry, the granular cells are strongly positive for S100 protein (see Table 127-1). When differentiating from melanoma, HMB-45 expression is 100% specific for the diagnosis of melanoma. Rare cases of GCT show focal Melan-A positivity, similar to melanoma.[105] Ultrastructurally, the granules consist of phagolysosomes containing granular and membranous debris.[104] An unusual plexiform variant has been described.[106] Cutaneous and mucosal lesions typically have pseudoepitheliomatous hyperplasia of the overlying epithelium.

Only 1%–2% of GCTs are malignant.[104] Clinical findings that should raise concern are a size larger than

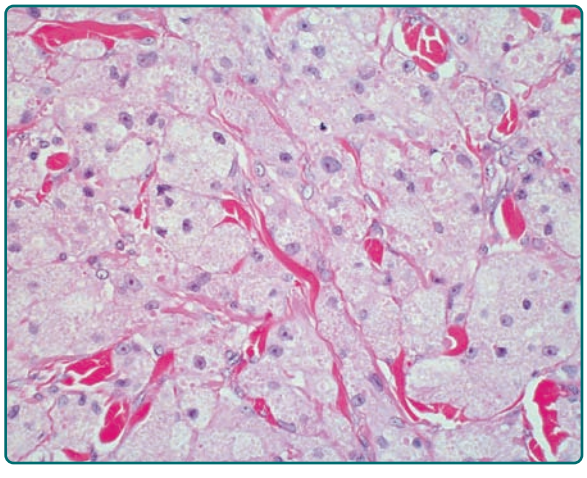

Figure 127-8 Histologic examination of granular cell tumor. The cells have distinct cell borders; small, round, central nuclei; and abundant granular cytoplasm. (Hematoxylin and eosin, ×400.)

4–5 cm, location in deep soft tissue, and recurrence. Histologic warning signs are the presence of increased cellularity, cytologic atypia, and especially mitotic figures and necrosis. However, some clinically malignant GCTs were small and/or histologically innocuous.[104] Therefore, the only definite proof of malignancy is metastasis. Other malignant cutaneous tumors that can contain a subpopulation of cells with granular cytoplasm, such as leiomyosarcoma, melanoma, or angiosarcoma have to be excluded pathologically.

DIFFERENTIAL DIAGNOSIS. Differential diagnosis of GCTs includes squamous cell carcinoma of the tongue, leiomyosarcoma, melanoma, and angiosarcoma.

TREATMENT. Excision is the treatment of choice.

NEUROGLIAL HETEROTOPIA

NEUROGLIAL HETEROTOPIA AT A GLANCE

- Rare congenital lesion commonly referred to as *nasal glioma*.
- Developmental anomaly consists of mature displaced neuroglial tissue; not a true neoplasm.
- Presentation: most commonly as round, firm papule on the nose.
- Rarely connected to intracranial cavity.

MENINGEAL HETEROTOPIA

MENINGEAL HETEROTOPIA AT A GLANCE

- Rare lesion characterized by meningothelial elements in skin.
- Occurs in children secondary to developmental defect; occurs in adults secondary to extension of intracranial meningioma.
- Can be connected to intracranial cavity.

CUTANEOUS GANGLIONEUROMA AND GANGLION CELL TUMOR

Ganglioneuromas are neoplasms composed of large mature neurons (ganglion cells) growing in a Schwann cell stroma. Pure ganglion cell tumors (or gangliocyto-mas) do not contain the Schwann cell component. Although they are usually seen as tumors of the autonomic nervous system, some very rare examples have been encountered in the skin or subcutis where they presented as small papules or nodules. Of the half dozen or so reported cases,[114,115] only one was congenital.[115] These lesions have to be distinguished from cutaneous metastases from a neuroblastoma, which can mature into ganglioneuroma. Furthermore, some plexiform neurofibromas in patients with NF arise in autonomic ganglia and can therefore contain residual, entrapped ganglion cells.[116]

Chapter 128 :: Kaposi's Sarcoma and Angiosarcoma

:: Erwin Tschachler

KAPOSI'S SARCOMA AT A GLANCE

- Multifocal tumor of endothelial cell origin with stage-dependent characteristic histopathology.
- Occurs in four clinical variants:
  1. Classical Kaposi's sarcoma (KS)—in old men; starts as localized form; progresses slowly.
  2. Endemic African KS—most frequent neoplasm in some Central African countries; also includes a rapidly progressive lymphadenopathic variant.
  3. KS associated with immunosuppressive therapy—most frequently in organ-transplant recipients.
  4. AIDS-related KS—rapidly progressive form in HIV-infected patients with early involvement of extracutaneous sites.
- KS development is invariably linked with human herpesvirus (HHV)-8 infection.
- Despite presumed viral pathogenesis, KS responds well to chemotherapy and radiation therapy.

GENERAL CONSIDERATIONS

In 1872, the Austro-Hungarian dermatologist Moriz Kaposi described five patients with multicentric cutaneous and extracutaneous neoplasm that primarily affected older individuals.[1] This disease, originally described as "idiopathic multiple pigment sarcoma," was later eponymously designated Kaposi's sarcoma (KS). Since then, different variants of this tumor have been described that have distinct epidemiologic features and run distinct clinical courses but show comparable histopathologies.

ETIOLOGY AND PATHOGENESIS

HHV-8 AND KAPOSI'S SARCOMA

Several decades of epidemiological data and electron microscopic studies have suggested an infectious agent as an etiologic factor in KS.[2,3] This suspicion was substantiated in 1994 when Chang and colleague discovered DNA of an unknown virus in KS lesions.[4] This finding led to cloning, isolation, and characterization of a novel human herpesvirus now referred to as KS-associated herpesvirus (KSHV) or alternatively, human herpesvirus (HHV)-8.[5,6]

HHV-8 is a member of the γ-Herpesviridae subfamily, genus Rhadinovirus.[5–9] Its 165-kb DNA genome has been entirely sequenced and shown to contain approximately 90 open reading frames.[5,7,8] Many of the HHV-8 regulatory genes are homologous to genes of other Rhadinoviruses, and several are homologous to human genes involved in the regulation of apoptosis, cell proliferation, and angiogenesis.[5,9,10] As with other herpesviruses, HHV-8 gene expression is tightly controlled and either associated with viral latency, such as LANA-1, V cyclin, and vFLIP, or lytic viral replication, such as vGPCR, vIL 6, and v-bcl-2.[5,10] Several HHV-8 gene products, both of the lytic and the latent viral life cycles, have been shown to transform cells in vitro as well as in animal models in vivo.[6,10–13] Therefore, it is generally accepted that this transforming capacity of HHV-8 plays a direct role in the development of KS.

The host range of HHV-8 in vivo and in vitro comprises vascular and lymphatic endothelial cells as well as different types of hemopoietic cells.[6] The widely expressed 12-transmembrane light chain of the human cystine/glutamate exchange transporter system xc and the C-type lectin DC-SIGN have recently been proposed as receptors of HHV-8.[14,15] The latter is of particular interest since in contrast to the former it is expressed by activated B cells, which are important host cells for HHV-8 in vivo.[6,15]

The routes of HHV-8 transmission are not yet completely known. The high incidence of KS in homosexual and bisexual patients and the association of tumor development with certain sexual practices originally suggested a role for the sexual transmission of the virus.[3] In later epidemiological studies, sexual activities were confirmed as a route for HHV-8 transmission, and it was demonstrated that the transmission risk increases with the number of sexual partners[16] and with certain practices such as oral/genital and oral/anal sex.[16] By contrast, in areas where the virus is widespread such as in Mediterranean countries and Africa, strong evidence exists that nonsexual transmission among family members[16,17] plays a major role. The oropharynx is the site of the most robust viral replication and high HHV-8 copy numbers are present in saliva.[18] On the basis of these findings, the nonsexual transmission via saliva is widely assumed to play the most important role in childhood transmission in endemic areas.[19] Vertical transmission from mother to child during pregnancy or birth seems not to play an important role for the spread of the virus.[16] For the medical profession, it is important to remember that HHV-8 may also be transmitted by blood and blood products as well as from donor organs in the course of transplantations.[16,20]

HHV-8 is present in all KS-variants,[21,22] and the evidence for a causal relationship between HHV-8 infection and KS tumor development is overwhelming. Amongst the most important arguments for the role of HHV-8 in KS pathogenesis are the findings that (1) the HHV-8 viral genome is detectable in KS lesions at all stages regardless of the clinical variant,[5,6,21,22] (2) within KS lesions HHV-8 is present in the latent form in virtually all tumor cells,[23,24] and (3) KS tumor cells show oligoclonal or monoclonal integration of viral DNA.[5,6] Furthermore, the prevalence of HHV-8 is largely congruent with that of KS: in areas of low incidence of KS, such as the United States and Northern Europe, HHV-8 infection is very rare (below 0.1%;[16,25] By contrast, in areas where high incidence of KS has been reported such as in southern Italy, HHV-8 prevalence is much higher and approaches 20%.[16,26] As expected the highest HHV-8 prevalence has been found in Central Africa in the regions known to be hot spots of African endemic KS. In this region, the seroprevalence in adults ranges from 22% to 71%.[16] Similarly, in HIV-1-infected patients in industrialized countries HHV-8 prevalence is highest in homosexual and bisexual men and reflects the incidence of KS in this risk group.[16,27]

The time span from infection with HHV-8 to development of KS depends on the clinical type. Immunosuppression/dysregulation plays an important aggravating role and leads to disease manifestation in organ-transplant recipients within 1–2 years and in HIV-1-infected patients 5–10 years after infection.[16] For classic KS, this time span is far longer and the contributions of either host-related or environmental factors are not yet established.[16]

In addition to KS, HHV-8 has been implicated in the pathogenesis of pleural effusion lymphoma, a rare B cell neoplasm seen primarily in AIDS patients, and multicentric Castleman's disease (MCD).[10,16,28,29] In the former HHV-8 is in variably present and diagnostic, in the latter it is found in the majority (>95%) of HIV-infected patients with MCD but only in about 40% of HIV-negative MCD patients.[10] Castleman's disease has been associated in the past also with classic KS.[30]

HISTOGENESIS

The histogenetic derivation of the KS tumor cells, i.e., the cells lining the irregular vascular-like spaces of early and angiomatous lesions and the cells composing the bundles and interlacing fascicles of solid tumors, has been the subject of intense research interest over the past two decades. The immunophenotype of these cells (i.e., vWF$^{+/-}$, PAL-E^{-}, CD31^{+}, CD34^{+}, VEGFR3^{+}) characterizes them as part of the lymphatic endothelial differentiation lineage.[31,32] The recent demonstration that HHV-8 replicates better in lymphatic than in blood vascular endothelial cells is a further argument for this assumption.[33] However, the finding that infection of blood vascular endothelial cells with HHV-8 leads to a phenotypic switch toward lymphatic endothelial cells[33,34] leaves the possibility open that an immature angioblast either resident in the skin or circulating and able to differentiate into both endothelial cell lineages is the initial precursor of KS tumor cells.[35]

Some discussion surrounds the question as to whether KS is a reactive proliferative disorder or a true malignant neoplasm. Analyses of the methylation pattern of the human androgen receptor gene by several investigators have shown that lesions with both clonal and polyclonal proliferations can be identified.[36,37] Similarly, studies of HHV-8 terminal repeat sequences have demonstrated both viral mono- and oligoclonality in KS lesions.[38,39] Taken together, these findings indicate that KS starts out as a polyclonal disease, i.e., as a reactive process, which with disease progression may develop into monoclonal tumors.

CLINICAL MANIFESTATIONS

CLASSIC KAPOSI'S SARCOMA

The typical patient with classic KS is a Caucasian male in his sixties with a Mediterranean or Jewish background. The tumors usually start on the skin as unilateral or bilateral bluish-red (hematoma-like) macules on the distal portions of the lower extremities. These lesions tend to progress only slowly both horizontally and vertically and develop into firm plaques (Fig. 128-1) and, subsequently, into nodules. During tumor progression, the color might change to brownish and the skin overlying the tumor becomes hyperkeratotic and, in particular on the lower extremities, might exulcerate. The tumor surroundings frequently show a pitting edema, which may evolve into fibrosis. Classic KS usually runs a rather prolonged benign course and patients may sometimes live with slowly progressive disease for decades.[40,41] After several years, progression (Fig. 128-2) and dissemination to other body sites

Figure 128-1 Classic variant. Plaques and papules localized on the dorsum of the foot, a site of predilection of classic KS.

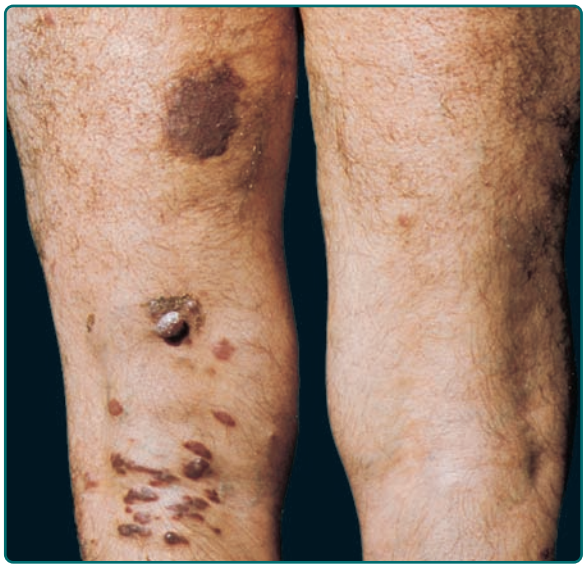

Figure 128-2 Tumor nodules of advanced classic KS with severe involvement of extremities.

are frequently seen, and tumors may become manifest in lymph nodes, on mucous membranes and in inner organs, in particular the gastrointestinal tract although it becomes rarely symptomatic.[40,41] Since mostly elderly patients are affected by KS, death from other causes may precede its full spread.

The annual incidence rates for classic KS vary greatly in different geographic regions and ranges from 0.14 per million inhabitants (for both women and men) in Great Britain to 10.5 per million in men and 2.7 per million in women in Italy.[40] A preponderance of male patients has persisted since the original description with a male:female ratio of about 3:1 noted in large surveys of most regions.[40,41] The higher KS incidence in countries surrounding the Mediterranean has led some authors to propose a Mediterranean KS variant as a distinct entity.[42] However, since the clinical course is comparable to the one of classical KS, Mediterranean KS will not be treated separately here.

AFRICAN ENDEMIC KAPOSI'S SARCOMA

An increased frequency of KS in black Africans in Central Africa was noted several decades before the outbreak of the AIDS pandemic.[43,44] In some countries of this region, KS accounts for up to 10% of all malignancies in men.[16,43,44] A prevalence of male patients, with ratios ranging from 3:1 in children and up to 18:1 in adults, is seen with endemic African KS.[40] The age at onset is lower than that in classical KS—around 35–39 years for males and 25–39 for females.[40]

According to clinical features, African endemic KS occurs as nodular-, florid-, infiltrative-, and lymphadenopathic-types.[45,46] The florid/vegetating and infiltrative variants are characterized by a more aggressive biologic behavior and lesions may extend deeply into the dermis, subcutis, muscle, and bone. Lymphadenopathic African KS predominantly affects children and young adults and may run fulminant courses with rapid progression[47]; skin and mucosa are affected to a lesser degree. The reasons for the different courses observed in African KS are not clear and potential cofactors have not unequivocally been identified.

KAPOSI'S SARCOMA IN THERAPEUTICALLY IMMUNOSUPPRESSED PATIENTS

During the 1970s, a high incidence of KS was described in organ-transplant recipients receiving immunosuppressive therapy with an up to 500-fold increase as compared to the control population.[48,49] Transplantation-associated KS is observed predominantly in kidney allograft recipients, while it occurs rarely in recipients of other solid organs and bone marrow allografts.[48–50] KS has also been reported in individual patients receiving immunosuppressive therapy for other reasons, most notably the treatment of autoimmune diseases.[51–53]

The clinical appearance and the course of KS in therapeutically immunosuppressed patients may be slowly progressive as with the classical variant. It can also rapidly disseminate as is the case with AIDS KS. KS can occur as early as 1 month and as late as more than 10 years after transplantation.[54] A very important risk factor for developing KS and determining its clinical course is the dose and type of the immunosuppressive drug.[40,50] For example, the risk associated with cyclosporine is higher than with other drugs such as glucocorticoids and azathioprine and the disease onset is earlier.[49,50] Regression of KS can be achieved by reduction or withdrawal of the immunosuppressive agent (see below). Similarly, rapid tumor progression can occur after increase of the dosage.[49,50] In transplantation-associated KS, a preponderance of male patients with a ratio of about 3:1 is observed,[50] and in geographic regions with a high incidence of classical KS as well as in ethnic groups with a higher risk of KS development, the risk for transplantation-associated KS is increased.[50] Skin involvement is most common in transplantation-associated KS. In a large series, skin involvement was found in more than 85% of the patients with transplantation-associated KS, whereas less than 15% had visceral (gastrointestinal, lungs, lymph nodes) disease without skin involvement.[50]

AIDS-ASSOCIATED KAPOSI'S SARCOMA

A major harbinger of the AIDS pandemic was clusters of young homosexual men suffering from KS identified in large US cities in 1981.[55] During the first decade of the AIDS pandemic, KS had been diagnosed as the AIDS defining disease in more than 20% of HIV-1-infected patients in Europe.[56] Despite a decline in recent years, KS is still the most frequent AIDS-associated tumor in homosexual patients. Other patient groups at risk for AIDS including intravenous drug users, hemophiliacs, blood-transfusion recipients, and children

born to HIV-positive mothers in industrialized countries are far less affected.[3,57] The situation is different in Africa where KS is the most frequent tumor arising in HIV-1-infected patients independently of their risk group and includes children suffering from AIDS.[58,59]

Clinically, AIDS KS differs from classical KS by its more rapid course and its rapid multifocal dissemination: early AIDS-KS lesions that appear as small oval violaceous macules develop rapidly into plaques and small nodules, which frequently are present at multiple locations at disease onset and have a tendency for rapid progression. In contrast to other variants of KS, the initial lesions in AIDS patients frequently develop on the face, especially on the nose, eyelids, ears, and on the trunk, where the lesions follow the relaxed skin tension lines (Fig. 128-3). If untreated, disseminated AIDS-KS lesions may coalesce to form large plaques involving large parts of the face, the trunk, or the extremities leading to functional impairment. The oral mucosa is frequently involved and represents the initial site of a 10%–15% of AIDS KS (Fig. 128-4). Involvement of the pharynx is not uncommon and may result in difficulty in eating, speaking, and breathing.[60]

The involvement of extracutaneous sites occurs more rapidly and more dramatically in patients with AIDS KS than those with classical KS. Besides the oral mucosa, KS lesions are most frequently found in the lymph nodes, the gastrointestinal tract, and the lungs.[61–63] Although gastrointestinal KS is usually found when cutaneous lesions are present, exclusive gastrointestinal involvement is possible as is noted in transplantation-associated KS. KS lesions have a predilection for the stomach and duodenum and can cause bleeding and ileus. Although visible by gastroscopy, such lesions are underdiagnosed histologically because they are located in the submucosa and may escape the biopsy forceps. Pulmonary KS can cause respiratory symptoms such as bronchospasm, coughing, and progressive respiratory insufficiency.[62] Bronchoscopy with transbronchial biopsy is most appropriate for the diagnosis of pulmonary KS.

Figure 128-3 AIDS-associated KS. Multiple lesions at all stages of development (macules, papules, nodules) are present on the trunk. Note that the lesions follow the skin relaxed tension lines.

Figure 128-4 KS lesions on the hard palate are typical manifestations of AIDS-associated KS.

The differential diagnosis of cutaneous KS depends on the clinical stage and hematoma, pseudo-Kaposi's sarcoma, melanoma, pyogenic granuloma, spindle cell hemangioendothelioma, arteriovenous malformations (pseudo-KS), severe statis dermatitis (pseudo-KS), bacillary angiomatosis, angiosarcoma, cavernous hemangioma, angiokeratoma, and nodal myofibromatoma. In the oral mucosal non-Hodgkin's lymphoma, squamous cell carcinoma, bacillary angiomatosis, and melanoma have to be considered (Table 128-1).

HISTOPATHOLOGY

The histopathology of KS is dependent on the stage of KS development[64–66]: early patch-like lesions exhibit rather discrete histopathologic changes, consisting mainly of a discrete increase in the number of dermal vessels, outlined by slightly irregular endothelial cells (Fig. 128-5). These vessels are parallel to the skin surface, which are frequently slightly irregular and may form bizarre slits and clefts mainly located on the superficial dermis. In the surrounding dermis, focal hemosiderin deposits and extravasated erythrocytes, as well as a moderate inflammatory infiltrate, can be found. Important differential diagnoses of this stage include lymphangioma and granulation tissue.

The pathology of KS plaques is more characteristic and reveals extensive vascular proliferation at all levels of the dermis with multiple dilated and angulated vascular spaces dissecting the collagen and leaving a spongy network of collagen tissue. A characteristic sign of KS papules is the presence of solid cords and

TABLE 128-1
Clinical Differential Diagnoses of Cutaneous and Mucosal Kaposi's Sarcoma

Most Likely
- Localized early disease
  - Hematoma
  - Bacillary angiomatosis
  - Well-differentiated angiosarcoma
- Advanced disease
  - Acroangiodermatitis (pseudo-Kaposi)
  - Bacillary angiomatosis
  - Pyogenic granuloma
- Oropharyngeal lesions
  - Non-Hodgkin's lymphoma
  - Squamous cell carcinoma
  - Bacillary angiomatosis

Consider
- Localized disease
  - Dermatofibroma
  - Melanoma
  - Dermatofibrosarcoma protuberans
  - Leiomyosarcoma
  - Kaposiform hemangioendothelioma (in children)
  - Blue rubber bleb nevus syndrome
- Advanced disease
  - Metastasing melanoma
  - Cutanous metastasis of internal malignancies and leukemias
  - Erythema elevatum et diutinum

Always Rule Out
- HIV-1 infection
- Non-HIV-1-related causes of immunosuppression

fascicles of spindle cells arranged between the jagged vascular channels. This biphasic angiomatous and solid tumor morphology changes to a clear-cut sarcomatous morphology with progression of the disease.

Nodular lesions consist predominantly of spindle cells arranged in bundles and interlacing fascicles and interspersed irregular slit-like vascular spaces without endothelial linings (Fig. 128-5). Advanced lesions may display pronounced pleomorphism, nuclear atypia, and mitotic figures. At the periphery of solid tumors, (lymph)angiomatous-like portions of KS with bizarre vascular lumina and intravascular and extravasated erythrocytes, as well as siderophages, may be preserved. Erythrocytes, which appear as eosinophilic globules, are trapped within the slits and clefts formed by the spindle cells, and occasionally erythrophagocytosis is observed. Like in all other stages of KS, a moderate inflammatory infiltrate consisting of lymphocytes, histiocytes, plasma cells, and, sporadically, neutrophils is regularly present.

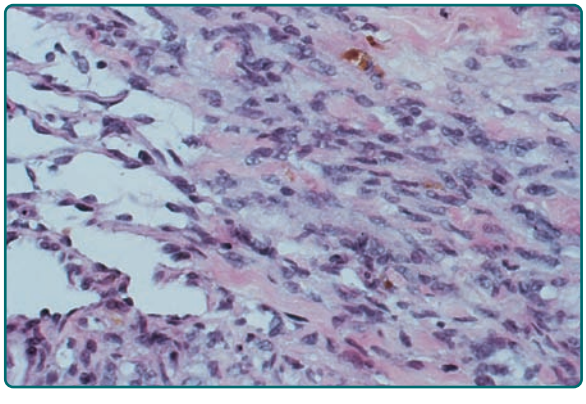

Figure 128-5 Histopathology of KS (biopsy taken from a nodular KS lesion). Angiomatous portions, reminiscent of a lymphangioma, as well as solid, sarcomatous fascicles are present.

TREATMENT

The treatment modalities for KS depend on the clinical type, the extent of the lesions, and on which organ system is involved (Table 128-2). Despite the overwhelming evidence that the infection with an oncogenic herpesvirus, i.e., HHV-8 plays a central role in KS pathogenesis, antiherpetic drugs so far have been only of experimental value.[67] Because in past decades the incidence of AIDS KS has been much higher than that of the other clinical variants and KS in AIDS patients quickly progresses into a life-threatening disease, studies on AIDS KS have brought about many of the recent insights and advances in the treatment of KS.[68,69]

TABLE 128-2
Treatment Options for Kaposi's Sarcoma

Localized Disease—Local Therapy
- Surgical excision
- Cryotherapy
- Topical 9-*cis*-retinoic acid
- Radiation therapy

Disseminated Disease/Internal Organ Involvement—Systemic Therapy
- For patients with AIDS: initiate highly active antiretroviral therapy (HAART)
- For patients on immunosuppressive therapy—reevaluate drug regimen
- For AIDS patients not responding to HAART alone—systemic cytotoxic chemotherapy
  - Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2 every 2–4 weeks)
  - Paclitaxel (100 mg/m^2 given every 2 weeks)
- For patients with classical KS
  - Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2 every 2–4 weeks)
  - Vinblastine (6 mg IV once a week)
  - Doxorubicin/bleomycin/vincristine (20–30 mg/m^2, or 10 mg/m^2, or 1–2 mg every 2–4 weeks)
  - Interferon-α (3–30 million units daily three times a week)
- Investigational treatments
  - Thalidomide
  - VEGF-antisense
  - COL-3 (MMP inhibitor)

LOCALIZED CUTANEOUS DISEASE

Regardless of the clinical variant, if a patient presents with only limited disease confined to the skin, local therapies aimed at eliminating individual lesions are frequently used as initial treatment.[68,69] Although recurrence rates are high, local therapies might be satisfactory for several years in slowly progressing classical KS. By contrast, in the other clinical variants it is imperative that local therapy is supported by additional measures such as change of the immune suppressive therapy in transplantation-associated KS and initiation of highly active antiretroviral therapy (HAART) in patients with AIDS KS.

Local therapies include surgical excision,[70] local destruction with liquid nitrogen, laser or photodynamic therapy,[71] and topical therapy with 9-*cis*-retinoic acid.[72] Radiation therapy[73] may be effective in localized disease at body sites that are otherwise difficult to reach, such as the oral mucosa and in more advanced KS in resource-poor settings.

PROGRESSIVE CUTANEOUS DISEASES AND INVOLVEMENT OF OTHER ORGANS

AIDS-ASSOCIATED KAPOSI'S SARCOMA. Until the advent of HAART, treatment of advanced AIDS KS has been mostly palliative with either combination chemotherapies or radiation therapy.[74] When HAART became available during the mid 1990s, it was possible for the first time to achieve sustained suppression of HIV-1 replication and immune recovery. Subsequent to the introduction of HAART, a decrease of AIDS KS incidence and frequent remission of early KS lesions were observed during therapy.[75] However, HAART alone is not sufficient to control advanced KS. Therefore, if widespread lesions and/or involvement of other organs develop despite successful HAART and the control of HIV-1 replication, addition of chemotherapy is required.[76] Amongst several chemotherapeutic regimens used in the past decades, liposomal anthracyclines have been shown to be more efficient and better tolerated than combination therapies such as bleomycin combined with vincristine or both combined also with doxorubicin.[77–79] A typical drug regimen consists of 20 mg/m^2 liposomal anthracyclines given intraveneously every 2–4 weeks.[80,81] An advantage of the use of liposomal anthracyclines is their continued therapeutic efficacy in patients who have been previously treated by other forms of chemotherapy. For patients with anthracycline-refractory AIDS KS paclitaxel is another treatment option.[82] Interferon-α, which has been a mainstay therapeutic approach for AIDS KS during the 1980s and early 1990s, still holds some promise for AIDS patients with early disseminated KS who simultaneously receive HAART.

KAPOSI'S SARCOMA IN PATIENTS WITH THERAPEUTIC IMMUNOSUPPRESSION. KS in transplant patients responds well to a reduction of immunosuppressive therapy.[49,50] Recently, replacement of calcineurin inhibitors by rapamycin has led to dramatic therapeutic effects with complete remission of advanced KS lesions.[83,84] This effect seems to be due to the modulation of the immune response by the change of therapy and to direct antitumor effects of the drug.[84] Therefore, rapamycin might potentially be of benefit for treating KS in nonimmunosuppressed persons.

CLASSIC KAPOSI'S SARCOMA. Chemotherapy, including doxorubicin, bleomycin, vincristine, etoposide, and dacarbazine, alone or in combination has been given to patients with rapidly progressive or widespread classic KS, in particular, when there is involvement of internal organs.[85] However, due to the low incidence of classic KS, large comparative, prospective studies are not available. As with AIDS KS, liposomal anthracyclines are efficient[86] and appears to be superior to low-dose interferon-α.[87]

In addition to the therapies mentioned above, there are several experimental therapies currently being evaluated in clinical trials ranging from vascular endothelial growth factor (VEGF) antisense to antiherpetic drugs.[67]

ANGIOSARCOMA

ANGIOSARCOMA AT A GLANCE

- Malignant tumor of endothelial cell origin.
- Occurs in three clinical variants:
  1. Primary angiosarcoma (mostly affects elderly with a predilection for head, neck, and face).
  2. Angiosarcoma in areas of chronic lymphedema (most frequently in patients after lymph node dissection due to mammary carcinoma—Stewart–Treves syndrome).
  3. Postirradiation angiosarcoma.
- Despite complete surgical excision and/or chemotherapies, the prognosis of angiosarcoma is poor.

EPIDEMIOLOGY AND PATHOGENESIS

Angiosarcoma is a highly malignant vascular tumor with an incidence of approximately 0.01/100,000/year affecting primarily adult patients.[88] It may occur in different organs, but in over 50% of the patients the cancer localizes to the skin of the head and neck region.[89,90] Besides primary tumors, which appear in previously normal skin, angiosarcoma has an increased incidence in skin with chronic lymphedema most frequently, but not exclusively, after mastectomy with lymph node

dissection. This variant is referred to as Stewart–Treves syndrome[91] and was formerly classified as lymphangiosarcoma. A further rare variation is postirradiation angiosarcoma, which may develop after radiation therapy for mammary carcinoma.[92]

Tumor cells of angiosarcoma express differentiation markers of both the lymphatic and vascular endothelial cell lineage to varying degrees.[93] Whether common precursor cells, i.e., angioblasts give rise to the tumor cells has not been determined. Therefore, the designation of angiosarcoma instead of either lymphangiosarcoma or hemangiosarcoma seems appropriate at this time. In contrast to KS, angiosarcoma is usually negative for HHV-8.

CLINICAL MANIFESTATIONS

Initially, primary angiosarcoma of the skin presents as singular or multifocal "bruise"-like patches on the skin, most frequently on the face (Fig. 128-6), the scalp, or the neck regions. Upon progression, the lesions become violaceous, ill-defined spongy nodular tumors that bleed easily. Horizontal spread can lead to the involvement of large skin areas (Fig. 128-7). Angiosarcoma that develops in chronic lymphedema (Fig. 128-8) as well as postirradiation angiosarcoma (Fig. 128-9) present as infiltrating hemorrhagic plaques or violaceous nodules.

DIFFERENTIAL DIAGNOSES

Early lesions can be confused with other skin lesions, which have vascular involvement including bruises, rosacea, and early KS. For advanced tumors, pyogenic granuloma, lymphoma, and cutaneous metastasis of internal malignancies have to be considered.

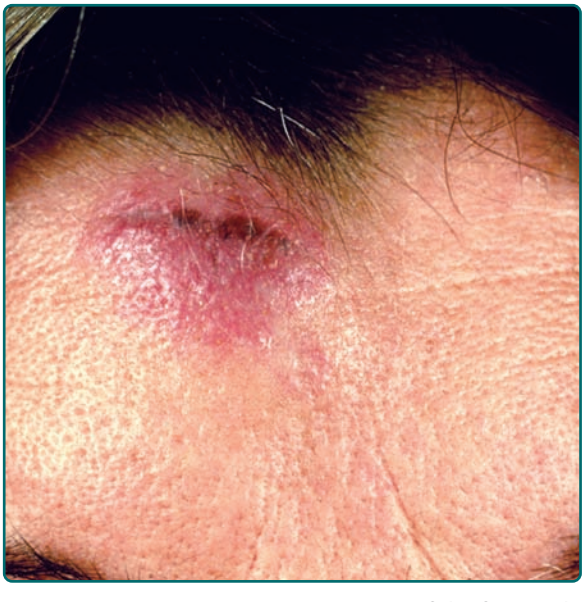

Figure 128-6 Cutaneous angiosarcoma of the face. Early bruise-like lesions on the forehead.

Figure 128-7 Cutaneous angiosarcoma of the head. Advanced lesion presenting as violaceous patch extending over the right forehead, ear, and scalp regions.

HISTOPATHOLOGY

The clinical variants are indistinguishable histologically and great variability with regard to differentiation of vascular elements can be seen even within individual lesions. Irregular, anastomosing vascular channels lined by endothelial cells with different degrees of atypia and mitotic activity may alternate with areas of closely packed cells with a high mitotic index and sometimes spindle-like morphology (Fig. 128-10). In the latter, less well-differentiated areas, little or no luminal differentiation is present. In particular, in these instances immunostaining for vascular markers, such as CD31 and CD34, is helpful for the establishment of the diagnosis.

Figure 128-8 Stewart–Treves syndrome on the right forearm and hand.

Figure 128-9 Postirradiation angiosarcoma of the breast.

TREATMENT

The overall estimated 5-year survival is 15%, reflecting the fact that the treatment of angiosarcoma[90,94] is currently not highly effective. Due to the rarity of angiosarcoma, comparative therapeutic trials are not available. The treatment of choice for small tumors is excision with wide margins.[94] When surgery is not an option, palliative radiotherapy or chemotherapy should be applied.[94–97] Both pegylated liposomal doxorubicin and paclitaxel were recently demonstrated to be of benefit for patients with widespread disease.[95–98] Recently, the tyrosine protein inhibitor sorafenib has also shown promise either alone[99] or together with paclitaxel[100]; however, larger clinical studies are necessary to confirm the benefit.

Chapter 129 :: Neoplasms of Subcutaneous Fat

:: Thomas Brenn

NEOPLASMS OF SUBCUTANEOUS FAT AT A GLANCE

- Adipocyte tumors are the most frequently encountered group of mesenchymal neoplasms. This is due to the high prevalence of lipoma and angiolipoma.
- Tumors range from entirely benign neoplasms (e.g., lipomas) to those of intermediate malignant potential with risk for local recurrence (e.g., atypical lipomatous tumor) to high-grade pleomorphic sarcomas (e.g., pleomorphic liposarcoma).
- Although liposarcoma is the single most frequently encountered sarcoma, the large majority of adipocyte tumors are benign.
- The clinical presentation of adipocyte tumors is generally nonspecific.
- Most adipocyte tumors show distinctive cytogenetic abnormalities that may be of diagnostic value.
- Treatment is surgical excision. Adjuvant radiation therapy and/or chemotherapy may be of benefit for treatment of malignant tumors that are not amenable to complete excision or in cases of advanced disease.

LIPOMA

LIPOMA AT A GLANCE

- Lipoma is the most common soft-tissue tumor.
- It is benign and presents in adulthood as a small circumscribed mass. The anatomic distribution is wide with relative sparing of the head, hands, and feet.
- Histologically, the tumors are circumscribed, encapsulated, and composed of mature white adipose tissue.

EPIDEMIOLOGY

Lipomas are the most common soft-tissue neoplasm. Although they affect individuals in a wide age range, they occur predominantly in adults between the ages of 40 and 60 years; presentation in childhood is rare. There is no gender predilection. Lipomas are multiple in approximately 5% of cases.[1]

ETIOLOGY AND PATHOGENESIS

The majority of lipomas (approximately 75%) show karyotypic abnormalities. The cytogenetic findings are heterogeneous, but rearrangements of 12q13–15 are most common.[2–4] Other affected loci are on chromosomes 6 and 13.[2–4] Numerical abnormalities are scarce, and most tumors are diploid.

CLINICAL FINDINGS

The most common presentation is as a painless, slowly enlarging mass involving the subcutaneous tissue of the trunk, neck, or proximal extremities. Involvement of the head, hands, and feet is uncommon. These superficial lipomas are typically small, measuring less than 5 cm.[1] Lipomas may be multiple and familial and show a predilection for the arms and thighs in familial multiple lipomatosis (Fig. 129-1).[5] The constellation of multiple lipomas, macrocephaly, lymphangiomas, and hemangiomas is known as *Bannayan (Bannayan–Zonana)* syndrome.[6,7] This autosomal dominant disease shares features with other independently described entities and is currently also referred to as *Bannayan–Riley–Ruvalcaba syndrome*.[8,9] Further clinical findings include intestinal polyposis, genital pigmented macules, and other hamartomas. The syndrome is caused by mutations in the *PTEN* gene and belongs to the larger family of PTEN hamartoma-tumor syndromes,

Figure 129-1 Familial multiple lipomatosis: multiple lipomas of variable size show a symmetric distribution involving the forearms of this middle-aged man.

including Cowden disease.[10–15] Lipomas may also be seen as a manifestation of Gardner's syndrome. Gardner's syndrome is part of the spectrum of familial adenomatous polyposis and includes extracolonic manifestations such as desmoid fibromatosis, osteomas, cysts, and lipomas.

Less frequently, lipomas may be deep-seated and grow to sizes larger than 5 cm. They can affect a variety of anatomic locations, including the surface of bone (parosteal lipoma) and skeletal muscle (intramuscular and intermuscular lipoma). Intramuscular lipoma arises within skeletal muscle and may be circumscribed or infiltrative. It presents in adulthood and only rarely affects children. The range of anatomic sites is wide, but there appears to be a predilection for the trunk.[16,17] In contrast, intermuscular lipoma develops between individual muscles and does not infiltrate skeletal muscle bundles. It is a rare lipomatous tumor with a predilection for the anterior abdominal wall.[16,17] Lipomas of the forehead are frequently deep-seated, presenting in a submuscular or subgaleal location. They show a predilection for male adults.[18,19] Lipoma arising in the orbit (orbital lipoma) is rare but may lead to exophthalmus and visual disturbances.[20–22]

HISTOLOGIC FEATURES

Conventional lipomas are circumscribed masses surrounded by a thin fibrous capsule. They are composed of lobules of mature white adipose tissue divided by delicate and inconspicuous fibrous septa containing thin-walled capillary-sized vessels (Fig. 129-2). The adipocytes are univacuolated and mature with eccentrically placed, compressed nuclei. There is only slight variation in adipocyte size, and nuclear atypia is not a feature. Morphologically, lipomas are indistinguishable from the surrounding adipose tissue and the identification of a distinct mass is necessary for the diagnosis. Lipomas may show changes of trauma with varying amounts of fat necrosis and inflammation. Extensive involvement of the dermis is known as *dermal lipoma*. These tumors are not encapsulated and

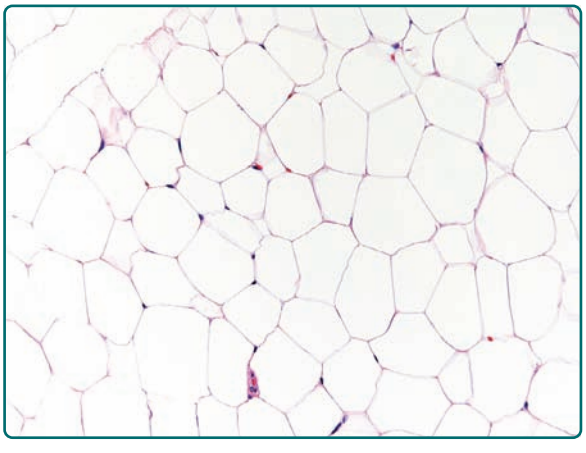

Figure 129-2 Lipoma: mature univacuolated adipocytes show only mild variation in size. Delicate intervening capillaries are present.

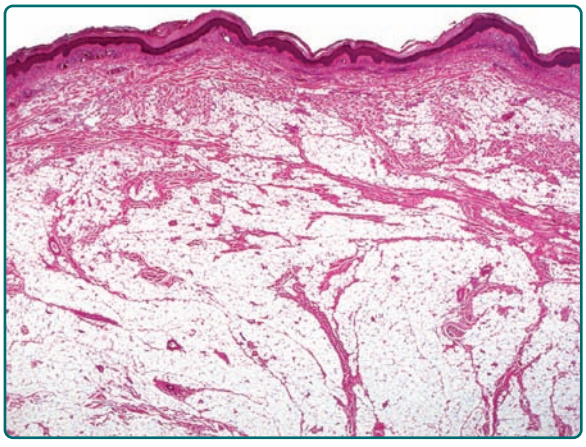

Figure 129-3 Intradermal lipoma: mature adipocytes diffusely infiltrate preexisting dermal collagen bundles. Note the sparing of the papillary dermis.

are frequently less circumscribed than other forms of superficial lipoma (Fig. 129-3). Lipomas with increased fibrous tissue are referred to as *fibrolipomas* (Fig. 129-4). In contrast to atypical lipomatous tumors, cellularity is low within the fibrous strands, and no nuclear atypia is present. *Myxolipomas* are characterized by the presence of conspicuous myxoid stroma. *Angiomyxolipoma* or vascular myxolipoma is characterized by a myxoid stromal background in addition to a proliferation of vessels of variable sizes.[23,24] A lipoma containing metaplastic bone or cartilage within the tumor is referred to as an *osteolipoma* or *chondrolipoma*, respectively. Cutaneous adenolipoma refers to the presence of intratumoral sweat ducts and sweat glands may be cystically dilated.[25,26]

Intramuscular lipoma can either present as a circumscribed intramuscular mass or show an infiltrative growth of adipocytes in between skeletal muscle fibers (Fig. 129-5).

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

Lipomas are entirely benign tumors and, with the exception of intramuscular lipomas, local recurrence is rare. The infiltrative variant of intramuscular lipoma is associated with an approximately 19% chance of local recurrence, but metastasis does not occur.[16]

LIPOMATOSIS

LIPOMATOSIS AT A GLANCE

- Lipomatosis is characterized by diffuse overgrowth of adipose tissue infiltrating through preexisting structures.
- Different clinical presentations are recognized.

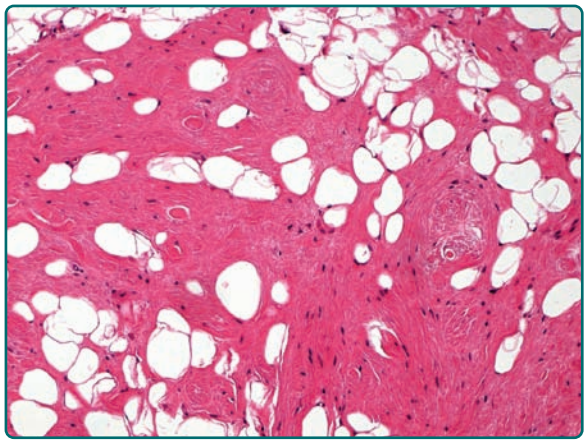

Figure 129-4 Fibrolipoma: this variant is characterized by the presence of increased fibrous tissue within a lipoma. The expanded fibrous bands contain bland appearing and uniform spindle cells. Cytological atypia is not a feature.

EPIDEMIOLOGY AND CLINICAL FINDINGS

Diffuse lipomatosis [27,28] is characterized by overgrowth of adipose tissue involving subcutaneous tissue and skeletal muscle of the trunk and extremities. Osseous involvement may also be a feature. Young children are predominantly affected, but presentation may become apparent in adulthood. Tumors can grow to a large size, causing disfigurement and loss of function of the affected limb. Due to the diffuse growth of these tumors, complete excision may not be possible and recurrences are frequent.

Benign symmetric lipomatosis (Madelung's disease, multiple symmetric lipomatosis)[29–36] is characterized by multiple symmetric masses composed of nonencapsulated adipose tissue with a predilection for the subcutaneous tissue and skeletal muscle of the neck, shoulder, and proximal upper limbs (Fig. 129-6). Presentation is in adulthood with a marked male predominance of 15:1. The estimated overall incidence is 1 in 25,000, with increased frequency in the Mediterranean region. The disease is associated with increased alcohol intake in the majority of cases. Two clinical variants are currently recognized. Type 1 disease is characterized by a symmetric distribution of adipose tissue, giving rise to a "pseudoathletic" appearance, whereas type 2 disease shows a more diffuse distribution, giving rise to a picture of more generalized obesity. An associated polyneuropathy affecting sensory, motor, and autonomic function is frequently present. The disease course is slowly progressive, and treatment is difficult due to infiltration of deep-seated structures and major nerves and vessels. There is significant disease-related mortality due to compression of vital structures as well as autonomic neuropathy with sudden cardiac death. Etiologically, the disease has been speculated to be a result of hypertrophy of brown fat due to a defect in adrenergic lipolysis.

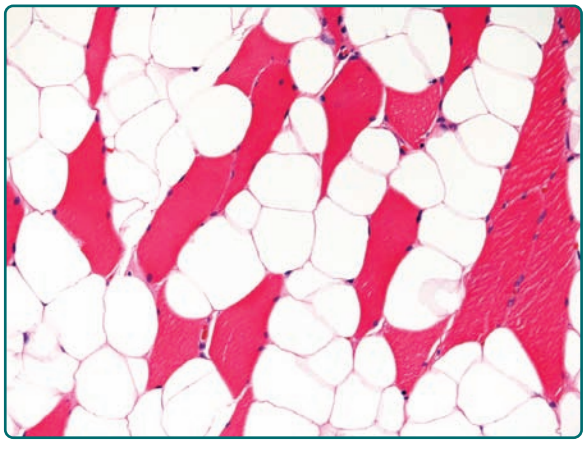

Figure 129-5 Intramuscular lipoma: mature adipocytes show an infiltrative growth pattern within skeletal muscle splaying apart individual muscle fibers.

Figure 129-6 Symmetric lipomatosis: there is diffuse and symmetric overgrowth of adipose tissue affecting predominantly the upper trunk, neck, and proximal arms.

Pelvic lipomatosis[37–40] is an unusual proliferation of adipose tissue involving the pelvis and retroperitoneal space. The disorder is most common among men in the third and fourth decades, and blacks account for about two-thirds of cases. Urinary symptoms are frequent presenting signs, and the disease is associated with cystitis in 75% of cases. Obstructive uropathy and renal failure may be complications of the disease.

Adiposis dolorosa (Dercum's disease)[41–48] is rare and typically affects middle-aged women, although men may occasionally also be affected. The disease is typically sporadic, and familial cases are exceptional. There is an increased incidence with obesity. Patients present with multiple painful subcutaneous lipomatous lesions frequently associated with other symptoms such as weakness, depression, confusion, lethargy, or dementia. The disease predominantly involves the arms and trunk but may be progressive to involve

large parts of the body. Treatment modalities include pain relief as well as surgical control with excision or liposuction. Weight reduction can be beneficial.

Human immunodeficiency virus lipodystrophy[49–53] occurs in the setting of protease inhibitor treatment or other forms of antiretroviral therapy in patients with acquired immunodeficiency syndrome (see Chapter 198). There is a predilection for cervical fat pads, the breast, and visceral fat. Other associations include hyperlipidemia, insulin resistance, type 2 diabetes, and fat wasting affecting the face and limbs.

HISTOLOGIC FEATURES

The histologic features of all forms of lipomatosis are similar and show unencapsulated adipose tissue diffusely infiltrating preexisting structures such as skeletal muscle.

LIPOMATOSIS OF NERVE (FIBROLIPOMATOUS HAMARTOMA OF NERVE)

LIPOMATOSIS OF NERVE (FIBROLIPOMATOUS HAMARTOMA OF NERVE) AT A GLANCE

- Lipomatosis of nerve is a rare tumor that affects infants and children and presents as a growing mass with a predilection for the hand.
- Pathology shows a proliferation of adipose and fibrous tissue within the epineurium and perineurium. The median nerve is predominantly affected.

NEVUS LIPOMATOSUS SUPERFICIALIS

NEVUS LIPOMATOSUS SUPERFICIALIS AT A GLANCE

- Nevus lipomatosus superficialis is a rare entity that affects children and young adults.
- Papules and plaques show a predilection for the buttocks, lumbar back, and posterior thighs.
- Bands of mature adipose tissue infiltrate dermal collagen.

ANGIOLIPOMA

ANGIOLIPOMA AT A GLANCE

- Angiolipoma is a relatively common lesion that presents as a small nodule with a predilection for the forearm.
- Young adults are affected, and lesions are frequently multiple and painful.
- Histologically, this circumscribed lesion shows an admixture of mature adipose tissue and a proliferation of capillary-sized vessels.

EPIDEMIOLOGY

Subcutaneous angiolipomas are relatively frequent and typically occur in young adults in their teens and 20s, with a strong male predilection.[72–74] They are rare in children and in the elderly.

ETIOLOGY AND PATHOGENESIS

Angiolipomas have traditionally been classified as adipocyte tumors. However, in contrast to most lipomas they appear to have a consistently normal karyotype, and it has been suggested that they may be reactive or hamartomatous rather than neoplastic.[74] The fact that angiolipomas can occasionally be almost exclusively composed of blood vessels (cellular angiolipoma) has led to the speculation that they may in fact be hemangiomas rather than lipomas.[74] There is an increased familial incidence, but no inheritance pattern has been elucidated as yet.[75]

CLINICAL FINDINGS

A wide range of sites can be affected, but there is a predilection for the forearm followed by the trunk, upper arm, and legs.[72–74] Angiolipomas are often multiple and present as subcutaneous nodules characteristically smaller than 2 cm. Tenderness and pain are frequently associated symptoms.

HISTOLOGIC FEATURES

Angiolipomas are circumscribed and encapsulated. They show an admixture of mature fat and capillary-sized small branching vessels in varying proportions (Fig. 129-7 and eFig. 129-7.1 in online edition). The vascular density is often increased at the periphery in a subcapsular distribution. Fibrin thrombi are typically encountered. The term *cellular angiolipoma* is applied to

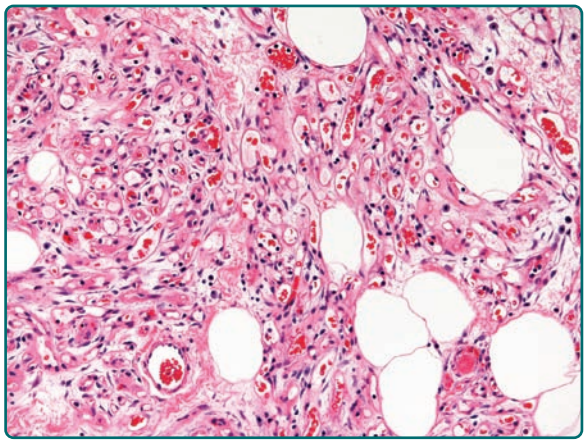

Figure 129-7 Angiolipoma: a proliferation of capillary-sized vessels is admixed with mature adipose tissue.

those lesions that are almost exclusively composed of vascular elements (eFig. 129-7.2 in online edition).[76–78]

DIFFERENTIAL DIAGNOSIS

The appearances of angiolipoma are quite characteristic. The differential diagnosis of cellular angiolipoma includes vascular tumors such as Kaposi sarcoma, spindle cell hemangioma, and angiosarcoma.

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

The clinical behavior of angiolipomas is entirely benign. The tumors are frequently multiple as well as painful, however, and clinical management can be a challenge.

SPINDLE CELL AND PLEOMORPHIC LIPOMA

SPINDLE CELL AND PLEOMORPHIC LIPOMA AT A GLANCE

- Spindle cell lipoma and pleomorphic lipoma are currently considered to represent a morphologic continuum.
- They typically occur on the posterior neck, upper back, and shoulder of middle-aged men.
- Morphologically characteristic is the admixture of mature fat with bland and uniform spindle cells in a myxoid stroma containing ropey collagen bundles and mast cells. Multinucleate (floret-type) giant cells are present in pleomorphic lipoma.

HIBERNOMA

HIBERNOMA AT A GLANCE

- Hibernoma is a benign neoplasm that resembles brown fat and typically presents in adulthood.
- A wide range of anatomic locations may be affected.

EPIDEMIOLOGY

Hibernoma is a well recognized but rare benign adipocyte tumor that shows a wide age distribution. Young adults (mean age, 38 years) are predominantly affected, but presentation in the pediatric population as well as in the elderly is possible. Males appear to be affected only slightly more frequently than females.[107]

ETIOLOGY AND PATHOGENESIS

The etiology of this rare tumor is unclear. Karyotypes can be slightly more complex than those observed in other benign lipomatous tumors, but structural rearrangements involving chromosome band 11q13 appear to be reproducible.[108–111]

CLINICAL FINDINGS

Hibernoma is a painless, slowly enlarging tumor affecting a wide range of anatomic sites. There appears to be a predilection for areas in which brown fat can be found physiologically, and presentation on the trunk, especially the scapular area, the shoulder, and the head and neck is common. However, curiously the thigh appears to be the single most frequently affected site.[107] Hibernomas are typically located in subcutaneous tissue or skeletal muscle but may occasionally affect the abdominal cavity, retroperitoneum, or intrathoracic location.[112]

Presentation as multiple separate lesions is exceptional.[113] The average size is around 10 cm, but larger tumors up to 24 cm are not unusual.[107] Imaging studies reveal a well-demarcated lobulated and septated mass showing contrast enhancement and tissue attenuation intermediate between those of fat and skeletal muscle.[114–117]

HISTOLOGIC FEATURES

Hibernoma is a well-demarcated and lobulated neoplasm. The hallmark feature is its morphologic resemblance to brown fat. The tumors are composed of variable numbers of multivacuolated adipocytes with small, centrally placed nuclei and pale to eosinophilic and granular cytoplasm (eFig. 129-7.13 in online edition). On the basis of the appearance of these brown fat cells, the quality of

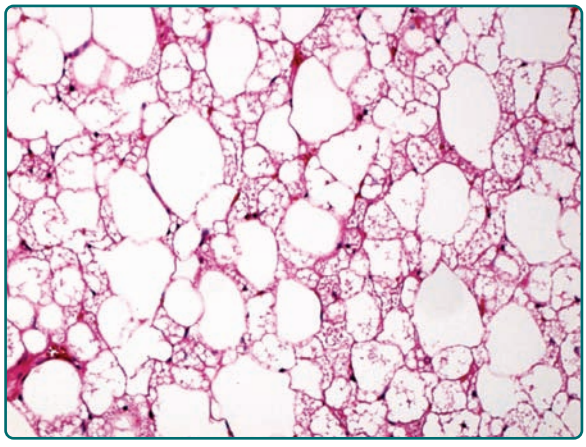

Figure 129-8 Hibernoma: brown fat is admixed with mature adipose tissue.

intervening stroma, and the presence of a spindle cell component, six histologic variants are recognized.[107]

The typical variant is the most frequently encountered form and is characterized by large numbers of brown fat cells admixed with mature white fat (Fig. 129-8). Those tumors composed almost exclusively of brown fat cells with palely staining cytoplasm are further subclassified as the *pale cell subtype*. Tumors are labeled *eosinophilic subtype* when at least 50% of brown fat cells contain a deeply eosinophilic and granular cytoplasm. The *mixed subtype* is intermediate between the two and shows a roughly equal distribution of eosinophilic and pale-staining brown fat cells. Myxoid, lipoma-like, and spindle cell variants exist.

Hibernomas showing acellular myxoid areas of the intervening stroma are recognized as the myxoid variant. This variant affects predominantly men and presents in the head and neck and shoulder area.

The lipoma-like variant shows large areas of white fat differentiation with only scattered hibernoma cells lying in between.

The least frequent is the spindle cell variant, showing overlapping features of spindle cell lipoma and hibernoma. Areas of brown fat are admixed with the short and bland spindle cells typical of spindle cell lipoma, and ropey collagen bundles, myxoid stroma, mast cells, and mature white fat are also present. As with spindle cell lipoma, this variant presents in the posterior neck and scalp.

By immunohistochemical analysis, hibernomas stain positively for S100. CD34 expression is seen in the spindle cells of the spindle cell variant of hibernoma.[107]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hibernoma includes the following:

- Granular cell tumor
- Spindle cell lipoma
- Atypical lipomatous tumor/well-differentiated liposarcoma

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

The behavior of hibernoma is entirely benign without recurrence after local excision.

LIPOBLASTOMA/ LIPOBLASTOMATOSIS

LIPOBLASTOMA/ LIPOBLASTOMATOSIS AT A GLANCE

- Morphologically, the benign adipocyte neoplasm lipoblastoma resembles fetal adipose tissue. It is most frequently found in individuals younger than 5 years of age.
- Lipoblastoma has a multilobular and circumscribed appearance, whereas lipoblastomatosis shows an infiltrative growth.

ATYPICAL LIPOMATOUS TUMOR/WELL-DIFFERENTIATED LIPOSARCOMA

ATYPICAL LIPOMATOUS TUMOR/WELL-DIFFERENTIATED LIPOSARCOMA AT A GLANCE

- Atypical lipomatous tumor/well-differentiated liposarcoma is a tumor of adulthood that presents as an enlarging mass with a predilection for the extremities, retroperitoneum, and paratesticular tissue.
- Best prognostic predictor is anatomic location:
  - Recurrence, risk of dedifferentiation, and mortality negligible if excised.
  - Retroperitoneum and paratesticular region, where complete excision is difficult, characterized by high long-term mortality.
  - When excision is curative, tumors are called atypical lipomatous tumors; when clear margins cannot be obtained should be regarded as *well-differentiated liposarcoma*.

EPIDEMIOLOGY

Atypical lipomatous tumor/well-differentiated liposarcoma is a neoplasm of adulthood with a peak incidence in the sixth decade.[145–153] It represents the largest subgroup of liposarcomas. There is no gender predilection.

ETIOLOGY AND PATHOGENESIS

Cytogenetically, atypical lipomatous tumors are characterized by supernumerary circular "ring" chromosomes as well as giant long marker chromosomes derived from the 12q13–15 region and resulting in consistent amplification of the *MDM2* gene along with adjacent genes such as *CDK4*.[154–160]

CLINICAL FINDINGS

Tumors typically present in deep soft tissue. The subcutaneous tissue may occasionally also be involved. The predominantly affected site is the musculature of extremities with a predilection for the thigh, followed by the retroperitoneum, groin, and paratesticular area as well as the mediastinum.[145–153] A wide range of other anatomic sites including the larynx, orbit, oral cavity, and vulva may be affected.[161–164] An enlarging painless mass is the typical presenting sign, and especially in a retroperitoneal location, tumors can grow to a very large size before becoming symptomatic.

HISTOLOGIC FEATURES

Atypical lipomatous tumors are large, multilobulated, and most often circumscribed. The most frequently observed adipocytic (lipoma-like) morphologic variant closely resembles a lipoma. It is composed of relatively mature-appearing adipocytes with marked variation in cell size (Fig. 129-9). Additional findings include focal adipocyte atypia (eFig. 129-9.1 in online edition) and the presence of hyperchromatic and often multinucleate bizarre stromal cells in cellular fibrous septa (eFigs. 129-9.2 and 129-9.3 in online edition).

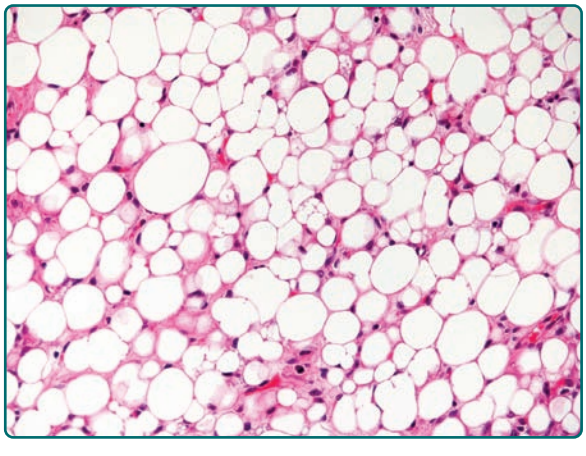

Figure 129-9 Atypical lipomatous tumor/well-differentiated liposarcoma: note the marked variation in adipocyte size.

Floret-type giant cells may also be a feature (eFig. 129-9.4 in online edition). Lipoblasts may be monovacuolated or multivacuolated and vary in number (eFig. 129-9.5 in online edition). They may be entirely absent and are not a prerequisite for the diagnosis. Sclerosing, inflammatory, and spindle cell variants exist.

The sclerosing variant occurs most commonly in a retroperitoneal or paratesticular location and is the second most frequently encountered histologic pattern (eFig. 129-9.6 in online edition). It is characterized by a paucicellular fibrillary collagenous matrix containing scattered hyperchromatic and bizarre-appearing stromal cells as well as rare multivacuolated lipoblasts (eFig. 129-9.7 in online edition). The adipocytic component may be inconspicuous, and often extensive sampling is required for the diagnosis.

Rarely, there is a marked chronic inflammatory infiltrate potentially obscuring the underlying adipocytic component. Such tumors have been designated as the *inflammatory* subtype. This variant occurs in the same distribution as the adipocytic subtype and is characterized by a heavy lymphoplasmacytic infiltrate arranged in a multinodular pattern and separated by variably cellular stroma. The lipogenic areas show features of the adipocytic variant. However, they comprise only a small fraction of the tumor.[165]

The spindle cell variant has only recently been recognized. It is rare and shows a predilection for the subcutaneous tissue of the shoulder girdle and upper limb. The characteristic finding is the presence of a proliferation of bland-appearing spindle cells arranged in fascicles and whorls and set in a myxoid matrix (eFig. 129-9.8 in online edition). This is accompanied by an atypical adipocytic component showing classic lipoblasts.[166]

Immunohistochemistry for *MDM2* and *CDK4* aided by fluorescence in situ hybridization to detect *MDM2-CDK4* amplification is a useful ancillary diagnostic tool to distinguish well-differentiated as well as dedifferentiated liposarcoma from benign adipocyte tumors as well as other nonlipogenic tumors.[160,167]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of atypical lipomatous tumor/well-differentiated liposarcoma includes the following:

- Lipoma
- Spindle cell/pleomorphic lipoma
- Dedifferentiated liposarcoma
- Angiomyolipoma
- Massive localized lymphedema

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

The clinical behavior and prognosis are largely dependent on the anatomic site.[168] Surgery is curative at anatomic locations where complete surgical excision with clear margins can be achieved (e.g., somatic soft tissue such as the limbs). The estimated rate of progressing to dedifferentiated liposarcoma is less than 2% with a

mortality rate of virtually zero at these anatomic locations. In contrast, tumors arising at deep locations such as the retroperitoneum, mediastinum, or spermatic cord, where complete surgical clearance is not possible, are characterized by repeated local recurrence and ultimately may result in death from uncontrolled local disease or dedifferentiation with metastasis. The overall risk of development of dedifferentiated liposarcoma is estimated to be higher than 20% with an overall mortality rate of around 80% for tumors occurring in the retroperitoneum. The disease has a protracted course, and the median survival time ranges from 6 to 11 years.[149,152,169] The primary approach to treatment is surgical excision. Adjunct chemotherapy and radiation treatment are reserved for advanced disease.

DEDIFFERENTIATED LIPOSARCOMA

DEDIFFERENTIATED LIPOSARCOMA AT A GLANCE

- Tumors typically present as large masses in the retroperitoneum of adults.
- The disease course is protracted, with a high rate of local recurrence and a significant risk for metastasis and associated mortality.
- The morphologic characteristic is the presence of nonlipogenic areas adjacent to well-differentiated liposarcoma.

MYXOID/ROUND CELL LIPOSARCOMA

MYXOID/ROUND CELL LIPOSARCOMA AT A GLANCE

- Presentation is as a large mass involving the extremities and in particular the thigh of middle-aged adults.
- There is a significant rate of local recurrence as well as metastasis.
- Tumors are lobulated and circumscribed and are composed of a myxoid matrix containing primitive mesenchymal cells and lipoblasts in varying stages of differentiation. A prominent vascular pattern is a characteristic feature.
- Round cell liposarcoma is currently regarded to represent the high-grade end of the morphologic spectrum.

EPIDEMIOLOGY

Myxoid liposarcomas represent approximately 10% of all soft-tissue sarcomas. They comprise more than one-third of all liposarcomas and are the second most frequent variant of liposarcoma.[178] The tumor presents in young to middle-aged adults with a peak in the fourth to fifth decade and a slight male predominance.[178–180]

ETIOLOGY AND PATHOGENESIS

Cytogenetically, myxoid liposarcoma is characterized by the translocation t(12;16)(q13;p11), present in approximately 95% of cases. The translocation involves the *CHOP* (*DDIT3*) gene on chromosome band 12q13 and the *TLS* (also known as *FUS*) gene located on 16p11 resulting in the generation of the *TLS–CHOP* hybrid gene.[170,180–184] Rarely, the translocation t(12;22)(q13;q12), resulting in the *EWS–CHOP* hybrid gene, is observed.[185–187] CHOP belongs to the family of leucine zipper transcription factors and is implicated in adipocyte differentiation and growth arrest, whereas TLS, similar to EWS, is a potent activator of transcription. In turn, the *TLS–CHOP* hybrid gene is speculated to interfere with normal adipocyte development and proliferation by aberrant transcriptional activation.

CLINICAL FINDINGS

Presentation as a large, painless mass with a predilection for the extremities is characteristic. Tumors are located in deep soft tissue and involve the thigh in over two-thirds of cases.[178–180] Presentation in subcutis or retroperitoneum is rare. Not infrequently, patients are found to have multifocal disease at initial presentation, which is generally regarded to represent metastases.[185]

HISTOLOGIC FEATURES

Tumors are large, well circumscribed, and multinodular with a gelatinous cut surface on gross examination. The appearance becomes fleshier in areas with increased cellularity, but large areas of tumor necrosis are not typically seen.

Microscopically, myxoid liposarcoma is a lobulated tumor composed of a mixture of bland-appearing oval mesenchymal cells without evidence of adipocyte differentiation and small univacuolated or bivacuolated lipoblasts, often with a signet-ring cell appearance (eFig. 129-9.12 in online edition and Fig. 129-10). The cellularity is low but increased toward the periphery of the tumor lobules (eFig. 129-9.12 in online edition). The cells are placed in a myxoid matrix showing a characteristic pattern of delicate, branching capillary-sized vessels often referred to as *chicken wire* or *crow's feet* (eFig. 129-10.1 in online edition). In the central areas,

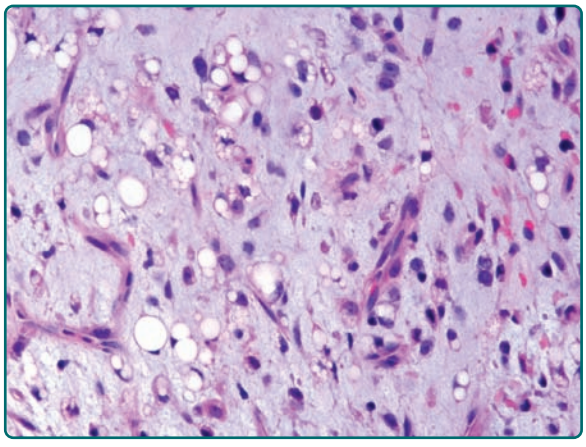

Figure 129-10 Myxoid liposarcoma: the presence of uni- to bivacuolated lipoblast and bland appearing oval shaped cells within a myxoid matrix is a characteristic feature.

the extracellular mucin may become confluent to form mucin pools, giving rise to a pulmonary edema-like appearance (eFig. 129-10.2 in online edition). In the well-differentiated areas, the tumors lack significant cytologic atypia, mitotic activity, or tumor necrosis. Poorly differentiated, high-grade tumors are characterized by increased cellularity with the formation of solid sheets of small-to-medium-sized round cells showing scant acidophilic cytoplasm (eFig. 129-10.3 in online edition). Mitotic figures are more easily identified, but nuclear pleomorphism is not a feature.

These cases have traditionally been classified as round cell liposarcoma and are associated with an adverse prognosis. However, the presence of classical myxoid and round cell areas within the same tumor with gradual transition from one to the other and the finding of identical cytogenetic alterations provide strong evidence that round cell liposarcoma represents the poorly differentiated, high-grade end of the spectrum of myxoid liposarcoma. Spindle cell differentiation may occasionally be seen in poorly differentiated tumors.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of myxoid liposarcoma includes the following:

- Lipoblastoma
- Myxofibrosarcoma
- Low-grade fibromyxoid sarcoma
- Chondroid lipoma
- Myxoid melanoma

CLINICAL COURSE, PROGNOSIS, AND TREATMENT

The clinical course of myxoid liposarcoma is characterized by local recurrence with a rate of distant metastasis of 30%–40%.[178–180] There is an unusually high incidence of soft-tissue and bone metastases in addition to metastases to the lung. Patients with multifocal disease at presentation have a poor prognosis, and adverse histologic features include the presence of round cell differentiation in more than 5% of the tumor, tumor necrosis, and p53 overexpression.[179,180,188,189]

PLEOMORPHIC LIPOSARCOMA

PLEOMORPHIC LIPOSARCOMA AT A GLANCE

- Pleomorphic liposarcoma is an aggressive sarcoma that shows a predilection for the extremities of adults and is associated with a high rate of metastasis and mortality.
- Histologic examination shows a pleomorphic high-grade sarcoma containing variable numbers of lipoblasts.

PART 8 The Skin in Systemic Disease

Skin in Nutritional, Metabolic, and Heritable Disease

Chapter 130 :: Cutaneous Changes in Nutritional Disease

:: Melinda Jen & Albert C. Yan

PROTEIN ENERGY MALNUTRITION AT A GLANCE

- Marasmus: caused by chronic global nutrient deficiency and characterized by dry, loose, and wrinkled skin with a loss of subcutaneous fat.
- Kwashiorkor: caused by inadequate protein or fat in the context of ongoing carbohydrate intake and characterized by generalized edema with a "flaky paint" dermatosis.
- Rice milk intake during infancy has caused cases of kwashiorkor in the Western world.
- Particular attention should be taken to prevent refeeding syndrome, characterized by electrolyte abnormalities.

Nutrition is the complex series of events by which living organisms consume and assimilate foods and other nutrients in order to live, grow, and maintain homeostasis. Proper nutrition involves the consumption of key macronutrients in balanced tandem with essential micronutrients. Consisting of carbohydrates, proteins, and lipids, macronutrients are those that are needed in large quantities by an organism to both fuel metabolic processes and provide the substrate for building and maintaining cellular structure. By contrast, micronutrients signify vitamins and minerals, which while necessary to good health, are required in relatively minute quantities. Because humans are unable to synthesize these molecules, clinical disease results when disturbances occur in that equilibrium—most commonly from nutrient deficiencies, but also from an unbalanced ratio of consumed nutrients, or less commonly from nutrient excesses.

With an improved understanding of the role of diet in health and the advent of nutritional supplements, long-standing named scourges such as scurvy, beriberi, and pellagra have largely become diseases of historical interest. Even so, nutritional diseases remain problematic in developing countries and in settings of war, famine, and poverty. In industrialized countries, nutritional diseases may still arise among the disenfranchised: the homeless and those suffering from alcoholism or other forms of substance abuse. Individuals at risk also include those with derangements in their normal diets such as might be encountered with eating disorders or unusual dietary habits as well as with parenteral nutrition. Hypercatabolic states, exemplified by those with cancer, AIDS, hepatic or renal disease, and certain disease states such as carcinoid syndrome, may develop nutrient deficiencies even in the face of normal intake due to increased metabolic requirements. Excessive nutrient losses may occur as a result of decreased absorption arising from gastrointestinal diseases such as cystic fibrosis, inflammatory

bowel disease, celiac disease, or following gastrointestinal surgery. Those receiving chronic medications such as anticonvulsants or antibiotics may experience impaired utilization of their nutrients when their medications interfere with gastrointestinal absorption and normal metabolism. Impaired utilization may derive from underlying genetic metabolic defects, enzyme deficiencies, hepatic disease, or drug–nutrient interactions. By contrast, syndromes of nutrient excess generally stem from dietary surplus or iatrogenic therapeutic intake.

Because macronutrients and micronutrients are intrinsically involved in multiple biochemical pathways, disorders of nutrition may produce extracutaneous consequences. Moreover, those at risk for one nutrient deficiency may be suffering from other concomitant deficiencies as well. Appropriate evaluation of the patient with suspected nutritional disease should commence with a detailed history of dietary and medication intake, a review of past medical and family history, and careful inspection of the skin with special attention to the status of hair, nails, and mucous membranes. While some skin findings may be pathognomonic for certain nutritional disorders, physical findings are more oftentimes nondiagnostic. Laboratory analysis of blood and urine nutrient levels may be useful, but poor correlation with tissue levels limits their utility. Radiologic imaging studies may also offer corroboration for diseases such as scurvy, rickets, or beriberi. Clinical improvement following replacement therapy may represent the best or only means to confirm the clinical diagnosis of some nutritional deficiencies. This chapter reviews the important clinical features observed in nutritional disease states.

MACRONUTRIENTS

PROTEIN-ENERGY MALNUTRITION

EPIDEMIOLOGY. Malnutrition is a medical concern of global significance. The United Nations estimates that 1.02 billion individuals worldwide were malnourished in 2009.[1] The most recent approximation of child malnutrition estimates that 150 million children under the age of 5, or a quarter of children in this age group, suffered from malnutrition. Approximately 5 million children under the age of 5 die from malnutrition each year.[2]

In developing countries, malnutrition most commonly arises as a result of inadequate dietary intake, often compounded by disease. War, famine, and poverty states often aggravate the inadequate access to food, which may arise from political unrest, natural disasters, infectious diseases, seasonal and climactic factors, insufficient food production, lack of education, poor sanitation, regional and religious practices, and the limited availability of health care.[3] The availability of food in these settings may be limited to diets of corn, rice, and sometimes beans, which provide inadequate amounts of macronutrients, vitamins, and minerals. In Western industrialized countries such as the United States, less than 1% of children nationally suffer from protein–energy malnutrition (PEM). When it is encountered, chronic illness, malabsorption, presumed food allergies, food aversion, nutritional ignorance, and fad diets are more typical etiologies.

ETIOLOGY AND PATHOGENESIS. PEM refers to a spectrum of disorders describing varying degrees of protein and calorie deficiency. Several subtypes of PEM have been defined on the basis of relative deficiencies in protein and total calorie intake.

Children with marasmus are defined as those with severe wasting and stunting and are at less than 60% expected body weight for age. The term marasmus derives from the Greek *marasmos* meaning wasting. These changes are the result of chronic and global nutrient deficiencies, often because of a lack of available food. Children with kwashiorkor have body weights less than 60%–80% expected for age, generally as a result of being fed grain-derived foods without adequate accompanying protein or fat. This might occur in geographic areas where grains are more plentiful, but more expensive proteins and fats are not. In fact, the term kwashiorkor derives from the Ghanese term for "the one who is deposed," referring to the child who is weaned off of breastmilk onto a carbohydrate-rich but often protein-poor diet when the next child is born. The exclusive use of rice beverages, so-called "rice milk" products, as a substitute for baby formulas—either because of their lower cost or because of their perceived hypoallergenicity—has been linked to the development of kwashiorkor among infants in the United States and other Western countries.[4–6] A hybrid form of malnutrition in which stunting is associated with edema has been termed marasmic kwashiorkor.

The pathophysiology of these disorders can also be conceptualized as adapted and nonadapted forms of starvation. In adapted starvation (marasmus), decreased intake of all macronutrients, particularly carbohydrates, results in suppressed insulin production. As a result, catabolic hormones act unopposed and allow the appropriate conversion of glycogen into glucose. In the early stages of adapted starvation, muscle breakdown occurs within the first 24 hours, which permits gluconeogenesis to release glucose into the systemic circulation. Later, fat breakdown creates ketone bodies, which can also be utilized by the brain and central nervous system. This reduces the need for further muscle breakdown and therefore ammonia synthesis, so that lean body mass and some protein synthesis can be spared. In prolonged states of adapted starvation, wasting occurs and lean body mass is eventually utilized when all other sources are expended; in the absence of additional nutrient intake, the organism dies. In nonadapted starvation states (kwashiorkor), an imbalance results when intake of carbohydrate is increased relative to decreased intake of protein and fat. In this setting, insulin production is not appropriately suppressed. Without concomitant fat and protein intake, insulin inhibits protein synthesis. Hypoproteinemia, edema, and diarrhea develop, and without protein synthesis, affected individuals are unable to manufacture lipoproteins so fats accumulate resulting

in a fatty liver; more importantly, necessary immune proteins are not produced so patients become susceptible to opportunistic infection and septicemia, which represent major causes of mortality in these patients.

While the concepts of adapted and nonadapted starvation provide convenient explanations for why some children develop marasmus and others develop kwashiorkor, some controversy exists. For instance, aflatoxins have been detected with greater frequency in patients with kwashiorkor than in those with marasmus.[7] Also, the role of oxidative and nitrosative stress in kwashiorkor is supported by data showing that patients with edematous PEM have lower levels of erythrocyte glutathione and total plasma antioxidants than healthy controls.[8]

CLINICAL FINDINGS. Childhood is marked by periods of significant and rapid growth and development, and nutritional deprivation often manifests as alterations in these patterns of normal growth and development. Failure to thrive, a key finding in patients with PEM, may appear first as wasting in which patients have poor weight gain, and eventually, as decreased rates of linear growth (stunting). Various measurements have been recommended as markers for malnutrition, and include: body weight and length/height relative to age, body mass index, triceps or middle upper arm circumference, as well as skin and hair characteristics.[9,10] Suboptimal neurodevelopmental outcomes, heightened susceptibility to infection, and increased mortality may also be observed in chronically malnourished children.

Marasmus typically affects infants under 1 year of age. The physical findings of marasmus include dry, thin, loose, wrinkled skin resulting from loss of subcutaneous fat with an emaciated appearance (Box 130-1 and Fig. 130-1).[11] Hair growth slows and examination may reveal easy hair loss leading to thin, fine, brittle hair and alopecia. Increased lanugo hair may also be present. Nails may also show signs of fissuring with impaired growth.[12] As the body mobilizes all endogenous energy stores to survive, both subcutaneous fat and muscle mass are lost. The loss of buccal fat pads creates the aged or wizened appearance attributed to children with marasmus that has been referred to disparagingly as "monkey facies"(Fig. 130-2). Perianal fat loss can lead to rectal prolapse and abdominal muscle hypotonia may result in abdominal distention.[13] Constipation may alternate with periods of diarrhea that may or may not be associated with concomitant gastrointestinal infection. Angular cheilitis and mucous membrane changes have also been observed in patients with marasmus.[14] Patients often show both decreased resting body temperature and bradycardia.

Figure 130-1 Marasmus. General appearance with advanced disease.

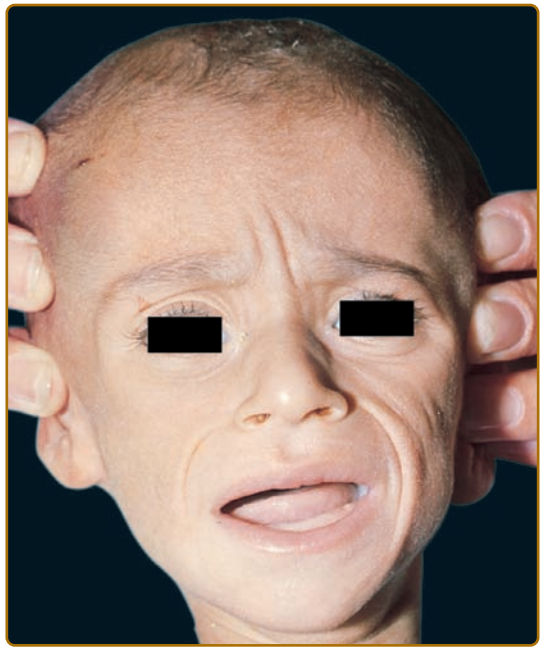

Figure 130-2 Marasmus. "Monkey facies" in an Arab infant, with wrinkled skin and loss of subcutaneous fat.

BOX 130-1 CLINICAL FEATURES OF MARASMUS

- Affects infants <1 year
- Failure to thrive
- Dry, thin, loose, wrinkled skin
- Hair loss; fine brittle hair; alopecia
- Fissuring and impaired growth of nails
- Loss of subcutaneous fat and muscle mass
- Loss of buccal fat (monkey facies)
- Rectal prolapse, abdominal distension
- Diarrhea, constipation
- Angular cheilitis

BOX 130-2 CLINICAL FEATURES OF KWASHIORKOR

- Affects children between 6 months and 5 years
- Failure to thrive, edema
- Irritability, lethargy, apathy
- Generalized dermatitis "flaking enamel paint," "cracked pavement"
- Increased pigmentation on arms and legs
- Hair color changes (red tint → gray–white; "flag sign")
- Distension of abdomen

Figure 130-3 The "flaky paint" or "crazy pavement" dermatitis of kwashiorkor.

The hallmark features of kwashiorkor—also known as edematous or "wet" PEM—include failure to thrive in association with edema and is primarily noted in children between 6 months and 5 years of age (see Box 130-2). Children are often irritable, but may become lethargic and apathetic. In contrast to marasmus, skin findings are common in kwashiorkor. The generalized dermatitis in edematous PEM has been likened to flaking enamel paint, with the pattern of skin fissuring suggesting cracked or "crazy" pavement (Fig. 130-3). Increased pigmentation of skin may be observed on extensor surfaces of the arms and legs. Hair often changes from its natural color, typically developing a red tint before further pigment dilution results in light, gray–white hair (Fig. 130-4B). If a child experiences intermittent periods of kwashiorkor and improved nutrition, alternate bands of light- and dark color within the hair shaft may be observed and has been referred to as the "flag sign" (Fig. 130-4A). Increased lanugo hair can also be noted in kwashiorkor. In addition to the peripheral edema, a direct consequence of hypoproteinemia, distention of the abdomen is noted as a result of fatty infiltration of the liver.

Adults may also be at risk for PEM, particularly those suffering from chronic illnesses, eating disorders such as anorexia nervosa, and the elderly. The prevalence of PEM in adult dialysis patients has been estimated at 25%–50% and is posited to occur as a result of semistarvation with inadequate caloric and protein intake, possibly complicated by the presence of a chronic systemic inflammatory response to dialysis.[15,16] Cases of macronutrient PEM have been reported as a complication of bariatric surgery.[17] The manifestations of PEM in adults may be less prominent, manifesting more as xerosis or acquired ichthyosis and may be the result of decreased sebaceous gland secretions or concurrent micronutrient deficiency.[18] Hyperpigmentation at characteristic sites may also be present, including the perioral, periocular, and malar areas. Diffuse telogen effluvium, lanugo, and thin, dry, dull hair has also been reported in adult PEM.[19]

LABORATORY TESTING. Initial laboratory testing in PEM recommended by the World Health Organization[20] includes screening for hypoglycemia, anemia, and an investigation into potential comorbid infectious diseases. Since patients with PEM are at

Figure 130-4 **A.** Flag sign in a Salvadoran child. **B.** Hypomelanization of the hair and skin.

significantly increased risk of serious infection, examination of urinalysis for bacterial infection, blood smear for malaria parasites, and feces for blood, ova, and parasites are essential. Skin testing for tuberculosis should be performed. Chest radiography may demonstrate concomitant signs of bacterial pneumonia, tuberculosis, heart failure, rickets, and fractures. Patients with kwashiorkor will also demonstrate hypoproteinemia, which may help guide treatment and prognosis. Evaluation of electrolyte levels before treatment should be interpreted with caution, as refeeding will likely alter mineral balances.

Elevated soluble CD14 levels have been associated with indicators of protein energy wasting, such as low body mass index and muscle atrophy, and increased mortality in hemodialysis patients. CD14 is a coreceptor that triggers immune activation in response to various ligands, including endotoxins and bacterial products. In patients with chronic renal failure on hemodialysis, increased soluble CD14 is associated with elevated markers of systemic inflammation, such as *C*-reactive protein, interleukin 6, fibrinogen, and plasma pentraxin 3. This suggests a possible link between chronic inflammation, PEM, and mortality in hemodialysis patients.[21]

Histologic evaluation is generally unnecessary since the clinical features in association with an appropriate history are diagnostic. However, histologic evaluation of the skin reveals increased thickness of the stratum corneum, atrophy of the granular layer, increased basal layer pigmentation, reduction of collagen fibers, and crowding of elastic fibers. Atrophy of the hair appendages with sparing of the sweat gland apparatus can also be noted.[22]

DIFFERENTIAL DIAGNOSIS. (See Box 130-3)

Treatment. Patients with severe PEM often require hospitalization due to the concurrent risks of hypoglycemia, hypothermia, dehydration, and sepsis. Individuals who are not awake and responsive may require intravenous hyperalimentation during the initial stages of therapy; care must be taken to avoid excessively rapid rehydration due to the risks of congestive heart failure. Oral refeeding is generally preferred using oral rehydration salts containing a mixture of essential electrolytes at least until diarrhea subsides or fortified formulas as soon as these can be tolerated. Since severely malnourished children are relatively immunocompromised, empiric antibiotic therapy may be considered on admission for suspected sepsis, and any identified infections should appropriately addressed.[20]

BOX 130-3 DIFFERENTIAL DIAGNOSIS

- Acrodermatitis enteropathica
- Atopic dermatitis
- Seborrheic dermatitis
- Langerhans cell histiocytosis

ESSENTIAL FATTY ACIDS

ESSENTIAL FATTY ACIDS AT A GLANCE

- Function: cell membrane fluidity, inflammatory mediators, and lamellar granule formation in the stratum corneum.
- Sources: fish oil and vegetable oil.

EPIDEMIOLOGY.

Naturally occurring essential fatty acids (EFA) deficiency states are uncommon in humans. Cases of deficiency arise instead from inadequate intake, malabsorption, or excessive loss. In the past, parenteral nutrition was a common cause of EFA deficiency, but with the introduction of lipid supplementation during parenteral nutrition in 1975, the incidence of EFA deficiency has decreased substantially. Patients at risk for EFA deficiency include those with poor dietary intake, including alcoholics and patients with anorexia nervosa, or those with malabsorptive conditions such as biliary disease, inflammatory bowel disease, postgastrointestinal surgery (e.g., bariatric surgery), and may represent one of the primary etiologies for the rash observed in cystic fibrosis patients.[23] Premature low birthweight infants are born with inadequate EFA stores and are also at risk.

ETIOLOGY AND PATHOGENESIS.

EFA represent a group of 18-, 20-, or 22-carbon polyunsaturated fatty acids that cannot be synthesized de novo by the human body. The ω-3 series of fatty acids is found in fish oils, and is derived from α-linoleic acid. The ω-6 series is found in vegetable oils, and is derived from linoleic acid.[11] Linoleic acid and α-linoleic acid are the two EFA– that serve as precursors for other EFA and therefore must be obtained from dietary intake. In cell membranes, EFAs increase lipoprotein unsaturation to modulate cell membrane fluidity. Arachidonic acid, a derivative of linoleic acid, is converted into prostaglandins, eicosanoids, and leukotrienes. In the epidermis, linoleic acid contributes to lamellar granule formation in the stratum corneum. Therefore, EFAs play a number of key roles in maintaining homeostasis.

CLINICAL FINDINGS.

Skin manifestations of EFA deficiency include: xerosis and scaly, diffuse erythema, and associated intertriginous erosions. Poor wound healing, traumatic purpura secondary to capillary fragility, brittle nails, and alopecia may be observed. Affected individuals may also demonstrate hyperpigmentation or hypopigmentation of the hair (Box 130-4). Extracutaneous findings include fatty liver infiltration, increased susceptibility to infection, a blunted immune response, anemia, thrombocytopenia, and growth retardation.

LABORATORY TESTING.

In EFA deficiency states, linoleic acid levels are low and the enzymes that normally

BOX 130-4 SKIN MANIFESTATIONS OF EFA DEFICIENCY

- Hyper- and hypopigmentation of hair

convert linoleic acid to arachidonic acid use oleic acid to create an abnormal byproduct. Laboratory evaluation would therefore demonstrate decreased levels of linoleic and arachidonic acids, and elevated plasma levels of an abnormal intermediary, 5,8,11-eicosatrienoic acid. Measurements documenting an increased ratio (≥0.2) of this abnormal intermediary relative to arachidonic acid are diagnostic for EFA deficiency.

TREATMENT. While topical application of sunflower seed and safflower oils that contain linoleic acid may improve the clinical cutaneous findings of EFA deficiency,[24] topical absorption is unpredictable[25] and optimal treatment typically consists of oral or intravenous supplementation of EFA. In order to prevent EFA deficiency, EFA should represent 1%–2% of total daily calories.[26]

MICRONUTRIENTS

FAT-SOLUBLE VITAMINS

FAT-SOLUBLE VITAMINS AT A GLANCE

- Vitamin A, D, E, K.
- Vitamin A deficiency is the most common cause of preventable childhood blindness in the world.
- Carotenemia results from excess carotene not converted to vitamin A in the intestinal mucosa deposits in stratum corneum.
- Understanding of the full function of vitamin D is still evolving.
- Vitamin D supplementation is recommended for exclusively breast-fed infants, and others who have inadequate oral intake or sun exposure.
- Hemorrhagic disease of the newborn results from vitamin K deficiency and can present with a spectrum of bleeding, from ecchymoses to intracranial hemorrhage.

VITAMIN A (RETINOL)

Etiology and Pathogenesis. Vitamin A is a fat-soluble vitamin important in retinal photoreceptor function, epithelial proliferation, and keratinization. The two most clinically important metabolites of vitamin A are retinal, which is a key component of rhodopsin generation, and retinoic acid, which regulates cell differentiation.[27] Dietary intake of vitamin A derive from both plant and animal sources. Plant sources include dark, green, leafy vegetables, red palm oil, and brightly colored fruits such as papaya, mango, carrots, tomatoes, apricots, and cantaloupe. In plants, the vitamin A precursor β-carotene can be found as a two-molecule complex of the carotenoid known as retinal. The retinal can be later reduced to retinol in the intestinal villous cells. Animal sources of vitamin A include egg yolk, liver, fish, fortified milk, and other dairy products. In animal sources, vitamin A exists as retinyl esters, which are then hydrolyzed to retinol in the intestinal lumen and then absorbed into intestinal mucosal cells. All retinol vitamin A alcohol is esterified to retinyl esters within the intestinal mucosa, released into the bloodstream bound to chylomicrons, and then transported to the liver for storage. Here, retinol can be stored as retinyl esters in the liver; when needed, this storage form may be converted to retinol and bound to retinol binding protein and transthyretin and circulated throughout the body.

Vitamin A Deficiency

Epidemiology. Vitamin A deficiency (VAD) can result in cutaneous as well as ocular complications. It is, in fact, the most common cause of preventable blindness in children according to the World Health Organization. VAD has also been associated with defects in immune regulation.

Etiology and Pathogenesis. The primary causes of VAD continue to be inadequate intake, fat malabsorption states, and liver disease. In the United States, inadequate intake can be seen in individuals with eating disorders, restrictive diets, and chronic illness. Since vitamin A is fat-soluble, conditions associated with malabsorption of fat such as pancreatic or biliary tract disease, celiac disease, Crohn disease, Shwachman–Diamond syndrome, cystic fibrosis, cholestatic liver disease, chronic intestinal parasitic infection, and gastric bypass surgery can predispose to VAD.

Clinical Findings. (See Box 130-5). The earliest manifestations of VAD are ocular changes. Impaired dark adaptation (nyctalopia), is followed by xerophthalmia, and as corneal keratin desquamates and overgrowth of *Corynebacterium xerosis* on the sclera occurs, white patches known as Bitot spots develop. Severe deficiency may lead to corneal xerosis, ulceration, and keratomalacia, which may result in corneal perforation, prolapse of the iris, and blindness (Fig. 130-5).

The cutaneous findings of VAD are the result of abnormal keratinization. Mild deficiency may manifest as xerosis and scaling, while more severe deficiency may result in deep skin fissuring referred to as dermomalacia. Squamous metaplasia of the salivary glands as well as

the nasal and oral mucosa may occur, leading to xerostomia, hyposmia, and hypogeusia. Laryngeal, bronchial, and vaginal mucosa can also become involved.

Phrynoderma, "toad skin," (Greek for toad + skin) is typically associated with VAD. These keratotic follicular papules often first develop on the anterolateral thighs and posterolateral upper arms, which then spread to extensory surfaces of the extremities, shoulders, abdomen, back, buttocks, face, and posterior neck (Fig. 130-6). Lucius Nicholas noted the association between this hyperkeratotic folliculitis or phrynoderma with VAD in 1933 when he observed these cutaneous findings among East African workers who developed night blindness and xerophthalmia.[28] While originally reported in association with VAD, phrynoderma is a nonspecific finding that can be observed with deficiencies in B-complex vitamins, vitamins C, E, as well as essential fatty acid deficiency, PEM, and general malnutrition states.[29]

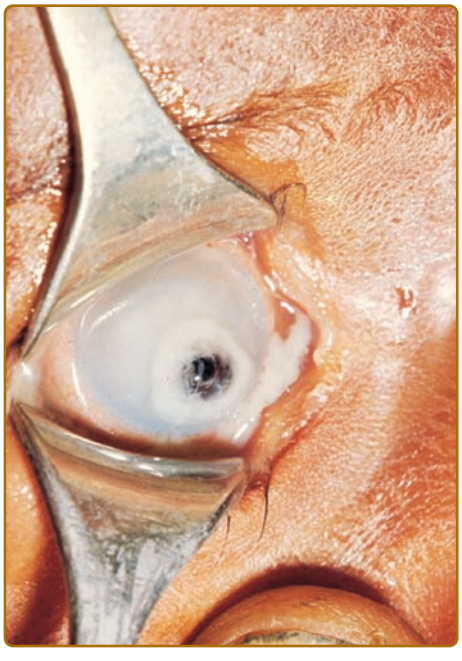

Figure 130-5 Vitamin A deficiency, advanced keratomalacia, in a 5-month-old Arab child. Note hyperkeratosis of facial skin. Serum vitamin A level was 2 µg/dL (normal, 20–50 µg/dL).

Figure 130-6 Vitamin A deficiency. Typical perifollicular hyperkeratosis of the chest in a Tanzanian adult male.

Laboratory Testing. Vitamin A levels can be measured from serum. Normal serum levels are between 20 and 50 µg/dL. Recently, assessment for the hydrolysis of retinoyl glucuronide to retinoic acid has shown promise as an adjunctive test for VAD. Retinoyl glucuronide is a water-soluble form of vitamin A that is not absorbed or hydrolyzed to retinoic acid in vitamin A-replete humans. The presence of serum retinoic acid for 4 hours after oral administration of retinoyl glucuronide was correlated with low serum retinol.[30]

Treatment. The recommended daily allowance (RDA) of vitamin A is between 1,000 and 5,000 IU, with younger individuals requiring a lower intake of vitamin A. Recommended treatment for VAD is 100,000–300,000 IU of oral vitamin A daily until symptoms resolve and serum levels normalize.

Vitamin A Toxicity. (See also Chapter 228)

Epidemiology. In 1856, Elisha Kent Kane published his two-volume *Arctic Explorations*, which included accounts of vitamin A toxicity that resulted after his team ingested polar bear liver during his expedition. The toxic substance in polar bear liver was later identified as vitamin A. Since that time, studies have shown that animal livers contain exceptionally high amounts of vitamin A.

Vitamin A toxicity is the result of excess intake of vitamin A and can occur on an acute or chronic basis. Acute toxicity occurs when excessive amounts of vitamin A are ingested over a period of several hours or days. Toxicity typically results when intake exceeds 20 times the RDA in a child or 100 times the RDA in an adult. Chronic toxicity results from daily ingestion of

greater than 25,000 IU for more than 6 years or greater than 100,000 IU for more than 6 months of preformed vitamin A. Children appear to be more sensitive to vitamin A intake than adults. Individuals most at risk for toxicity include patients taking systemic vitamin A derivatives for the treatment of dermatologic conditions such as acne, psoriasis, and ichthyosis. The other population at risk includes vitamin food faddists who consume large quantities of nonprescription vitamin A supplements.[31] Two notable episodes of vitamin A toxicity occurred in the 1950s when very high levels of vitamin A supplementation were added to infant formulas and the 1970s when high doses of vitamin A were used to treat a variety of dermatologic diseases.[32]

Recently, vitamin A derivatives have been studied in chemoprevention of keratinocytic carcinomas, such as squamous cell and basal cell carcinomas. A large, blinded randomized controlled study of elderly men with a history of two keratinocytic carcinomas in the 5 years prior to initiation of the study compared topical tretinoin 0.1% cream to placebo. Surprisingly, the study was terminated 6 months early because of a statistically significant increase in all-cause mortality in the tretinoin group compared to the placebo group.[33] Analysis of this increased risk was limited by its post hoc nature and suggests that further studies are needed to clarify this association.

Clinical Findings. (See Box 130-6). Individuals with acute vitamin A toxicity have dry, scaly skin, with large areas of desquamation and fissuring of the lips and angles of the mouth. Other signs and symptoms include headache, fatigue, anorexia, nausea, vomiting, blurred vision, pseudotumor cerebri, myalgias, and arthralgias. An early cutaneous sign of chronic vitamin A toxicity in adults is dryness of the lips, which may progress to diffuse, dry, pruritic, scaly skin with peeling of palms and soles, alopecia, follicular hyperkeratosis, and hyperpigmentation of the face and neck. Anorexia, fatigue, and weight loss may also occur. It is interesting to note that follicular hyperkeratosis may occur in the settings of both VAD and toxicity.

In children, chronic toxicity presents as coarse hair with diffuse alopecia, coarse skin with generalized exfoliation, hyperpigmentation, and exfoliative cheilitis. Associated pseudotumor cerebri with headaches and papilledema, and in infants may a bulging fontanelle may be present. Skeletal changes are common with vitamin A toxicity, and may present with growth retardation secondary to premature closure of the epiphyses and spontaneous bone fractures. Proposed mechanisms for the pathologic bone findings seen in vitamin A toxicity involves antagonism between vitamin A- and vitamin D-mediated intracellular signaling pathways and interactions with calcium-regulating hormones.[19,31]

Laboratory Testing. Laboratory findings in patients with hypervitaminosis A include elevated levels of calcium and alkaline phosphatase. This alteration in calcium homeostasis can lead to calcification of tendons, ligaments, and soft tissues. Deposition of excess vitamin A in adipose tissue and perisinusoidal fibrosis of the liver, which can lead to cirrhosis, are the most significant effect of long-term vitamin A toxicity.

Treatment. Almost all of the symptoms of vitamin A toxicity subside after the excess vitamin intake is discontinued, with the exception of liver cirrhosis and consequences of pseudotumor cerebri.

BOX 130-6 MANIFESTATIONS OF VITAMIN A TOXICITY

- Dry, scaly skin with desquamation
- Peeling of palms and soles, follicular hyperkeratosis
- Cheilitis, fissuring of lips and angles of mouth
- Alopecia
- Anorexia, nausea, vomiting
- Myalgias, arthralgias
- Blurred vision, pseudotumor cerebri
- Skeletal changes: premature closure of the epiphyses, spontaneous bone fractures

Carotenemia and Carotenoderma

Epidemiology. While hypervitaminosis A is a disease that causes a broad spectrum of clinical findings, excessive intake of carotene results in a benign disorder characterized by yellow–orange skin pigmentation. The condition was described as "carotenemia" in 1919 by Hess and Meyers who reported a connection between yellow skin pigmentation and increased serum carotene levels.[34] During World War I and World War II, carotenemia was more commonly seen because of the dietary shift from a meat-based diet to a more plant-based diet due to food shortages.

As antioxidants, carotenoids have also been studied in cancer prevention. Interestingly, β-carotene supplementation of 20–30 mg per day was associated with an increased risk of lung and gastric cancers.[35,36] β-Carotene supplementation is also associated with an increased risk of aggressive prostate cancer.[37] Animal studies suggest that excessive carotenoids may increase cyclic AMP signaling and cause deleterious effects on oxidative stress pathways, leading to the increased risk of malignancy.[38,39]

Etiology and Pathogenesis. Carotenes are not synthesized endogenously and are obtained through intake of carotene-rich foods. Plant carotenes are converted to vitamin A in the gastrointestinal tract, but approximately one-third of carotene is directly absorbed. Several factors can affect carotene absorption, including thyroid hormone, pancreatic lipase and bile acid concentrations, processing of foods, and dietary fat and fiber content. Hypothyroid patients notice an elevation of carotene levels as a result of decreased conversion to retinol. Pancreatic lipase and bile acids digest carotene so that a deficiency of these enzymes due to pancreatic or biliary or hepatic dysfunction could result in elevated carotene levels. Mashing, cooking, and pureeing fruits and vegetables increase

the availability of carotene because cell membranes are ruptured in the process. Dietary fiber decreases absorption. Because carotene is fat-soluble, a high-fat meal increases absorption. Patients with conditions that lead to hyperlipidemia, like diabetes mellitus, nephrotic syndrome, and hypothyroidism, also predispose patients to carotenemia because of a linear relationship between the amount of β-lipoprotein and carotene. Impaired conversion of carotene to vitamin A in patients with hypothyroidism and liver disease further contributes to carotenemia. Some patients with anorexia nervosa can present with carotenemia because of increased intake of vegetables. Other groups at risk for carotenemia are food faddists, those with excessive intake of nutritional supplements, dried seaweed (nori), carrots, and papayas, and infants ingesting a large amount of pureed vegetables.[40–42]

Clinical Findings. Excessive ingestion of carotenes does not result in hypervitaminosis A because the slow conversion of carotene to vitamin A in the intestinal mucosa is not rapid enough to produce toxic amounts of vitamin A.

Carotene deposits in the stratum corneum because of its high lipid content. The yellow discoloration of skin secondary to carotenemia is called carotenoderma. The carotene is excreted by sebaceous glands and in sweat, so the yellow pigmentation appears first on the face, predominantly in the nasolabial folds and forehead, and then progresses to manifest diffusely, especially on the palms and soles. The pigmentation is particularly noticeable in artificial light. Of note, carotenoderma, in contrast to jaundice, spares mucous membranes, like the sclera.

Laboratory Testing. Carotenemia does not occur until serum levels reach three to four times normal levels, greater than 250 µg/dL, and is detectable approximately 4–7 weeks following initiation of a carotenoid-rich diet.

Treatment. Treatment involves discontinuation of excessive carotene intake, and carotenoderma typically fades as the intake of carotene decreases.

VITAMIN D (CALCITRIOL)

Etiology and Pathogenesis. Vitamin D is essential for regulation of calcium and phosphorus metabolism. Vitamin D acts on the gastrointestinal tract to increase dietary calcium and phosphate absorption, stimulates increased bone resorption of calcium and phosphate, and stimulates the renal tubules to increase reabsorption of calcium and phosphate.

Humans obtain vitamin D from two sources: (1) dietary intake, and (2) synthesis in the skin from exposure to ultraviolet light. Common dietary sources of vitamin D include fortified milk, fish oil, and fishes such as salmon, sardines, herring, tuna, cod, and shrimp. Vitamin D can also be synthesized in the epidermis from the precursor molecule 7-dehydrocholesterol (provitamin D_3) by ultraviolet light in the 290–320 nm range. Previtamin D_3 then undergoes a spontaneous, temperature-dependent isomerization to vitamin D_3 (cholecalciferol), which enters the dermal capillaries. At this point, endogenous vitamin D_3 joins with exogenous D_2 (ergocalciferol) for hydroxylation in the liver to 25-hydroxyvitamin D. This molecule travels to the kidney where it is again hydroxylated to make mature vitamin D (1,25-hydroxyvitamin D, also known as calcitriol).

The most common disorder seen with vitamin D is vitamin D-deficient rickets related to decreased dietary intake of vitamin D. Several genetic causes of rickets also deserve mention. Two types of vitamin D-dependent rickets have been described. Type I represents an autosomal recessive defect in renal vitamin D-1α-hydroxylase, and is therefore treated with supplements of 1,25-hydroxyvitamin D. Type II, also referred to as hereditary vitamin-D resistant rickets, is associated with a rare autosomal recessive end-organ resistance to physiologic levels of 1,25-hydroxyvitamin D. Supplementation with high doses of 1,25-hydroxyvitamin D and calcium may overcome this resistance.

A surge in interest regarding the multisystem effect of vitamin D has spurred numerous studies. Evidence suggests that vitamin D deficiency is associated with increased systolic blood pressures,[43] fasting plasma glucose and insulin concentrations,[44] risk of cardiovascular disease,[45–47] risk of hip fractures in postmenopausal women,[48] and colon cancer mortality.[49] Vitamin D deficient individuals have an increased rate of all cause mortality when compared to those who are vitamin D replete.[47,50] Studies into the function of vitamin D in the immune system have indicated that vitamin D is involved in the innate immune response. Toll-like receptors (TLR) activation triggers expression of vitamin D receptor and vitamin D-1-hydroxylase, which promotes macrophage activation.[51] A low vitamin D level is associated with an increased risk of active *Mycobacterium tuberculosis* infection.[52]

Vitamin D-deficient rickets continues to occur in modern times. Groups at risk for vitamin D deficiency include those with inadequate diet, malabsorption, and decreased exposure to sunlight. This includes the elderly or debilitated who have decreased sun exposure or decreased vitamin intake; patients on anticonvulsant therapy; those with malabsorption from gastrointestinal surgery, celiac disease, or pancreatic or biliary disease; those with chronic renal failure; dark-skinned individuals living in areas with poor sun exposure; and breast-fed babies exclusively breastfed without vitamin supplementation.

A recent resurgence in vitamin D-deficient rickets has prompted further evaluation of those at risk. A review of 166 cases of rickets in the United States between 1986 and 2003 showed that most cases presented between 4 and 54 months of age. Eighty-three percent were African-American or black and 96% were breastfed.[55]

> *These results emphasized that exclusively breastfed infants, especially those with dark skin tones, may require vitamin supplementation. In response to the continued increase in cases of vitamin D-deficient rickets, the American Academy of Pediatrics in 2003*

outlined three populations who should be given supplemental vitamin D (200 IU): 1) all breastfed infants unless they take in 500 mL/day of fortified formula or milk; 2) all non-breastfed infants taking in less than 500 mL/day of fortified formula or milk; and 3) children and adolescents who do not obtain regular sun exposure, do not ingest at least 500 mL of fortified milk a day, or do not take a multivitamin with at least 200 IU vitamin D.[56]

Vitamin D-deficient rickets has been associated with congenital ichthyoses, such as lamellar ichthyosis,[57–59] nonbullous ichthyosiform erythroderma,[60] X-linked ichthyosis,[58] and epidermolytic hyperkeratosis.[61] Factors contributing to vitamin D deficiency include avoidance of sun exposure, excessive transepidermal calcium loss, defective vitamin D synthesis in affected skin, and decreased intestinal calcium absorption secondary to systemic retinoid therapy.

Given the movement to encourage sunscreen use, there has been concern regarding secondary vitamin D deficiency. Theoretically, regular use of the recommended amount of sunscreen can decrease 25-hydroxyvitamin D levels, but with real-life application of inadequate amounts of sunscreen and the tendency for increased sun exposure in individuals wearing sunscreen, there seems to be no significant impact on the incidence of vitamin D deficiency.[62]

At the same time, it appears that only limited sunlight exposure is necessary to produce adequate amounts of vitamin D3. For patients with Fitzpatrick skin type II, it has been calculated that only 5 minutes of summertime noon sun 2–3 times weekly provides adequate vitamin D production to satisfy physiologic requirements (see also Chapter 90).[63,64]

Clinical Findings. The classic manifestations of vitamin D-deficient rickets are skeletal (Box 130-7). Calcium and phosphorus deficiency leads to poor calcification of new bones, resulting in fraying and widening of the metaphysis. This can be seen at costochondral junctions of the anterior ribs, creating the well-known "rachitic rosary." Poor calcification of the skull bones results in craniotabes, a softening of the skull bones giving them a ping-pong ball feel. As the bones become weaker, they cannot support the weight of the child and progressive lateral bowing of the lower extremities occurs. Other findings can include frontal bossing, widening of the wrists, scoliosis, hypotonia, fractures, dental defects, and rarely hypocalcemic seizures or tetany. Early radiographic signs of rickets include widening of the epiphyseal plate and blurring of the epiphyseal and metaphyseal junction. If the disease progresses, deformities at the growth plate develop, including cupping, splaying, formation of cortical spurs, and stippling. The bone cortices appear thinner and generalized osteopenia is noted.

A potentially fatal manifestation of vitamin D deficiency is a dilated cardiomyopathy. In a report of 16 British cases, three infants died and six additional infants were successfully resuscitated from cardiopulmonary arrest.[65] Importantly, the cardiomyopathy is responsive to vitamin D supplementation and can result in complete resolution.[65–67]

Vitamin D-dependent rickets type II has also been associated with cutaneous features that are clinically indistinguishable from the syndrome of generalized atrichia associated with mutations in the hairless gene.[68,69] Affected patients in both conditions are born with hair. However, within a few months after birth, scalp and body hair are lost with the exception of eyebrows and eyelashes. Small papules and cysts representing abnormal, rudimentary hair structures characteristically develop on the face and scalp. These cysts typically show disintegration of the lower two-thirds of the follicular unit. While the cutaneous features—notably the alopecia and cysts—are phenotypically and histologically identical, these are distinct clinical entities (Table 130-1).

Laboratory Testing. In addition to the clinical and radiological signs of rickets, laboratory examination may be helpful. Elevated alkaline phosphatase levels and low serum 25-hydroxyvitamin D levels are often useful laboratory indicators of vitamin D deficiency. In the early stages of rickets, parathyroid hormone levels increase to compensate, but this compensatory mechanism becomes inadequate if the deficiency continues.

Treatment. The recommended daily value of vitamin D is 5–10 µg. Treatment includes oral vitamin D

BOX 130-7 CLINICAL MANIFESTATIONS OF RICKETS

- Rachitic rosary
- Craniotabes, frontal bossing
- Lateral bowing of lower extremities
- Widening of wrists, scoliosis, fractures
- Dental defects
- Rarely hypocalcemic seizures

Alopecia by 1–3 months of age	Alopecia by 40 days to 4 months

repletion with dihydroxyvitamin D in addition to a calcium-rich diet. Supplementation with 200–400 μg vitamin D per day until resolution of symptoms, about 2–3 months, is usually adequate.[176] Additional therapy can include judicious sun exposure.

Two additional therapies can be used in cases of hepatic rickets, which is unresponsive to oral vitamin D supplementation because of decreased intraluminal bile salts. D-α-tocopheryl polyethylene glycol-1,000 succinate (TPGS), a water-soluble vitamin E that forms micelles at low concentrations, enhances vitamin D absorption and successfully treated eight pediatric cases of hepatic rickets. These patients maintained adequate levels of vitamin D while on continued TPGS and vitamin D supplementation, without elevation of vitamin E levels.[70] Promoting cutaneous synthesis of vitamin D through ultraviolet radiation successfully treated two cases of hepatic rickets secondary to chronic cytomegalovirus hepatitis and to Alagille's syndrome.[71] Ultraviolet light therapy has also treated an Asian male with poor dietary intake of vitamin D.[72]

VITAMIN E (TOCOPHEROL).

Vitamin E is rarely associated with deficiency or excess states of disease. Found in oils and shortenings, as well as various fortified grains, dark-green leafy vegetables, legumes, nuts, avocado, and small fishes such as herring and sardines.[73] Because it is a fat-soluble vitamin, excessive intake may augment the effects of anticoagulant medications leading to purpura and propensity for hemorrhage.[74] Deficiency states are rare. However, ataxia with isolated vitamin E deficiency (AVED) is a rare and severe spinocerebellar neurodegenerative disorder with autosomal recessive inheritance. Patients with mutations in the α-tocopherol transfer protein are unable to properly transfer α-tocopherol from lysosomes into lipoproteins that results in a predisposition to oxidative stress in affected cells.[75–77]

VITAMIN K (PHYTONADIONE)

Etiology and Pathogenesis. Vitamin K is a necessary cofactor in the carboxylation of glutamate residues on coagulation factors II, VII, IX, X, and proteins C and S. Dietary vitamin K, phylloquinone, is found in green, leafy vegetables, certain legumes, soybeans, cereals, and beef liver. Phylloquinone is actively transported in the distal small bowel. Approximately half of the body's vitamin K is obtained though these dietary sources, and the other half is synthesized by gastrointestinal flora as menaquinones, which are passively absorbed in the distal small bowel and colon.

Vitamin K is derived from the German word "*Koagulationsvitamin*," which literally translates to mean "clotting vitamin." In the early-1900s, Henrik Dam of Denmark discovered an "antihemorrhagic factor" that reversed diet-induced bleeding disorders in chicks. In 1943, Edward Doisy and Henrik Dam were awarded the Nobel Prize in Physiology and Medicine for their separate work on isolating vitamin K.

Clinical Findings. Vitamin K deficiency leads to impaired coagulation and hemorrhage, which in neonates is referred to as hemorrhagic disease of the newborn (HDN). Neonates are particularly prone to vitamin K deficiency because of poor transplacental transfer, low dietary intake, and a sterile bowel. HDN is divided into early presentation and late presentation. The incidence of early HDN is 0.25%–1.7% and causes unexpected bleeding in the first week of life in an otherwise healthy neonate. It can present as ecchymoses, cephalohematomas or nasal, subgaleal, umbilical, intestinal, or intracranial hemorrhages. Late HDN is defined by the American Academy of Pediatrics as unexpected bleeding from severe vitamin K deficiency in 2–12 week old infants who are primarily breastfed and who received no or inadequate neonatal vitamin K prophylaxis.[78] Vitamin K deficiency beyond the newborn period is rare, but may result from malabsorption, liver disease, inadequate dietary intake, or medications. Fat malabsorption occurs in conditions such as regional ileitis, topical sprue, celiac disease, cystic fibrosis, pancreatic insufficiency, and biliary obstruction. Antibiotic use can result in vitamin K deficiency by altering the populations of normal bowel flora. Coumarin interferes with vitamin K epoxide reductase, an enzyme important in the recycling of inactive vitamin K into its active form. Other medications that can interfere with vitamin K metabolism include anticonvulsants (phenytoin), rifampin, isoniazid, high-dose salicylates, cholestyramine, and cephalosporins.[11,79] Vitamin K deficiency in older children and adults can present as purpura, ecchymoses, gingival bleeding, and gastrointestinal, genitourinary, and retroperitoneal hemorrhage.

Laboratory Testing. Because vitamin K is a key cofactor in the coagulation pathway, deficiency of vitamin K typically manifests as elevations in both prothrombin time and activated partial thromboplastin time (PT and PTT). Serum levels of vitamin K can also be measured.

While des-γ-carboxyprothrombin (DCP), also known as the abnormal "protein induced by vitamin K absence" (PIVKA), can be a sensitive indicator for vitamin K deficiency, its presence has also been strongly linked to certain malignancies, in particular, hepatocellular carcinoma. It appears that hepatocellular carcinoma cells produce DCP directly rather than as a byproduct of low vitamin K levels, which may be normal in patients with hepatocellular carcinoma.[80]

Treatment. Neonatal prophylaxis is traditionally with a single intramuscular dose of 0.5–1.0 mg vitamin K. There have been some studies regarding the use of oral vitamin K prophylaxis, but there is no definitive data on efficacy, safety, or bioavailability.[78]

Acute treatment is with fresh frozen plasma to replace deficient coagulation factors. Vitamin deficiency can also be treated with parenteral or intramuscular 5–10 mg vitamin K per day to correct severe deficiency.

WATER-SOLUBLE VITAMINS AT A GLANCE

- B complex vitamins, vitamin C, biotin.
- Niacin supplementation should be given with isoniazid therapy to prevent pellagra, characterized by a photosensitive dermatitis, diarrhea, dementia, and death.
- Vitamin C is an essential cofactor in multiple biologic reactions, including collagen synthesis. Deficiency causes scurvy, which presents with follicular hyperkeratosis, curled corkscrew hairs, and a bleeding diathesis.

VITAMIN B_1 (THIAMINE)

Etiology and Pathogenesis. Disorders of thiamine may have broad-ranging implications because thiamine is an essential coenzyme for three separate enzymes involved in NADPH synthesis, carbohydrate metabolism, and deoxyribose and ribose synthesis. Thiamine is used as a coenzyme for transketolase in the pentose phosphate pathway to produce NADPH. Thiamine pyrophosphate acts as a coenzyme in pyruvate dehydrogenase and α-ketoglutarate dehydrogenase, which are involved in oxidative decarboxylation reactions in the metabolism of carbohydrates and branched-chain amino acids.

Epidemiology. Thiamine is obtained from whole grains, enriched bread products, dried peas and beans, potatoes, and fish. Polished rice eliminates the thiamine-containing husk and predisposes to thiamine deficiency.

Disorders of thiamine excess are extremely rare. Most arise as a result of intravenous administration for suspected thiamine deficiency in the context of chronic alcoholism. Local irritation at the site of intravenous administration, generalized pruritus, and anaphylactic or anaphylactoid reactions have been described.[81] Neurotoxicity can occur in experimental settings when thiamine is administered directly into the central nervous system.[82] In general, thiamine excess states are extremely rare in humans.

Beriberi refers to a thiamine deficiency state. The word is derived from Sinhalese meaning "extreme weakness." The symptoms of beriberi have been recognized in East Asian countries for thousands of years because polished white rice is a dietary staple. The Japanese navy observed in the 1890s that beriberi could be eradicated by adding meat, fish, and vegetables to the diet.[83] Beriberi became an epidemic in the Dutch East Indies in the late 1800s. Christiaan Eijkman was part of the medical team stationed in the Dutch East Indies to study beriberi. In 1929, Eijkman was awarded the Nobel Prize in Physiology and Medicine for his work starting in 1886 studying the effect of polished rice and unpolished rice on the incidence of beriberi in chickens. Through a series of detailed experiments on populations of chickens fed various diets and injected with various bacteria, he concluded that there was a direct correlation between diet and beriberi, but like many, had initially misattributed the cause to a nonexistent infectious agent in polished rice. In 1926, Barend Coenraad Petrus Jansen and William Frederick Donath successfully isolated thiamine from rice polishings, and Robert Williams was able to synthesize thiamine in the 1930s.[84]

Clinical Findings. Thiamine deficiency in the United States is now rare. Predisposing factors for pediatric thiamine deficiency include unsupplemented parenteral nutrition, breastfed infants of thiamine-deficient mothers, congestive heart failure,[85] and severe malnutrition. Early signs include irritability, apathy, restlessness, and vomiting. As the disease progresses, neurologic signs of Wernicke's encephalopathy may develop, such as ophthalmoplegia, ataxia, nystagmus, and characteristic laryngeal nerve paralysis resulting in aphonia, which is a classic manifestation of infantile beriberi. Other symptoms include congestive heart failure, tachycardia, dyspnea, and cyanosis. In 2003, a series of infants presenting with ophthalmoplegia as a manifestation of Wernicke's encephalopathy was reported in Israel as a result of a thiamine-deficient infant soy formula. In all these cases, a prodromal illness was observed. Early symptoms included vomiting, anorexia, diarrhea, lethargy, irritability, and developmental delay. Upbeat nystagmus and ophthalmoplegia were the primary neurological signs. Following treatment, those with early disease had complete recovery, but those with severe disease had residual neurological complications.[86]

Adult beriberi has been categorized into dry and wet forms. Dry beriberi describes a symmetric distal peripheral neuropathy involving both sensory and motor systems. Wet beriberi includes neuropathy and signs of cardiac involvement, including cardiomegaly, cardiomyopathy, congestive heart failure, peripheral edema, and tachycardia. Rarely, wet beriberi can be associated with pulmonary hypertension that is reversible after thiamine supplementation.[87] A red, burning tongue and peripheral edema have also been observed with wet beriberi.

Laboratory Testing. Diagnosis of thiamine deficiency is made by measurement of erythrocyte thiamine transketolase or blood thiamine concentration. The more reliable measure is erythrocyte thiamine transketolase before and after thiamine pyrophosphate stimulation, represented as a percentage of thiamine pyrophosphate effect (TPPE). Normal values are up to 15%.

Treatment. Because thiamine is a cofactor in a variety of metabolic pathways, daily thiamine requirements are calculated from an individual's ideal total caloric intake, with current recommendations indicating 0.5 mg per 1,000 kcal.

Treatment of thiamine deficiency can be via intravenous, intramuscular, or oral routes of administration. Usually, treatment for beriberi is initiated with intravenous or intramuscular thiamine of 50–100 mg per day for 7–14 days, then oral supplementation is provided until full recovery is documented.

VITAMIN B_2 (RIBOFLAVIN)

Etiology and Pathogenesis. Riboflavin was discovered in 1879 as a fluorescent yellow–green substance found in milk. Its chemical structure was later determined in 1933. Riboflavin is used in two coenzymes, (1) flavin mononucleotide (FMN) and (2) flavin-adenine dinucleotide (FAD), both of which are involved in oxidation-reduction reactions in cellular respiration and oxidative phosphorylation. These two enzymes are also involved in pyridoxine (vitamin B_6) metabolism. Recent studies have suggested that riboflavin deficiency may contribute to increase plasma homocysteine levels, impaired handling of iron, and night blindness.[88]

Riboflavin is typically obtained through dairy products, nuts, meat, eggs, whole grain and enriched bread products, fatty fish, and green leafy vegetables. A small amount of dietary riboflavin is present as free riboflavin; most are found as FAD or FMN. Dietary FAD and FMN are hydrolyzed to riboflavin by brush border membranes or enterocytes. Free riboflavin in the intestinal lumen is then taken up by active transport in the proximal small bowel.

Deficiency states can be caused by decreased intake, inadequate absorption, and phototherapy. Alcoholics, elderly, and adolescents are groups at risk for riboflavin deficiency secondary to poor nutritional intake. Malabsorption after gastric bypass surgery can also predispose individuals to riboflavin deficiency.[89] In areas of India, China, and Iran, riboflavin deficiency is endemic because of their dependence on an unenriched cereal diet. Infants of riboflavin-deficient mothers are also at risk of deficiency because breast milk concentrations of the vitamin are proportional to maternal concentrations. Once weaned from the breast, these infants are at additional risk if they are not transitioned to milk. When confounded by PEM, riboflavin deficiency may be worsened because the usual renal compensatory mechanism of increased riboflavin absorption is impaired in this setting. Visible light phototherapy for jaundiced neonates causes photodecomposition of riboflavin.[90] Certain drugs also affect riboflavin levels through effects on absorption or metabolic inhibition. Chlorpromazine and other tricyclic drugs inhibit transport of riboflavin in the gastrointestinal tract predisposing to deficiency states.[91] Borate displaces riboflavin from binding sites, increases urinary riboflavin excretion, and inhibits riboflavin-dependent enzymes contributing to riboflavin deficiency.[92]

Clinical Findings. Signs of acute riboflavin deficiency include a deep red erythema, epidermal necrolysis, and mucositis. The severity of symptoms depends on the severity of deficiency[93] (Box 130-8).

Clinical signs of chronic riboflavin deficiency or ariboflavinosis begin 3–5 months after initiation of an inadequate diet. Skin and mucous membrane findings predominate. Initially, angular stomatitis manifests as small papules at the corners of the mouth that enlarge and ulcerate before developing into macerated fissures that extend laterally and often bleed (Fig. 130-7). Pronounced cheilosis with erythema, xerosis, and vertical fissuring of lips can occur. Early glossitis appears as prominent lingual papillae, but after these papillae are lost, the tongue becomes smooth, swollen, and magenta in color. The dermatitis of riboflavin deficiency resembles seborrheic dermatitis in that it involves the nasolabial folds, nostrils, nasal bridge, forehead, cheeks, and posterior auricular regions. Flexural areas of the limbs may also be affected. Plugging of the sebaceous glands (dyssebacia) may be observed around the nose. The dermatitis can affect the genitalia, more often to a greater extent in males than in females. A red, confluent, crusty, or lichenified dermatitis of the scrotum often spreads to involve the inner thighs. In general, the dermatitis is worse in areas of chafing or trauma. Infants frequently manifest the dermatitis in the

BOX 130-8 CLINICAL SIGNS OF RIBOFLAVIN DEFICIENCY

Acute

- Erythema
- Epidermal necrolysis
- Mucositis

Chronic

- Angular stomatitis
- Cheilosis with erythema, xerosis, and fissuring
- Glossitis
- Seborrheic dermatitis-like dermatitis affecting typical sites and flexural areas of limbs and genitalia
- Photophobia and conjunctivitis

Figure 130-7 Riboflavin deficiency. Angular stomatitis with maceration in an Arab child. Riboflavin excretion in the urine was diminished.

inguinal areas. In older individuals, the dermatitis is often more pronounced in facial creases and wrinkles, and if incontinent, can involve the perianal and buttock areas. Cutaneous findings are not aggravated by light exposure, but are exacerbated by heavy physical activity. Ocular findings are also a prominent feature of this disorder with photophobia and conjunctivitis being most notable. Oculo-orogenital syndrome is the term used to describe this constellation of symptoms.

Laboratory Testing. A normochromic, normocytic anemia may be observed. Erythrocyte glutathione reductase activity can be used as a screening test, but a trial of riboflavin supplementation is often the most optimal method to confirm a riboflavin deficiency.

Treatment. The recommended daily value of riboflavin is 0.6 mg per 1,000 kcal. Treatment for deficient infants and children are 1–3 mg per day, and 10–20 mg in adults.

VITAMIN B_3 (NIACIN)

Etiology and Pathogenesis. Niacin is a vitamin cofactor that can be obtained for the diet or synthesized endogenously from the essential amino acid tryptophan. Niacin is found in whole grains and enriched bread products, nuts, dairy products, liver, animal meat, mushrooms, and dried beans. Dietary niacin exists primarily in the form of nicotinamide-adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP). NAD and NADP are hydrolyzed in the intestinal lumen to form nicotinamide. Nicotinamide can be converted to nicotinic acid by intestinal bacteria or be absorbed into plasma. Nicotinamide and nicotinic acid then travel to the liver, kidney, enterocytes, where they are converted back to NAD and NADP. These two agents act as hydrogen donors and acceptors in oxidation-reduction reactions involved in the synthesis and metabolism of carbohydrates, fatty acids, and proteins.

Deficiency of niacin or vitamin B_3 results in pellagra.

Historical Background. (See online edition)

Pellagra remains endemic in parts of the world, including South Africa, China, and India, where corn and maize continue to be a dietary mainstay. Corn and maize contain bound niacin, so without alkaline hydrolysis to release the niacin, it is unavailable for absorption. Jowar, a type of millet found in parts of India, contains adequate levels of niacin, but large quantities of leucine interfere with the conversion of tryptophan to niacin.[96] Although Mexicans have a predominantly maize-based diet, pellagra is relatively uncommon because preparation of the maize includes washing it in lime water, which releases the complexed niacin.

Because niacin is absorbed from the gastrointestinal tract, gastrointestinal disorders can predispose to pellagra. Impaired absorption of tryptophan and niacin occurs in patients with jejunoileitis, gastroenterostomy, prolonged diarrhea, chronic colitis, ulcerative colitis, cirrhosis, Crohn disease, and subtotal gastrectomy.[97] Patients with Hartnup disease, a rare autosomal recessive disorder, develop pellagra-like symptoms in childhood. This is caused by a defect in the neutral brush border system, resulting in malabsorption of amino acids, including tryptophan. Alcoholics develop pellagra from a combination of poor diet and malabsorption. Overly restrictive diets from eating disorders such as anorexia nervosa, presumed food allergies, or food faddism can also cause pellagra.

Patients with increased metabolic needs as seen in carcinoid syndrome can develop pellagra. Normally, about 1% of tryptophan is metabolized to serotonin, but in carcinoid syndrome, an excessive amount, about 60%, of tryptophan is converted to serotonin. Because of this diversion of tryptophan to serotonin production, less tryptophan is available to make niacin.

Medications can also induce pellagra symptoms. Isoniazid is a competitive inhibitor of NAD because of their similar structures, and also impairs pyridoxine functioning, which is essential for niacin synthesis from tryptophan. 5-fluorouracil inhibits conversion of tryptophan to niacin, and 6-mercaptopurine inhibits NAD phosphorylase, which inhibits NAD production. Other implicated medications include phenytoin, chloramphenicol, azathioprine, sulfonamides, and antidepressants.[98]

Clinical Findings. Pellagra is classically described with the four Ds of (1) dermatitis, (2) diarrhea, (3) dementia, and (4) death. The characteristic dermatitis begins as painful, erythematous, pruritic patches in photodistributed areas. The skin becomes progressively more edematous, and several days later may develop vesicles and bullae, which can rupture, leaving crusted erosions, or develop into brown scales. Over time, the skin thickens into sharply demarcated, keratotic, hyperpigmented plaques. Painful fissures can develop in the palms and soles, resembling goose skin. The dorsum of the hands is the most commonly affected sites, and when the rash extends proximally, more on the radial than ulnar side, it forms the "gauntlet" of pellagra (Fig. 130-8A). A butterfly distribution may be apparent on the face when it extends from the nose to the cheeks, chins, and lips. When the dermatitis affects the upper central portion of the chest and neck, it is referred to as "Casal's necklace" (Fig. 130-8B). It can sometimes extend down over the sternum to create a "cravat." Mucous membrane involvement may manifest as cheilitis, angular stomatitis, a red tongue, and ulceration of the buccal mucosa and vulva. Half and half nails may also be present[99] (Box 130-9).

Gastrointestinal symptoms may represent the earliest signs of pellagra. Diarrhea, nausea, vomiting, abdominal pain, and anorexia have been reported. Neurologic symptoms, such as insomnia, fatigue, nervousness, apathy, impaired memory, and depression, can progress to psychosis and dementia in later stages. Without treatment, pellagra leads to death from multiorgan failure.

Laboratory Testing. Diagnosis is primarily made on clinical grounds and through a rapid response to vitamin supplementation. However, measurement of urinary metabolites of niacin—*N*-methylnicontinamide and pyridone—may be used to aid in the diagnosis.

Figure 130-8 Pellagra. Acute dermatosis. **A.** "Glove" or "gauntlet" exudative and crusted lesions on the hands. **B.** "Casal's necklace" on the neck with facial involvement.

Treatment. The recommended daily value of niacin is 15–20 mg of niacin, or about 60 mg of exogenous tryptophan. Treatment with 500 mg per day of nicotinamide or nicotinic acid is given over several weeks. Nicotinamide is preferred over nicotinic acid because nicotinic acid is frequently associated with headache and flushing. Neuropsychiatric symptoms may remit after 24–48 hours of treatment, but skin lesions often take 3–4 weeks to clear.[100]

VITAMIN B_6 (PYRIDOXINE)

Etiology and Pathogenesis. Pyridoxine deficiency was elucidated by Albert Szent-Gyorgi in 1934 while studying pellagra in rats. Esmond Snell identified the two other forms of vitamin B_6 and worked extensively to clarify the biochemical properties of these molecules in the mid 1900s.

Vitamin B_6 describes three interchangeable molecules: (1) pyridoxine, (2) pyridoxamine, and (3) pyridoxal. Humans are unable to synthesize any of these molecules, but fortunately they are widely available in both plant and animal products. Meats, whole grains, vegetables, and nuts are the best sources for vitamin B_6. Processing of these foods can decrease the amount of vitamin available. They are absorbed through passive diffusion in the jejunum and undergo phosphorylation to become components of active coenzymes. The most common form existing is pyridoxal-5-phosphate. Vitamin B_6 is employed in multiple pathways including the decarboxylation and transamination of amino acids, gluconeogenesis, and conversion of tryptophan to niacin, sphingolipid synthesis, prostaglandin synthesis, and neurotransmitter synthesis. As such, clinical features of pyridoxine deficiency may overlap with those of niacin deficiency.

Due to the availability of dietary vitamin B_6, deficiency is seldom caused by inadequate intake, but can occur in alcoholics due to poor diet. More commonly, malabsorption and medication-induced deficiency is etiologic. Small bowel disorders, such as Crohn disease and celiac disease, can interfere with absorption and produce deficiency. Medications that have been implicated in causing deficiency include isoniazid, hydralazine, penicillamine, and oral contraceptives. Isoniazid, hydralazine, and penicillamine bind to pyridoxal-5-phosphate to increase excretion or decrease activity of the coenzyme.

Clinical Findings. Vitamin B_6 toxicity from excessive intake does not typically produce skin findings, although it can be associated with peripheral neuropathy.

BOX 130-9 CLINICAL MANIFESTATIONS OF PELLAGRA

- Painful pruritic dermatitis in photo-exposed areas
- May be vesicular, crusted, and develops into scaly, keratotic plaques
- Dorsum of hands ("gauntlet"), neck (Casal's necklace), dorsa of feet ("gaiter" of pellagra); butterfly distribution in face.
- Angular stomatitis, cheilitis, glossitis
- Diarrhea, nausea, vomiting, abdominal pain, anorexia
- Insomnia, fatigue, nervousness, apathy, impaired memory, depression, psychosis, dementia

Vitamin B_6 deficiency classically presents as a seborrheic-like dermatitis of the face, scalp, neck, shoulders, buttocks, and perineum. Clinical features overlap those of niacin deficiency including features of photodermatitis, glossitis, and cheilitis. Glossitis appears as redness, burning, and ulceration of the tongue, leading to flattening of the filiform papillae. Other areas of oral mucosa also become red and ulcerated, resulting in angular stomatitis, cheilosis, and conjunctivitis. This condition produces an oculo-orogenital syndrome quite similar to that seen with riboflavin deficiency.[101] Neurological signs such as somnolence, peripheral neuropathy, paresthesias, weakness, and confusion. Other signs and symptoms are nonspecific, and include nausea, vomiting, depression, anorexia, and anemia. The clinical manifestations of vitamin B_6 deficiency often resemble pellagra because vitamin B_6 is needed for the conversion of tryptophan to niacin.

Laboratory Testing. Vitamin B_6 can be evaluated by mean measurement of plasma pyridoxal-5-phosphate. Low levels of plasma pyridoxal-5-phosphate indicate deficiency.

Treatment. Recommended daily values of pyridoxine depend on age and gender. Adult males require at least 2 mg per day; adult females require at least 1.6 mg per day; and infants require about 0.3 mg per day. Treatment involves discontinuation of inciting medication and initiating replacement therapy of 100 mg of pyridoxine per day. Oral lesions resolve in days, skin, and hematologic changes resolve in weeks and neurologic symptoms over several months.[11]

VITAMIN B_9 (FOLATE)

Etiology and Pathogenesis. Folate can be found in almost all foods, particularly in liver, wheat bran and other grains, leafy green vegetables, and dried beans. Tetrahydrofolate, the coenzyme form of folate, is used for single-carbon transfers in amino acid, purine, and pyrimidine metabolism. The poor diets of alcoholics, malabsorption, and medications can produce folate deficiency. Malabsorptive states (such as celiac disease, chronic diarrhea, status post total gastrectomy) and antifolate medications (such as methotrexate, trimethoprim, oral contraceptives and pyrimethamine) have been implicated in producing folate deficiency. The antiepileptics phenobarbital and phenytoin can also lead to folate deficiency states through induction of microsomal hepatic enzymes by antiepileptics, which deplete folate stores.[102] In children, folate deficiency can be also be associated with excessive boiling of milk, or a goat's milk diet. Human milk has greater bioavailability of folate when compared with goat's milk.[103,104]

Clinical Findings. As with vitamin B_{12} deficiency, the primary manifestation is hematologic: hypersegmented neutrophils, followed by macrocytosis and megaloblastic anemia. Neutropenia, thrombocytopenia, diarrhea, and irritability may also be observed. In contradistinction to vitamin B_{12} deficiency, folate deficiency is not associated with neurologic symptomatology.

Mucocutaneous findings include glossitis with atrophy of the filiform papillae, angular cheilitis, mucosal ulceration, perirectal ulcerations, perineal seborrheic dermatitis, and diffuse brown hyperpigmentation concentrated in the palmar creases and flexures.[105,106]

Laboratory Testing. Macrocytic and megaloblastic anemia with hypersegmentation of neutrophils is suggestive. Diagnostic confirmation can be accomplished through measurement of serum folic acid levels.

Treatment. Folic acid supplementation is typically curative. Discontinuation of antifolate agents is recommended if involved. Ruling-out concurrent vitamin B_{12} deficiency is crucial before initiating treatment for folate deficiency. If vitamin B_{12} deficiency is present but not treated, the hematologic symptoms may be respond to folate, but the neurologic symptoms will progress. Treatment involves 1–5 mg of folic acid per day.

VITAMIN B_{12} (COBALAMIN)

Historical Background. (See online edition)

Etiology and Pathogenesis. Vitamin B_{12} is an important coenzyme for two biochemical pathways in humans. The first enzyme uses methylcobalamin as a coenzyme for methyltransferase to methylate homocysteine to methionine, which is used in DNA, protein, and lipid metabolism. The second requires 5′-adenosylcobalamin to catalyze the reaction by methylmalonyl CoA mutase to convert methylmalonic acid to succinyl-CoA, which is used in fat and carbohydrate metabolism.

Vitamin B_{12} is found primarily in animal products, with liver, eggs, milk, beef, and organ meats being excellent sources. Gastric acid separates vitamin B_{12} from food proteins so it can bind to intrinsic factor in the duodenum. This complex is taken up by specific ileal receptors in the terminal ileum. In the enterocyte, vitamin B_{12} dissociates from intrinsic factor and enters the portal circulation bound to transcobalamin II for transport to tissues. Between 1% and 5% of free cobalamin is absorbed along the intestinal wall by passive diffusion. The body is able to store large amounts of vitamin B_{12}, so symptoms of deficiency often take 3–6 years to develop.

Epidemiology. Causes of vitamin B_{12} deficiency can be divided into three groups: inadequate intake, malabsorption, and other. Elderly individuals and psychiatric patients with poor diets, and strict vegetarians and their breastfed infants are most likely to become deficient from inadequate intake. Cases related to malabsorption can be further divided into four groups: (1) decreased gastric acid states leaving more B_{12} food-bound (chronic proton pump inhibitors and histamine H_2 receptor blockers), (2) decreased intrinsic factor (pernicious anemia, atrophic gastritis, postgastrectomy), (3) microbial competition in the gut (bacterial overgrowth, *Diphyllobothrium latum* infection), and (4) impaired absorption (Crohn disease, Whipple

disease, Zollinger–Ellison syndrome, celiac disease, short bowel syndrome). The other causes of cobalamin deficiency relate to inborn errors of transport or metabolism.[110]

Clinical Findings. Vitamin B_{12} deficiency manifests primarily in four systems. As with cases of folate deficiency, mucocutaneous manifestations include glossitis, angular cheilitis, hair depigmentation, and cutaneous hyperpigmentation. Glossitis is characterized by an atrophic, red, and painful tongue with atrophy of the filiform papillae, which is referred to as Hunter's glossitis. Early vitamin B_{12} deficiency can manifest as a linear glossitis.[111] Hair depigmentation may be localized or diffuse. Hyperpigmentation can be diffuse and symmetric or few scattered macules. The greatest concentration is usually observed on the hands, nails, and face, with the most commonly affected areas being the palmar creases, flexural regions, and pressure points. This hyperpigmentation often resembles Addison's disease, but patients show no evidence of adrenal insufficiency.[112–115]

Three proposed hypotheses exist regarding the pathophysiology of the hyperpigmentation. Vitamin B_{12} maintains glutathione in reduced form, which is used to regulate tyrosinase, an enzyme necessary in melanogenesis. In B_{12} deficiency, increased tyrosinase activity results in hypermelanosis. Another proposed hypothesis involves defective melanin transport between melanocytes and keratinocytes. Finally, megaloblastic changes in keratinocytes from B_{12} deficiency may affect melanin distribution.[11,19,114,115]

The importance of cobalamin deficiency lies in its association with the classically described neurologic manifestations of subacute combined degeneration of the dorsal and lateral spinal column. Generalized weakness with paresthesias progresses to ataxia and symmetric loss of vibration and proprioception, worse in the lower extremities, eventuating in severe weakness, spasticity, paraplegia, and incontinence. Other neurological findings include apathy, somnolence irritability, memory loss, dementia, and psychosis. Early neurologic findings may present before hematologic signs.

Laboratory Testing. The hematologic findings are similar to those found in folate deficiency, namely macrocytic anemia and hypersegmented neutrophils. Bone marrow biopsy reveals a hypercellular marrow secondary to disordered maturation.

Deficiency is diagnosed by measuring serum cobalamin levels, with levels less than 200 pg/mL indicating definite B_{12} deficiency and 200–300 pg/mL being borderline low.

Treatment. Treatment depends on treating the cause of deficiency and supplementing with vitamin B_{12}. Oral and parenteral supplementations have both been used. Oral supplementation can even be used in patients with pernicious anemia, but require much larger doses of enteral B_{12} than when parental since absorption has to be through the intrinsic-factor-independent mechanism. Supplementation with cyanocobalamin of some form is 1 mg per week for 1 month. If symptoms persist, or if deficiency is to be a long-term problem, as in pernicious anemia, then addition supplementation is with 1 mg of cyanocobalamin every month.

VITAMIN C (ASCORBIC ACID)

Etiology and Pathogenesis. Vitamin C is an antioxidant and essential cofactor in several biological reactions, including collagen biosynthesis, prostaglandin metabolism, fatty acid transport, and norepinephrine synthesis. Humans are unable to synthesize ascorbic acid because they lack gulonolactone oxidase, an enzyme most other animals possess use to convert glucose to ascorbic acid. Other organisms that require ascorbic acid include: the guinea pig, the fruit bat, and certain fish and bird species.

The majority of Western dietary vitamin C is obtained from fruits and vegetables, like potatoes, tomatoes, berries, citrus fruits, and green vegetables. Vitamin C is absorbed in the distal small bowel. Most dietary vitamin C is completely absorbed, but there is a decrease in absorption as dietary intake increases. Vitamin C is found in greatest concentration in the pituitary, adrenal glands, liver, leukocytes, and eyes. Depletion of body stores occurs after 1–3 months of a deficient diet.

As a water-soluble vitamin, ascorbic acid excess states are not typically associated with significant clinical disease. However, vitamin C deficiency is a disease of both great clinical importance and one of great historical significance. Vitamin C deficiency results in scurvy.

Historical Background. (See online edition)

Etiology and Pathogenesis. Causes of scurvy include insufficient vitamin C intake, increased vitamin requirement, and increased loss. Inadequate intake is the most common cause. Elderly individuals living alone may have limited diets as a result of poverty, immobility, poor dentition, poor access to groceries, or dementia.[121,122] Alcoholics, food faddists, individuals with presumed food allergies, and cancer patients may have decreased overall dietary intake or may simply avoid fruit and vegetables.[123] Iatrogenic scurvy occurs when physicians recommend dietary restrictions for certain conditions, such as in ulcerative colitis, Whipple disease, peptic ulcers, and gastroesophageal reflux, or with inadequate vitamin supplementation with parenteral nutrition. Increased vitamin C requirements are encountered with certain drugs, including aspirin, indomethacin, tetracycline, oral contraceptives, corticosteroids, and tobacco smoking. Scurvy has been reported as a complication of interleukin-2 treatment of metastatic renal cell carcinoma.[124] Peritoneal dialysis and hemodialysis can induce scurvy because the water-soluble vitamin is removed during the dialyzing process.[125] Scurvy has also been reported among patients receiving liver transplants.[126]

Impaired collagen synthesis is the basis for many cutaneous manifestation of scurvy. Ascorbic acid is required for the hydroxylation of proline residues on procollagen, allowing the formation of hydrogen–hydrogen bonding in the triple helix of mature collagen. Without ascorbic acid, the polypeptides are

BOX 130-10 CLINICAL MANIFESTATIONS OF SCURVY

Skin	Follicular keratotic plugging Corkscrew hairs Perifollicular purpura Lower extremity edema with ecchymosis Poor wound healing and dehiscence
Mucosa	Swelling, ecchymoses, and bleeding of gingiva Hemorrhagic gingivitis, necrosis, loss of teeth
Other Organs	Hemorrhagic intraarticular, subperiosteal, intramuscular, disruption of growth plates, bowing of bones, depressed sternum Epistaxis, hematuria, gastrointestinal, and cerebral hemorrhage

unstable and unable to form stable triple helices. This results in decreased collagen secretion from fibroblasts, increased collagen solubility, and unstable collage fibrils. This abnormal collagen creates pathology in skin, mucous membranes, blood vessels, and bone, leading to the four Hs of scurvy: (1) hemorrhagic signs, (2) hyperkeratosis of hair follicles, (3) hypochondriasis, and (4) hematologic abnormalities (Box 130-10).

Clinical Manifestations. (See Box 130-10). The earliest cutaneous sign of scurvy is phrynoderma—enlargement and keratosis of hair follicles, especially on the posterolateral aspect of the arms, resembling keratosis pilaris. The keratotic plugging generalizes, extending to the back, buttocks, posterior thighs, calves, and shins. The hairs within these plugged follicles become curled, resulting in corkscrew hairs. The corkscrew hair results from impaired keratin cross-links by disulfide bonds. As the disease progresses, the follicles red from congestion and proliferation of surrounding blood vessels, then turn purple, and finally red and hemorrhagic (Fig. 130-9). This palpable perifollicular purpura is characteristically found on the legs. Lower extremity edema is often referred to as "woody edema," associated with pain and ecchymosis. Other nonspecific cutaneous findings include xerosis and acne. Poor wound healing and even dehiscence of old wounds involving skin and bone can occur because vitamin C is necessary for wound healing and maintenance of healed wounds. Hemorrhage in the nail bed is noted as subungual linear (splinter) hemorrhages.

Oral manifestations are common. Gingival disease manifests as swelling, ecchymoses, bleeding, and loosening of teeth. Interdental and marginal gingivae become red, smooth, swollen, and shiny before becoming purple, black, and necrotic. This hemorrhagic gingivitis is secondary to poor osteodentin formation, which produces softer teeth that are prone to infection. Existing gingivitis and poor dentition predispose to more severe disease, but those without teeth do not develop hemorrhagic gingivitis.

Figure 130-9 Vitamin C deficiency in an 18-year-old girl after gastrointestinal surgery. Note the "corkscrew" or "swan-neck" hairs associated with perifollicular purpura.

Hemorrhage can occur in areas other than the skin, mouth, and nails. Bone disease is a frequent manifestation in children. Hemorrhage can be intra-articular, intramuscular, and subperiosteal. All of the above can lead to pain and disruption of the growth plates. Bowing of the long bones and a depressed sternum with and outward projection of the end of the ribs are noted on musculoskeletal examination. Metaphyseal spurs with marginal fractures (Pelkan sign), a ring of increased density surrounding the epiphysis (Wimberger sign), widening of the zone of provisional calcification (white line of Frankl), and a transverse band of radiolucency in the metaphysis (scurvy line or Trummerfeld zone) are seen on radiographs of extremities. Periosteal bleeding may occur. Epistaxis, hematuria, intracerebral hemorrhage, subconjunctival hemorrhage, and gastrointestinal hemorrhage have been reported. Weakness, fatigue, emotional lability, hypochondriasis, weight loss, arthralgias, hypotension, anorexia, and diarrhea are nonspecific findings associated with vitamin C deficiency.

The causes of a normochromic, normocytic anemia are multifactorial, including blood loss from hemorrhage, intravascular hemolysis, intracellular iron depletion, and decreased folate levels.

Laboratory Testing. Scurvy is a clinical diagnosis, but when unsure of the diagnosis, measurement of leukocyte ascorbate level can be helpful. Levels less than 75 mg/L indicate a deficient state.

Treatment. Recommended daily intake of vitamin C is 40–60 mg of ascorbic acid. With vitamin C supplementation, clinical symptoms rapidly improve within several days following initiation of supplementation. Therapeutic doses of 100–300 mg of ascorbic acid are administered daily until symptoms completely resolve.

BIOTIN

Etiology and Pathogenesis. Biotin is an essential cofactor for four carboxylating enzymes: (1) acetyl-CoA

carboxylase in fatty acid synthesis and lipogenesis, (2) pyruvate carboxylase in gluconeogenesis, and (3) propionyl-CoA carboxylase (4) 3-methylcrotonyl-CoA carboxylase—both involved in amino acid catabolism.

Eggs, liver, milk, peanuts, mushrooms, chocolates, and hazelnuts are common sources of biotin. Release of protein-bound dietary biotin depends on pancreatic biotinidase. Free biotin diffuses across the gut to bind to plasma proteins. Since biotin is found in many dietary sources and can be synthesized by enteric bacteria, deficiency is uncommon. In 1941, Paul Gyorgy described that avidin in egg white bound and inactivated biotin. Virgil Sydenstricker took this observation and induced biotin deficiency by feeding normal volunteers raw egg white rich diets. Avidin, a protein found in egg whites, binds free biotin in the bowel, therefore preventing absorption of both dietary and synthesized biotin. Although an uncommon cause of biotin deficiency, individuals following fad diets high in raw egg whites can be at risk for deficiency.[127] Biotin deficiency may arise from long-term parenteral nutrition without biotin supplementation.[128] Individuals on unsupplemented parenteral nutrition and on long-term antibiotics are particularly at risk because the antibiotics eradicate biotin-producing enteric flora.[129] Anticonvulsants, such as valproic acid, carbamazepine, and phenytoin, can increase biotin catabolism or impair liver function, leading to biotin deficiency.[130–132] A series of biotin deficiency cases were reported in Japan secondary to an elemental infant formula without supplemental biotin.[133,134]

Clinical Findings. Symptoms can develop 3–6 months after initiation of unsupplemented parenteral nutrition or raw egg white rich diet, but appear earlier in infants because of the greater biotin requirement for growth. The cutaneous manifestations are similar to those of acrodermatitis enteropathica (AE) (see below) and essential fatty acid deficiency (see above) (Box 130-11). An erythematous, scaling, and crusting dermatitis usually begins around the eyes, nose, and mouth and continues to involve multiple periorificial areas, including the perianal region. Alopecia, conjunctivitis, and glossitis have also been associated. Neurological findings include irritability, lethargy, paresthesias, hypotonia, developmental delay, and myalgias. Nausea and anorexia have also been described.

Two inborn errors of metabolism, both autosomal recessive multiple carboxylase deficiencies, also alter normal biotin metabolism. The neonatal (early onset) form is associated with a defect in holocarboxylase synthetase. This enzyme is used to catalyze the formation of the amide bond linking biotin to several carboxylase enzymes. Symptoms develop during the first 6 weeks of life and the condition is typically fatal. Patients present with a bright red scaling dermatosis that starts on the scalp, eyebrows, and eyelashes, which can spread to involve the perioral, perinasal, and intertriginous regions. Hair thinning can progress to patchy or total alopecia. Holocarboxylase synthetase deficiency can also present as a collodion membrane and subsequent ichthyosis.[135] Neurological findings are common and manifest as difficulty feeding and breathing, hypotonia, ataxia, seizures, lethargy, and global developmental delay. Associated metabolic derangements are metabolic acidosis, mild-to-moderate hyperammonemia, lactic acidosis, ketoacidosis, and organic aciduria, all of which can be exacerbated by intercurrent illness.[136]

The juvenile (infantile or late-onset) form presents after 3 months of age and is caused by biotinidase deficiency. Biotinidase is found in pancreatic secretions to recycle endogenous biotin and release protein-bound dietary biotin. Since symptoms derive from a relative biotin deficiency, large supplemental doses of biotin are used to treat this disorder. In biotinidase deficiency, children present with a scaly, erythematous periorificial dermatitis. Severe cases develop lichenification, crusting, and eroded lesions, which can become infected by *Candida*. Keratoconjunctivitis, total alopecia including eyebrows and eyelashes, and glossitis are associated mucocutaneous findings. Ataxia, developmental delay, hypotonia, seizures, optic nerve atrophy, hearing loss, and myoclonic spasms are common neurological findings. Hypertonia does not rule out this deficiency.[137] Sensorineural hearing loss is preventable with early diagnosis of biotinidase deficiency, but once present, is irreversible.[138] In contrast, the metabolic encephalopathy is reversible once appropriate therapy is initiated.[139] Like holocarboxylase synthetase deficiency, metabolic acidosis, lactic acidosis, and organic aciduria are found. Humoral and cellular immunodeficiencies can predispose to cutaneous and systemic infections.

Laboratory Testing. If dietary history is not explanatory, consultation to evaluate for inborn errors of metabolism is recommended in children who present with findings suggestive of a biotin deficiency. Biotinidase levels, serum amino acids, urine organic acids, carnitine studies, and ammonia may be helpful in differentiating this disorder from other metabolic diseases.

Treatment. The recommended daily value increases from 30 µg in neonates to 100–200 µg in adults. Acquired deficiency is treated with 150 µg of biotin per day until resolution of symptoms. Although holocarboxylase synthetase deficiency can be treated with 10–40 mg of biotin per day to reverse cutaneous symptoms, neurological deficits may persist. Patients with biotinidase deficiency are treated with 5–10 mg of

BOX 130-11 CLINICAL MANIFESTATIONS OF BIOTIN DEFICIENCY AND MULTIPLE CARBOXYLASE DEFICIENCY

- Erythematous, crusting, scaly dermatitis around eyes, nose, mouth, and other periorificial areas
- Alopecia, glossitis, conjunctivitis
- Irritability, lethargy, paresthesias, hypotonia, developmental delay

biotin and have better clinical outcomes than that seen with holocarboxylase synthetase deficiency.

MINERALS

MINERALS AT A GLANCE

- Cutaneous changes associated with iron deficiency include koilonychia, spoon-shaped nails; brittle, lusterless hair; aphthous stomatitis; and angular stomatitis.
- Acrodermatitis enteropathica is an inherited defect in the intestinal zinc transporter ZIP4.
- Zinc deficiency presents with a periorificial and acral eczematous and erosive dermatitis.
- Zinc status can be measured by serum zinc or alkaline phosphatase, a zinc-dependent enzyme.
- Menkes disease is an X-linked disorder of intestinal copper transport, and results in characteristic kinking of the hair and neurologic deficits.

COPPER

Etiology and Pathogenesis. Copper is an essential component of several metalloenzymes, including tyrosinase and lysyl oxidase. Tyrosinase is involved in melanin biosynthesis, and lysyl oxidase deaminates lysine and hydroxylysine in the first step in collagen cross-linking. Other copper enzymes are involved in catecholamine production, free radical detoxification, and oxidation-reduction reactions.

Epidemiology. Copper is found in fish, oysters, whole grains, beef and pork liver, chocolate, eggs, and raisins. Copper deficiency is uncommon, but can result from malnutrition, malabsorptive states, chronic unsupplemented parenteral nutrition, infants with a strictly cow's milk diet, and excessive intake of antacids, zinc, iron, or vitamin C, that can interfere with absorption. Celiac disease, cystic fibrosis, gastric bypass surgery, and short bowel syndrome lead to malabsorption of dietary copper.

Clinical Findings. Clinical manifestations in these cases include hypopigmentation of hair and skin and bony abnormalities (osteoporosis, fractures, periosteal reaction, and flaring of anterior ribs). Copper deficiency myeloneuropathy presents as a progressive and symmetric sensory loss and motor weakness of both upper and lower extremities.[140–142] All sensory modalities are affected. If untreated, optic nerve involvement may occur, with permanent vision loss.[142] Copper supplementation prevents further neurologic deterioration, but recovery of function is not guaranteed.

Laboratory Testing. Microcytic anemia, neutropenia, hypocupremia, and hypoceruloplasminemia can be observed. Neutropenia is the earliest and most common sign of copper deficiency and is a sensitive measure of treatment adequacy.

Treatment. Treatment is with supplemental copper in the diet.

Copper and Menkes Disease

Epidemiology. Menkes disease, also known as kinky hair disease, was described by John Menkes in 1962 as a multifocal degenerative disease of gray matter. The connection between copper deficiency and demyelinating disease was first suggested in the 1930s by Australian veterinarians after observing ataxia in lambs born to mothers grazing in copper-deficient pastures. Menkes described five male infants born into an English-Irish family who showed an X-linked syndrome of neurologic degeneration, particular hair, and failure to thrive. The incidence of Menkes' disease ranges from 1 in 100,000 to 1 in 250,000 live births.

Etiology and Pathogenesis. The Menkes gene, MNK, was identified on chromosome Xq13 in 1993. The protein product is a copper-transporting *P*-type ATPase, which is expressed in almost all tissues, except the liver. Mutations in MNK lead to decreased concentrations of copper because of impaired intestinal absorption and consequent decreased activity of cuproenzymes.

Clinical Findings. Classically, signs of Menkes disease begin at 2–3 months of age, although neonatal indicators include preterm labor, large cephalohematomas, hypothermia, hypoglycemia, and jaundice. The characteristic facies of Menkes disease is a cherubic appearance with a depressed nasal bridge, ptosis, and reduced facial movements. At 2–3 months of age, there is loss of developmental milestones, hypotonia, seizures, and failure to thrive. Structural changes in the hair are seen, with the general appearance of short, sparse, lusterless, tangled, and depigmented hair. The eyebrows have the same steel wool appearance as scalp hair. On light microscopy, pili torti is classically seen. Monilethrix, segmental shaft narrowing, and trichorrhexis nodosa, small beaded swelling of the hair shaft with fractures at regular intervals, may also be observed. Other cutaneous findings include follicular hyperkeratosis and soft, inelastic, depigmented skin especially at the nape of the neck, axillae, and trunk. A high arched palate and delayed tooth eruption may be noted on oral examination (Box 130-12).

Neurologic deficits represent the major morbidity in this disorder. Profound truncal hypotonia with poor head control is typical, while appendicular tone may be increased. Deep tendon reflexes are hyperactive. Suck and cry remain strong. Optic disks are pale with impaired visual fixation and tracking. Hearing remains normal. Developmental arrest occurs at occasional smiling and babbling. Bony changes most often involve the extremities and the skull, and less often the thorax, vertebrae, and pelvis. They include osteoporosis, metaphyseal widening and lateral spur formation,

BOX 130-12 CLINICAL FEATURES OF MENKES DISEASE

- Depressed nasal bridge, ptosis, and reduced facial movements
- Loss of developmental milestones, hypotonia, seizures, hypothermia, and failure of thrive
- Steel wool appearance of hair: short, sparse lusterless, tangled, and depigmented. Microscopically: pili torti, trichorrhexis nodosa
- Follicular hyperkeratosis, inelastic depigmented skin at nape of neck, axillae, and trunk
- Arched plate, delayed tooth eruption
- Severe neurologic deficits
- Bony and renal changes

ossification of sutures, a diaphyseal periosteal reaction, and scalloping of the posterior aspects of the vertebral bodies, and subperiosteal new bone formation. Renal involvement as hydronephrosis, hydroureter, and diverticula of the bladder can occur. Elongation and tortuosity of many large vessels lead to severe arterial disease, a frequent cause of death by age of 3–4 years.

Laboratory Testing. Diagnosis is through the clinical history, physical examination, and reduced levels of serum ceruloplasmin and copper.

Treatment. Early treatment with copper histidinate has resulted in good outcomes, including normal neurodevelopmental milestones, in some patients. Initiation of therapy in older patients may be helpful in alleviation of symptoms like irritability and insomnia.[143,144]

SELENIUM

Etiology and Pathogenesis. Selenium is an essential component of glutathione peroxidase, an antioxidant. Selenium is found in seafood, red meat, egg yolks, grain products, and chicken. The amount of selenium available in cereal grains depends on the selenium content of the soil where it was grown. An area with low soil selenium is Keshan, China, where selenium deficiency in humans is endemic. Selenium-deficient soil is seen in the context of heavy erosion of the surface soil, resulting in trace mineral depletion.[145,146]

Selenium Deficiency

Epidemiology. Selenium deficiency is primarily seen in geographic areas where low soil selenium exists, but can also occur in the context of restricted protein diets, unsupplemented parenteral nutrition, malabsorption states, and increased losses.[147,148]

Clinical Findings. Two disorders have been attributed to selenium deficiency: (1) Keshan disease and (2) Kaschin–Beck disease. These diseases have only been reported in endemic areas of Asia.

Keshan disease is a multifocal myocarditis leading to fatal cardiomyopathy that is seen primarily in women and young children in endemic areas. Acute or chronic insufficiency of cardiac function, cardiomegaly, arrhythmias, and electrocardiographic abnormalities have been noted. Muscle pain and weakness with hepatic congestion, mesenteric lymphadenosis, erythrocyte macrocytosis without anemia, and pancreatic exocrine dysfunction have also been seen. Cutaneous findings in these patients have included white nail beds, similar to those of Terry's nails in hepatic cirrhosis, and hypopigmentation of skin and hair (pseudoalbinism). These findings resolve with selenium supplementation.

Kaschin-Beck disease is an osteoarthropathy that affects the epiphyseal and articular cartilage and the epiphyseal growth plates, resulting in enlarged joints, and shortened fingers and toes.

Laboratory Testing. Diagnosis of selenium deficiency is through measurement of plasma selenium levels and glutathione peroxidase activity.

Treatment. Selenium supplementation is used for both acute correction and long-term maintenance.

Selenium Excess

Epidemiology. Selenium toxicity can be acutely fatal. Cases of toxicity have been associated with increased soil selenium. Marco Polo described findings consistent with selenium poisoning in Western China during his explorations in 1,295. In the 1960s, reports of selenium toxicity came out of Enshi County in Hubei, China. The cause of this endemic toxicity arose from coal contaminated with selenium that was then used to fertilize the soil.[149] Sporadic cases of selenium intoxication secondary to excess supplement ingestion have been reported.[150] Additional cases of acute selenium toxicity have been documented after ingestion of glass blue (used in stained glass manufacturing),[151] selenite broth (enriched culture media used to isolate *Salmonella bacilli*), and gun bluing agent (a finishing product for firearms).[152]

Clinical Findings. Hair becomes dry and brittle in association with an exfoliative dermatitis on the scalp, often resulting in broken hairs and alopecia. Nails also become brittle with white horizontal streaking on the surface. Breaks in the wall of then nail eventually leads to nail loss. The new nail is fragile and thickened with a rough surface. Nails, hair, and teeth can all develop a reddish hue. Skin on the extremities and neck can become red, swollen, blistered, and occasionally ulcerate that heal slowly. Neurologic complaints of peripheral anesthesia, hyperreflexia, numbness, convulsions, and paralysis have been reported. Nausea, vomiting, diarrhea, garlic or sour-milk breath odor, and hypersalivation can occur. Severe corrosive hemorrhagic gastritis can progress into a deep gastric ulcer after acute intoxication. Acute tubular necrosis of the kidneys with the potential for acute renal failure requiring dialysis may also complicate selenium toxicity.[153]

Laboratory Testing. Screening of plasma can be used to document elevation selenium levels.

Treatment. Treatment involves removal of the source of excess selenium and supportive care for complications.

MANGANESE

Etiology and Pathogenesis. Manganese activates glycosyltransferases used in the synthesis of glycosaminoglycans and glycoproteins and is used in two metalloenzymes [(1) pyruvate carboxylase and (2) superoxide dismutase]. Manganese is also found in high concentrations in melanocytes. Reported cases of manganese deficiency are rare. Manganese deficiency was reported during a study of vitamin K requirements, when a study subject was accidentally placed on a manganese-deficient diet. He developed a mild dermatitis, reddening of his black hair, slowed hair and nail growth, and occasional nausea and vomiting with moderate weight loss. A subsequent study of manganese-deficient states showed no hair changes, but miliaria crystallina developed in half the subjects, and disappeared after repletion. Long-term parenteral nutrition without adequate supplementation can induce manganese-deficient states.[154] Likewise, in cases where manganese is supplemented in parenteral nutrition, hypermagnesemia can occur and has been associated with neurologic sequelae.[155]

IRON.

Iron is used in several biological pathways including heme synthesis, oxidation-reduction reactions, collagen synthesis, and as a cofactor for enzymes such as succinic dehydrogenase, monoamine oxidase, and glycerophosphate oxidase. Iron is found in red meats, egg yolks, dried beans, nuts, dried fruits, green leafy vegetables, and enriched grain products.

Iron Deficiency. Iron deficiency continues to be an international problem that crosses socioeconomic and ethnic divides. Deficiency states result from inadequate intake or chronic blood loss. Groups at high risk include infants, menstruating females, and individuals with chronic gastrointestinal bleeds. Infants on an iron-fortified formula are at risk for deficiency 3–6 months after transitioning to cow's formula because of the lower iron content of cow's milk.[156]

Skin changes have been seen in iron deficiency involve the skin, mucous membranes, hair, and nails (Box 130-13). Moderate iron deficiency causes fragile, longitudinally ridged, lamellated, or brittle nails. As deficiency progresses, the nail plate shows thinning, flattening, and a spoon-shaped convexity known as koilonychia. The index and third fingernails are usually the most severely involved. Even after iron replacement therapy begins, koilonychia resolves slowly.

Hair changes include a lusterless, brittle, dry, and focally narrow or split hair shafts, likely caused by impaired keratin production. Heterochromia of black scalp hair with alternating segments of dark brow, white, and liver bands have been described. Cunningham noted in 1932 that hair loss occurred in iron deficiency, but Hard was the first to show an etiologic connection between iron deficiency anemia and diffuse scalp hair loss.[157,158] However, the role of iron deficiency in hair loss continues to be a controversial topic.[159,160]

BOX 130-13 CUTANEOUS FEATURES OF IRON DEFICIENCY

- **Nails:** Fragile, longitudinally ridged Lamellated brittle nails → thinning, flattening of nail plate, koilonychia
- **Hair:** Lusterless, dry, focally narrow and split hair shafts, heterochromia of black hair. Hair loss.
- **Mucous Membranes:** Aphthous stomatitis, angular stomatitis, glossodynia, atrophied tongue papillae
- **Blue sclerae**
- **Pruritus**

Mucous membrane manifestations include aphthous stomatitis, angular stomatitis, glossodynia, and absent or atrophied tongue papillae. Blue sclerae that persists after iron replacement is likely secondary to impaired collagen synthesis. Generalized pruritus of variable severity has been reported in some individuals with iron deficiency, and sometimes associated with dermatitis herpetiformis. Plummer–Vinson syndrome is an iron deficiency associated syndrome encountered predominantly in middle-aged women with microcytic anemia, dysphagia, glossitis, koilonychia, and angular stomatitis. This is considered to be a precancerous phenomenon, associated with carcinoma of the mouth or upper respiratory tract.

Iron deficiency in a microcytic anemia is diagnosed by measurement of serum iron levels, ferritin, total iron binding capacity, transferrin saturation, as well as free or zinc protoporphyrin levels. Treatment involves appropriate iron supplementation.

Iron Excess. Chronic iron overload, hemosiderosis, can be associated with tissue injury, which is called hemochromatosis. Hyperpigmentation and ichthyosis-like changes of the skin are seen. Associated findings are cirrhosis of the liver, diabetes mellitus, and cardiomyopathy.

ZINC.

Zinc is an important micronutrient that is an essential component of many metalloenzymes involved in a variety of metabolic pathways and cellular functions, and is particularly important in protein and nucleic acid synthesis. Adequate zinc levels are also important for wound healing and for T-cell, neutrophil, and natural killer cell function. Zinc homeostasis depends on adequate zinc absorption and maintenance of appropriate intracellular and extracellular zinc levels as well as its regulated transport across luminal surfaces. Dietary sources of zinc include meat,

fish, shellfish, eggs, dairy products, and legumes, with the highest and most bioavailable forms of zinc found in meats, fish, and shellfish. Other vegetables, fruits, and refined carbohydrates contain very little zinc. Phytates (found in cereal grains, legumes, and nuts) and fiber interfere with intestinal zinc absorption. Human breast milk contains very high levels of zinc during the first 1–2 months of lactation, averaging 3 mg/L; subsequently, zinc levels decrease. Human breast milk also contains a zinc-binding ligand that increases the bioavailability of breast milk zinc. Although cow's milk formula contains higher levels of zinc, the bioavailability is significantly less than that in human breast milk.

Enteral zinc absorption occurs in the small intestine. Zinc excretion occurs primarily via the gastrointestinal tract via pancreatic and intestinal secretions, with lesser amounts excreted in the urine complexed to free amino acids. Two important families of zinc transporter proteins, including *9 ZnT* (zinc transporter) genes and 15 Zip (Zrt- and Irt-like proteins) transporters, have been identified in humans.

Although total body zinc is stored primarily in the bones, muscles, prostate, and skin, there is no free exchange of stored zinc, and metabolic needs must be met by a continued supply of dietary zinc. In plasma, approximately 50% of the total zinc is complexed with albumin, while the remainder is bound to other serum proteins, including transferrin and α_2-macroglobulin, or bound to free amino acids. Plasma levels may decrease transiently in response to intercurrent illness, surgery, or other stressors. Excess plasma zinc levels inhibit copper absorption, possibly through competitive inhibition of a common divalent cationic transporter. Zinc deficiency also results in impaired mobilization of hepatic retinol stores and is associated with impaired night vision (nyctalopia). Conversely, excessive calcium intake can interfere with normal zinc absorption, likely also a result of competitive inhibition.

Zinc Deficiency

Epidemiology. Zinc deficiency occurs worldwide. Populations at special risk include patients with intestinal malabsorption syndromes liver disease, anorexia nervosa or food faddism, extensive cutaneous burns, and nephritic syndrome. Iatrogenic zinc deficiency may result from prolonged parenteral or enteral nutrition that contains inadequate zinc levels to meet the metabolic demands. Certain rural populations with diets high in phytates, as have been reported in certain parts of Iran, Turkey, and the former Yugoslavia, are also at risk for acquired zinc deficiency (AZD).

Etiology and Pathogenesis. Zinc deficiency may be either inherited, a form commonly referred to as AE, or acquired, and therefore referred to as AZD.

Acquired Zinc Deficiency. AZD may result from states associated with inadequate intake, impaired absorption, or increased excretion, including pregnancy, lactation, extensive cutaneous burns, generalized exfoliative dermatoses, food faddism, parenteral nutrition, anorexia nervosa, and even excessive sweating. Intestinal malabsorption syndromes, such as inflammatory bowel disease and cystic fibrosis, result in impaired intestinal absorption of zinc, whereas alcoholism and nephrotic syndrome result in increased renal zinc losses. Penicillamine has been reported to cause zinc deficiency in a patient with Wilson disease. Ornithine transcarbamylase deficiency has also been associated with zinc deficiency.

Acrodermatitis Enteropathica. The inherited form of zinc deficiency, AE, is a rare autosomal recessive disorder of zinc absorption. These infants have a defect in an intestinal zinc transporter, the human ZIP4 protein encoded on the *SLC39A4* gene. Mutations in this gene prevents appropriate enteral zinc absorption.[161–163]

AE classically presents during infancy on weaning from breast milk to formula or cereal, which have lower zinc bioavailability than breast milk. There is a form of AZD that may also present during infancy but, in contrast to AE, these infants become symptomatic while breast-feeding and improve after weaning to formula or table foods. Many of these reported infants have been premature, but cases have also been reported in full-term infants. The mothers of these infants have a presumed defect in mammary excretion of zinc into their breast milk, resulting in inadequate zinc intake in their infants.[164,165] In a case we evaluated, breast milk zinc deficiency occurred as a result of excessive maternal intake of calcium that the mother was taking in the belief that calcium supplements might mitigate postpartum depression. Measured breast milk zinc levels were significantly decreased and rebounded to normal levels upon discontinuation of maternal calcium supplementation. Measurement of breast milk zinc levels is a useful tool and is diagnostic when less than 70 µg/dL.

AE presents soon after weaning in affected infants or during the fourth to tenth week of life in infants who are not breast-fed. The classic features of AE include alopecia, diarrhea, lethargy, and an acute eczematous and erosive dermatitis favoring periorificial (perioral, periocular, anogenital) and acral areas (hands and feet) (Box 130-14). The cutaneous findings are highly characteristic and often present initially as a nonspecific, acrally distributed, symmetric, eczematous dermatitis.

BOX 130-14 CLINICAL FEATURES OF ACRODERMATITIS ENTEROPATHICA

- Eczematous and erosive dermatitis
- Preferentially localized to periorificial and acral areas
- Alopecia
- Diarrhea
- Lethargy, irritability
- Whining and crying
- Superinfection with *Candida albicans* and *Staphylococcus aureus*

Figure 130-10 **A.** Patient with acrodermatitis enteropathica. These clinical findings resolved within 2 weeks of initiating zinc supplementation. **B.** This crusted and scaly, erosive, and sharply demarcated eruption appeared shortly after weaning. The child was highly irritable, whining and crying, and had diarrhea.

Over time, bullae and erosions with a characteristic peripheral crusted border develop (Fig. 130-10). Vitiligo-like depigmented patches have been described.[167] In addition to dry and brittle hair, alternating dark and light bands with polarized light can be seen.[168] Patients also appear to be predisposed to systemic infections as a result of impaired cell-mediated immunity, and superinfection with *Candida albicans* and bacteria, usually *Staphylococcus aureus*, is common. Delayed wound healing, acute paronychia, conjunctivitis, blepharitis, and photophobia may also be observed. Diarrhea may be prominent but is not seen in all cases. If untreated, the disease is fatal.

Acquired Zinc Deficiency. Acute AZD secondary to impaired absorption of zinc, inadequate intake, or excessive renal or intestinal losses may result in a clinical picture that resembles AE (see above) and occurs also in adults (Fig. 130-11).

A chronic or subacute form of zinc deficiency is also recognized. These patients often have zinc levels in the mildly deficient range (40–60 µg/dL). Clinical manifestations include growth retardation in children and adolescents, hypogonadism in males, dysgeusia, poor appetite, poor wound healing, abnormal dark adaptation, and impaired mentation. Cutaneous manifestations, when present, are usually less striking and present predominantly as a psoriasiform dermatitis involving the hands and feet and, occasionally, the knees.

Laboratory Testing. A low plasma zinc level is the gold standard for diagnosing zinc deficiency. Use of contaminated needles, catheters, and sample tubes may

Figure 130-11 Zinc deficiency. **A.** There are plaques of dry, scaly, eczematous skin around the buttocks. The lesions often become secondarily infected with *Candida albicans*. **B.** Hands. The fingers are enlarged, and there are paronychia and bright erythema on the terminal phalanges.

lead to erroneously high measured zinc levels. Contact with collection tubes with rubber stoppers should be avoided as they may contain high levels of zinc. Normal plasma zinc levels range from 70 to 250 µg/dL. Measurement of serum alkaline phosphatase—a zinc-dependent enzyme—is another useful and rapid indicator of zinc status, as alkaline phosphatase may be low-normal; serum alkaline phosphatase will increase with zinc supplementation, thus confirming the diagnosis.

In cases in which the plasma zinc level is equivocal and the diagnosis is uncertain, skin biopsy for routine histology may be helpful. The characteristic features are variable psoriasiform hyperplasia with confluent parakeratosis, spongiosis and pallor of the upper epidermis, focal dyskeratosis, and variable epidermal atrophy. However, these findings are not specific; and may be seen in a number of other nutritional deficiencies.

Treatment. Zinc supplementation with either an enteral or parenteral formulation is appropriate. Clinical response is usually rapid, with initial improvement noted within several days. Irritability and whining disappear first, followed by improvement of skin lesions. Although several zinc formulations are available, the most commonly used enteral formulation is zinc sulfate. Zinc chloride is recommended for parenteral supplementation.

In children, 0.5–1.0 mg/kg of elemental zinc given as one to two daily doses is recommended for mild-to-moderate zinc deficiency. Higher doses may be required in cases of AZD due to intestinal malabsorption. In adults, 15–30 mg of elemental zinc per day is usually sufficient in cases of AZD. Serum zinc levels should be monitored during therapy. Patients with AE require lifelong treatment. Patients with AZD may need variable levels of supplementation, depending on their underlying disease. Of note, excess zinc levels may interfere with copper metabolism.

Zinc Toxicity. Zinc toxicity has been reported with exposure to zinc-containing fumes, intravenous poisoning, and ingestion of large amounts of zinc. There are no cutaneous manifestations, but patients may present with severe vomiting, nausea, lethargy, dizziness, neuropathy, and dehydration. Hypocupremia may result.

NOMA

NOMA AT A GLANCE

- Devastating gangrene of the soft and hard tissue of the face found in developing countries.
- Malnutrition, vitamin deficiencies, and immune dysregulation create an environment for this rapidly progressive destructive polymicrobial infection.

BOX 130-15 CLINICAL PRESENTATION OF NOMA

- Rapid progression of soreness of mouth, halitosis, purulent oral discharge, tenderness of lips and cheeks
- Necrotizing stomatitis starting at alveolar margin and extending to mucosal surface of cheek
- Swelling and blue–black discoloration of cheek → cone-shaped black necrosis, tissue destruction, and ulceration

EPIDEMIOLOGY

Noma (necrotizing ulcerative stomatitis, stomatitis gangrenosa, or cancrum oris) is a devastating gangrenous condition that destroys soft and hard tissue of the face that predominantly affects children between the ages of 1 and 4. "Noma" originates from the Greek word *νομη*, which means to graze or to devour, which reflects the rapid progression of this condition.

In 1848, Tourdes was the first to define noma as

> *a gangrenous disease affecting the mouth and face of children living in poor hygiene conditions and suffering from debilitating diseases, especially eruptive fevers. Beginning with an ulcer on the oral mucosa rapidly spreading outside and destroying the soft and hard tissues of the face—and almost always fatal*[169]

As public health initiatives improved sanitation in developed countries, the global epidemiology of noma likewise improved. In general, noma has become a rare occurrence in developed countries and is predominantly encountered now only in parts of Africa, Latin America, and Asia. Intermittent epidemics of noma have been noted during World War I, the malaria epidemic in 1938, and World War II in the Belsen and Auschwitz concentration camps.[170] In response to reports from humanitarian organizations, the World Health Organization declared noma a health priority in 1994. The WHO estimates the worldwide incidence of noma to be 500,000 cases per year with a 79% mortality rate. An estimated 25,000 children are affected in the developing countries bordering the Sahara every year.[171] Unfortunately, the data on the incidence of noma are likely an underestimation of the true incidence since less than 10% of affected individuals actually seek medical care.[53] The high mortality rate and rapid progression of disease means that many patients die before reaching medical attention. Moreover, many cultures perceive noma as a curse on the family, so affected children are often ignored or hidden. Finally, the nomadic lifestyles of many patients make them difficult to register and follow.

An increase in noma has been observed in developed countries over the last two decades, mostly in association with immunosuppressive therapy, HIV/AIDS, and severe combined immunodeficiency.[54]

Noma neonatorum is thought to be a related but separate entity from noma. The original description

by Ghosal in 1978 described 35 premature and low birthweight infants in India who developed gangrenous lesions on their noses, eyelids, oral cavities, anal regions, and genitalia. These infants had *Pseudomonas aeruginosa* isolated from their skin lesions and many of their blood cultures. This condition is almost uniformly fatal. Since Ghosal's description, clinical experience has shown that preterm and low birthweight newborns, especially those with severe intrauterine growth retardation, are at highest risk. The causative organism is usually *Pseudomonas*, but *Escherichia coli*, *Klebsiella*, and *Staphylococci* have occasionally been isolated. Since most cases of noma neonatorum are caused by *Pseudomonas*, some have wondered if it is really ecthyma gangrenosum.[55] Almost all reported cases have been from India, China, Lebanon, or Israel, but there was one reported case in the United States in 2002.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of noma is a complex, and yet undefined, interaction between infection, impaired host defense, and malnutrition. The one known risk factor for noma is poverty. There have been no reported cases of noma in well-nourished African children. An epidemiological study in a Nigerian hospital in 2002 revealed that 98% of affected children lived in very poor homes with an average of seven children per family.[56]

Malnutrition and associated vitamin deficiencies contribute to the pathogenesis of noma. Deficiencies in vitamin A, B_6, C, and E, and the trace elements iron, zinc, and amino acids cysteine, methionine, serine, and glycine have been identified as possible contributing factors to immune dysfunction in the malnourished. Adrenal hyperfunction in PEM has also been implicated in depression of cell-mediated immunity, and decrease in mucosal resilience. Early malnutrition and chronic infections due to early weaning from breast milk may also represent predisposing factors.[172]

In the early 1940s, Albert Eckstein proposed that acute necrotizing gingivitis (ANG), a painful inflammation and necrosis of the interdental papillae, was the precursor to noma. He hypothesized that progression to necrotic stomatitis and noma occurred if appropriate dental hygiene and antibiotics were not initiated. ANG is associated with poor oral hygiene, stress, and malnutrition. However, any oral mucosal ulceration or trauma, including tooth eruption and viral ulcers, can develop into noma.[173]

Patients with noma frequently have a recent history of debilitating infections, with measles and malaria being the most frequent. Unfortunately, the causative link between these preceding infections and noma remain unclear. Studies in Nigeria show that the frequencies of malaria in northern and southern regions are equal, but the prevalence of noma in the north is higher than in the south. The link between measles and noma appears stronger, but still elusive. The ulcerative oral lesions in patients with measles are one proposed site of initiation of noma.[174]

Noma is a polymicrobial infection, with *Prevotella intermedia* and *Fusobacterium necrophorum* being the two most frequently isolated organisms.[175] Other frequently identified organisms are *Tannerella forsynthesis*, *Peptostreptococcus micros*, *Campylobacter*, *Streptococci*, and enteric Gram-negative rods. Although organisms are isolated from noma lesions, there is a low likelihood of transmissibility. There are no reports of outbreaks in families or villages after one child develops noma. Groupings of noma seem to be more associated with common risk factors rather than true transmission.

CLINICAL FINDINGS

The prodrome of noma is not well documented because of late presentation to medical care and rapid progression. Parents often describe fever and apathy. Early acute noma often presents with soreness of the mouth, halitosis, tenderness of the lip or cheek, cervical lymphadenopathy, and purulent oral discharge. The intraoral lesion is a necrotizing stomatitis generally starting on the alveolar margin and extending to the mucosal surface of the cheek. This evolution is rapid, taking 24–48 hours. Swelling and blue–black discoloration of the skin overlying the intraoral lesion develops and rapidly becomes necrotic with well-defined borders. As it becomes black, this necrotic zone expands and forms a classic cone shape, cone gangreneux, with internal destruction greater than external involvement (Fig. 130-12). Laboratory investigation often shows severe anemia, a high white blood cell count, and hypoalbuminemia (see Box 130-15).

Healing noma lesions are also difficult to manage because of the extensive fibrous scars. These scars can lead to strictures of the mouth, severe dental malposition, defective speech, and even complete closure of the mouth from contractures.

TREATMENT. Management of acute noma is geared toward minimizing damage, but invasive intraoral

Figure 130-12 Cancrum oris (noma). Massive destruction of the face in a Tanzanian child.

procedures are contraindicated. Key goals of acute management are:

1. Correction of dehydration and electrolyte imbalances
2. Treatment of predisposing disease, i.e., malaria, measles, HIV, TB
3. Antibiotics: some researchers recommend broad-spectrum antibiotics, while others believe that metronidazole is adequate since anaerobic organisms predominate.
4. Oral hygiene with chlorhexidine digluconate rinses
5. Nutritional rehabilitation: oral, enteral, or parenteral
6. Local wound care
7. Physiotherapy: to reduce strictures from fibrous scarring

Surgical intervention should not occur until the acute phase has ended, and is aimed at restoring function and improving appearance to allow patients to reintegrate into society.

CONCLUSION

Nutritional disorders arise most commonly as a result of nutrient deficiencies, but may also derive from imbalances in nutrients or at times from nutrient excess. Because macronutrients and micronutrients play roles in multiple biochemical pathways, these disorders often present with clinical features in a variety of organ systems. The key to diagnosis is in having a familiarity with the range of clinical presentations associated with these disorders and maintaining an appropriate index of suspicion for these disorders when evaluating dermatologic patients with skin findings or a history that might suggest a nutritional etiology.

Chapter 131 :: Cutaneous Changes in Errors of Amino Acid Metabolism

:: Peter H. Itin

Inborn errors of amino acid metabolism are inherited defects of enzymes that result in important disturbance in amino acid biology.[1] Most of them are autosomal recessive disorders. Amino acids are the molecular units that make up proteins, and all proteins are various combinations of 20 specific naturally occurring amino acids.

Diseases of amino acid metabolism may lead to multiorgan disorders with signs and symptoms of mental retardation and dysfunction in numerous additional organs, including skin and hair.[2] With more sophisticated diagnostic techniques, metabolic diseases have gained increasing importance, and numerous rare entities have been identified, including hyperphenylalaninemias, hypertyrosinemias, disorders of histidine metabolism, disorders of proline and hydroxyproline metabolism, hyperornithinemias, dysfunctions of urea cycle enzymes, disorders of lysine metabolism, disorders of branched-chain amino acid and keto acid metabolism, disorders of transsulfuration with homocystinuria and homocystinemia, sarcosinemia, and nonketotic hyperglycinemia.[3]

Several diseases have important cutaneous manifestations that might be a clue to diagnosis (Table 131-1). An example of such a key manifestation representing errors of amino acid metabolism is acrodermatitis

TABLE 131-1
Inherited Disorders of Amino Acid and Organic Acid Metabolism with Skin Manifestations

Disease	Skin Manifestations	Deficient Enzyme/ Pathophysiology (Mode of Inheritance)
Alkaptonuria	Ochronosis Black cerumen, eccrine, and apocrine secretions	Homogentisic acid oxidase (AR)
Argininosuccinic aciduria	Trichorrhexis nodosa Rough skin	Argininosuccinase (AR)
Aspartylglycosaminuria	Thick skin Coarsening of face Sagging skinfolds Increased acne Photosensitivity	Aspartylglycosamidase (AR)
Biotinidase deficiency	Erythematous rash Alopecia Oral candidiasis Seborrheic dermatitis Glossitis	Biotinidase (AR)
Citrullinemia	Light, short hair with interrupted cuticle	Argininosuccinate synthetase (AR)
Hartnup disease	Pellagra-like lesions Photosensitivity	Defect of neutral amino acid transport in renal and intestinal brush border (AR); increases excretion of tryptophan metabolites
Histidinemia	Light-colored hair and eyes	Histidase (AR)
Holocarboxylase synthetase deficiency	Seborrheic dermatitis Alopecia	Holocarboxylase synthetase (AR)
Homocystinuria	Fine, sparse, friable hair Thin skin Livedo reticularis Malar flush Vascular occlusions Marfanoid habitus	Cystathionine β-synthetase (AR)
Hydroxykynureninuria	Chronic stomatitis Ulcerated gums, gingivitis Photosensitivity	Kynureninase (AR)
Hyperprolinemia	Ichthyosis	Proline oxidase (AR)
Iminodipeptiduria (prolidase deficiency)	Chronic skin ulcers Recurrent infections	Prolidase (AR)
Isovaleric acidemia	Odor of sweaty feet, alopecia	Isovaleryl-coenzyme A dehydrogenase (AR)
Methionine malabsorption syndrome	White hair Dried celery or oasthouse odor Edema	Defective methionine transport
Phenylketonuria	Hypopigmentation Atopic dermatitis Scleroderma	Phenylalanine hydroxylase (AR) Dihydropterine reductase Defective dihydropterine synthesis
Tyrosinemia II	Painful, acral erosions Hyperkeratosis Corneal/conjunctival plaques and erosions	Tyrosine aminotransferase (AR)
Xanthurenic aciduria	Urticaria	Kynureninase (AD)

AD = autosomal dominant; AR = autosomal recessive.

acidemica. These patients have characteristic cutaneous lesions that are similar to those in acrodermatitis enteropathica (see Chapter 130). Psoriasiform dermatitis on the trunk and extremities may occur together with diffuse alopecia and brittle hair.[4] In general, acral dermatitis with perioral erythema and desquamation is associated with poor feeding, lethargy, hypotonia, vomiting, and dehydration. Patients often have progressive neurologic symptoms. Patients with branched-chain aminoacidopathies may have methylmalonic acidemia, propionic acidemia, glutaric acidemia, biotinidase deficiency, multiple carboxylase deficiency, or maple syrup urine disease, all of which are sometimes accompanied by cutaneous problems.

In general, all patients with acrodermatitis acidemica have absolute missing enzyme activity of their autosomal recessive mutated gene. Diagnosis is confirmed by documentation of increased amounts of amino acids in the urine. Exact diagnosis is the first step for adequate treatment of these diseases.

Hartnup disease results from a deficiency of neutral amino acid transport within the kidneys and small intestine and leads to pellagra-like features in a photodistribution (see Chapter 130). Neurologic deficiencies and reduced mental skills are often associated. The treatment of choice is nicotinamide.

TYROSINEMIAS

TYROSINEMIA AT A GLANCE

- Approximately 100 cases are reported worldwide.
- Tyrosinemia is an autosomal recessive disease induced by a deficiency of cytoplasmic tyrosine aminotransferase related to a defect on chromosome bands 16q22.1–22.3 (OMIM #276600).
- Dermatologic manifestations include focal/diffuse palmoplantar keratosis with erosions, bullae or erythema, hyperhidrosis, and painful corneal erosions with photophobia; 50% of patients have mental retardation.
- Diet restriction of phenylalanine and tyrosine leads to amelioration of cutaneous symptoms and eye lesions.
- Differential diagnosis includes other forms of palmoplantar keratodermas and herpetic keratitis.
- Prenatal diagnosis is possible by amniocentesis with tyrosine aminotransferase assay and DNA analysis.

The genetic tyrosinemias are characterized by the accumulation of tyrosine in body fluids and tissue.[5,6] Tyrosine is a semiessential amino acid, derived from the liberation of tyrosine from hydrolysis of dietary or tissue protein, or from the hydroxylation of the essential amino acid phenylalanine, and is the starting point for the synthesis of catecholamines, thyroid hormones, and melanogenesis. There are three types of tyrosinemia. The skin is not involved in tyrosinemia types I and III, but it is involved in tyrosinemia II, which is also called the *oculocutaneous tyrosinemia* and *Richner–Hanhart syndrome* [Online Mendelian Inheritance in Man (OMIM) #276600]. Tyrosinemia II is a rare distinctive clinical symptom complex involving the eyes, skin, and central nervous system and is potentially treatable. Tyrosine levels are elevated because of a deficiency of hepatic tyrosine aminotransferase (TAT).

CLINICAL FEATURES

Approximately 100 patients with this clinical syndrome have been reported. Goldsmith and Reed were the first to correlate the oculocutaneous syndrome with an underlying tyrosinemia.[7] All patients had tyrosinemia, phenolic aciduria, and inflammatory skin and eye lesions. The sexes are affected equally, and the disease is worldwide in distribution. Transmission of tyrosinemia II is autosomal recessive. Consanguinity has been documented, and occurrence in several siblings within a family is well known (pseudodominant pattern). Heterozygotes are unaffected clinically and demonstrate no biochemical alterations of tyrosine or its metabolites in blood or urine.

DERMATOLOGIC FEATURES. Patients have hyperkeratotic yellowish skin lesions limited to the palms and soles, which in 80% of cases occur on the peripheral pressure-bearing areas.[5,7] Lesions usually begin during the first year of life. The skin lesions are painful, nonpruritic, and frequently associated with hyperhidrosis (Fig. 131-1). Diffuse plantar keratoderma and self-mutilation have been observed in individuals with tyrosinemia II.[8] Leukokeratosis of the tongue has been reported. Bullous lesions may occur and progress rapidly to erosions; these then become crusted and hyperkeratotic.[9] The fingertips and hypothenar eminences are commonly involved. Rare patients have hyperpigmentation and/or hyperkeratotic subungual lesions, and in older persons hyperkeratosis in the elbows, knees, and ankles may appear.[2]

OPHTHALMOLOGIC FEATURES. The most important manifestations of oculocutaneous tyrosinemia are those involving the eye, because they can lead to permanent visual impairment.[10] Eye lesions occur weeks to months before the skin lesions. Ophthalmologic symptoms start as early as the first day of life and as late as 38 years of age. Tearing, redness, pain, and photophobia are early signs and symptoms; late findings include corneal clouding and central or paracentral opacities, which are initially intraepithelial and can progress to superficial or deep pseudodendritic

Figure 131-1 Hyperkeratotic (**A**) and erosive (**B**) lesions in a patient with tyrosinemia II.

keratitis (Fig. 131-2). Slit-lamp examination may reveal some degree of corneal ulceration, and occasionally birefringent crystals of tyrosine may be observed. Neovascularization is prominent. The eye disease occurs in 75% of affected patients and may lead to scarring, nystagmus, and exodeviation. Ocular symptoms may show spontaneous remission and recurrences and may occur independently of other manifestations. Topical therapy is ineffective, and herpes simplex virus and bacterial cultures consistently yield negative results.

Figure 131-2 Corneal changes in tyrosinemia II. **A.** Cornea before treatment (left eye); corneal opacity and neovascularization are prominent. **B.** The right eye has even more extensive involvement. **C.** After 6 weeks of therapy, there is marked clearing of the lesions.

NEUROLOGIC FEATURES. Mental retardation of varying degrees is reported in half the cases, as is normal mental development. Hyperactivity has been observed in several affected children, as has abnormal language development. Untreated tyrosinemia II during pregnancy may be associated with mental retardation or seizures in the children resulting from that pregnancy.[11]

LABORATORY FINDINGS

AMINO ACID ABNORMALITIES. In establishing the diagnosis in a child with tyrosinemia II, laboratory verification of plasma amino acid and urine organic acid levels is mandatory. The blood and urine tyrosine levels of affected patients are markedly elevated. Levels of other amino acids are not increased. Urinary tyrosine metabolite levels are elevated; these include *p*-hydroxyphenylpyruvic acid, *p*-hydroxyphenyllactic acid, *p*-hydroxyphenylacetic acid, and *N*-acetyltyrosine (Fig. 131-3). All these metabolic effects are consequences of the deficiency of hepatic TAT. A fluorometric procedure exists as well as a tandem mass spectrometry, which is used for neonatal screening. Recently, an asymptomatic newborn was detected to have Richner–Hanhart syndrome on the third day of life as a result of the newborn screening. Interestingly the 8-year-old brother with persistent plantar hyperkeratotic plaques of the soles of yet unknown origin was subsequently identified to be also affected tyrosinemia type II.[12]

TAT is a pyridoxal phosphate-dependent cytoplasmic enzyme that transaminates tyrosine, forming *p*-hydroxyphenylpyruvate (PHPPA). The human *TAT* gene contains 12 exons and transcribes a 2.75-kb messenger RNA (mRNA) that codes for a 454-amino acid protein.[5] The liver is the richest source of TAT; this specific TAT is not present in skin. In tyrosinemia II, the liver biopsy specimen shows little or no soluble TAT, although there is normal or slightly increased mitochondrial tyrosine (aspartate) transaminase activity.[12,13] Mitochondrial aspartate aminotransferase using tyrosine as a substrate produces increased amounts of PHPPA from the increased amounts of tyrosine available in tyrosinemia II. Because mitochondria do not have PHPPA oxidase activity, PHPPA and its metabolic products increase and appear in the urine, which creates the unusual situation in which metabolites are increased both proximally and distally to the defective enzyme.

HISTOPATHOLOGY. Routine histopathologic analysis of the skin is not diagnostic; it shows hyperkeratosis, parakeratosis, and acanthosis.[9] In some cases, electron microscopy studies have shown lipid droplets in the cornified layer, increases in tonofibrils and keratohyalin, very tightly packed microtubular and microfibrillar masses, and minute tyrosine crystals in keratinocytes and Merkel cells.[14]

GENETICS. Mutations occur in the human *TAT* gene, which results in high levels of tyrosine. *TAT* maps to the q22-q24 region of chromosome 16 and has been sequenced.[5] Multiple point mutations scattered throughout the *TAT* gene have been associated with tyrosinemia II.[15]

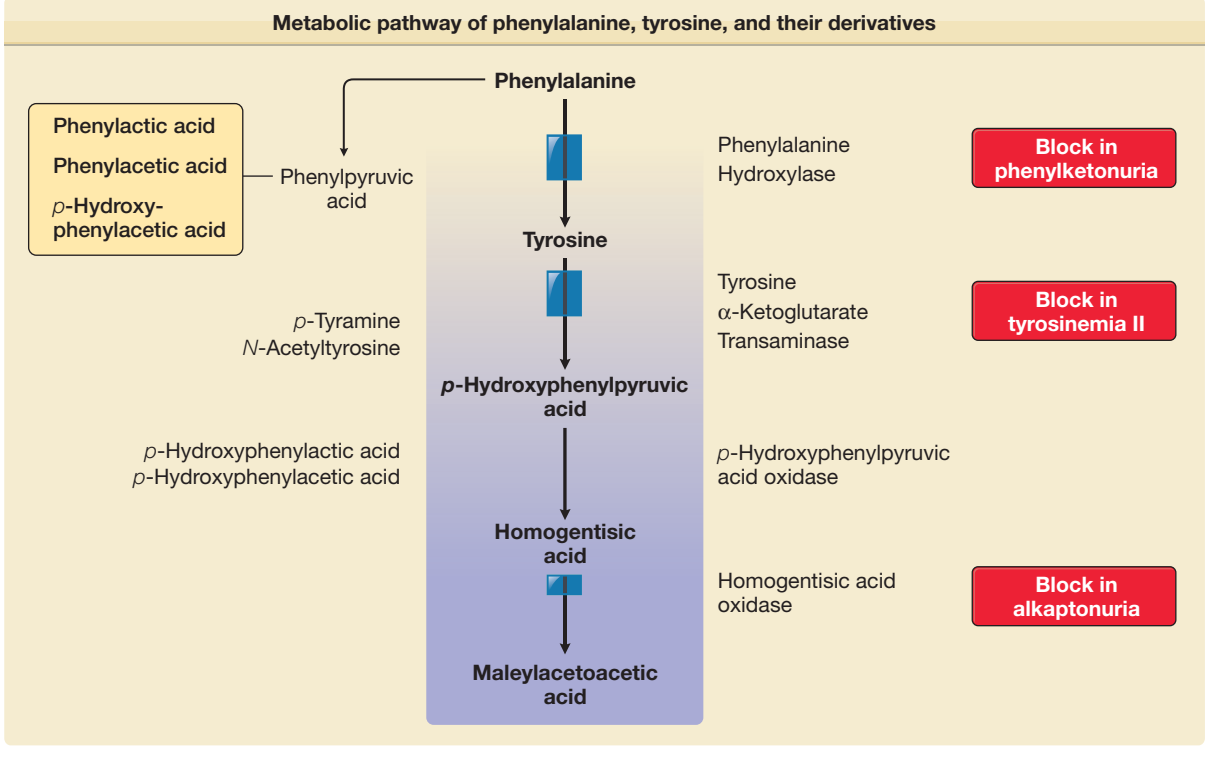

Figure 131-3 Metabolic pathway of phenylalanine, tyrosine, and their derivatives.

BOX 131-1 DIFFERENTIAL DIAGNOSIS OF TYROSINEMIA

Main Features

- Eyes
  - Herpetiform corneal ulcers
- Skin
  - Punctate, painful palmoplantar keratoderma on weight-bearing areas
- Neurologic features
  - Mental retardation
  - Hyperactivity

Consider

- Palmoplantar keratoderma with associated features
  - Corneodermatoosseous syndrome

Always Rule Out

- Eyes
  - Viral and bacterial infection
- Skin
  - Other forms of keratodermas, acquired or genetic

BOX 131-2 TREATMENT OF TYROSINEMIA

- Low-tyrosine, low-phenylalanine diet
- Etretinate systemically

DIFFERENTIAL DIAGNOSIS. (See Box 131-1). Corneodermatoosseous syndrome (OMIM #122440), an autosomal dominant symptom complex of volar keratosis and keratitis that is clinically similar to tyrosinemia II, has been described in one family.[20] The lesions were more extensive than those in the classic Richner–Hanhart syndrome. In addition, brachydactyly with short distal phalanges, short stature, and soft teeth may occur.

TREATMENT

With consumption of a low-tyrosine, low-phenylalanine diet (Mead Johnson, Tyromex-Ross), there is a rapid decrease in tyrosine to normal levels (30–90 μM). Skin and eye lesions cleared within days and weeks in all individuals treated with the diet[7,12] (see Fig. 131-2C; Fig. 131-4; Box 131-2).

Some patients have responded objectively to etretinate, although plasma tyrosine levels remained unchanged.[21] In none of the patients studied has there been a response to cortisone acetate, ascorbic acid, pyridoxine, or folic acid, which are cofactors or known inducers of TAT and PHPPA oxidase. Surgical treatment is recommended for palmar lesions but not for the plantar form.

Because the consequences of tyrosinemia II are serious and a safe treatment is available, a patient presenting with any atypical bullous or hyperkeratotic disease on the palms and soles in the first months of life should be screened for tyrosine and its metabolites; screening tests are available in most hospital laboratories.[22] Amino acid analysis is necessary to confirm the diagnosis and follow the response to diet therapy. Dietary control in pregnancy should be recommended. A patient with tyrosinemia II was reported who had undergone two untreated pregnancies. During the pregnancies, plasma tyrosine level was raised, and the infants were retarded. On the other hand, several normal children of mothers with the disease have been observed.[23]

PHENYLKETONURIA

Phenylketonuria (phenylpyruvic oligophrenia, PKU) is an autosomal recessive disorder of aromatic amino acid metabolism (OMIM #261600) in which phenylalanine cannot be converted to tyrosine. Its discovery over 70 years ago has established the link between metabolic disease and intellectual impairment, and led to the development of neonatal screening programs across the globe. In addition, it demonstrated how effective treatment could lead to a near normal outcome for affected individuals. PKU is caused by a deficiency of hepatic

Figure 131-4 **A.** Diffuse plantar hyperkeratosis in an adult with tyrosinemia. **B.** The hyperkeratosis cleared on a low-tyrosine, low-phenylalanine diet without topical treatment.

PHENYLKETONURIA AT A GLANCE

- Autosomal recessive disorder induced by phenylalanine hydroxylase deficiency (OMIM #261600). Gene on chromosome bands 12q22–24.1; incidence of 1 in 10,000 live births among Europeans.
- Clinical features include mental retardation, generalized hypopigmentation, blond hair, blue eyes, eczematous rash, vomiting in infancy, hyperactivity and seizures, mousy odor.
- Diagnosis is confirmed by a positive result on urinary ferric chloride test.
- Treatment consists of restricting phenylalanine in the diet.
- Differential diagnosis includes albinism, Chédiak–Higashi syndrome, and scleroderma.
- Prenatal diagnosis is possible by chorionic villus sampling/amniocentesis, measurement of metabolite levels, and DNA analysis.

phenylalanine hydroxylase or cofactors for phenylalanine hydroxylase. PAH deficiency seems to be a protein-misfolding disease in which global conformational changes hinder molecular motions essential for physiological enzyme function.[24] There are additional causes that may lead to hyperphenylalaninemias, and eight subtypes have been described. Maternal PKU may lead to hyperphenylalaninemia. Unless the mother follows a special diet, the child is at risk to develop the typical signs and symptoms of PKU. Defects of biopterin metabolism, prematurity, liver disease, use of medications such as methotrexate, and high-protein diets may produce findings similar to those in PKU. Genotype-based prediction and classification of the biochemical phenotype is now possible in the majority of newborns with hyperphenylalaninemia.[24]

EPIDEMIOLOGY

The prevalence of PKU varies markedly in various countries. The highest incidence of PKU is found in Ireland and Scotland (1 in 4,000), whereas in Finland only 1 in 40,000 births are affected. The overall frequency among northern Europeans was calculated to be approximately 1 in 10,000 and in the United States classic PKU was estimated to occur in approximately 1 in 11,000 births in the white population. Among blacks the frequency was estimated to be only approximately 1 in 50,000.[25]

CLINICAL FEATURES

The clinical hallmarks of PKU are mental retardation, diffuse hypopigmentation, seizures, eczematous dermatitis, and photosensitivity.[26] Newborns appear to be normal and develop manifestations of psychomotor alterations between 4 and 24 months of age. Early symptoms include heavy vomiting. The most important defects are marked mental retardation with irritability, hyperactivity, self-destructive behavior, hypertonicity, and seizures. Peculiar gait and increased deep tendon reflexes are noted. Microcephaly, brain calcification, and cataracts are observed quite commonly. Typically, a mousy odor induced by phenylacetic acid is noted in urine and sweat.

Early infantile eczema, indistinguishable from atopic dermatitis, or seborrheic dermatitis may be one of the first signs of PKU and occurs in 20%–50% of affected infants during the first year of life. Later on, the incidence may be even higher. Dramatic clearing of eczematous skin lesions with a low-phenylalanine diet has been reported in some patients, and a potential role for altered biotin recycling is suggested.[27] A further skin clue in PKU is pigment dilution, with impressive pale pigmentation, blond hair, and blue eyes seen in 90% of patients. The pigment dilution and hair loss is reversible with phenylalanine restriction.[28] The color changes may be especially striking in the rare black or Japanese patient with PKU, whose eye or hair color may be very different from that of other members of the ethnic group. The increased levels of phenylalanine and its oxidation products (phenylpyruvic acid, *o*-hydroxyphenylacetic acid, phenylacetic acid) inhibit the enzyme tyrosinase and therefore reduce melanization.[28]

Patients develop moderate photosensitivity. Edematous scleroderma-like induration of the skin of the extremities, which spares the hands and feet, is characteristic.[29] Plaque, guttate or generalized morphea, and atrophoderma of Pasini and Pierini (see Chapter 64) as well as lichen sclerosus et atrophicus (see Chapter 65) have been observed in PKU.[30]

DIAGNOSIS

Diagnosis of PKU is made by documenting elevated levels of phenylalanine in the serum (20 mg/dL or higher, 10–50 times the normal level). Plasma tyrosine levels may be normal or elevated. In addition, elevated urinary phenylpyruvic acid levels can be documented. Additional laboratory abnormalities include phenylalanine hydroxylase deficiency, phenylpyruvic acidemia, and increased urinary levels of *o*-hydroxyphenylacetic acid and phenylacetylglutamine. Increased urinary levels of phenylpyruvic acid can be detected by a typical green coloration of urine after addition of 10% ferric chloride. In numerous countries, PKU screening is performed in the neonatal screening program either by the semiquantitative bacterial inhibition assay method in which several drops of capillary blood may show an elevated level of phenylalanine in a microbiologic procedure (Guthrie test) or by a quantitative chemical

reaction method (Quantase test).[31] In affected babies, serum phenylalanine levels begin to rise on the third or fourth day of life. Prenatal diagnosis is possible by performing amniocentesis or chorionic villus sampling with identification of the gene. In addition, preimplantation genetic diagnosis for PKU made possible the birth of PKU-free children.[32]

PATHOPHYSIOLOGY AND HISTOLOGY

The classic type of PKU is induced by a deficiency of phenylalanine hydroxylase or its cofactor tetrahydrobiopterin and a consequent accumulation of the precursor phenylalanine. The normal phenylalanine–tyrosine ratio is 1:1, whereas in PKU it is more than 3:1. It is widely believed that the pigment dilution is a result of the inhibitory effect of phenylalanine on tyrosinase. Biopsy specimens show increased fibroblasts and histiocytes and atrophy of skin appendages. The elastic fibers are scanty and fragmented and are thus different from those found in true scleroderma. Histologic examination shows a normal number of melanocytes but a decrease in mature melanosomes.

DIFFERENTIAL DIAGNOSIS

Atopic dermatitis and scleroderma as primary disorders must be distinguished from PKU (Box 131-3). Premature infants and individuals with liver disease may also show elevated plasma levels of phenylalanine.

TREATMENT

With a low-phenylalanine diet, which should probably be followed for life, the skin color, photosensitivity, odor, and eczema are reversible. In addition, early diet can dramatically reduce mental retardation, and if the blood phenylalanine levels are maintained at reasonable levels in early childhood, normal to low-normal intelligence can be expected[33] (Box 131-4). However, rigorous control of diet can lead to protein deficiency and an eczematous dermatitis. Recently, sapropterin has been shown to increase phenylalanine tolerance while maintaining blood phenylalanine control.[34–37]

BOX 131-3 DIFFERENTIAL DIAGNOSIS OF PHENYLKETONURIA

Main Features

- Skin
  - Pale pigmentation, dry skin and eczema, scleroderma-like lesions, fair hair
- Eyes
  - Blue eyes
- Neurologic features
  - Mental retardation
  - Seizures
  - Irritability and increased deep tendon reflexes

Consider

- Other disorders of amino acid metabolism with neurocutaneous features

Always Rule Out

- Atopic dermatitis
- Scleroderma

BOX 131-4 TREATMENT OF PHENYLKETONURIA

- Low-phenylalanine diet
- Fish oil supplementation, which seems to improve visual evoked potentials
- Tyrosine supplementation (?)
- New phenylalanine-free formulas
- Reduction of phenylalanine uptake with purified phenylalanine ammonia-lyase
- Recombinant or pegylated phenylalanine ammonia-lyase
- Tetrahydrobiopterin supplementation to increase phenylalanine hydroxylase activity
- Large neutral amino acids supplementation to compete for blood-brain barrier carriers

ARGININOSUCCINIC ACIDURIA

DEFINITION AND CLINICAL FEATURES

Argininosuccinic aciduria (ASA; OMIM #207900) is an autosomal recessive disorder of the urea cycle. Its incidence is estimated to be 1 in 70,000. ASA is characterized by hepatomegaly, mental retardation, seizures, episodic lethargy and ataxia, and friable, brittle hair with the morphology of trichorrhexis nodosa (see Chapter 88). The deficiency of an essential cytosolic enzyme in the urea cycle, argininosuccinase (argininosuccinate lyase), causes citrullinemia and an increase in blood ammonia. Argininosuccinate is increased in the blood and spinal fluid and is excreted in large amounts (2–9 g/day) in the urine.

The detailed clinical and biochemical features of the disease and the principles of therapy are reviewed by Nyhan, Barshop, and Ozand.[2] The hair abnormality is more characteristic of the late-onset disease, but in the early cases this peculiar type of alopecia brought the first patients to clinical attention.[38] Weaning and a change to a diet with a higher protein content can be precipitating factors in clinical disease. Essential to current therapeutic regimens are diets providing adequate energy, protein, and arginine.

The molecular pathology of the nucleic acids in this disease has been clarified, but the detailed pathophysiology of the hair defect remains to be determined.[39–41]

HAIR DEFECTS

CLINICAL AND MORPHOLOGIC FEATURES.[42]

About half the reported patients have had abnormally friable hair with visible trichorrhexis nodosa (see Chapter 88); the other half have had grossly normal hair. Brushing and combing accentuate breaking (i.e., brittle hair). No definite correlation can be made between liver argininosuccinase level, argininosuccinic acid levels, arginine levels, and the degree of hair abnormalities; some patients with severe ASA have had seemingly normal hair. Some patients' hair has improved with diet or without specific therapy. Hair shafts may show pseudotrichothiodystrophy under polarizing microscopy with the typical dark and light banding.[45] Diet reverses grooving and abnormal polarization of hair shafts in argininosuccinase deficiency.[44] Eyelashes, eyebrows, and general body hair, as well as the nails, may be involved.

MOLECULAR NATURE OF HAIR DEFECTS.

The basic nature of the hair defects is not known.[45,46]

Increasing arginine in the diet aids hair growth and structure in this disease, which suggests that the decrease in arginine may be related to the defective hair. Because the urea cycle is depressed in ASA, the arginine required for protein synthesis would come predominantly from dietary sources. Hair protein is rich in arginine (up to 10% of the amino acid residues are arginine); furthermore, the citrulline present in certain specialized proteins in the medulla and internal root sheath is derived from arginine.

OTHER DISORDERS OF THE UREA CYCLE[30]

In citrullinemia (OMIM #215700), a rare recessive disease caused by the absence of argininosuccinic acid synthetase, there is somatic and mental retardation and increased levels of citrulline in blood, urine, and cerebral spinal fluid; low to normal values of plasma arginine; and increased blood ammonia levels.[48] Hair in such patients may be brittle, breaking easily. Microscopically, plucked hairs may be flattened, may be twisted through 180° on their own axes, and may show breakage at the point of twisting.[47] Irregular areas of dystrophy and interruption of the cuticle were observed.

Deficiency of the cytosolic enzyme argininosuccinic acid synthetase is associated with trichorrhexis nodosa (see Chapter 88). Its overall clinical presentation is almost identical to that of ASA, although the plasma citrulline levels are usually higher (more than 1 mM) in the former disease. Enzymatic and genetic analyses confirm the diagnosis.

DIAGNOSIS

Retardation, ammonia intolerance, and abnormal hair will suggest these syndromes. The diagnosis is confirmed by high-voltage electrophoresis or ion-exchange chromatography of the urine, blood, or spinal fluid.[48] Only a tiny percentage of the cases of trichorrhexis nodosa and brittle hair are due to ASA. Prenatal diagnosis is possible after chorionic villus sampling or amniocentesis to ensure the birth of unaffected infants.[40]

ALKAPTONURIA

ALKAPTONURIA AT A GLANCE

- Autosomal recessive metabolic disease in which homogentisic acid, an intermediate product in the metabolism of phenylalanine and tyrosine, cannot be further metabolized (OMIM #203500). The cause is a mutation in the homogentisate 1,2-dioxygenase acid oxidase gene on chromosome bands 3q21-q23.
- Clinical features are blue–black or gray discoloration of sclerae, face, pinnae, cartilage, and nails; dark sweat; arthritis; and homogentisic aciduria. Urine is dark after standing in alkaline pH.
- It is suggested that high tissue concentrations of ascorbic acid might delay and possibly reduce the degree of pathologic changes in the connective tissue.
- Differential diagnosis includes argyria, chrysiasis, and pigmentation after treatment with amiodarone and other medications.
- Prenatal diagnosis is possible through DNA analysis.

Alkaptonuria (OMIM #203500), or homogentisic acid oxidase (HGO) deficiency, is a rare metabolic disorder. Excessive homogentisic acid (HGA) is excreted in the urine, which often turns dark, and HGA accumulates in connective tissues, including the dermis[49] (ochronosis).

EPIDEMIOLOGY

Alkaptonuria is inherited as an autosomal recessive trait. Pedigrees suggestive of a dominant mode of transmission contain a high degree of consanguinity and, when subjected to careful scrutiny, are actually found to show pseudodominance. In general populations, alkaptonuria is rare (1 in 250,000), but clusters of high incidence are found in certain groups with inbreeding (e.g., in Slovakia and Santo Domingo). Among Slovakian newborns the incidence is 1 in 19,000. Disease distribution is worldwide, and there is an approximately equal incidence in both sexes.[50]

ETIOLOGY AND PATHOGENESIS

The *HGO* gene maps to the q21-q23.60 region of chromosome 3. Multiple mutations have been found and the mutation spectrum was reviewed recently.[50,51–53] The mutations change residues, which are conserved evolutionarily between *Aspergillus* HGO and human HGO, which suggests that they are fundamental to the activity of HGO. Both compound heterozygotes and homozygotes have been detected.[54]

The biochemical pathway by which phenylalanine and tyrosine normally undergo oxidative degradation to acetoacetic acid is shown in Fig. 131-3. HGA (2,5-dihydroxyphenylacetic acid), the last molecule in the sequence to contain an intact aromatic ring, is cleaved to maleylacetoacetic acid (Fig. 131-5). The enzyme catalyzing ring cleavage, HGO, is normally present in the soluble fraction of liver and kidney cells. It is highly specific for HGA. HGO mRNA is found in liver, kidney, and prostate.[54] Atmospheric oxygen, ferrous ion, and sulfhydryl groups are required for enzymatic function. Quinones inhibit the enzyme. HGO activity is totally absent in both liver and kidney tissue from alkaptonuric subjects. In patients with alkaptonuria, HGA undergoes renal excretion or is transformed to ochronotic pigment within connective tissue. HGA may not be present in the first days of life due to the absence of enzymatic activity of other enzymes in the pathway of tyrosine catabolism.

The renal clearance of HGA is extremely high (up to 400–500 mL/minute) in both normal and alkaptonuric subjects, which indicates active tubular secretion of HGA. This explains how with relatively low fasting plasma concentrations of HGA (in the range of 3 mg/dL) excretion may be up to 4–8 g/day in HGO deficiency. Compounds inhibiting this secretion may be an important factor in ochronosis. Once excreted, HGA (which is itself colorless in solution) gradually oxidizes to dark products. Oxidation occurs by degrees when the urine is exposed to air, but it can be hastened markedly by alkalinization. Urinary pH is the major variable causing the darkening of the urine, and some patients with acidic urine may never have spontaneously black urine. A diet high in protein or tyrosine increases the amount of HGA excreted in disease.

The precise manner by which HGA accumulation in tissues leads to ochronosis is only partially understood. A presumed HGA polymer has never been characterized.[55]

Alkaptonuric mice (*aku*) do not have black urine or deposition of pigment, which is possibly related to the mouse's ability to synthesize ascorbic acid.[56]

Experimental ochronosis induced by prolonged feeding of high-tyrosine diets to rats may delineate the precise interaction between HGA and its products and connective tissue.[57] HGO also has been produced in experimental animals by L-phenylalanine feeding and diets deficient in sulfur amino acids or tryptophan and the iron chelator α,α′-dipyridyl.

HGA inhibits lysyl hydroxylase, an enzyme crucial for collagen cross-linking, in chick embryo calvaria, which suggests that a reduction in the structural integrity of collagen consequent to deficient hydroxylysine-derived cross-linkages may be responsible for cartilaginous degeneration in alkaptonuria.[58]

Metabolic pathway of phenylalanine and tyrosine degradation with homogentisic acid metabolites

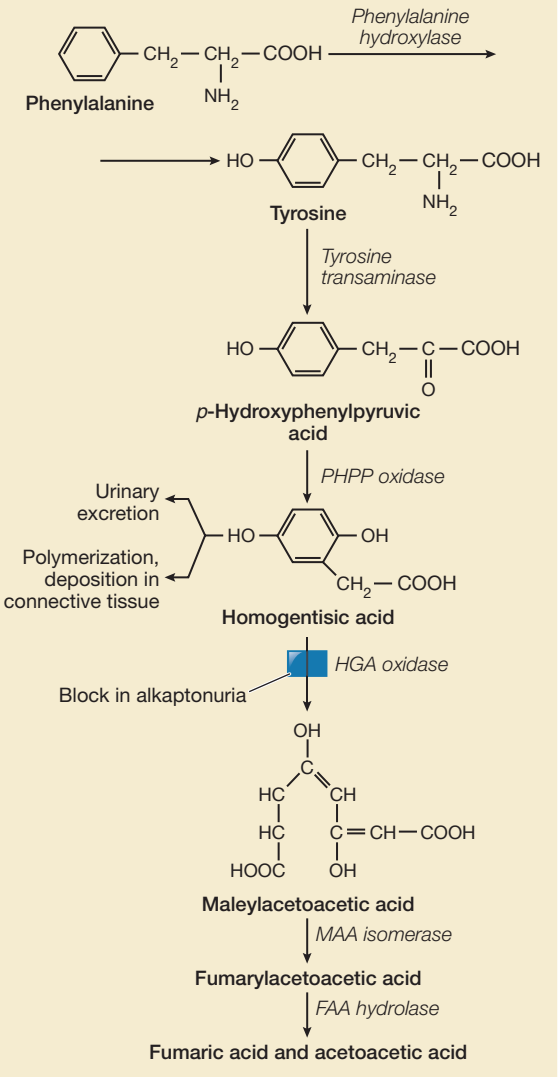

Figure 131-5 Metabolic pathway of phenylalanine and tyrosine degradation with homogentisic acid metabolites. FAA = fumarylacetoacetic acid; HGA = homogentisic acid; MAA = maleylacetoacetic acid; PHPP = *p*-hydroxyphenylpyruvic.

CLINICAL FEATURES

Dark urine is not always the initial manifestation of HGO deficiency. The urine is most apt to discolor rapidly when pH is above 7.0 and when reducing substances, such as ascorbic acid, which normally protect HGA from oxidation, are not present in sufficient quantity. An early diagnosis of HGO deficiency is frequently made when (1) it is specifically sought because of family history, (2) discoloration of diapers occurs after cleansing in (alkaline) soap, (3) the urinary pH favors the oxidation of HGA, or (4) testing for urinary glucose with

Benedict's solution yields an orange precipitate (which indicates a reducing substance) accompanied by a dark supernatant. A positive finding for Benedict's reaction and a negative result on glucose analysis with a glucose oxidase test reagent strongly suggests the diagnosis.

Although the diagnosis of alkaptonuria may be made during childhood, in rare cases the disorder is not detected until the individual develops pathologically significant changes in connective tissue in the third or fourth decade.[59] If coincidental renal disease prevents effective HGA excretion, the development of ochronosis may be accelerated, and diffuse hyperpigmentation may result.

Dark brown or black cerumen may be present in the first decade, even in those younger than 5 years of age. Axillary skin pigmentation (greenish blue, blue, greenish yellow, or brown) in the pattern of glandular orifices may be present late in the first decade. This may be accompanied by staining of underwear ("sweat that stains"). A patient with pigmentary changes confined to sun-exposed areas has been described.[60] Caviar-like ochronotic papules have been reported recently in a patient with ochronosis.[51]

A grayish blue tinge overlying ear cartilage is common in adulthood but is rarely seen before 20 years of age.[61] Ochronotic discoloration is rarely seen in childhood but is common in adulthood and can affect the sclera, cornea, conjunctiva, tarsus, and eyelid skin. Scleral involvement is noted in most patients[62,63] (Fig. 131-6). Scleral discoloration generally is restricted to that portion of the globe exposed by the palpebral fissure. The scleral pigmentation is usually triangular, with the base of the triangle facing the cornea. Tiny "oil droplets" of ochronotic pigment appear at the inner and outer poles of the corneas in advanced ochronosis. Later in the disease, structural changes result in loss of transillumination, stiffening, irregular contours, and eventually, in the third decade, calcification of the pinnae. The tympanic membrane may be blue. Tinnitus and variable degrees of deafness have been ascribed to ochronotic degeneration of the tympanic membrane and underlying ossicles. Laryngeal and tracheal cartilage becomes heavily pigmented but is asymptomatic.

The visible changes that occur with the passage of time are primarily due to the formation of ochronotic pigment granules in the dermis and sweat follicles and, most important, to the transmission of ochronotic discoloration through thin areas of skin overlying pigmented cartilage and tendon. The latter pigmentation, which is fairly uniform in ochronosis, is most apparent at the nose tip, ear (Fig. 131-7), costochondral junctions, and extensor tendons of the hands. Pigmented colloid milium on the dorsa of the hands have been reported.[64] Pigmentation of the skin is less prominent but may occur in a butterfly pattern on the nose and cheeks and even the palms as a presenting sign.[65] Rarely, bluish gray fingernails and intensely dark nevi have been reported.[66] Insidious progression of ochronotic arthropathy, which generally begins in the third and fourth decades in men and approximately 10 years later in women, is the most disabling manifestation of alkaptonuria.[67] The disease is more severe in males. Bouts of acute inflammation may occur. Hip, knee, and shoulder limitation is an early sign. Lumbar pain, lordosis, kyphosis, and sciatica are common. Radiographs

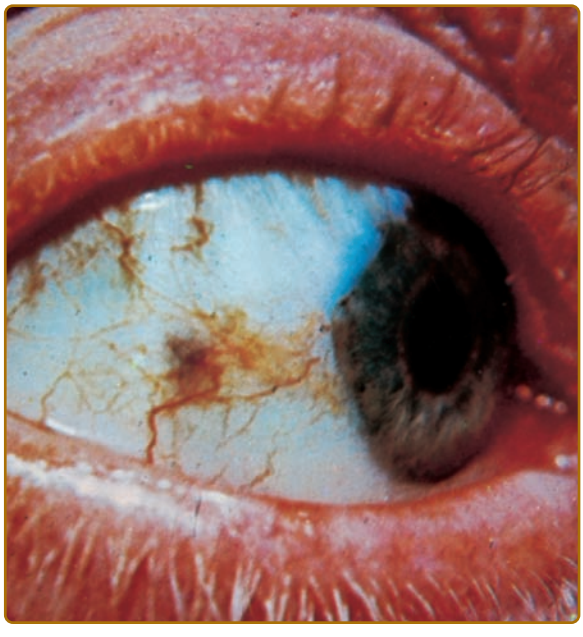

Figure 131-6 Ochronosis (alkaptonuria) has pathognomonic ocular signs. The first to appear is grayish black scleral pigmentation anterior to the tendon insertions of the horizontal recti muscles. At times, pigmentation of the elastic tissue in pinguecula may stain a dark brown or black, and it usually has the configuration of small, dark rings. In advanced cases of ochronosis, Bowman's membrane, adjacent to the limbus, may have areas of black pigmentation.

Figure 131-7 Ochronotic discoloration seen through the thin area of skin overlying the pigmented cartilage of the ear.

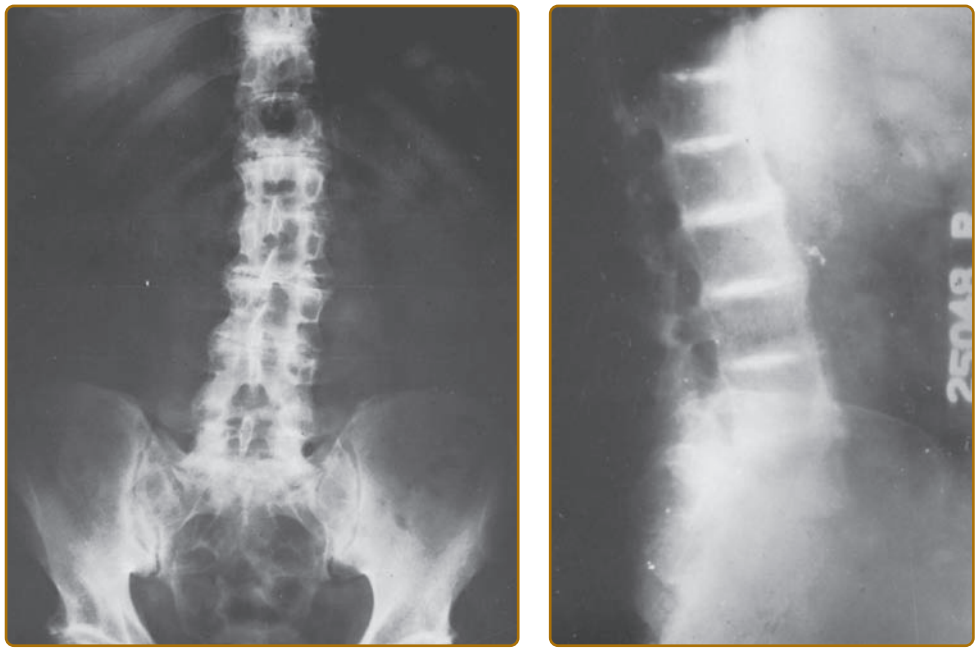

Figure 131-8 Roentgenographic findings in ochronosis. Marked intervertebral disk calcification is present.

show a characteristic appearance of early calcification of the intervertebral disk and later narrowing of the intervertebral spaces, with eventual disk collapse and progressive loss of height (Fig. 131-8). The hands and feet generally are spared. Pseudogout may coexist with ochronosis. It is of note that exogenous ochronosis and striae atrophicae may follow the use of bleaching creams in individuals who do not have alkaptonuria.[66]

There is some suggestion of an increased incidence of cardiovascular disease in patients with ochronosis, but accelerated arteriosclerosis has not been clearly documented. At postmortem examination, pigmentation is commonly observed in the heart valves and annuli and in arteriosclerotic plaques.[68] Prostatic symptoms in older men frequently are due to the formation of soft pigmented calculi in the alkaline secretions of the ducts and sinuses of that gland. Porous black renal stones containing calcium, phosphate, and oxalate also have been reported. The prostate has high levels of HGO mRNA, which may explain the black prostate calculi that are occasionally present in the disease.[41]

LABORATORY FINDINGS

Aside from the excretion of HGA, alkaptonuric patients show no abnormalities on routine clinical laboratory tests. Normal individuals do not excrete HGA; therefore, darkening of the urine on the addition of sodium hydroxide is presumptive evidence of alkaptonuria.

Other tests based on the reducing properties of HGA include the black reaction after treatment with $FeCl_3$ and blackening of photographic emulsion paper on application of a drop of alkaptonuric urine followed by a drop of sodium hydroxide. Specific identification and quantification of urinary (as well as blood) HGA can be achieved by the use of a direct spectrophotometric method using HGO or with high-performance liquid chromatography or stable isotopes.[54]

With the development of ochronotic arthropathy, radiographs of the spine show characteristic disk calcification, which occurs rarely in other forms of spondylitis (see Fig. 131-8). Periostitis, ligament calcification, and sacroiliac sclerosis are not features of ochronotic spondylitis.

PATHOLOGY. Yellow to light-brown (ochre) pigment granules, which led to the original designation of *ochronosis*, are present as free bodies in dermal macrophages.[69] Irregular masses may be over 100 µm in diameter. The pigment, in contrast to melanin, is not bleached by 10% H_2O_2 after 72 hours.[69] Routine special stains for melanin react with the ochronotic pigment.

Electron microscopic studies show smaller-sized homogeneous bodies fusing to form larger nonmembrane-bound structures.[69] Although the original pigment is brown, Tyndall scattering of light makes involved skin appear blue.

The tendency of connective tissue, cartilage in particular, to darken gradually over the years constitutes the cardinal pathologic finding in alkaptonuria. Intervertebral disks are pigmented (jet black) and darken when examined. Articular cartilage, when heavily pigmented, displays the degenerative changes of fibrillation, fissuring, fragmentation, and erosion to bare bone. Phagocytosis of collagen fibrils is found in synovial macrophages.[70]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of alkaptonuria may be made on the basis of typical urinary discoloration or may await

the onset of ochronosis in adulthood. Inasmuch as the disease behaves in a quite stereotypical manner with few confusing variants in its mode of presentation, it has been concluded that the diagnosis need only be thought of to be made. Other causes of dark urine—melaninuria, porphyria, myoglobinuria, bilirubinuria, and hematuria—should not to be confused with alkaptonuria. An ochronosis-like pigmentation of skin and cartilage has been produced iatrogenically by quinacrine administration over a period of months and at the site of quinine injections.[63] Pigmentation due to antimalarial treatment is usually much more pronounced on mucosal surfaces and will fluoresce with a Wood's lamp. A slate gray to blue pigmentation in sun-exposed sites occurs after amiodarone treatment, and similar discoloration also involving the mucous membranes is seen in argyria and chrysiasis (Box 131-5).

It is possible that the reversible ochronotic pigmentation caused by prolonged carbolic acid treatment is due to polymerization of the carbolic acid by HGA polyphenol oxidase to an HGA polymer-like substance that differs from the polymer found in the genetic disease by the reversibility of the polymerization.

Exogenous ochronosis and pigmented colloid milia have been reported in a number of South Africans who used hydroquinone bleaching creams at strengths greater than 2% for a prolonged period.[66,71,74] Forty-two percent of women and 15% of men who used hydroquinones developed exogenous ochronosis.[72] A similar condition has been seen in American blacks.[73–75]

BOX 131-5 DIFFERENTIAL DIAGNOSIS OF ALKAPTONURIA

Main Features

- Skin
  - Black–gray skin on ear cartilage
- Eyes
  - Brown to black pigmentation of the sclera
- Rheumatologic features
  - Skeletal pathologies, including spinal degeneration with kyphosis
  - Ochronotic arthritis and arthropathy
  - Thickened Achilles tendon
- Miscellaneous
  - Urolithiasis
  - Ochronotic prostate stones
  - Aortic and mitral valve calcification

Consider

- Exogenous ochronosis
- Argyria
- Chrysiasis
- Treatment-induced pigmentation (amiodarone, quinacrine, quinine)

BOX 131-6 TREATMENT OF ALKAPTONURIA

- Avoidance of high-protein diet
- Avoidance of high-phenylalanine diet
- Avoidance of high-tyrosine diet
- Large amounts of dietary vitamin C
- 2(-2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione
- Nitisinone in investigative stage

TREATMENT

The course of alkaptonuria is generally slow but irreversible. Treatment is primarily supportive, with close observation for the development of arthropathy, cardiac disease, and urinary tract disease (Box 131-6). Appropriate management includes genetic counseling, pain management with nonsteroidal anti-inflammatory agents, physical therapy to increase range of motion, and regular follow-up visits.[20] Avoidance of high-protein, high-phenylalanine, and high-tyrosine diets has been reported to be important. A well-balanced normal diet seems the best approach during childhood.[76–78] It has been postulated that large amounts of dietary vitamin C may be helpful, because vitamin C protects HGA against oxidation and thus may prevent the deposition of ochronotic pigment; however, no long-term clinical studies have been undertaken to verify the effectiveness of this approach.[76] In recent years nitisinone has been used in ochronotic patients in an investigational basis and excretion of homogentisic acid could be decreased.[49,78]

It is disappointing that despite advances in our biochemical understanding of alkaptonuria and the disposition of accumulated HGA to form ochronotic pigment in connective tissue, this information has yet to be translated into a successful therapeutic program for managing the disease. Exogenous cutaneous ochronosis induced by hydroquinone has been treated with the carbon dioxide laser.[79]

COURSE AND PROGNOSIS

The ultimate course in adults with alkaptonuria is that of increasing pigmentation and skeletal incapacity. Little can be done to interrupt this progression; however, the disease is not incompatible with a normal life span, and the oldest patient on record lived to 99 years of age.

OTHER ABNORMALITIES OF AMINO ACID METABOLISM

Table 131-1 lists some of the abnormalities of amino and organic acid metabolism and their associated skin manifestations.

Chapter 132 :: The Porphyrias

:: David R. Bickers & Jorge Frank

The porphyrias are among the most intriguing human diseases. Widely variable, even bizarre in their clinical manifestations, these disorders of porphyrin or porphyrin-precursor metabolism result from aberrations in the control of the heme biosynthetic pathway. Heme is essential for oxygen binding and transport (as in hemoglobin and myoglobin), for electron transport (as in cytochromes), and for monooxygenases such as cytochrome P_{450}. Chlorophyll, a magnesium-chelated porphyrin, is another important tetrapyrrole that is critical for photosynthesis, the specialized energy-storing system found in plants in which the conversion of light energy into stabilized chemical energy is achieved with a sequence of oxidation-reduction reactions. The corrin ring, a cobalt-chelated tetrapyrrole, is a major constituent of vitamin B_{12}, the lack of which results in pernicious anemia. Therefore, porphyrins are ubiquitous and essential biochemical constituents of living beings. The biologic importance of the porphyrins and their iron complexes lies in their capacity to facilitate metabolic reactions, either as oxidative components in the metabolism of steroids, drugs, and environmental chemicals or by enhancing gas exchange, such as oxygen and carbon dioxide, between the environment and the tissues of the body.

Daily synthesis of porphyrins and heme in humans occurs in amounts sufficient to provide for the body's metabolic requirements. The control of heme synthesis is so precise that, under normal circumstances, only microgram quantities or less of pathway intermediates are present in plasma, red blood cells (RBC), urine, and stool (Table 132-1).

The porphyrias are a clinically and genetically heterogeneous group of metabolic diseases, which result from an either inherited or acquired dysfunction of enzymes crucial for heme biosynthesis (Fig. 132-1). Heme synthesis is controlled by eight enzymes along the heme biosynthetic

TABLE 132-1
Normal Values of Porphyrins and Porphyrin Precursors in Humans

Porphyrins or Precursors	Urine (μg/24 h)	Red Blood Cells (μg/100 mL Packed Cells)	Plasma (μg/100 mL)	Feces (μg/g Dry Weight)
δ-Aminolevulinic acid (ALA)	<4,000	—	15–23	—
Porphobilinogen (PBG)	<1,500	—	—	—
Uroporphyrin (URO)	<40	0–2.0	0–2	10–50
Coproporphyrin (COPRO)	<280	0–2.0	0–1	10–50
Protoporphyrin (PROTO)	Absent	<90	0–2	0–20
X-porphyrin	Absent	Absent	Absent	Trace
Isocoproporphyrin (ISOCOPRO)	Absent	Absent	Absent	—
	(nmolL/Day)	**(nmol/dL)**	**(nmol/dL)**	**(nmol/g Dry Weight)**
ALA	8.8×10^3	—	$1.1–1.8 \times 10^2$	—
PBG	4.6×10^4	—	—	—
URO	<40	—	24	—
COPRO	<280	—	46	—
PROTO	0	285	0.5	134

pathway. Deficient activity of seven of these eight enzymes can give rise to a specific type of porphyria (Fig. 132-1).[1–3] A gain of function of the first enzyme in the pathway, δ-aminolevulinic acid synthase (ALAS) is responsible for X-linked dominant protoporphyria (XLDPP), a recently recognized type of porphyria.[4] Each of these enzymes will be discussed separately below, in the context of the corresponding type of porphyria.

Biochemically, the different porphyrias are characterized by particular patterns of accumulation and excretion of porphyrins and/or their precursors. In general, the porphyrins excreted in a specific type of porphyria are the irreversibly oxidized substrate(s) of the deficient enzyme (Table 132-2). These intermediates, when present in excess amounts, exert toxic effects that are responsible for the cutaneous and neurological signs and symptoms of clinically overt porphyria. The porphyrias are of particular dermatologic interest because several types exhibit cutaneous manifestations that may permit diagnosis from clinical signs alone.

PORPHYRIN-HEME BIOSYNTHESIS

The major sites of heme synthesis in the body are the bone marrow and the liver. Heme is the prosthetic group for a number of proteins, including among others hemoglobin, myoglobin, mitochondrial cytochromes, microsomal cytochromes (including cytochrome P_{450}), catalase, peroxidase, tryptophanpyrrolase, prostaglandin endoperoxide synthase, and the soluble form of guanylate cyclase. Approximately 85% of heme synthesis occurs in the bone marrow where it is utilized for the production of hemoglobin; the majority of the rest occurs in the liver for making cytochrome P_{450}, catalase, and various mitochondrial cytochromes. Heme is a critical cellular constituent essential for a variety of metabolic processes, primarily because of its unique ability to take up and release oxygen and to facilitate electron transport. Heme synthesis is regulated by the interplay of a number of factors and is directly dependent upon its concentration within cells and upon the requirements of the cell for production of the various hemoproteins described above. Many of these have rapid turnover times (minutes to hours), thereby necessitating continuously high rates of hepatic heme synthesis. For example, cytochrome P_{450}, an important membrane-bound enzyme in the liver involved in the detoxification and metabolism of drugs, has a half-life of 90–180 minutes.

REGULATION OF HEME BIOSYNTHESIS

Heme synthesis begins in the mitochondrion of the cell where succinate and glycine (single molecules of glycine and succinyl CoA) are conjugated by ALAS to form a five-carbon aminoketone, δ-aminolevulinic acid (ALA). This reaction requires pyridoxal 5′-phosphate as a cofactor. The regulation of heme biosynthesis (and indeed the ability to synthesize heme at all) is dependent upon the serial interaction of eight intracellular enzymes (Figs. 132-1 and 132-2). The first, as well as the last three enzymes involved, coproporphyrinogen oxidase (CPOX), protoporphyrinogen oxidase (PPOX),

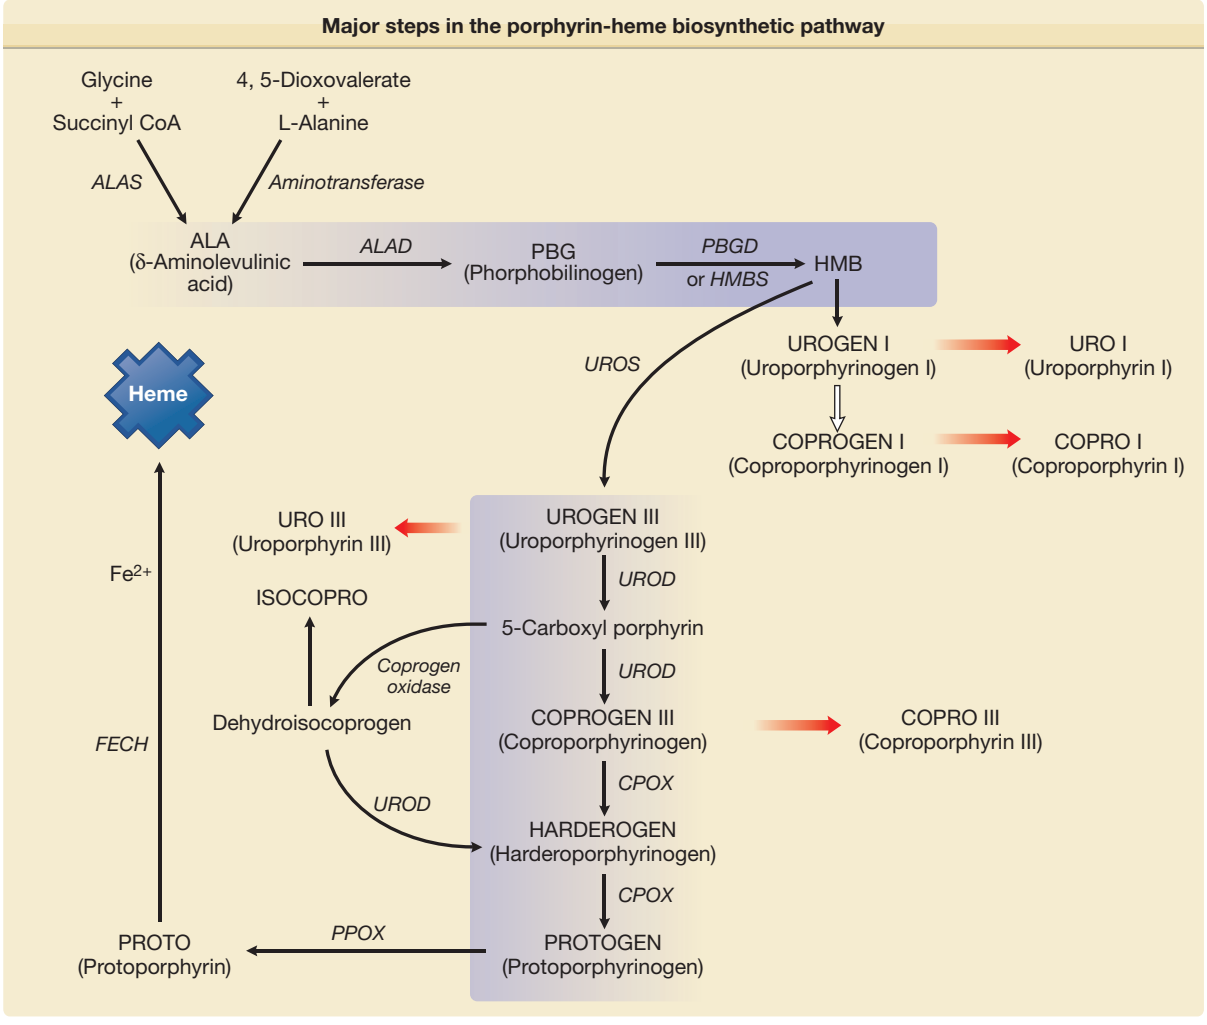

Figure 132-1 Major steps in the porphyrin-heme biosynthetic pathway. δ-Aminolevulinic acid (ALA) can be formed from glycine and succinyl coenzyme A (SCoA), which is the primary source in mammalian systems and is catalyzed by the mitochondrial enzyme ALA synthase (ALAS). Two molecules of ALA form the monopyrrole porphobilinogen (PBG) in a reaction catalyzed by the enzyme ALA dehydratase (ALAD). Four molecules of PBG are converted by PBG deaminase (PBGD) also known as hydroxymethylbilane synthetase (HMBS) to a linear tetrapyrrole, hydroxymethylbilane (HMB), which can cyclize spontaneously to form uroporphyrinogen (UROGEN) I. The four acetyl groups of UROGEN I are sequentially decarboxylated by UROPORPHYRINOGEN decarboxylase (UROD) to form coproporphyrinogen (COPROGEN) I. HMB can also be converted to UROGEN III by the enzyme UROPORPHYRINOGEN III synthase (UROS). In this reaction, one of the monopyrrole rings is "flipped over," which alters the sequence of the side chains. The acetyl groups of UROGEN III are sequentially decarboxylated by UROD to form COPROGEN III. COPROGEN III is converted to protoporphyrinogen (PROTOGEN) IX by the enzyme COPROPORPHYRINOGEN oxidase (CPOX), which oxidatively decarboxylates each of the propionyl groups. PROTOGEN IX is converted to protoporphyrin (PROTO) IX by PROTOPORPHYRINOGEN oxidase (PPOX). PROTO IX is converted to heme by ferrochelatase (FECH), which catalyzes the insertion of ferrous iron into the molecule.

and ferrochelatase (FECH) are mitochondrial, whereas the remaining enzymes including δ-aminolevulinic acid dehyratase (ALAD), porphobilinogen deaminase (PBGD), uroporphyrinogen synthase (UROS), and uroporphyrinogen decarboxylase (UROD) are localized in the cytosol. The degradation of heme is catalyzed by the microsomal enzymes NADPH-cytochrome C reductase, heme oxygenase 1 and 2. Heme oxygenase 1 is a -signature of oxidative tissue injury and is a potent antioxidant. Heme oxygenase 2 is an oxygen sensor. The metabolic by-products of these enzymes are the linear tetrapyrrole biliverdin IXα and carbon monoxide and also possess antioxidant properties. cDNAs for each of the eight enzymes involved in heme biosynthesis as well as the enzymes responsible for heme catabolism have been cloned in mammalian cells.[1–3] Abnormal regulation of heme synthesis may result from defects in enzymes of the synthetic pathway, and this may occur as the result of inherited and/or environmental factors leading to the accumulation in the body of one or more heme pathway intermediates, such as the porphyrins or their precursors. Although a diagnosis of porphyria can often be made from a careful medical history (including the family history) and physical examination, the definitive diagnosis requires measurement of: (1) porphyrins and/or porphyrin precursors in urine, stool, plasma, or RBCs, or (2) the residual activity of specific enzymes in the heme pathway, or (3) the identification

TABLE 132-2
Pattern of Enzyme Activities in Various Porphyrias

Enzyme	Tissue	Enzymatic Defect in Porphyria
δ-Aminolevulinic acid synthase 1 (ALAS1) δ-Aminolevulinic acid synthase 2 (ALAS2)	Liver, kidney, fibroblasts, and lymphocytes Erythrocytes	Increased in AIP, HCP, VP Increased in XLDPP
ALA dehydratase (ALAD)	Erythrocytes, liver, and kidney	Decreased in lead intoxication Decreased in ALA dehydratase deficiency porphyria
Porphobilinogen deaminase (PBGD)	Erythrocytes, liver, fibroblasts, lymphocytes, and amnion cells	Decreased in AIP
Uroporphyrinogen III synthase (UROS)	Erythrocytes and fibroblasts	Decreased in CEP
Uroporphyrinogen decarboxylase (UROD)	Erythrocytes and liver	Decreased in all tissues in hereditary or familial PCT and HEP Only decreased in the liver in acquired or sporadic PCT
Coproporphyrinogen oxidase (CPOX)	Fibroblasts, lymphocytes, and liver	Decreased in HCP
Protoporphyrinogen oxidase (PPOX)	Liver and fibroblasts	Decreased in VP
Ferrochelatase (FECH)	Bone marrow and fibroblasts	Decreased in EPP and lead poisoning

AIP = acute intermittent porphyria; CEP = congenital erythropoietic porphyria; EPP = erythropoietic protoporphyria; HCP = hereditary coproporphyria; HEP = hepatoerythropoietic porphyria; PCT = porphyria cutanea tarda; VP = variegate porphyria; XLDPP = X-linked dominant EPP.

of mutations in the genes encoding these enzymes (Fig. 132-1). Modern molecular biological techniques have helped to clarify the mechanistic basis of the porphyrias.[3–8] The steps involved in the biosynthesis of porphyrins and heme and their regulatory control are summarized in Figs. 132-1–132-4.

δ-AMINOLEVULINIC ACID SYNTHASE

THE PORPHYRIAS AT A GLANCE

- The porphyrias result from a dysfunction of specific enzymes involved in heme biosynthesis.
- At least eight different types of porphyria are known, classified as nonacute and acute.
- Cutaneous features manifest predominantly on sun-exposed body areas.
- Life-threatening acute neurologic attacks can occur.
- Diagnosis is often difficult due to overlapping clinical and biochemical findings.
- All genes encoding the enzymes involved in heme synthesis are well characterized, which allows for accurate molecular diagnosis and genetic counseling.

CLASSIFICATION OF THE PORPHYRIAS

Traditionally, most classifications of the porphyrias are based on the primary site of expression of the specific enzymatic defect, thereby distinguishing erythropoietic and hepatic types. From a dermatologic perspective, the porphyrias might also be classified into cutaneous and noncutaneous forms. However, from a general clinical perspective, we have chosen to classify the porphyrias into two subtypes: (1) nonacute and (2) acute thereby distinguishing patients in whom dermatologic findings predominate from those susceptible to potentially life-threatening acute neurovisceral attacks (Tables 132-3 and 132-4). We will employ this classification throughout this chapter. It should be pointed out that two of the acute porphyrias, variegate porphyria (VP) and hereditary coproporphyria (HCP), are also referred to as neurocutaneous porphyrias since patients with these diseases may have both neurovisceral and cutaneous manifestations.

An acute porphyric attack can present a constellation of symptoms and signs, among them, intense abdominal pain, vomiting, electrolyte dysregulation (hyponatremia), constipation, tachycardia, hypertension, muscle pain and weakness, seizures, paresis of the upper and lower extremities, paralysis, and a variety of other neurological and psychiatric symptoms.[11] These myriad clinical manifestations inevitably mimic other diseases, thereby challenging the diagnostic acumen of even the most experienced clinicians particularly since the porphyrias are rare disorders.[12] It is known that acute porphyric attacks can be precipitated by a variety of external factors, in particular porphyrinogenic drugs, ethanol, hormonal fluctuations, and

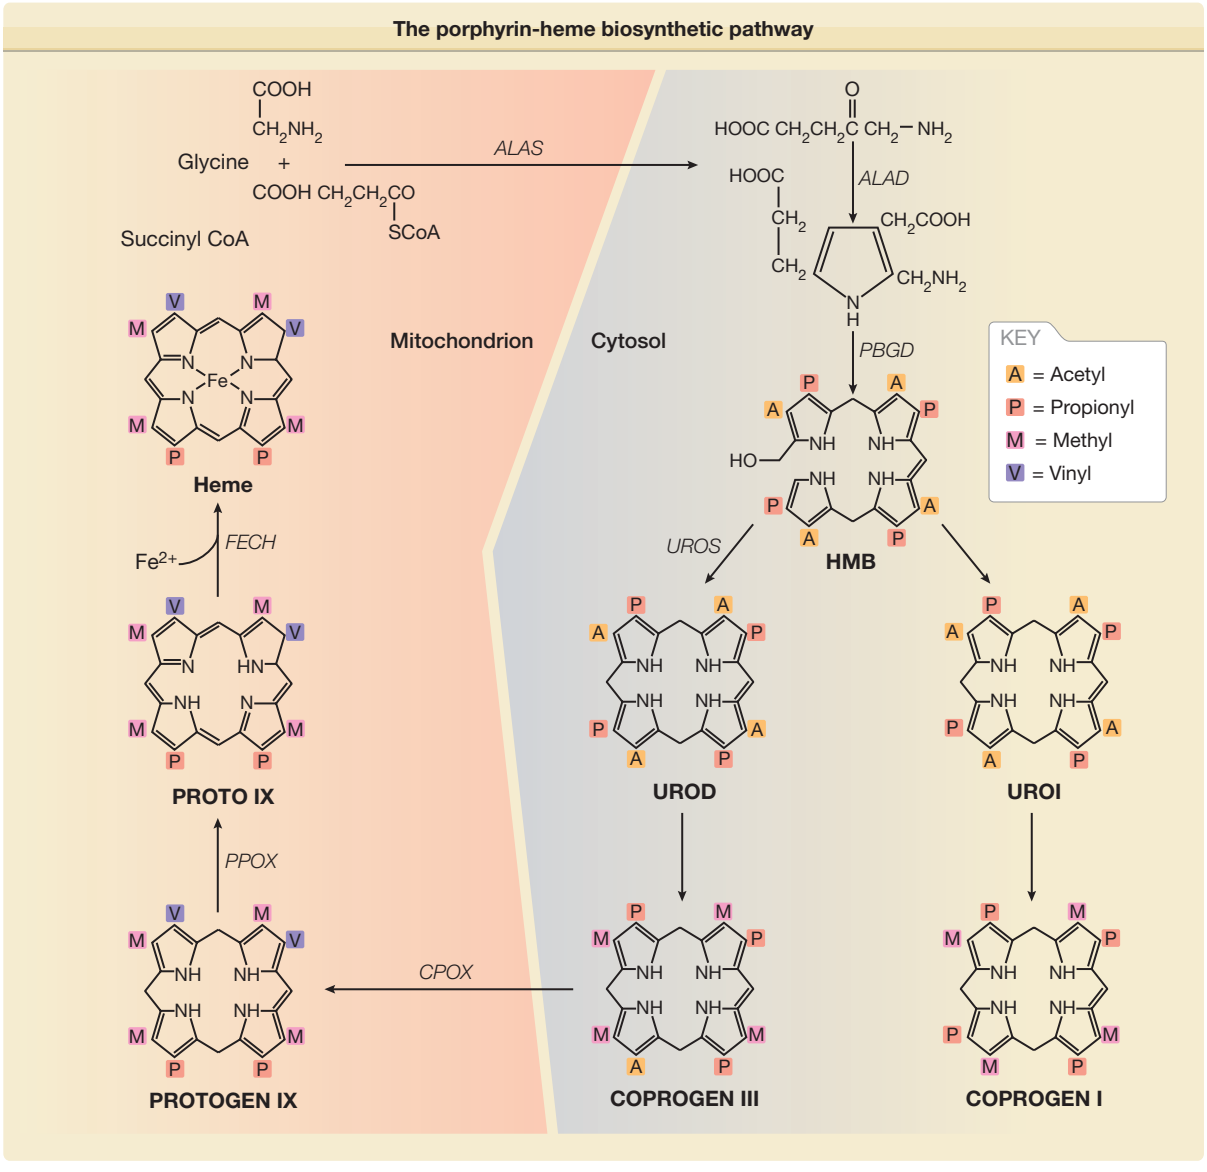

Figure 132-2 The porphyrin-heme biosynthetic pathway (with structural components). (See also Figure 132-1.)

diminished caloric intake from dieting or fasting.[11,13] Yet in practice, it is often impossible to identify the immediate cause of an acute attack in an individual patient. Timely diagnosis of an acute porphyric attack can be lifesaving because several complications may have fatal consequences if not recognized and treated. It is crucial to keep in mind that many drugs are capable of inducing heme synthesis in the liver.[11,13] Thus, in a patient an acute porphyria with episodic abdominal pain, treatment with certain analgesics may prolong or aggravate the attack. Diffuse abdominal pain can mimic acute appendicitis, diverticulitis, intestinal obstruction, or other painful gastroenterological disorders that may necessitate urgent surgical intervention.[14,15] After administration of certain drugs (e.g., barbiturates) or during general anesthesia, acute attacks may ensue.[1] A particularly problematic complication is muscle weakness. This can range from mild paralysis of small muscle groups to flaccid paralysis of multiple muscle groups resulting in paraplegia and respiratory compromise. These findings may be accompanied by severe sensory loss and amyotrophy.[16] In some cases, paralysis may progress rapidly and can affect cranial nerves or develop into a Guillain–Barré-like syndrome.[17]

NONACUTE AND ACUTE PORPHYRIAS

(See Tables 132-3 and 132-4)

Patients with all forms of nonacute porphyria manifest cutaneous findings predominantly on sun-exposed body areas. The nonacute porphyrias include porphyria cutanea tarda (PCT), the most prevalent

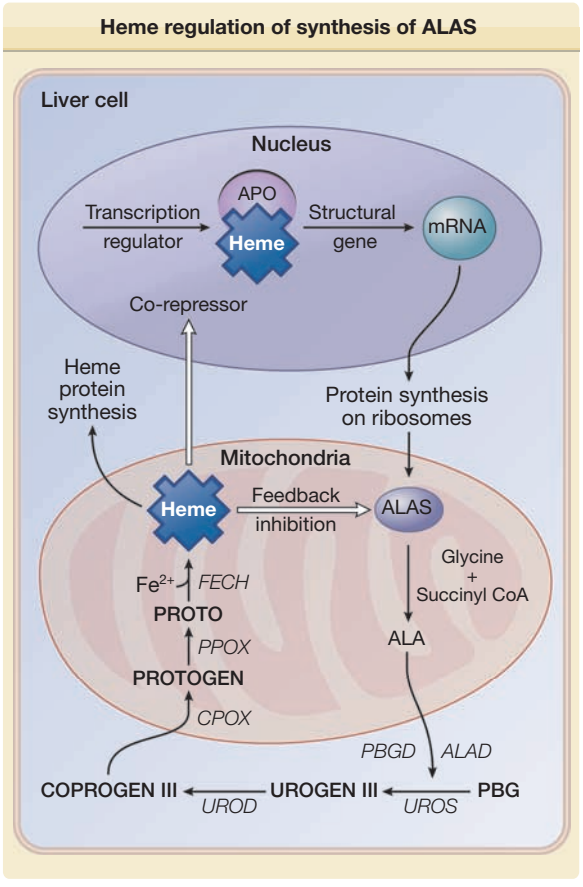

Figure 132-3 Heme is capable of regulating its synthesis by either directly inhibiting or repressing the synthesis of its rate-limiting enzyme ALAS. The repression may result from the binding of heme, as a corepressor, to an aporepressor protein (APO), which, when combined with heme, becomes a functional unit that blocks transcription of ALAS messenger RNA (mRNA). Heme may also block transport of the holoenzyme into the mitochondrion. ALA = δ-aminolevulinic acid; ALAD = δ-aminolevulinic acid dehydratase; CoA = coenzyme A; COPROGEN = coproporphyrinogen; PBGD = porphobilinogen deaminase; PROTO = protoporphyrin; PROTOGEN = protoporphyrinogen; UROGEN = uroporphyrinogen.

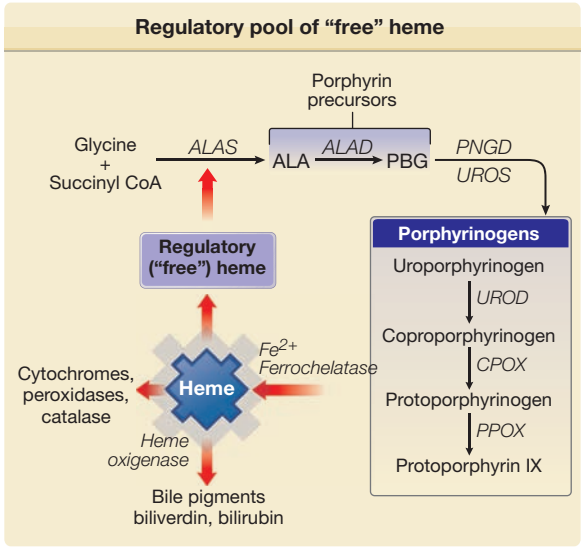

Figure 132-4 A regulatory pool of "free" heme unbound to apoproteins may be the critical determinant for regulation of synthesis of ALAS activity. ALA = δ-aminolevulinic acid; ALAD = δ-aminolevulinic acid dehydratase; CoA = coenzyme A; PBG = porphobilinogen; PBGD = porphobilinogen deaminase; COPROGEN = coproporphyrinogen; PROTOGEN = protoporphyrinogen; UROGEN = uroporphyrinogen.

type of porphyria overall, hepatoerythropoietic porphyria (HEP), the homozygous variant of PCT, erythropoietic protoporphyria (EPP), XLDPP, the most recently recognized type of porphyria, and congenital erythropoietic porphyria (CEP) (Table 132-3). The nonacute porphyrias can present with variable cutaneous features, including mild-to-severe photosensitivity, increased skin fragility, vesicles and bullae, scarring with milia formation, burning and stinging, edema, pruritus, hypertrichosis, hyperpigmentation, and mild-to-severe scleroderma-like changes with tissue calcification.[4]

The acute porphyrias include acute intermittent porphyria (AIP), VP, HCP, and δ-aminolevulinic acid dehydratase (ALAD) deficiency porphyria (also known as plumboporphyria) (Table 132-4). Whereas AIP is the most prevalent form of acute porphyria worldwide, in some countries other acute forms may predominate, as is the case for VP in South Africa.[1,2,18,19] Besides neurovisceral symptoms, individuals suffering from VP or HCP can also present with cutaneous findings, including increased photosensitivity, abnormal skin fragility, and bullous skin lesions on sun-exposed areas, erosions, chronic scarring, and postinflammatory pigmentary change. Thus, VP and HCP are also referred to as neurocutaneous porphyrias, to distinguish them from AIP and ALAD deficiency porphyria in which there are no cutaneous abnormalities.[4,20]

It is of interest that ethanol and estrogens, which can trigger acute porphyric attacks in AIP, VP, and HCP, can also exacerbate PCT, although acute attacks do not occur in this disease and the mechanisms likely differ.[21]

PATHOPHYSIOLOGY OF CUTANEOUS SIGNS AND SYMPTOMS IN THE NONACUTE PORPHYRIAS

The most common cutaneous manifestation of the nonacute porphyrias is photosensitivity; it is observed in patients with several of these disorders (PCT, HEP, EPP, XLDPP, CEP) as well as in patients with VP and HCP who have both cutaneous and neurovisceral findings. The sine qua non of photosensitivity in porphyria is increased plasma and tissue porphyrins. Patients with AIP, in whom only nonphotosensitizing porphyrin precursors (ALA, PBG) are formed in substantially increased amounts, do not have photosensitivity nor do any patients with ALAD deficiency porphyria.

TABLE 132-3
Overview and Summary of the Features of the Nonacute Porphyrias

	Porphyria Cutanea Tarda	Erythropoietic Protoporphyria	Congenital Erythropoietic Porphyria	Hepatoerythropoietic Porphyria
Synonym(s)	Symptomatic porphyria, acquired hepatic porphyria, chemical porphyria	Erythropoietic porphyria, protoporphyria	Günther disease, congenital hematoporphyria, erythropoietic uroporphyria	Hepatoerythrocytic porphyria
Inheritance	Autosomal dominant in approximately 20% of patients; otherwise acquired	Autosomal dominant with hypomorphic IVS3–48C allele; X-linked dominant; Autosomal recessive	Autosomal recessive	Autosomal recessive
Age of onset	Usually in third or fourth decade; rare before puberty	Early childhood (1–4 years); late onset extremely rare	Usually infancy or first decade	Early infancy, before age 2 years
Incidence	Most common porphyria worldwide	Second most common of the cutaneous porphyrias	Very rare (fewer than 250 cases)	Extremely rare (fewer than 40 cases)
Photosensitivity	Moderate-to-severe with high interindividual variation; indistinguishable from variegate porphyria	Mild-to-severe; onset immediate (in minutes); interindividual variation	Severe to very severe	Severe
Skin reactions (on sun-exposed areas)	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis; indistinguishable from variegate porphyria	Edema, erythema, urticarial plaques; very rarely bullae, skin thickening, waxy scars	Vesicles and bullae, erosions, hypertrichosis, hypermelanosis, mutilation	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis, mutilation

TABLE 132-4
Overview and Summary of the Features of the Acute Porphyrias

	Acute Intermittent Porphyria	Variegate Porphyria	Hereditary Coproporphyria	ALA Dehydratase Deficiency Porphyria
Synonym(s)	Swedish porphyria	Mixed porphyria, South African genetic porphyria, protocoproporphyria hereditaria, PCT hereditaria	Idiopathic coproporphyria	Plumboporphyria
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive
Age of onset	10–40 years; extremely rare before puberty	Usually between ages 15 and 30 years	Any age	Early and late clinical onset has been described
Incidence	1.5 in 100,000; more common in Scandinavia and Lapland	Common in South Africa (3 in 1,000); relatively rare elsewhere	Rare (fewer than 50 cases reported)	None reported
Photosensitivity	Absent	Moderate to severe with high interindividual variation; similar to that in PCT	Very rare	Absent
Skin reactions (on sun-exposed areas)	None	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis; similar to those in PCT	Usually blistering	None

ALA = δ-aminolevulinic acid; PCT = porphyria cutanea tarda.

TABLE 132-5
Fluorescence Characteristics of Porphyrin-Containing Plasma Diluted with 1:10 Phosphate Buffered Solution

Type	Peak Excitation (nm)	Peak Emission (nm)	Fluorescent Porphyrins
Congenital erythropoietic porphyria	398	619	URO I, COPRO I
Erythropoietic protoporphyria X-linked dominant Erythropoietic protoporphyria	409	634	FREE PROTO FREE and ZINC PROTO
Porphyria cutanea tarda	398	619	URO I, III; COPRO III
Variegate porphyria	405	626	COPRO III, PROTO
Acute intermittent porphyria	398	619	URO III
Hereditary coproporphyria	398	619	COPRO III
Hepatoerythropoietic porphyria	398	619	URO I

COPRO = coproporphyrin; PROTO = protoporphyrin; URO = uroporphyrin.

Patients with the erythropoietic porphyrias frequently complain of a painful and intense burning sensation and pruritus during or following sun exposure. A "priming" effect of sun exposure on cutaneous photosensitivity in EPP has been described in which a threshold exposure on one day that evokes virtually no reaction seems to augment the response to subsequent exposure on the following day.[22] The cause of this is unknown, but the phenomenon suggests that repair of damage to skin by photosensitized porphyrins may be prolonged. These acute symptoms are notably absent in patients with the chronic hepatic porphyrias such as PCT and VP. Although there is some information about the pathophysiology of photosensitivity and sclerodermoid skin changes in the chronic hepatic porphyrias, the causes of the pigmentary alterations and hypertrichosis seen in these patients remain to be elucidated.

Porphyrins have certain unique photobiologic and spectroscopic properties that make them potent photosensitizers. Importantly, metal-chelated porphyrins (e.g., heme or FePROTO) show no fluorescence and are not photosensitizers. Porphyrins that are chelated to other paramagnetic metals, such as Mn^{2+}, Co^{2+}, or Zn^{2+} (e.g., chlorophyll, ZnPROTO), also do not fluoresce. For this reason patients with lead intoxication, in which ZnPROTO is elevated, do not have photosensitivity.[23,24] However, metal-free porphyrins including, Uroporphyrin (URO), Coproporphyrin (COPRO), and Protoporphyrin (PROTO) in acidic solutions show a major absorption peak in the 400- to 410-nm region (Soret band); they also exhibit four additional absorption bands with decreasing intensity between 500 and 700 nm. Exposure of porphyrins to the Soret band spectra results in fluorescence emission peaks between 550 and 680 nm (Table 132-5). Although there is no single clearly defined pathway that can currently explain the photosensitization evoked by porphyrins and light, there are a number of potential cellular and soluble factors that are likely to be involved. Among them, reactive oxygen species (ROS) and their effect upon certain cells (erythrocytes, mast cells, polymorphonuclear cells, and fibroblasts), and soluble mediators (the complement system and matrix metalloproteinases) are discussed (Table 132-6). It is likely that a combination of these factors will prove to be responsible for the pathogenesis of the cutaneous lesions in the porphyrias.

Of note, porphyrin abnormalities can also occur in lead poisoning, sideroblastic, hemolytic and iron deficiency anemia, renal failure, cholestasis, liver disease, and gastrointestinal hemorrhage. Of these, however, cutaneous photosensitivity has only been documented in rare cases of sideroblastic anemia.

PATHOPHYSIOLOGY OF NEUROVISCERAL SIGNS AND SYMPTOMS IN THE ACUTE PORPHYRIAS

Two acute porphyrias, AIP and ALAD deficiency porphyria, do not manifest cutaneous symptoms. In these diseases, the dysfunctional enzymes function early in heme biosynthesis and their substrates are nonphototoxic porphyrin precursors. However, patients with both AIP and ALAD deficiency porphyria as well as VP and HCP can manifest life-threatening acute neurovisceral attacks. Although the exact pathogenesis of these attacks is not well understood, it is known that the porphyrin precursors ALA and PBG are massively excreted from the liver during an acute attack and in particular ALA is known to be have neurotoxic properties. Furthermore, as a result of porphyria-related enzyme defects the net result may be heme deficiency in nerve tissue. Thus, the autonomic and peripheral nervous systems are particularly susceptible to porphyrin precursor induced neuropathy.[25]

CELLULAR AND SOLUBLE FACTORS CONTRIBUTING TO PHOTOSENSITIVITY

(See Table 132-6)

REACTIVE OXYGEN SPECIES. Porphyrins such as URO, COPRO, and PROTO absorb light intensely around 400 nm and in the longer visible spectrum between 580 and 650 nm. Absorption results in the generation of "excited" state porphyrin molecules (Fig. 132-5). The initial excited state porphyrin generated has an extremely short half-life of less than 0.01 µs. Singlet excited state porphyrins may spontaneously convert to a triplet, another excited state that has a lower energy level but a longer half-life (in the order of microseconds to milliseconds). Because of their longer half-life, triplet-state porphyrins have a higher probability of reacting with biologic substrates and are likely candidates to mediate most porphyrin-associated photobiological reactions. Excited state porphyrin molecules ultimately must return to their normal ground states by releasing their absorbed energy in the form of light (fluorescence is emitted by singlet state molecules and phosphorescence by triplet states), heat, or by transferring energy to cell constituents (cell membranes, organelles, proteins, DNA) (Figs. 132-5 and 132-6).

Excited porphyrins in their singlet and triplet states can also transfer their absorbed energy to oxygen molecules thereby creating reactive "excited" oxygen states.[26] Cellular and tissue damage induced by photoactivated porphyrins is believed to occur primarily as a result of the formation of reactive singlet oxygen ($^1O_2$), as illustrated in Figs. 132-5 and 132-6.[27,28] In some cases, the sensitized porphyrin may further react with oxygen to yield hydrogen peroxide (H_2O_2) or with water to form hydroxyl radicals ($^{\bullet}OH$). Those processes in which activated oxygen species play a role in photosensitization are referred to as photodynamic reactions.[29] Most of the porphyrin-mediated cutaneous photosensitization reactions are essentially photodynamic (oxygen-dependent) and can be minimized or prevented if ROS are eliminated by inactivation processes known as quenching or scavenging.

Although these concepts regarding excited porphyrins and ROS are valid in simple systems and several hypotheses have been advanced regarding the mechanism of porphyrin-induced photosensitivity, their applicability to complex tissues such as the skin remains to be established.

Photoexcited porphyrins

	$PP_0 + h\nu \longrightarrow {}^1PP$		(Singlet state)
1	$^1PP \longrightarrow$ a)	$PP_0 + h\nu$	(Fluorescence)
2	$\longrightarrow$ b)	PP_0	(Non-radiative decay)
3	$\longrightarrow$ c)	^3PP	(Triplet-state transition)
4	$^3PP \longrightarrow$	$PP_0 + h\nu$	(Phosphorescence)
5	$^3PP + {}^3O_2 \longrightarrow$	$PP_0 + {}^1O_2$	(Singlet state oxygen)
6	$^1O_2 + A \longrightarrow$	A (ox)	(Substrate oxidation, lipid peroxidation, and cell membrane damage)

Figure 132-5 Photoexcited porphyrins release energy in a variety of ways when returning to their ground state, and these may contribute to damaging reactions in biologic systems. A = acceptor; A (ox) = oxidized acceptor; hν = radiant energy; PP = photoexcited porphyrin.

ERYTHROCYTES. Photoexcited PROTO elicits peroxidation of cholesterol groups in erythrocyte membranes, whereas URO or COPRO has no such effect. This difference is also true of mast cells, polymorphonuclear leukocytes (PML), and fibroblasts, and most likely relates to variations in lipid-water partitioning of the different porphyrins, which may in turn relate to their polarity. Lipophilic PROTO, a 2-carboxyl porphyrin, is more damaging to lipid-rich membranes as compared to the more hydrophilic COPRO and URO.[30]

MAST CELLS. Phototoxic damage to mast cells is associated with elevated serum histamine levels and dermal mast cell degranulation,[31] and the phototoxic response can be suppressed by pretreatment with antihistamines (H_1 blockers) or by intradermal injection of a mast cell secretagogue (compound 48/80).[32]

Mast cell degranulation occurs in the exposed skin of patients with EPP.[33] Irradiation of PROTO-treated mast cells in vitro induces release of mast cell-derived mediators, although exposure to lower doses of PROTO and radiation results in inhibition of secretagogue-induced

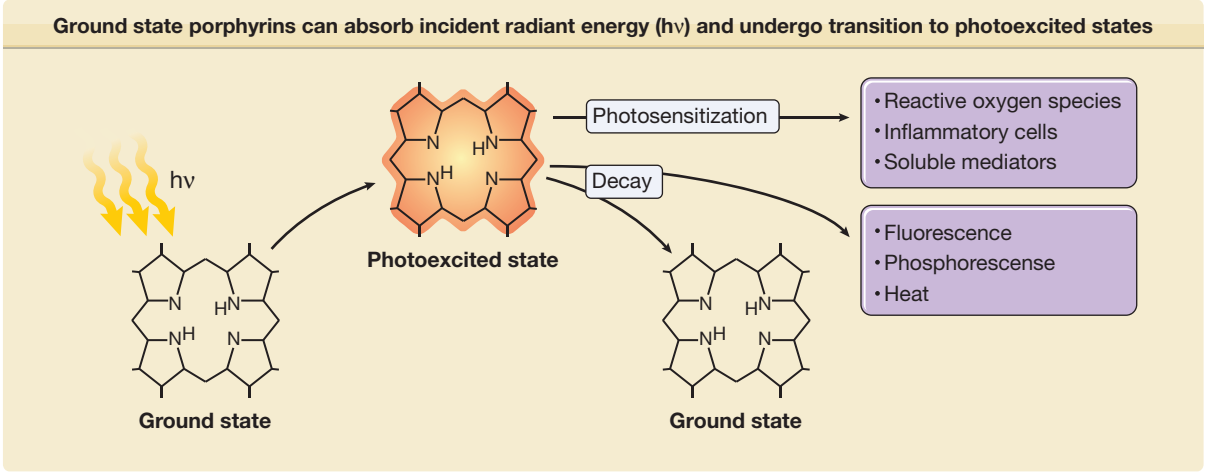

Figure 132-6 Ground state porphyrins can absorb incident radiant energy (hν), and undergo transition to photoexcited states. The photoexcited porphyrins generate reactive oxygen species, which damage cells by release of proinflammatory mediators; in turn, these may contribute to damaging reactions in biologic systems such as skin.

histamine release from these cells.[34] In contrast, no mediator release is detectable when cells are radiated in the presence of URO. These findings may help to explain the differences in the clinical presentation of patients with EPP and PCT. The elevated PROTO in patients with EPP may induce the release of mast cell mediators in vivo following sun exposure, resulting in painful, pruritic erythema and edema. The absence of these changes in patients with PCT may be explained by the apparent inability of photoexcited URO to damage cutaneous mast cells.

POLYMORPHONUCLEAR CELLS. Exposure of human PML to PROTO and radiation in vitro results in membrane damage, whereas photoexcited URO induces no such alterations.[35] These results are strikingly similar to those obtained in studies with mast cells (see above). In an animal model, porphyrin-induced phototoxicity was associated with a dermal PML infiltrate[31,36] and the response was markedly suppressed in leukopenic animals.[32] These results appear to suggest that PML may be necessary but not sufficient to induce porphyrin-induced phototoxicity.

FIBROBLASTS. Differential phototoxic effects of various porphyrins have also been verified in studies using dermal fibroblasts. An increase in collagen biosynthesis is observed following incubation of fibroblasts with URO.[37] This effect is independent of irradiation and may partly explain the sclerodermoid changes observed in patients with PCT, which can occur in sun-exposed and in sun-protected areas. In contrast, PROTO induces photolysis of fibroblasts in vitro.[38,39]

MATRIX METALLOPROTEINASES. Photoexcited URO has been shown to coordinately induce interstitial collagenase (MMP-1), 72-kDa type IV collagenase (MMP-2) and stromelysin-1 (MMP-3) in human dermal fibroblasts in vitro.[40] The induction of the MMPs by porphyrin photosensitization suggests that activation/release of these enzymes could contribute to the blistering process.

COMPLEMENT SYSTEM. The complement system is activated by photoexcited porphyrins such as URO and PROTO. In vitro exposure to Soret band radiation activates the complement cascade and releases anaphylatoxins.[41,42] Exposure of the skin of patients with EPP and PCT to Soret band energy in vivo also generates anaphylatoxins.[43] Granular and homogeneous deposits of the complement membrane attack complex C5b9 have been observed in skin biopsies obtained from the skin of patients with PCT.[44] It is of interest that target tissue heme pathway enzymes may be a crucial determinant of skin susceptibility to porphyrin photosensitization. Using a mouse model of EPP it has been shown that in transplanting bone marrow from EPP animals to wild-type mice the skin of the recipients was resistant to photosensitivity despite very high levels of plasma porphyrins suggesting that the normal FECH levels in the recipients somehow protected them against phototoxicity.[45]

In summary, cutaneous phototoxicity in the porphyrias is directly related to the interaction of porphyrins with light of the Soret and other bands in the solar spectrum, resulting in the generation of ROS. This in turn can induce lipid peroxidation and cell membrane alterations. Release of mediators and enzymes from cells such as mast cells and PML contributes to the inflammatory response. Variations in solubility influenced by the lipid–water partitioning of porphyrins may account for the striking patterns of the skin findings observed in various types of porphyria. It is important to emphasize that porphyrinogens (reduced porphyrins) are the true intermediates in heme synthesis. The irreversibly oxidized porphyrins, with the exception of PROTO, do not function as substrates for the enzymes of the pathway. Thus, porphyrins are actually heme pathway by-products, which are of special interest to dermatologists because of their unique photosensitizing properties.

THE NONACUTE PORPHYRIAS

(See Table 132-3)

PORPHYRIA CUTANEA TARDA (PCT)

PORPHYRIA CUTANEA TARDA AT A GLANCE

- Most frequently occurring type of porphyria worldwide.
- Sporadic and inherited (autosomal dominant) forms of the disease arise due to deficiency of UROD.
- Age of onset is usually in the third to fourth decade of life; the disorder is unusual before puberty.
- Characterized by moderate-to-severe photosensitivity; cutaneous signs include vesicles and bullae, erosions, crusts, milia, sclerodermoid changes and scarring, hyperpigmentation, and hypertrichosis.
- Cutaneous features overlap with those of variegate porphyria and hereditary coproporphyria.

EPIDEMIOLOGY. PCT occurs throughout the world and is the most common of all the porphyrias.[46] The prevalence is estimated at 1:10,000.[47] The disease most often begins in middle-aged individuals but can develop earlier. Prior to the widespread use of oral contraceptives, PCT developed predominantly in males.[48,49] In contrast, others have emphasized that the sex incidence is approximately equal.[50] The rising incidence of PCT in females is probably due to the widespread ingestion of estrogens in oral contraceptives or in hormone supplements. It should be noted that males treated with estrogens, for example, as adjunctive therapy for carcinoma of the prostate, have also developed PCT.

ETIOLOGY AND PATHOGENESIS

PCT is due to either an inherited or acquired deficiency of UROD, the fifth enzyme in the heme pathway (Figs. 132-1 and 132-2) and it has a molecular mass of about 42 kDa.[51] UROGEN I and III each contain eight carboxyl groups as side chains, four of which are acetate ($-CH_2COOH$) and four of which are propionate ($-CH_2-CH_2-COOH$) moieties (Fig. 132-2). The soluble cytosolic enzyme UROD catalyzes the sequential oxidative decarboxylation of the four carboxyl groups of the acetate side chains to methyl groups to form COPROGEN (Fig. 132-2). Decarboxylation first occurs on ring D, after which the enzyme turns around to decarboxylate rings A, B, and C in a clockwise fashion. This converts the original 8-carboxyl porphyrinogen (UROGEN I or III) first to 7-carboxyl, then to 6-carboxyl, and 5-carboxyl porphyrinogen. The 5-carboxyl porphyrinogen can then undergo decarboxylation of its last acetyl group to form the 4-carboxyl porphyrinogen that is known as coproporphyrinogen (COPROGEN I or III) (Fig. 132-2). These intermediates are also referred to as hepta-, hexa-, penta-, and tetracarboxylate porphyrinogens. COPROGEN I cannot be further metabolized to heme.

Human UROD is encoded by a single copy of the gene of the same name that is located on chromosome 1p34 spreads over a genomic distance of 3 kb, and contains ten exons.[51] The human UROD cDNA has been isolated, and the deduced sequence was found to be equivalent to 367 amino acids, consistent with the molecular mass and the amino acid composition of the purified protein.

Most classifications of PCT separate the disorder into at least two broad categories, both associated with decreased UROD activity: (1) acquired PCT, also referred to as sporadic or type I PCT; and (2) hereditary PCT, also referred to as familial or type II PCT.

In acquired (type I) PCT, the enzyme is deficient only in the liver and no mutations have been detected in the coding or promoter sequences of the *UROD* gene (Table 132-2).[46,52] Some of the precipitating substances (e.g., alcohol and estrogen) may provoke PCT only in selected individuals and others [e.g., hexachlorobenzene (HCB)] in practically all exposed individuals (Table 132-7).

Hereditary (type II) PCT is an autosomal dominant disorder and the residual UROD activity is decreased approximately 50% in all tissues, including RBC and cultured skin fibroblasts.[53–56] Decreased enzyme concentration appears to follow a bimodal distribution, suggesting two overlapping groups of patients: a large group (>80%) with normal UROD concentration and a small group (<20%) in who the amount of detectable enzyme is about half normal. Some patients with type II PCT were found to have UROD activity at the lower end of the normal range. The clinical penetrance of type II PCT is relatively low (approximately 20%), so that the majority of individuals with the inherited enzyme defect do not manifest the disease, suggesting that additional genetic or nongenetic factors are needed for

TABLE 132-7
Drugs and Chemicals Associated with the Clinical Expression of Porphyria Cutanea Tarda

- 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD)
- Polychlorinated biphenyls (PCB)
- Herbicides 2,4-dichloro- and trichlorophenoxyacetic acid

disease expression. To date, more than 50 mutations in the *UROD* gene have been identified in type II PCT, mostly in exons 5–10, which encode 75% of the protein that either decrease the stability of the enzyme or produce defective pre-mRNA splicing.[3,46,47,51,56–59]

It is important to emphasize that not all patients with a positive family history of PCT will have type II disease. In support of this notion, several patients have been described with one or more relatives with type I PCT but with normal RBC UROD activities.[60] This latter category of PCT has been designated as type III by some investigators.[54] These patients could either have inherited some form of UROD that is immunochemically indistinguishable from the normal enzyme but which is uniquely susceptible to inhibition in the liver, or they may have a second inherited enzyme deficiency unrelated to UROD. These possibilities require further investigation.

It is likely that some patients who were initially reported as having hereditary PCT actually had VP, another dominantly inherited porphyria. PCT and VP may occur in different members of the same family, in the so-called dual porphyrias.[61–63] Another form of dual porphyria in which PCT and AIP coexist has also been described.[64]

Numerous agents are known to contribute to the development of PCT (type I, acquired, or sporadic) including alcohol, estrogens, iron, viral infections (hepatitis C and HIV), polychlorinated hydrocarbons, particularly HCB and TCDD, and hemodialysis in patients with renal failure (Table 132-7). Each of these precipitating factors is discussed briefly below.

Alcohol. Alcohol ingestion has long been recognized to exacerbate PCT. Ethanol has been shown to induce hepatic ALAS1 in patients with PCT.[65] Erythrocyte UROD activity is diminished in healthy subjects following acute ethanol ingestion and in chronic alcoholics.[66] Ethanol can also inhibit the activity of other enzymes in the heme pathway, including FECH and ALAD. Chronic alcoholism leads to suppression of erythropoiesis[67] and increased absorption of dietary iron, perhaps linked to inherited mutations associated with hemochromatosis (see below). The fact that ALAS1 is increased in patients with hepatic cirrhosis without porphyria raises questions concerning the relevance of alcohol effects on ALAS1 in the clinical expression of PCT.[68]

Estrogens. The widespread use of estrogens as contraceptive agents or as hormone supplements for postmenopausal replacement therapy in females and as adjunctive hormonal therapy in males with prostatic carcinoma has been associated with PCT.[50] The mechanism of the estrogen effect on the expression of PCT has not been elucidated. Although diethylstilbestrol, an estrogen, induces hepatic ALAS1,[69] this would not explain the distinctive porphyrin excretion pattern found in PCT. The vast majority of patients receiving estrogens do not manifest the biochemical abnormalities associated with PCT.

Hexachlorobenzene. This fungicide caused an "epidemic" of a PCT-like syndrome in Southeastern Turkey in the 1950s.[70] It was added as a preservative to wheat intended for planting, but, because of a famine, several thousand individuals of diverse ethnic origin, mostly children, ingested the seed wheat and subsequently developed typical PCT. Over 4,000 cases of this syndrome were reported from 1956 to 1961. The porphyrin excretion pattern and the cutaneous findings in these patients were quite similar to those seen in PCT evoked by ethanol or estrogens. The outbreak of PCT in Turkey caused by ingestion of HCB indicated that the disease could occur in nongenetically predisposed individuals.

Twenty-five years later, the most common clinical findings in these HCB-poisoned individuals were those of chronic porphyria, including sclerodermoid scarring (84%), hyperpigmentation (78%), hirsutism (49%), thyromegaly, and increased skin fragility (38%).[71] A painless arthritis was seen in two-thirds of affected individuals, and a variety of neurologic signs and symptoms occurred in the majority. Stool and urine porphyrins remained elevated in many patients.

Studies have shown that the chronic administration of HCB to experimental animals produces excessive porphyrin accumulation in the liver in a pattern quite similar to that seen in PCT in humans.[72] These data are consistent with the hypothesis that chlorinated hydrocarbons, such as HCB, or their metabolites inhibit hepatic UROD, leading to excessive hepatic storage of URO and other acetate-substituted porphyrins.[73,74] Experimental studies have also shown that HCB can inactivate UROD, thereby abolishing catalytic activity without changing the amount of immunoreactive enzyme protein.[75] Chemical porphyria, similar to PCT, is caused by other chlorinated hydrocarbons such as the polychlorinated biphenyls (PCBs) and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a by-product in the synthesis of the herbicide 2,4,5-trichlorophenoxyacetic acid.[76] Additional studies of the porphyrinogenic effects of chlorinated hydrocarbons suggest that metabolic activation of the compounds mediated by cytochrome $P_{450\ 1A2}$ and involving iron-generated ROS is associated with an attack on the catalytic site of UROD.[56,77]

Tetrachlorodibenzo-*p*-Dioxin. TCDD is a toxic environmental pollutant chemical. Among its numerous effects are chloracne, liver damage, and hepatic porphyria in experimental animals and perhaps also in humans.[78] It has been shown that the hepatic porphyrinogenic effect of TCDD can be abolished in mice by first depleting them of iron.[79] Furthermore, it is known that highly inbred mouse strains vary in their susceptibility to induction of hepatic porphyria by TCDD, indicating that the porphyrogenic effect of this hydrocarbon is modulated by as yet undefined genetic factors.[80]

Iron. Serum iron and ferritin concentrations are often elevated or in the upper range of normal in PCT, confirming the important role of iron in the pathogenesis of the disease.[81] Hepcidin is a 25-amino acid peptide that is encoded in humans by the HAMP gene and it is secreted by the liver and inhibits iron transport

by binding to the iron channel ferroportin located on the surface of gastrointestinal enterocytes and the plasma membrane of reticulo-endothelial cells. The net result is that iron is trapped in these cells and cannot be absorbed. Ajioka et al showed that hepatic HAMP expression is decreased in patients with PCT suggesting that the hepatic siderosis associated with PCT likely results from dysregulated HAMP.[82] Hepatic iron overload accompanies clinical PCT in practically all cases, and elevation of plasma iron is found in one-third to one-half of patients.[50] In PCT, the quantity of iron that can be mobilized by phlebotomy indicates that total body iron stores are approximately twice normal. Ferrokinetic studies in patients with PCT are said to be normal. The long remissions that follow repeated phlebotomy and the apparent ineffectiveness of this treatment if supplemental iron is administered concomitantly suggest that iron plays a role in the excessive hepatic porphyrin production of PCT.[83] PCT is particularly common where alcoholism and iron overload occur together.

The role of iron in the pathogenesis of PCT is complex, and several hypotheses have been proposed to explain it. Iron may directly inhibit UROD. However, studies with purified UROD prepared from human erythrocytes show that the purified enzyme is not inhibited by Fe^{2+} or Fe^{3+}.[84] Chronic iron overload can produce peroxidative damage to lipid-rich mitochondrial and microsomal membranes in the liver of experimental animals, but the relationship of this toxic effect to changes in hepatic heme synthesis has not been clearly defined.[85] An increased frequency of the hemochromatosis (*HFE*) gene *C282Y* mutation has been found in British patients with sporadic PCT.[86,87] This mutation is responsible for much of the iron overload in populations of European descent. A second mutation in the *HFE* gene, *H63D*, may also be associated with PCT in some populations.[88] PCT is rare in heterozygotes for each of these mutations but 20% of British patients with PCT are *C282Y* homozygotes. *C282Y* homozygosity is an important susceptibility factor for both type I and type II PCT.[57] However, iron stores are increased in many patients with PCT without mutations in the *HFE* gene.[46]

Iron may have a permissive effect on the inhibition of UROD by halogenated hydrocarbons, and it can also enhance the induction response of hepatic ALAS1 to drugs.[89,90] Although such an iron-augmented increase in ALAS1 activity could lead to enhanced porphyrinogenesis, this alone would not explain the porphyrin excretion pattern seen in PCT. It is known that addition of ferrous iron to liver in vitro causes a marked increase in porphyrin synthesis and inhibits UROS activity, providing an explanation for the URO isomer I excess characteristic of PCT.[91] A mouse model of type II PCT has been described in which one allele of UROD is disrupted and the animals bred to mice null for HFE thereby creating a PCT-like phenotype.[92]

Viral Infections. There is an association between PCT and hepatitis C virus (HCV) infections and combined HCV and HIV infections.[56,93,94] The role of these viruses in the pathogenesis of PCT is unclear, although some connection with the *HFE* gene mutation *H63D* has been suggested. It is also possible that the connection is fortuitous and secondary to nonspecific hepatotoxic effects of these viruses.

From these known effects of alcohol, estrogens, chlorinated hydrocarbons, iron, and viral infections on the heme pathway, it is clear that each of these could contribute to the excessive hepatic porphyrinogenesis characteristic of PCT.[56] There is growing evidence that hepatic siderosis is the critical pathologic endpoint in PCT and that the other agents somehow intensify the ability of iron to attack the catalytic site of UROD. The clinical expression of PCT is therefore dependent upon the interaction of a number of factors, both genetic and environmental. However, it is important to note that the ingestion of drugs that have been associated with inducing acute neurovisceral attacks in the acute porphyrias is not known to exacerbate similar neurological crises in PCT.

Vesicles and bullae followed by erosions and crusting occur predominantly in areas subject to repeated trauma (Figs. 132-7 and 132-8). There is increased skin fragility, usually on the dorsa of the hands (Fig. 132-8). The traumatized skin becomes crusted and, as the lesions resolve, areas of scarring may ensue. Numerous small milia can develop, particularly on the fingers and hands. These pearly white to yellow papules occur in each of the hepatic porphyrias with cutaneous photosensitivity (PCT, VP, and HCP) (Fig. 132-7). Although the cutaneous lesions are primarily seen on the light-exposed areas, patients are often unaware that sunlight plays a role in producing their lesions because the acute painful and burning photosensitivity, so

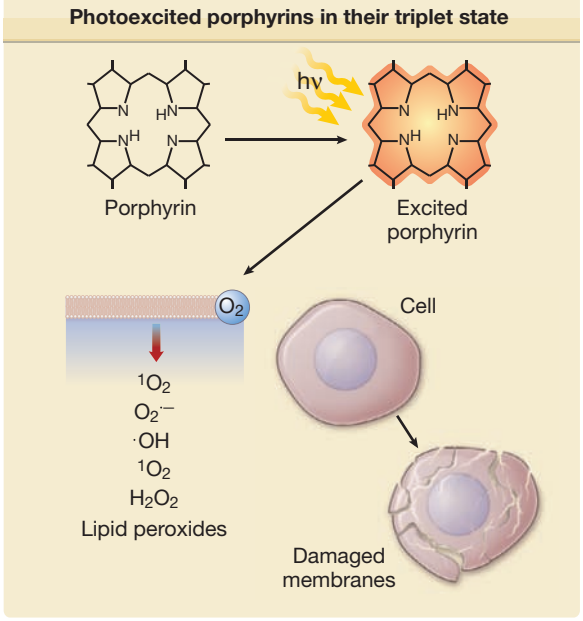

Figure 132-7 Photoexcited porphyrins in their triplet state transfer the absorbed hν to oxygen (O_2) molecules, thereby producing reactive oxygen species ($^1O_2$, $O_2^{\bullet-}$, $^\bullet OH$, and lipid peroxides). These reactive oxygen species interact with cell membranes to cause tissue damage.

Figure 132-8 Porphyria cutanea tarda. This shows bullae filled with clear fluid. Elsewhere are remnants of blisters and over the second metacarpophalangeal joint are small milia.

characteristic of the erythropoietic porphyrias, is rare in PCT. However, most patients do recognize that their skin condition worsens in the spring and summer and seems to improve in the fall and winter.

Other skin changes seen in PCT include hyperpigmentation and hypopigmentation that may be mottled, resembling chloasma. There may be an associated purplish-red ("heliotrope") suffusion of the central part of the face, particularly involving the periorbital areas, which may bear a striking resemblance to the plethora seen in polycythemia rubra vera (Fig. 132-9). This is not seen in the porphyrias of bone marrow origin.

Hypertrichosis (nonvirilizing) is a useful diagnostic sign that often brings the female patient to the dermatologist (Fig. 132-10). Facial hypertrichosis develops gradually and occurs in both males and females. The hair may vary in texture between fine and coarse and in color between light and dark. These hairs are particularly prominent along the temples and the cheeks, but may occasionally involve the trunk and extremities in severe cases. Such hair may continue to grow, darken, and thicken, particularly on the cheeks, the forehead between the eyes, and at the hairline of the scalp. Males may complain that shaving is more difficult and that the growth pattern of their beard has changed. A particularly severe form of hypertrichosis may occur in younger children with PCT and HEP. In the reports of HCB poisoning in Turkey, some of the children were described as "monkey-like" because of marked hypertrichosis.[95] The mechanism of this phenomenon is unknown; androgen levels are reported to be normal. It is possible that surface receptors or growth factors for hair bulb keratinocytes are activated by the dual action of light and porphyrins. The hypertrichosis of PCT usually improves slowly following depletion of excessive hepatic iron stores.

Sclerodermoid plaques can occur in PCT and in HEP and typically develop on both light-exposed and light-protected body areas (Figs. 132-11A and 11B). These are usually scattered, waxy yellow to white, indurated plaques that closely resemble, both clinically and histopathologically, morphea or scleroderma. There is some evidence to indicate that PCT may occur concomitantly with true scleroderma but this seems to be quite rare. As discussed earlier, URO I stimulates collagen synthesis in human skin fibroblasts.[37] In some patients,

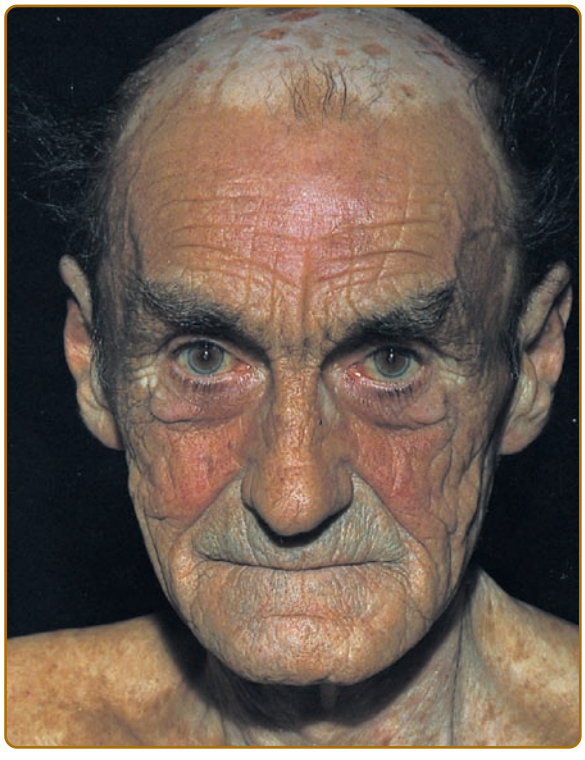

Figure 132-9 Porphyria cutanea tarda. Purple–red suffusion ("heliotrope") of central facial skin is most pronounced in the periorbital and frontal areas. Note also sclerodermoid plaque on scalp.

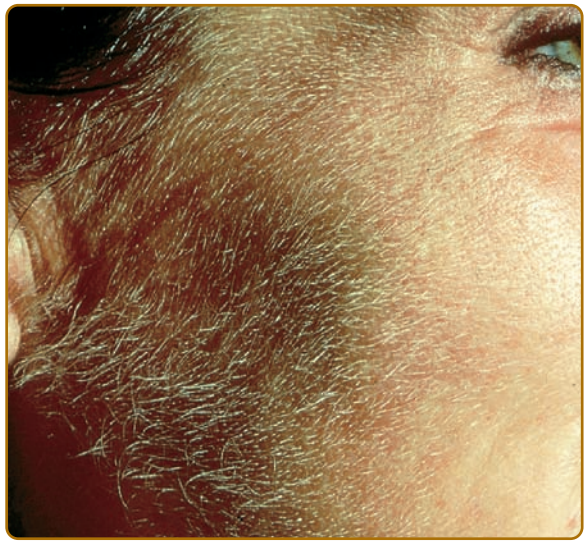

Figure 132-10 Porphyria cutanea tarda. Hypertrichosis occurring in a female with that is most pronounced on the zygomatic and malar skin.

calcification has developed in these sclerodermoid plaques, necessitating surgical excision and grafting.

PCT-like syndromes are occasionally seen in association with hepatic tumors and lupus erythematosus.[96,97] Subepidermal bullous dermatoses mimicking PCT clinically and histologically have been described (see Section "Pseudoporphyria"). A number of cases of true PCT have occurred in patients with renal failure undergoing hemodialysis.[98] Confirmation of the diagnosis rests on detection of markedly elevated plasma porphyrins (usually 5–100-fold) and increased ISOCOPRO in the feces.

LABORATORY TESTS. Patients with PCT excrete increased amounts of porphyrins in the urine, which rarely may exhibit characteristic pink–red fluorescence when examined with a Wood's lamp. The porphyrin excretion pattern of PCT has three main features: (1) increased urinary excretion of URO and of other acetate-substituted porphyrins; (2) a distinctive pattern of excretion of isomer series I and III porphyrins; and (3) increased excretion of fecal ISOCOPRO.[56,99,100] PCT patients excrete greatly increased amounts of urinary 8-carboxyl URO and also porphyrins with 7-, 6-, and 5-carboxyl groups; 4-carboxyl porphyrin (COPRO) is also increased but to a lesser extent than URO and rarely surpasses 600 µg per 24 hours (Table 132-8). In PCT, the hepatic UROD deficiency results in the accumulation of 5-carboxylporphyrinogen III (Figs. 132-1 and 132-2). This can be utilized as a substrate by the enzyme CPOX and thereby forming dehydroisocoproporphyrinogen, which in turn is oxidized to ISOCOPRO, resulting in the characteristic elevation of this compound in the feces of these patients.

The 8-carboxyl URO and 7-carboxyl porphyrins are the predominant urinary porphyrins in PCT (>90% of total porphyrins). The urinary porphyrin excretion pattern is a mixture of type I and type III isomers. URO is about 60% type I isomer and 40% type III; the 7- and 6-carboxyl porphyrins are >90% type III and <10% type I isomer; the 5- and 4-carboxyl porphyrins are about 50% each isomer. This distinctive isomer pattern is found consistently in patients with PCT.

In general, only trace amounts of URO are present in the stools of normal individuals. The porphyrin content of stool is increased in PCT and consists primarily of ISOCOPRO (type III), 7-carboxyl porphyrin, and lesser amounts of URO and COPRO. The total daily 24-hour fecal porphyrin excretion may exceed total urinary porphyrin excretion.

The ratio of URO to COPRO in the urine is often helpful in differentiating PCT and VP. Thus, in PCT, the URO:COPRO ratio usually exceeds >3:1, whereas in VP the ratio is typically less than 1:1. Occasionally, 24-hour urine porphyrins will be normal or only slightly increased in a patient with the cutaneous findings of PCT. This should alert the physician to suspect the diagnosis of VP and thus to evaluate stool porphyrins, as these are almost always elevated in patients with VP (see Section "Variegate Porphyria").

It should be emphasized that in patients with clinical signs of PCT a fluorescent screening test for urinary porphyrins is often negative. In such patients, it is absolutely essential to measure plasma porphyrin levels and perform quantitative 24-hour urine URO and COPRO determinations and quantitative stool PROTO and COPRO determinations preferably using high-performance liquid chromatography, which often permit differentiation of PCT from VP. Rarely, some patients with VP will have normal fecal porphyrin excretion, and bile porphyrin measurements may be helpful in evaluating such patients.[101]

Virtually all patients with PCT have excessive total body iron stores manifested as increased serum iron, ferritin, and/or hepatocellular iron.[46,56] Occasionally, there is mild erythrocytosis. An abnormal glucose tolerance test occurs in a minority of patients.

Biochemical tests for liver function often reveal elevated serum transaminases and γ-glutamyltranspeptidase levels. Serum iron and ferritin concentrations may be elevated. The measurement of erythrocyte UROD is useful for the detection of patients with type II PCT. Mutational analysis is an essential part of evaluating these patients (see below).

HISTOPATHOLOGY. The characteristic histopathologic finding in PCT is a subepidermal blister (Fig. 132-12). Bullae characteristically show a corrugated, undulating base that has been termed *festooned*.[102] There is little or no inflammatory infiltrate. PAS stain reveals a mild degree of thickening of the papillary vessel wall, not nearly so marked as that seen in patients with EPP. Reticulin staining demonstrates slight proliferation of fibers along

the basement membrane. Direct immunofluorescence studies reveal deposition of C3, C5b-9, and IgG in a granular pattern at the dermal–epidermal junction and in and around vessel walls in affected individuals.[44,103] These changes are most apparent in sun-exposed areas of patients with active disease and high urinary porphyrin excretion, and they decrease substantially in patients after appropriate treatment. It is possible that the deposition of immunoglobulins and complement is a nonspecific result of injury to the cutaneous tissue. Damage of the upper dermal vessels and at the dermal–epidermal junction suggests that structural changes evoked by porphyrin photosensitivity may be responsible for the unique skin fragility seen in PCT.

Regardless of these findings, it should be emphasized that histopathologic examination does not substantially contribute to confirming the diagnosis of PCT. This is also true for the other cutaneous porphyrias and, consequently, it is not essential to obtain a skin biopsy if one of the cutaneous porphyrias is suspected, mainly for two reasons. First, simple noninvasive biochemical laboratory techniques (see above) can usually permit presumptive diagnosis of porphyria and, second, external trauma (such as a biopsy or excision) inevitably constitutes an avoidable risk for delayed and/or dysfunctional wound healing that is a characteristic feature of all cutaneous porphyrias.

DIFFERENTIAL DIAGNOSIS. Other dermatoses that can be confused with PCT include VP, HCP, mild forms of HEP and/or CEP, pseudoporphyria, scleroderma, and epidermolysis bullosa acquisita (EBA). Each of these can be differentiated by appropriate porphyrin studies. Careful evaluation of urine, stool, and plasma porphyrins will almost always permit confirmation of the diagnosis of PCT. Nonsteroidal anti-inflammatory drugs such as naproxen and antibiotics such as the tetracyclines and nalidixic acid as well as a variety of other agents may rarely produce bullous lesions closely resembling PCT but in contrast show no evidence of abnormal porphyrins (see Section "Pseudoporphyria").

TREATMENT. (See Box 132-1). Initially, a careful history should be taken in an effort to identify an environmental toxin, for example, alcohol, estrogen, or chlorinated hydrocarbon, which may have triggered the disease.[46,56] If HCV or HIV infection is present these should be managed appropriately. Elimination of toxin exposure alone may result in gradual improvement. However, in most patients with PCT, more aggressive treatment is usually appropriate to accelerate therapeutic benefit and this currently consists of either repeated phlebotomy[56,104,105] or orally administered antimalarial drugs, either chloroquine or hydroxychloroquine[106,107] or a combination of both.[108] Other forms of treatment that have been described include administration of iron chelators[109,110] and the oral administration of cholestyramine.[111]

Phlebotomy. Phlebotomy is still the treatment of choice for PCT. Numerous reports have confirmed the safety and efficacy of this form of therapy[112] which was introduced by Ippen.[104] Phlebotomy is effective because it depletes the excessive hepatic iron stores characteristic of PCT. Biochemical remission of PCT has occurred in patients treated with phlebotomy with iron overload as well as in patients with quantitatively normal iron stores. Replenishment of iron following phlebotomy-induced remission of PCT has resulted in biochemical and clinical exacerbation of the disease. Abstinence from the environmental triggers alone, especially alcohol, may induce a clinical and biochemical remission, although this may take months to years.[112]

The efficacy of phlebotomy may relate to several effects:

1. *Iron effect on ALAS1*. Iron can enhance the induction response of ALAS1 to drugs and the hepatic porphyrinogenic response to HCB in experimental animals, and its depletion could render ALAS1 less inducible and thereby diminish hepatic porphyrinogenesis.
2. *Iron depletion effects on other heme pathway enzymes*. Ferrous iron inhibits UROD and increases the rate of hepatic porphyrin synthesis from ALA or PBG, suggesting that removal of iron can allow UROD activity to return to normal and/or reduce excessive porphyrinogenesis.[81,91] This concept has been verified by the creation of genetically engineered mice in which iron overload inhibits the enzyme.
3. *Iron effects on hepatic lipid peroxidation secondary to ROS*. Iron depletion could reverse this response of the liver to iron overload.[85]
4. *Iron effects on oxidation of URO*. Removal of iron could result in a diminished capacity of the ferrous metal to irreversibly oxidize the UROGEN substrate to nonmetabolizable porphyrins.[113] The first product in the oxidation of UROGEN to URO is uroporphomethene in which one methane bridge is oxidized.[46] This metabolite is an inhibitor of UROD.

Phlebotomy is carried out as an ambulatory procedure. The total amount of blood removed varies widely, usually ranging from 1,500 to 12,000 mL. It is most convenient to use plastic blood-drawing bags

BOX 132-1 TREATMENT OF THE NONACUTE PORPHYRIAS

TYPE	MANAGEMENT
Porphyria cutanea tarda	▪ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ▪ Avoidance of sun exposure and trauma ▪ Discontinuation of alcohol ingestion and estrogen therapy ▪ Phlebotomy (venesection): 400–500 mL every 2 weeks over 3–6 months ▪ Low-dose chloroquine treatment: 125 mg twice weekly for 6–12 months until porphyrin excretion is within normal range ▪ Measurement of urinary porphyrin excretion and plasma porphyrins quarterly to monitor progress
Erythropoietic protoporphyrias	▪ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ▪ Avoidance of sunlight exposure (common window glass does not provide protection) ▪ Oral β-carotene: 30–90 mg/day in children; 60–180 mg/day in adults; desirable maximum plasma level is 600–800 µg/dL
Congenital erythropoietic porphyria	▪ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ▪ Strict avoidance of sunlight exposure ▪ Change of day-night rhythm ▪ Splenectomy if hemolytic anemia is severe ▪ Bone marrow transplantation
Hepatoerythropoietic porphyria	▪ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ▪ Strict avoidance of sunlight exposure and trauma ▪ Change in day-night rhythm ▪ *Caution:* Therapeutic approaches used in porphyria cutanea tarda (phlebotomy, antimalarials) are ineffective.

available in any blood bank. Approximately 500 mL of blood is removed at weekly or biweekly intervals until the hemoglobin decreases to approximately 10 g/dL or until the serum iron drops to 50–60 µg/dL. Some believe that phlebotomies should be continued until serum ferritin falls to the lower range of normal. Patients are strongly encouraged to discontinue or decrease exposure to porphyrinogenic agents as this usually hastens clinical and biochemical remission.

It is particularly important to reassure the patient that clinical improvement may not become apparent for variable intervals after beginning the phlebotomies. Porphyrin excretion continues to fall long after phlebotomies are discontinued. Urinary URO excretion reaches normal levels (<100 µg per 24 hours) after 5–12 months in more than 90% of patients treated with regular phlebotomy. Blistering is the first sign to disappear, followed by improvement in skin fragility and in hypertrichosis over a period of 3–18 months. Even sclerodermoid changes can resolve slowly, although this may take several years. There are few published data on long-term follow-up of treatment, but most relapsed patients have again responded to repeated courses of phlebotomies.[105] The length of remission induced by phlebotomy varies widely and ranges from 6 months to more than 10 years. At least 10%–20% of patients will relapse within 1 year.

Phlebotomy is a safe, effective, and relatively simple form of therapy with minimal associated morbidity. A few patients may complain of mild-to-moderate fatigue and weakness during the treatment period, but this usually resolves as the hemoglobin returns to normal. Phlebotomy remains the treatment of choice for uncomplicated PCT. The availability of more effective oral iron chelators such as deferiprone and deferasirox suggest that these agents may prove to be a useful alternative to phlebotomy in managing the iron overload of PCT.[114]

Antimalarials. In some patients, phlebotomy is not recommended or is contraindicated owing to the presence of anemia or cardiopulmonary disorders or HIV infection. In such cases low-dose antimalarial therapy is a useful alternative. The antimalarial aminoquinolines, chloroquine, and hydroxychloroquine, are used.[106,107] The cutaneous signs of the disease cleared within 1 year in one patient who received 500 mg daily for several months. However, such doses may trigger severe hepatotoxicity in many PCT patients and this is no longer considered an acceptable approach.

Instead, low-dose chloroquine therapy at a dose of 125 mg twice weekly is effective in treating PCT and obviates the hepatotoxic effects of high-dose therapy.[115] Beside the successful therapeutic outcome in single patients and small cohorts,[116] low-dose chloroquine (125 mg twice weekly for 8–18 months) was employed successfully in more than 100 patients with PCT.[117] Liver function tests and urinary porphyrins are

monitored quarterly, and the medication continued until urinary URO is <100 µg per 24 hours. This usually requires 6–12 months of treatment. Studies comparing the therapeutic efficacy of phlebotomy with that of low-dose chloroquine suggest that they are equally efficacious and, likewise, the clinical and biochemical remission of PCT obtained with chloroquine appears to be identical in all respects to that evoked by phlebotomy. However, it has been reported that rapid relapse occurred in several patients treated with hydroxychloroquine[118] and, therefore, chloroquine may be preferable. The mechanism of action of chloroquine may relate to formation of water-soluble drug-porphyrin complexes that are then excreted from the liver.[119] However, Taljaard et al feel that chloroquine chelates iron in the hepatocyte and that the bound iron is then eliminated.[116]

The combination of phlebotomy and chloroquine treatment may reduce the severity of the hepatotoxic response to chloroquine and also accelerate remission of the disease.[108] Patients are treated with a series of one to four phlebotomies prior to starting chloroquine (250 mg daily for 7 days). The procedure is repeated when signs of biochemical or clinical relapse develop, which may occur in 1–2 years. It should be emphasized that despite the tendency of the antimalarials to evoke hepatotoxic responses in patients with PCT, there is no evidence to suggest that the changes in hepatocellular pathology characteristic of PCT worsen as a result of treatment with these drugs.[120] The antimalarials may cause retinopathy, and the low-dose regimen helps to minimize the risk of this complication. Pretreatment and semiannual ophthalmologic examinations should be obtained on patients treated with these drugs. In patients with PCT and chronic renal failure standard phlebotomy and antimalarial therapy are not feasible. The combination of high-dose recombinant erythropoietin and small volume phlebotomy has been successful in selected patients.[121]

HEPATOERYTHROPOIETIC PORPHYRIA

HEPATOERYTHROPOIETIC PORPHYRIA AT A GLANCE

- Extremely rare (approximately 40 cases reported).
- Autosomal recessive disorder due to homozygous deficiency of UROD.
- Patients have been reported in the United States and Europe.
- Age of onset in early childhood (1–4 years).
- Characterized by severe photosensitivity, including vesicles and bullae, erosions, excoriations, crusts, and milia; mutilating scarring; and hypertrichosis.

HEP is the homozygous/compound heterozygous variant of PCT and results from a profound deficiency of UROD due primarily to a *G281E* mutation (GGG → GAG, codon 281). Measurement of the enzyme in hemolyzed whole blood or skin fibroblasts from three unrelated patients with the disease showed that it was reduced to less than 5% of normal levels. There is no evidence as yet to show that clinical expression of HEP is related to exposure to environmental drugs or chemicals, as is true for PCT. In one family clinical, biochemical, and enzymatic studies of three generations in which a second-generation 31-year-old male was shown to have HEP revealed that both of the proband's parents and each of his three children had a moderate deficiency of UROD.[122] Additional cases of HEP with *UROD* gene mutations other than *G281E* have been reported in which there is 30% residual UROD activity associated with a milder phenotype.

EPIDEMIOLOGY. Patients with HEP have been reported in Europe (predominantly in Spain), America, and Japan.

CLINICAL MANIFESTATIONS. The disease typically manifests in early childhood and dark-red urine is often the first sign. Severe cutaneous photosensitivity with blistering and pruritus then ensues. The photosensitivity may diminish with age and is followed by hypertrichosis, hyperpigmentation, and scleroderma-like scarring similar to that seen in CEP (Günther's disease) (Fig. 132-13). Ocular manifestations include ectropion associated with cutaneous sclerosis and scleromalacia perforans. Splenomegaly has occurred in a small percentage of affected individuals, particularly

Figure 132-13 Hepatoerythropoietic porphyria. Sclerodermoid thickening and scarring of facial and scalp skin with ulcerations occurring in a patient with this disease. The sclerodermoid changes are particularly pronounced.

after the age of 10, and hemolytic anemia has been documented as well. In some patients, liver function tests have been abnormal, but serum iron and iron binding are normal. In summary, the clinical manifestations of HEP resemble a combination of PCT and CEP.

LABORATORY FINDINGS. The urinary porphyrin pattern is similar to that found in PCT (see Table 132-8). However, elevated RBC PROTO in HEP helps to distinguish it from PCT. Elevated urinary URO I and III (URO:COPRO ratio>5~1) and 7-carboxyl porphyrins (>90% isomer III), elevated fecal COPRO and ISO-COPRO, and elevated RBC PROTO (zinc-chelated) have been observed in all patients. These findings suggest that there is abnormal porphyrin synthesis in both the liver and the bone marrow. In contrast to PCT patients, serum iron concentrations are usually normal in HEP.

HISTOPATHOLOGY. Skin biopsies of blistering lesions show subepidermal bullae resembling those of PCT and PAS-positive material is seen in and around dermal capillaries. However, skin biopsy is not essential for making the diagnosis of HEP.

DIFFERENTIAL DIAGNOSIS. These include childhood porphyrias (e.g., the rare homozygous or compound heterozygous variants of VP and HCP), clinically severe forms of PCT, and CEP. In contrast to HEP, CEP manifests erythrodontia and mutilating scarring.

TREATMENT. There is no known treatment aside from careful photoprotection, including protection from visible light.

PSEUDOPORPHYRIA

This term is used to describe patients who clinically exhibit cutaneous manifestations resembling PCT without the characteristic abnormal porphyrin profile. This disorder may develop in association with ingestion of certain drugs such as furosemide,[123] nalidixic acid.[124] tetracycline,[125] naproxen,[126] pyridoxine,[127] and isotretinoin.[128]

In the drug-induced type of pseudoporphyria, the blistering process is subepidermal with little or no dermal inflammation. Staining with PAS reveals little or no positive deposition around upper dermal blood vessels and capillary walls. Indirect immunofluorescence studies conducted on split skin reveal no dermal deposition of fluorescent material in pseudoporphyria. Direct immunofluorescence studies have shown patchy granular deposition of IgG and C3 at the basement membrane zone in pseudoporphyria, PCT, and in epidermolysis bullosa acquisita.

A bullous dermatosis that is morphologically and histologically indistinguishable from PCT has also been observed in patients with chronic renal failure treated with long-term hemodialysis. Such patients have moderately elevated plasma porphyrins (two- to fourfold) secondary to impaired renal clearance as well as diminished clearance through dialysis filters.

ERYTHROPOIETIC PROTOPORPHYRIA

ERYTHROPOIETIC PROTOPORPHYRIA AT A GLANCE

- Second most common of the cutaneous porphyrias.
- Autosomal dominant or autosomal recessive disorder involving a deficiency of ferrochelatase or X-linked dominant disorder involving gain of function of δ-ALAS2.
- Age of onset in early childhood (1–4 years); rarely late onset can occur.
- Cutaneous findings include erythema, edema, purpura, skin thickening, and waxy scars; blistering is rare.
- Symptoms include acute burning and stinging of the skin that may be severe.
- In approximately 5% of patients, potentially fatal hepatic failure develops.

EPIDEMIOLOGY

Although the exact incidence of EPP is unknown, it has been reported with increasing frequency since its initial recognition in 1961, indicating that it is likely the second most common type of cutaneous porphyria after PCT. The disease occurs globally with a prevalence estimated between 1:75,000 and 1:200,000.[129] A recent review of the demographic, clinical, biochemical and genotypic features of EPP in Sweden showed that the prevalence was 1: 180,000 and the most commonly reported age of onset of symptoms was the first year of life and the mean age at diagnosis was 22 years.[130]

ETIOLOGY

The specific defective enzyme in EPP is FECH, which is decreased in various tissues of affected patients, including RBC, mitogen-stimulated lymphocytes, and cultured skin fibroblasts of patients and unaffected carriers.[131–134] FECH is located at the matrix face of the inner mitochondrial membrane and catalyzes the final step in the formation of heme, the incorporation of ferrous iron (Fe^{2+}) into PROTO (Figs. 132-1 and 132-2). This lysine-rich enzyme has a molecular mass of 63 kDa, a pH optimum of 7.8, and is also referred to as heme synthase or proto-heme-ferro-lyase. Unlike other enzymes in the heme biosynthesis pathway, that require reduced forms of the porphyrins (porphyrinogens) as substrates, FECH, utilizes PROTO, the oxidized isomer of PROTOGEN. The endproduct

of the pathway, ferrous-PROTO (FePROTO) or heme, diffuses out of the mitochondrion into the cytoplasm, where it is available to function as a prosthetic group by combining with appropriate apoproteins (Figs. 132-1, 132-3, and 132-4). Through rate of consumption of heme in the cytoplasm, heme thus controls its own synthesis based upon the needs of the cell.

The cDNA for human FECH has been cloned, sequenced, and shown to have 88% homology to the mouse enzyme. Human FECH mRNA is encoded by a single nuclear gene of the same name, *ferrochelatase* (*FECH*), that is located on chromosome 18q21.3 and spans about 45 kb of genomic DNA.[134] The gene consists of eleven exons and ten introns. Molecular genetic studies have been conducted in patients with EPP and revealed more than 110 different mutations of various types with deletions and insertions being the most common. The molecular epidemiology of EPP involves three patterns of inheritance.[135] In the majority, the disease is inherited in a pseudodominant manner such that disease expression only occurs in the setting of a *FECH* mutation that is inherited *trans* to a hypomorphic allele (*FECH* IVS3–48C, c.315–48C). This additional nucleotide alteration *in trans* leads to modulation of splicing and the use of a constitutively aberrant acceptor splice site. The aberrantly spliced mRNA is degraded by a nonsense-mediated decay mechanism, producing a decreased steady-state level of mRNA. This results in an additional in vivo decrease in residual FECH activity of about 15%–40% that diminishes catalytic activity to the point where the EPP phenotype is expressed.[136] The second pattern of inheritance of EPP (approximately 5%) is autosomal recessive in which a *FECH* mutation occurs on both alleles and the third pattern is due to *C*-terminal deletions in the *ALAS2* gene resulting in gain of function that causes EPP without anemia or iron overload. This is inherited in an X-linked dominant manner (see below).[5]

CLINICAL MANIFESTATIONS

Skin. Typically, the disease begins early in life and is characterized by acute episodes of cutaneous photosensitivity including burning, stinging (smarting), and pruritus affecting light-exposed skin, particularly the nose, cheeks, and dorsal aspects of the hands. These are followed by erythema, edema (Fig. 132-14), urticarial lesions, and less commonly purpura. Symptoms may occur within minutes of sun exposure; it is often seasonal, starting early in the spring, continuing through the summer, and diminishing in the winter. The skin lesions often resolve slowly, leaving small, atrophic, waxy, or pitted scars (Fig. 132-15). There may be some pursing of perioral skin (pseudorhagades). The skin of the knuckles and fingers, particularly over the metacarpophalangeal and interphalangeal joints, often appears thickened, wrinkled, and waxy, resembling the features of aging (so-called old knuckles, in a child). This subtle change is pathognomonic. Superficial scarring over the bridge of the nose and small annular shallow scars occur on the face. Vesicular or bullous lesions are rare in temperate climates, although they have been reported in patients exposed to tropical sunlight. In most affected individuals cutaneous involvement persists throughout life, although some patients seem to become less symptomatic over time.

Liver. Severe life-threatening hepatotoxicity occurs in approximately 5% of patients with EPP. PROTO is a lipophilic molecule that is cleared by the liver and

Figure 132-14 Erythropoietic protoporphyria **A.** One hour after exposure to sunlight, the face of this 35-year-old woman is edematous and erythematous, and there is purpura on the forehead, cheeks, and nose. The patient experiences severe burning pain in the affected areas. **B.** Swelling and purpura on the dorsa of the hands resulting from exposure to solar radiation.

Figure 132-15 Erythropoietic protoporphyria. A 15-year-old patient with severe photosensitivity. The nose, lower lip, and chin show erythematous, eroded, and crusted lesions. Nose and cheeks show erythematous lesions, a few small slightly depressed scars, and characteristic waxy thickening of skin. Linear scars are seen in the infranasal area and on the cheeks and face.

these patients are at increased risk for cholelithiasis and obstructive hepatic disease that ultimately compromises liver function. This may be aggravated by hemolysis of PROTO-laden RBCs creating a vicious cycle of increased erythropoiesis and increased PROTO loading of the liver. The net result of these alterations is terminal hepatic failure in about 5% of EPP patients.[137] Affected individuals become severely jaundiced, develop hepatic cirrhosis, and may go into hepatic coma and die. Some EPP patients with end-stage liver disease may develop axonal neuropathy resembling that in the acute hepatic porphyrias despite normal serum ALA and PBG.[138] Risk factors for EPP-associated hepatic failure remain unknown but parenchymal crystallization of incompletely cleared hepatic PROTO is a likely explanation. Mitoferrin1 (Mfrn1) is 1 of 2 homologous mitochondrial **iron** transporters and is required for mitochondrial **iron** delivery in developing erythroid cells. Deletion of Mfrn1 in hepatocytes has no phenotype or biochemical effect under normal conditions but in the presence of increased porphyrin synthesis, Mfrn1 deletion in hepatocytes results in decreased ability to convert protoporphyrin IX into heme, leading to protoporphyria, cholestasis, and bridging cirrhosis. Altered heme synthesis can cause hepatotoxicity.[139] Experimental studies have shown that perfusion of rat liver with PROTO induces a dose-dependent cholestasis that could contribute to the hepatotoxicity of PROTO.[140] Liver failure has also occurred in two siblings who inherited EPP in an autosomal recessive pattern as compound heterozygotes, suggesting that this genotype may somehow augment the risk of this complication.[141] This is debatable since some compound heterozygotes maintain normal liver function while others develop liver failure.[142]

The cutaneous and hepatic symptoms described above are the major findings in EPP. There is no hypertrichosis, milia, sclerodermoid change, or hyperpigmentation as in PCT and no erythrodontia as in CEP. Hemolytic anemia is decidedly uncommon, although about 11% of patients with EPP have a mild anemia of unknown cause.[129] Gallstones have been reported in some patients with EPP at a relatively early age; in one series, 12% of patients had cholelithiasis, of whom three underwent cholecystectomy.[143]

LABORATORY FINDINGS.

The diagnosis of EPP is based on the detection of elevated free PROTO in the RBC and/or feces (Table 132-8). Controversy exists concerning the tissue origin of the excessive PROTO. Some have shown that RBC PROTO levels alone are sufficient to explain the increased levels of PROTO,[24,144] whereas others have suggested that hepatic PROTO production contributes to the excessively high levels of circulating PROTO.[145] In addition, there may be increased plasma PROTO, increased fecal COPRO, and occasionally slightly increased RBC COPRO. In patients with deteriorating hepatic function, the fecal excretion of PROTO may decrease as plasma levels and cutaneous photosensitivity increase.[146]

Examination of a blood smear under a fluorescent microscope reveals red-fluorescing RBC (5%–30%) (Fig. 132-16). Since the fluorescence is often transient and quite light sensitive the procedure should be carried out in subdued light or preferably in the dark. However, this is not a reliable diagnostic test, since RBCs from patients with chronic lead intoxication also show fluorescence.

A rapid quantitative microfluorometric assay for free erythrocyte and plasma PROTO may be used to screen for suspected EPP.[147] In one series of 32 patients with EPP, the RBC PROTO levels ranged from 131 to 1617 μg/dL of RBC (normal <90 μg/dL of RBC).[148] It has been shown that erythrocyte accumulation of PROTO in EPP patients influences hematologic and iron status. Patients with EPP had a mild anemia and thrombocytopenia that positively correlated with the amount of erythrocyte PROTO. Iron and transferrin saturation saturation negatively correlated with erythrocyte PROTO.

HISTOPATHOLOGY

Skin. Immediately following irradiation, endothelial cell damage, mast cell degranulation, and polymorphonuclear cells are seen in the dermis.[33] In sun-exposed areas, there is often marked eosinophilic homogenization and thickening of vessels in the papillary dermis due to the accumulation of an amorphous, homogeneous, slightly basophilic (hyaline-like) substance in and around the vessel walls.[129] The perivascular deposits of concentric eosinophilic layers of hyaline-like material stain strongly

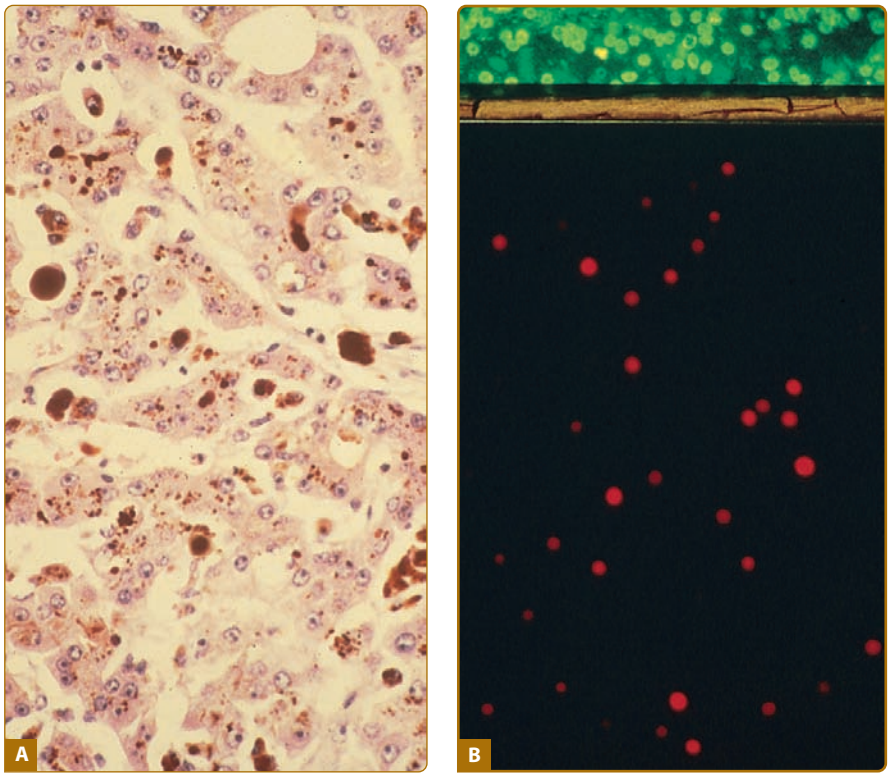

Figure 132-16 Erythropoietic protoporphyria. **A.** Brown pigment deposits in the liver are present in bile canaliculi, hepatocytes, and Kupffer cells. **B.** Bright red fluorescence in red blood cells (RBCs) of a fresh smear from a patient with this disease. Whereas almost all RBCs on the slide show green fluorescence only (*top*), a few RBCs contain increased amounts of protoporphyrin and the characteristic red–pink fluorescence of porphyrins (*bottom*).

positive with periodic acid-Schiff (PAS) and are diastase positive (Fig. 132-17). Histochemical studies suggest that this material may be a neutral glycoprotein with smaller amounts of acid mucopolysaccharide and lipids.[149] The histologic findings are similar to those of lipoid proteinosis (hyalinosis cutis et mucosae).[150] Electron microscopic studies in EPP show that the amorphous material consists of a multilayered partially fragmented basement membrane and finely fibrillar material of moderate density that permeates and surrounds the vessel walls.[151] Other studies have shown that type IV collagen and laminin as well as amyloid P and fibronectin are deposited in the walls of dermal blood vessels.[152]

Liver. Light microscopy of liver biopsies has revealed slight portal and periportal fibrosis and deposition of brown pigment, which may occlude bile canaliculi and ducts; it is also present in hepatocytes, in Kupffer cells, and in periportal macrophages. The pigment is birefringent on polarization microscopy.[153] Hepatocytes may also contain cytoplasmic or mitochondrial inclusions, which at the ultrastructural level appear as needle-like crystals (Maltese crosses), probably due to precipitated PROTO (Fig. 132-16).[154] Biliary excretion of PROTO is coupled to secretion of phospholipid, translocated from the inner to outer canalicular membrane leaflet by the mdr2P glycoprotein.[135] PROTO excretion from the liver requires bile acids and excessive amounts of the porphyrin inhibit its transport out of the hepatocyte.

DIFFERENTIAL DIAGNOSIS.

EPP must be differentiated from other photosensitivity diseases, primarily, polymorphous light eruption, drug-induced phototoxicity, actinic prurigo, hydroa vacciniforme, idiopathic solar urticaria, and other types of porphyria, in particular the newly identified variant XLDPP. Photoallergic and phototoxic contact dermatitis and angioedema should also be considered.

In polymorphous light eruption (PMLE), the lesions are characteristically papules, plaques, and papulovesicles. A family history of photosensitivity is less common. Burning and stinging of the skin during or soon after sun exposure is unusual in PMLE, whereas it is a common feature of EPP. If doubts persist, RBC PROTO measurement or plasma porphyrin determination will differentiate the two. The same is true for idiopathic solar urticaria. Airborne contact dermatitis may involve nonlight-exposed areas such as the skin folds and the submental areas. Patch testing with suspected allergens and negative porphyrin values help to differentiate this condition. The lesions of angioedema may occur anywhere on the body, including the mucous membranes. Because the discomfort described by patients with EPP is often disproportionate to visible lesions, the disease can be confused with psychoneurosis or even malingering. Porphyrin determinations will clarify this issue.

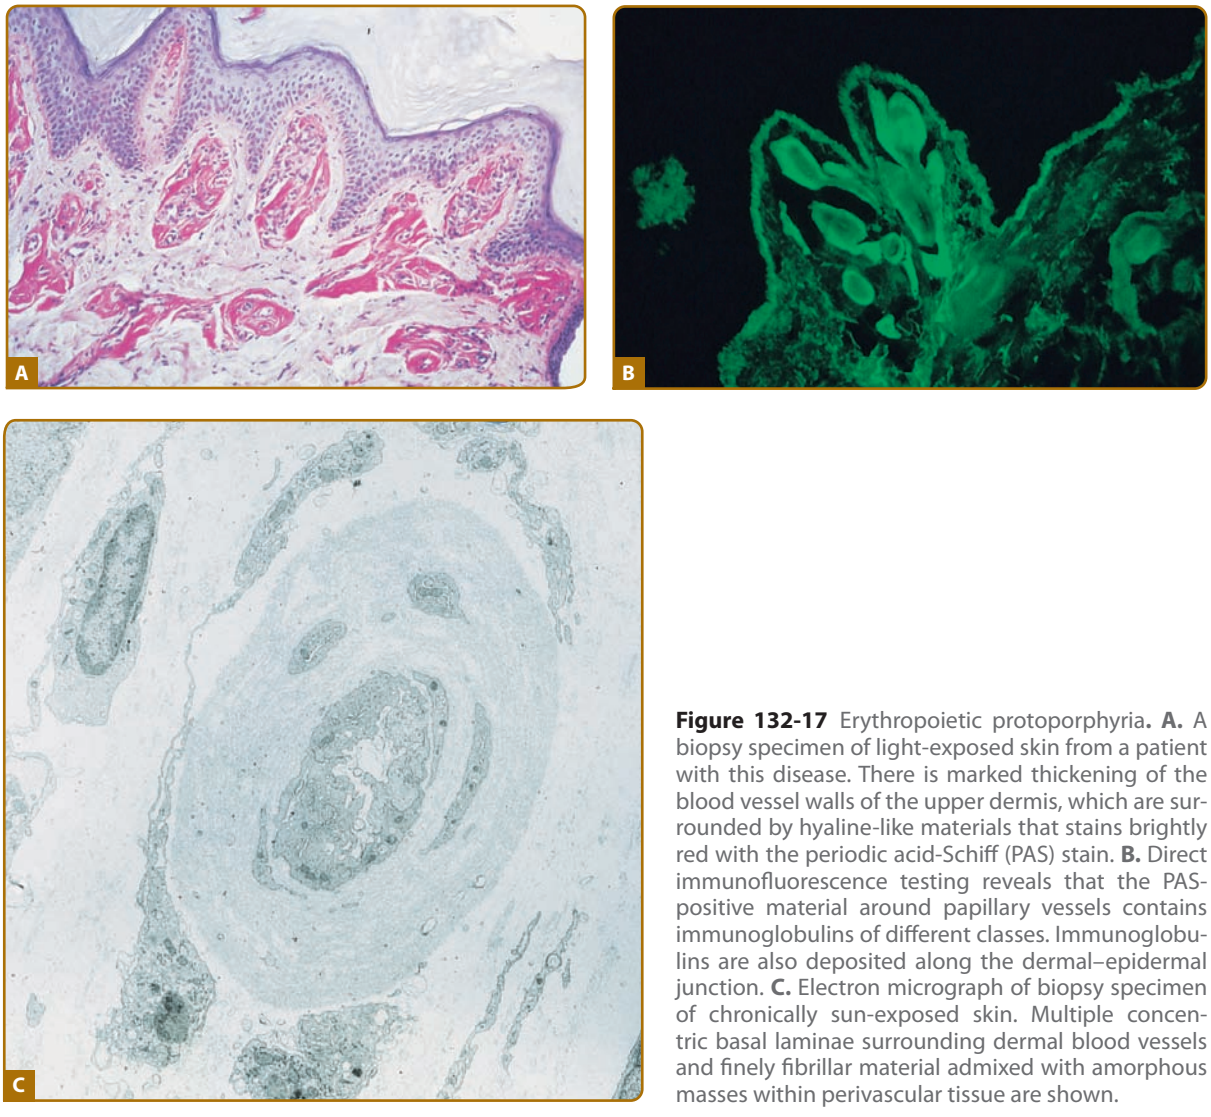

Figure 132-17 Erythropoietic protoporphyria**. A.** A biopsy specimen of light-exposed skin from a patient with this disease. There is marked thickening of the blood vessel walls of the upper dermis, which are surrounded by hyaline-like materials that stains brightly red with the periodic acid-Schiff (PAS) stain. **B.** Direct immunofluorescence testing reveals that the PAS-positive material around papillary vessels contains immunoglobulins of different classes. Immunoglobulins are also deposited along the dermal–epidermal junction. **C.** Electron micrograph of biopsy specimen of chronically sun-exposed skin. Multiple concentric basal laminae surrounding dermal blood vessels and finely fibrillar material admixed with amorphous masses within perivascular tissue are shown.

TREATMENT. (See Box 132-2). Photoprotection is absolutely essential although the use of topical sunscreens, such as products containing mexoryl, titanium, or zinc oxides are at best only marginally helpful because absorption and reflection of visible light is modest. Other agents such as orally administered antimalarial drugs, cholestyramine, and vitamins E and C have all been suggested but are of unproven benefit.

Although not confirmed by double-blind placebo-controlled trials, tolerance to sunlight in some patients with EPP may improve with the use of orally administered β-carotene.[155] Many patients claimed to triple their tolerance to sunlight after a course of β-carotene exceeding 2 months. However, these results are based on limited controlled laboratory testing and uncontrolled clinical impressions. Indeed, a recent review concluded that the available data are insufficient to prove the efficacy of any treatments for dermal photosensitivity in EPP.[156,157] The mechanism of the putative photoprotective effect of β-carotene is not precisely known. Recent studies in cultured keratinocytes showed that β-carotene can suppress induction of matrix metalloproteinases (MMPs) including MMP-1, MMP-3, and MMP-10, and that these effects are mediated by quenching singlet oxygen-mediated induction of MMPs.[158] In further studies using microarrays it was shown that β-carotene inhibited UVA-induced extracellular matrix degradation.[159]

The amino acid cysteine has been shown to improve photosensitivity.[160] Hematin infusions may decrease the production of heme temporarily and are associated with a decrease in fecal and plasma PROTO in some patients.[144] The use of RBC exchange with autologous washed cells has also been explored for its ability to induce clinical and biochemical remission of EPP. In one patient with EPP, such therapy resulted in a marked decrease in photosensitivity associated with a decline in free erythrocyte PROTO levels.[161] In summary, the currently available treatments for EPP are minimally effective and do not address the underlying molecular pathogenesis of the disease.

BOX 132-2 TREATMENT OF THE ACUTE PORPHYRIAS

A. TREATMENT OF THE ACUTE PORPHYRIAS

Type	*Management*
Acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, δ-aminolevulinic acid dehydratase deficiency porphyria	▪ Acute attacks ▪ Identification and elimination of precipitating factors (porphyrinogenic drugs, alcohol, hormones) ▪ Monitoring in intensive care unit and/or contacting of specialized porphyria center (centers are available worldwide) ▪ Provision of appropriate analgesia (e.g., with pethidine or other opiate derivatives) ▪ Management of nausea and vomiting (e.g., with promazine, chlorpromazine, or triflupromazine) ▪ Intravenous administration of either heme arginate (Normosang, Europe) in a dose of 3 mg/kg body weight once daily over four consecutive days or hematin (Panhematin, USA; see http://www.blooddiagnostics.com/Product%20Inserts/Ovation/panhematin_pi.pdf) ▪ If necessary, intravenous glucose loading ▪ Measurement of excretion of urinary porphyrin precursors (δ-aminolevulinic acid and porphobilinogen) during the acute attack (daily, if possible)
Variegate porphyria, hereditary coproporphyria	▪ Cutaneous manifestations ▪ Photoprotection (e.g., with broadband sunscreens and/or protective clothing) ▪ Avoidance of sunlight exposure and trauma

B. TREATMENT OF SPECIFIC SIGNS AND SYMPTOMS

Symptom/Sign	*Treatment*
Abdominal pain	Acetylsalicylic acid; morphine chlorpromazine; promethazine
Vomiting	
Hypertension and tachycardia	Propranolol
Hyponatremia	Electrolyte balance; saline infusions
Convulsions	Gabapentin
Constipation	Neostigmine

Liver Disease. Management of EPP-associated hepatic failure is particularly challenging. Orally administered bile salts may diminish the enterohepatic recirculation of the excessive PROTO and thereby enhance the clearance capacity of the liver.[162] Orally administered iron was attempted in one patient who manifested incipient hepatic failure as well as elevated erythrocyte and plasma PROTO levels with concomitant iron deficiency anemia but proved ineffective.[163] In another patient oral iron therapy exacerbated the disease.[164] Liver transplantation, bone marrow transplantation, and a combination of both have been used successfully in EPP, but in the case of liver transplantation recurrence of EPP hepatic disease is a significant risk.[165–167] Future therapy could include recombinant enzyme replacement of defective FECH. The feasibility of obtaining detectable levels of the enzyme in fibroblasts from EPP patients by adding the cDNA for normal FECH employing a retroviral vector has been demonstrated. Gene replacement has been achieved in a mouse model of EPP in which ex vivo preselection of hematopoietic stem cells transduced with a polycistronic retrovirus expressing human FECH resulted in complete correction of skin photosensitivity.[168]

X-LINKED DOMINANT PROTOPORPHYRIA

ALAS is the mitochondrial enzyme that catalyzes the formation of ALA and is a homodimer of two identical catalytically active subunits of molecular mass 55 kDa, linked to catalytically inactive substrates of higher molecular mass.[3,8,9]

X-LINKED DOMINANT PROTOPORPHYRIA AT A GLANCE

- Most recent type of porphyria to be recognized.
- Very rare; prevalence data not yet available.
- X-linked dominant disorder due to gain-of-function mutation of erythroid ALAS2.
- Age of onset, skin symptoms and complications similar to EPP.
- Prevalence of liver disease may exceed that of EPP.

The major significance of this enzyme is its role in controlling the rate of heme synthesis in the liver via a negative feedback mechanism. Heme acts at multiple sites to regulate hepatic ALAS. Currently, two differentially expressed isoforms of ALAS are known, one with ubiquitous expression, including the liver ALAS1, and the other with exclusive expression in erythroid tissues, ALAS2. It is thought that two pools, one cytosolic and one nuclear, regulate the respective isozymes. Two genes encoding different, tissue-specific ALAS mRNAs have been found. The human housekeeping gene is located on chromosome 3p21 and the erythroid gene has been assigned to a distal subregion of chromosome Xp21-Xq21. The erythroid preprotein reveals more than 75% homology with the hepatic protein. Immunochemical differences exist between the hepatic and erythroid enzyme in various animal species.[9,10] In contrast to deficiencies of the second to eighth enzyme in the heme biosynthetic pathway, a reduction in residual ALAS activity is not associated with a specific type of porphyria.

Mutations in the *ALAS2* gene were previously associated with X-linked sideroblastic anemia (see below.). However, eight families have been described with *ALAS2* deletions resulting in frameshifts that cause replacement or deletion of the 19–20 terminal residues of the enzyme that in turn creates gain-of-function of the enzyme and markedly increases its catalytic activity.[5] A characteristic biochemical feature in these patients is elevation of both free and zinc-chelated PROTO in the erythrocytes. The clinical manifestations of XLDPP closely resemble those of EPP (see above).

CONGENITAL ERYTHROPOIETIC PORPHYRIA

EPIDEMIOLOGY. CEP occurs globally; fewer than 500 cases have been reported. The disease nearly always begins in childhood, although apparent adult onset has occurred in 13 cases.[169] CEP also occurs in animals, including swine, cattle, and cats, and these animal models have greatly aided research in this disease.

CONGENITAL ERYTHROPOIETIC PORPHYRIA AT A GLANCE

- Very rare (approximately 250 patients reported).
- Autosomal recessive disorder involving a deficiency of UROS.
- Age of onset in infancy or first decade of life.
- Cutaneous manifestations include vesicles and bullae, erosions, crusting, milia, mutilating scarring, hyperpigmentation, and hypertrichosis.
- Systemic findings include hemolytic anemia and hepatosplenomegaly.
- Porphyrin deposition occurs in bones and teeth (erythrodontia).

ETIOLOGY. CEP is an autosomal recessive disorder that results from a variable but profound deficiency of UROS, the fourth enzyme in the heme synthetic pathway, which catalyzes the formation of uroporphyrinogen III from hydroxymethylbilane (HMB) or from PBG if PBGD is also present. The only difference between the porphyrinogen isomers I and III is the reversal of the side chains on the "D" ring of this tetrapyrrole. By simple inversion of one PBG molecule during synthesis of UROGEN I, the III isomer is formed (Fig. 132-2). This apparently minor structural alteration is of considerable biologic importance as only III isomers can form heme. The formation of UROGEN III is catalyzed by the cytoplasmic enzyme UROS, closely linked to PBGD. This enzyme has been purified from human erythrocytes, is monomeric, and has a molecular mass of approximately 29.5 kDa; it is thermolabile and exhibits maximum catalytic activity at pH 7.4.[170] In most tissues, UROGEN III synthase is present in considerable excess as compared to PBGD, thus assuring efficient conversion to the III isomer. The hepatic and erythroid forms of the enzyme are identical.

Human UROS is a cytosolic protein encoded by a single copy gene of the same name, *UROS*, which consists of ten exons, and is located on chromosome 10q25.2-q26.3 Human UROS cDNA has been cloned and sequenced and encodes a protein of 265 amino acids.[171] To date, approximately 30–40 mutations in the *UROS* gene have been identified including several in the erythroid-specific promoter. UROS deficiency results in the accumulation of HMB that mostly converts spontaneously to URO-1. CEP has also been reported in association with thalassemia secondary to

a novel germ line mutation in the X-linked erythroid-specific transcription factor GATA binding protein 1 (GATA-1).[172]

CLINICAL MANIFESTATIONS. The disease usually develops during the first few months of life with moderate-to-severe cutaneous photosensitivity associated with pink to red urine.[173] The patients have excessive URO I and COPRO I in RBC, plasma, and skin.

Cutaneous manifestations include increased skin fragility, vesicles and bullae, which may contain pink fluorescent fluid. Secondary infection, delayed healing, and scarring is common. This may lead to loss of acral tissue, such as the tips of the ears, the nose, and fingers (Figs. 132-18A and 132-18B), and facial mutilation. CEP is the most mutilating of the cutaneous porphyrias. Hirsutism, with long, dark, lanugo-like hair, may occur and is particularly evident in light-exposed areas such as the face, neck, and extremities. The scalp may develop a cicatrizing alopecia. Other chronic findings include eye changes (photophobia, keratoconjunctivitis, ectropion, symblepharon, and even loss of vision) and irregular hyper- and hypopigmentation of the skin. Erythrodontia (red-stained teeth) is a common finding in both deciduous and permanent teeth and is virtually pathognomonic of CEP. The urine may also fluoresce reddish pink.

Associated, noncutaneous findings include splenomegaly, porphyrin-rich cholelithiasis, and fluorescent bone marrow normoblasts. Hemolytic anemia associated with shortened erythrocyte life span and hypersplenism (36 vs. 120 days) occurs. Whether the hemolytic anemia is due to "photohemolysis" of circulating porphyrin-laden erythrocytes or to an associated intracorpuscular red cell defect is unresolved.[174]

LABORATORY FINDINGS. The primary defect in CEP is decreased UROS activity resulting in accumulation of predominantly type I porphyrins in the tissues. The pink to burgundy red color of the urine from excess URO I is often visible on inspection. Marrow normoblasts exhibit relatively stable fluorescence

Figure 132-18 Congenital Erythropoietic (Günther's) porphyria. **A** and **B.** Severe scarring of nasal cartilage, hair loss, and discolored teeth (erythrodontia). (Used with permission from A. Wiskemann, MD, and J. Kimmig, MD.) **C.** Skin fragility, blisters, erosions, and contractures due to severe scarring of the hands.

and contain markedly elevated URO I, COPRO I, and PROTO. Urinary excretion of ALA and PBG is normal. COPRO I may be present in large amounts in the feces. The typical biochemical findings of CEP are summarized in Table 132-8.

HISTOPATHOLOGY. The bullous lesion of CEP is subepidermal with minimal inflammation. Thickening of collagen bundles may be seen in areas of scarring. Perivascular deposits of porphyrin can be found when the unstained sections of skin or liver are viewed with a fluorescence microscope.

DIFFERENTIAL DIAGNOSIS. The diagnosis of CEP can usually be made from the early onset of severe cutaneous photosensitivity associated with reddish-pink fluorescent urine and erythrodontia. Distinguishing CEP from other congenital photodermatoses is important. Cutaneous findings in patients with xeroderma pigmentosum, epidermolysis bullosa, hydroa vacciniforme, and bullous pemphigoid may mimic those of patients with CEP, but porphyrin analysis will distinguish them.

Patients with chronic hepatic porphyrias such as PCT and VP have normal RBC PROTO. The cutaneous manifestations of HEP may be strikingly similar to those of CEP and measurement of RBC UROS (decreased in CEP) and UROD (decreased in HEP) will distinguish the two. The dual occurrence of HCP and CEP in a single patient who inherited the HCP trait from her mother and the CEP trait from both of her parents has been reported.[175]

TREATMENT. The treatment of CEP is essentially preventive and symptomatic and includes avoidance of sun exposure, surveillance of the anemia, and treatment of recurrent skin infections. Absolute protection from sunlight using photoprotective clothing may be of substantial benefit. Topical sunscreens have no proven efficacy. Orally administered β-carotene is not effective. Splenectomy performed to relieve intractable hemolytic anemia has occasionally resulted in marked improvement of both the anemia and cutaneous photosensitivity. Suppression of erythropoiesis by transfusion of packed erythrocytes can diminish porphyrin production and excretion[176]; however, secondary iron overload is of concern. Oral administration of activated charcoal to a single patient (60 g three times a day) for 9 months decreased porphyrin levels in plasma and skin with complete remission of photosensitivity during the treatment period.[177] Charcoal is thought to interfere with the enterohepatic recirculation of the porphyrin. However, this beneficial effect has been disputed.[178] Allogeneic bone marrow transplantation has been curative for a small number of patients and, thus, seems to be the current first-line treatment.[179,180]

THE ACUTE PORPHYRIAS

(See Table 132-4)

ACUTE INTERMITTENT PORPHYRIA

ACUTE INTERMITTENT PORPHYRIA AT A GLANCE

- Most common of the acute porphyrias.
- Autosomal dominant disorder involving deficiency of PBGD also known as hydroxymethylbilane synthetase (HMBS).
- Frequency as high as 1–2 in 100,000.
- Age of onset in second to fourth decade of life; rare before puberty.
- Acute neurologic attacks but no photosensitivity or cutaneous findings.

EPIDEMIOLOGY. This form of porphyria occurs globally and the incidence in the human population is approximately 1.5:100,000, although it is much higher in Scandinavia, particularly Lapland (1:1,000).[181] AIP rarely, if ever, manifests before puberty. Most published series emphasize the female predominance of affected patients, ranging from ratios of 1.5–2.0:1.[7]

ETIOLOGY. AIP is due to a deficiency of PBGD also known as hydroxymethylbilane synthetase (HMBS), the third enzyme in the heme biosynthetic pathway (Figs. 132-1 and 132-2). This enzyme combines four molecules of the monopyrrole PBG to form the linear tetrapyrrole HMB, which cyclizes spontaneously to form the initial porphyrinogen, or tetrapyrrole, known as uroporphyrinogen I (UROGEN I) (Fig. 132-2). Depending on the manner in which the PBG molecules are arranged, several different isomers of the tetrapyrroles are possible. The sole difference between type I and type III porphyrinogens is that one of the four pyrrole rings is "flipped over." Only two of them (labeled I and III) are known to occur in the mammalian heme synthetic pathway. PBGD was purified from human RBC and shown to have a molecular mass of approximately 37 kDa and a pH optimum of 8.2.[182] In AIP patients, PBGD activity is approximately 50% of that in unaffected normal individuals, consistent with an autosomal dominant mode of inheritance. Diminished PBGD partially blocks heme synthesis, which in turn decreases the regulatory heme pool and leads to derepression of ALAS mRNA synthesis.

The *PBGD* gene has been cloned and characterized.[183] Two isoforms, one ubiquitous, and one erythroid-specific, are encoded by a single gene localized to chromosome 11q23→11qter.[3] It comprises 15 exons spread over 10 kb of DNA. The two isoforms of the enzyme are encoded by two distinct mRNAs that arise from two overlapping transcription units, the first of which (upstream) is active in all tissues and

its promoter has some features of a housekeeping promoter, whereas the second, located 3 kb downstream, is active only in erythroid cells and displays structural homology with β globin gene promoters. Differential splicing gives rise to two isozymes of slightly different molecular size.[8] To date, more than 200 mutations have been reported at the *PBGD* locus, including deletions, insertions, missense, nonsense, and splicing mutations.[2,184]

PBGD is present in the second lowest concentration of any enzyme in the heme pathway; ALAS is the lowest. This suggests that additional factors (genetic or acquired) that influence PBGD activity may have important regulatory influences on the rate of heme synthesis. Consequently, if excessive PBG is formed because of increased ALAS activity, as is often seen in the acute hepatic porphyrias, there may be only partial conversion of this monopyrrole to UROGEN I. These factors account for the elevated urinary PBG characteristic of attacks of the acute hepatic porphyrias. PBGD activity is known to be reduced by about 50% in the tissues of patients with AIP and is currently thought to be the primary enzymatic abnormality in this autosomal dominant disorder. There is a variant form of AIP (perhaps 10% of cases) in which the PBGD defect is restricted to nonerythropoietic tissues due to mutations in exon 1 that is absent from the erythroid mRNA.

CLINICAL MANIFESTATIONS.

(See Table 132-4). Less than 10% of latent carriers of the PBGD defect ever express the clinical phenotype. Hence, the gene defect alone seems to be inconsequential unless the individual is exposed to additional triggering factors, of which certain drugs that induce hepatic cytochromes (CYPs), are particularly important (Table 132-9).[185,186] The clinical signs and symptoms of AIP may also relate to the effects of excessive porphyrin precursors or to heme depletion in the autonomic nervous system.[5]

The acute porphyric attack is characterized by abdominal pain (in 80%–90% of AIP patients) and neurologic and psychiatric symptoms that can mimic numerous disorders. The pain may be vague or localized and is often intermittent and spastic. Vomiting and constipation are frequently associated. Mild fever and leukocytosis may occur, making differential diagnosis extremely difficult. This is one reason many patients with AIP may have undergone multiple exploratory laparotomies prior to establishing the correct diagnosis. Between attacks patients are often remarkably symptom free. Attacks are often precipitated by ingestion of drugs such as those listed in Table 132-9. Acute attacks of AIP may be accompanied by seizures, especially in patients with hyponatremia resulting from vomiting and inappropriate fluid therapy. Peripheral neuropathy is a major part of the clinical syndrome in many patients varying from sensory (localized pain) to motor (weakness progressing to generalized flaccid paralysis).[12,187] Patients may die during an attack, usually due to respiratory failure, or may improve slowly, although residual muscle weakness may be permanent.

TABLE 132-9
Examples of Drugs Potentially Hazardous in Patients with the Acute Hepatic Porphyrias

Amidopyrine	Hydralazine
Aminoglutethimide	Isopropylmeprobamate
Aminopyrine	Mephenytoin
Amphetamines	Meprobamate
Antipyrine	Methyldopa
Barbiturates	Methyprylon
Bemegride	*N*-butylscopolammonium bromide
Carbamazepine	Nalidixic acid
Carbromal	Nikethamide
Chloromethazone	Nitrazepam
Chlorpropamide	Nortriptyline
Chloroquine	Novobiocin
Danazol	Pargyline
Dapsone	Pentazocine
Diclofenac	Pentylenetetrazole
Diethylpropion	Phenoxybenzamine
Diphenylhydantoin	Phenylbutazone
Dramamine	Primidone
Enflurane	Pyrazinamide
Ergot preparation	Rifampin
Erythromycin	Sedormid
Ethchlorvynol	Succinimides
Ethinamate	Sulfonamides
Ethosuximide	Sulfonethylmethane
Ethyl alcohol	Sulfonylureas
Fentanyl	Synthetic estrogens, progestins
Furosemide	Theophylline
Furoxone	Tolazamide
Glutethimide	Tolbutamide
Griseofulvin	Trimethadione
Halothane	Sodium Valproate
Heavy metals	

Cutaneous photosensitivity does not occur in AIP. This is logical as the abnormal excretion pattern of the disease consists mostly of the nonphotosensitizing porphyrin precursors ALA and PBG.

LABORATORY FINDINGS.

The primary gene defect in AIP results in PBGD deficiency, which causes excessive urinary excretion of ALA and PBG. Urinary porphyrins may also be slightly elevated (Table 132-8). Urinary excretion of ALA and PBG may be as high as 100 mg/24 hours in an acute attack. During remission urinary excretion of ALA and PBG decreases but usually remains above normal values. This is in contrast to patients with VP and HCP who often exhibit normal urinary excretion of ALA and PBG between acute attacks.

Two rapid screening tests are available to test freshly voided urine for increased PBG. The first is simply to expose the urine to bright sunlight for several hours. Darkening to a deep-red color suggests but does not prove that excessive PBG is present since porphobilin, another dark pigment, can also be photocatalytically formed in urine from AIP patients. The second rapid screening procedure, known as the Hoesch test is more definitive and involves a simple

assay for detecting excessive urinary PBG.[188] Two drops of fresh urine are added to 2 mL of Ehrlich's reagent (3 g of *p*-dimethylaminobenzaldehyde dissolved in 125 mL of acetic acid and 24 mL of perchloric acid). A uniform cherry-red color of the sample indicates a positive reaction. This test is based upon the formation of a chromogen by PBG and Ehrlich's aldehyde reagent that produces a red pigment with strong absorbance at 552 nm. The classic Watson–Schwartz test is based on this same principle. These qualitative tests while potentially useful for screening must be confirmed by quantitative 24-hour measurement of urinary ALA and PBG using ion-exchange chromatography or high-performance liquid chromatography.[189]

HISTOPATHOLOGY. AIP does not manifest cutaneous symptoms.

DIFFERENTIAL DIAGNOSIS. The clinical manifestations of AIP are protean and resemble so many different diseases that Waldenström has used the term *little imitator* to describe it.[12,181] Several excellent reviews have summarized the differential diagnosis of AIP and because this disorder has no cutaneous findings it will not be discussed further here.[3,184,190]

TABLE 132-10
Drugs Considered to be Safe (or Probably Safe) in Patients with the Acute Hepatic Porphyrias

Acetaminophen	Indomethacin
Adrenaline	Insulin
Amitriptyline	Labetalol
Aspirin	Lithium
Atropine	Mandelate
Bromide	Methenamine
Cephalosporins	Naproxen
Chloral hydrates	Narcotic analgesics
Chloramphenicol	Neostigmine
Chlordiazepoxide Clonazepam	Nitrofurantoin
Colchicine	Nitrous oxide
Digoxin	Oxazepam
Diphenhydramine	Penicillin and derivatives
Ethylenediaminetetraacetic acid (EDTA)	Phenothiazines
	Propranolol
Ether	Prostigmin
Glucocorticoids	Rauwolfia alkaloids
Guanethidine	Streptomycin
Heparin	Succinylcholine
Hyocine	Tetracycline
Hypocine	Thiouracil
Ibuprofen	Thyroxine

TREATMENT. There is no cure for AIP. A major component of managing patients with the acute hepatic porphyrias including AIP is focused on prevention of the acute attacks. This is accomplished by minimizing exposure to porphyrinogenic drugs and chemicals.[11] Management of the acute attack utilizes multiple approaches including glucose loading (2 liters of 20% glucose over 24 hours in divided doses of 500 mL through a central venous line).[120,190,191] Administration of a gonadotropin-releasing hormone analogue has also been recommended.[192] Intravenous infusion of hematin in the form of heme arginate (Normosang®, Orphan Europe, Paris, or Panhematin®, Ovation Pharmaceuticals, Deerfield, Il) is effective in shortening attacks.[190] Precipitating factors such as drugs (Table 132-9), sex steroid hormones, starvation, etc, should be avoided.[11] AIP patients should wear medical warning bracelets and be given lists of drugs to avoid. Drugs thought to be safe for AIP patients are listed in (Table 132-10).

Currently, recommended therapeutic regimens for the treatment of an acute porphyric attack and associated prophylactic/preventive measures are described below in detail. These procedures are applicable for all patients with acute porphyrias presenting with neurovisceral manifestations.

Treatment of the Neurovisceral Attacks in the Acute Porphyrias. (See Box 132-2). Most patients with acute porphyria experiencing an attack can now be treated successfully and life-threatening complications like muscle paralysis, respiratory failure, and coma can be avoided if appropriate aggressive treatment is implemented immediately. Untreated or inappropriately treated patients suffering an acute porphyric attack may have a 10%–15% risk of mortality.[11] Today with mechanism-based therapeutic intervention the mortality rate of the acute attack has decreased to approximately 2%. There are four major steps in treating an acute porphyria attack.

First, all potentially porphyrinogenic drugs should be stopped immediately and the patient should be monitored carefully and admitted to an intensive care unit if possible. Several sources are available that categorize drugs as relatively "safe" or "unsafe" in patients with acute porphyria.[13] Additional information is available on the Internet at the Web site of the European Porphyria Initiative (EPI) at: http://www.porphyria-europe.com/. See also Tables 132-9 and 132-10.

Second, symptomatic treatment of neurovisceral manifestations like abdominal pain, vomiting, tachycardia, and seizures should be initiated promptly. These recommendations originate from different sources including recently published guidelines from the EPI and a consortium of North American porphyria specialists.

Third, intravenous infusion of high doses of carbohydrates, preferably 400–500 g of glucose/24 hours using 5% or 10% glucose solutions. Simultaneously, diuresis should be induced by administration of furosemide with careful monitoring of serum electrolytes. Patients experiencing an acute attack are often unable to eat or drink because of severe nausea and recurrent vomiting. The rationale for high doses of glucose is based on experimental evidence showing that carbohydrates suppress the induction of ALAS, the first and rate-limiting enzyme of the heme biosynthetic pathway. Recent studies have shown that ALAS is regulated by the peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α).[193] Elevation of PGC-1α in

mice increases the levels of heme precursors in vivo as observed in acute porphyric attacks, whereas the induction of ALAS by fasting is lost in liver-specific PGC-1α knockout animals, as is the ability of porphyrogenic drugs to dysregulate heme biosynthesis. These data show that PGC-1α links nutritional status to heme biosynthesis and acute hepatic porphyria and provides a rationale for high-dose glucose infusions. Unfortunately, in many patients this regimen is only partially helpful and, thus, glucose infusions are considered to be adjuvant therapy until hematin preparations are available.

Fourth, intravenous administration of heme arginate (Normosang®), currently non-FDA approved, is the most efficient method to suppress heme synthesis. The rationale for this approach is based on intravenous administration of high doses of the end-product heme to repress the synthesis of ALAS.[194] Initially the available hematin preparations were quite unstable and were prothrombotic.[120,195] One derivative that is now available, heme arginate, consists of human hemin and L-arginine as an additive to increase the solubility and stability of the product. This preparation does not affect coagulation and fibrinolysis and the frequency of thrombophlebitis is markedly reduced.[196] Heme arginate exerts its specific action by correcting the underlying heme deficiency and restoring the negative feedback control of heme on ALAS, thereby decreasing the excessive hepatic production of porphyrins and porphyrin precursors. Heme arginate should be administered intravenously as a short infusion at a dose of 3 mg/kg body weight/day over a period of 4 days. Further, administration can be continued if the attack is not aborted; however, use of heme arginate for more than 7 days is not recommended. In the United States, an alternative form of heme known as hemin (Panhematin®) can be administered for the treatment of an acute attack. It is currently recommended that Panhematin should be considered only after an appropriate period of alternate therapy (i.e., 400 g glucose/day for 1–2 days).

Prevention of Attacks. Patients should be advised to avoid crash dieting, to abstain from alcohol, and to be fully conversant with porphyrinogenic drugs, such as barbiturates, sulfonamides, and estrogens to name several.[11,13,189] Lists of safe and unsafe drugs are available on the Web site of the America Porphyria Foundation: http://www.porphyriafoundation.com/about_por/drugs/drugs02.html and, in ten different languages, on the Web site of the EPI (see above).

Using appropriate screening procedures, asymptomatic family members of individuals with known acute porphyria should be screened for enzymatic deficiency/mutations to help define inheritance patterns and to identify individuals at risk.

VARIEGATE PORPHYRIA

(See Table 132-9)

VARIEGATE PORPHYRIA AT A GLANCE

- Incidence of approximately 1 in 300 in South Africa; relatively rare elsewhere, with the exception of Chile.
- Autosomal dominant disorder involving deficiency of PPOX.
- Age of onset in second to third decade of life; rare before puberty.
- Skin manifestations are indistinguishable from those of porphyria cutanea tarda; acute attacks similar to those in acute intermittent porphyria can occur (neurocutaneous porphyria).
- Founder mutations have been identified in South Africa and Chile.

EPIDEMIOLOGY

The disease occurs worldwide but is most prevalent in South Africa and Chile, mainly due to founder effects in both countries.[5,18,197–199] Within South Africa, this form of porphyria is quite common among the Caucasian and so-called Cape-Colored South Africans. A high proportion of the present Caucasian population in South Africa is descended from a pair of early Dutch settlers who emigrated from the Netherlands in 1688. The incidence of VP in South Africa is the highest in the world, with approximately 1:300 individuals in the white population.

ETIOLOGY

VP results from decreased PPOX activity and is an autosomal dominant disorder.[200–202] PPOX is an integral protein of the inner mitochondrial membrane and catalyzes the oxidation of PROTOGEN IX to PROTO thereby removing six hydrogens from PROTOGEN IX (Figs. 132-1, and 132-2). This reaction can also occur nonenzymatically, but the enzyme appears to be necessary for normal heme synthesis. The enzyme acts specifically on PROTOGEN IX, the penultimate step in heme synthesis. COPROGEN I or III or UROGEN I or III are not substrates for this enzyme. PPOX isolated from rat liver mitochondria has been shown to have a molecular mass of 51 kDa and requires molecular oxygen to catalyze the oxidation of PROTOGEN to PROTO.

Human PPOX is encoded by a single copy gene of the same name, *PPOX*, which has been mapped to chromosome 1q22–23, spans 8 kb, and consists of 13 exons. Northern blot analyses from a variety of tissues indicate that there is a single transcript of 1.8 kb encoding a protein of 477 amino acids.[203] Multiple mutations have been identified, including founder mutations in South Africa (R59W) and Chile (1239delTACAC).[19,204]

CLINICAL MANIFESTATIONS

The clinical manifestations of VP encompass those of both PCT and the other acute hepatic porphyrias, which can occur simultaneously or separately in the same individual. The major difference between VP and PCT is that skin signs and symptoms usually develop at an earlier age in VP (second and third decades) as compared to PCT (fourth and fifth decades). The major difference between VP and the other acute hepatic porphyrias (AIP and HCP) is that acute attacks are much less common in VP. In South Africa, excessive intake of home-brewed spirits (Kaffir beer) and dietary iron overload from cooking vessels have been considered to be important factors in the development of clinically overt disease. Thus, VP occurring in the descendants of the Dutch immigrants of South Africa is quite distinct from the PCT seen in the native black population. As pointed out by Dean in a group he designated as Cape-Colored, (descendants of white European and Indian immigrants who intermarried with black natives), VP and PCT may cosegregate in the same family.[205]

Skin. The cutaneous lesions of VP are indistinguishable from those of PCT and HCP. These include bullae and erosions on light-exposed skin (Figs. 132-19 and 132-20). Hyperpigmentation, milia, hypertrichosis, and increased skin fragility are also seen. They appear to be more common in the hot climate of South Africa and are less frequently seen in affected individuals in colder climates. Blisters often contain blood, heal slowly, and result in scarring and milia formation. Occasionally, the patient gives a history of acute sun sensitivity occurring during or soon after a period of exposure; this may include burning, erythema, and edema. In its chronic state, the skin changes may include thickening and scarring. Some believe that melanin pigmentation may reduce the severity of the photocutaneous findings. The skin manifestations do not correlate with the acute attacks in most patients and, in general, males are more likely to have the PCT-like skin findings, whereas females are more prone to AIP-like acute attacks.

Figure 132-19 Variegate porphyria. Large bullae on the dorsum of foot and toes of a patient with this disease. Note that these patients also develop pigmentary changes and milia identical to the findings in porphyria cutanea tarda.

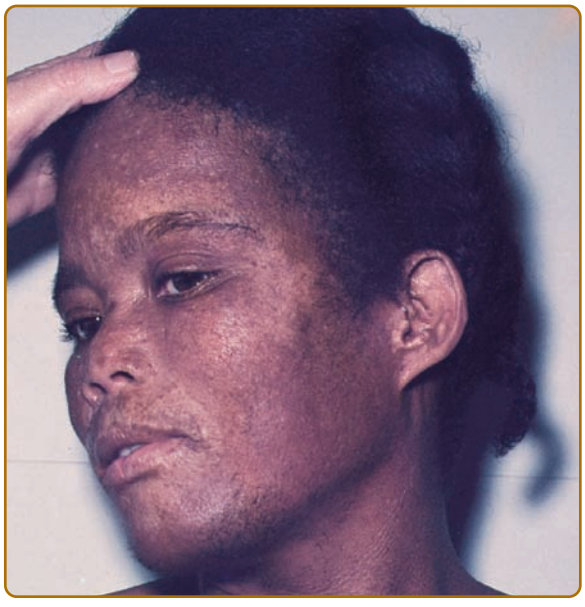

Figure 132-20 Variegate porphyria. South African patient showing facial pigmentary changes similar to that in porphyria cutanea tarda.

Neurovisceral Symptoms. These are identical to those occurring in AIP and HCP consisting of attacks of abdominal pain, constipation, vomiting, muscle weakness, and neuropsychiatric manifestations of stupor and coma. Factors that trigger attacks of AIP and HCP also appear to induce VP (various drugs, starvation, etc.). All patients with the skin findings of PCT should be screened for VP because of the life-threatening potential of the acute neurovisceral attacks.

These clinical features rarely develop before puberty, except in the rare homozygous patients who may develop cutaneous signs and symptoms at or shortly after birth. Beside the early onset of skin symptoms, these patients frequently manifest short stature and small hands with shortening of the digits.[206–208]

LABORATORY FINDINGS. Urinary ALA and PBG are elevated during acute attacks of VP (when the Watson–Schwartz test may be positive) but characteristically fall to normal levels between attacks (Table 132-8), whereas in AIP patients, the urinary

ALA and PBG are elevated, both during and between attacks. Another distinguishing feature of the two disorders is stool porphyrin excretion. Asymptomatic patients with VP commonly have marked elevations of stool PROTO and COPRO between attacks.[209] These may fluctuate somewhat during acute attacks and PROTO typically exceeds COPRO. In AIP, fecal porphyrins are not elevated between attacks and usually increase only slightly during attacks. It is said that certain patterns of fecal and urinary porphyrin excretion may help in distinguishing VP from PCT.[210] URO in the urine is only moderately elevated in VP and urinary COPRO typically exceeds URO. This is in marked contrast to active PCT where the reverse is seen, i.e., urinary URO is usually several-fold higher than COPRO. Again in VP, fecal porphyrins usually exceed 500 µg/g dry weight in >90% of patients, whereas in PCT this amount of stool porphyrin is excreted by only 1% of patients. Furthermore, the ratio of stool PROTO to COPRO in VP usually exceeds 1.5:1, whereas in PCT the ratio is almost always <1:1 due to the increased ISOCOPRO content characteristic of the latter disease. Stool porphyrin excretion patterns consistent with both VP and PCT have been found in different members of single families.[61,62] These types of findings have led to the suggestion that measurement of bile porphyrins may be decisive in confirming a diagnosis of VP when excretory porphyrin patterns are ambiguous.[101] Saline-diluted plasma specimens from patients with VP have characteristic fluorescence emission spectra (626-nm emission peak) that can be used to differentiate this disease from other forms of acute porphyria, PCT, EPP, and lead poisoning (Table 132-6).[211]

HISTOPATHOLOGY. The histopathologic alterations in VP are indistinguishable from those of PCT.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of VP should be considered from two perspectives. The skin lesions of VP are identical to those of PCT and HCP, and, as such, the differential diagnosis includes the bullous diseases as well as other photosensitivity disorders. HEP must also be considered, but this usually begins in early childhood and is characterized by markedly deficient erythrocyte UROGEN decarboxylase activity and elevated erythrocyte PROTO as well as increased stool ISOCOPRO. HCP is characterized by increased excretion of COPRO III in urine and feces. Markedly elevated (usually 10–100-fold) fecal COPRO, more than 90% of which is the III isomer, is present at all times in these patients. The presence of skin lesions rules out AIP. The determination of urinary ALA and PBG concentrations may help to rule out PCT and HEP. Screening of family members by measuring fecal porphyrins may also be helpful in differentiating VP from PCT and HCP.

Acute attacks of abdominal pain and neurologic signs and symptoms are identical to those described for AIP. Fecal and biliary PROTO and COPRO determinations and plasma fluorescence spectra are decisive in making the diagnosis. In HCP, there may be identical acute attacks, but markedly elevated fecal COPRO III is diagnostic for this disease.

TREATMENT. Preventive and symptomatic treatment of the acute attacks in VP is identical to that described in AIP, including avoidance of inducing drugs (Table 132-4) and glucose loading as well as hematin infusions. In contrast to PCT, there is no evidence of iron overload in VP and therefore phlebotomy and the antimalarials are ineffective.[212]

HEREDITARY COPROPORPHYRIA

(See Table 132-9)

HEREDITARY COPROPORPHYRIA AT A GLANCE

- Very rare (fewer than 50 cases reported).
- Autosomal dominant disorder involving a deficiency of CPOX.
- Age of onset in second to third decade of life; rare before puberty.
- Skin findings that are indistinguishable from those of porphyria cutanea tarda occur in fewer than 10% of patients; acute attacks similar to those of acute intermittent porphyria are the most common feature (neurocutaneous porphyria).

EPIDEMIOLOGY. Although apparently rare, the disease occurs worldwide and, like AIP and VP, has a female preponderance. To date, fewer than 75 patients have been reported. Beside classical HCP, an extremely rare form of porphyria, designated as harderoporphyria, has been described. This disease is a homozygous variant of HCP in which CPOX activity is very low (10% of control values).[213–215]

ETIOLOGY. HCP is an autosomal dominant disorder resulting from a decrease in the residual catalytic activity of CPOX (Figs. 132-1 and 132-2).[216,217] The enzyme is localized in the mitochondrial intermembrane space, has a molecular mass of 74 kDa and catalyzes the conversion of COPROGEN III to PROTOGEN. COPROGEN III has four carboxyl groups, each of which is part of a propionate side chain. COPROGEN oxidase catalyzes the sequential oxidative removal of the carboxyl group from two of the propionate groups, forming first the 3-carboxyl porphyrinogen known as, harderoporphyrinogen (HARDEROGEN), and next the 2-carboxylporphyrinogen, known as PROTOGEN (Fig. 132-2).

CPOX is encoded by a single copy gene of the same name, *CPOX*, as suggested by Southern blot analysis of human restriction fragments. The *CPOX* gene is located on chromosome 3q12, spans a genomic distance of 14 kb, and consists of seven exons and six

introns.[218] Multiple mutations have been found in patients with heterozygous and homozygous HCP. These include point mutations resulting in base substitutions or exon skipping. This results in increased excretion of COPRO in the urine and stool suggesting the presence of a single gene.[218]

CLINICAL MANIFESTATIONS. As in VP, the spectrum of clinical symptoms includes both cutaneous manifestations and potentially life-threatening acute neurological attacks. Cutaneous symptoms apparently occur in less than 10% of the patients and are clinically indistinguishable from those seen in PCT and VP.[189] (Fig. 132-21).

The acute attacks are similar to those of AIP, and neurovisceral symptomatology predominates in HCP. This includes abdominal pain, vomiting, constipation, neuropathy, and psychiatric symptoms. The oral hypoglycemic agent glipizide has been reported to exacerbate a coproporphyria-like syndrome that was reversible following discontinuation of the drug.[219]

LABORATORY FINDINGS. HCP is characterized by increased excretion of COPRO III in urine and feces. Markedly elevated (usually 10–100-fold) fecal COPRO, more than 90% of which is the III isomer, is present at all times in these patients. In addition, the feces may also contain increased amounts of hepta-, hexa-, and pentacarboxylic porphyrins. Urinary COPRO III is also raised, as are the precursors ALA and PBG, during attacks. The latter may be normal between attacks (Table 132-8).

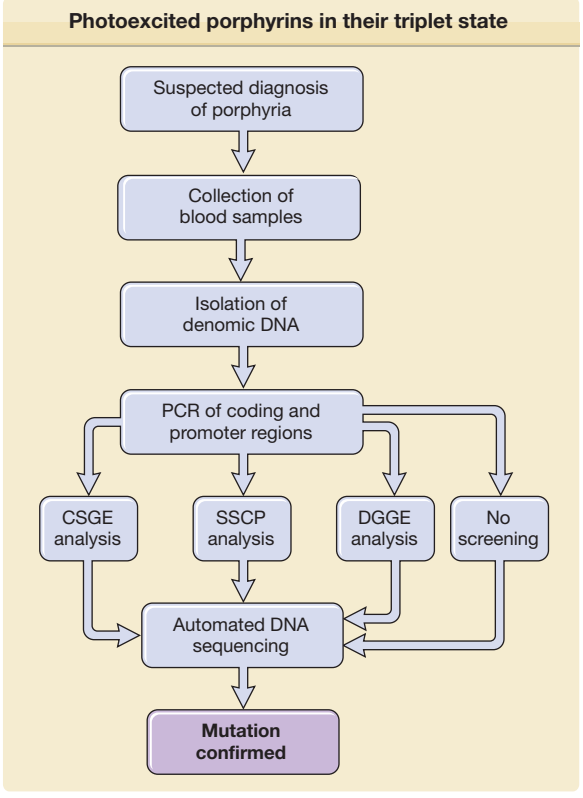

Figure 132-21 Algorithm for detecting gene mutations in patients with human porphyria. CSGE = conformation sensitive gel electrophoresis; DGGE = denaturing gradient gel electrophoresis; PCR = polymerase chain reaction; SSCP = single strand conformational polymorphis.

HISTOPATHOLOGY. None

DIFFERENTIAL DIAGNOSIS. In HCP, cutaneous signs are uncommon and if they do occur are most often seen in homozygous patients with onset in childhood and the skin manifestations resemble those seen in PCT and VP (Fig. 132-21). Fecal predominance of COPRO III is more suggestive of HCP than VP, in which PROTO and COPRO are usually increased.

Acute attacks are similar to those of AIP. The differential diagnosis rests on stool porphyrin determinations and measurement of CPOX in fibroblasts or leukocytes. DNA analysis for mutations in the *CPOX* gene can also be performed.

TREATMENT. (See Table 132-4). Same as for AIP and VP described above and in Table 132-4.

ALA DEHYDRATASE DEFICIENCY PORPHYRIA

(See Table 132-9)

δ-AMINOLEVULINIC ACID DEHYDRATASE DEFICIENCY PORPHYRIA AT A GLANCE

- Extremely rare (fewer than ten cases reported).
- Early and late clinical onset has been described.
- Neurologic symptoms similar to those in other acute hepatic porphyrias can occur; no photosensitivity or cutaneous symptoms.

This is a very rare autosomal recessively inherited type of acute hepatic porphyria, and not more than ten patients have been reported.[220–223] Clinically, these patients have symptoms similar to AIP. Alcohol ingestion is reported to precipitate attacks.

The disease results from a profound deficiency of ALAD, the second enzyme in heme biosynthesis, i.e., <5% of normal. ALAD is a cytosolic enzyme and catalyzes the formation of PBG from two molecules of ALA.

The enzyme is encoded by the *ALAD* gene that is located on chromosome 9q34 and the mutations described to date are very heterogeneous. Although it has been suggested that ALAD deficiency porphyria may represent a homozygous *ALAD* defect, cloning of a mutant ALAD cDNA in a patient showed that the

patient was compound heterozygous for two independent mutant alleles of the enzyme.[221]

In the few patients studied, the urinary porphyrin excretion shows elevated ALA, COPRO, and, to a lesser extent, URO. Fecal porphyrins revealed mildly elevated COPRO and PROTO in one patient, elevated COPRO in another, and a normal profile in two others. Erythrocyte PROTO was elevated in all patients. Increases of plasma ALA, COPRO, and PROTO have been reported.[224] The porphyrin excretion pattern in these patients is unexplained.

MANAGING SUSPECTED CASES OF PORPHYRIA

Disease management consists of a combination of obtaining a thorough medical history (particularly a complete family history), clinical examination, and biochemical determination of porphyrins and porphyrin precursors in urine, feces, and blood. In specialized laboratories, these diagnostic procedures can be extended to the measurement of specific enzymatic activities in erythrocytes, lymphocytes, or fibroblasts of affected patients and family members. Molecular techniques now provide the most precise diagnostic information based on DNA isolation from peripheral blood followed by polymerase chain reaction (PCR) and automated DNA sequencing (Fig. 132-22B). Furthermore, these methodologies permit detailed analyses of genes and their function and provide affected individuals and their family members with genetic counseling.

But even with the use of these sophisticated diagnostic tools, there are times when the results may remain inconclusive. This is particularly true for the so-called dual porphyrias.

DUAL PORPHYRIAS

In the dual porphyrias, laboratory tests may point to the simultaneous deficiency of two enzymes in the heme biosynthetic pathway either in one individual or within one family. To date, approximately 15 patients and families with this constellation of findings have been reported, indicating that these porphyria variants are very rare.

The majority of the so-called dual porphyrias encompass combined deficiency of UROD, with PBGD, CPOX, or PPOX, respectively, and this is not surprising since the prevalence of PCT exceeds that of any other type of human porphyria. In three families, the simultaneous deficiency of CPOX and either PBGD, UROS, or ALAD was detected. In one patient with CEP, the UROS defect was accompanied by a deficiency of UROD.

Until recently, the diagnosis of dual porphyria in all patients and families was established based on biochemical measurement of porphyrins and/or porphyrin precursors in urine and feces and enzymatic assays.

Porphyria patients have been described in whom DNA analysis unequivocally confirmed the presence of mutations in two different genes encoding distinct enzymes in the heme synthetic pathway. Harraway et al described a young female patient who developed skin symptoms on the sun-exposed areas of the body and had increased urinary PBG excretion.[225] The initial diagnosis of VP, however, could not be confirmed and biochemical analysis of urine, feces, and plasma suggested a combined deficiency of PBGD and UROD. Subsequent automated sequencing of the *PBGD* and *UROD* genes revealed mutations in both confirming the diagnosis of dual porphyria. Akagi et al studied a patient who suffered from acute porphyric attacks accompanied by increased urinary excretion of ALA, PBG, and COPRO.[226] Although these findings were suggestive of HCP, the authors observed marked elevation of ALA and increased erythrocyte zinc PROTO, suggesting ALAD deficiency. Subsequent automated sequencing of both the *CPOX* and *ALAD* genes led to the detection of disease-causing mutations in each gene. Both genetic defects were confirmed by in vitro expression experiments, establishing the molecular basis of dual porphyria in a single individual consisting of simultaneous CPOX and ALAD deficiencies.

These reports emphasize that in patients with biochemical and enzymatic studies indicating coexistent deficiency of two enzymes in the heme biosynthetic pathway, molecular genetic analysis of the corresponding genes should be carried out to identify the disease-causing mutations underlying a particular variant of dual porphyria.

ABNORMAL PORPHYRIN PROFILE AND SIDEROBLASTIC ANEMIA

Some cases of sideroblastic anemia may be associated with abnormal porphyrin profiles.[227–229] These patients may have cutaneous photosensitivity closely resembling that of EPP and they subsequently develop sideroblastic anemia; in some cases, the two conditions may develop within a few months of each other. All patients have elevated PROTO in RBC and/or plasma; many also have elevated stool PROTO levels. Urinary COPRO and URO are also elevated. The activities of FECH and, less frequently, of ALAS may be decreased. Chromosomal abnormalities, which include deletions in chromosomes 18 and 20, have been described.

MOLECULAR GENETIC STRATEGIES FOR THE PORPHYRIAS

In the various types of porphyrias, discrepancies between clinical findings and the results of biochemical tests or enzyme assays often lead to doubtful or incorrect diagnoses. In the case of the acute porphyrias, this can have fatal consequences for the patient if an accurate diagnosis is not established in a timely manner.

Once a mutation is identified in a patient with porphyria, the detection of asymptomatic gene carriers

within the patient's family is easily accomplished using standard molecular biological techniques. In the acute porphyrias, the identification of these "silent" carriers is the first and most important step in the prevention of life-threatening acute attacks. Genetic analysis provides an effective way to make an early diagnosis thereby enhancing the likelihood of providing patients and asymptomatic gene carriers in their family with advice regarding the avoidance of precipitating factors.

ANIMAL MODELS AND FUTURE OPTIONS FOR GENE THERAPY

Animal models for EPP and PCT have been described.[92,168,230] These models afford unique opportunities to explore the pathogenesis of these types of porphyria using in vivo models, and to study the feasibility of achieving phenotypic reversion by gene therapy. Retrovirus-mediated gene transfer of human FECH cDNA into deficient fibroblasts from an EPP patient has been achieved.[167] In transduced cells, FECH catalytic activity increased from 7% to 550% of the normal value, and partial metabolic correction of the phenotype was demonstrated. In CEP, correction of the underlying enzymatic defect in cultured cells was also accomplished by retrovirus-mediated gene transfer leading to partial normalization.[231] Excessive porphyrin levels in the transduced cells were reduced to normal. These investigations demonstrate the potential utility of somatic stem cell gene therapy for the treatment of different types of human porphyria.

CONCLUSIONS AND FUTURE PROSPECTS

Human porphyrias often present with overlapping clinical and laboratory findings making precise diagnosis a challenging proposition, especially in the acute porphyrias. The clinical signs and symptoms are highly variable in different patients and even in the same patient at different times. Biochemical analyses of urinary and/or fecal porphyrins/precursors often display overlapping values. These methods, as well as the measurement of enzymatic activities in fibroblasts or lymphocytes, are somewhat imprecise, and it is not uncommon to find values that do not distinguish between clinically unaffected gene carriers (so called "silent" carriers), and normal controls. Once a DNA-based diagnosis is made, patients and their families can be provided with genetic counseling and with advice regarding the avoidance of precipitating factors. In case of a life-threatening acute attack, a prior genetic diagnosis permits the attending physician to begin appropriate treatment immediately.[189]

Chapter 133 :: Amyloidosis of the Skin

:: Helen J. Lachmann & Philip N. Hawkins

AMYLOIDOSIS AND THE SKIN AT A GLANCE

- In amyloidosis normally soluble plasma proteins are deposited in the extracellular space in an abnormal insoluble fibrillar form.
- Amyloid deposition is remarkably diverse and can be localized or systemic, rapidly lethal or incidental.
- Diagnosis of amyloidosis relies on the demonstration of pathognomonic red–green birefringence when biopsies stained with Congo red are viewed under cross-polarized light.
- Management relies on determining the type (defined by the precursor protein) and discriminating systemic from localized forms.
- Treatment of systemic disease centers on reducing the production of the fibril precursor protein and management of localized disease is usually surgical or symptomatic.

EPIDEMIOLOGY

Amyloidosis is a rare condition and the exact incidence remains unclear. The overall sex and age adjusted rate per million person years was reported as 6.1 from 1950 to 1969 and 10.5 from 1970 to 1989 in the United States of America, and localized amyloidosis accounts for less than 10% of all diagnoses. Both localized and systemic forms of the disease become more frequent with age, and presentation before the age of 30 years is extremely unusual. No known racial, occupational, geographic, or other environmental factors have been implicated in the genesis of systemic amyloidosis, although there is evidence for a slight male preponderance.

ETIOPATHOLOGY AND PATHOGENESIS

Amyloidosis is caused by extracellular deposition of insoluble abnormal fibrils, derived from the aggregation of misfolded protein.[1,2] At least 26 unrelated proteins are known to form human amyloid fibrils in vivo.[3] The ultrastructural morphology and histochemical properties of all amyloid fibrils, regardless of the precursor protein type, are remarkably similar and fibril diffraction studies have confirmed that they all share a common core structure consisting of a cross β core and polypeptide chains lying perpendicular to the long axis of the fibril. This extremely abnormal, highly ordered conformation underlies the distinctive physicochemical properties of amyloid fibrils, including their relative stability and resistance to proteolysis. Amyloid deposits universally contain the normal plasma glycoprotein, serum amyloid P component (SAP), and heparan sulfate and dermatan sulfate proteoglycans and glycosaminoglycan chains as nonfibrillar constituents Other plasma proteins, such as apolipoprotein E, are sometimes detectable in amyloid deposits, but without the universality and abundance of SAP.

Amyloid formation in vivo occurs with both normal wild-type proteins and with genetically variant proteins. The fibrils may contain the intact amyloidogenic protein or proteolytic cleavage fragments. There is always a lag period, often of many years, between first appearance of the potentially amyloidogenic protein and the deposition of clinically significant amyloid. There are many ways of classifying amyloidosis of which the most useful is according to the deposited protein (Table 133-1). In addition, it is vital to determine whether the amyloid deposits are localized, distributed in only one tissue or organ, or deposited more widely.

SYSTEMIC AL AMYLOIDOSIS

This is the commonest type of systemic amyloidosis, accounting for more than 60% of cases. AL amyloidosis may occur in association with any monoclonal B cell dyscrasia.[4] AL fibrils are derived from monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain.[5] A degree of amyloid deposition is seen in up to 15% of patients with myeloma, but the vast majority, more than 80%, of patients who present with clinically significant AL amyloidosis have very low grade and otherwise "benign" monoclonal gammopathies.

SYSTEMIC AA AMYLOIDOSIS

Reactive systemic, AA, amyloidosis is a potential complication of any disorder associated with a sustained acute phase response and the list of chronic inflammatory, infective, or neoplastic disorders that can underlie it is almost without limit.[6] Although 60% of patients have inflammatory arthritis, some of the underlying diseases have cutaneous features that may facilitate diagnosis. These include: psoriatic arthritis, epidermolysis bullosa, basal cell carcinoma,

TABLE 133-1
Classification of Systemic Amyloidosis

Type	Fibril Protein Precursor	Clinical Syndrome
AA	Serum amyloid A protein	Reactive systemic amyloidosis associated with chronic inflammatory diseases
AL	Monoclonal immunoglobulin light chains	Systemic amyloidosis associated with monoclonal plasma cell dyscrasias
$A\beta_2M$	β_2-microglobulin	Periarticular and, occasionally, systemic amyloidosis associated with long-term dialysis
ATTR	Normal plasma transthyretin	Senile systemic amyloidosis with prominent cardiac involvement
ATTR	Genetically variant transthyretin	Autosomal dominant systemic amyloidosis Familial amyloid polyneuropathy
ACys	Genetically variant cystatin C	Hereditary cerebral hemorrhage with cerebral and systemic amyloidosis
AGel	Genetically variant gelsolin	Autosomal dominant systemic amyloidosis Predominant cranial nerve involvement with lattice corneal dystrophy
ALECT2	Leukocyte cell-derived chemotaxin-2 (LECT2)	Systemic amyloidosis with predominant renal involvement
ALys	Genetically variant lysozyme	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent liver and renal involvement
AApoAI	Genetically variant apolipoprotein AI	Autosomal dominant systemic amyloidosis May be neuropathic, prominent liver and renal involvement
AApoAII	Genetically variant apolipoprotein AII	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent renal involvement
AFib	Genetically variant fibrinogen A α chain	Autosomal dominant systemic amyloidosis Non-neuropathic with prominent renal involvement

chronic cutaneous ulcers, and hereditary periodic fever syndromes, particularly cryopyrin-associated periodic syndrome (CAPS) and TNF receptor associated periodic syndrome (TRAPS).[7] Biopsy and postmortem series suggest that the prevalence of AA amyloid deposition in patients with chronic inflammatory diseases is between 3.6% and 5.8%, though a smaller proportion of patients have clinically significant amyloidosis. The amyloid fibrils are derived from the circulating acute phase reactant, serum amyloid A protein (SAA). SAA is an apolipoprotein of high-density lipoprotein (HDL)[8] which, like C-reactive protein (CRP), is synthesized by hepatocytes under the transcriptional regulation of cytokines. A sustained high plasma level of SAA is a prerequisite for the development of AA amyloidosis, but why amyloidosis develops in only a small proportion of cases remains unclear.

HEREDITARY AMYLOIDOSIS

These are very rare autosomal dominantly inherited conditions. The most common cause of hereditary amyloidosis is mutations in the gene for transthyretin (TTR), which affects around 10,000 individuals worldwide, and causes familial amyloid polyneuropathy (FAP). The other hereditary systemic amyloidoses are derived from apolipoproteins AI and AII, fibrinogen A α chain, gelsolin, and lysozyme.[9]

LOCALIZED AMYLOIDOSIS

Localized amyloid deposition is not uncommon, although often undiagnosed, and reportedly accounts for 9.3% of all amyloidosis.[10] It results either from local production of fibril precursors or from properties inherent to the particular microenvironment, which favor fibril formation of a widely distributed precursor protein. The vast majority of deposits are AL in type, and symptomatic deposits occur most frequently in the eye, skin, gastrointestinal, respiratory, or urogenital tracts.[8] They are often associated with extremely subtle focal monoclonal B cell proliferation confined to the affected site and surgical resection of these localized "amyloidomas" can sometimes be curative. Symptomatic apparently localized amyloid deposits can rarely be manifestations of systemic disease and patients should always be fully investigated to exclude more generalized amyloid deposition.[11] Progression from localized to systemic amyloidosis is very rare. In lichen and macular amyloidosis, the fibrils are derived from proteins released from apoptotic keratinocytes. The etiology is not entirely clear but the association with other pruritic conditions suggests that mechanical factors associated

with chronic scratching and skin friction are probably crucial.[12]

CLINICAL FINDINGS

APPROACH TO PATIENT ALGORITHM

(See Fig. 133-1)

HISTORY. In the majority of patients with systemic amyloidosis the presentation is nonspecific, and as a result amyloid is often an unexpected finding on biopsy of an affected organ.

AL AMYLOIDOSIS. AL amyloid usually presents in patients over the age of 50 years, although it can present in very young adults.[4] In the majority of cases, the underlying plasma call clone is not detected prior to presentation with amyloid-related organ dysfunction. Clinical manifestations are extremely variable since almost any organ other than the brain can be directly involved.[13] Although certain clinical features such as macroglossia and periorbital ecchymoses are very strongly suggestive of AL amyloidosis (Table 133-2), and multiple vital organ dysfunction is common, many patients present with nonspecific symptoms such as malaise and weight loss.

AA AMYLOIDOSIS. AA amyloidosis can present anytime between childhood and old age with a median age at presentation of 48 years in the United Kingdom. Almost 95% of patients have a clinically overt previously diagnosed chronic inflammatory disease such as rheumatoid or one of the other inflammatory arthritides,

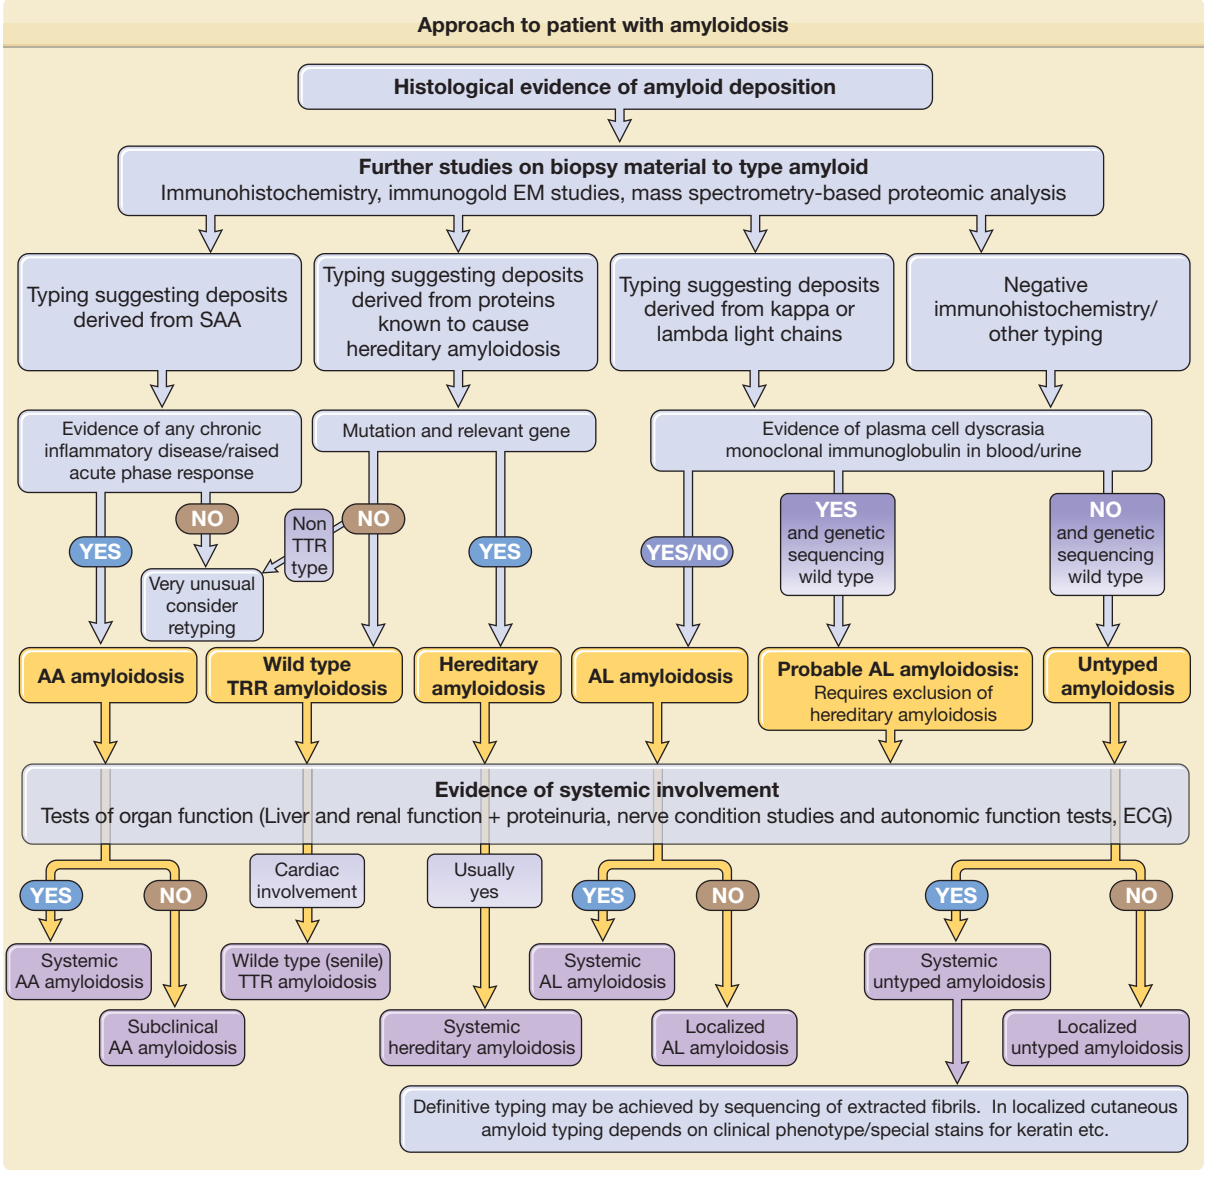

Figure 133-1 Approach to patient algorithm. Management of amyloidosis depends entirely on correct typing. This is both highly specialized and complex. Definitive typing requires a number of special tests and is best done in experienced centers.

TABLE 133-2
Clinical Features that may be Seen in Association with Systemic AL Amyloidosis

Visible tissue infiltration	Bruising (particularly periorbital) Macroglossia Muscle or joint pseudohypertrophy
Renal	Proteinuria Hypertension Chronic renal failure
Cardiac	Restrictive cardiomyopathy Arrhythmias Congestive cardiac failure
Hepatic	Hepatomegaly Liver failure (very rare)
Peripheral nervous system	Carpal tunnel syndrome Symmetrical sensorimotor neuropathy
Autonomic nervous system	Orthostatic hypotension Impotence Disturbed bowel motility Impaired bladder emptying
Gastrointestinal	Weight loss GI blood loss Disturbed bowel motility
Lymphoretiicular	Splenomegaly Lymphadenopathy
Adrenal axis	Hypoadrenalism

chronic sepsis usually bronchiectasis, complications of paraplegic conditions, or drug abuse. It is slightly more common in men. Although the disease can develop very rapidly, the median latency between presentation with a chronic inflammatory disorder and clinically significant amyloidosis is almost two decades. It usually presents with proteinuria and subsequently progressive renal dysfunction, often accompanied by nephrotic syndrome.[6]

Hereditary Amyloidosis. The presentation of hereditary amyloidosis varies depending on the variant protein, mutation, and even within kindreds.[14,15] Severe progressive peripheral and/or autonomic neuropathy is the major feature of hereditary TTR amyloidosis (FAP), but cardiac involvement is also common. ApoAI amyloidosis sometimes causes neuropathy, but this is not a feature of the other hereditary types, which typically involve the viscera. All the amyloidogenic mutations are dominant, but they are variably penetrant and therefore a family history may be absent.

CUTANEOUS LESIONS

Systemic AL Amyloidosis. Cutaneous manifestations are common in systemic amyloidosis, particularly the AL type, and are reported in up to 40% of patients.[4] The lesions usually reflect capillary infiltration and fragility with petechiae and purpura, particularly affecting the eyelids, beard area, and upper chest (Fig. 133-2A).[16] Xanthomatous papules or plaques are also frequently observed and amyloidotic hyperpigmented keratotic lesions have been reported occasionally. Other rare cutaneous lesions include scleroderma-like changes (Fig. 133-2B), alopecia, and

Figure 133-2 Cutaneous manifestations of systemic AL amyloidosis. **A.** Purpura due to capillary fragility. **B.** Scleroderma-like skin changes affecting the hands. **C.** Nail dystrophy.

Figure 133-3 Purpuric rash in hereditary lysozyme amyloidosis.

nail dystrophy (Fig. 133-2C). Bullous amyloidosis affecting the skin and mucosa has been described.[17] The bullae can be intradermal or subepidermal and present as tense, often hemorrhagic blisters. Generalized infiltration of cutaneous tissues can frequently cause the appearance of skin thickening with loss of facial wrinkles and can limit mouth opening.

Hereditary Amyloidosis. Lysozyme amyloidosis frequently causes petechial eruptions (Fig. 133-3) and apolipoprotein AI amyloidosis can also manifest as yellowish infiltrated plaques and acanthosis nigricans-type lesions.[15,18] Cutaneous lesions in FAP seem to be largely due to the peripheral neuropathy. They manifest as xerosis in 82%, seborrheic dermatitis in 22%, trauma or burn lesions in 20%, neuropathic ulcers in 14%, and onychomycosis in 10.5% of patients.[19]

Localized Cutaneous AL Amyloidosis. As in systemic AL amyloidosis, the fibrils are derived from *N*-terminal cleavage fragments of monoclonal immunoglobulin light chains. The lesions are those seen in systemic AL amyloidosis and present as single or more frequently multiple lesions anywhere on the skin.[20] In our series of 20 patients; 35% had indolent papular, nodular, or xanthomatous lesions (Fig. 133-4), 20% purpuric rash, 20% pruritus, 15% local bleeding, and 10% localized swelling. In only 15% of cases were the lesions painful.[21]

Macular Amyloidosis and Lichen Amyloidosis. Macular and lichen amyloidosis are variants of a single pathology in which the amyloid fibrils are derived from galectin-7 following epidermal damage and keratinocyte apoptosis.[22] They are usually idiopathic or friction related, but have been reported in association with connective tissue diseases (primary biliary cirrhosis, systemic lupus erythematosus and Sjögren's syndrome)[23] and in a few kindreds with pachyonychia congenita[24] or multiple endocrine neoplasia type 2a.[25]

Macular amyloidosis usually affects the upper back and limbs and can persist for many years. The rash is pruritic in the great majority of cases and consists of small brownish macules distributed in a rippled pattern. There may be a female preponderance,[26] and it is more common among Central and South Americans, Middle Easterners, and non-Chinese Asians. Amyloid deposits usually are confined to the papillary dermis and do not involve blood vessels or adnexal structures. Early lesions contain small, multifaceted, amorphous globules within the papillae, and these are missed easily without the use of special stains. Later lesions show globules that coalesce, expand the papillae, and displace the rete ridges laterally. Lichen amyloidosis is the commonest type of cutaneous amyloidosis in Chinese individuals and usually affects adults.[12,27] It is clinically characterized by an intensely pruritic eruption of multiple discrete hyperkeratotic papules that may coalesce to form gray–brown plaques that are distributed on the extensor surfaces of the lower extremities. There may be spread to the extensor aspects of the arms and the trunk. Histologically, the deposits are very similar to macular amyloid but slightly larger and are accompanied by irregular acanthosis and hyperkeratosis of the overlying epidermis.

Other Localized Cutaneous Amyloidosis. Deposition of insignificant microscopic amounts of amyloid in relation to a variety of cutaneous lesions is well recognized. Reported predisposing conditions include intradermal nevi, sweat gland tumors, pilomatrixoma, dermatofibroma, seborrheic keratosis, solar elastosis, photosensitive annular elastolytic giant cell granuloma, actinic keratosis, porokeratosis of Mibelli,[28] Bowen's disease, and basal cell carcinoma and following PUVA therapy.

Anosacral Cutaneous Amyloidosis. This is a rare syndrome described in Japanese and Chinese males in which pigmented macules and glossy hyperkeratotic lesions radiate out from the anus.[29]

Insulin-Derived Amyloidosis. A rare complication of long-term insulin use in diabetics is formation of insulin-derived amyloidomas at sites of repeated insulin injection. These can be confused with tumors.[30]

Familial Primary Localized Cutaneous Amyloidosis. This very rare autosomal dominant disorder is characterized by chronic pruritus from childhood or early teenage-years and hyperkeratotic papules and/or hyperpigmented macules on the limbs or trunk. It is relatively common in Southeast Asia and the amyloid appears to be confined to the skin. It is associated with mutations in the *OSMR* and *IL31RA* genes, related genes which are members of the interleukin-6 cytokine receptor family.[31]

RELATED PHYSICAL FINDINGS

SYSTEMIC AL AMYLOIDOSIS. Systemic AL amyloidosis is protean in its manifestations (Table 133-2,

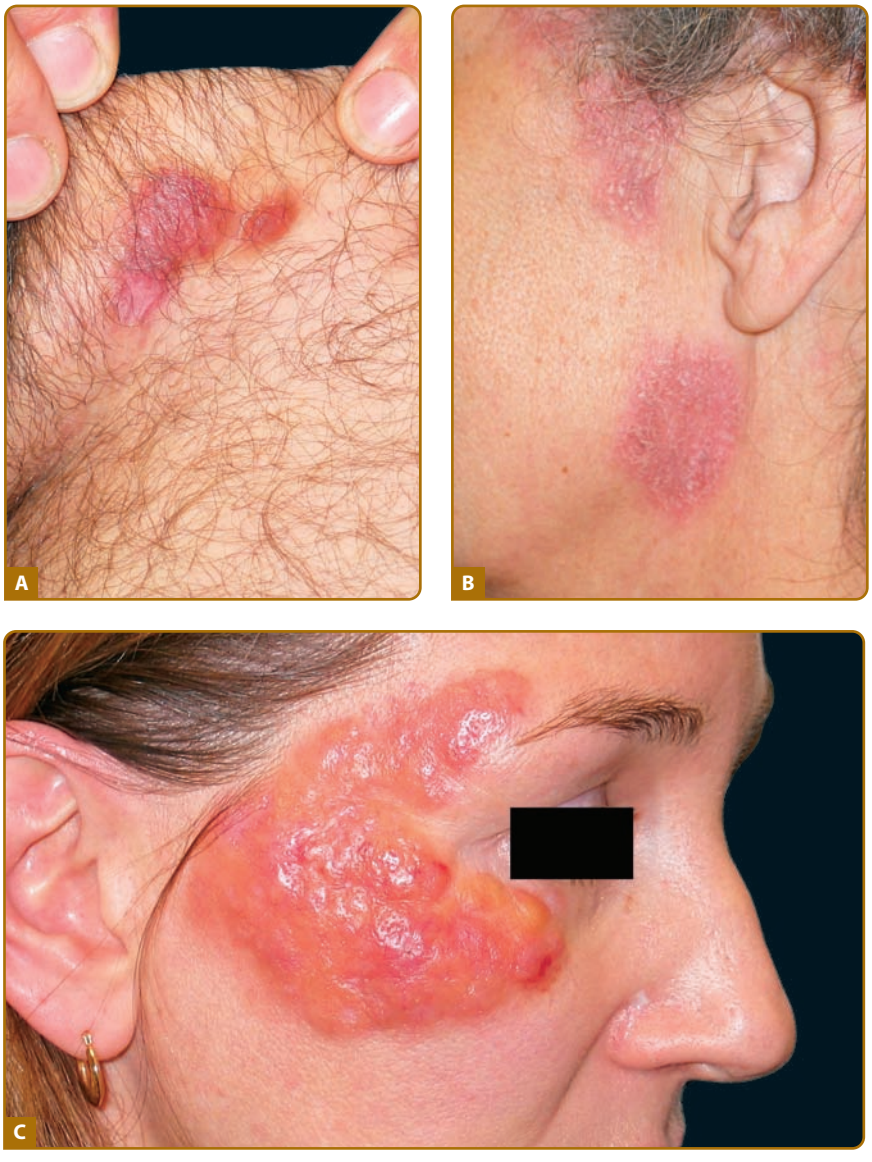

Figure 133-4 **A–C.** Localized AL amyloidosis resulting in slowly progressive papular lesions.

Fig. 133-5) and can cause signs in any organ system except the brain.

SYSTEMIC AA AMYLOIDOSIS. This presents with nephrotic syndrome in just under half of patients. Clinically, splenomegaly is frequent and hepatomegaly is detected in 10% of cases. Cardiac involvement and peripheral or autonomic neuropathy are very rare.

HEREDITARY AMYLOIDOSIS. The physical findings depend on the variant protein and specific mutations and may vary even within individual families.

LABORATORY TESTS

All patients should have comprehensive assessment of renal and liver function, including blood tests, and quantification of creatinine clearance and proteinuria.[32] A search should be made for evidence of an underlying plasma cell dyscrasia by serum and urine electrophoresis and immunofixation.[33] In suspected amyloid of AL type, a bone marrow aspirate and trephine are usually mandatory. Where available serum assays of potential fibril precursor proteins; free immunoglobulin light chains in AL type and SAA in AA amyloidosis are very valuable.[34]

SPECIAL TESTS

HISTOLOGY

The identification of amyloid depends on the pathognomonic red-green dichroism observed when tissue stained with the aniline dye Congo red is viewed under cross-polarized light (Fig. 133-6).[35] This optical effect

Figure 133-5 Visible tissue infiltration in systemic AL amyloidosis causing: **A.** Lymphadenopathy. **B.** Macroglossia. **C.** Muscle pseudohypertrophy. **D.** Periorbital purpura.

is produced by alignment of the dye molecules along the fibrils. Binding of thioflavin T usually corresponds with Congo red birefringence but is less specific. Congo red staining for amyloid is not a very sensitive test and requires the presence of an adequate amount of amyloid, use of sufficiently thick tissue sections, technically correct staining and visualization procedures, and adequate observer experience. In negatively stained electron microscopy amyloid fibrils are usually about 10 nm in diameter, straight, rigid, nonbranching, of indeterminate length, and composed of twisted protofibrils.

Positive histology for amyloid must be followed up by immunohistochemistry to determine the fibril protein type.[11] Suitable antibodies are widely available but, although immunohistochemistry usually yields

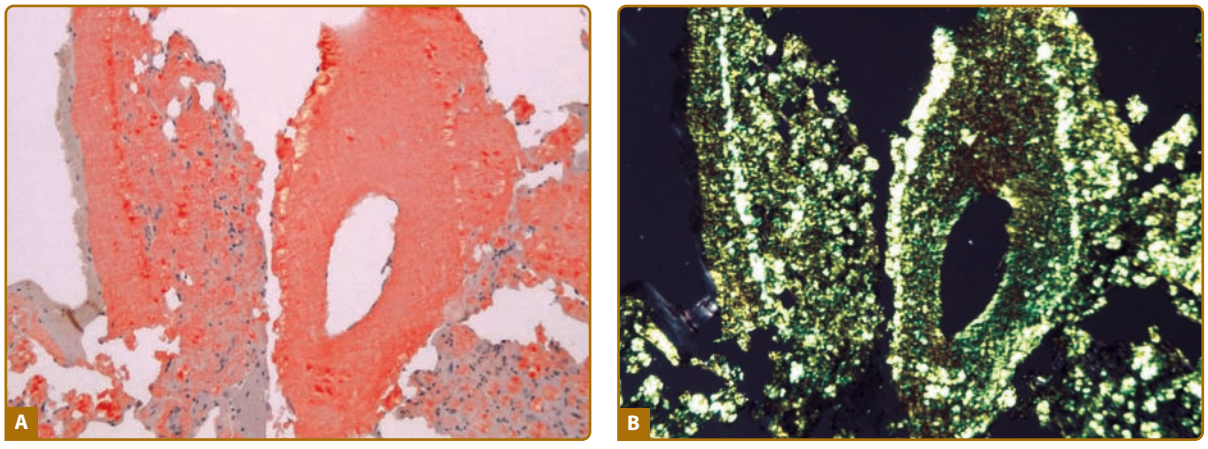

Figure 133-6 Typical appearances of amyloid deposits. **A.** Congo Red staining. **B.** Same section viewed under cross-polarized light with red–green birefringence.

definitive results in AA amyloidosis, it is frequently not diagnostic with AL deposits. Expertise in the immunohistochemical typing of hereditary amyloid is restricted, and definitive immunohistochemical typing of amyloid deposits cannot always be achieved.[36] Direct sequencing of extracted fibrils permits identification of the amyloid type as does laser microdissection and mass spectrometry[37] however, these techniques are generally only available in a research setting.

GENETIC SEQUENCING

Amyloidogenic mutations should be sought in all patients in whom the amyloid type remains undetermined as hereditary amyloidosis accounts for a substantial number of these cases.[38]

IMAGING AMYLOID IN VIVO

SAP SCINTIGRAPHY. SAP is a highly conserved, invariant plasma glycoprotein of the pentraxin family that becomes specifically and highly concentrated in amyloid deposits of all types as a result of its calcium-dependent binding to amyloid fibrils. Radiolabeled SAP scintigraphy can be used for diagnosis and quantitative monitoring of amyloid deposits.[39] This safe noninvasive method provides information on the presence, distribution and extent of visceral amyloid deposits, and serial scans monitor progress and response to therapy (Fig. 133-7). Unfortunately, the method is not informative about amyloid deposition in the moving heart and is not commercially available.

CARDIAC IMAGING. Cardiac amyloidosis is best evaluated by a combination of echocardiography and ECG.[40] Two-dimensional Doppler echocardiography classically reveals concentric biventricular wall thickening with a restrictive filling pattern. Amyloid causes diastolic dysfunction with well-preserved contractility until a very late stage. The ECG may be normal in patients with substantial cardiac amyloidosis, but in advanced disease commonly shows small voltages, pathological "Q" waves (pseudoinfarct pattern). Recent developments in magnetic resonance imaging can also contribute to assessment of the severity of cardiac amyloidosis,[41] as can serum assays of the cardiac biomarkers, *N*-terminal-pro-BNP[42] and troponin T.[43]

DIFFERENTIAL DIAGNOSIS

(See Box 133-1)

Figure 133-7 Anterior whole body I^{123}-labeled SAP scintigraphy demonstrating amyloid deposition in the liver and spleen.

BOX 133-1 DIFFERENTIAL DIAGNOSIS OF CUTANEOUS AMYLOIDOSIS

Most Likely

- Atopic dermatitis
- Lichen sclerosus
- Prurigo nodularis
- Poikiloderma of Civatte
- Postinflammatory hyperpigmentation
- Sebaceous hyperplasia
- Xanthoma

Consider

- Dermatomyositis
- Scleroderma
- Mastocytosis
- Pseudoxanthoma elasticum
- Colloid milium
- Pretibial myxedema
- Nodular pseudolymphomas

Always Rule Out

- Systemic amyloidosis

COMPLICATIONS

AL AMYLOIDOSIS

Restrictive cardiomyopathy is the presenting feature in up to one-third of patients and ultimately the cause of death in one-half.[44] Renal involvement is frequent and presents with proteinuria and progressive renal impairment.[45] Gut involvement can cause motility disturbances (often secondary to autonomic neuropathy), malabsorption, perforation, hemorrhage, or obstruction.[46] Peripheral neuropathy occurs in one-fifth of cases and typically presents with a painful sensory polyneuropathy followed later by motor deficits.[47] Autonomic neuropathy causing orthostatic hypotension, impotence, and gastrointestinal disturbances may occur in isolation or with a peripheral neuropathy.

AA AMYLOIDOSIS

Progressive renal failure and nephrotic syndrome are the usual complications in AA amyloidosis. Although splenic amyloid deposits are almost universally present in AA type, they are usually asymptomatic. Hepatic involvement and autonomic neuropathy are well recognized, but usually occur very late in the disease. Cardiac amyloidosis occurs in less than 2% of cases.[6]

HEREDITARY AMYLOIDOSIS

Familial polyneuropathy causes progressive peripheral and/or autonomic neuropathy and cardiomyopathy and in some cases visual loss due to vitreous amyloid deposits.[14] Apolipoprotein AI amyloidosis can cause peripheral neuropathy but, in common with Apolipoprotein AII, lysozyme, and fibrinogen A α chain types renal or hepatic amyloidosis is typical.[8] Gelsolin-related amyloidosis causes a characteristic clinical picture of corneal lattice dystrophy and cranial neuropathy.

LOCALIZED CUTANEOUS AMYLOIDOSIS

This only produces local complications usually in the form of pruritus or bleeding and is rarely painful.

PROGNOSIS/CLINICAL COURSE

Although recent advances have greatly extended median survival, the prognosis of systemic amyloidosis remains grave.

AL AMYLOIDOSIS

Prognosis is particularly poor in AL disease as the diagnosis is often made late, when patients already have substantial visceral and/or neural involvement. Indeed, a 5-year survival of approximately 10% and a 10-year survival of less than 5% have been reported for the AL type,[4] although more recent series suggest a median survival of 40 months.[48] Most affected individuals eventually die of heart failure, uremia, or autonomic failure.

AA AMYLOIDOSIS

The prognosis of AA amyloidosis depends on the degree of renal dysfunction at presentation and whether the underlying chronic inflammatory disease can be effectively suppressed, so that the plasma SAA is maintained within the normal healthy range. In our cohort of 374 patients, median survival was just over 11 years and a third of patients developed end-stage renal failure, which was the major cause of death.[6]

HEREDITARY AMYLOIDOSIS

In FAP median survival is 10–15 years without liver transplantation.[49] Death is from progressive neuropathy and or cardiomyopathy. In the other hereditary amyloidosis, organ failure either renal or hepatic is the major cause of mortality, but the time to reach end-stage organ failure is very variable.

LOCALIZED CUTANEOUS AMYLOIDOSIS

These skin-limited conditions are not usually associated with any increase in mortality.

TREATMENT

Treatment of all types of amyloidosis is focused on measures that can reduce the supply of the respective amyloid fibril precursor protein, while supporting or replacing compromised organ function. Under favorable circumstances, this results in regression of existing amyloid deposits, preservation or recovery of the function of amyloidotic organs, and much improved patient survival. Such treatment requires precise identification of the amyloid fibril type through immunochemistry, DNA sequencing and direct fibril sequencing. Monitoring of therapeutic efficacy and rational decisions about further treatment options are enhanced by the recent availability of routine assays for circulating free immunoglobulin light chains in AL amyloidosis and SAA in AA type.

AL AMYLOIDOSIS

Treatment in AL amyloidosis aims to suppress the proliferation of the underlying B-cell clone and, therefore, production of the amyloidogenic monoclonal immunoglobulin. This is not without problems[50]: chemotherapy regimens are based on those used in multiple myeloma, but the majority of plasma cell dyscrasias in AL patients are low grade and may be less chemosensitive. Diagnosis can be delayed, and many patients have advanced multisystem disease, which limits their options for chemotherapy. Regression of amyloid is a gradual process that may not lead to measurable clinical improvement or recovery of organ function for many months, or even years after successful suppression of the causative plasma cell dyscrasia.[48] Mobilization of amyloid from the heart is much slower than from the liver or kidneys, and many patients with cardiac or multisystem dysfunction do not live long enough to benefit from chemotherapy, even when it has suppressed their clonal disease. Nonetheless, many patients with AL amyloidosis do benefit substantially from chemotherapy. Prolonged low-intensity cytotoxic regimes such as oral melphalan and prednisolone are beneficial in about 20% of patients. Although there have been few comparative clinical trials,[51] chemotherapy regimens containing melphalan and dexamethasone, cyclophosphamide, thalidomide and dexamethasone,[52] or velcade,[53] and autologous peripheral blood stem-cell transplantation are almost certainly much more effective.[54] Very rigorous patient selection for high-dose chemotherapy is essential because the procedure-related mortality is extremely high in individuals with multiple organ involvement.[55]

AA AMYLOIDOSIS

Treatment of the primary inflammatory conditions responsible for AA amyloidosis reduces amyloid levels, dramatically improves survival, and is associated with arrest of amyloid deposition and frequently regression of deposits. The new biological drugs targeting key cytokine mediators of inflammation potently suppress the acute phase response in many patients with inflammatory arthritis, Crohn's disease, and some hereditary periodic fevers.[56] Colchicine is the treatment of choice to prevent AA amyloidosis in familial Mediterranean fever.

HEREDITARY AMYLOIDOSIS

At present, apart from transplantation to replace failed organs and liver transplantation to reduce production of amyloidogenic proteins that are synthesized by the liver, only symptomatic treatment is available for hereditary systemic amyloidosis. The liver is the source of plasma TTR, and over 1,000 liver transplants have been performed for treatment of hereditary TTR amyloidosis since this "surgical gene therapy" approach was introduced in 1991.[49] In younger patients carrying the common *Val30Met* mutation, the outcome is generally good, with arrest of neuropathy and regression of visceral amyloid, but the outcome in patients with other mutations has been less successful.[57]

NOVEL TREATMENTS FOR SYSTEMIC AMYLOIDOSIS

Better understanding of the mechanisms underlying amyloid formation has led to the development of novel treatment strategies aimed at inhibiting fibrillogenesis or destabilizing existing amyloid deposits.[58,59] Preliminary work in mice has demonstrated that antiamyloid antibodies were effective in clearing cutaneous amyloid deposits without the necessity of an immune response.[60]

LOCALIZED CUTANEOUS AL AMYLOIDOSIS

Small localized amyloid deposits can be removed surgically or by laser if they are cosmetically disfiguring or bleeding, but there is a very high rate of local recurrence. The possibility that systemic chemotherapy may be of any benefit in localized AL amyloidosis has not been systematically tested.

MACULAR AND LICHEN AMYLOIDOSIS

Chronic friction is a major etiological factor in these and treatment modalities should be directed toward the relief of pruritus in these conditions. Sedating antihistamines have been found to be moderately effective and intralesional steroids are beneficial if combined with other modalities. Topical dimethyl sulfoxide (DMSO), a solvent, has been used with modest success at best[61] but is often unacceptable to patients due to the smell. Treatment with ultraviolet B (UVB) light can provide symptomatic relief.[62] There is one report of improvement following treatment with 0.1% topical tacrolimus ointment.[63] Systemic cyclosporine or retinoids may also be beneficial.[64]

Chapter 134 :: Systemic Autoinflammatory Diseases

:: Chyi-Chia Richard Lee & Raphaela Goldbach-Mansky

SYSTEMIC AUTOINFLAMMATORY DISEASES AT A GLANCE

- Autoinflammatory diseases are disorders of the innate immune system. Excessive, innate immune responses lead to uncontrolled systemic and organ inflammation.
- Although these syndromes can mimic infections clinically, the inflammatory lesions in autoinflammatory disorders are aseptic. Fever typically accompanies some autoinflammatory diseases but is not present in all disorders.
- A number of pediatric autoinflammatory syndromes are caused by single gene mutations that have been crucial in pointing to key proinflammatory pathways, in particular the regulation of the cytokine interleukin-1 (IL-1).
- Most monogenic autoinflammatory syndromes typically present in childhood and can be differentiated on the basis of their clinical features.
- These disorders present with evidence of systemic inflammation often accompanied by generalized lymphadenopathy. Organ-specific inflammation can affect the skin, the joints/bones, serosal surfaces, the eyes, cochlea, meninges, but are often specific for one of the syndromes.
- Autosomal recessive autoinflammatory syndromes include: familial Mediterranean fever (FMF) and hyperimmunoglobulinemia D with periodic fever syndrome (HIDS), Majeed syndrome, *d*eficiency of the *I*L-1 *r*eceptor *a*ntagonist (DIRA), and deficiency of the IL-10 receptor.
- Autosomal dominant autoinflammatory syndromes include: i) tumor necrosis factor receptor-associated periodic syndrome (TRAPS) and the spectrum of the cryopyrinopathies or cryopyrin-associated periodic syndromes (CAPS)—familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID); ii) pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome; and iii) pediatric granulomatous arthritis (PGA).
- Characteristic skin eruptions are associated with a number of these disorders and include, neutrophilic urticaria, skin erythema, macular papular eruptions, and pustulosis.
- Colchicine effectively prevents the inflammatory attacks and the development of amyloidosis in FMF.
- Anti-IL-1 therapy is the standard of care in treating the cryopyrinopathies (CAPS), and DIRA. Anti-IL-1 therapy is also used to treat syndromes with more variable responses to IL-1 blockade such as resistant patients with HIDS, TRAPS, FMF, PAPA, and PGA.
- Mutations for these disorders are available in an online database called Infevers: available at http://fmf.igh.cnrs.fr/ISSAID/infevers/).

OVERVIEW OF AUTOINFLAMMATORY DISEASES

This chapter focuses on the clinical and immunologic description of the currently known monogenic autoinflammatory syndromes. Most of these syndromes present with predominantly neutrophilic skin eruptions and either fever or systemic inflammation, with elevation of acute-phase reactants during the attacks. Disease-specific organ inflammation often involves the skin, serosal surfaces, the eyes, the inner ear the meninges, the bones, the gastrointestinal tract, lymphadenopathy and more rarely, the vasculature. The characteristic clinical pattern of organ-specific inflammation in the various syndromes can, in most cases, be used to make a clinical diagnosis, which is then confirmed by genetic testing. The syndromes are summarized here and are detailed in the online edition of this chapter.

CRYOPYRINOPATHIES (FCAS, MWS, NOMID)

EPIDEMIOLOGY AND ETIOLOGY

The spectrum of cryopyrinopathies includes (1) the familial cold autoinflammatory syndrome (FCAS; OMIM #120100),[29] (2) Muckle–Wells syndrome (MWS; OMIM #191900),[30] and (3) the noninherited sporadic disease neonatal-onset multisystem inflammatory disease (NOMID) also called *c*hronic *i*nfantile *n*eurologic, *c*utaneous and *a*rthritis (CINCA) syndrome (OMIM #607115).[31] These three clinical disorders were initially described as distinct disorders, but the discovery that the familial disorders FCAS and MWS and the sporadic disease NOMID/CINCA are all caused by autosomal dominant gain of function mutations in *NLRP3*, which is also called *NALP3*, *CIAS1* or *PYPAF1*[10–12] led to the recognition that these disorders form a disease spectrum with FCAS on the mild and NOMID on the most severe end of the spectrum.

The prevalence of CAPS is estimated to be between 1 and 2 patients per 1,000,000 people in Europe and the United States based on known cases in centers studying these patients, but actual epidemiologic studies to assess incidence and prevalence have thus far not been conducted.

PATHOGENESIS

NLRP3/CIAS1 encodes the protein, cryopyrin, which belongs to a family of intracellular sensor molecules, the NLRs (NOD-like receptors). Cryopyrin can associate with adaptor proteins to form a multimolecular complex called the NLRP3 inflammasome that activates caspase-1, an enzyme that cleaves pro-IL-1β into its 17-kDa active IL-1 fragment.[32] Mutations in cryopyrin result in an "overactive" inflammasome that leads to higher production of active IL-1.[12,33–35] The inflammasome can be activated by a number of different triggers including bacterial triggers and molecules released during cell injury or stress [such as adenosine triphosphate (ATP) and uric acid], which leads to formation and activation of the NLRP3 inflammasome and activation of caspase-1, an enzyme that cleaves the proinflammatory cytokine IL-1β into its active form.

CRYOPYRINOPATHIES AT A GLANCE

- Rare autosomal dominant disorders.
- Disease spectrum includes familial cold autoinflammatory syndrome (FCAS; OMIM #120100), Muckle–Wells syndrome (MWS; OMIM #191900), and neonatal-onset multisystem inflammatory disease (NOMID/CINCA; OMIM #607115).
- Most cases of NOMID caused by sporadic, de novo mutations.
- Mutations in *NLRP3,* (also referred to as *NALP3* or *CIAS1*) on chromosome 1q11, encode an intracellular danger receptor that activates the proinflammatory cytokine IL-1. 50% of NOMID patients and small percentages of patients with FCAS or MWS have no detectable mutation in *CIAS1*.
- Features include urticaria-like eruption, fever, conjunctivitis, arthralgia (FCAS, MWS, NOMID); progressive hearing loss, progressive vision loss (MWS, NOMID); mental retardation, hydrocephalus, bony overgrowth (NOMID).
- Histopathological evaluation of lesional skin shows papillary dermal edema and telangiectasis of the superficial dermal capillaries. A predominantly perivascular and perieccrine neutrophilic inflammatory infiltrate is present in the superficial dermis and middermis, but leukocytoclasis and vasculitis are absent.
- Anti-IL-1 therapy is very effective and the standard of care in treating cryopyrinopathies (CAPS).
- Information for patients and professionals at http://www.nomidalliance.net/.

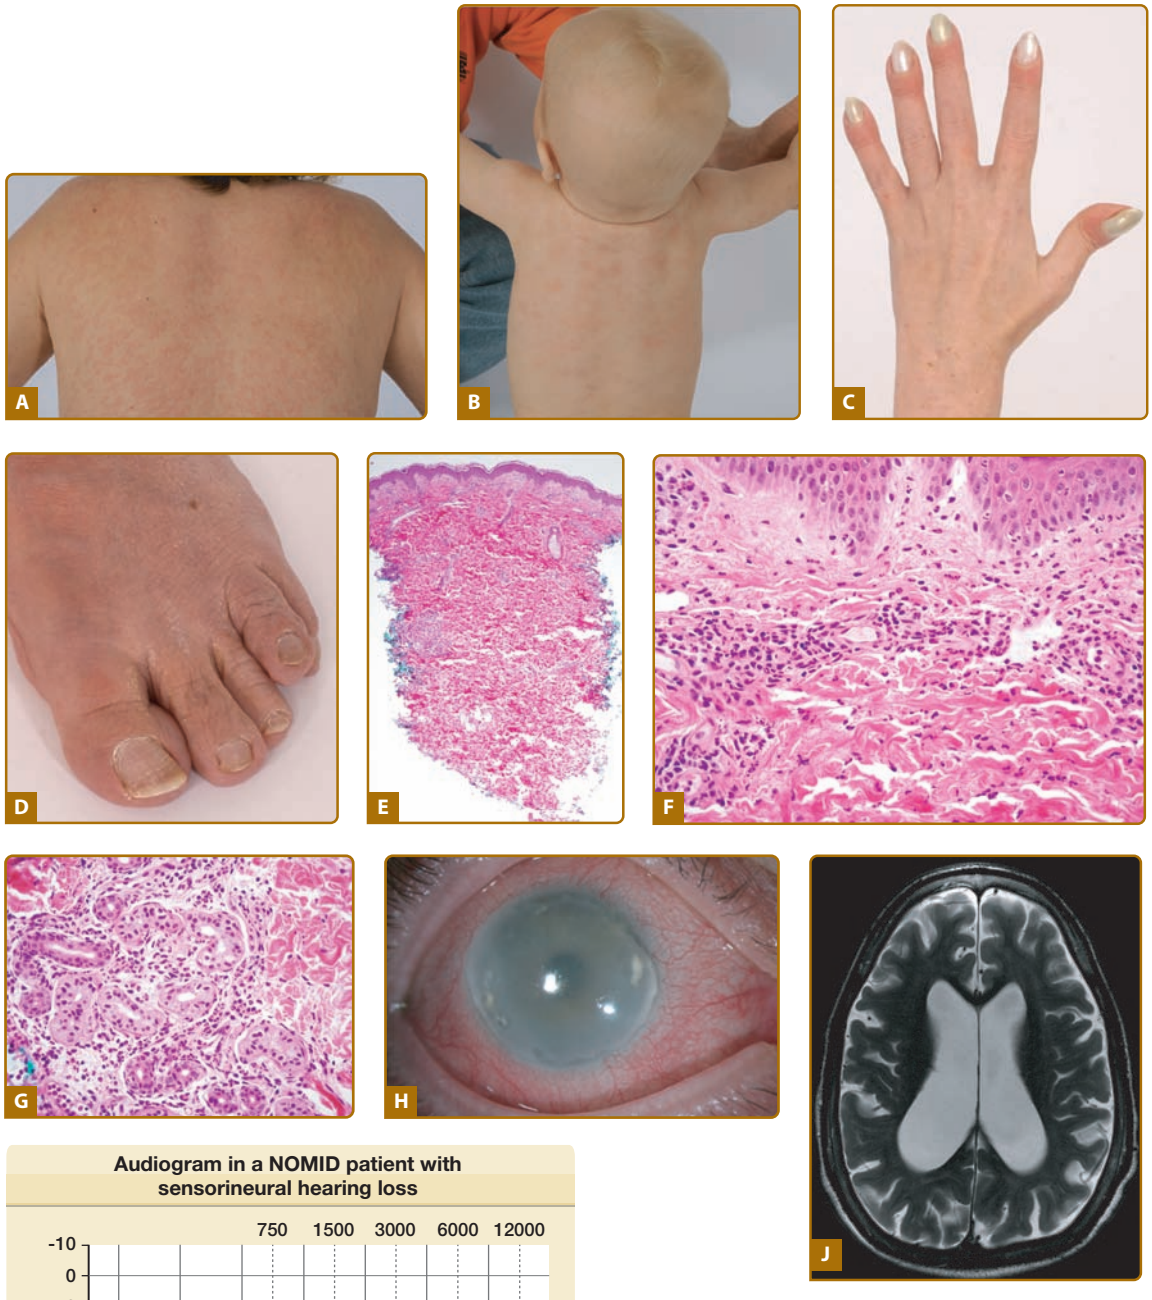
CLINICAL FINDINGS

All CAPS patients present with episodes of fever, urticaria-like eruption, conjunctivitis (Fig. 134-1H), arthralgia, and elevations in acute-phase reactants, but differ in the spectrum of multiorgan disease manifestations and in long-term morbidity and mortality.

TABLE 134-1
"Monogenic" Autoinflammatory Syndromes

Inflammatory Pathogenesis	Disease	Gene	Protein	Inheritance Pattern	Disease Onset	Flare/Fever Pattern	Specific Organ Inflammation	Treatment
IL-1-mediated	CAPS:							
	FCAS	*CIAS1* (1q44)	Cryopyrin	Autosomal dominant	First 6 months of life, cold induced	<24 hours	Skin, eyes, joints	IL-1 blockade
	MWS	*CIAS1* (1q44)	Cryopyrin	Autosomal dominant	Infancy to adolescence	24–48 hours	Skin, eyes, joints, inner ears, meninges (mild)	IL-1 blockade
	NOMID	*CIAS1* (1q44)	Cryopyrin	Autosomal dominant/de novo	Neonatal or early infancy	Continuous with flares	Skin, eyes, joints, inner ears, meninges, bony epiphyseal hyperplasia	IL-1 blockade
	DIRA	*IL1RN* (2q14)	IL-1 receptor antagonist	Autosomal recessive	Neonatal or early infancy	Continuous with flares	Skin, bones, lungs (rare), vasculitis (rare)	Anakinra
Partially IL-1-mediated	FMF	*MEFV* (16p13)	Pyrin	Autosomal recessive	80% of the cases occur before the age of 20	1–3 days	Skin, joints, peritoneum, pleura	Colchicine, rarely IL-1 and TNF blockade or thalidomide if colchicine-resistant
	HIDS	*MVK* (12q24)	Mevalonate kinase	Autosomal recessive	Median age at onset 6 months	3–7 days	Skin, eyes, joints, prominent lymph nodes	NSAIDS, corticosteroids, TNF and IL-1 blockade
	Mevalonic aciduria	*MVK* (12q24)	Mevalonate kinase	Autosomal recessive	Neonatal or early infancy	Continuous with flares	Lymph nodes, hepatosplenomegaly, eyes microcephaly, cerebellum, GI tract	TNF and IL-1 blockade? Allogeneic bone marrow transplant
	PAPA	*CD2BP1* (15q24)	PSTPIP1	Autosomal dominant	Early childhood	Common	Skin, joints	Local and systemic corticosteroids, TNF or IL-1 blockade
Other pathways/ effector pathway not yet known	TRAPS	*TNFRSF1A* (12p13)	TNF receptor 1	Autosomal dominant	Median age at onset 3 years	1–4 weeks	Skin, eyes, joints, peritoneum, pleura	TNF blockade, steroids, IL-1 blockade, colchicine is ineffective
	PGA[a]	*NOD2* (16q12)	Nod2	Autosomal dominant/de novo	Early childhood	Uncommon	Skin, eyes, joints	NSAIDS, corticosteroids, methotrexate, cyclosporine, TNF or IL-1 blockade
	Majeed's syndrome	*LPIN2* (18p11)	Lipin-2	Autosomal recessive	Early infancy (1–19 months)	Weeks–months	Bones, periosteum, anemia	NSAIDS, corticosteroids, interferon-α
	Early-onset inflammatory bowel disease (IBD)	*IL10RA* (11q23) *IL10RB* (21q22)	IL-10 receptor, *IL10RB* also forms IL-22, -26, -28, -29 receptors	Autosomal recessive	Neonatal or early infancy	Continuous with flares	Colitis with fistula formation, folliculitis in patients with *IL10RB* mutations	Bone marrow transplantation in severe cases

[a]Including Blau syndrome (OMIM #186580) and early-onset sarcoidosis (OMIM #609464).
CAPS = cryopyrin-associated periodic syndromes; DIRA = deficiency of the IL-1-receptor antagonist; FCAS = familial cold autoinflammatory syndrome; FMF = familial Mediterranean fever; HIDS = hyperimmunoglobulin D syndrome; OMIM = Online Mendelian Inheritance in Man number; MWS = Muckle–Wells syndrome; NOMID = neonatal-onset multisystem inflammatory disease; PAPA = pyogenic arthritis, pyoderma gangrenosum, and acne syndrome; PGA = pediatric granulomatous arthritis; TRAPS = tumor necrosis factor receptor-associated periodic syndrome.



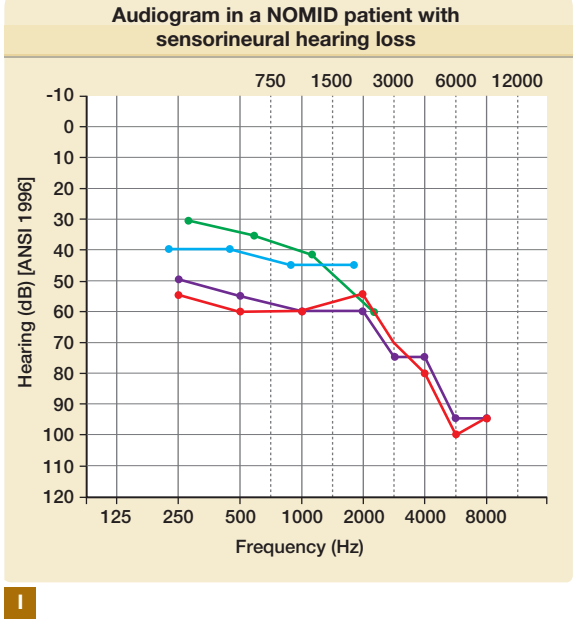


Figure 134-1 CAPS/NOMID. **A.** Urticaria-like skin eruption in a patient with NOMID/MWS. **B.** Urticaria-like skin eruption in an infant with NOMID/MWS. **C.** Clubbing fingers. **D.** Wrinkled, excess skin around the toenails and toes. **E.** At scanning magnification, there is a perivascular and periadnexal inflammatory infiltrate, extending from the superficial dermis to middermis. The epidermal changes are unremarkable. **F.** The superficial dermal capillaries are dilated and are surrounded by neutrophils. Changes of frank leukocytoclastic vasculitis are absent. **G.** The eccrine glands are also surrounded and infiltrated by neutrophils. **H.** Conjunctivitis and corneal clouding due to subcorneal inflammatory infiltrates. **I.** Sensorineural hearing loss most pronounced at high frequencies. **J.** Ventriculomegaly and brain atrophy.

In patients with FCAS the episodes are triggered by exposure to cold temperatures or air drafts and present with fevers, eruption, joint pain, conjunctivitis, and headaches. Typical episodes last for 12–48 hours and then resolve. The disease typically starts in early childhood.

Patients with MWS or NOMID typically present with urticaria-like eruptions at birth or within hours of birth; however, in some patients the first symptoms can present later. Patients with MWS have similar symptoms of fevers, urticaria-like eruption, joint pain, conjunctivitis, and headaches; however, in contrast to patients with FCAS, these symptoms can be continuous and are not typically precipitated by cold exposure. Episcleritis and optic disc edema are exceedingly uncommon in FCAS but are seen in some Muckle Wells patients; sensorineural hearing loss typically develops in the second to third decade of life in MWS patients.[33] Patients with NOMID/CINCA present with the most severe phenotype. Often their initial presentation is thought to be neonatal sepsis as they present with fevers, urticaria-like eruption, leukocytosis, and high elevation of the acute-phase reactants around birth. Joint swelling and conjunctivitis can develop at birth but usually within the first months of life. CNS inflammation with aseptic leptomeningitis and neutrophilic pleocytosis in the cerebrospinal fluid are common. Severely affected children develop hydrocephalus (Fig. 134-1J), brain atrophy, and cognitive impairment. Patients typically develop sensorineural hearing loss within the first year of life (Fig. 134-1I), and on magnetic resonance imaging (MRI) cochlear enhancement is seen and suggests cochlear inflammation as the cause of hearing loss.[35] Conjunctivitis, anterior and posterior uveitis, and subcorneal infiltrates can lead to retinal scarring, corneal clouding, and blindness. Arthralgia is common, true arthritis in most cases is very mild; however, between 50% and 70% of patients with NOMID develop characteristic bony overgrowth of the epiphyses of the long bones.[38] Most commonly involved is the epiphyses of the distal femur and proximal tibia of the knee, which frequently leads to joint deformities and contractures. Other features include elevated inflammatory markers, short stature, and leukocytosis.

CUTANEOUS LESIONS. All CAPS patients present with an urticaria-like skin eruption (Figs. 134-1A and 134-1B). In most cases, the eruption is nonpruritic and is not associated with any particular sensation, but some patients describe the eruption as burning or stinging. The skin eruption is often the first noticeable disease manifestation particularly in the less severe cases and is typically considered to be allergic. The eruption is often present at birth or develops within hours of birth but in FCAS patients can also be discovered later in childhood. The eruption is migratory and nonscarring and can vary in severity from day to day and from patient to patient. A persistent livedoid or cutis marmorata pattern, in addition to the urticarial lesions that come and go, is often seen in older patients with long-standing disease. Other cutaneous manifestations can include soft, doughy palms, soles, fingers and toes (Fig. 134-1D) and clubbing of the finger (Fig. 134-1C) and toenails, without any evidence of pulmonary disease. In contrast to true familial and acquired cold urticaria, the ice cube test is negative in CAPS patients.[39,40]

DERMATOPATHOLOGY

The histological features in FCAS, MWS, and NOMID are very similar and are discussed together. Histologically, the epidermis in CAPS is usually unaffected. There may be mild edema of the papillary dermis. The superficial dermal capillaries are dilated. A predominantly perivascular neutrophilic inflammatory infiltrate is present in the superficial dermis and middermis (Fig. 134-1E and 134-1F); however, there is no evidence of vascular destruction or true vasculitis and the number and appearance of mast cells is within normal limits.[40–43] The eccrine glands are also surrounded and infiltrated by neutrophils (Fig. 134-1G). The histological finding of neutrophilic urticaria contrasts with the lymphocytic and eosinophilic infiltrate seen in classical urticaria and is an important clue to the diagnosis of CAPS.[44]

LABORATORY TESTS AND SPECIAL TESTS (INCLUDING IMAGING STUDIES)

Evidence of systemic inflammation is present with marked leukocytosis, thrombocytosis, and mild anemia of chronic disease. Elevated levels of acute-phase reactants, *C*-reactive protein, erythrocyte sedimentation rate and serum amyloid A (SAA) levels are typically seen. Eosinophilia can be present and is variable. Careful assessment of central nervous system disease in NOMID/CINCA is indicated. Lumbar punctures are performed in patients with NOMID to diagnose leptomeningitis and to monitor intracranial pressures and leukocytosis, which predominantly consists of neutrophils, and the elevation of protein in the cerebrospinal fluid when patients are on treatment. High-resolution gadolinium-enhanced MRI can show leptomeningeal and cochlear enhancement at various degrees in patients with NOMID. X-rays of the long bones indicate the location of epiphyseal lesions and are used to follow the bony overgrowth in patients with NOMID and MRIs of an individual lesion can be helpful to rule out bone tumors and to distinguish the presence of synovial inflammation which is usually fairly nonimpressive compared to the bony abnormalities in NOMID patients.[38]

Genetic testing for *NLRP3/CIAS1* mutations confirms the diagnosis. Although almost all patients with FCAS and MWS are mutation positive, only 50%–60% of patients with NOMID have germ-line mutations that can be detected on genetic testing; therefore, a negative genetic test does not exclude the diagnosis of CAPS.

DIFFERENTIAL DIAGNOSIS

In the neonate the differential diagnosis includes benign newborn eruptions, NOMID patients can present more dramatically, mimicking neonatal sepsis or congenital

"TORCH" infections. Still's disease, systemic-onset juvenile idiopathic arthritis (SoJIA), and adult-onset Still's disease (AOSD) need to be considered in the differential diagnosis; although they typically do not present at birth. Patients with FCAS are often diagnosed with allergies or acquired cold urticaria. The bony lesions in NOMID patients can be painful and can initially resemble other benign or malignant bone tumors.

COMPLICATIONS AND PROGNOSIS/ CLINICAL COURSE

As treatment with IL-1 blocking agents has radically changed the outcome of these disorders, the prognosis in untreated and treated patients with CAPS differs significantly. In addition, the prognosis of the spectrum of CAPS depends on the disease phenotype. Untreated patients with FCAS usually have a good prognosis without hearing loss and the development of amyloidosis is rare. However, in a few families with cold-induced urticaria, the development of hearing loss and amyloidosis have been reported.[45,46] The most severe complications of untreated MWS are hearing loss and the development of amyloidosis in up to 30% in European cohorts. Untreated NOMID/CINCA patients present with early-onset hearing loss usually in the first decade of life, develop mental retardation, progressive vision loss due to progressive optic nerve atrophy, hydrocephalus, cerebral atrophy, and children with severe bony overgrowth and the development of joint contractures can develop limb length discrepancies and severe physical disabilities.[47]

TREATMENT AND PREVENTION

Despite clinical heterogeneity, all patients with FCAS, MWS, and NOMID respond dramatically and invariably to IL-1 blockade. Studies have shown efficacy of anakinra (Kineret®, recombinant IL-1 receptor antagonist) and the long-acting drugs rilonacept (Arcalyst®, IL-1 Trap, a fusion protein of the IL-1 receptor and the Fc portion of IgG) and canakinumab (Ilaris®, IL-1β-blocking antibody) for the treatment of CAPS. All patients show rapid improvement in clinical and laboratory parameters with treatment.[58–63]

The drugs are generally well tolerated and these medications have now become the standard of care in the treatment of these conditions. Although anakinra has been used longer in the treatment of CAPS, rilonacept and canakinumab have undergone a development program for orphan diseases and are now FDA approved for the treatment of FCAS and MWS.[48,49,64] Consistent with the clinical observations of the varied disease severity in FCAS, MWS, and NOMID/CINCA, increasing doses of IL-1-blocking agents such as anakinra are necessary to control more severe disease. Typically, subcutaneous injections of anakinra at 0.5–1.5 mg/kg/day is sufficient to suppress disease activity in FCAS patients. However, in NOMID patients doses up to 6 mg/kg/day or even 10 mg/kg/day[50] have been administered to control disease.

The resolution of symptoms and the achievement of inflammatory remission not only in the blood but also in the specific organs with treatment by IL-1 inhibitors are an important proof of concept that the systemic and organ-specific inflammation seen in these disorders is dependent on IL-1β. Notably, only bony overgrowth changes progress on treatment with IL-1-blocking agents which suggests that the continuation of lesional bone growth is likely independent of IL-1.[65]

DEFICIENCY OF THE IL-1 RECEPTOR ANTAGONIST

DEFICIENCY OF IL-1 RECEPTOR ANTAGONIST (DIRA) AT A GLANCE

- Rare autosomal recessive disorders (DIRA; OMIM #612852).
- Autosomal recessive inheritance.
- Mutations in *IL1RN* on chromosome 2q14 encodes the IL-1 receptor antagonist, a negative regulator of the IL-1 type 1 receptor.
- Cutaneous features include pustular eruption/folliculitis, onychomadesis.
- Extracutaneous features include aseptic osteomyelitis of long bones and vertebra and ribs and periosteitis of long bones.
- Dermatopathology is characterized by intraepidermal neutrophils and neutrophilic pustules, marked papillary dermal edema with subepidermal vesiculation, and an intense neutrophilic inflammatory infiltrate throughout the dermis and superficial subcutis; changes of frank vasculitis are absent in most patients.
- Anti-IL-1 therapy with the recombinant IL-1 receptor antagonist anakinra is very effective and can be lifesaving.

FAMILIAL MEDITERRANEAN FEVER

EPIDEMIOLOGY AND ETIOLOGY

Familial Mediterranean fever (FMF; OMIM #249100) is an autosomal recessive disease caused by mutations in *MEFV* (MEditerranean FeVer), the gene encoding the protein pyrin.[2,3] FMF is the most common monogenic autoinflammatory disease. FMF is most common among populations around the Mediterranean Sea. Clinical symptoms of FMF present in most patients before the age of 20 and therefore the diagnosis is mainly made by pediatricians.

FAMILIAL MEDITERRANEAN FEVER (FMF) AT A GLANCE

- Most common monogenic autoinflammatory disorder (FMF; OMIM #249100).
- Autosomal recessive inheritance first genetically characterized autoinflammatory disease.
- Mutations in *MEFV* on chromosome 16p13 and encoding pyrin/marenostrin.
- Cutaneous features erysipeloid erythema.
- Extracutaneous features include 1–3-day episodic attacks of fever, abdominal pain, pleuritis.
- Histopathologic evaluation of erysipeloid lesions shows a perivascular and interstitial neutrophilic infiltrate, with prominent edema of the papillary dermis and dilatation of superficial dermal capillaries.
- Colchicine is effective in most patients and prevents the development of amyloidosis
- Information for patients and professionals at http://ghr.nlm.nih.gov/condition=familialmediterraneanfever.

CLINICAL FINDINGS

FMF typically presents with 1–3-day episodes of fever with serositis, which typically consists of sterile peritonitis, but pleuritis, arthritis, and eruption can also be present. The arthritis attacks can last up to 1 week. The frequency of the attacks can vary from once weekly to once every few years. Physical exertion and emotional stress can induce these attacks, but in many instances there are no obvious triggers associated with the onset of attacks. In infants, particularly children under the age of 2, fever alone can be the initially presenting feature which typically progresses to more classic features within 3 years,[84] which may be complicated by the development of amyloidosis.[22] Abdominal pain is the second most common clinical finding in FMF presenting at some time in over 90% of patients. The peritonitis can be severe and mimic a surgical abdomen with a rigid abdominal wall, rebound tenderness, and absent bowl sounds. Not uncommonly, FMF patients have a history of a nondiagnostic exploratory laparoscopy and/or laparotomy. Small peritoneal effusions can be seen on abdominal CT and likely present an inflammatory exudate. Pleurisy is also common and is usually unilateral. A sharp chest pain, worse on inspiration and coughing, can give a clue to the diagnosis.

Symptomatic pericarditis during the attacks occur but are rare,[85,86] but on echocardiogram small, nonclinically significant effusions can be present during attacks.

Other rare clinical features of FMF include, protracted febrile myalgia, which presents with up to 6-week episodes of debilitating muscle pain, fever and elevation of acute-phase reactants but normal CK levels.[87] Inflammation of the tunica vaginalis, an embryological remnant of the peritoneal membrane,[88] can lead to severe scrotal pain and ischemic testicular necrosis and rarely aseptic meningitis have been seen.[89]

CUTANEOUS LESIONS. Erysipeloid erythema is the most characteristic eruption of FMF, but it is rarely present in isolation.[90] These lesions appear on the lower limbs, usually below the knee. They tend to affect the dorsum of the foot and ankle and lower extremity. They consist of warm, tender, swollen erythematous plaques, 10–15 cm in diameter, with well-defined borders (Fig. 134-2A). The lesions may be bilateral, may be initiated by prolonged walking, and subside within 24–48 hours. Other cutaneous manifestations described in FMF include a localized edema affecting the upper or lower limbs, face, or neck, and subcutaneous nodules.[91] In children, episodic scattered nonspecific purpuric papular lesions that affect the face, trunk, or extremities are more frequently observed.[92] A higher incidence of vasculitic purpura, including Henoch–Schönlein purpura, has also been described in FMF patients in some case series.[69]

DERMATOPATHOLOGY

Biopsies of erysipeloid skin eruptions are rarely reported; on biopsies, a perivascular and interstitial inflammatory infiltrate composed of predominantly neutrophils and lymphocytes in the dermis, with prominent edema of the papillary dermis and dilatation of superficial dermal capillaries, can be seen. The epidermal changes may include mild hyperkeratosis and acanthosis[90,91] (Fig. 134-2B). In one series, direct immunofluorescence studies show deposition of complement C3 in the vessel wall of the small superficial dermal vessels in all cases and deposition of fibrinogen and IgM in some case.

LABORATORY TESTS AND SPECIAL TESTS

During the inflammatory attacks nonspecific markers of inflammation, the acute-phase reactants, ESR, CRP, and SAA levels are typically elevated.[93] Mild hypergammaglobulinemia including elevation of IgD, mostly in patients who are homozygous for the *M694V* mutations, can be seen during as well as in between attacks.[94] In between the febrile attacks, elevation of the acute-phase reactants can persist—a finding that has also been observed in heterozygous carriers for the mutation.[95,96] Similar to many other autoinflammatory diseases, autoantibodies to ANA, RF, and

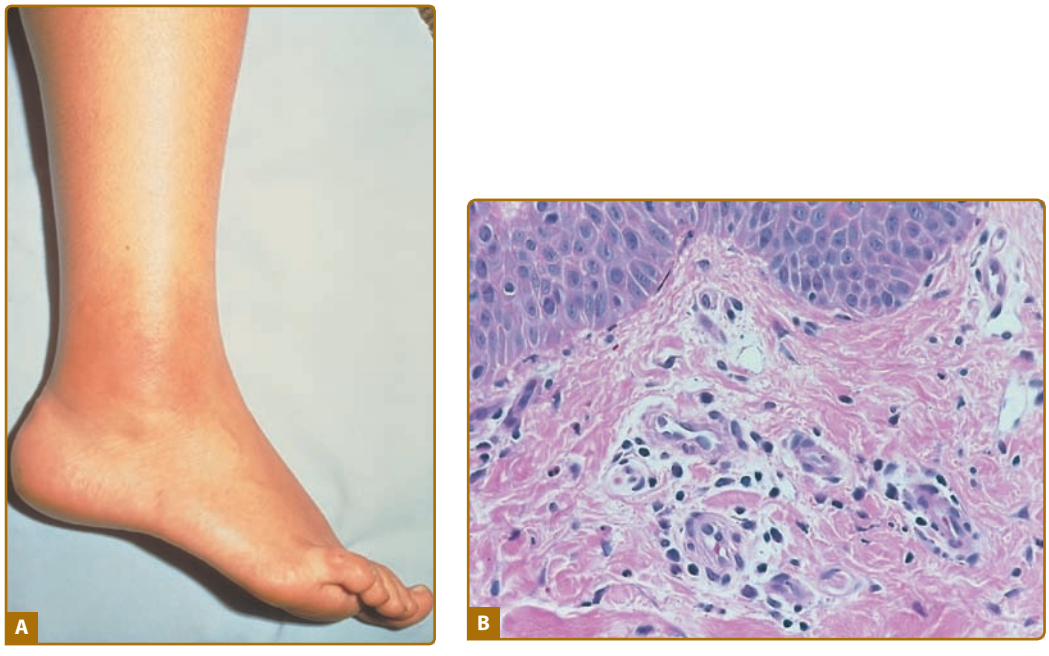

Figure 134-2 FMF. **A.** Erysipelas-like eruption on right ankle showing sharply demarcated, swollen, bright erythematous skin. (From Azizi E et al: Cutaneous manifestations of Familial Mediterranean Fever. *Arch Dermatol* **112**:364–366, 1976, with permission. © 1976 by the American Medical Society.) **B.** Histology of erysipeloid eruption showing a perivascular inflammatory infiltrate in the superficial dermis. (Used with permission from Dan Kastner.)

ANCA are typically not found, which initially led to the hypothesis that these disorders are caused by an innate immune defect.

DIFFERENTIAL DIAGNOSIS

In patients with peritonitis, acute appendicitis may be suspected; however, spontaneous resolution of fever is a clue to the diagnosis of FMF. Hereditary angioedema may present with abdominal pain but usually does not cause fever. Hypertension and a pattern of dominant inheritance help to differentiate porphyria from FMF in patients with abdominal pain and fever. In children, systemic-onset juvenile idiopathic arthritis (SOJIA) is a consideration; however, an evanescent eruption, quotidian fever pattern, lymphadenopathy, and polyarthritis and the absence of abdominal pain are suggestive of SoJIA. FMF needs to be distinguished from the other familial fever disorders.

COMPLICATIONS AND PROGNOSIS/ CLINICAL COURSE

The most common and severe complication of FMF is the development of AA amyloidosis.[22] Before the use of colchicine, renal failure secondary to amyloidosis was the most common cause of death in patients with FMF. Acquired amyloidosis in patients with inflammatory conditions, including FMF, is caused by deposition of a degradation product of SAA, which is an acute-phase reactant that is released during inflammation by the liver. Although AA amyloid is deposited in kidneys, the GI tract, lungs, testes, thyroid, and adrenal glands can also be affected, but the renal involvement usually dominates the clinical course.[97] Amyloidosis usually presents in patients with a long-standing history of febrile attacks, it rarely can be a first manifestation of FMF.[98–100]

All patients with FMF should be monitored for the development of amyloidosis by following the development of proteinuria in between the febrile attacks. Renal failure typically develops 3–5 years after the onset of proteinuria. SAA levels are a sensitive measure for predicting progression of renal dysfunction in patients with amyloidosis and the therapeutic goal should be normalizing SAA levels or decreasing them at least below 10 mg per liter[97] (see Chapter 133).

Risk factors for the development of amyloidosis were evaluated in a survey that collected data from 14 countries on genetically confirmed cases of FMF. The prevalence of renal amyloidosis in these patients was 11.4%. The country of recruitment—Armenia, Turkey, and Arab countries—conferred the highest risk of amyloidosis followed by homozygosity for *M694V*. The infant mortality rate, which can be used as a sensitive proxy indicator of population health and hygiene,[101] correlated with the risk for amyloidosis suggesting an environmental impact on the development of amyloidosis. These data were strengthened by the fact that one-third of the patients currently living in countries with the lower risk of renal amyloidosis (Israel and "other" including the US) were Arabs, Turks, or Armenians, who were from ethnic groups originating from high-risk countries.[102] Another factor associated with the risk of developing AA amyloidosis is an allelic variant in the *SAA1* gene encoding for SAA.[103,104] Deterioration of amyloid deposits was seen in patients with

a median of 28 mg per liter and regression of amyloid deposits was seen in 60% of patients with a median SAA concentration of less than 10 mg per liter.

TREATMENT AND PREVENTION

Antipyretics are typically administered during the acute febrile attacks to lower the fever and prevent the development of febrile seizures. Colchicine is first-line treatment and is very effective in the treatment of most patients in preventing amyloidosis.[105] Daily use of colchicine results in near complete remission in three-fourths of patients, with 95% noting a marked improvement. Recently, the similarity between symptomatic patients who present with two versus one mutation has been noted. Patients with only one mutation but typical disease require and respond to treatment with colchicine.[106] Daily oral colchicine doses of 1.2–1.8 mg are often required for clinical effect in most adults and children over 5 years[107] and younger children can be treated with lower doses. Commonly, colchicine causes diarrhea, but gradual uptitration of the dose helps to overcome this problem. Bloating and abdominal pain can also be caused by lactose intolerance that may develop in patients on colchicine. Elderly patients or those with renal impairment treated with colchicine may develop a myopathy or neuropathy.[108] In patients with persistent disease, IL-1- and TNF-blocking therapies are used to treat the disease.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME AND MEVALONATE ACIDURIA

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (HIDS) AND MEVALONIC ACIDURIA (MA) AT A GLANCE

- Rare autosomal recessive autoinflammatory disorders, mainly in patients with Dutch ancestry HIDS (milder, OMIM #260920) and MA (most severe, OMIM #610377).
- Mutations in *MVK* on chromosome 12q24, which encodes mevalonic kinase.
- Cutaneous features include erythematous macules and papules with attacks.
- Extracutaneous features include 1–3-day episodic attacks of fever, lymphadenopathy, and eruption abdominal pain.
- NSAIDs, anti-TNF and anti-IL-1 therapy.
- Information for patients and professionals at http://www.hids.net.

EPIDEMIOLOGY AND ETIOLOGY

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) (OMIM #260920) and mevalonic aciduria (OMIM #610377) are autosomal recessive disorders caused by mutations in *MVK*, the gene which encodes mevalonate kinase an enzyme involved in the cholesterol and isoprenoid biosynthesis pathway.[5,109] The discovery that HIDS is caused by mutations in the mevalonate kinase gene led to the recognition that MA, a "classic" metabolic disorder that had previously been associated with autosomal-recessive mutations in *MVK*, are indeed similar disorders along a severity spectrum with HIDS on the milder and MA on the most severe side of the disease spectrum.[110,111] Most patients with HIDS are of Western European (particularly Dutch and French) ancestry, suggesting a founder gene effect in these populations.[109]

HIDS mutations are evenly distributed along the coding region of the *MVK* gene, in contrast to mutations causing MA, which cluster between amino acids 243 and 334.[112] Most patients carry two missense mutations and *V377I* which is the most common mutation in patients with HIDS, followed by mutations in *I268T*; these two mutations accounted for 65%–80% of the cases in two case series,[112,113] including a recent cohort of 103 genetically defined patients.[113] The male–female ratio was 1.5:1 and the prevalence of the disease is not known. In the recent case study, patients were contributed from 13 countries and three continents but the majority came from the Netherlands.[113] The carrier frequency for the common mutation *V377I* mutation is 0.6% in the Dutch population and the marked underrepresentation of homozygotes for this mutation suggests that homozygotes may have a milder clinical phenotype or no clinical phenotype.[114,115]

PATHOGENESIS

The activity of mevalonate kinase, the enzyme that catalyzes the first step in mevalonate metabolism, can be examined in the patient's fibroblasts, lymphocytes, and lymphoblasts. Residual enzyme function is associated with the severity of the clinical phenotype. In most patients with MA, the enzyme activity is below the level of detection, while patients with the HIDS phenotype still have residual mevalonate kinase enzyme activity between 1% and 8% of the activities measured in normal controls.[116] The metabolite mevalonic acid accumulates at higher levels in plasma, urine, and tissues in patients with the MA phenotype and no enzyme function and to low-to-moderately increased levels in patients with the HIDS presentation and residual enzyme activity. During febrile attacks, the MVK activity in peripheral blood mononuclear cells of HIDS patients drops two- to eightfold, which suggests that minor elevations in body temperature can trigger a chain of events, leading to a temporary deficiency of products which cannot be produced because of the enzyme block.[117] Mevalonate kinase is the rate-limiting step in the conversion from mevalonate to mevalonate

phosphate and end products of this pathway include cholesterol and a number of isoprenoids, molecules that participate in cellular processes related to cell growth and differentiation, cytoskeletal function, and vesicle trafficking.[118] In peripheral blood, mononuclear cells from patients with HIDS, but not from normal controls, and the shortage of isoprenoid end products, but not the excess of mevalonate, contribute to increased IL-1β production.[119] IL-1 secretion can be lowered by the addition of geranylgeranyl, suggesting that isoprenoids have an anti-inflammatory role and their lack of production during an attack further aggravates the disease.[120]

CLINICAL FINDINGS

The median disease onset ranges from the first week of life to 10 years. Episodes may occur once or twice per month and typically last 3–7 days. Prodromal symptoms such as malaise, headache, and chills are found in two-thirds of patients. A rapid rise in temperature, often over 40°C, typically follows. In 63% of cases, childhood vaccinations induce the first attack; other nonspecific triggers are physical and emotional stress. Painful lymphadenopathy accompanies the fever in 90% of patients. Axillary and inguinal lymphadenopathies are less frequent and splenomegaly occurs in one-third of patients. Gastrointestinal symptoms, including abdominal pain, vomiting, and/or diarrhea, are present in over 90% of patients, and the severity may prompt exploratory surgery, leading to the discovery of residual adhesions from past episodes of aseptic peritonitis.[113] Articular symptoms are seen in over 80% of patients, and predominantly affect the large joints and metacarpophalangeal and proximal interphalangeal joints of the hands.[113] Similar to HIDS, patients with MA present with febrile episodes and systemic inflammation, but other features include severe failure to thrive, lymphadenopathy, developmental delay, anemia, hepatosplenomegaly, central cataracts, and dysmorphic facies (microcephaly), cerebellar ataxia, as well as diarrhea and malabsorption.

CUTANEOUS LESIONS. Two-thirds of patients with HIDS have an eruption with the fevers. Erythematous macules, papules, and nodules ranging from 0.5 to 2.0 cm in diameter, which may be confluent or solitary in distribution, are frequently observed during attacks[121] (Fig. 134-3). Petechiae and purpura are also seen during attacks.[122] Oral aphthous ulcers with or without genital lesions occur in 48.5% of patients and may mimic Behçet's disease.[113] MA is much more severe then HIDS, but the cutaneous manifestations are similar.[122]

DERMATOPATHOLOGY

Biopsies of lesional skin reportedly show a perivascular neutrophilic and lymphocytic inflammatory infiltrate with slight leukocytoclasis and fibrinoid changes of vessel walls, consistent with leukocytoclastic vasculitis. Perivascular deposits of IgD and C3 in a granular staining pattern can be detected on direct immunofluorescence studies of skin biopsies from some of the patients.[123] Sweet syndrome-like or cellulitis-like findings and deep vasculitis have also been reported. Erythema elevatum diutinum have been reported in association with HIDS.[124,125]

Figure 134-3 HIDS. Erythematous macules and papules distributed over both palms, arms, legs, and trunk (not shown) during an attack of hyperimmunoglobulinemia D with periodic fever syndrome (HIDS). (From Takada K et al: Favorable preliminary experience with etanercept in two patients with the hyperimmunoglobulinemia D and periodic fever syndrome. *Arthritis Rheum* **48**:2645, 2003. Copyright © 2003 by the American College of Rheumatology. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

LABORATORY TESTS AND SPECIAL TESTS

The diagnosis of HIDS is usually suspected clinically, but the definitive diagnosis is made by genetic testing. During the attacks, patients usually have elevated acute-phase reactants. Most patients have a persistently elevated serum IgD level (>100 U/mL), and in 82% of cases the serum IgA was likewise elevated[121] with median concentrations for IgD being 400 U/mL.[113] Between attacks some patients continue to have elevations of the acute-phase reactants. Although the elevation of IgD is not specific for HIDS and can be normal in genetically proven cases, it is often a helpful clue in considering the diagnosis.

DIFFERENTIAL DIAGNOSIS

The diagnosis of HIDS is often delayed by a median of 9.9 years after onset of symptoms. The differential diagnoses include other forms of hereditary fever syndromes including FMF. However, FMF does not present with lymphadenopathy or oral ulcers, and HIDS attacks do not respond to colchicine. In patients with prominent oral and genital ulcers, the disease can mimic Behçet's disease. Other erroneous diagnoses

include adult-onset Still's disease, juvenile idiopathic arthritis, rheumatic fever, and chronic infection.[113] MVK deficiency can mimic congenital infections, myelodysplastic syndromes, or chronic leukemia, and emphasizes the importance of considering a broad differential in patients with hematologic abnormalities.[126]

COMPLICATIONS AND PROGNOSIS/ CLINICAL COURSE

Long-term consequences of inadequately treated disease included amyloidosis in less than 3%, joint contractures, abdominal adhesions in ~10%. School children with HIDS miss more school days and adults have higher rates of discharges from their jobs and a higher rate of unemployment in comparison to the control population.[113]

TREATMENT AND PREVENTION

NSAIDs are administered for fever and arthralgia. Short courses of corticosteroids may be effective in some patients, but colchicine is ineffective. Based on the assumption that mevalonate accumulation is pathogenic, simvastatin, an HMG-CoA reductase inhibitor, was given to six patients, of whom five had a nonstatistically significant decrease in the number of febrile days.[127] In 80% of patients in whom anticytokine therapy with either anti-IL-1 or anti-TNF agents was offered, benefit was observed. One patient with severe MA was treated with an allogeneic bone marrow transplant and achieved complete inflammatory remission.[128]

PYOGENIC ARTHRITIS, PYODERMA GANGERENOSUM, AND ACNE SYNDROME

EPIDEMIOLOGY AND ETIOLOGY

Pyogenic arthritis, pyoderma gangrenosum and cystic acne (PAPA) syndrome (OMIM #604416) is a very rare autosomal dominant disorder characterized by pyogenic arthritis, pyoderma gangrenosum and cystic acne, and is caused by mutation in *CD2BP1*, a gene on chromosome 15q24.[129]

PATHOGENESIS

PAPA syndrome is caused by mutations in *CD2BP1* that encodes proline-serine-threonine-phosphatase-interacting protein 1 (PSTPIP1). PSTPIP1 undergoes phosphorylation by PTP-PEST, a protein tyrosine phosphatase. In its phosphorylated form, PSTPIP1 cannot bind to pyrin. Mutations in PSTPIP1 prevent its phosphorylation and lead to a prolonged binding to pyrin. It is hypothesized that mutations in the *CD2BP1* gene result in production of a hyperphosphorylated protein that binds excessively to pyrin, and that the PSTPIP1/pyrin complex prevents the inhibitory function of pyrin on the NLRP3 inflammasome, which would lead to increased IL-1β production and inflammation.[9,82,130,131]

PYOGENIC ARTHRITIS, PYODERMA GANGRENOSUM AND CYSTIC ACNE (PAPA) AT A GLANCE

- Very rare autosomal dominant autoinflammatory disorder PAPA (OMIM #604416).
- Mutations in *CD2BP1*, on chromosome 15q24, which encodes PSTPIP1.
- Pyoderma gangrenosum, cystic acne, pyogenic arthritis.
- Dermatopathology: biopsies of pyoderma gangrenosum show a predominantly neutrophilic inflammatory infiltrate in the dermis and superficial ulceration. Acne conglobata shows burrowing and interconnecting abscesses and scars.
- Corticosteroids, and anti-TNF and anti-IL-1 therapies.
- Information for patients and professionals at http://dermnetnz.org/systemic/papa.html.

CLINICAL FINDINGS

The clinical manifestations of this disorder include pyoderma gangrenosum, cystic acne, and pyogenic sterile arthritis.[9] Arthritis first begins in the first decade of life and may be triggered by episodes of mild trauma; the arthritis can be progressively destructive. Pyoderma gangrenosum lesions often occur at sites of injury. Nodulocystic acne can cause scarring if untreated. The recurrent sterile arthritis usually occurs after minor trauma, but may also occur spontaneously. PAPA attacks can be self-limiting or chronic, which can then lead to joint destruction and joint deformities.[129]

CUTANEOUS LESIONS. Dermatologic manifestations include pyoderma gangrenosum (Fig. 134-4A) and acne conglobata (nodulocystic acne of the face and trunk) (Fig. 134-4B). The acne begins in childhood or adolescence and persists into adulthood.[131] The pyoderma gangrenosum lesions start as violaceous nodules, usually on the legs, resulting in poorly healing ulcers with undermined rolled edges.

Figure 134-4 PAPA. **A.** Forearm of a patient with pyogenic arthritis with pyoderma gangrenosum and acne syndrome (PAPA) showing a large ulcerated lesion with granulation tissue and purulent exudate at the base and with erythematous, slightly elevated borders, typical of pyoderma gangrenosum. (From Shoham NG et al: Pyrin binds the PSTPIP1/CD2BP1 protein, defining familial Mediterranean fever and PAPA syndrome as disorders in the same pathway. *Proc Natl Acad Sci USA* **100**:3501, 2003, with permission. © 2003 by the National Academy of Sciences of the USA.) **B.** Severe cystic acnes with scarring in a patient with PAPA syndrome. (Used with permission from Daniel Kastner.)

DERMATOPATHOLOGY

Biopsies of lesional skin of pyoderma gangrenosum show a predominance of neutrophilic inflammatory infiltrate in the dermis and superficial ulceration. Biopsies of acne conglobata are characterized by burrowing and interconnecting abscesses and scars.

LABORATORY TESTS AND SPECIAL TESTS

Elevations of acute-phase reactants are seen during the acute attacks and can be persistently elevated in patients with more chronic lesions. The diagnosis is established by genetic testing. Cultures of the skin and joint lesions from these patients are sterile.

DIFFERENTIAL DIAGNOSIS

Pyoderma gangrenosum is primarily a clinical diagnosis, after excluding other causes of ulcers such as infection. The histologic differential for pyogenic granuloma may include infectious causes of abscesses and other diseases with neutrophils in the dermis such as Sweet syndrome.

TREATMENT AND PREVENTION

Treatment of pyoderma gangrenosum is challenging since it is not responsive to antibiotics and only responds partially to systemic glucocorticosteroids and immunosuppressive therapies. Treatment with infliximab[132,133] or anakinra[134] has been effective in treating the skin and joint findings in these patients.

TNF RECEPTOR-ASSOCIATED PERIODIC SYNDROME

TNF RECEPTOR-ASSOCIATED PERIODIC SYNDROME (TRAPS) AT A GLANCE

- Rare autosomal dominant autoinflammatory disorder, TRAPS or tumor necrosis factor receptor-associated periodic syndrome (OMIM #191190).
- Mutations in *TNFRSF1A*, on chromosome 12p13, encoding TNF receptor 1.
- Cutaneous features include centrifugal migratory, erythematous patches.
- Extracutaneous features include fever, myalgia, serositis, periorbital edema, conjunctivitis, and arthritis.
- Histopathology is relatively nonspecific.
- NSAIDs, corticosteroids, anti-TNF and anti-IL-1 therapies for treatment.

EPIDEMIOLOGY AND ETIOLOGY

TNF receptor-associated periodic syndrome (TRAPS) (OMIM #191190) is an autosomal dominantly inherited disease caused by mutations in *TNFRSF1A*, the gene located on chromosome 12p13 that encodes the 55-kDa TNF receptor 1.[4] The reported incidence is 5.6 per 10,000,000 person-years.[136] Male to female ratio is 1.5:1.[135]

PATHOGENESIS

More than 50 mutations in *TNFRS1A* have been described in patients with clinical disease. Most are missense mutations, leading to cysteine substitutions in the extracellular domain of the TNF receptor.[137–139] Mutations resulting in loss of a cysteine residue correlate with clinically more severe disease and a higher risk of amyloidosis.[141]

Most of the mutations are single nucleotide missense mutations occurring within exons 2, 3, and 4. The TNF type 1 receptor or p55 receptor is expressed on leukocytes and endothelial cells. The extracellular domain of the receptor is composed of four cysteine-rich domains (CRD), each containing six cysteine residues that form three intradomain disulfide bridges in each CRD.[140] Nearly all TRAPS mutations are found in the first two CDRs at the *N*-terminal region of the receptor. The interpretation of noncysteine substitutions in TNFRSF1A has been more difficult, as some substitutions such as the P46L variant occur in up to 20% of clinically asymptomatic individuals in a West African population, which suggests that this variant in this population represents a polymorphism rather than a disease-causing mutation. The presence of another TNFRSF1A variant, R92Q, did not correlate with the TRAPS phenotype, although it was associated with heterogeneous clinical inflammatory symptoms suggesting a reduced penetrance variant that may play a role in a wider clinical spectrum of inflammatory disorders.[142,143] Despite the known genetic defect, the mechanism of disease pathogenesis remains incompletely understood. In some patients, delayed TNF receptor cleavage from cells may account for an increased signaling through the TNF receptor; however, the majority of patients do not have receptor shedding defects,[143,144] which led to the search for other pathways. Interestingly, most mutations in the TNF receptor affect receptor folding and trafficking, resulting in the retention of misfolded TNF receptor complexes in the endoplasmic reticulum and the presence of only the wild-type receptor on the cell surface.[145,146] This phenomenon was examined in a mouse knockin model confirming that the mutant TNFR1 receptor can no longer oligomerize with wild-type receptor molecules but rather forms disulfide-linked homooligomers that can bind TNF with high affinity but not on the cell surface. Mutant receptors accumulate in the endoplasmic reticulum within the cells and LPS stimulation of these cells leads to enhanced activation of mitogen-activated protein kinases (MAPKs) and secretion of proinflammatory cytokines upon stimulation with the bacterial cell wall component, lipopolysaccharide (LPS).[147] The presence of an intact TNF receptor on the cell surface is necessary in this model to from an autocrine loop between mutated TNFR1 signaling in the endoplasmic reticulum and wild-type TNF receptor on the cell surface receiving a TNF signal.[147] These findings provide a rationale as to why the disease is inherited in an autosomal dominant manner and also offer an explanation regarding the partial response to TNF blockade.[148] In one report, NF-κB activation may in fact be decreased in response to TNF stimulation of leucocytes from patients with TRAPS.[151] This was not seen in response to LPS or IFN-γ suggesting that there may be an alternative stimulus other than TNF that is responsible for the previously observed activation of NF-κB.

Cytokines other than TNF have also been implicated in the disease. Patients with TRAPS have increased NF-κB activation, the major signaling molecule involved in the secretion of proinflammatory cytokines; they also have higher than expected levels of functional TNFR1 at the cell surface.[149] Interestingly, some TRAPS patients have an exaggerated inflammatory response to treatment with infliximab.[150]

CLINICAL FINDINGS

The median age of onset is 3 years with initial presentation ranging from 2 weeks to 53 years of age.[135] TRAPS attacks present with fever, disabling myalgia, skin eruption, serositis (pleuritic and abdominal pain), arthritis, and eye involvement. Attacks last on average 21 days per month and occur every 5–6 weeks; however, there is considerable variability in the length and the time between attacks. An early sign of an impending attack often is a "deep" muscle cramping that increases in severity over 1–3 days and then remains severe for more than 3 days before the symptoms gradually resolve. A minority of patients present with daily symptoms that vary in severity. Although the actual trigger for an attack is often unknown, physical and emotional trauma and menstruation can be associated with attacks. Pregnancy may be associated with amelioration. Fevers of between 38°C and 41°C for more than 3 days usually precede other inflammatory symptoms. Fever is invariably seen in pediatric patients but may be absent during some attacks in adults.

The involved areas often move centrally and the tissues over the involved muscles are warm, tender to palpation, and erythematous. Other findings include arthralgia and frank synovitis. The arthritis is nonerosive, asymmetric, and monoarticular, and affects primarily large joints including the hips, knees, or ankles. Tenosynovitis of flexor and extensors also occurs and is not confined to febrile episodes.

Abdominal pain is present in more than 90% of patients. Often, fever and abdominal pain are the only manifestations of a clinical attack of TRAPS. Patients can present with vomiting and constipation, suggestive of bowel obstruction, and the abdominal findings can present as an acute abdomen leading to laparotomy and appendectomy without histologic evidence of inflammation. The presence of intra-abdominal adhesion on laparotomy and a mononuclear infiltrate on tissue biopsies from resected bowel suggest peritonitis and some mucosal inflammation.

More than 80% of patients present with conjunctivitis and/or periorbital edema. Lymphadenopathy, if observed, is usually limited to a single anatomical location. Severe uveitis and iritis may be seen. Chest

pain may be either musculoskeletal or pleuritic and was present in 57% in one large cohort.[135]

CUTANEOUS LESIONS. Over 80% of patients present with skin eruptions during the attacks. Patients often present with periorbital edema (Fig. 134-5A). The most characteristic cutaneous manifestation is a centrifugal migratory, erythematous patch (Figs. 134-5B and 134-5C), which typically migrates from the periphery to the center of the body. The tissue

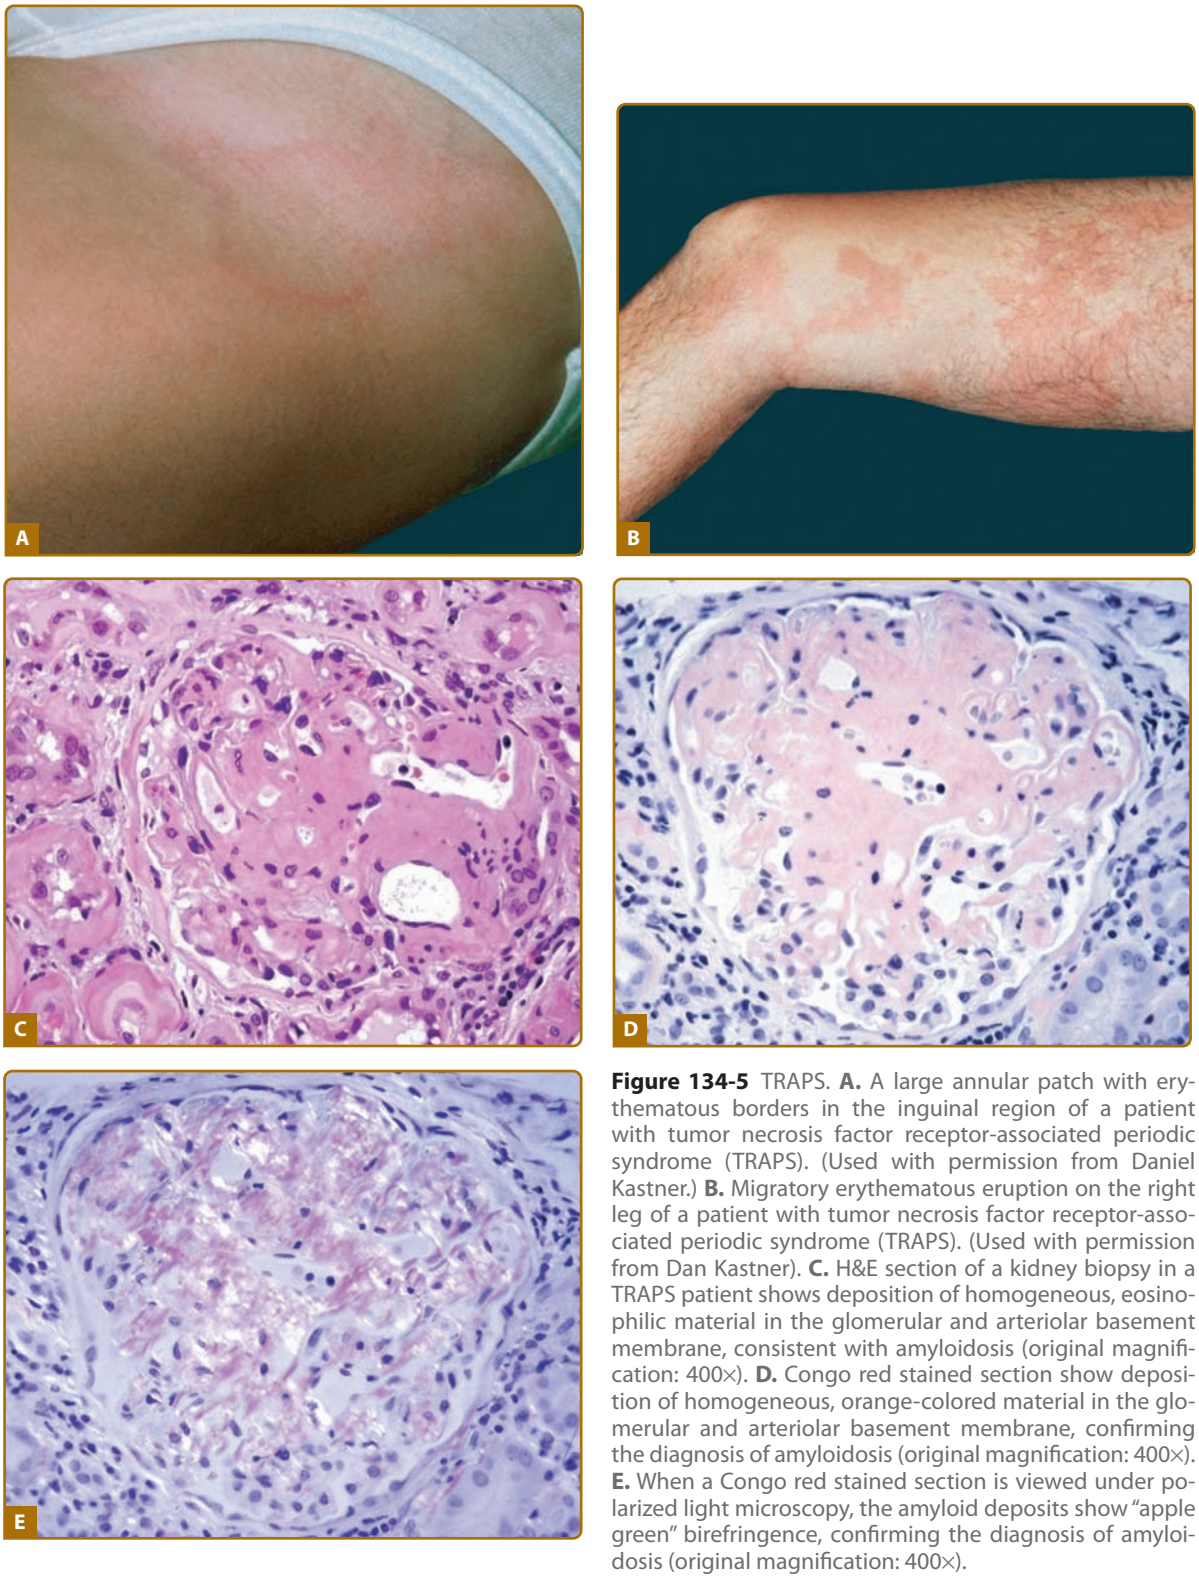

Figure 134-5 TRAPS. **A.** A large annular patch with erythematous borders in the inguinal region of a patient with tumor necrosis factor receptor-associated periodic syndrome (TRAPS). (Used with permission from Daniel Kastner.) **B.** Migratory erythematous eruption on the right leg of a patient with tumor necrosis factor receptor-associated periodic syndrome (TRAPS). (Used with permission from Dan Kastner). **C.** H&E section of a kidney biopsy in a TRAPS patient shows deposition of homogeneous, eosinophilic material in the glomerular and arteriolar basement membrane, consistent with amyloidosis (original magnification: 400×). **D.** Congo red stained section show deposition of homogeneous, orange-colored material in the glomerular and arteriolar basement membrane, confirming the diagnosis of amyloidosis (original magnification: 400×). **E.** When a Congo red stained section is viewed under polarized light microscopy, the amyloid deposits show "apple green" birefringence, confirming the diagnosis of amyloidosis (original magnification: 400×).

overlying the local area of myalgia is often tender to palpation, warm and erythematous and blanchable.[152] Some patients present with diffuse erythema of cheeks and confluent salmon-pink-colored macules and papules or mottled erythema of the chest, abdomen, and extremities.[153]

DERMATOPATHOLOGY/ HISTOPATHOLOGY

Microscopic evaluation of lesional skin shows a mild perivascular lymphocytic inflammatory infiltrate in the dermis and edema of the upper dermis, and may reveal slight C3 and C4 deposition around the small vessels in the dermis.[153] A fascia/muscle biopsy shows normal myofibril architecture without evidence of inflammation, but extensive acute and chronic inflammation of the surrounding connective tissue, including panniculitis, fasciitis, and perivascular chronic inflammation.[154]

LABORATORY TESTS AND SPECIAL TESTS

Elevations of acute-phase reactants are seen during the acute attack, including elevation of erythrocyte sedimentation rate, C-reactive protein, haptoglobin, fibrinogen, and ferritin. A large percentage of patients also demonstrate an elevated acute-phase response between clinically symptomatic attacks. Anemia of chronic disease is seen in patients with long-standing elevation of acute-phase reactants and most patients demonstrate a polyclonal gammopathy. MRI of affected muscle groups reveals focal areas of edema in discrete muscular compartments and intramuscular septa myalgia.[154] As seen with the other diseases, autoantibodies, including antinuclear antibodies and rheumatoid factor, are typically negative.

DIFFERENTIAL DIAGNOSIS

TRAPS can mimic other autoinflammatory disorders and the diagnosis needs to be made by genetic testing. TRAPS can also mimic SoJIA or AOSD, but the characteristic migratory, erythematous eruption with underlying myalgia and periorbital edema seen in TRAPS are not seen in SoJIA or AOSD. The quotidian fever pattern observed in SoJIA/AOSD has also not been seen in TRAPS.

COMPLICATIONS AND PROGNOSIS/ CLINICAL COURSE

Similar to descriptions in the FMF section, systemic AA amyloidosis and the development of renal failure is the most severe complication of TRAPS (Figs. 134-5D–134-5F). As in FMF, all patients, particularly those with cysteine mutations, need to be closely monitored for the development of proteinuria. The majority of patients with kidney involvement develop nephritic syndrome and ultimately renal failure.

Amyloidosis is common among families with the *C30R*, *C52F*, and *C88R* mutations and is uncommon in patients from families with the *C33Y*, *T50M*, and *C88R* mutations.[135,143]

TREATMENT AND PREVENTION

Nonsteroidal anti-inflammatory drugs may be sufficient to treat mild attacks. Corticosteroids suppress the attacks, but the steroid requirement may increase over time and is associated with considerable side effects. Colchicine is not effective in treating TRAPS symptoms nor in the prevention of amyloidosis. Etanercept, the p75 TNF receptor fusion protein, suggests a favorable clinical response.[135,155–158] In patients at risk of amyloidosis, tailoring the dose of anticytokine therapy to lower SAA levels in an attempt to prevent the development of amyloidosis is indicated. Anakinra has been reported to be successfully used in some therapy-resistant cases and is often considered before using anti-TNF agents.[159,160]

PEDIATRIC GRANULOMATOUS ARTHRITIS

PEDIATRIC GRANULOMATOUS ARTHRITIS (PGA) AT A GLANCE

- Very rare autosomal dominant autoinflammatory disorders, PGA includes the familial disorder Blau syndrome (OMIM #186580) and the sporadic form caused by de novo mutations early onset sarcoidosis (OMIM #360464).
- Mutations in *NOD2*, on chromosome 16q12, encoding a protein belonging to the family of NACHT-leucine-rich repeat (LRR) receptors.
- Cutaneous features: early-onset cutaneous "sarcoidosis" with generalized skin eruption.
- Extracutaneous features include arthritis and recurrent uveitis.
- Dermatopathology is characterized by nonnecrotizing well-demarcated dermal granulomas.
- Treatment includes methotrexate, NSAIDs, and anti-TNF and anti-IL-1 therapies.

MAJEED SYNDROME

MAJEED SYNDROME AT A GLANCE

- Very rare autosomal recessive autoinflammatory disorders, Majeed syndrome (OMIM #609628).
- Mutations in *LPIN2*, on chromosome 18p, encoding the protein lipin-2.
- Cutaneous features include a neutrophilic dermatosis seen in Sweet syndrome.
- Extracutaneous features include early-onset chronic recurrent multifocal osteomyelitis (CRMO) and congenital dyserythropoietic anemia (CDA).
- Dermatopathology: neutrophilic infiltrate in the dermis and no histologic evidence of vasculitis.
- NSAIDs or corticosteroids for the treatment of CRMO; red blood cell transfusion for the treatment of CDA if clinically indicated.

EARLY-ONSET INFLAMMATORY BOWEL DISEASE (IBD)

EARLY-ONSET INFLAMMATORY BOWEL DISEASE (IBD) AT A GLANCE

- Very rare autosomal recessive disorder, early onset IBD (OMIM #613148).
- Mutations in *IL10RA*, on chromosome 11q23 or on IL10RB, on chromosome 21q22, encoding the IL-10 receptor
- Cutaneous features can include early onset folliculitis, enterocutaneous fistulae, perianal abscess and anocutaneous fistulas.
- Extracutaneous features are dominated by the early onset, before the age of 1 year of early onset enterocolitis.
- Corticosteroids, NSAIDs, azathioprine, anti-TNF agents, and in severe cases bone marrow transplantation.

Chapter 135 :: Xanthomatoses and Lipoprotein Disorders

:: Ernst J. Schaefer & Raul D. Santos

XANTHOMATOSES AND LIPOPROTEIN DISORDERS AT A GLANCE

- Several lipoprotein disorders manifest as xanthomas, which contain cholesterol and triglycerides in macrophages.
- Tendinous xanthomas with thickening of the Achilles tendons and disposition in tendons on the hands, elbows, and knees are observed in familial hypercholesterolemia (FH), phytosterolemia, or cerebrotendinous xanthomatosis (CTX).
- Familial Hypercholesterolemia is diagnosed by finding a markedly elevated low-density lipoprotein (LDL) cholesterol level (usually >300 mg/dL), which can be treated with statins, ezetimibe, anion exchange resins and, if necessary, LDL apheresis.
- Xanthelasma on the eyelids are common and can be associated with elevated LDL cholesterol, but more often are seen in patients with normal lipids and treated cosmetically.
- Phytosterolemia, associated with moderately elevated LDL cholesterol levels and markedly elevated plasma β-sitosterol and campesterol, is best treated with ezetimibe.
- Cerebrotendinous xanthomatosis is due to markedly elevated plasma levels of cholestanol and therapy consists of oral chenodeoxycholate to prevent progression of xanthomas and neurologic disease.
- Tubo-eruptive, planar, and palmar xanthomas can be observed with combined hyperlipidemia as well as occasionally with marked high-density lipoprotein deficiency, and can be treated with dietary modification, statins, fibrates, and niacin.
- Eruptive xanthomas are usually due to severe hypertriglyceridemia (fasting level >1,000 mg/dL, with chylomicrons present), and are often transient.
- Patients with severe hypertriglyceridemia are at increased risk of pancreatitis and need to restrict dietary fat and sugars, control diabetes if present, and use fibrates and fish oil.
- Xanthomas are occasionally observed in patients with monoclonal gammopathies or multiple myeloma.

XANTHOMAS

Xanthomas are plaques or nodules consisting of abnormal lipid deposition and foam cells in skin or in tendons. They do not represent a disease but rather are signs of a variety of lipoprotein disorders. Xanthomas are occasionally seen without an underlying metabolic effect. Xanthomas are thought to develop through several mechanisms. Through scavenger receptors for enhanced low-density lipoprotein (LDL) uptake, macrophages (converted from monocytes) incorporate lipid that has been transported through the capillary walls, thus becoming foam cells. Foam cells can also develop as a result of in situ lipid synthesis by the macrophage. Further, lipid that has been extravasated by the capillaries can also recruit additional foam cells into an already established xanthoma. Extravasated and oxidized LDL recruits foam cells by inducing vascular cellular adhesion molecule and E-selectin.[1,2] Local factors such as heat, movement, and friction may increase LDL capillary leakage, and, hence, result in the development of xanthomata.[3] These local factors help explain the location of tuberous xanthomas, tendinous xanthomas, and xanthelasmata.

CLINICAL FINDINGS

CUTANEOUS LESIONS. Clinically, xanthomas can be classified as eruptive, tubo-eruptive or tuberous, tendinous, or planar.[4] Planar xanthomas include xanthelasma palpebrarum/xanthelasma, xanthoma striatum palmare, and intertriginous xanthomas. There are characteristic clinical phenotypes associated with specific metabolic defects (Tables 135-1 and 135-2 showing older Frederickson classification).

Eruptive xanthomata are multiple, reddish-yellow papules that appear suddenly and are arranged in crops on the extensor surface of the extremities and the buttocks (Figs. 135-1 and 135-2). Tuberous xanthomata are nodules that are frequently localized to the extensor surfaces of the elbows, knees, knuckles, and buttocks (Fig. 135-3). Tendinous xanthomata are

TABLE 135-1
Clinical Presentations of Xanthomas

Type of Xanthoma	Genetic Disorders	Secondary Disorders
Eruptive	Familial lipoprotein lipase deficiency ApoC-II deficiency ApoA-I and apoA-I/C-III deficiency Familial hypertriglyceridemia Familial hypertriglyceridemia with chylomicronemia	Obesity Cholestasis Diabetes Medications: retinoids, estrogen therapy, protease inhibitors
Tuberous	Familial hypercholesterolemia Familial dysbetalipoproteinemia Phytosterolemia	Monoclonal gammopathies Multiple myeloma Leukemia

Tonsillar	Tangier disease	

apo = apolipoprotein.

TABLE 135-2
Frederickson Classification of Familial Hyperlipidemias (Only Occasionally Used)

Frederickson Classification	Condition	Defect	Lipoprotein Increase	Type of Xanthoma
Type I	Familial chylomicronemia	Decreased lipoprotein lipase or altered apoC-II	Chylomicrons (and VLDL)	Eruptive xanthomata
Type IIa	Familial hypercholesterolemia Heterozygous Homozygous	LDL receptor or apoB deficiency	LDL	Tendon, tuberous, plane xanthomas (xanthelasma and intertriginous) 15% with xanthoma by second decade Xanthomata by age 6 years
Type IIb[a]	Familial combined hypercholesterolemia	Decreased LDL receptor and increased apoB	LDL and VLDL	Usually absent, but can have xanthomas as in type IIa
Type III	Familial dysbetalipoproteinemia	Defective apoE-2 synthesis	IDL	Palmar, tuberous, tubo-eruptive xanthoma, xanthelasma
Type IV[b]	Familial hypertriglyceridemia (pure)	Increased VLDL production and decreased elimination	VLDL	Rare eruptive xanthomas
Type V	Mixed hyperlipidemia	Increased VLDL production and decreased LPL	VLDL and chylomicrons	Eruptive xanthomas

Most familial hyperlipidemias associated with xanthomas are rare.
[a]~10% of population.
[b]~16% of population.

Figure 135-1 Eruptive skin xanthomata characteristic of severe chylomicronemia.

Figure 135-2 Eruptive skin xanthomata in an African-American woman characteristic of severe chylomicronemia.

firm subcutaneous nodules found in fascia, ligaments, Achilles tendons, or extensor tendons of the hands, knees, and elbows (Fig. 135-4). Planar xanthomata are yellow macules, soft papules, or plaques found commonly on the upper eyelids (xanthelasma palpebrarum), the wrists and palms (xanthoma striatum palmare) (Fig. 135-5), and in intertriginous areas. Xanthelasmas (eFig. 135-5.1 in online edition) can be found in patients with elevated LDL cholesterol levels, but most often occur in patients with relatively normal lipid levels and the occurrence of these lesions on the eyelids usually not associated with coronary heart disease (CHD). If xanthelasmas cause cosmetic concern, treatment options include surgical excision,[42] ablative laser therapy, trichloroacetic acid, or cryotherapy.[40]

HISTOPATHOLOGY. Foam cells are macrophages that contain lipid. These cells characterize xanthomata.

Figure 135-3 Tubo-eruptive and tuberous xanthomata typical of familial dysbetalipoproteinemia. **A.** Knee. **B.** Palm.

Figure 135-4 Tendon xanthomata typical of heterozygous familial hypercholesterolemia. Similar xanthomata occur in patients with familial defective apolipoprotein B-100, cerebrotendinous xanthomatosis, and sitosterolemia.

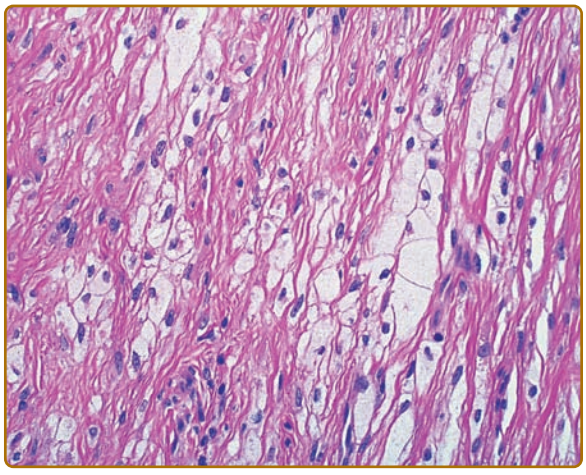

Figure 135-6 Histopathologic evaluation of skin from a tuberous xanthoma reveals foam cells.

Along with foam cells, eruptive xanthomata often consist of lymphoid cells, histiocytes, neutrophils, and, frequently, free lipid in the dermis. Tuberous xanthomata reveal foam cells and cholesterol clefts (Fig. 135-6). Cholesterol is doubly refractile whereas other types of lipid are not. Tendon xanthomata are histopathologically similar to tuberous xanthomata; however, xanthelasmata

Figure 135-5 Signs of dysbetalipoproteinemia due to apolipoprotein E deficiency. Tubo-eruptive xanthomas are seen on the ears (**A**), elbows (**C**), and hands (**D**), while palmar xanthomas in the creases of the hands are also observed (**B**).

BOX 135-1 DIFFERENTIAL DIAGNOSIS OF XANTHOMAS

- Eruptive xanthomas
  - Sarcoid
  - Interstitial granuloma annulare
  - Xanthoma disseminatum
  - Juvenile xanthogranulomas
- Tuberous or tendinous xanthomas
  - Cyst
  - Lipoma
  - Neurofibroma
- Plane xanthomas
  - Pseudoxanthoma elasticum
  - Amyloidosis
  - Sarcoidosis
- Xanthelasma
  - Syringoma
  - Sebaceous hyperplasia
  - Adnexal neoplasms

can be differentiated by their superficial location. Along with the foam cells, xanthelasmata may reveal striated muscle, vellus hair, and/or a thinned epidermis, indicative of the superficial location.[5]

DIFFERENTIAL DIAGNOSIS

See Box 135-1.

TREATMENT

The treatment for xanthomas depends on the underlying etiology (see below).

LIPID AND LIPOPROTEIN METABOLISM

See Fig. 135-7.

CHOLESTEROL

Cholesterol is a waxy substance of molecular weight 387 Da, and is by far the most abundant sterol in plasma. Cholesterol is synthesized in cells in the body, and this source accounts for about 75% of the cholesterol in the bloodstream. Cholesterol serves as a precursor for the bile acids—cholic acid and chenodeoxycholic acid, and steroid hormones including estrogen, testosterone, and cortisol. Cholesterol is also an important constituent of cell membranes. Precursors of cholesterol include lathosterol and desmosterol, which can be measured in plasma or serum and high values indicate increased cholesterol production. Subjects who overproduce cholesterol have elevated absolute levels of these constituents as well as increased values normalized to blood cholesterol levels. Cholesterol production is increased in patients with obesity and metabolic syndrome. There are also patients who have defects in producing the bile acid chenodeoxycholate from cholesterol, leading to cerebrotendinous xanthomatosis.

There are many steps in the cholesterol synthesis pathway from acetate to cholesterol. The rate-limiting enzyme in cholesterol synthesis is 3-hydroxy-3-methylglutaryl CoA reductase or HMG-CoA reductase. Statins competitively inhibit this enzyme, thereby lowering cholesterol production in the body, and decreasing cellular cholesterol synthesis by up to 80%. The cells in the body respond by increasing the level and activity of LDL receptors on their surface, enhancing the clearance of LDL particles from the bloodstream, and lowering LDL cholesterol levels in plasma.[3] However, in intestinal cells statins can also increase the amount of cholesterol absorption. Statins are especially effective in subjects who have elevated markers of cholesterol production, and are least effective in patients with elevated plasma markers of absorption.[31]

Cholesterol is also absorbed in the intestine. About 25% of the cholesterol found in the bloodstream is from dietary sources. The cholesterol found in the intestine is derived from the diet and also made by the liver, secreted into the bile, and reabsorbed. Major dietary sources include eggs, butter, whole milk, and animal fats as found in meat.[3] The equivalent substances to cholesterol in plant cells are known as plant sterols (β-sitosterol and campesterol). Almost all of dietary cholesterol and plant sterols are transported into the intestine via the Niemann-Pick C-like protein 1 (NPC1L1) transporter.[32–35] This process is blocked about 50% by ezetimibe, a specific inhibitor of NPC1L1.[34] Cholesterol in the intestinal cell is either placed onto chylomicrons or high-density lipoproteins (HDL) for entry into the bloodstream, stored in the intestine as either free cholesterol or cholesteryl ester (cholesterol with a fatty acid attached), or transported back out into the intestinal lumen via the action of the two transporters—ATP-binding cassette transporters G5 and G8 (ABCG5 and ABCG8). About 50% of the intestinal cholesterol and more than 95% of the intestinal β-sitosterol and campesterol are transported back out into the intestinal lumen via these ABC transporters. Patients who have defects in ABCG5 and ABCG8 have elevated plasma levels of β-sitosterol as in phytosterolemia, and often develop tendinous xanthomas.[5]

PLASMA LIPOPROTEINS

Cholesterol and triglyceride along with phospholipids are carried in plasma or serum on lipoproteins. Lipoproteins have a surface layer of phospholipids (each phospholipid has two fatty acids attached to it) with the fatty acids directed toward the core of the particle, as well as proteins known as apolipoproteins, and free cholesterol. The hydrophobic components of

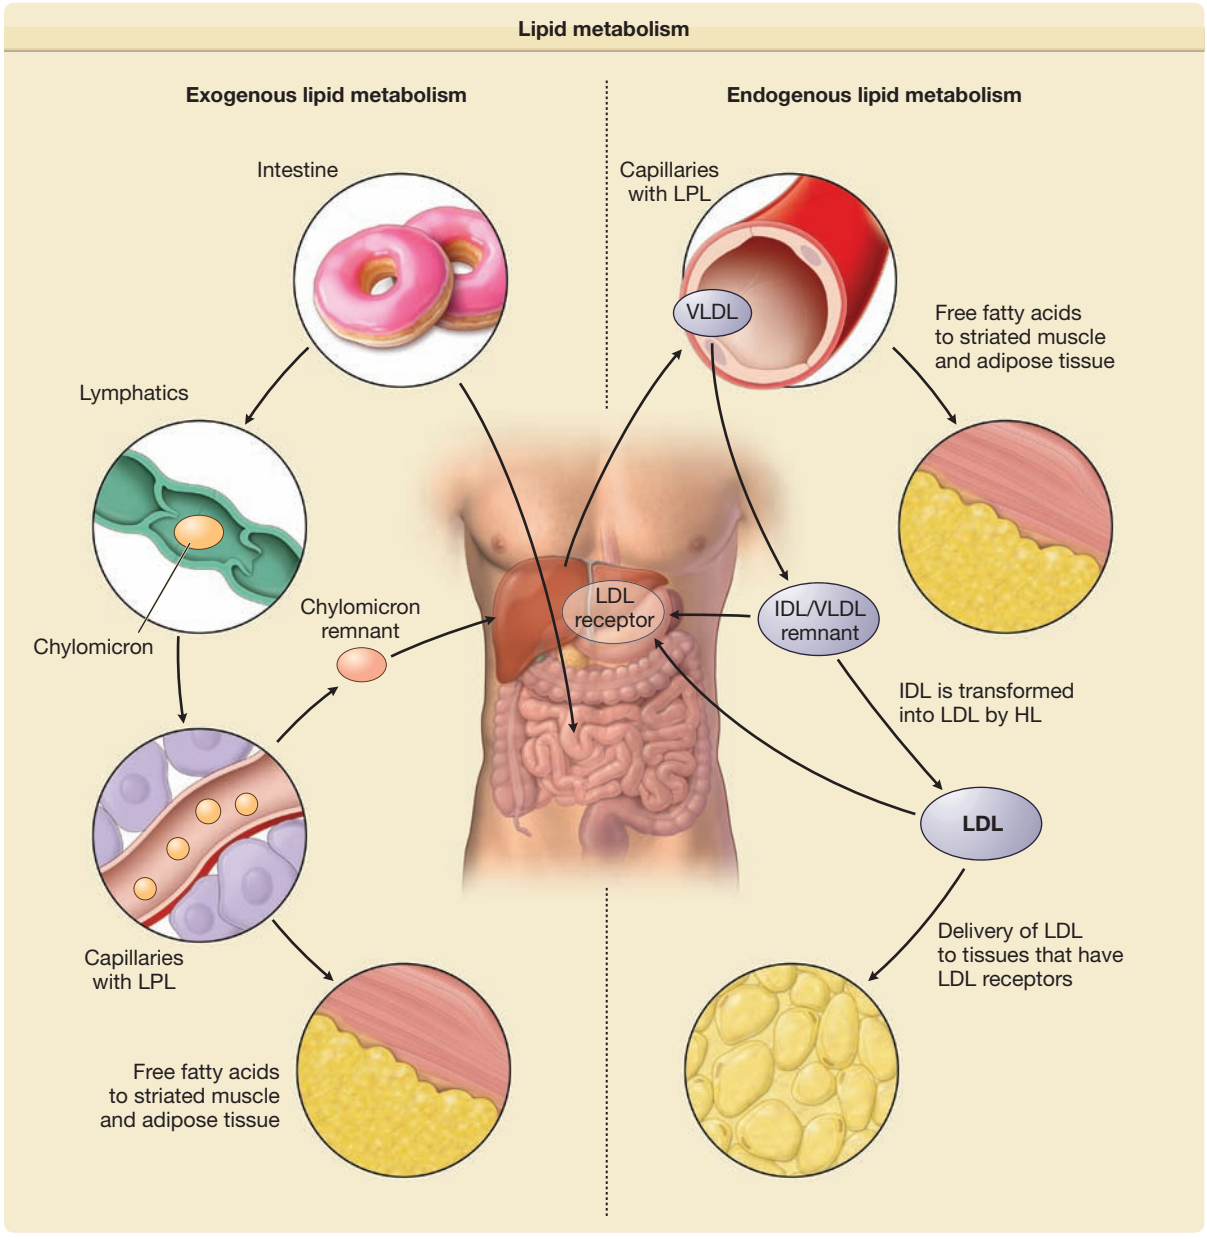

Figure 135-7 Lipid metabolism. The exogenous pathway of lipid metabolism involves eating foods that contain fat and delivering the fatty acids to tissues. The triglycerides in the intestines are packaged into chylomicrons in the intestinal enterocytes. Capillary lipoprotein lipase (LPL), which requires apolipoprotein IIC (apoC) as a cofactor, hydrolyzes the triglycerides and releases fatty acids to the peripheral tissues. The remaining chylomicron particle is called a *chylomicron remnant* and is recycled by the liver in a process that requires apoE as a ligand for the LDL receptors in the liver. The endogenous pathway of lipid metabolism involves the hepatic production of very low-density lipoprotein (VLDL) and the delivery of free fatty acids to peripheral tissues. VLDL particles have apoB-100 apoB-100 instead of apoB-48 on the chylomicron. LPL, which requires apoC as a cofactor, hydrolyzes the triglycerides and releases fatty acids to the peripheral tissues. This remnant is called an *intermediate-density lipoprotein* (IDL). The LDL receptor of the liver removes these remnants by binding to apoE on the remnant. IDL can also be transformed into LDL by hepatic lipase (HL) in the liver. The new particles of LDL can bind to the LDL receptor through apoB-100.

lipoproteins, namely, cholesteryl ester and triglyceride, are carried within the core of generally spherical lipoprotein particles. Plasma lipoproteins exist in a variety of sizes and densities, ranging from very large triglyceride-rich lipoproteins of density <0.94 g/mL made in the intestine (chylomicrons) to small HDL of density up to 1.21 g/mL.

A model of a spherical lipoprotein particle with proteins (*yellow*), phospholipids with two fatty acids attached (*blue*), and free cholesterol (*green*) on the particle surface, and triglyceride with three fatty acids attached (*purple*) and cholesteryl ester with one fatty acid attached (*green*) in the core of the particle is shown in eFig. 135-7.1 in online edition.

CHYLOMICRONS

Lipoproteins known as chylomicrons are made in the intestine and vary greatly in molecular weight (50–1,000 × 10^6 Da) and size (diameter 75–1,200 nm), have a plasma density of <0.93 g/mL, and migrate at the origin on lipoprotein electrophoresis. These particles are very rich in triglyceride (about 85% by weight in the core of the particle) and contain about 3% cholesteryl ester. These particles can also carry significant amounts of fat-soluble vitamins in their core, namely, vitamin A as retinyl palmitate, carotenoids, vitamin D, vitamin E as α- or γ-tocopherol, and vitamin K. On their surface these particles contain about 2% protein, 2% free cholesterol, and 7% phospholipids. The major protein of these particles is known as apolipoprotein (apo) B-48. After chylomicrons are released into the lymph, they pick up apoA-I, apoA-IV and the C apolipoproteins (C-I, C-II, and C-III) on their large surface. The average daily production of apoB-48 in humans is about 2 mg/kg/day.[3]

Once chylomicrons enter the bloodstream, much of the triglyceride is rapidly removed via the action of lipoprotein lipase (LPL). LPL cleaves the free fatty acids off the glycerol backbone of triglycerides. The apoC-II acts as a cofactor for LPL in this reaction and apoA-V promotes LPL-mediated triglyceride lipolysis. The free fatty acids are taken up by adjacent myocytes and adipocytes. Some free fatty acids bind to albumin and are taken up by fat tissue or transported to a variety of other tissues in the body, including the liver. In the fat the free fatty acids are converted back into triglyceride for long-term energy storage. ApoC-III inhibits this process of lipolysis. When much of the chylomicron triglyceride has been removed, the particles pick up cholesteryl ester from HDL in exchange for triglyceride via the action of cholesteryl ester transfer protein (CETP). They then are much smaller particles and are called chylomicron remnants. In this process of being metabolized to remnants, chylomicrons have lost virtually all of their surface apoA-I, apoA-IV, apoA-V, and C apolipoproteins to HDL, but have retained all of their apoB-48, and have picked apoE from HDL. While the plasma residence time of chylomicron triglyceride is about 5–10 minutes that of chylomicron apoB-48 is about 5 hours.[3] Chylomicron remnants are taken up by the liver, a process that is mediated by the binding of apoE to the LDL receptor.[3]

VERY LOW-DENSITY LIPOPROTEINS

Very low-density lipoproteins (VLDLs) are made in the liver. They vary in molecular weight (10–80 × 10^6 Da) and in size (diameter 30–80 nm), have a plasma density of 0.93–1.006 g/mL, and migrate in the prebeta region on lipoprotein electrophoresis. These particles are rich in triglyceride (about 60% by weight in the core of the particle) and contain about 10% cholesteryl ester. On their surface these particles contain about 8% protein, 7% free cholesterol, and 15% phospholipids. Although they resemble chylomicrons, the major protein of these particles is apoB-100, compared to apoB-48 in chylomicrons. Other surface proteins include apoC-I, apoC-II, and apoC-III. In the fed state, the average daily production of VLDL apoB-100 in humans is about 20 mg/kg/day.[3] When VLDLs enter the bloodstream, the particles pick up apoE and other apolipoproteins from HDL. Most of the triglycerides in VLDLs are rapidly removed via the action of LPL, similar to intestinal chylomicron particles. In the fat, the free fatty acids are converted back into triglyceride for long-term energy storage. As with chylomicrons, apoC-III inhibits this process of lipolysis. Once VLDL dissociates from LPL, they become intermediate-density lipoproteins (IDLs), which have approximately the same amount of cholesterol and triglyceride. The liver takes up IDL by binding apoE to the LDL receptor and subsequent endocytosis of the IDL. The rest is converted to LDL by hepatic lipase (HL). This conversion process takes about 4–5 hours.[3]

LOW-DENSITY LIPOPROTEINS

Low-density lipoproteins (LDLs) are the end product of VLDL catabolism and are mainly produced from the conversion of VLDL to IDL and then to LDL. They are the major cholesterol-transporting lipoproteins in the plasma. LDL have a molecular weight of about 2 × 10^6 Da, a diameter of 18–25 nm, a plasma density of 1.019–1.063 g/mL, and migrate in the beta region on lipoprotein electrophoresis. These particles are rich in cholesteryl ester (about 40% by weight in the core of the particle) and contain about 5% triglyceride. On their surface, these particles contain about 25% protein, 10% free cholesterol, and 20% phospholipids. The predominant protein of LDL is apoB-100. Occasionally, LDL can contain trace amounts of other surface proteins, namely, apoC-I, apoC-II, apoC-III, and apoE. In the fed state, the average daily conversion of VLDL apoB-100 to LDL apoB-100 in humans takes about 4–5 hours, and is about 12 mg/kg/day. In normal plasma, LDL contains about 60%–70% of the total cholesterol and about 80%–90% of the total apoB. LDL apoB-100 has a plasma residence of about 3.5 days, and is taken by various tissues through the action of the LDL receptor. LDL has been divided into large LDL (density 1.019–1.044 g/mL) and small dense LDL (density 1.044–1.063 g/mL). Small dense LDL is reported to be more atherogenic than large LDL, and its apoB-100 has also has a significantly longer residence time than that of apoB-100 in large LDL.[3]

Another lipoprotein particle similar to LDL is lipoprotein (a) or Lp(a). This particle is often a small dense LDL particle, with a protein known as apo(a) attached to apoB-100. The apo(a) protein has multiple and variable copies of kringle 4-like domains and one copy of a kringle 5-like domain. These kringles have a high degree of homology with the kringle domains of plasminogen, important for clot lysis. High levels of Lp(a) (>30 mg/dL) are associated with an increased risk of CHD.[36,37] Lp(a) is atherogenic because it not only is directly deposited in the artery wall, but also because it may prevent clot lysis by plasminogen. Moreover,

Lp(a) serves as an acceptor of oxidized phospholipid from LDL.

HIGH-DENSITY LIPOPROTEINS

High-density lipoproteins (HDLs) (density 1.063–1.21 g/mL) contain about 50% protein, 30% phospholipid, 20% triglyceride, and 5% triglyceride by weight. HDLs show alpha mobility on lipoprotein electrophoresis and have a diameter of about 5.5–12 nm. The major proteins of HDL are apoA-I and apoA-II, and HDL apoA-I has a residence time of about 4.5. HDL participate in reverse cholesterol transport, in which HDL pick up cholesterol from cells from peripheral tissues, and then deliver them to the liver for excretion or transfer it to triglyceride-rich lipoproteins in exchange for triglyceride. In HDL, the enzyme lecithin–cholesterol acyltransferase (LCAT) catalyzes the formation of the cholesterol ester, which are later transferred to lipoproteins via CETP. Decreased HDL cholesterol <40 mg/dL is a significant CHD risk factor.[1]

Xanthomas are caused by excess deposition of lipid in skin or in tendons, with resultant monocyte migration and uptake of lipid by scavenger receptor on the surface of macrophages (converted from monocytes). Clinically, patients who develop accumulations of chylomicrons and VLDL, remnant lipoproteins, LDL, Lp(a), synthesize excess cholestanol, overabsorb plant sterols, have marked decreases in HDL, or have monoclonal gammopathies or multiple myeloma can develop xanthomas.[4–60]

Patients that have defects in the catabolism of triglycerides on chylomicrons and VLDL can develop severe hypertriglyceridemia, which can lead to eruptive xanthomas. Patients that have defects in the clearance of chylomicron and VLDL remnant particles can develop combined hyperlipidemia and tubo-eruptive xanthomas. Such xanthomas can also be observed in marked HDL deficiency due to lack of HDL apoA-I production. Patients that have defects in the clearance of LDL can develop very high LDL cholesterol levels and may develop tendinous xanthomas. Such xanthomas can also be seen in patients who synthesize excess cholestanol or overabsorb pant sterols. Both cholestanol and plant sterols (β-sitosterol and campesterol) are then carried in excess on LDL particles.

Xanthomas are uncommonly seen in common familial lipoprotein disorders associated with premature CHD.

Common genetic lipoprotein disorders associated with premature coronary heart disease include familial Lp(a) excess (Lp(a) >30 mg/dL), seen in about 20% of families with premature CHD, familial combined hyperlipidemia (LDL cholesterol >160 mg/dL and triglyceride >150 mg/dL) (15% of families) and familial dyslipidemia (triglycerides >150 mg/dL and HDL cholesterol <40 mg/dL) (15% of families), and familial hypoalphalipoproteinemia (isolated low HDL cholesterol <40 mg/dL) (5% of families).[38] Patients with markedly elevated Lp(a) levels or with markedly elevated levels of LDL cholesterol and triglycerides due to familial combined hyperlipidemia occasionally develop tendinous or tubo-eruptive xanthomas. In addition, patients with elevated levels of triglycerides (>400 mg/dL) and low HDL cholesterol (<40 mg/dL) or marked HDL deficiency alone may occasionally develop tubo-eruptive xanthomas. Tangier disease is a rare, autosomal-recessive condition that often leads to CHD, but is not typically associated with xanthomas.

FAMILIAL DISORDERS IN WHICH XANTHOMAS ARE MORE LIKELY TO OCCUR

In contrast to the previously mentioned disorders where any form of xanthoma is rare, the disorders listed below, are commonly associated with xanthomas.

DISORDERS ASSOCIATED WITH TENDINOUS XANTHOMAS

Tendinous xanthomas are usually associated with markedly elevated levels of either LDL cholesterol (>300 mg/dL), or plant sterols (β-sitosterol and campesterol) or cholestanol within LDL.[4–30]

FAMILIAL HYPERCHOLESTEROLEMIA

FAMILIAL HYPERCHOLESTEROLEMIA AT A GLANCE

- Homozygous familial hypercholesterolemia, heterozygous familial hypercholesterolemia, or defective apoliprotein-B100 causes this type of hyperlipidemia.
- Severe hypercholesterolemia can present with tendinous or tuberous xanthomas.
- Usually treated by statins.
- Significant risk of coronary atherosclerosis.

About 1 in 500 subjects in the general population, and about 1% of families with premature CHD (age <60 years) have heterozygous familial hypercholesterolemia (type II hyperlipoproteinemia), due to delayed clearance of LDL associated with defects in the LDL receptor or apoB genes.[4–21] These patients can develop arcus senilis (eFig. 135-7.2 in online edition, tendinous xanthomas in the Achilles tendons (Fig. 135-4 and eFig. 135-7.3 in online edition) and on the hands, as well as xanthelasma (eFig. 135-5.1 in online edition), due to cholesterol deposition. Homozygous patients are also at risk for the development of tubo-eruptive xanthomatous plaques (over the extremities, buttocks, and hands) (Fig. 135-8 and eFig. 135-8.1 in online edition). Intertriginous xanthomas are rare but usually associated with this

Figure 135-8 Tubo-eruptive xanthomas. This 10-year-old boy with homozygous familial hypercholesterolemia shows tubo-eruptive xanthomas on his hands (**A**), elbows (**B**), and knees (**C**); the same locations demonstrate marked regression of xanthomas 1 year after he started every 2 weeks LDL apheresis (**D**, **E** and **F**).

condition. The rate of xanthoma deposition and growth is associated with the duration and severity of the LDL elevation, and can regress significantly with weekly LDL apheresis over time (Fig. 135-8). Heterozygotes with this disorder usually have LDL cholesterol levels in excess of 300 mg/dL, while homozygotes often have value over 600 mg/dL.[4–21] Triglyceride and HDL levels are typically normal. Homozygotes are at high risk of developing CHD and aortic stenosis prior to age 20 years, unless treated.[4] Optimal therapy in homozygotes includes LDL apheresis, as well as ezetimibe and high-dose statin therapy. Heterozygotes can usually be effectively treated with the combination of a statin and ezetimibe. Effective control of LDL cholesterol levels below 130 mg/dL will prevent the development of xanthomas in these patients, or promote their regression.[4–21] It should be noted now that many FH patients never develop xanthomas because of the availability of effective statin therapy.

PHYTOSTEROLEMIA. Patients with rare defects in the ABCG5 and ABCG8 transporters have markedly elevated plasma levels of plant sterols or phytosterols (specifically β-sitosterol and campesterol)

and develop tendinous and tuberous xanthomas and premature CHD.[22–26] Normally, these sterols are excreted very efficiently back into the intestinal lumen by the intestinal ABCG5 and ABCG8 transporters. However, these patients have defects in these transporters resulting in the retention of these sterols in the intestinal cell and their secretion on chylomicrons into the plasma space. The definitive diagnosis in these patients is made by the measurement of plasma sterols by gas chromatography, with markedly elevated levels of β-sitosterol and campesterol. Such subjects are at increased risk for developing CHD, and the most effective treatment for them is ezetimibe, which lowers their levels of plant sterols by 50% and stabilizes xanthomas.[22–26]

CEREBROTENDINOUS XANTHOMATOSIS. There are a rare group of patients with cerebrotendinous xanthomatosis who develop cholestanol deposits in their tendons and brain tissue, despite have only modest elevations in plasma cholesterol levels. They are at increased risk of developing severe neurologic disease including cerebellar ataxia and dementia. They cannot convert cholesterol to chenodeoxycholate, one of the major bile acids, due to defects in the sterol 27-hydoxylase gene.[27–30] Instead, they produce excess amounts of cholestanol, a physiologic sterol found in lower concentrations than cholesterol. The diagnosis is established by the finding of markedly elevated plasma cholestanol levels as measured by gas chromatography. The treatment of choice is 250 mg orally three times daily of chenodeoxycholate, which prevents them from getting severe neurologic disease, and also prevents the progression of their xanthomas.

TUBO-ERUPTIVE, PALMAR, AND PLANAR XANTHOMAS. Tubo-eruptive and palmar xanthomas are observed in patients with significant combined elevations of both plasma or serum cholesterol and triglycerides, due to increases in intestinal and liver remnant lipoprotein particles (dysbetalipoproteinemia). Very rarely, tubo-eruptive, planar, and palmar xanthomas are observed in severe HDL deficiency (HDL cholesterol levels <10 mg/dL) or in patients with monoclonal gammopathies or multiple myeloma.

DYSBETALIPOPROTEINEMIA AT A GLANCE

- Defined by accumulation of chylomicron remnants and very low-density lipoprotein remnants.
- Xanthoma striatum palmare is the characteristic cutaneous feature.
- Tuberous xanthomas can also be seen.
- Treatment: fibrates, nicotinic acid, or statin therapy.

DYSBETALIPOPROTEINEMIA

Patients with dysbetalipoproteinemia (also called type II hypolipoproteinemia or Frederickson type III hyperlipidemia) have elevations in total plasma cholesterol and triglyceride that are both in the range of 250–500 mg/dL. Their non HDL cholesterol (total cholesterol—HDL cholesterol) and remnant lipoprotein cholesterol levels are markedly elevated (>200 and >100 mg/dL, respectively), their direct LDL cholesterol levels are usually decreased, and their HDL cholesterol levels are usually relatively normal. These patients usually present in adulthood with tubo-eruptive xanthomas on their elbows, hands, and even ears, and palmar xanthomas. They also develop premature CHD, other vascular disease, gout, and diabetes. They usually have the apoE2/2 genotype, but may occasionally have apoE deficiency (undetectable plasma apoE) or hepatic lipase deficiency. Deficiency in apoE can lead to very defective clearance of both chylomicron and VLDL remnants from plasma. With deficiency of apoE, HDL cholesterol levels may be elevated.[43–46] Tubo-eruptive and palmar xanthomas in a homozygous patient with dysbetalipoproteinemia or type III hyperlipoproteinemia due to familial apoE deficiency with undetectable plasma apoE levels is shown in Fig. 135-5.[44] The patient pictured died at age 59 years of a stroke. The diagnosis in these patients is established by the measurement of apoE in plasma or serum and/or apoE genotyping of their DNA.[43,44] When apoE is present and the genotype is normal (i.e., apoE3/3), the patient may have familial hepatic lipase deficiency diagnosed by the measurement of hepatic lipase activity in postheparin plasma (obtained 10 minutes after the injection of 100 units/kg body weight of heparin). The plasma must be promptly isolated and frozen at –80°.[45,46] Treatment of these patients consists of a diet low in cholesterol, saturated fat, and sugar, as well as niacin 2 g/day, micronized fenofibrate 200 mg/day, and/or a statin. Treatment often can lead to complete regression of their xanthomas. These patients are also at increased risk of developing diabetes, gout, and premature CHD.

MARKED HDL DEFICIENCY. Undetectable plasma levels of apoA-I can be observed in various familial forms of homozygous HDL deficiency (HDL cholesterol <10 mg/dL) such as apoA-I/C-III/A-IV deficiency, apoA-I/C-III deficiency, or apoA-I deficiency.[47–54] These patients generally have normal LDL cholesterol and normal or decreased triglyceride levels, and often develop strikingly premature CHD in their 30s. The defect in these patients is an inability to produce apoA-I, the major protein of HDL. Planar xanthomas have been observed in homozygous apoA-I/C-III deficiency, and marked tubo-eruptive and planar xanthomas filled with lipid-laden macrophages have been noted in homozygous apoA-I deficiency, along with palmar and planar xanthomas (Fig. 135-9).[49–54] These patients also often have corneal opacification were their eyes are examined by slit lamp examination. Therapy in these patients consists of optimizing all other CHD risk factors (LDL cholesterol <70 mg/dL, triglycerides <150 mg/dL, no smoking, systolic blood pressure <130 mmHg, and glycosylated hemoglobin <7.0%), because it is not

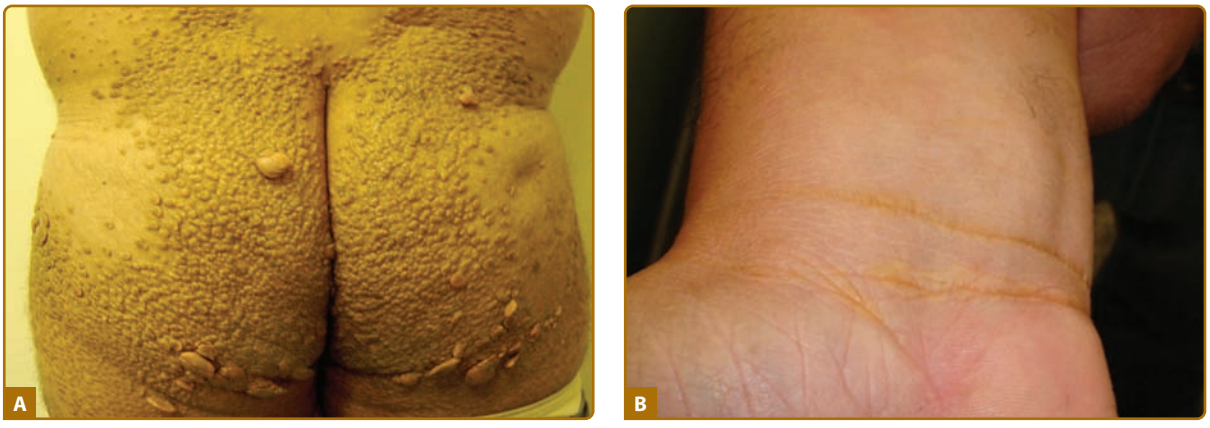

Figure 135-9 Marked HDL deficiency. This 39-year-old man with apoA-I deficiency shows tubo-eruptive xanthomas on the buttocks and lower back (**A**) and yellow creases on the palms of the hands and wrists (**B**).

feasible to raise their HDL cholesterol levels without gene therapy, which is still unavailable.

XANTHOMAS AND SYSTEMIC DISEASE

Various types of xanthomas, including tubo-eruptive and planar xanthomas, have been observed in patients with monoclonal gammopathies, multiple myeloma, lymphoma (Fig. 135-10) and various forms of leukemia.[55–58] It is known that immunoglobulins can bind to plasma lipoprotein particles and in some cases, can markedly delay the clearance of chylomicron remnants or VLDL remnants, resulting in combined hyperlipidemia or dysbetalipoproteinemia, and the potential for lipid deposition in many tissues, including the skin.

Figure 135-10 Diffuse plane xanthoma in a patient with lymphoma.

The treatment consists of management of the underlying disorder, as well as fenofibrate therapy.

Prolonged obstruction of the biliary tree leads to accumulation of cholesterol in the serum. Causes include primary biliary cirrhosis and secondary biliary obstruction. Serum cholesterol is high in unesterified cholesterol. Long-term hypercholesterolemia can lead to plane xanthomas (beige–orange plaques on hands, feet, and trunk), xanthelasma, and occasionally, tuberous xanthomas. Patients with prolonged biliary obstruction can also manifest jaundice, pruritus, and hyperpigmentation of the skin. Treatment involves relieving the underlying cause of obstruction. The underlying treatment is the use an anion exchange resin to prevent pruritus, and liver transplantation for stage 4 disease.

ERUPTIVE XANTHOMAS

Eruptive xanthomas may rapidly emerge and then disappear as rapidly. They are associated with severe hypertriglyceridemia, or moderate hypertriglyceridemia aggravated by uncontrolled diabetes or oral estrogen therapy. Eruptive xanthomas can also be a result of secondary causes, and it is important to rule out obesity, excessive alcohol intake, diabetes (type 2), and drugs as a cause of these lesions. Drugs that can cause eruptive xanthomas include retinoids, estrogen therapy, and protease inhibitors.

SEVERE HYPERTRIGLYCERIDEMIA (SOMETIMES CALLED FREDERICKSON TYPE I HYPERLIPIDEMIA)

Patients with this disorder generally present in childhood or young adulthood with plasma triglyceride values over 1000 mg/dL. They usually have defects in lipoprotein lipase, but may also have apoC-II deficiency, or mutations in the *ApoA-V* gene.[59,60] Plasma cholesterol levels are usually around about one-fifth to one-tenth of the triglyceride levels, with remnant lipoprotein cholesterol levels that are about twofold increased, direct LDL cholesterol levels that are less than 50 mg/dL,

FAMILIAL CHYLOMICRONEMIA SYNDROME AT A GLANCE

- Chylomicronemia and hypertriglyceridemia often presents with eruptive xanthomas.
- Chylomicronemia is due to lipoprotein lipase deficiency or apolipoprotein-C2 deficiency.
- Secondary causes of elevated chylomicrons include obesity, diabetes, alcohol abuse, or medications.
- Medications that can cause elevated triglycerides, and thus eruptive xanthomas, include oral retinoids, estrogen therapy, and protease inhibitors.
- There is very little risk of coronary atherosclerosis.
- Treatment is most commonly through dietary modification.

with HDL cholesterol levels that are usually around 20 mg/dL. These patients have marked elevations of chylomicrons and VLDL in plasma or serum, and its color is usually white. When lipoprotein lipase activity is measured in postheparin plasma (plasma obtained 10 minutes after injecting 100 units of heparin/kg of body weight, and promptly separated and frozen at –80°), it is usually very low or absent. However, some patients may have a deficiency of the activator protein of lipoprotein lipase, namely, apoC-II or abnormalities of apoA-V that modulates lipoprotein lipase activity. Patients with severe hypertriglyceridemia can present with recurrent episodes of severe abdominal pain and develop recurrent pancreatitis and enlarged livers because of triglyceride deposition in these organs. They can also develop transient eruptive xanthomas. Lipemia retinalis (milky plasma which can be visualized in retinal veins) is associated, but patients are generally are not at increased risk for CHD.

In general, the treatment of choice is dietary fat restriction to less than 15% of calories from fat, but to ensure some intake of essential fatty acids by using vegetable oil and fish oil capsules (1–2/day). Fenofibrate may help those that have decreased LPL activity, since fibrates are known to increase LPL gene expression and activity. In children the dose of generic micronized fenofibrate is 67 mg/day, while in adults the dose is 200 mg/day. When such patients present in adulthood, they are usually heterozygous for LPL deficiency or apoC-II deficiency, and are often obese, and diabetic. Sometimes, in women their disease has been exacerbated by oral estrogen therapy for the treatment of perimenopausal symptoms. Treatment with a low calorie, low saturated fat, and low refined carbohydrate diet is indicated in such patients. Weight loss is important if indicated, along with exercise, and tight control of blood glucose levels in diabetic patients. If after treatment for triglyceride elevation, with triglycerides below 300 mg/dL, their LDL cholesterol may become elevated, and at that point a statin may need to be added to control their LDL cholesterol levels.

XANTHOMAS IN CHILDREN

Xanthomas in children are uncommon and must always be investigated. The differential for xanthomas in children includes homozygous FH, phytosterolemia/sitosterolemia, cerebrotendinous xanthomatosis (CTX), and Alagille syndrome. If laboratory investigation reveals a childhood hyperlipidemia, treatment algorithms are available.[36]

In children, Alagille syndrome is an inherited syndrome of biliary hypoplasia leading to elevated serum cholesterol. Children with Alagille syndrome have a characteristic facies with a prominent forehead, hypertelorism, pointed chin, and nasal dystrophy. In Alagille syndrome, serum cholesterol is elevated when patients are young but can decrease over time. Cirrhosis develops in approximately 12% of patients with Alagille syndrome. Treatment for Alagille syndrome is medical management or, if cirrhosis develops, liver transplantation. Xanthomas have been found to resolve after liver transplantation.[35]

VERRUCIFORM XANTHOMA

Verruciform xanthomas commonly occur in the oral cavity and are discussed in Chapter 76. Histologically, it shows foamy histiocytes within elongated dermal papillae. Nonmucosal verruciform xanthoma is the characteristic lesion in *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects (CHILD) syndrome (see Chapter 49), and mutations in the 3β-hydroxysteroid dehydrogenase gene (the gene that is mutated in CHILD syndrome) have been shown to underlie two cases of sporadic verruciform xanthoma. Verruciform xanthomas have also been described in a variety of other skin disorders, among them in epidermolysis bullosa.

TESTING LIPID LEVELS

For dermatologists seeking to evaluate the causes of xanthomas or xanthelasmas, the standard approach is to order a serum or plasma lipid profile, performed after the patient fasts overnight. This test provides a measurement of the concentration of total cholesterol, triglyceride, HDL cholesterol, and calculated LDL cholesterol. A total cholesterol of >240 mg/dL and associated LDL cholesterol value of >160 mg/dL have been classified as elevated and are associated with an increased CHD risk.[1] A total cholesterol value of <200 mg/dL and an LDL cholesterol value of <100 mg/dL have been classified as optimal.[1] A triglyceride value of >150 mg/dL

has been classified as increased, while an HDL cholesterol of <40 mg/dL has been classified as decreased, and both of these abnormalities have been associated with an increased CHD risk.[1]

Occasionally, patients will have elevated total cholesterol levels due to increased levels of β-sitosterol (>225 μmoles/mmol of total cholesterol) and campesterol (>270 μmoles/mmol of total cholesterol), as in phytosterolemia, or elevated cholestanol, as in cerebrotendinous xanthomatosis.[22–30] These abnormalities can only be detected by measuring plasma sterols using gas chromatography. A triglyceride level of >1,000 mg/dL has been classified as markedly elevated and is associated with an increased risk of pancreatitis, as well as eruptive xanthomas.[55,56] A full evaluation of patients with xanthomas includes complete metabolic profile with a serum creatinine and a hepatic panel, fasting glucose, thyroid function tests, urine protein, a fasting lipid profile, lipoprotein(a), apoE genotyping and, as appropriate, measurement of β-sitosterol, campesterol, and cholestanol. These studies permit consideration of secondary causes of lipid abnormalities, particularly if the patient has elevations of LDL cholesterol (>160 mg/dL) or triglycerides (>150 mg/dL), or decreased levels of HDL cholesterol (<40 mg/dL). Diabetes and renal disorders, notably nephrotic syndrome, are both associated with elevated triglycerides and decreased HDL cholesterol. Hypothyroidism and obstructive liver disease (with elevated levels of alkaline phosphatase) are both often associated with elevated LDL cholesterol. Hepatocellular disease with elevated transaminases is often observed in patients with hypertriglyceridemia. Oral estrogens and alcohol intake can significantly raise triglyceride levels and raise HDL, while anabolic steroids usually markedly lower HDL cholesterol levels. If no secondary causes are present then a familial disorder may be present, and measuring lipids in first-degree relatives is warranted, especially when premature CHD and/or xanthomas runs in the family.[1]

TREATMENT OF HYPERLIPIDEMIAS

LIFESTYLE THERAPY

Lifestyle represents the cornerstone of therapy for lipid disorders. Increased physical activity (at least 30 min/day of walking, riding on an exercycle, or some other activity) as well as weight control are very important for preventing diabetes, lowering triglycerides, and raising HDL cholesterol levels.[1,3] In patients with elevated LDL cholesterol and high-risk patients, referral to a nutritionist for dietary restriction is appropriate.

Dietary management involves restriction of dietary saturated fat to <7% of calories, minimization of trans fats, restriction of dietary cholesterol to <200 mg/day, replacement of animal fats by vegetable oils, and increasing fish intake.[1] This is best accomplished by: (1) replacing butter with soft no trans fats margarine (including high plant sterol margarines) and vegetable oils (especially soybean and canola oils); (2) replacing whole milk, and cream with 1% low-fat or skim milk; (3) replacing red meat with chicken, turkey (white meat) or fish; and (4) replacing high-fat/high-sugar desserts, with fruits, vegetables, and whole grains. Replacing animal fat with vegetable oil has been shown to be an extremely powerful modality to reduce CHD risk, and polyunsaturated oils lower LDL cholesterol and increase reverse cholesterol transport.[1,3]

PHARMACOLOGIC AGENTS

Statins are the best available agents for lowering LDL cholesterol, followed by ezetimibe, and then resins. Fibrates, such as fenofibrate, are the best available agents for triglyceride lowering, followed by fish oil and niacin therapy. Niacin is the best available agent for raising HDL and lowering Lp(a).

Chapter 136 :: Fabry Disease

:: Atul B. Mehta & Catherine H. Orteu

FABRY DISEASE AT A GLANCE

- Incidence estimated at 1:3,200 to 1:170,000 in all ethnicities.
- X-linked lysosomal storage disorder.
- Highly penetrant in males; female heterozygotes have variable expressivity.
- Partial or complete deficiency of α-galactosidase A with deposition of glycosphingolipids (mostly globotriaosylceramide).
- Classical variants affect predominantly skin, kidneys, heart, eyes, and brain.
- Life expectancy shortened by 20 years in males and 15 years in females.
- Later onset variants: milder, predominantly single organ involvement, for example, renal or cardiac.
- Dermatologic manifestations: angiokeratomas, telangiectasias, "pseudoacromegalic" facies, hypo- and hyperhidrosis, lymphedema, and Raynaud's phenomenon.
- Light microscopy: ectatic upper dermal vessels, peripheral epidermal acanthosis, variable hyperkeratosis.
- Electron microscopy: intracytoplasmic electron dense vacuolar "Zebra bodies."
- Treatment: symptomatic, enzyme replacement.

EPIDEMIOLOGY

Fabry disease (α-galactosidase A, GLA, deficiency) is generally considered the second most prevalent lysosomal storage disorder, after Gaucher disease[1,2] with an estimated incidence ranging between 1:40,000 to 1:170,000 persons. All ethnic groups are affected. Milder variants of the disease are associated with significant residual enzyme activity and may occur with much higher frequency (e.g., 1:3,200), as suggested by a recent survey of neonates in Northern Italy.[3] These variants often have predominant involvement of a single organ (e.g., heart or kidney) and have onset in adult life.

ETIOLOGY AND PATHOGENESIS

Fabry disease (OMIM #301500) is caused by the partial or complete deficiency of a lysosomal enzyme, α-galactosidase A (Fig. 136-1). As a result of this enzyme deficiency, neutral sphingolipids with terminal α-galactosyl residues [predominantly globotriaosylceramide (Gb3)] accumulate in the lysosomes of different tissues and fluids (epithelial cells of glomeruli and tubules of the kidneys; cardiac myocytes; ganglion cells of the autonomic system; cornea; endothelial, perithelial, and smooth muscle cells of blood vessels; and histiocytic and reticular cells of connective tissue). Clinical onset is variable (Fig. 136-2). Although the condition is X linked, heterozygous females are frequently affected and may be as severely affected as hemizygous males.[4] Clinical symptoms typically occur a decade or so later in females than in males and organ damage is usually less severe. Variable expression in females is attributed to the Lyon hypothesis, whereby one X chromosome is inactivated on a random basis in the female, while the other provides the genetic information.

The *GLA* gene for α-galactosidase A is located at the Xq22.1 region. More than 400 mutations have been identified in the *GLA* gene,[5,6] including missense, nonsense mutations, and single amino acid deletions and insertions. Most of these mutations are "private," having been identified only in individual families. Some (e.g., the *p.N215S* mutation) have been associated with single organ or late onset variants and patients have normal levels of urinary Gb3, despite having clinical evidence of Fabry disease.

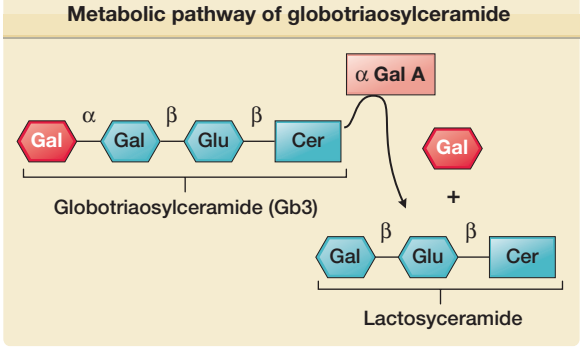

Figure 136-1 Metabolic pathway: α-galactosidase A (α-Gal A) metabolizes globotriaosylceramide to galactose (Gal) and lactosylceramide. Cer = ceramide; Glu = glucose.

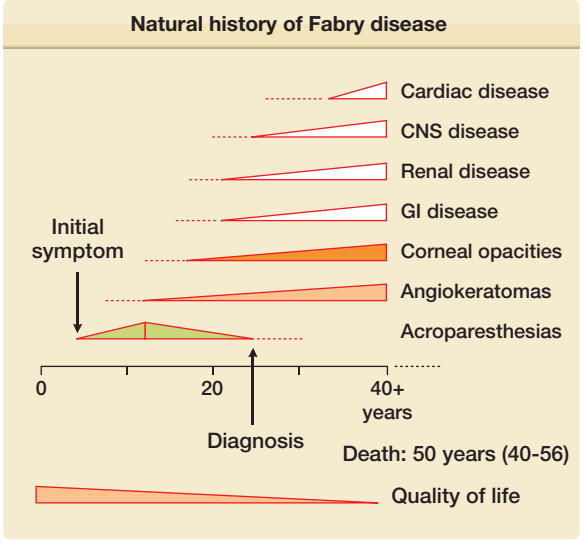

Figure 136-2 Natural history of Fabry disease: acroparesthesias, angiokeratomas, corneal opacities, and gastrointestinal symptoms are often the first manifestations. Diagnosis is usually delayed and occurs around the second decade. CNS = central nervous system; GI = gastrointestinal.

HISTORICAL ASPECTS

CUTANEOUS MANIFESTATIONS

CUTANEOUS VASCULAR LESIONS

ANGIOKERATOMA. Angiokeratoma (AK), the cutaneous hallmark of Fabry disease,[7,8] are present in 70% of males and 39% of females.[9,10] They are pinpoint to 4-mm diameter, dark-red to blue–black, macular, and papular lesions, which do not blanch on pressure (Fig. 136-3). Overlying hyperkeratosis is variable and frequently absent at sites other than the genitalia and umbilicus.[9,11] AKs appear between the ages of 5 and 15 years in males and 3–10 years later in females.[12–15] They were a presenting feature in 14.2% of 352 pediatric patients,[15] 31.7% of adult males (n = 359), and 11.2% of adult females (n = 118).[4] They may be widespread or grouped. In males, lesions are typically within the "bathing trunk" area (genitals, buttocks, lower abdomen, umbilicus, groins, inner thighs, and sacrum). AK are also often seen on the proximal limbs, particularly their medial aspects, the elbows and knees, the palms and soles, and over the distal phalanges of the digits (Fig. 136-4). Lesions may occur on the lips, particularly along the vermilion border, and occasionally on the mucosal surfaces (Fig. 136-5). They rarely occur elsewhere on the face. In females, AK are usually sparsely distributed (Fig. 136-6) and may occasionally occur in a dermatomal distribution.[9,16] The commonest sites are the trunk and proximal limbs.[9] Female genital lesions are relatively infrequent.

HISTOPATHOLOGY. Histologic evaluation of lesional skin typically shows dilated, ectatic capillaries in the papillary dermis, a variably thinned epidermis centrally, with epidermal acanthosis at the edges of the lesion, and variable degrees of overlying focal compact orthohyperkeratosis (eFig. 136-6.1A in online edition). Endothelial, perithelial, perineural, eccrine, smooth muscle cells, and fibroblasts are filled with cytoplasmic vacuoles containing glycosphingolipid that can be visualized with toluidine blue stains. Characteristic, electron dense, lamellated intracytoplasmic vacuolar inclusions (zebra bodies) are typically seen on electron microscopy[17] (eFig. 136-6.1B in online edition; Fig. 136-7; eFig. 136-7.1 in online edition; and Figs. 136-8A and 136-8B). They exhibit a pattern of alternating light and dark 4–6-nm bands. These inclusions may be present in biopsies from AK or from normal skin. They may be absent in the skin of heterozygous females.[17] Electron microscopy and immunoelectron microscopy using anti-Gb3 antibodies are useful tools when other diagnostic tests are not conclusive.[18]

ANGIOMAS AND TELANGIECTASIAS. Up to a third of Fabry males and two-thirds of females do not have AKs.[9,10,13,14] A proportion have no cutaneous vascular lesions (CVL),[9] and others have bright red macular angiomatous lesions, which could represent

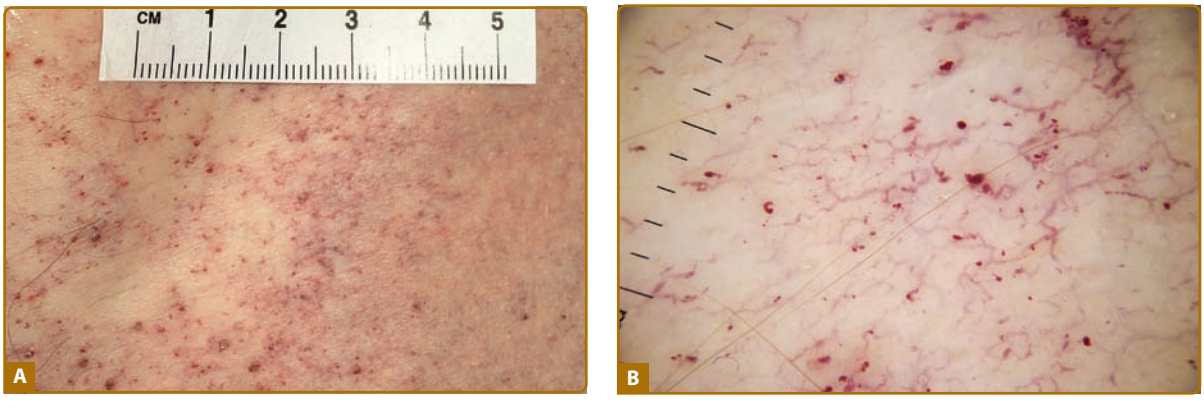

Figure 136-3 **A.** Angiokeratomas and telangiectatic vessels on the flank in a patient with angiokeratoma corporis diffusum. **B.** Dermatoscopic view showing angiokeratomas and upper dermal vessel tortuosity.

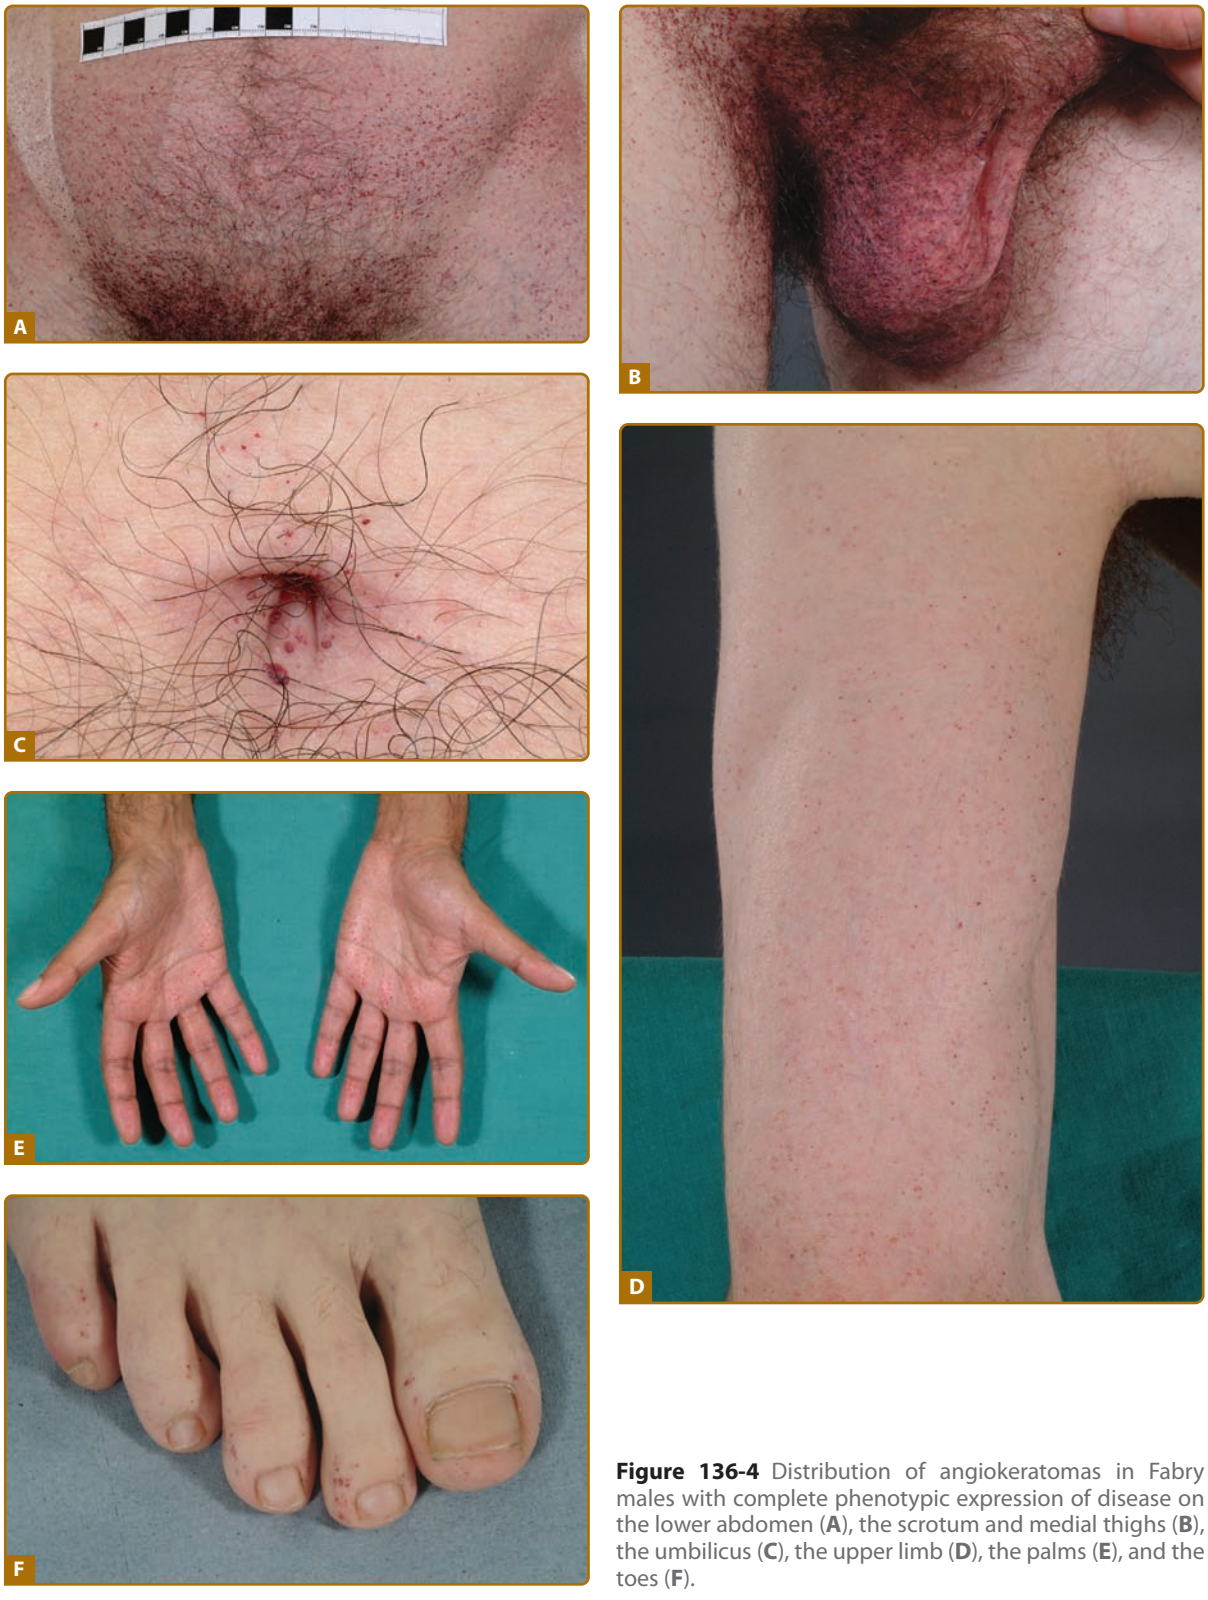

Figure 136-4 Distribution of angiokeratomas in Fabry males with complete phenotypic expression of disease on the lower abdomen (**A**), the scrotum and medial thighs (**B**), the umbilicus (**C**), the upper limb (**D**), the palms (**E**), and the toes (**F**).

early AKs or macular angiomas clinically.[11] Patients with widespread papular angiomas clinically and histologically in keeping with cherry angiomas are also recognized. In one series, patients with a predominantly cardiac phenotype (*N215S* mutation) rarely had classical AK, but a third of males in this group had widespread (>100) cherry angiomas.[19] Since the prevalence of such lesions in the general population may be as high as 50%, their significance in patients with Fabry disease is not clear. Telangiectasias are also common,[9] and may be distinguished from AKs and macular and cherry angiomas by the presence of blanching

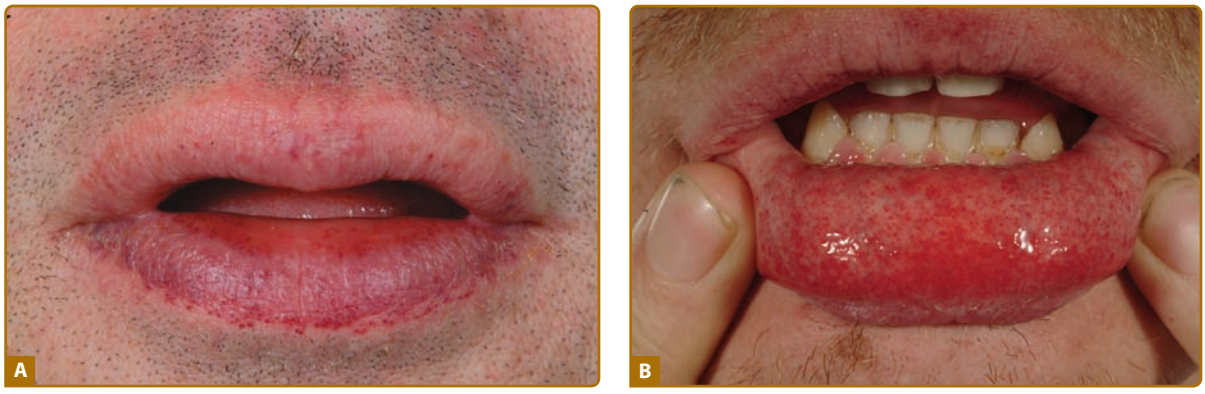

Figure 136-5 Angiomatous lesions on the lips concentrated along the vermilion border (**A**) and on the mucosal surface of the lower lip (**B**).

on diascopic pressure. Registry data show that they are more common in males (23%) than in females (9%).[9,10] Although based on patient recall, data suggest that they appear later than AK, with a mean age at onset of 26 years in males (range 3–70) and 42 years in females (range 5–73).[9] In a majority of cases, telangiectasias occur at sun-exposed sites, such as the face and V of the neck, often in patients with skin type I or II. Occasionally, telangiectasias may be seen at unusual sites such as the flanks, groins, elbow, and knee flexures. Dermoscopy of these areas reveals dilated, tortuous upper dermal vessels (Fig. 136-3 and eFig. 136-8.1 in online edition). This tends to occur in patients with widespread AK and full phenotypic expression of disease.

RELATIONSHIP TO DISEASE SEVERITY. In both sexes, the presence of CVL, namely telangiectasias and/or AK, has been associated with higher disease severity scores and a higher prevalence of major organ involvement.[9,10] Thus, cerebrovascular involvement (stroke and transient ischemic attacks) was present in 38% females and 32% males with CVL, but only in 12% females and 9% males without CVL. Cardiac involvement occurred in 80% females and 73% males with CVL versus 38% females and 49% males without; renal involvement in 62% females and 72% males with CVL versus 29% females and 42% males without. Similar differences are observed for hypertension, eye, ear, gastrointestinal (GI), and other neurological involvement.[10] These findings demonstrate the importance of dermatological assessment and its possible predictive value in terms of systemic morbidity.

FACIAL FEATURES

A "pseudoacromegalic" facial appearance has been described in some families with Fabry disease (Fig. 136-9 and eFig. 136-9.1 in online edition). This feature is

Figure 136-6 Sparsely distributed pinpoint dark-red macular and papular lesions on the trunk of a Fabry female.

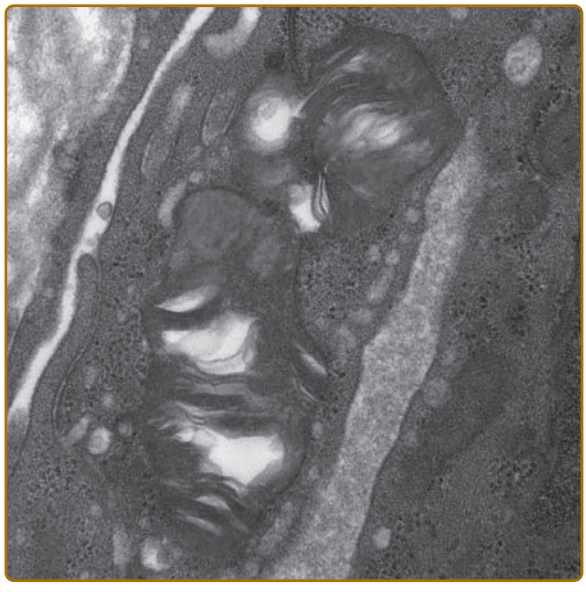

Figure 136-7 Histopathologic features of angiokeratoma. At high power electron microscopy a lamellar or "zebra" body is seen (×63,000 magnification).

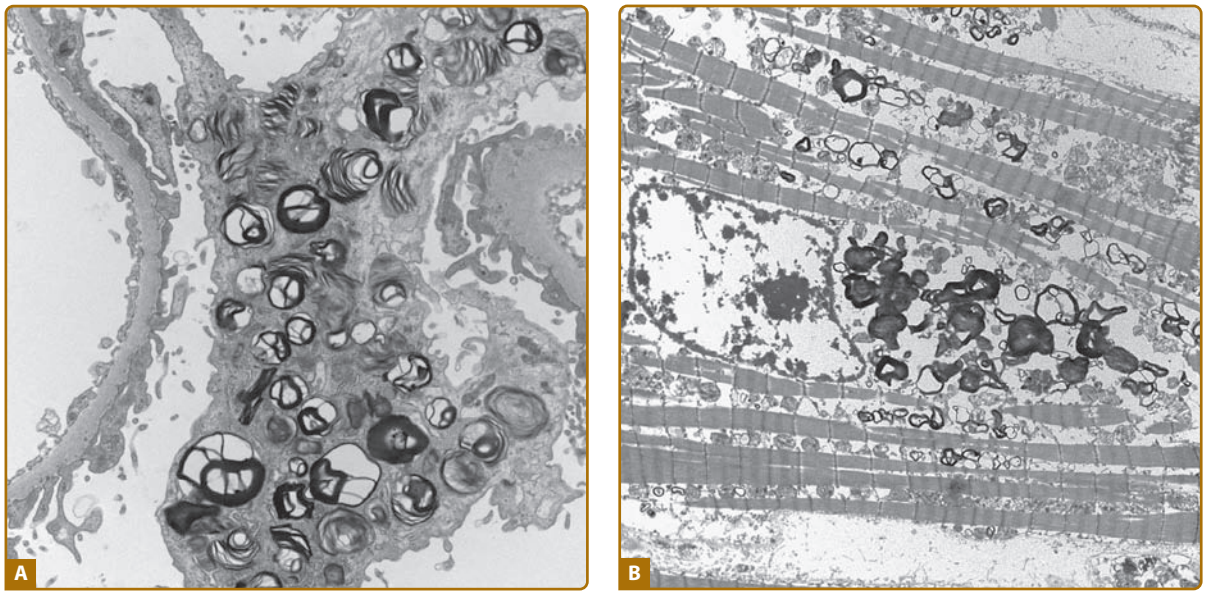

Figure 136-8 Electron microscopy: multiple electron dense inclusions in the kidney (**A**) and cardiac muscle in Fabry disease (**B**).

documented in two larger studies. An assessment of 38 patients by a panel of three clinical geneticists, based on standardized medical photography[20] identified (in order of decreasing frequency): periorbital fullness, prominent ear lobes, bushy eyebrows, recessed forehead, pronounced nasal angle, generous nose/bulbous nasal tip, prominent supraorbital ridges, shallow midface, full lips, prominent nasal bridge, broad alar base, coarse features, posteriorly rotated ears, and prognathism. A second study, in which facial dysmorphism was objectively assessed by three-dimensional (3D) dense surface modeling and anthropometric analysis using a 3D photogrammetric camera, compared facial features in 20 males and 22 females with Fabry disease with controls.[21] This study confirmed, in males and less prominently in females, the presence of the facial features noted above. The presence of these facial features should prompt appropriate investigations for Fabry disease.

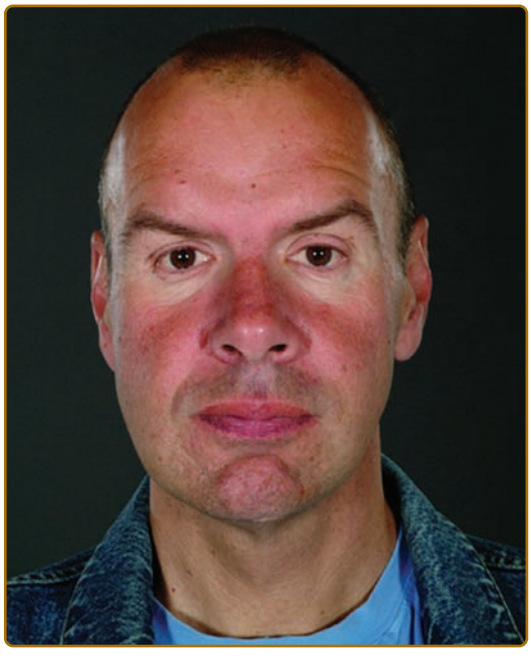

Figure 136-9 Typical facial features: bushy eyebrows, prominent supraorbital ridges, periorbital fullness, large bitemporal width, broad nasal base, full lips, and prominent chin.

The Fabry face appears commoner in patients with widespread AKs and classical disease at the more severe end of the spectrum. Moderate or marked facial changes were present in 63% of 41 males with a classical disease phenotype, 61% of whom had AK corporis diffusum. In contrast, facial features were present to a very mild degree (periorbital puffiness only) in only 10.5% of 19 males with a predominantly cardiac phenotype of disease.[10]

LOWER LIMB EDEMA AND LYMPHEDEMA

Edema and lymphedema, particularly affecting the lower limbs, is frequently observed in Fabry patients (Fig. 136-10). Lymphedema was cited in the original description of Fabry Disease (FD) and is recognized in other lysosomal storage disorders (LSDs) such as α-*N*-acetylgalactosaminidase deficiency.[22] Case reports document it as an unusual presenting feature of the condition[23] and some suggest that familial lymphedema and Fabry disease might be linked.[24] Registry data from the Fabry Outcome Survey (FOS) on more than 700 patients confirm that reversible peripheral edema of the lower limbs was present in 25% of Fabry males and 17% of females; lymphedema was present in 16% of males and 7% of females. The mean age of onset was 37 years for males (range 13–70) and a

Figure 136-10 Bilateral lower limb lymphedema in a 43-year-old Fabry male.

decade or so later for females.[9] This is significantly more than the documented UK community prevalence of 1.33/1,000.[25] In the community it is five times commoner in women. The mechanism underlying the changes is unclear; their presence does not correlate with renal or cardiac involvement. Contributory factors may include glycosphingolipid accumulation,[26] recurrent edema, and primary abnormality of the lymphatics.[27,28] Using the technique of fluorescence microlymphography and measurement of lymph capillary pressure, Amann-Vesti et al demonstrated fragmentation of the microlymphatic network in 5/5 hemizygous males and 5/5 heterozygous females but in none of 12 healthy controls.[28] Severe structural and functional changes in the initial lymphatics of the skin were present, even when lymphedema was not manifest.[28] The possibility that abnormalities in expression or function of recently identified mediators of lymphangiogenesis (VEGF-C/-D and VEGF-Rs)[29] may be involved in the development of lymphedema in Fabry disease remains to be investigated.

ABNORMALITIES OF SWEATING

Reduced sweating is a classical feature of Fabry disease and thought largely to be a consequence of autonomic neuropathy, though substrate accumulation within sweat glands may play a role.[30,31] Hypohidrosis was reported by 53% of males and 28% of females, with earlier onset in males (23 years vs. 26 years). Anhidrosis was described by 25% of males, but only by 4% of females.[9] Heat intolerance is a commonly associated and disabling symptom, resulting in reduced exercise tolerance, nausea, dyspnea, light-headedness and headache, or complete collapse with loss of consciousness. Previous studies[31,32] have demonstrated an improvement in sweating in Fabry patients undergoing enzyme replacement therapy (ERT). Hyperhidrosis may also occur, more commonly in females (11.9%) than in males (6.4%).[33] This is higher than the estimated prevalence of 1%–2.8% of the general population in the United States.[34] In a majority of Fabry patients, it affects palms and soles and is not generalized.[33]

RAYNAUD PHENOMENON

"Cold intolerance" and the development of pain in the extremities in cold environments is a frequent complaint amongst Fabry patients. More recently, Raynaud phenomenon has been documented in 8% of 710 females and 11% of 644 males (data from FOS). This reversal of the sex ratio and high prevalence in males suggest a possible causal link to the underlying Fabry disease. A recent fluoroscopic nail fold capillaroscopy study[35] examined 25 Fabry patients (17 males) and showed significantly more bushy capillaries and clusters in cases (72%) than controls (10%). Morphological and functional abnormalities of nail fold capillaries were present. This abnormal vasoreactivity of digital vessels could be related to autonomic dysfunction. Abnormalities of nitric oxide synthetase and increased oxidative stress in vascular endothelium and smooth muscle might also be important triggers.[36]

NONCUTANEOUS FINDINGS

(Table 136-1, see Fig. 136-2)

The noncutaneous findings in Fabry disease are illustrated in Fig. 136-2 and listed in Table 136-1 in relation to their typical age of onset. Fabry disease is a progressive, multisystem disorder, which typically results in a global reduction in quality of life of affected individuals. Symptoms in childhood typically relate to lethargy, tiredness, pain, cutaneous abnormalities, changes to sensory organs, and often GI disturbances. In early adulthood, patients may suffer extension of any of the above symptoms and often develop lymphedema, proteinuria, and the first signs of renal, cardiac, or central nervous system (CNS)/cerebrovascular disease. In later adulthood (age >30 years), symptoms include worsening of the above and more severe organ dysfunction (cardiac disease, renal disease, and cerebrovascular disease).

NEUROLOGIC FINDINGS

Acroparesthesias occur in 80%–90% of affected individuals and typically occur in the first decade.[37] Patients describe the sensation as pain, feeling like pins and needles in hands and feet, often radiating proximally. Triggers include increased body temperature, exercise, or stress. Pain typically declines over time and this may be due to damage to nerve fibers as a result of inflammation and substrate accumulation.

TABLE 136-1
Typical Signs and Symptoms of Fabry Disease According to Age

Typical Time at Onset	Signs and Symptoms
Childhood and adolescence (≤16 years)	▪ Pain (acroparesthesia) particularly in the extremities ▪ Angiokeratomas ▪ Ophthalmological abnormalities (cornea verticillata and tortuous retinal blood vessels) ▪ Hearing impairment ▪ Dyshidrosis (hypohidrosis and hyperhidrosis) ▪ Hypersensitivity to heat and cold ▪ Gastrointestinal disturbances and abdominal pain ▪ Lethargy and tiredness ▪ Onset of renal and cardiac signs, e.g., proteinuria, arrhythmia
Early adulthood (17–30 years)	▪ Extension of any of the above ▪ Proteinuria and progressive renal failure
Later adulthood (age >30 years)	▪ Worsening of any of the above ▪ Heart disease (e.g., left ventricular hypertrophy, angina, arrhythmia, and dyspnea) ▪ Stroke and transient ischemic attacks ▪ Osteopenia and osteoporosis

SENSORY ORGAN ABNORMALITIES

The commonest ocular finding is cornea verticillata (opacities in the cornea characterized by one or more lines radiating from the near the center of the cornea), which occurs in over 90% of males and 70% of females. Other changes include increased tortuosity of retinal vessels, optic atrophy, cataracts, and lenticular changes. The extent of ocular abnormalities correlates with the overall extent of the disease.[38] Tinnitus and high frequency sensorineural hearing loss are also common manifestations, occurring in over 50% of subjects. Sudden deafness and dizziness due to vestibular pathology can also occur.

GASTROINTESTINAL CHANGES

Cramping abdominal pain, nausea, diarrhea, and occasionally constipation are frequent and are often the presenting symptom.[39] The pathogenesis is probably related to neurologic abnormalities.

ORGAN DAMAGE IN FABRY DISEASE

Renal manifestations are seen in over 90% of males.[37] Microalbuminuria and hyperfiltration are early features, proteinuria is typically seen in the third and fourth decades, and progressive decline in renal filtering capacity occurs. Females frequently show proteinuria, although progression to end-stage renal failure is less common. A renal variant of Fabry disease has been described in patients with decreased,[1] but not absent, α-galactosidase A activity; these patients lack other characteristic manifestations.

Cardiac manifestations are a constant feature and increasingly recognized as the major cause of death in both male and female patients.[40] Substrate deposition can be demonstrated throughout the myocardium, valves, and conduction system and is often accompanied by an inflammatory cell infiltrate. A common presentation is with left ventricular hypertrophy, but mitral valve prolapse, arrhythmia, and coronary artery disease can all be present. A cardiac variant[1] has been described in patients with reduced, but not absent, α-galactosidase A activity and presents later in life (often above 40 years) with predominant cardiac symptomatology.

Cerebrovascular manifestations include ischemic or hemorrhagic strokes occurring early in life, transient ischemic attack and strokes affecting the posterior circulation. Stroke is often reported as the presenting feature of Fabry disease, and Fabry disease should be considered in the differential diagnosis of young patients with cryptogenic stroke.[41]

Other manifestations: Global manifestations of Fabry disease include lethargy, tiredness, failure to thrive in children, and anemia. Depression is frequent and often underdiagnosed, affecting up to 50% of Fabry males and females.[42] Sexual activity is often affected by the presence of AKs in the genital region, which can lead to decreased self-esteem and libido. Autonomic dysfunction is underrecognized and can lead to hyperhidrosis, abnormal tear and saliva formation, abnormal cardiac reactivity, GI dysmotility, altered pain, and temperature perception. Endocrine abnormalities are uncommon but osteopenia and hypothyroidism[43] are well described. Pulmonary abnormalities are underrecognized; Fabry disease can lead to an obstructive airways pattern[44] in some patients, but asthma is the presenting feature in other patients. In contrast to other lysosomal storage disorders, cognitive impairment is not generally seen; however, older patients (above 50 years) are increasingly seen with memory loss, global intellectual deterioration, and personality change.

DIAGNOSIS

The definitive diagnosis of Fabry disease is usually delayed, with a mean time between the onset of symptoms and diagnosis of 15 years.[45] The diagnosis must be confirmed by the demonstration of deficient α-galactosidase A activity in plasma, serum, or leukocytes and the identification of a pathogenic mutation. Female patients have variable and, occasionally, even normal levels of enzyme activity and DNA confirmation of the diagnosis is essential.

Biopsy of tissues, such as skin and kidney, demonstrates the presence of lipid deposition and multilamellated intracytoplasmic electron dense bodies in electron micrographs (see eFig. 136-6.1 in online edition; Fig. 136-7; and eFig. 136-7.1 in online edition). As Gb3 deposition starts in utero, prenatal

diagnosis can be performed from chorionic villi or culture of amniotic cells, where low α-galactosidase A activity can be demonstrated.[1]

DIFFERENTIAL DIAGNOSIS

(Box 136-1, Tables 136-2 and 136-3)

The pain associated with acroparesthesia is often misdiagnosed as rheumatoid arthritis, rheumatic fever, erythromelalgia, Raynaud disease, or simply as "growing pains."[37]

The clinical diagnosis of AKs in Fabry disease may be difficult. Careful inspection of the skin may be required to distinguish AKs from purpura, petechiae, and angioma serpiginosum. AKs should also be distinguished from the solitary and localized forms of AK, which occur in the absence of underlying systemic disease[46] (Box 136-1 and Table 136-2).

Widespread AKs occur in other lysosomal storage disorders, which should be considered in the differential diagnosis. They include fucosidosis, in which more than 50% of patients have the changes, α-*N*-galactosaminidase deficiency, and galactosialidosis[47–50] (Box 136-1 and Table 136-3). In addition to the distinct enzyme deficiency in each of these storage diseases and other clinical features, AKs from

Differential Diagnosis of Angiokeratoma Corporis Diffusum

Group	Name	Enzyme Deficiency	Gene	Electron Microscopy Findings[55]	Clinical Findings	Dermatologic Findings
Sphingolipidoses	Fabry (OMIM #301500)	α-Galactosidase A	*Xq22*	Electron-dense lysosomal deposits	Acroparesthesias, heart and renal failure, stroke, cornea verticillata	Angiokeratoma (AK) corporis diffusum, telangiectasias, hypo/anhidrosis, lymphedema
	GM1 gangliosidosis (OMIM #230500)	β-Galactosidase	*3p21–3pter*	Electron-lucent lysosomal dilation	Facial dysmorphism, hematologic signs, mental retardation, organomegaly	AK corporis diffusum
Glycoproteinoses	Aspartylglucosaminuria (OMIM #208400)	Aspartylglycosaminidase	*4q32–33*	Electron-lucent lysosomal dilation	Coarse facies, macroglossia, organomegaly, ocular findings, cardiac valve involvement	AK corporis diffusum, facial angiofibromas, oral fibromatosis and leukokeratosis
	Fucosidosis (OMIM #230000)	α-Fucosidase	*1p34*	Electron-lucent lysosomal dilation	Mental retardation, coarse facies, growth retardation, recurrent respiratory infections, dysostosis multiplex, visceromegaly	AK corporis diffusum, widespread telangiectasias, acrocyanosis, purple transverse distal nail bands, increased vasculature in hands and feet, sweating abnormalities
	β-Mannosidosis (OMIM #248510)	β-Mannosidase	*4q22-q25*	Electron-lucent lysosomal dilation	Mental retardation, neuropathy, hearing loss, recurrent infections	AK corporis diffusum in bathing trunk area
	Sialidosis II (OMIM #256550)	Neuraminidase	*6p21.3*	Electron-lucent lysosomal dilation	Mental retardation, dysostosis multiplex, vacuolated lymphocytes, subtle coarse facial features	AK corporis diffusum
Multiple enzyme deficiency	Galactosialidosis (OMIM #256540)	β-Galactosidase and neuraminidase	*20q13.1*	Electron-lucent lysosomal dilation	Dwarfism, gargoyle facies, mental retardation, seizures, corneal clouding, dysostosis multiplex, and hearing loss	AK corporis diffusum scattered along entire body, especially knees, elbows, and bathing trunk area
	Kanzaki (OMIM #104170)	α-N-acetylgalactosaminidase (α-Nacetylgalactosaminidase)	*22q11*	Electron-lucent lysosomal dilation	Mental retardation, coarse facial features, ocular signs, hearing loss, neuropathy	AK corporis diffusum of entire body, more dense on the bathing trunk area, axillae, and breasts Telangiectasias on lips and oral mucosa

OMIM = Online Mendelian Inheritance in Man.

Fabry disease can be differentiated by electron microscopic examination by the characteristic electron-dense, lamellar (zebra-like) inclusions within endothelial and other cell types.[51] Chloroquine therapy may result in storage of biochemically and ultrastructurally similar inclusions in many of the same cells as Fabry disease and may result in similar clinical manifestations, including the development of AK.[52] Widespread AKs have also been described in association with tuberous sclerosis,[53] juvenile dermatomyositis,[54] and without an associated metabolic disorder.[55]

PROGNOSIS AND CLINICAL COURSE

Earlier studies suggested that males with Fabry disease typically die in the fourth or fifth decade, and females live perhaps 15 years longer. More recently, the life expectancy for males has been estimated as 58.2 years (compared to 74.7 in the general US population) and 75.4 years for females (compared to 80 years).[56] There is also evidence that, whereas renal failure was previously the commonest cause of death, cardiac and cerebrovascular diseases are increasingly common. Some of these changes may be due to the impact of ERT.[56,57]

TREATMENT

(Box 136-2)

Fabry disease is a multisystem disorder and patients should be assessed within a multidisciplinary setting. The advent of ERT has meant that patients and families are increasingly assessed in a specialty center, where they will have access to a primary care physician, dermatologist, and possibly cardiologist/nephrologist/neurologist. Access to audiologists, ophthalmologists, gastroenterologists, and psychiatrists/counselors, as well as to genetic counselors and nurses, is desirable and available at larger centers.

SYMPTOMATIC THERAPIES

Individual end-organ manifestations of disease are treated symptomatically (Box 136-2).

SKIN-DIRECTED THERAPIES. Clearance of Gb3 from the skin following ERT[58,59] does not necessarily translate into clearance of AKs. The variety of vascular lesions seen in Fabry disease can, however, be treated effectively with quasicontinuous wave and pulsed lasers, and intense pulsed light systems.[60,61] Newer lasers, which combine a high-powered pulsed-dye laser and a 1064-nm long-pulse Nd:YAG laser penetrate deeper and seem to work particularly well for the larger genital AKs.[62,63]

Prophylactic therapy with grade II graduated below knee compression hosiery can prevent the development of lymphedema in patients whose edema is still fully reversible. Once lymphedema is established, control can be maintained by regular skin care, exercise, manual lymphatic draining and/or self-massage, and the use of appropriate specialist bandaging and hosiery.[25,64]

There is some evidence that hypohidrosis improves with ERT.

For those patients with hyperhidrosis, treatment options include the use of topical aluminium chloride hexahydrate, tap water iontophoresis and local botulinum toxin injections, oral glycopyrrolate sodium up to 2 mg three times daily (a well-tolerated anticholinergic with minimal side effects, provided there are no

BOX 136-2 TREATMENT: A MULTIDISCIPLINARY APPROACH IS ALWAYS ADVISABLE

SYMPTOMATIC

Angiokeratomas
Liquid nitrogen, electrocoagulation, surgical excision, laser (pulsed-dye 585-nm, neodymium YAG 1,064 nm, combined pulsed-dye and Nd:YAG) and intense pulsed light (IPL)

Lymphedema
Manual lymphatic drainage massage and compression

Hyperhidrosis
Aluminium chloride hexahydrate, electrophoresis, botulinum toxin, glycopyrrolate sodium

Raynaud Phenomenon
Avoid smoking, cold and vasoconstrictor therapies; losartan, diltiazem, fluoxetine, sildenafil

Pain
Avoid triggers; carbamazepine, gabapentin

Stroke
Antiplatelet, Anticoagulant

Hearing
Hearing aid devices, avoid noise trauma

Lungs
Avoid smoking; bronchodilators

Gastrointestinal
Pancrelipase, metoclopramide

Cardiovascular
Antihypertensive drugs, antiarrhythmic drugs, Artificial pacemakers, implantable defibrillators, coronary bypass

Chronic Renal Failure
Angiotensin converting enzyme inhibitors
Hemodialysis, allograft transplant

SPECIFIC
Enzyme replacement
α-Galactosidase B (Fabrazyme), α-galactosidase A (Replagal)

cardiac contraindications), and chemical or endoscopic sympathectomy.[65,66]

For patients with cold extremities, standard measures such as stopping smoking, avoiding vasoconstricting medications such as β-blockers, and maintaining warm hands and feet with suitable clothing during winter months are generally recommended. Drug therapies with proven efficacy for Raynaud phenomenon in other patient groups include angiotensin II receptor antagonists, calcium channel blockers, fluoxetine, and sildenafil.[67,68] Possible cardiac and renal contraindications should be taken into account before prescribing these drugs in Fabry patients.

THERAPIES DIRECTED AT OTHER ORGAN SYSTEMS. Pain is the most disturbing and early symptom, and can sometimes be partially managed with diphenylhydantoin, carbamazepine, or gabapentin. Patients should be encouraged to identify and try to avoid their personal precipitating factors. For the primary or secondary prevention of stroke and other vascular pathologies, such as retinal artery occlusion, antiplatelet, and anticoagulant therapy might be needed.

Metoclopramide and pancrelipase are used to reduce GI symptoms. Hypertension must be controlled, as it significantly affects three of the most affected organs, the kidney, brain, and heart. Angiotensin receptor blockade should be undertaken at the first sign of proteinuria and is an important adjunct to ERT in slowing the decline in renal function. Fabry patients are good candidates for kidney transplant in the event of end-stage renal failure and the role of ERT in this situation is to preserve the function of other organs. Ancillary care from a cardiac perspective includes consideration of antiarrhythmics, artificial pacemakers, and surgery, including septal ablation or even cardiac transplant.

SPECIFIC THERAPEUTICS: ENZYME REPLACEMENT THERAPY

Two formulations of ERT have been developed, agalsidase β (Genzyme, Massachusets, USA) and agalsidase α (Replagal, Shire HGT). Only agalsidase β is licensed in the United States, whereas both formulations are available in most other parts of the world. Agalsidase β is administered at a dose of 1.0 mg/kg biweekly and is manufactured using a recombinant technology in a Chinese hamster ovary (CHO) cell line. Agalsidase α is given at a dose of 0.2 mg/kg biweekly and is manufactured using a gene activation methodology in a human fibroblast cell line. The efficacy of both ERT formulations has been demonstrated in randomized controlled trials[69,70,71] and both improve biochemical (e.g., levels of Gb3 in plasma, urine, and tissue biopsy) and clinical parameters. The main clinical parameters chosen for study are renal function, pain, cardiac size and function, and quality of life. Longer term trials have been reported for both preparations. Long-term effectiveness has been demonstrated in Registry studies of agalsidase α. Both preparations are considered safe and well tolerated. The main side effects are infusion related (fever, temperature) and both preparations can induce antibody formation. However, the impact of antibodies on clinical effectiveness has not been demonstrated. The two ERT formulations are generally considered to be of equivalent effectiveness. The optimum time for commencement of treatment has not been established. ERT is recommended for all symptomatic males and at the first sign of organ dysfunction in females. Patients receiving ERT should be regularly monitored with serial measurements of pain, quality of life, and renal and cardiac function. Their data should be entered onto Registries wherever possible.[72] ERT has been shown to improve hearing and GI symptoms. Direct beneficial effects of ERT on CNS abnormalities have not been demonstrated and enzyme cannot cross the blood brain barrier.

NEW TREATMENTS[73]

Chaperone-based enzyme enhancement therapy (phase III clinical trial by Amicus/Glaxo Smith Klein) consists of small molecules that rescue misfolded/mistrafficked enzymes from the lysosomes and transport them to the endoplasmic reticulum. Chaperone-based therapy can be administered orally but is useful only for patients with residual enzyme activity. Substrate deprivation (inhibition of an early step in the synthesis of glycosphingolipids) and the infusion of galactose are other therapeutic options that are still in the research state. Gene therapy and hematopoietic cell transplantation are still being developed.

GENETIC COUNSELING

All families that have a member with Fabry disease should have an opportunity to receive genetic counseling. Given the X-linked nature of Fabry disease, female patients have a 50% chance of transmitting the gene both to their sons and daughters, while male patients will have no affected sons and 100% of daughters are affected. The genotype–phenotype variability should also be stressed especially among patients with subtle manifestations.

Chapter 137 :: Lipoid Proteinosis and Heritable Disorders of Connective Tissue

:: Jonathan A. Dyer

Inherited connective tissue disorders are clinically and genetically diverse conditions affecting the skin, joints, and a variety of extracutaneous tissues, including the cardiovascular (CV) system. The nature and severity of the skin phenotype is dependent on the type of mutation as well as the role of the affected protein on dermal structure and function (see Chapter 63). The diagnosis of many inherited connective tissue disorders is clinical, although CLIA-approved genetic testing is increasingly available. A listing of research laboratories that may offer testing can be found at http://www.genetests.org.

EHLERS–DANLOS SYNDROME

EHLERS–DANLOS SYNDROMES AT A GLANCE

- Combined incidence of almost 1 in 5,000 persons.
- Seven subtypes.
- Most commonly autosomal dominant (classical and hypermobile types).
- The gene encoding collagen V is most often affected.
- Cutaneous features include soft, velvety skin that bruises easily and wounds that heal as thin, atrophic, gaping scars.
- Extracutaneous manifestations include hypermobile joints with frequent dislocations, problems with pregnancy and delivery, and, less commonly, cardiovascular manifestations, particularly aortic root dilatation.
- Information for patients and professionals at http://www.ehlers-danlos.org and http://www.ednf.org.

A variety of genetically and clinically heterogeneous inherited conditions characterized by varying degrees of skin fragility and hyperextensibility, joint hypermobility, and easy bruising, have been collected under the rubric of the Ehlers–Danlos syndromes (EDS). A new classification system was proposed in 1997[1] to consolidate and simplify existing subgroups (Table 137-1). Despite these revisions, many patients defy clear-cut classification due to overlapping features. The spectrum of EDS disease severity ranges from nearly imperceptible findings to severe, debilitating disease. As such, it is difficult to estimate EDS prevalence, but if milder forms are included it may be as high as 1:5,000 individuals. The kyphoscoliosis, arthrochalasia, and dermatosparaxis types are considerably less common than the classical, hypermobility, and vascular types. Confusion over the diagnosis of the hypermobility type and its overlap with joint hypermobility syndrome interferes with prevalence estimates. If inclusive definitions are used, it may be the most common subtype. Generalized joint hypermobility is the consistent and unifying finding in all forms of EDS.[3] EDS types other than the common classic type and the life-threatening vascular type are discussed in the online edition of the book.

CLASSICAL TYPE

EPIDEMIOLOGY. Classical EDS occurs in 1 in 10,000–20,000 newborns.[4]

ETIOLOGY AND PATHOGENESIS. Approximately half of classical EDS cases are caused by autosomal dominant (AD) defects in the α1 or α2 chain of type V collagen (COL5A1 and COL5A2). Type V collagen is a minor fibrillar collagen that regulates collagen fibril diameter. These mutations may result in dominant negative or haploinsufficient states and approximately one-third of cases are due to haploinsufficiency of the *COL5A1* gene.[5] Recently, mutations in the signal peptide region of COL5A1, which disrupt type V collagen secretion, have also been identified in patients with classical EDS.[6] An additional locus may exist, as several families do not exhibit linkage to *COL5A1* or *COL5A2*.[7,8]

TABLE 137-1
The Ehlers–Danlos Syndromes: Clinical Subtypes and Associated Defects

Villefranche Type/ (OMIM)	Clinical Features	Inheritance	Protein/(Gene Defect)
Classical/(130000 and 130010)	Hyperextensible skin; easy bruising; wide, atrophic scars; hypermobile joints	AD	Collagen type V/(*COL5A1*, *COL5A2*)
Hypermobility/(130020)	Smooth, velvety skin; joint hypermobility	AD/AR	Unclear for most; collagen type III; tenascin XB/(*COL3A1*; *TNXB*)[a]
Vascular/(130050)	Thin, translucent skin with easy bruising; arterial and visceral rupture; typical facies	AD	Collagen type III/(*COL3A1*)
Kyphoscoliosis/(225400 and 229200)	Atrophic scars, easy bruising; neonatal hypotonia; scoliosis; ocular rupture; marfanoid habitus	AR	Lysyl hydroxylase/(*PLOD1*)
Arthrochalasia/(130060)	Hyperextensible and fragile skin; severe joint hypermobility; congenital hip dislocation	AD	Collagen type I/(*COL1A1*; *COL1A2*)
Dermatosparaxis/(225410)	Severely fragile, sagging, redundant skin; hernias and premature rupture of fetal membranes	AR	Procollagen I *N*-peptidase/(*ADAMTS2*)
Other types[a]	Wrinkled, loose facial skin; curly fine hair; scanty eyebrows and eyelashes	AR	Due to mutations in galactosyltransferase
Progeroid variant[2]/(130070)			

AD = autosomal dominant; AR = autosomal recessive; OMIM = Online Mendelian Inheritance in Man.
[a]Few reported cases.

Patients with features of classic EDS exhibiting defective type I collagen due to AD *COL1A1* mutations have also been described.[9] These patients have nonglycine substitutions in the type I collagen triple helical domain and, during adulthood, some have developed vascular complications, including spontaneous arterial rupture, similar to the complications of the vascular EDS subtype.[10] An autosomal recessive (AR) "cardiac valvular subtype of EDS" exhibits clinical findings of classic EDS as well as the onset of severe cardiac valve problems later in life and results from total loss of the proa2(I) chains of type I collagen due to homozygous or compound heterozygous mutations in COL1A2.[11] An AR form of EDS resembling a mild version of classic EDS can result from homozygous tenascin-X (TNX) deficiency. Heterozygotes (especially females) for these mutations may exhibit hypermobility EDS.[12]

Electron microscopy of the skin in EDS reveals thickened collagen fibrils, highlighting the role of type V collagen in regulating their size. It is proposed that the amino terminus of α1(V) carries a negative charge, conferred by abundant tyrosine residues, and appears to limit fibril growth. Less than 5% of fibrils may exhibit "collagen cauliflowers," which are rare composite fibrils.[13–15]

CLINICAL FINDINGS.

Patients with classic EDS typically exhibit some degree of skin and joint hyperextensibility, tissue fragility, and bruising. In the past, patients exhibiting very mild features were termed "mitis." Typical patients have hyperextensible skin (Fig. 137-1) that recoils easily to its normal position after stretching, in contrast to the skin in cutis laxa (CL). Skin hyperextensibility should be assessed by pulling until resistance is met at a site not subjected to mechanical forces or scarring, such as the volar surface of the forearm. The normal upper limit of extensibility

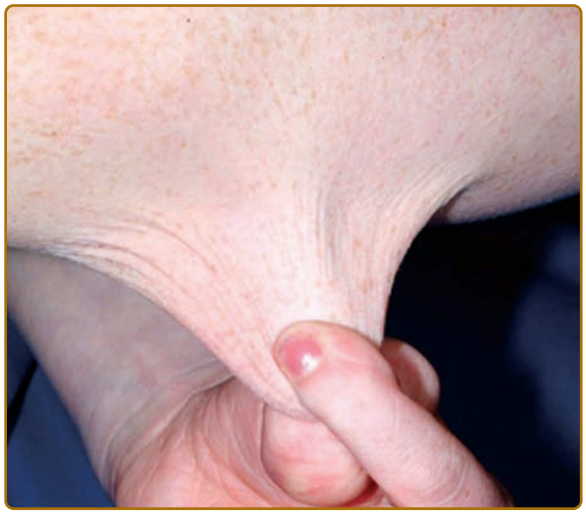

Figure 137-1 Classical Ehlers–Danlos syndrome. Dermal elasticity is demonstrated. Unlike cutis laxa, the skin returns to original shape after stretching.

Figure 137-2 Classical Ehlers–Danlos syndrome. Chronic discolored scars on the shin and ankle after repeated trauma. This is often associated with firm subcutaneous nodules that can be confused with subcutaneous granuloma annulare. Note the widened scar at the knee area.

at the volar forearm is 1–1.5 cm. Skin overlying extensor joints tends to be redundant and should not be used to assess extensibility.

The skin is velvety, thin, and bruises easily. Fetuses with classical EDS may exhibit growth retardation, hernias, and joint dislocations. Bruising manifests early in childhood and is often persistent in areas prone to trauma in young children, especially the shins (Fig. 137-2) Tissue fragility can be striking, with seemingly innocuous trauma resulting in disproportionately large skin tears that are relatively painless without excessive bleeding. Wounds often gape.

Even with surgical repair, wounds in EDS often exhibit slow healing and frequent infection. Postoperative wound dehiscence is common if wounds are not adequately secured, often necessitating repeated repairs or secondary intention healing (Fig. 137-3). Even with surgical repair, dehiscence upon suture removal may occur. Healed wounds result in atrophic, often widened cigarette paper-like (or "fish mouth") scars, especially on pressure points (knees, elbows, forehead, chin) (Figs. 137-2 and 137-3). Hematoma formation, especially at pressure points, often results in persistent hyperpigmentation. Calcification and fibrosis of hematomas produce subcutaneous, nodular molluscoid pseudotumors, most frequently around the elbow and knee. These are often associated with scars. Spheroids are small subcutaneous spherical hard nodules, usually on the forearms

Figure 137-3 Classical Ehlers–Danlos syndrome. After suturing for a laceration, the wound dehisced with secondary infection and marked widening. Note the evidence of former sutures at the lower border, now 3 weeks after the injury and treatment with antibiotics. Scars tend to stretch further in the 6 months after closure.

and shins that may become calcified and thus detectable radiographically. Additionally, subcutaneous fat herniation on the medial or lateral aspects of the heels or wrists with pressure (piezogenic pedal papules) may be seen. Acrocyanosis and chilblains have also been described in affected individuals.

Joint hypermobility is frequent (Fig. 137-4), and often greatest at the fingers and/or wrists. In suspected patients, including older children and adolescents, it is assessed using the Beighton scale Table 137-2).[1,3] Sprains, dislocations or subluxations, scoliosis, and pes planus are common complications and patients frequently describe chronic joint and limb pain, although skeletal radiographs may be normal.[16] Patients are

Figure 137-4 Classical Ehlers–Danlos syndrome. Hyperextensibility of digits is demonstrated.

TABLE 137-2
Beighton Criteria for Joint Hypermobility

1. Passive dorsiflexion of the fifth finger >90°
2. Passive apposition of the thumbs to the flexor aspect of the forearm (Beighton sign)
3. Hyperextension of the elbow >10°
4. Hyperextension of the knees >10°
5. Ability of the palms to completely touch the floor during forward flexion of the trunk with knees fully extended

Numbers 1–4 are scored for each side, so that a maximal score of two is possible if both left and right sides show criteria; number 5 is scored as 1. A score of ≥5/9 is hypermobile.

typically "double-jointed" and often able to perform various "tricks" with their joints as a result. Such chronic and excessive joint hypermobility frequently leads to early-onset osteoarthritis. Osteoporosis is more common when compared to age-matched controls. Muscle hypotonia and delayed gross motor development are also described. EDS may carry a diagnosis of chronic fatigue syndrome or fibromyalgia due to persistent fatigue and chronic pain.

Most patients with classic or hypermobile EDS are able to extend the tongue to touch the tip of the nose (Gorlin's sign) (Fig. 137-5), although this sign can be displayed by ~10% of individuals without inherited disorders of connective tissue. Lack of lingual and labial frenulae has recently been noted to be a minor feature of EDS, and is particularly common in patients with the vascular type[17] Hypermobility and absence of the frenulae allow some EDS patients to "swallow" their own tongue (eFig. 137-5.1 in online edition). Hiatal and postoperative hernias as well as anal prolapse have been noted as manifestations of the tissue hyperextensibility and fragility.[18] Sexual dysfunction, including dyspareunia is reported, and functional bowel disorders occur in up to half of patients.[19]

Figure 137-5 Classical Ehlers–Danlos syndrome (EDS). Gorlin's sign is the ability to touch the tip of the nose with the tongue and is described in approximately 50% of patients with Ehlers–Danlos, in contrast to 10% of individuals who do not have EDS.

Approximately 40%–50% of affected individuals (in addition to ~20% of infants born to affected mothers) are born prematurely (32–37 weeks), either due to premature rupture of fetal membranes or chorioamnionitis.[20,21] Monitoring during pregnancy and the postpartum period is recommended, because of the risk of premature labor during the third trimester, the increased risk for skin tears, postpartum hemorrhage, and uterine/bladder prolapse.[19] The fragility of the already abnormal connective tissue may be worsened by the effect of pregnancy-related hormones that soften connective tissue, such as relaxin.

Patients with classical EDS occasionally exhibit structural heart malformations. Mitral valve prolapse (MVP), and less often tricuspid valve prolapse, may occur and recent reports suggest that aortic root dilatation may occur more frequently than past studies indicated.[22] Arterial rupture, intracranial aneurysms, and arteriovenous fistulae have been described in classic EDS, typically in patients exhibiting severe clinical phenotypes, but are much less common than in Marfan syndrome. Baseline echocardiography with measurement of aortic diameter is recommended,[19,22] with CT or MRI exams if needed.[16] Longitudinal data on progression of aortic dilatation in classic EDS do not exist. The current recommendation is yearly echocardiogram if cardiac abnormalities (aortic dilatation, MVP) are present. If no abnormalities are noted, subsequent studies are only recommended as dictated by symptoms. β-blocker therapy has been successful anecdotally.

VASCULAR TYPE

EPIDEMIOLOGY. This is the most clinically significant EDS subtype due to the risk of arterial or major organ rupture. Inherited in an AD fashion, the incidence is approximately 1 in 100,000–200,000 individuals.[4]

ETIOLOGY AND PATHOGENESIS. Vascular EDS is associated with dominant negative mutations in the type III collagen gene (*COL3A1*), resulting in reduced amounts of type III collagen in the dermis, vessels, and viscera, as well as decreased production and secretion of type III collagen by cultured fibroblasts.[35] More than 320 different mutations have been reported (exon-skipping or missense) and typically lead to disruption of the triple-helical structure of type III collagen. As type III collagen is a homotrimer, mutant proα1(III) chains affect most fibrils, interfering with secretion, and leading to intracellular accumulation. Type III collagen plays an important role in the integrity of both blood vessel walls and the upper dermis. Analysis of type III procollagen and collagen chains and direct genetic testing of *COL3A1* have been utilized to test for vascular EDS.

CLINICAL FINDINGS. The classic quadrad of vascular type of EDS includes a characteristic facial appearance (which may be subtle), thin, translucent

Figure 137-6 Vascular Ehlers–Danlos syndrome. The venous pattern is apparent in a fair-skinned individual. (In order to enhance visibility of the venous network, the image was colorized.)

skin with a prominent venous pattern (Fig. 137-6), extensive bruising or hematomas, and vascular or visceral rupture (or both).[18] Joint hypermobility is usually minimal and limited to the digits. The facial features include a thin nose and upper lip, small earlobes, and sunken, pigmented periocular regions. Subcutaneous fat is decreased, especially of the face and limbs. Widened, thin (papyraceous) scars may be noted on bony prominences. Hematomas, which may be frequent and/or quite large, may develop after minimal to no trauma, such as sphygmomanometer inflation.

Spontaneous rupture of arteries, particularly mid-sized arteries, may occur during childhood, although its peak age of incidence is the third or fourth decade of life. Mesenchymal abdominal, splenic, and renal arteries are often involved, as is the descending aorta. Aortic rupture/dissection is typically not preceded by detectable aortic dilatation,[22] occurs distal to the mid-aortic arch, and exhibits distal extension. Arterial or intestinal rupture often presents as acute abdominal or flank pain; arterial rupture is the most common cause of death. Stroke is also reported in vascular EDS. Pregnancies may be complicated by pre- and postpartum arterial bleeding, and by intrapartum uterine rupture. Pregnancies carry a 12%–25% fatality rate[20,36] Vaginal and perineal tears from delivery heal poorly and caesarean wounds often dehisce.[4]

LABORATORY FINDINGS. Routine histopathologic examination of the skin from EDS patients is typically normal. Electron microscopy demonstrates abnormalities in the appearance of collagen fibrils as noted above. Despite the bruising and increased bleeding, tests of platelet function and coagulation are usually normal, further highlighting the underlying defects in skin and blood vessel structural integrity. As noted above for specific subtypes, while genetic diagnosis is possible, especially as a research tool, a variety of biochemical tests are available as well.

DIFFERENTIAL DIAGNOSIS. EDS must be distinguished clinically and histologically from CL. In CL, the hyperelastic skin does not return to its normal position after stretching. The kyphoscoliotic and hypermobility forms of EDS must be distinguished from Marfan syndrome, which additionally is characterized by ectopia lentis and characteristic skeletal abnormalities. Molluscoid pseudotumors of the lower legs may mimic subcutaneous granuloma annulare. The easy bruisability and poor wound healing of EDS patients has led to concerns of child abuse.

Vascular EDS exhibits significant clinical similarities to Loeys–Dietz syndrome type 2, an aortic aneurysm syndrome caused by mutations in transforming growth factor (TGF)-β receptor 1 and 2 (*TGFBR1* and *TGFBR2*) genes. These patients also exhibit skin findings including velvety translucent skin, easy bruising, and widened, atrophic scars.[60] Prior to detection of arterial anomalies Loeys–Dietz syndrome patients may be misdiagnosed as classic or hypermobility EDS.

TREATMENT AND PREVENTION

A multidisciplinary preventative strategy is the most productive approach to the management of EDS patients. Early identification of affected patients with appropriate intervention (pain management, physical therapy, surgery) and education is important.[68–70] Nonweight-bearing exercise (swimming) can promote muscle development. Exercise regimens are typically designed to strengthen muscles to stabilize joints and relieve stress. Physical therapy focused on shoulder girdle strengthening, has decreased the frequency of shoulder dislocations in patients with a history of chronic or recurrent dislocation. Some patients use orthopedic devices such as orthotics and braces with benefit.

Avoiding and preventing injuries is of great importance. Assessment of the home environment with modifications to make homes "EDS safe," such as avoiding hard, sharp edges on furniture and arrangement to prevent or minimize falls, can be helpful. Patients with significant skin fragility or bruising may require protective padding or bandaging and should avoid contact sports and heavy exercise.

When cutaneous wounds do occur, they should be sutured using both subcuticular and cuticular sutures, which are tightly spaced and left in place for a prolonged duration (at least twice as long as standard). Adhesive tapes, bolsters, or pressure bandages are necessary to aid healing, diminish scarring, and lower the risk of hematoma and pseudotumor formation. Close monitoring for postoperative infection is critical and preventative antibiotic therapy is often employed. Pseudotumors of the elbows or knees are typically more easily surgically removed than those on the heels.

Ongoing rheumatologic and orthopedic care may be required to prevent progressive joint disease in certain patients. Low-impact sports are preferable to contact sports and weight training in patients with hypermobility EDS. Ascorbate therapy (~2 gm/day in adults with proportional decreases in pediatric patients) may improve bruising (but not other findings) in classic EDS.

Anti-inflammatory drugs may improve the musculoskeletal pain associated with EDS, but those interfering with platelet function (especially aspirin) should be avoided in patients with significant bruising. Patients with valvular heart disease should be followed by cardiologists, and a baseline echocardiogram with measurement of aortic diameter is recommended before 10 years of age.[25]

Joint dislocation (with the exception of congenital dislocation of the hip) in EDS typically spontaneously resolves or can be remedied with closed reduction. Patients with hypermobility EDS may benefit from a variety of physical therapy interventions, such as myofascial release therapies and low-resistance exercises for muscle toning. Exercise progression should involve increasing the number of repetitions, frequency, or duration of exercise, rather than increasing resistance and should progress slowly. Pain from writing utensils can be lessened by altering the grip to rest the shaft of writing utensils on the thenar web and holding the tip between the index and ring fingers. Transvaginal pelvic physical therapy has been successfully utilized for abdominal and back pain as well as radicular pain of the lower extremities and dyspareunia. Braces are commonly used to stabilize joints. Intervention is typically multidisciplinary and should involve rheumatology, orthopedic surgery, physical and occupational therapy, and pain management specialists as appropriate. Pain in hypermobility EDS is often undertreated. While reparative or corrective surgeries are often delayed as long as possible, the perioperative complication rate in patients with hypermobility EDS is not increased. Gastrointestinal (GI) symptoms may be quite troublesome and require aggressive therapy with proton pump inhibitors, H2-blockers, and other agents. Calcium and vitamin D supplementation is typically encouraged.[31]

Patients with vascular EDS should refrain from contact sports or isometric exercise and avoid medications, which impair platelet function. The traditional recommendation has been that invasive vascular procedures should be avoided, unless absolutely necessary (such as with arterial rupture), due to the extremely high risk of vascular rupture. When performed, tissues must be handled with extreme caution due to pronounced intraoperative tissue fragility. A recent series suggested early intervention by skilled surgeons and provided suggestions for management.[71] Studies examining the use of β-blockers in vascular EDS are in progress.

Fatigue is a common finding in EDS of most types, present in over three-fourth of patients. It appears most common in hypermobility EDS, but is seen in other forms as well. Contributing factors include disruptions of sleep, impaired self-efficacy, and pain.[72] A variety of neuromuscular findings, including reduction in vibration sense and mild-to-moderate muscle weakness, were commonly found in a small group of multiple types of EDS. These symptomatic findings correlated with myopathic features on needle electromyography (EMG) (a mixed neurogenic–myopathic pattern in 60%) as well as muscle ultrasound showing increased echo-intensity and atrophy. The subset of patients with hypermobility EDS resulting from TNX-B haploinsufficiency seem to have fewer neuromuscular issues, although TNX levels correlate inversely with neuromuscular symptoms.[73]

Pregnancy in the EDS patient should be considered high-risk. The effects of hormonally mediated connective tissue softening on the abnormal connective tissue of EDS have not been studied, but may account for the increased skin fragility, as well as other EDS sequelae, that occur during pregnancy and the immediate postpartum period. Prenatal diagnosis is possible by genetic and biochemical analyses. Unless children are severely affected by their disorder, they generally adjust well to the skin findings and joint hypermobility. The Ehlers–Danlos Foundation is a national support group (www.ednf.org).[70]

MARFAN SYNDROME

MARFAN SYNDROME AT A GLANCE

- Incidence: 1 in 5,000–10,000 (OMIM #154700).
- Autosomal dominant inheritance with mutations in fibrillin 1 (*FBN1*; chromosome 15q21.1).
- Cutaneous features include striae distensae (two-thirds of patients), inguinal or incisional hernias, and, rarely, elastosis perforans serpiginosa.
- Extracutaneous manifestations include hyperextensible joints, upward lens displacement, skeletal abnormalities, and cardiac aberrations, such as aortic aneurysm and rupture.
- Information for patients and professionals at http://www.marfan.org.

EPIDEMIOLOGY

Marfan syndrome is an AD disorder primarily affecting the skeletal, ocular, and CV systems.[74] About 25% of cases occur sporadically, particularly in patients born of older fathers. Parental germline mosaicism has been described.[75] The overall prevalence of Marfan syndrome is estimated at approximately 1:5,000–10,000 persons with no racial, gender, or geographic predilection.[76] The prognosis for patients with Marfan syndrome has improved over the past three decades due to better medical and surgical treatments.[77]

ETIOLOGY/PATHOGENESIS

While standard histopathology of affected skin appears normal, with electron microscopy dermal collagen in Marfan syndrome exhibits abnormal thickness, array,

and shape, including fibrils of variable thickness, disarray, twisted fibrils, and fibrils with a flower-like appearance and ragged margins, similar to those found in EDS. The content ratio of collagen I to collagen III is also decreased.[32] Recently, defects in the architecture of the collagen microfibrils of large vessels, rather than collagen content or cross-linking, have been described.[78] The resultant architecture is similar to that seen in abdominal aortic aneurysms and is proposed to explain the weakened aneurysmal vessels in Marfan syndrome.

Marfan syndrome results from heterozygous mutations[79] in the profibrillin 1 gene on chromosome 15q21.1.[80] The spectrum of clinical phenotypes resulting from *FBN1* defects extends beyond classic Marfan syndrome and these disparate conditions have been termed *fibrillopathies/fibrillinopathies*[81] These range from the severe neonatal Marfan phenotype to isolated aortic root dilatation or marfanoid skeletal features without typical CV pathology or ectopia lentis. Fibrillin is a 350-kDa glycoprotein that is a major component of extracellular matrix (ECM) microfibrils, which are structural components of the zonular fibers of the suspensory ligament of the lens and associated with elastic fibers in the aorta and skin. Virtually every family's mutation is different and over 500 mutations have been reported occurring in any of the 65 exons of the gene. No hot spots have been identified, except in cases of neonatal Marfan syndrome. Interestingly, mutations creating premature termination codons appear to lead to milder disease, while those in exons 24–31 are associated with neonatal Marfan syndrome and more severe disease.[76,82] Marfan syndrome type II is caused by mutations at the *TGFBR2* gene locus.

Fibrillin interacts with latent TGF-β binding protein, sequestering it, and controlling TGF-β availability. Deficiency of fibrillin increases TGF-β availability and fibrillin-1 mutation leads to constitutive activation of latent TGF-β with signaling through both "classic" and noncanonical TGF-β pathways. In vascular tissues, TGF-β is believed to be a critical mediator of both the structure and the function of the vascular ECM, via both matrix deposition and degradation. Increased TGF-β signaling enhances ECM degradation, leading to aneurysm development and progression. Stimulation of either TGF-β pathway can also lead to phosphorylation of Smad, which triggers a profibrotic signaling response. Angiotensin II signals through two receptor types, type 1 (AT1) and type 2 (AT2), which exhibit opposite signaling effects. Angiotensin II signaling through AT1 also increases expression of TGF-β ligands and receptors and stimulates vessel wall fibrosis. In addition to the action of activated TGF-β, macroaggregates of fibrillin monomers form the basic scaffold on which mature elastin fibers are assembled; as a result, abnormal fibrillin creates a disordered microfibril matrix that may further lead to disordered and weak elastic fiber formation and disruption of the microfibril network that connects elastic lamellae to neighboring interstitial cells.[83]

Research into the impact of these pathways and their potential therapeutic implications for Marfan syndrome is ongoing. Losartan, a blocker of angiotensin II type 1 receptor, has already shown promise in slowing the aortic root dilatation in individuals with Marfan syndrome. Losartan not only blocks TGF-β but appears to decrease phosphorylation of Smad2 independent of its TGF-β effects. Thus, AT1 blockade may interrupt several pathways, which affect vascular remodeling and disease progression.[84]

CLINICAL FINDINGS

Marfan syndrome is a generalized connective tissue disorder exhibiting abnormalities of three primary organ systems: ocular (typically lens dislocation); skeletal (excessive extremity length, loose joints, anterior chest deformities, and kyphoscoliosis); and most importantly, CV (classically aortic aneurysm and mitral valve redundancy).[81] Many of the typical physical features of Marfan syndrome are age-dependent, making diagnosis in childhood more difficult. No single clinical sign is pathognomonic.[85]

The "Marfanoid habitus" is characteristically dolichostenomelic (tall and thin), with a lower body segment (pubic symphysis to floor) that is longer than the upper segment (height minus lower segment) (Fig. 137-7). Characteristically, the arm span exceeds the person's height by several centimeters. The distal bones are excessively long (arachnodactyly). Skeletal features of Marfan syndrome are characterized by bone overgrowth and joint laxity. Kyphoscoliosis may be severe and increases with the adolescent growth spurt.[86]

Figure 137-7 Marfan syndrome. Frontal view of teenage girl with Marfan syndrome. Note the tall stature, arachnodactyly, abnormally low ratio of the upper segment to lower segment, and long arms.

Thoracic cage abnormalities, such as pectus excavatum (sternal depression) or carinatum (sternal projection), both result from excessive rib overgrowth and are common. The combination of kyphoscoliosis and pectus excavatum rarely compromises cardiopulmonary function. Joint laxity from capsular, ligamentous, and tendinous involvement may cause flat feet, knee or elbow hyperextensibility (genu recurvatum), and occasional joint dislocation. Patellar dislocation is not uncommon; dislocation of the hip, often detected during the newborn period, may be the first sign of Marfan syndrome. Screening tests for joint hypermobility are the thumb (or Steinberg) sign, in which the thumb extends well beyond the ulnar border of the hand when overlapped by the fingers, and the wrist (or Walker–Murdoch) sign, in which the thumb overlaps the fifth finger as they grasp the opposite wrist.[86] The underlying joint hyperextensibility and long extremities of Marfan patients often enable them to reach around their back and touch their umbilicus from the opposite side.

Most patients with Marfan syndrome exhibit myopia due to flattening of the corneas and an abnormally long anterior–posterior orbital axis.[87] An estimated 50%–70% of patients have ectopia lentis, typically with upward lens displacement. Subluxation and complete dislocation of the lens often lead to secondary ocular abnormalities, including ametropia, myopia, acute glaucoma, and increased risk of retinal detachment.[75] As mild displacements may be missed with standard ocular exams, referral to ophthalmology for a dilated slit lamp exam is necessary if a diagnosis of Marfan syndrome is suspected.

CV abnormalities are responsible for the majority of the morbidity and mortality in Marfan patients. CV abnormalities are detected in ~40% of patients with Marfan syndrome by cardiac examination and almost 100% of patients by autopsy examination. Medial necrosis of the aorta is the most common defect and diffuse dilatation of the proximal segment of the ascending aorta with aortic regurgitation often occurs. Such dilatation is progressive, and may even be detected in utero. The progression of dilatation is not always continuous and this unpredictability mandates frequent monitoring.[88] Death in Marfan patients usually occurs in adulthood as a result of CV sequelae, most commonly secondary to dilatation of the aortic root,[89,90] leading to aortic dissection or rupture and pericardial tamponade. MVP results from dilation of the mitral valve annulus, with stretching of the chordae and MV leaflet redundancy. It occurs in ~25% of affected children and adolescents, and in 86% with associated pectus excavatum.[91] MVP increases with age, and eventually occurs in ~75% of patients.[92] MVP may lead to abnormal findings on electrocardiogram, mitral valvular regurgitation, and even cardiac arrhythmias leading to sudden death.[74]

Lack of subcutaneous fat and the presence of striae, most prominent on the upper chest, arms, thighs, and abdomen, are the most common cutaneous manifestations of Marfan syndrome. These cutaneous features are found in up to two-third of patients. Elastosis perforans serpiginosa (see Chapter 69) is more common in individuals with Marfan syndrome, and inguinal or incisional hernias may occur. Skin findings are considered minor diagnostic features in the revised diagnostic criteria.[93]

Dural ectasia (stretching of the dural sac in the lumbosacral region) often develops in patients with Marfan syndrome. Emphysema has been described, and lung bullae increase the risk of pneumothorax, particularly involving the upper lobes. Oral findings may include a high-arched palate and crowding of anterior teeth.

NEONATAL MARFAN SYNDROME

Infants with the neonatal form of Marfan syndrome have the body disproportion of Marfan syndrome in addition to lax skin, emphysema, ocular abnormalities, joint contractures, kyphoscoliosis, adducted thumbs, crumpled ears, micrognathia, muscle hypoplasia, and deficient subcutaneous fat over joints.[94,95] Severe cardiac valve insufficiency and aortic dilatation result in death during the first 2 years of life.

MARFAN SYNDROME IN PEDIATRIC PATIENTS

A recent large retrospective study highlighted clinical features of children in a cohort of more than 1,000 patients with *FBN1* mutations. The median age of diagnosis was 6.5 years, and only 30% had a positive family history. Patients with neonatal Marfan syndrome represented 14% of the cohort. Of the affected children, 19% were noted to be severely affected, 32% to have classic Marfan, and 35% of the patients to have probable Marfan syndrome. In the pediatric population, 71% already exhibited dilatation of the ascending aorta. Ectopia lentis was present in approximately half and typical marfanoid skeletal findings in 28%. Aortic arch dilatation was more common in neonatal cases; however, aortic complications were rare in childhood. In uncertain cases the identification of *FBN1* mutations often aided diagnosis. While neonatal Marfan syndrome represents a severe de novo early-onset form with associated high mortality, patients diagnosed after adolescence typically resembled adult patients in phenotype. Milder cases were more often had a positive family history, likely because milder cases are more commonly survived to reproductive age. Importantly, pediatric patients often did not meet international criteria for the diagnosis of Marfan syndrome at the time of first examination. As the features of the syndrome increase with age, follow-up examination is critical in suspected pediatric cases to identify affected patients.[76]

LABORATORY INVESTIGATION

The diagnosis of Marfan syndrome is based on a constellation of clinical findings. There is no diagnostic laboratory test or histologic abnormality. Increased urinary hydroxyproline and desmosine are not consistent findings. Ophthalmologic examination by an experienced ophthalmologist with interventions as necessary should be performed as early as possible. Orthopedic

BOX 137-1 DIFFERENTIAL DIAGNOSES FOR MARFAN SYNDROME

DISORDER	CLINICAL SIMILARITIES TO MARFAN	CLINICAL DIFFERENCES FROM MARFAN	DEFECT
Homocystinuria	Dolichostenomelia Orthopedic abnormalities Ectopia lentis (downward displacement)	Elevated fasting homocysteine levels AR	Cystathionine β synthetase deficiency causes abnormal methionine metabolism and increased levels of urinary homocysteine
MASS (*M*itral valve prolapse; *A*ortic root diameter; *S*tretch marks; *S*keletal features) syndrome	Mitral valve prolapse Myopia Skin—striae Skeletal findings AD	Borderline aortic enlargement is not progressive	Heterozygous fibrillin 1 mutations
Mitral valve prolapse (MVP) syndrome	Mitral valve prolapse Skeletal findings AD	Lack of other features	Fibrillin 1
Familial ectopia lentis	Ectopia lentis Skeletal changes	Questionable risk of eventual aortic enlargement: Current recommendations are for periodic imaging	Heterozygous fibrillin 1 mutations
Shprintzen–Goldberg syndrome	Dolichostenomelia Arachnodactyly Scoliosis Pectus Highly arched palate Occasional aortic root enlargement	Craniosynostosis Developmental delay Hypertelorism Proptosis Rib anomalies Chiari malformation Equinovarus deformity	Fibrillin mutations not present in most cases
Loeys–Dietz syndrome (LDS)	Generalized arterial tortuosity with aneurysms and dissection occurring throughout Aneurysms more labile than Marfan syndrome Early dissections and ruptures even in childhood AD	No ectopia lentis Dolichostenomelia less frequent/obvious Hypertelorism Cleft palate with broad/bifid uvula Learning disabilities Chiari I malformation Hydrocephalus Blue sclerae Craniosynostosis Talipes Exotropia Soft, velvety, translucent, easily bruised skin	Mutations in *TGFBR1* and *TGFBR2* have been detected
Familial thoracic aortic aneurysms and aortic dissection (FTAAD) syndrome	Vascular disease AD	No other typical clinical features	*TGFBR2* mutations and other loci
Ehlers–Danlos syndrome (see above)	Kyphoscoliotic form EDS may exhibit increased risk for rupture of medium-sized arteries Vascular EDS has joint laxity (often only small joints), translucent skin, characteristic facies, organ rupture, and tendency for aneurysm or dissection of medium to large muscular arteries AD	Vascular pathology not limited to the aortic root, although this may be involved	
Weil–Marchesani syndrome	Ectopia lentis	Orthopedic features differ Short stature Brachydactyly Spherophakia Stiff joints	
Congenital contractural arachnodactyly (CCA; Beals syndrome)	Congenital contractures (elbows, knees, hips, and fingers)—improve with time Ocular (keratoconus) and/or cardiovascular (aortic root dilatation, mitral valve prolapse, and septal defects) findings rare Arachnodactyly, progressive severe kyphoscoliosis High, arched palate Muscular hypoplasia/weakness	Characteristic folded upper helix—"crumpled" appearance of ear—improves with time	Defects in second fibrillin gene (*FBN2*- typically in the "neonatal region" of exons 23–34)[96] Likely locus heterogeneity[97,98]

evaluation as needed and echocardiographic monitoring of aortic root size and valvular function is paramount with cardiology involvement depending on the findings.

DIFFERENTIAL DIAGNOSIS

Marfan syndrome is rarely confused with disorders other than homocystinuria (see online edition of this book). However, a variety of conditions exhibit partial phenotypic overlap with Marfan syndrome, including some also caused by fibrillin-1 mutations. These are summarized in Box 137-1.

TREATMENT

Management of Marfan syndrome has focused on prevention of the disabling and life-threatening potential complications. Early and regular ophthalmologic examinations are required to detect correctable amblyopia and retinal detachment. Ectopia lentis and even complete subluxation may be tolerated for decades. Lens extraction may be required to treat diplopia, glaucoma, cataracts, or retinal detachment. Lasix surgery is contraindicated.

Repair of pectus excavatum is appropriate if cardiopulmonary compromise develops, but is delayed until skeletal maturation is nearly complete to prevent recurrence and should utilize internal stabilization.[99] Scoliosis may be lessened in adolescent girls by estrogen therapy, but this may produce an overall decrease in height. Bracing, physical therapy, and vertebral fusion may all be required to prevent severe scoliosis.

A family history of early aortic dissection mandates aggressive monitoring. At a minimum, patients with Marfan syndrome should undergo yearly monitoring. Aortic complications have not been reported in patients with an aortic diameter normal for age or less than 40 mm in diameter (in adults)[74] Long-term propranolol therapy has been administered to prevent aortic dilatation by decreasing myocardial contractility,[100] but may not affect survival.[101] In a small number of children with Marfan syndrome who were recalcitrant to β-blockers, angiotensin II type 1 receptor blockers (losartan and irbesartan) led to a significant decrease in aortic root diameter and dilation of the sinotubular junction. Larger randomized trials examining the effect of these agents are underway.[102] Aneurysmal and valvular heart defects may require prosthetic replacement, but this should be delayed for as long as possible to avoid recurrent prosthesis replacement, particularly in growing children. Replacement of the aortic root has led to increased life expectancy and is indicated once the maximal measurement is greater than 5 cm in adults and older children, the rate of size increase is ~1 cm/year, or progressive aortic regurgitation develops. Patients with known aortic dilatation should avoid caffeine, stressful circumstances, and vigorous exercise. Patients with pulmonary involvement should avoid situations with rapid changes in air pressure, such as scuba diving or flying and, of course, should not smoke.[103]

Doxycycline inhibits matrix metalloproteinase and has been shown to improve aortic wall architecture and delay aortic dissection in mouse models. Future studies may focus on synergy between doxycycline and losartan, as matrix metalloproteinases can activate TGF-β.[77]

Children should be excused from participation in physical education in order to avoid potentially harmful exertion, contact sports, and isometric exercises, which might lead to aortic rupture or congenital heart failure. Unfortunately, this can add to the isolation of a child who may already be concerned about an unusual body image or is socially ostracized because of looking "different" or being excessively tall. Importantly, not all patients with Marfan syndrome exhibit striking "classic" phenotypes. When the diagnosis in a patient with an atypical presentation is suspected, one must make certain that appropriate studies are performed, so that potentially lethal internal manifestations are not neglected. The Web site for the National Marfan Foundation is www.marfan.org.

HOMOCYSTINURIA

HOMOCYSTINURIA AT A GLANCE

- Incidence: 1 in 65,000 to 344,000 (OMIM #236200).
- Autosomal recessive inheritance, mutations in cystathionine β-synthase, chromosome 21q22.3.
- Cutaneous features include malar flush, fair and thin skin and hair, and livedo reticularis.
- Extracutaneous manifestations include downward lens displacement, osteoporosis, mental retardation, thromboembolism, and severe hyperhomocysteinemia.
- Information for patients and professionals at http://www.pku-allieddisorders.org and http://www.hcusupport.com.

PSEUDOXANTHOMA ELASTICUM

EPIDEMIOLOGY

Also known as *Grönblad–Strandberg syndrome*, this rare entity is a multisystem disorder exhibiting progressive calcification of elastic tissue. It occurs in ~1:70,000–160,000 individuals but is likely underdiagnosed. Now classified as an AR disorder, occasional pseudodominance is reported and heterozygous carriers may exhibit a phenotype closely resembling pseudoxanthoma elasticum (PXE)[123] PXE appears to be more severe in female patients.[124] The average age of

PSEUDOXANTHOMA ELASTICUM AT A GLANCE

- Incidence: 1 in 25,000 to 100,000 (OMIM #177850 and #264800).
- Autosomal recessive inheritance, occasional pseudodominant.
- Mutations in multidrug resistance associated protein (MRP6), encoded by (*ABCC6*) on chromosome 16q13.1.
- Cutaneous features include yellow, flat papules in the neck, flexures, and per umbilical areas. Less frequent skin lesions include acneiform lesions, elastosis perforans serpiginosa, reticulate pigmentation, and granulomatous nodules.
- Extracutaneous manifestations include angioid streaks, visual impairment, *peau d'orange* retinal hyperpigmentation, cardiovascular disease, and bleeding.
- Histopathology shows swollen, clumped, fragmented elastic fibers and calcium deposits in the mid and deep reticular dermis. Alterations easily visualized with calcium (i.e., von Kossa) and elastic (i.e., Verhoeff–van Gieson or orcein) stains.
- Information for patients and professionals at http://www.pxe.org and http://www.napxe.org.

diagnosis in patients with a positive family history is 8–12 years.[125]

ETIOLOGY AND PATHOGENESIS

The mutated gene in typical PXE is *ABCC6*, a member of the ATP-binding cassette (ABC) transmembrane transporter family (subfamily C member 6). It encodes multidrug resistance protein 6 (MRP6) and is located on chromosome 16p13.1.[126] Most mutations are unique, although two occur more frequently: (1) *R1141X*, found predominantly in Europe (28.4% of European patients and 18.8% overall) and (2) *ABCC6del23–29*, which occurs at an overall frequency of 12.9% and is most prevalent in US patients (28.4%).[127] MRP6 is expressed primarily in the liver and kidney, two sites not affected by PXE, and little to none is expressed in tissues affected by PXE. Evidence supports the concept that PXE is a "metabolic" disease, with deficiency of hepatic ABCC6 leading to the deficiency of circulating factors necessary to prevent tissue mineralization. This hypothesis is supported by: (1) the progressive nature of the disease; (2) the delayed clinical onset; (3) the inability of serum from PXE patients and Abcc6 null mice to prevent calcium/phosphate precipitation in human smooth muscle cell cultures; and (4) the development of typical calcification in wild-type skin grafted onto a Abcc6 null mouse, but not in Abcc6 null skin grafted onto a wild-type mouse[125]; and (5) the rescue of PXE mice from developing typical PXE changes by parabiotic pairing with normal mice.[128] The great phenotypic heterogeneity exhibited by PXE patients suggests that additional genes or environmental factors contribute to and modify the development of clinical findings. Certain polymorphisms in the promoter of the *SPP1* gene (osteopontin) are more frequent in PXE patients than controls, and one is associated with a significantly reduced PXE risk.

Mutations in *GGCX*, which encodes an enzyme necessary for γ-glutamyl carboxylation of gla proteins, have been described in patients with PXE associated with multiple coagulation factor deficiency.[126] In patients with *GGCX* mutations, PXE, and in *ABCC6* null mice, matrix gla protein (MGP), which prevents tissue mineralization when fully carboxylated, is undercarboxylated. It is thought that a factor, such as vitamin K conjugated with glutathione, is potentially transported by ABCC6 from the hepatocyte to the extracellular space, and necessary for MGP carboxylation. ABCC6 deficiency disrupts this transport, leading to defective MGP carboxylation and inability to prevent peripheral tissue mineralization.[126] In support of this hypothesis, a recent report described significantly lower levels of vitamin K in the serum of patients with PXE.[129]

CLINICAL FINDINGS

Patients with PXE show marked clinical heterogeneity, with some patients displaying lesions of the skin, eye, and systemic vasculature (e.g., GI and coronary vessels),[130] while others in the same family (presumably with the same gene mutations) show only involvement of one system. Typically, the skin in PXE demonstrates yellowish, flat-topped, discrete, and confluent papules in the skin creases of the sides and nape of the neck (Fig. 137-8), perineum, axillae, umbilicus, and flexural folds with skin redundancy that increases with advancing age. These changes are often termed "plucked chicken skin." Calcification of affected skin is common. Multiple comedones have been described in association with the typical skin changes, likely related to elastic fiber degeneration similar to solar elastosis. Perforating periumbilical PXE has also been described.[131] Infiltrative oral, anal, and vaginal mucosal lesions may also occur. The dermatologic features generally begin in the second decade but are often subtle and overlooked. Rarely, progression may lead to diffuse skin involvement and/or CL-like laxity in the flexures. Some authors suggest that prominence of the horizontal and oblique mental creases (which separate the lower lip from the chin) prior to 30 years of age is highly specific for PXE. Skin biopsy can be quite helpful, as the typical histologic findings may be found even with minimal or absent skin lesions.[132] A differential

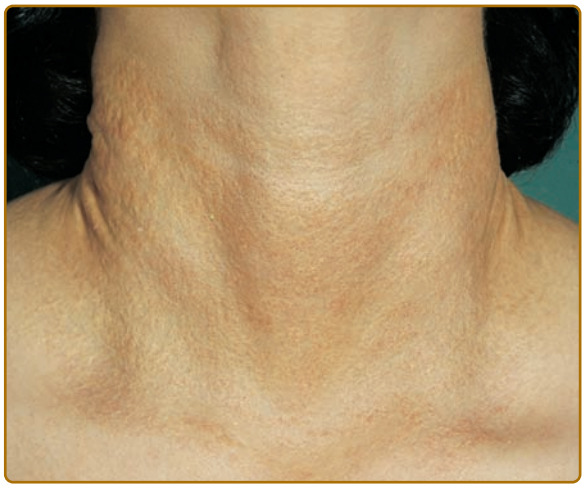

Figure 137-8 Pseudoxanthoma elasticum papules on the neck. There is a distinct yellowish hue. Loose, thickened skin with a pebbled appearance on the neck.

diagnosis for the characteristic skin lesions of PXE is provided in Box 137-2.

Elastosis perforans serpiginosa is reported in patients with PXE (see Chapter 69).[138] Hyperpigmented, reticulated macules, lip telangiectasias, and acneiform and granulomatous lesions have also been described.[138,139] While cosmetic concerns over cutaneous lesions may prompt some patients to seek medical input, it is more commonly a visual or vascular complication, such as a GI tract hemorrhage, which prompts patients to seek medical attention.

The most common ophthalmologic finding is angioid streaks (87% of patients). These are radial curvilinear extensions of gray, brown, or reddish coloration from the optic disc, caused by visualization of the choroid through tears in the elastic-rich Bruch's membrane. Calcification of its outer layer, the lamina elastica, leads to fragility and fissuring. Angioid streaks often develop during the third or fourth decade of life, although the youngest patient described was 10 years of age.[140,141] Angioid streaks rarely interfere with visual acuity and may progress or remain stationary. Trauma is likely a precipitating factor in the development of neovascularization and hemorrhagic complications. Characteristic irregular retinal epithelial mottling ("peau d'orange") is commonly seen resulting from degenerated elastic tissue. Peau d'orange retinal changes precede angioid streaks and are the more common ocular finding in children with PXE. Drusen of the optic nerve have also been described, and drusen-like lesions of the posterior pole have been reported in a 12-year-old boy with PXE.[140] Additional changes reported in PXE include healing subretinal hemorrhages ("salmon patches"); small scars or white foci that represent residua of past hemorrhage ("pearls"); or pigmented foci from previous hemorrhage ("black dots").

Loss of vision in PXE tends to occur later in life and is due to scarring and fibrosis from choroidal neovascularization and retinal hemorrhage. It can lead to a disc-shaped degeneration of the central visual area causing central visual loss, although peripheral vision often remains intact.

Calcification of degenerated elastic tissue of the internal lamina of blood vessels with subsequent hemorrhage and/or intimal proliferation is a common and potentially serious complication of PXE. The GI tract and renal vasculature are sites of early manifestations of this degenerative damage, which often presents as acute-onset hemorrhage in the second to fourth decade. It is estimated that 10%–15% of PXE patients will have at least one GI hemorrhagic event. Both hypertension from renal artery stenosis and GI bleeding (especially gastric) may occur as early as adolescence.[128] Late vascular sequelae in PXE include cerebrovascular accidents (subarachnoid hemorrhage has been a significant cause of mortality in PXE), intermittent claudication (most common) and myocardial infarction. Severe coronary artery disease has been noted, even in adolescents with PXE; coronary artery bypass surgery may be ameliorative.[142] Physical signs may include diminished peripheral pulses, hypertension (three times more common in PXE than the general population), murmurs related to MVP and/or congestive heart failure, and peripheral gangrene. Rectovesical prolapse may also occur.[143] Pulmonary and pulmonary vascular involvement is described, but not common. Pregnancy is not contraindicated, but miscarriage rates may be higher in the first trimester, and multiple pregnancies may accelerate the pace of the disease.[143]

LABORATORY INVESTIGATION

The histologic changes on biopsy of lesional skin from patients with PXE are diagnostic, showing distinctive broken curls of basophilic elastic fibers with routine hematoxylin and eosin or Verhoeff–van Gieson staining (Fig. 137-9). Calcium deposition on elastic fibers can be easily detected with von Kossa stain. Similar dystrophic fibers have been noted histologically as an incidental finding in inflammatory skin diseases in patients who do not have PXE.[144] Electron microscopy shows calcification in a centripetal pattern within

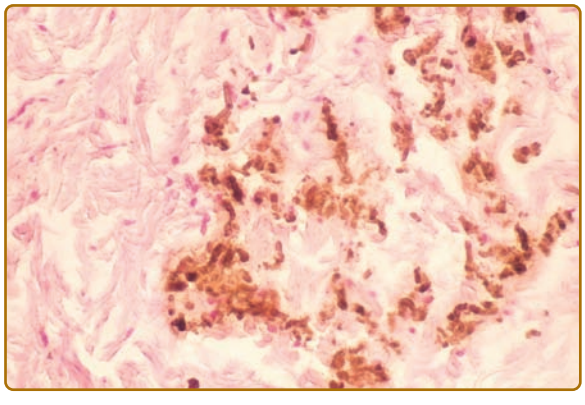

Figure 137-9 Pseudoxanthoma elasticum, elastic tissue stain. The elastic fibers show marked degeneration: They are swollen, tortuous, and irregularly clumped.

BOX 137-2 DIFFERENTIAL DIAGNOSIS OF THE SKIN LESIONS OF PSEUDOXANTHOMA ELASTICUM (PXE)

DISORDER	MORPHOLOGY	DISTRIBUTION	ASSOCIATIONS	DIFFERENTIATION
Dermatofibroma lenticularis[133]	Asymptomatic, flat-topped yellowish papules and nodules, which, when grouped, form large plaques several centimeters in diameter	Often proximal extremities, truncal; symmetric; may be more widespread	Osteopoikilosis, fractures in Buschke–Ollendorff syndrome—due to *LEMD3* (*MAN1*) mutations[133]	Clinical; biopsy shows increased elastic tissue
Localized acquired cutaneous PXE[134]	Asymptomatic, coalescing yellow macules and papules, occasional reticulate or checkered pattern; lax, redundant areas	Neck, axillae, groin, flexural surfaces, areas exposed to saltpeter fertilizer (calcium-ammonium-nitrate)	Older age, exposure to saltpeter fertilizer in Norwegian farmers, uremia	Histology shows fragmented, thickened, mineralized elastic fibers in mid- and deep-reticular dermis
Perforating periumbilical PXE[135]	Asymptomatic or pruritic, erythematous lesions that progress to hyperpigmented plaques, with central atrophy, a red, scaly border, and peripheral hyperkeratotic papules, sometimes expressing elastotic debris	Periumbilical or breast area	Multiparity, ascites, abdominal surgery; uremia, and hyperphosphatemia in chronic renal failure	Histopathology shows elimination of basophilic, elastotic debris through channels in addition to thickened and mineralized elastic fibers in mid- and deep-reticular dermis
Long-term penicillamine therapy[136]	Varied presentations; may resemble pseudoxanthoma elasticum, elastosis perforans serpiginosa, cutis laxa, and anetoderma	Similar to those seen in idiopathic forms of disease (i.e., neck and flexures for PXE, flexures in elastosis perforans serpiginosa)	Use of D-penicillamine	Histopathology shows thickened elastic bundles with prominent lateral protrusions ("bramble-bush"), granulomatous dermal inflammation, infrequent calcification, and transepidermal elimination of elastic fibers
Actinic damage to neck[137]	Numerous small, asymptomatic, discrete, white papules	Neck	Middle aged to elderly individuals	Histology shows elastolysis and fibrosis in papillary and midreticular dermis
Papular elastorrhexis[137]	Asymptomatic, firm, nonfollicular 1- to 5-mm whitish papules on trunk and upper extremities	Chest, abdomen, shoulders, back, proximal extremities	Rarely familial occurrence	Loss of elastic tissue in reticular dermis (relative increase in fibrillar component) and fragmentation, with occasional perivascular mixed infiltrate

TABLE 137-3
Monitoring Studies for Patients with Pseudoxanthoma Elasticum

Study	Reason
Complete blood cell count	Occult blood loss; iron-deficiency anemia
Calcium, phosphate	Rare reports of hypercalcemia and hyperphosphatemia
Fasting lipids	Hyperlipidemia aggravates risk of cardiovascular disease
Urinalysis	Hemorrhage from urinary tract
Fecal test for blood	Occult blood loss from GI hemorrhage
Eye examination	To detect angioid streaks, retinal hemorrhage, early retinopathy
Endoscopy	If evidence of GI bleeding
Echocardiography	If murmur, angina, or personal or family history of coronary artery disease
Doppler blood pressure (ankle, brachial)	To investigate claudication or if decreases peripheral pulses
Computed tomography of head	If focal neurologic problems or evidence of cerebral hemorrhage
Radiographs	If seeking calcifications

GI = gastrointestinal.

elastic fibers.[145] Soft tissue radiographs of the upper and lower extremities may reveal vessel wall calcification. Dental radiographs may demonstrate early vascular calcification. Ultrasonography shows a characteristic pattern of dotted increased echogenicity of renal arteries.[146] Similar patterns have been described on ultrasound of affected pancreas and spleen. The recommended testing for patients with PXE is summarized in Table 137-3.

DIFFERENTIAL DIAGNOSIS

(Box 137-2)

The pebbly pattern and yellow discoloration of flexural skin of classical PXE is quite distinctive. The later development of redundancy may be confused with the sagging skin of CL. Ten percent of patients with β-thalassemia have both angioid streaks and the skin manifestations of PXE, while 16% have only the skin lesions that are clinically and histopathologically typical of PXE.[147] D-Penicillamine may induce an acquired form of PXE, but elastic fibers do not become calcified.[136,148] PXE-like changes have also been noted both clinically and histologically in long-standing nephrogenic systemic fibrosis.[149] (See eFig. 137-9.1 in online edition.)

Angioid streaks have been described in a variety of disorders, among them EDS, Marfan syndrome, lead poisoning, sickle cell anemia, thalassemia,[150] Paget disease of bone, acromegaly and other pituitary disorders, and familial hyperphosphatemia.[151]

PREVENTION AND TREATMENT

There is no cure for PXE and a multidisciplinary approach is required to address the myriad manifestations of the disease. Plastic surgery may improve the appearance of sagging skin, although extrusion of calcium particles through the surgical wound may result in delayed healing and unsightly scars.[152] Fillers or autologous fat injections have been used to soften the prominent facial creases. GI bleeding can usually be managed conservatively with iced saline lavage and transfusion and rarely requires balloon embolization or surgery for control.[153] Anticoagulants [nonsteroidal anti-inflammatory drugs (NSAIDs)/aspirin] are typically avoided in PXE patients. All patients should be followed by a retina specialist and instructed in the use of an Amsler grid to detect early symptoms of retinal hemorrhage. There is no ideal treatment for the ophthalmologic complications, although laser photocoagulation (such as verteporfin photodynamic therapy every 3 months)[154] may ameliorate the choroidal neovascularization. Recently, intravitreal injections of bevacizumab have been employed for the choroidal neovascularization of PXE with promising results if initiated early.[155]

Although low calcium (60–1,200 mg/day)[156] and low-lipid diets have been advocated, their value has not been clinically tested. A report describing the use of aluminum hydroxide as an oral phosphate binder noted improvement in PXE skin lesions in three of six patients treated.[157] Oral ascorbic acid and tocopherol were administered to a single patient with apparent positive response after several years.[158] Most recently, a diet with fivefold the standard of magnesium to ABCC6 null mice prevented the development of connective tissue mineralization.[159,160] Dietary supplementation with magnesium carbonate, which is used as an antacid and commonly added to table salt to prevent caking, is a simple and attractive therapeutic intervention and studies are ongoing in PXE patients to determine its effectiveness at preventing or ameliorating the progression of the disease.

Regular evaluation and follow-up with a cardiologist should be encouraged. Patients should be advised to protect their eyes from even mild trauma, and about the potential for future visual loss. Because of the potential risk to eyes and calcified vessels when traumatized, contact sports and high-intensity CV exercise should be prohibited for persons with PXE. This can be quite life altering for the child or adolescent, who may not fully understand the consequences of the seemingly minor skin changes. Avoidance of high-cholesterol foods and smoking, control of blood pressure, and safe aerobic exercises may be recommended by the physician. Two support groups are available: (1) the National Association for Pseudoxanthoma Elasticum (www.napxe.org), and (2) PXE International, Inc. (www.pxe.org).

CUTIS LAXA (GENERALIZED ELASTOLYSIS)

CONGENITAL CUTIS LAXA AT A GLANCE

- Inheritance may be autosomal dominant (OMIM #123700), autosomal recessive (OMIM #219100 or #219200), or X-linked recessive (also known as *occipital horn syndrome* (OMIM #304150).
- Mutations in elastin (*ELN*) or fibulin-5 (*FBLN5*) in autosomal dominant; in fibulin-5 (*FBLN5*, *EVEC*, *DANCE*) or fibulin-4 (*FBLN4*) in autosomal recessive; a copper transport adenosine triphosphatase (*ATP7A*) in the X-linked type.
- Cutaneous features include pendulous, inelastic skin, with an aged facies.
- Extracutaneous manifestations may include pulmonary emphysema, aortic aneurysm, pulmonary artery and valve stenosis, hernias, gastrointestinal diverticula, joint laxity, low serum ceruloplasmin, and bilateral exostoses of the occiput (or occipital horn syndrome).
- Histopathology shows sparse and fragmented elastic fibers, better visualized with stains (i.e., Verhoeff–van Gieson or orcein).
- Information for patients and professionals at http://www.orpha.net/nestasso/cutislax/.

EPIDEMIOLOGY

CL is a heterogeneous group of disorders (Table 137-4) that results from abnormalities in elastic tissue. It is characterized by widespread laxity of skin and, in some cases, involvement of other organs. AD, AR, and X-linked forms exist, with recessive forms the most common. Review of the world literature suggests only ~200 cases and, importantly, only a striking minority of these patients have a known underlying molecular cause. It is estimated that the success for detecting mutations in patients with AR form of CL (ARCL) type I is only ~10%.[167]

ETIOLOGY AND PATHOGENESIS

The skin contains a variety of fibers, which contain increasing amounts of elastin as they progress deeper into the skin. Abnormalities in elastic fiber synthesis, stabilization, or degradation may all lead to the clinical phenotype of CL. Elastic fibers are composed of an amorphous elastin component (90% of fibril) surrounded by a microfibrillar sheath based on fibrillin. Elastic fibers do not spontaneously assemble; their construction requires a carefully orchestrated sequence of reactions.[161,166] Elastin is synthesized from individual tropoelastin molecules aligned on a network of elastic fibers and the alignment is stabilized via the formation of intermolecular cross-links mediated by copper-dependent lysyl oxidase. Skin elasticity (reversible deformability), as well as that of other tissues such as lung or larger arterial vessels, results from a network composed of elastin fibers. Mutations in the elastin gene (45 kb in length and mapped to 7q11.2.) lead to abnormal elastic fibers (in some due to decreased mRNA stability) and many cases of AD form of CL (ADCL; OMIM #123700).[166]

Superficial oxytalan fibers extend from the dermoepidermal junction and are composed primarily of microfibril bundles. These extend through elaunin fibers, which run perpendicularly in the papillary dermis and contain a small amount of elastin. Deeper, in the reticular dermis, thick horizontal elastic fibers contain higher amounts of elastin.[166] Mutations in genes whose protein products form part of the elastic fiber interface such as fibulin 4 (OMIM #604633) and fibulin 5 (*FBLN5*, *EVEC*, or *DANCE*, OMIM #604580) have been associated with the frequently fatal ARCL type I (OMIM #219100) in humans. Fibulin 5 binds cell surface integrin receptors and key components of elastic fibers, suggesting a role in cell-directed elastic fiber assembly. ARCL type I fibulin 5 mutations lead to abnormal protein folding, decreased secretion, and decreased interaction with elastin and fibrillin-1.[169] One patient with ADCL and a duplication in the fibulin 5 gene has been reported.[165] Missense mutations in fibulin 4 (EGF-containing fibulin-like ECM protein 2 (OMIM #604633)) have been noted in several patients with unusually severe ARCL type I. Elastic fibers in these patients are severely underdeveloped.[170]

ARCL type II (Debre type) patients exhibit loss of function mutations in *ATP6V0A2*, which encodes a subunit of the V-type H^+ ATPase. Defects in *ATP6V0A2* result in a congenital disorder of glycosylation (CDG-II), due to defective serum protein *N*- and *O*-linked glycosylation. Fibroblasts from affected patients demonstrate impaired Golgi trafficking, likely due to abnormal pH regulation in the Golgi compartments. Increased cellular apoptosis also occurs. The exact mechanism by which this leads to the connective tissue defects seen in this syndrome is unclear, although impaired intracellular trafficking may lead to suppressed transport of tropoelastin from the cell.[173] Analysis of apolipoprotein C-III isoelectric focusing is diagnostic in all cases.[172]

Recently, mutations in pyrroline-5-carboxylate synthase (PYCR1), a mitochondrial proline metabolic enzyme, were reported in a group of patients that had previously been diagnosed with a variety of disorders, including wrinkly skin syndrome, De Barsy syndrome, and gerodermia osteodysplastica (GO). This new subgroup has been designated ARCL type II with progeroid features. The resulting abnormal proline metabolism

TABLE 137-4
Cutis Laxa Syndromes: Clinical Subtypes and Associated Defects

Subtype/(OMIM)	Clinical Features	Inheritance	Protein (Gene Defect/ OMIM)	Cellular Defect
Autosomal dominant (ADCL)/(123700)[161,162]	Later onset Primarily cutaneous Hernias Rare vascular complications Normal life expectancy[163,164] Some clinical variability	AD	Elastin (ELN/130160) Fibulin 5 (FBLN5/604580)[165]	Abnormal elastic fibers[166]
X-linked recessive/ (304150)[167]	Congenital Skin laxity—often distal Characteristic facies Hoarse cry—vocal cord redundancy Brittle hair Joint laxity—mild Occipital exostosis—develop after several years of age Skeletal abnormalities Failure to thrive Diarrhea GU diverticulae	XLR	α polypeptide of Cu^{2+} transporting ATPase (ATP7A/300011)	Defective copper metabolism[168]
ARCL I (219100)[163,167]	Congenital Severe Loose hanging redundant skin Early lethality Emphysema Cor pulmonale Hernias (various including diaphragmatic) Mucosal prolapsed No mental retardation Cardiovascular abnormalities rare No hip dislocation	AR	Fibulin 5 (FBLN5/604580)	Abnormal protein folding Decreased secretion Decreased interaction with fibrillin-1 and elastin May have role in cell-directed elastic fiber assembly[169]
	Arachnodactyly Vascular anomalies Increased dissection risk Diaphragmatic abnormalities GI and GU diverticulae	AR	Fibulin 4 (FBLN4/604633)	Severely underdeveloped elastic fibers[170]
ARCL II (Debre type)/ (219200)[171]	Clinical variability Microcephaly Developmental delay Hypotonia Congenital hip dislocation Mental retardation Delayed fontanel closure Progressive neurologic abnormalities CL improves—especially after puberty[163,167] Dental caries common Apolipoprotein C-III isoelectric focusing is diagnostic[172]	AR	α2 subunit of V-type H^+–ATPase (ATP6V0A2/611716)	Congenital disorder of glycosylation (CDG-II) Abnormal pH regulation of Golgi compartments Leads to impaired Golgi trafficking[173] Increased cellular apoptosis ?Impaired transport of tropoelastin from cell Increased vascularization of dermis; reduced collagen Bundle size; underdeveloped elastic fibers distinguish from WSS
ARCL with Progeroid features/(612940)[171]	Progeroid appearance Osteopenia Variable connective tissue weakness Wrinkly, lax skin—especially over hands Finger contractures Triangular facies with mandibular hypoplasia causing prognathism Variable MR Agenesis of corpus callosum Overlap with WSS/GO/DBS Cataracts and dystonia in more severe cases similar to De Barsy syndrome No glycosylation defects	AR	Pyrroline-5-carboxylate reductase 1(PYCR1/179035)	Abnormal mitochondrial proline metabolism Increased cellular apoptosis Mitochondrial defects Elastic fiber abnormalities similar to other ARCL[171]

TABLE 137-4
Cutis Laxa Syndromes: Clinical Subtypes and Associated Defects (Continued)

Subtype/(OMIM)	Clinical Features	Inheritance	Protein (Gene Defect/ OMIM)	Cellular Defect
Gerodermia osteodysplastica (GO)/ (231070)[167]	Progeroid features Malar/mandibular hypoplasia Joint laxity Short stature dwarfism Normal mental development Osteoporosis Frequent fractures—especially vertebral Progressive No glycosylation defects	AR	SCYL1-binding protein 1 (GORAB (formerly SCYL1BP1)/607983)	Soluble protein present in both skin and osteoblasts Interacts with Rab6, which interacts with conserved oligomeric Golgi complex (COG complex) Disrupted Golgi trafficking[174]
De Barsy syndrome (DBS)/(219150)[175]	Cutis laxa Significant MR Eye anomalies Dystonia Progeroid features Progressive	AR	?	Frayed elastic fibers
Cantu syndrome/ (114620)	Cardiac anomalies Osteochondrodysplasia	AR	?	
Wrinkly skin syndrome (WSS)/(278250)[176]	Mild Cutis laxa—hands/feet/abdomen—more prominent while sitting Hypotonia Prominent venous pattern on chest Microcephaly and mental retardation Variable May not represent true entity	AR	Pyrroline-5-carboxylate reductase 1(PYCR1/179035)[a] α2 subunit of V-type H^+-ATPase (ATP6V0A2/611716)[a]	
Additional syndromes				
Latent transforming growth factor binding protein 4 (LTBP4) deficiency[177]	Cutis laxa GI and GU abnormalities Respiratory dysfunction Early lethality Prematurely aged appearance Distinctive facies Normal mental development Mild cardiovascular lesions Growth delay	AR	Latent transforming growth factor binding protein 4 (LTBP4)	Increased TGFβ activity Impaired elastic fiber assembly ?Role for angiotensin II type I receptor blockers
Transaldolase deficiency[178]	Congenital cutis laxa Hydrops fetalis Dysmorphic features Hypertrichosis Variable multiorgan involvement Hepatomegaly Cirrhosis Liver failure Hemolytic anemia GU malformation Renal Splenomegaly with thrombocytopenia Many exhibit gradual improvement including skin—except for liver and renal	AR	Transaldolase	Inborn error in pentose phosphate metabolic pathway
Accumulation of sugar-phosphate intermediates				

AD = autosomal dominant; AR = autosomal recessive; XLR = X-linked recessive; OMIM = Online Mendelian Inheritance in Man.
Table adapted from Morava et al.[167]
[a]Patients with mutations in these genes have been reported as wrinkly skin syndrome prior to identification of their underlying mutation.

leads to mitochondrial defects and increased cellular apoptosis.[171]

GO (OMIM #231070) results from mutations in GORAB (*SCYL1BP1*), a soluble protein highly expressed both in skin and osteoblasts. It interacts with Rab6, which interacts with the conserved oligomeric Golgi complex (COG complex) and is important in Golgi trafficking.[174] In contrast to ARCL of the Debre type, no glycosylation defects are present in GO.

The etiology of ARCL type III/De Barsy syndrome remains unknown, however, there is significant clinical overlap with ARCL type II with progeroid features. Molecular analysis of patients carrying the clinical diagnosis of De Barsy syndrome, including mutation screening of PYCR1, should clarify its position as a distinct clinical entity.

Mutations in the *ATP7A* gene, which encodes a protein member of the *P*-type adenosine triphosphatase family responsible for copper transport, cause X-linked CL, which is allelic to Menkes syndrome.[168] *ATP7A* mediates copper transport from the GI tract, efflux of excess copper from cells, and delivery of intracellular stores of copper to cuproenzymes.

Acquired forms of CL present after skin inflammation and structural damage of elastic fibers. Increased neutrophil elastase present in affected skin is presumed to disrupt elastic fiber integrity.[179] Abnormalities in the genes in which mutations lead to hereditary CL may also play a role in acquired forms of CL. For example, a patient with compound heterozygous elastin mutations showed partial rescue of elastic fiber synthesis by a heterozygous missense mutation in fibulin 5. The resultant elastic fiber system functioned normally, until challenged by *Toxocara canis* parasite infestation during adolescence, leading to acquired CL.[180]

CLINICAL MANIFESTATIONS

The skin in CL is inelastic and appears pendulous. At birth the infant may appear to have unusually soft and loose skin. The skin is hyperextensible, but does not resume its normal shape after stretching (see eFig. 137-9.2 in online edition). Persons with CL are often described as having a bloodhound-like facial appearance (Fig. 137-10) and loose skin of the face, neck, shoulders, and thighs often first attracts attention. Young affected children appear aged. Signs of skin fragility are typically absent in contrast to EDS. Both AR and X-linked forms of CL can exhibit congenital onset. Internal organ involvement may be seen with both inherited and acquired CL. The clinical features of described CL subtypes are summarized in Table 137-4.

The ADCL (OMIM #123700) primarily affects the skin. It may present in infancy or adulthood and tends to be relatively benign with a normal life expectancy.[163,164]

X-linked CL (OMIM #304150) includes patients with the *occipital horn syndrome* and Menkes disease. Patients with X-linked CL demonstrate distinct congenital findings, including skin laxity, often distal, a thin face with long philtrum and short columella, inverted lower eyelids, a high forehead, and a hooked/beaked nose, as well as large fontanels and brittle hair.

Figure 137-10 Cutis laxa due to fibulin-4 mutation. The facial skin hangs in loose folds, giving the appearance of premature aging. Note the prominent periorbital vessels. The tracheostomy was placed for diaphragmatic eventration and respiratory difficulty.

Clinical findings in the ARCL syndromes are quite heterogeneous in both severity and organ involvement. ARCL type I (OMIM #219100) exhibits a severe phenotype with hernias, visceral involvement, and early lethality resulting from profound elastic tissue defects in several organs. The cutaneous findings are pronounced, with loose, hanging, pendulous skin. Children with ARCL type II have distinct clinical findings and can be divided into two groups based on the presence or absence of *N*- and *O*-linked glycosylation defects (CDG type II). To date, obvious clinical differences between these groups are not evident. Additional syndromes considered subtypes of CL are summarized in Table 137-4.

LABORATORY INVESTIGATION

Special stains for elastic tissue (Verhoeff–van Gieson stain) of skin biopsy specimens demonstrate significantly decreased or absent dermal elastic fibers (in both AD and AR forms of CL).[166] Remaining fibers are often clumped, short, granular, and fragmented. Increased elastin-associated microfibrils are noted on electron microscopy. Calcification is not typically seen. Electron microscopy is considered diagnostic for most cases of ARCL, revealing moth-eaten elastic fibers, with abnormal elastin fiber branching and reduced elastin synthesis creating loose microfibrils. Increased vascularization of the dermis, reduced collagen bundle size, and underdeveloped elastic fibers reputedly distinguish ARCL type II from wrinkly skin syndrome

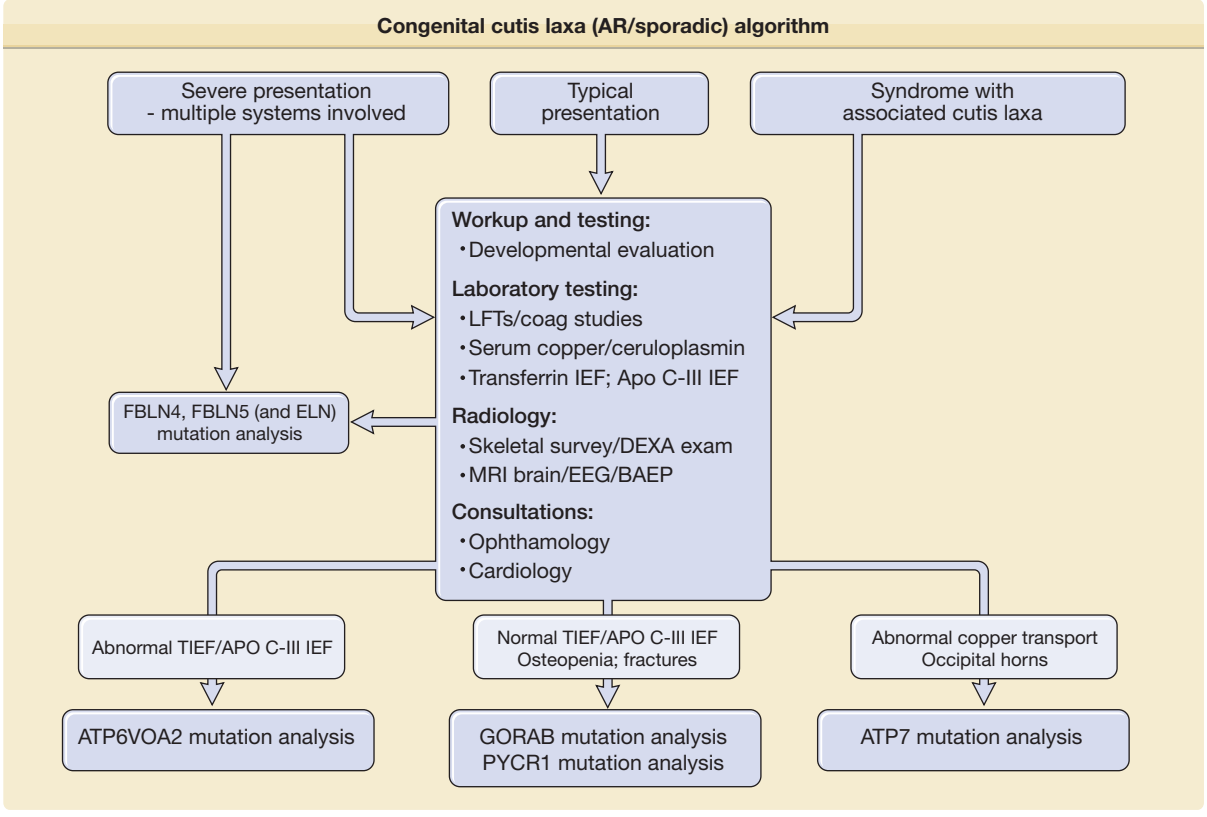

Figure 137-11 Congenital cutis laxa (AR/sporadic) algorithm.

(WSS).[167] Importantly, in both AD and ARCL some patients have exhibited relatively normal electron microscopy and thus the presence or absence of histologic or electron microscopic findings is not necessary for the diagnosis of CL in the clinical setting of loose, hanging skin with decreased elasticity.[167] In acquired cases a mononuclear or mixed inflammatory infiltrate containing neutrophils may be present.

An algorithm for evaluation of a new patient with suspected CL has been proposed (Fig. 137-11). Transferrin immunoelectric focusing studies (TIEF) and ApoC-III IEF should be considered in all patients with AR or sporadic CL (especially those with typical facies, late fontanel closure, and developmental delay or central nervous system involvement). It is important to note that CDG may be missed by the TIEF method in young children. However, the ApoC-III IEF pattern is typically abnormal, even in very young patients. Both studies should likely be repeated after 6 months of age.[167]

DIFFERENTIAL DIAGNOSIS

Patients with EDS have skin that regains a normal appearance when released after stretching. Other features of EDS, including joint laxity, increased bruising, and poor wound healing, are not seen with CL. Older patients with PXE may have laxity of skin, especially in flexural areas, but the skin shows a pebbly yellow appearance.[181] Histologic examination of lesional skin further distinguishes these entities. A disorder with features of both PXE and CL, as well as deficiency in multiple coagulation factors, results from mutations in the γ-glutamyl carboxylase (*GGCX*) gene. These patients exhibit mineralized elastic fibers with positive dermal von Kossa staining, and mild retinopathy similar to PXE but with the pronounced skin folds more typical of CL. Patients also exhibit an abnormal bleeding tendency from deficiency of vitamin K-dependent clotting factors (factors II, VII, IX, and X), atherosclerosis, and possibly cerebral aneurysms.[182] As in PXE, CL-like changes are also reported in long-standing nephrogenic systemic fibrosis.[183]

ACQUIRED CUTIS LAXA

Acquired forms of generalized and localized CL occasionally occur.[137] In type I-acquired CL, ill-defined areas of loose skin appear insidiously but progressively with elastolysis occurring beyond inflammatory areas in many cases. Type I skin lesions involve the head and neck and progress in a cephalocaudal direction. The development of CL is preceded by an inflammatory eruption (urticaria, erythema multiforme, eczematous eruption) in ~50% of cases. Although type I acquired CL usually begins in adulthood, children have been described with this condition. Pulmonary involvement presents as emphysema and is the most frequent cause of death in acquired cases.[137] Severe tracheobronchomegaly is described. Aortic aneurysms with subsequent rupture, and GI and genitourinary diverticulae

have also lead to mortality in these patients. Most affected children have not had evidence of systemic elastolysis.

Type II-acquired CL (Marshall syndrome) is a postinflammatory elastolysis characterized by more localized, well-demarcated, nonpruritic erythematous plaques that extend peripherally and have a hypopigmented center. These appear in crops over a period of days to weeks, often in association with fever, malaise, and peripheral eosinophilia. Localized, or less commonly generalized, areas of CL gradually occur at sites of previous inflammation.[184] While systemic involvement is rare, fatal aortitis has been reported.[185]

Acquired CL may develop after drug exposure to penicillin, D-penicillamine,[186] or isoniazid. It has been associated with α-1 antitrypsin deficiency, complement deficiency (C3, C4), sarcoidosis, syphilis, systemic lupus erythematosus, systemic amyloidosis, cutaneous mastocytosis,[187] and multiple myeloma.

Acquired CL is one of the primary presenting features of hereditary gelsolin amyloidosis (AGel amyloidosis), an AD condition resulting from mutations in gelsolin, an actin modulating protein. Cleavage of the mutant protein creates amyloidogenic protein fragments, which accumulate into amyloid fibrils and are deposited in most tissues. While normal at birth, CL develops with age, initially involving eyelid and scalp skin but eventually becoming more widespread. Patients also note dry skin, pruritus, and fissuring as well as loss of hair. Petechiae and ecchymoses are also common. Noncutaneous findings include corneal lattice dystrophy, as well as cranial and peripheral polyneuropathy. Skin biopsy reveals elastic fiber diminution and fragmentation as well as widespread deposition of AGel amyloid including around elastic fibers. How this leads to destruction of the elastic fibers over time is unknown.[188]

A transient form of neonatal CL with generalized skin laxity and inguinal hernias has been described in infants born to mothers administered D-penicillamine during pregnancy.[189,190] In these cases, the loose skin resolved during the first year of life.

TREATMENT

While some forms of CL improve with time, others worsen with age. It is important for the clinician to recognize that patients with CL often sustain significant psychological trauma due to their appearance. Intervention as appropriate or desired by the patient, addressing not only the physical aspects of the disease, but the psychological and emotional aspects as well, is critical.

Plastic surgery has been somewhat successful in improving the physical appearance of some patients temporarily and is a reasonable consideration as vasculature and wound healing capability are normal.[191] Numerous procedures may be necessary. Herniations are typically repaired when clinically indicated. In cases where cardiopulmonary failure occurs, appropriate drug and ventilatory support is managed by the appropriate specialties. Acquired CL is often recalcitrant to treatment. Dapsone is reported to control acute swelling, which may support a role for neutrophil elastase.[192] Botulinum toxin has been used to improve facial cosmesis.[193] Recently rescue of elastin insufficiency in mice via introduction of the human elastin gene was described, suggesting a potential avenue for future molecular therapies.[194]

OSTEOGENESIS IMPERFECTA

OSTEOGENESIS IMPERFECTA AT A GLANCE

- Combined incidence of 1 in 12,000 people (OMIM #166200 and #166240 type I; #166210 type II; #259420 type III; #166220 type IV; #166220 type V).
- Seven subtypes (ranging from mild, nondeforming (type I) to severe perinatal lethal (type II).
- Most commonly autosomal dominant inheritance.
- The gene encoding procollagen I is most often affected.
- Cutaneous features include hyperextensible skin and blue sclerae.
- Extracutaneous manifestations include increased fractures, dentinogenesis imperfecta, ligament laxity, triangular facies, short stature, hearing impairment, and wormian bones.
- Information for patients and professionals at http://www.oif.org.

BUSCHKE–OLLENDORFF SYNDROME

Buschke and Ollendorff originally reported the association of connective tissue nevi and osteopoikilosis.[207] The disorder is inherited in an AD manner with variable expressivity, but usually complete penetrance. The estimated incidence is 1:20,000.[208] It results from loss of function mutations in the *LEMD3* gene (also called *MAN1*).[133] *LEMD3* appears to antagonize both bone morphogenetic protein (BMP) and TGF-β signaling pathways in human cell lines and, consequently, loss of *LEMD3* leads to enhanced TGF-β signaling. Defects in *LEMD3* have also been detected in cases of both isolated osteopoikilosis and osteopoikilosis with melorheostosis ("flowing" hyperostosis over the cortex of tubular bones),[133] but not in cases of sporadic isolated melorheostosis.[209]

The connective tissue nevi appear as collections of skin-colored to yellow papules or plaques (dermatofibrosis lenticularis disseminata) that are most commonly located on the buttocks, proximal trunk, and limbs. Many patients begin to develop lesions in early childhood, although later onset and emergence of new lesions while others disappear have also been reported. Histopathologic examination of lesional skin may show increased amounts of elastic tissue (elastoma), although decreased or normal amounts of elastic tissue and abnormalities of collagen have also been described. The bony lesions most frequently appear after 15 years of age. They are discrete spherical areas of increased radiodensity, most frequently noted in the epiphyses and metaphyses of long bone, pelvis, scapulae, carpal, and tarsal bones. The radiographic appearance of the lesions may raise concerns for neoplasia. Although the osteopoikilosis is typically asymptomatic, functional limitation due to decreased mobility of an affected cutaneous area has been reported. Other skeletal abnormalities, including short stature, otosclerosis, and supernumerary vertebrae and ribs have been described. Cataracts and peptic ulcer disease have rarely been reported in patients with Buschke–Ollendorff syndrome. Connective tissue nevi without associated bony changes, morphea, and PXE are the most frequent disorders considered in the differential diagnosis. No therapy is available or necessary.

LIPOID PROTEINOSIS

EPIDEMIOLOGY

Lipoid proteinosis (LP) is also known as *hyalinosis cutis et mucosae* (OMIM #247100). Only about 300 cases have been reported in the literature. However, it is relatively common in the Namaqualand area of Northern Cape Province in South Africa (frequency of 1 in 300 population). To date, all South African LP patients studied have carried the same mutation (*Q276X*), likely contributed by a German settler who arrived in 1652 (founder effect).[210]

ETIOLOGY AND PATHOGENESIS

LP is inherited in an AR fashion and is caused by mutations in the gene encoding ECM protein-1 (ECM-1). Although given this name because of its discovery among various connective tissue proteins in a murine stromal cell line, ECM-1 likely has broader functions. ECM-1 is known to inhibit bone mineralization, contribute to epidermal differentiation, and stimulate angiogenesis.[211]

The *ECM1* gene is located next to the epidermal differentiation complex on chromosome band 1q21. ECM-1 is present both in the epidermis and as a secreted protein in the dermis. There are four splice variants: ECM-1a is encoded by the full gene, *ECM-1b* lacks exon 7, *ECM-1c* contains an additional exon 5a, and a fourth form shows truncation of 57 amino acids.[212] ECM-1a is widely expressed, whereas ECM-1b is expressed only in tonsils, keratinocytes, and the upper respiratory tract. ECM-1c is also expressed in the skin.

ECM-1 appears to have several functions. In the skin, it interacts with several ECM proteins, including perlecan (a heparin sulfate proteoglycan present in basement membranes), fibulin 1C/D, fibulin 3, matrix metalloproteinase 9, fibronectin, the β 3 chain

LIPOID PROTEINOSIS AT A GLANCE

- Rare worldwide occurrence, with the greatest incidence (1 in 300) in the Namaqualand region of South Africa.
- Autosomal recessive disorder with variable phenotype, even within families.
- Caused by defects in extracellular matrix protein-1.
- Hoarseness is the most frequent finding.
- Skin fragility and blistering occur in some affected children; blisters heal as infiltrated lesions with scar-like appearance.
- Progressive development of infiltrated papules and plaques is seen, especially on the elbows and extensor aspects of the arms and lower legs.
- Beaded papules on the eyelid margin (moniliform blepharosis) are a classic finding in adolescents and adults, but are not always present.
- Calcification of the temporal lobes and amygdala may lead to neurologic and/or psychiatric symptoms.
- Some patients have airway compromise from upper airway infiltration.
- Periodic acid-Schiff-positive, diastase-resistant thickening is seen at the dermal–epidermal junction, perivascularly, and along adnexal epithelia with hyaline material in the dermis.
- Electron microscopy reveals deposited dermal material and excess basement membrane material around blood vessels with irregular duplication of the lamina densa at the dermal–epidermal junction.
- No effective treatment exists. Laser ablation/dermabrasion of papules is helpful in some cases.

of laminin 332, and collagen type IV. ECM1 may well serve as a "binding core" for cutaneous extracellular and basement membrane proteins.[212] The second tandem repeat of ECM1, encoded by exon 7, binds fibulin-1, an extracellular component of most basement membranes. Thus, ECM-1a binds to fibulin, whereas ECM-1b, lacking exon 7, does not.[212,213] While ECM-1a is expressed in basal keratinocytes ECM-1b is only expressed in terminally differentiated keratinocytes. Given the differential expression of ECM-1 isoforms in skin, the ability to bind fibulin-1 may be important in keratinocyte differentiation. A report describing ultrastructural evidence of desmosomal detachment in cultured keratinocytes from a pediatric patient with the vesicular lesions of LP suggests a role in normal differentiation as well.[214] A recent report in mice found no epidermal alteration in association with over- or underexpression of ECM1, arguing against a role in epidermal differentiation in murine systems, but the relevance for human skin is unclear.[215] Both ECM-1a and ECM-1b may stimulate blood vessel endothelial cell proliferation and promote angiogenesis in chicken embryo.[216] Abnormalities of the cutaneous vasculature are described in LP.[217]

Mutations in ECM1 in LP lead to loss of function of ECM-1. The majority of mutations occur in exon 7, with frameshift mutations leading to ablation of the ECM-1a transcript but not that of ECM-1b, which typically lacks exon 7. Mutations outside of exon 7 typically occur in exon 6 and are nonsense or frameshift mutations. Patients with exon 7 mutations may have a slightly milder phenotype than those with nonexon 7 mutations with regard to respiratory and skin (but not neurologic) manifestations.

Antibodies to ECM-1 have been detected in patients with lichen sclerosus (see Chapter 65), which suggests that this disorder represents an acquired form caused by antibody-induced ECM-1 loss.[218]

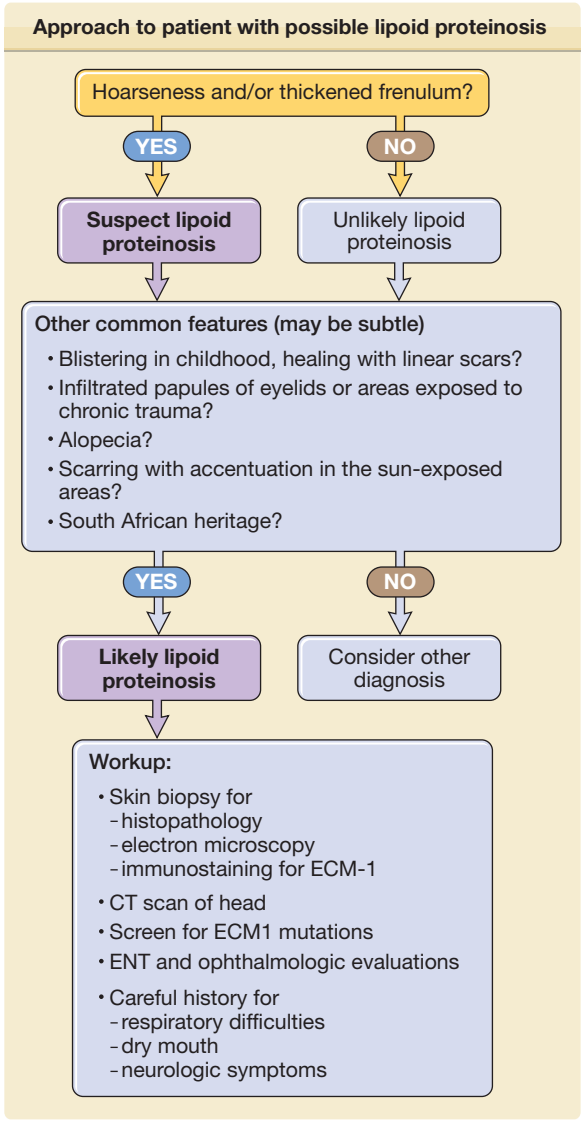

Figure 137-12 Approach to the patient with possible lipoid proteinosis. CT = computed tomography; ECM-1 = extracellular matrix protein-1; ENT = ear, nose, and throat.

CLINICAL FINDINGS

The most reliable clinical signs for diagnosing LP are a hoarse voice and thickened sublingual frenulum, which prevents patients from protruding the tongue. Secondary features include beaded eyelid papules, infiltration of warty papules of the skin around the elbows and extensor forearms, and mild alopecia. Increased scarring and photoaging of sun-exposed skin may be seen. Scars or scar-like lesions are present in areas of minor trauma but are not increased at sites of surgery or vaccination.[210] An algorithm outlining an approach to the patient with suspected LP is shown in Fig. 137-12.

CUTANEOUS LESIONS

The phenotypic features of LP are quite variable, even within families. This is well demonstrated in studies of South African patients, all of whom share the same mutation yet exhibit highly variable phenotypes. The variable expressivity can lead to difficulty in diagnosis of affected patients. The earliest finding in LP is hoarseness from vocal cord infiltration, which occurs at birth or in the first few years of life. Initially, this may be noted as a faint or weak cry and is one of the most striking and consistent features. Hoarseness may progress during the lifetime of a patient. Dysphagia may occur from involvement of the upper aerodigestive tract and esophagus.[210,219] Skin lesions usually develop in the first years of life, although the timing of their onset is variable. Importantly, two stages of skin lesions may be noted. A long-neglected and underappreciated clinical feature of LP is the erosions that can develop during childhood.

Blistering can be extensive enough to mimic epidermolysis bullosa. The associated vesicles (and rarely bullae) are typically noninflammatory and heal slowly

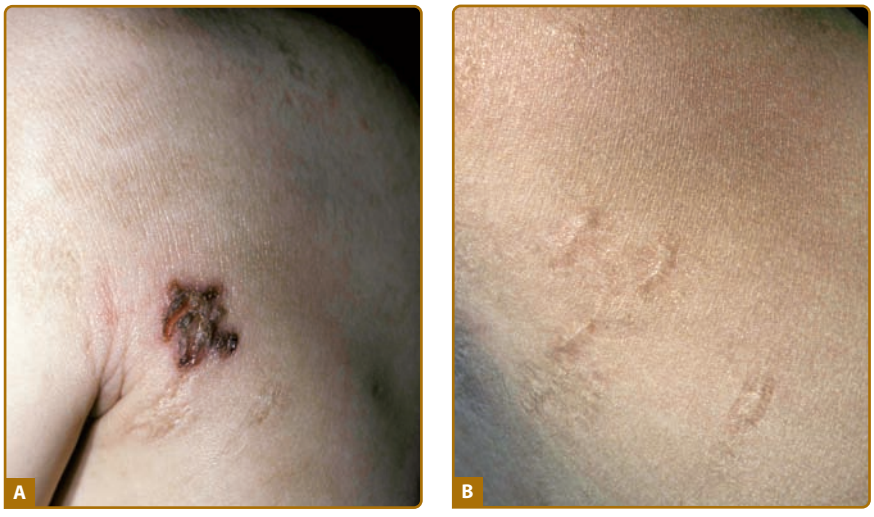

Figure 137-13 Lipoid proteinosis. **A.** Early bullous lesion with typical hemorrhagic crust, **B.** healing with scarring. (From Dyer JA, Yu QC, Paller AS: "Free-floating" desmosomes in lipoid proteinosis: An inherent defect in keratinocyte adhesion? *Pediatr Dermatol* **23**:1, 2006, with permission.)

with hemorrhagic crusting and resultant scarring (Fig. 137-13). Scars may be linear and resemble pseudoporphyria on the face. In some patients, blistering is worse during warmer weather. Skin fragility and easy wounding with minor trauma or friction are noted. Spontaneous development of extrafacial pustular lesions has also been noted. Shedding of sheets of skin, which leaves red oozing areas, has also been described.

The skin lesions of the second stage are better recognized. Although beaded papules along the eyelid margins (moniliform blepharosis) (Fig. 137-14) are considered a classic clinical finding, they are variable and may be subtle. Other cutaneous stigmata include generalized skin thickening with a waxy, yellow appearance as well as areas of distinct papules and nodules. Areas subject to repeated friction or trauma, such as the elbows, halluces, and extensor aspects of the arms and lower legs, may develop overlying hyperkeratosis, which may be quite striking and verrucous (eFig. 137.14.1 in online edition). The scarring usually begins during childhood and is often worst on the face. It may follow trauma or occur spontaneously, yet no tendency to excessive scarring is noted after surgery or vaccination. Pock-like or acneiform scarring is well described in LP, especially on the face and extremities. Some areas may resemble solar elastosis. Flexural lichenification may also be seen, and patients with LP have been misdiagnosed as having atopic dermatitis. Some patients report increased photosensitivity, and, in some patients, sun-exposed areas exhibit the greatest amount of scarring. Significant pruritus, alterations in the ability to sweat, and abnormal pain sensation have been noted. Alopecia may occur, although it is variable in severity. Nails are normal.[219]

Figure 137-14 Lipoid proteinosis. Beaded papules along margin of the eyelids (moniliform blepharosis). Note increased severity of yellowish, waxy lesions in sun-exposed areas. (Used with permission from O. Braun-Falco, Munich.)

RELATED PHYSICAL FINDINGS

The mucosae of patients with LP exhibit infiltration and thickening. Early in life, oral erosions may be noted and these may persist.[220] Thickening of the lingual frenulum leads to inability to protrude the tongue (Fig. 137-15). The pharynx, tongue, soft palate, tonsils, and lips are typically involved. Laryngeal and pharyngeal involvement may be severe enough to trigger respiratory difficulty, and tracheostomy has been required in rare cases. Shortness of breath or worsening of respiratory difficulties, as well as swelling of the salivary glands (submandibular and parotid), may be triggered by upper respiratory tract infections. Xerostomia and dental caries may be seen.[221] Dental abnormalities (absent permanent upper lateral incisors) have also been described. Parotitis from infiltration of Stenson's duct and subsequent blockage can occur.

Central nervous system involvement is a well-recognized, but variable, feature of LP. Amygdala

Figure 137-15 Restricted mobility of the tongue due to infiltration of the frenulum is seen in most patients with lipoid proteinosis. Note discoloration of the lips as well. (Used with permission from O. Braun-Falco, Munich.)

dysfunction has been described, which leads to abnormal perception and appraisal of fear. More recent studies have demonstrated subtle differences between LP patients and normal controls in the judgment of facial expression and emotion, in memory for negative and positive pictures, and in odor-figure association tests. Because of the frequent bilateral amygdala damage, LP has been used as a model disorder for investigation of the function of the amygdala. Neurologic and psychiatric findings include seizures, memory deficits, social and behavioral changes, paranoid symptoms, mental retardation, and aggressiveness. Severe generalized dystonia has also been reported.[222]

The ocular examination may reveal drusen-like fundal lesions.[168] Eyelid infiltration may induce corneal ulcers due to abnormal eyelash positioning, and alopecia of the eyebrows and eyelashes can occur. The abnormal deposition of hyaline material has been detected histopathologically in many internal organs, although this is typically asymptomatic.

LABORATORY TESTS

Light microscopic evaluation of lesional sections reveals deposition of amorphous eosinophilic material at the dermoepidermal junction, perivascularly, and along adnexal epithelia. There is deposition of hyaline material in the dermis, often perpendicular to the basement membrane (Fig. 137-16). The hyaline material is periodic acid-Schiff positive and diastase resistant, with a composition similar to that of basement membrane. Often arranged in concentric, "onion-skin" layers around vessels, these layers include type III and type IV collagen as well as laminin. Electron microscopy reveals irregular duplication of the lamina densa at the dermal–epidermal junction. Cytoplasmic vacuoles are noted in dermal fibroblasts.[223] The presence of lipids varies and is considered a secondary phenomenon due to lipid adherence to glycoproteins present in the hyaline material rather than a primary defect of LP.

The histologic features of the early bullous lesions of LP have only recently been described. Acantholysis of keratinocytes apparently is the cause.[224] Electron microscopy suggests an abnormality of desmosomal attachment, with "free-floating" desmosomes noted in bullous lesions. These preliminary findings require confirmation; but are intriguing given the pattern of expression of ECM-1 in the epidermis.[214]

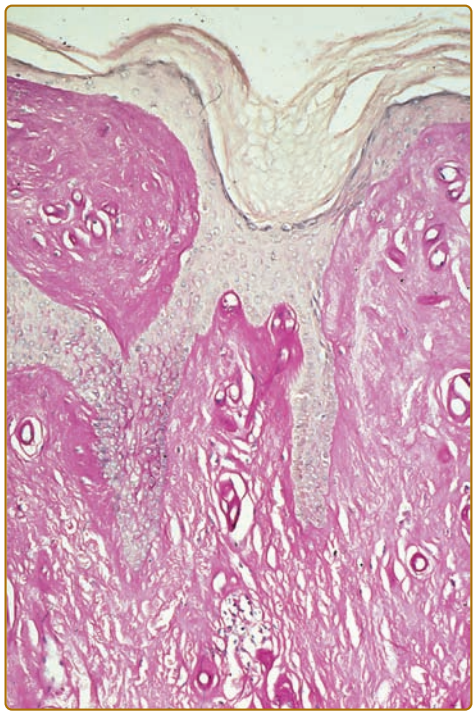

Figure 137-16 Extensive deposition of periodic acid-Schiff-positive, diastase-resistant hyaline material in the dermis of a scar-like lesion of lipoid proteinosis.

Three-dimensional analysis of the cutaneous vasculature in LP shows enlarged vessels in the mid- and deep dermis with an orientation parallel to the dermal–epidermal junction. The dermal papillary plexus also lacks capillary loops. As in lichen sclerosus, the subcutaneous plexus and transverse connecting vessels are atretic or poorly formed.[217] Such vascular abnormalities may reflect a disturbance of ECM-1 function during angiogenesis.

SPECIAL TESTS

Computed tomographic scans of the brain reveal bilateral anterior medial temporal lobe calcifications, often bean-shaped, and especially within the amygdala, in 50%–75% of LP patients.[222]

Histopathologic evaluation of these lesions shows amorphous masses of calcium and bone along with multiple haphazardly arranged small blood vessels with wall calcification and gliotic adjacent tissue. The cortex and white matter show isolated blood vessels occluded by fibrin, parietal calcification, small perivascular infarctions, and demyelination.[225] Immunohistochemical staining of skin biopsy specimens may show absence or attenuation of ECM-1. This may prove to

BOX 137-3 DIFFERENTIAL DIAGNOSIS OF LIPOID PROTEINOSIS

CLINICAL

Most Likely

- Erythropoietic protoporphyria (EPP) or pseudoporphyria (clinically and histologically)—in EPP most changes are in sun-exposed areas, whereas in lipoid proteinosis they are present in nonsun-exposed sites as well; EPP has no beading of the eyelids.
- Variegate porphyria—especially in South Africa
- Epidermolysis bullosa—hoarseness with blistering (infancy)
- Impetigo—childhood blisters and erosions

Consider

- Scarring from acne
- Scleromyxedema
- Amyloidosis
- Residual lichenification from atopic dermatitis

HISTOPATHOLOGIC

- Erythropoietic protoporphyria
- Diabetic microangiopathy
- Amyloidosis
- Lichen sclerosus

be a valid diagnostic test, not only to aid in diagnosis in mild cases but also potentially to direct molecular investigations.[226]

DIFFERENTIAL DIAGNOSIS

(Box 137-3)

PROGNOSIS AND CLINICAL COURSE. The prognosis of LP is variable. Often, there is progressive worsening of cutaneous features, with clearance during childhood of blistering lesions and progressive development of infiltrative lesions. The hoarseness and mucosal lesions also may progress with time. Although some patients have experienced respiratory complications from upper respiratory tract infiltration that have, in rare cases, led to early mortality, most patients have a normal life span. It is important to recognize the impact of LP on the quality of life of affected patients. The disfiguring nature of the skin lesions, along with the abnormal voice, significantly impacts the interactions of LP patients with others. Patients have increased difficulty in holding jobs.[210]

TREATMENT

Many agents, including topical and systemic corticosteroids, oral dimethyl sulfoxide,[227] and intralesional heparin, have been investigated and used in the treatment of LP. None of these agents has demonstrated any sustained benefits. A recent report describes the use of acitretin in one patient, with improvement in hoarseness but not skin lesions.[228] Given the apparent photoexacerbation of lesions in a subset of LP patients, photoprotection seems reasonable, although there are no data confirming any benefit. Additionally, avoidance of friction or trauma may be helpful given the prominence of lesions on frequently traumatized sites. Early intervention for developmental problems is important, and management of other stigmata by the appropriate specialists is warranted. Various surgical modalities such as dermabrasion and CO_2 laser procedures have been used to treat cutaneous lesions. CO_2 laser surgery for vocal cord lesions and eyelid papules has been helpful.[229,230]

PREVENTION

Prenatal genetic testing in families at risk is theoretically possible using DNA-based analysis.

Chapter 138 :: Cutaneous Mineralization and Ossification

:: Janet A. Fairley

CUTANEOUS MINERALIZATION AT A GLANCE

- Results from the deposition of calcium salts in the dermis, subcutaneous tissue, or vascular endothelium when the local calcium concentration exceeds its solubility in the tissue.
- Clinically, may be categorized as dystrophic, metastatic, idiopathic, or iatrogenic.
- Pathology shows aggregates of calcium that stain with Alizarin red S or von Kossa stains.

CALCIUM

Calcium is involved in many physiologic processes. It is key to skeletal muscle and myocardial contraction, neurotransmission, and blood coagulation. In addition, it is the primary mineral in the bony skeleton. On the cellular level, its diverse functions include transmission of information into and between cells, regulation of plasma membrane potential, and exocytosis. Only over the last 20 years has its effect on skin been fully appreciated. Calcium regulates major functions in the epidermal keratinocytes including proliferation, differentiation, and cell–cell adhesion.[1–6]

REGULATORY HORMONES

At least three regulatory hormones control the ionic calcium concentration in serum: (1) parathyroid hormone (PTH), (2) calcitonin, and (3) 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$).

PTH is an 84-amino acid, single-chain polypeptide that is synthesized in the parathyroid glands. Under normal conditions, a decrease in the serum concentration of ionized calcium results in an increase in PTH production, whereas an increase in the serum concentration of ionized calcium results in a decrease in PTH production. In the kidney, PTH increases renal tubular reabsorption of calcium and increases renal clearance of phosphate. PTH also acts directly on the bone to increase the plasma calcium concentration. It does this acutely by mobilizing calcium from bone into the extracellular fluid. Osteocytes and osteoblasts are the presumed target cells for this effect. PTH also stimulates osteoclastic bone resorption, possibly by stimulating osteoblasts to release factors that activate osteoclasts. PTH together with a decreased plasma phosphate concentration stimulates 1α-hydroxylase activity in the kidney, causing an increase in the plasma concentration of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ increases intestinal absorption of calcium.

Calcitonin is a 32-amino acid polypeptide that is produced by parafollicular or C cells of the thyroid gland. Calcium is the primary stimulant for calcitonin secretion. Calcitonin lowers the serum calcium concentration, primarily through osteoclast inhibition, but whether it plays a major role in serum calcium metabolism outside of the neonatal period in vivo is unclear.

Vitamin D_3, or cholecalciferol, is a secosteroid (steroid with a "broken" ring) formed by the opening of the β ring of 7-dehydrocholesterol. In humans, this formation occurs in the basal layer of the epidermis. First, there is an ultraviolet B-mediated conversion of 7-dehydrocholesterol to previtamin D_3. Previtamin D_3 then undergoes thermal isomerization to form vitamin D_3. To become biologically active, vitamin D_3 must first be hydroxylated at carbon position 25 in the liver and then at carbon position 1α by the enzyme 1α-hydroxylase in the kidney. 1α-hydroxylase is tightly regulated. PTH and calcitonin increase its activity, whereas calcium, phosphate, and $1,25(OH)_2D_3$ inhibit it.[7]

$1,25(OH)_2D_3$, similar to PTH, increases the concentration of plasma calcium. Its primary action is to stimulate the active transport of calcium across the intestine. $1,25(OH)_2D_3$ also increases the plasma calcium concentration by mobilizing calcium from bone.[8] The simultaneous presence of PTH appears to be necessary for this effect.

$1,25(OH)_2D_3$ also plays a major role in the growth and differentiation of tissues, including skin.[9] $1,25(OH)_2D_3$ acts through its nuclear receptor (vitamin D receptor, VDR), which is a member of the superfamily of steroid/thyroid/retinoid nuclear receptors. In the skin, receptors for $1,25(OH)_2D_3$ are present on epidermal keratinocytes, pilosebaceous structures, and in the dermis.[10–13] In human keratinocyte cultures, $1,25(OH)_2D_3$ causes a dose-dependent decrease in proliferation, an increase in morphologic differentiation, and an increase in terminal differentiation markers.[14] Cultured human keratinocytes can also convert $25(OH)D_3$ to $1,25(OH)_2D_3$, suggesting that the epidermis may regulate its own growth and differentiation by endogenously produced $1,25(OH)_2D_3$.[14] The mechanism by which $1,25(OH)_2D_3$ may induce differentiation of epidermal cells may be through calcium, because calcium is required for terminal differentiation of keratinocytes. $1,25(OH)_2D_3$ may facilitate calcium entry into cells and, through induction of calcium-binding proteins, facilitate the ability of calcium to regulate various cellular processes.

ABERRANT CALCIFICATION AND OSSIFICATION

Despite the careful regulation of serum calcium, calcification and ossification of cutaneous and subcutaneous tissues may occur.[15] Calcification is the deposition of insoluble calcium salts; when it occurs in cutaneous tissues it is known as *calcinosis cutis*. Ossification is the formation of true bony tissue by the deposition of calcium and phosphorus in a proteinaceous matrix as hydroxyapatite crystals. Cutaneous calcification may be divided into four major categories: (1) dystrophic, (2) metastatic, (3) idiopathic, and (4) iatrogenic. Dystrophic calcification is the most common type of calcinosis cutis and occurs as a result of local tissue injury. Although calcium and phosphate metabolism and serum levels are normal, local tissue abnormalities, such as alterations in collagen, elastin, or subcutaneous fat may trigger calcification. The internal organs usually remain unaffected. Metastatic calcification is the precipitation of calcium salts in normal tissue secondary to an underlying defect in calcium and/or phosphate metabolism. The calcification may be widespread and, in addition to the skin, affects predominantly blood vessels, kidneys, lungs, and gastric mucosa. All patients presenting with signs of metastatic calcification should receive a calcium and phosphate metabolic evaluation. Idiopathic calcification occurs without identifiable underlying tissue abnormalities, abnormal calcium, and/or phosphate metabolism. Cutaneous calcification also may be iatrogenic. Cutaneous ossification most commonly occurs secondary to local tissue alteration or preexisting calcification. Any calcifying disorder of the skin may ossify secondarily. On rare occasions, primary cutaneous ossification may occur without underlying tissue abnormalities or preexisting calcification.

DYSTROPHIC CALCIFICATION

CONNECTIVE TISSUE DISEASES

Dystrophic calcification frequently occurs in connective tissue diseases.[16] Scleroderma and CREST syndrome (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, *t*elangiectasia) are notable examples that are frequently associated with calcinosis cutis (Fig. 138-1; see Chapter 157). In these disorders, nodules and plaques of calcium deposits may occur in the skin, subcutaneous tissue, muscle, or tendons. The calcium deposits most commonly occur on the upper extremities, especially on the fingers and wrists, but may occur in any area subject to trauma or motion. As the calcifications enlarge, they may ulcerate and exude a chalky material.

Dystrophic calcification also occurs in dermatomyositis (see Chapter 156). It is more commonly associated with juvenile rather than adult-onset dermatomyositis (formerly in about 44% of children as opposed to 20% of adults); nevertheless, the more aggressive early

Figure 138-1 Dystrophic calcification in CREST syndrome (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, *t*elangiectasia).

treatment of juvenile dermatomyositis has been associated with a decrease in the occurrence of dystrophic calcification.[17] The calcification tends to occur 2–3 years after disease onset and most frequently appears on the elbows, knees, shoulders, and buttocks.[18] The calcium deposits may be painful and can ulcerate. They also may exude a chalky material, form sinuses, and become chronically infected. Calcium salt deposition may become quite extensive, progressing along fascial planes of skin and muscle, forming an "exoskeleton," and leading to significant morbidity and mortality. Calcinosis cutis in dermatomyositis is difficult to treat; however, if the patient survives long enough, the calcified nodules may improve spontaneously. Although uncommon, calcinosis cutis has been described in all clinical subsets of lupus erythematosus.[19–22]

There is no standard treatment for dystrophic calcification. A diet low in calcium and phosphate along with aluminum hydroxide has been reported to arrest or facilitate regression of the calcified nodules.[23] Disodium etidronate has also been used with some success.[24] Several series report long-term treatment with diltiazem improves the calcinosis in some patients.[25,26] Other reported treatments include warfarin, colchicine, probenecid, and bisphosphonates.[16,27] Occasionally, calcium deposits must be removed surgically to clear sinus tracts, ulcers, or chronic infections.

PANNICULITIS

Pancreatic enzyme panniculitis (see Chapter 70) is a lobular panniculitis that commonly demonstrates dystrophic calcification. It occurs in patients with pancreatitis or pancreatic adenocarcinoma and is presumably caused by the action of liberated pancreatic enzymes on subcutaneous fat. The fatty acids formed by lipolysis may combine with calcium and form calcium soap.

In subcutaneous fat necrosis of the newborn, erythematous, well-defined nodules and plaques occur during the first few weeks of life over the cheeks, back, buttocks, and extremities.[28,29] The affected infants are generally otherwise healthy, and the nodules and plaques usually clear spontaneously. Occasionally, the lesions calcify, and in a small subset of

patients symptomatic hypercalcemia may develop, sometimes several months after birth.

INHERITED DISORDERS

Dystrophic calcification occurs in patients with pseudoxanthoma elasticum (PXE; see Chapter 137). PXE is a hereditary disorder of elastic tissue characterized by progressive calcification of elastin fibers, primarily within the skin, Bruch's membrane of the retina, and the cardiovascular system. The cause of PXE was recently identified as a mutation in the *ABCC6* gene.[30] This gene is thought to play a critical role in transmembrane transport. Most patients with PXE have normal calcium phosphate metabolism, but a few have been identified who have abnormal calcium, phosphate, and/or vitamin D metabolism. Patients in this subset may develop metastatic calcification in the form of calcified or ossified tumors, calcification of the falx cerebri, and arterial calcification.[31–33]

Ehlers–Danlos syndrome (EDS; see Chapter 137) is a group of inherited disorders of fibrillar collagen metabolism. Mutations in the collagen genes or enzymes that regulate collagen biosynthesis have been determined to underlie a number of EDS subtypes.[34–36] The skin characteristically shows hyperelasticity and fragility with formation of pseudotumors and large gaping scars. Subcutaneous calcified nodules, termed *spheroids* may appear, and are thought to represent calcified ischemic fat lobules.[37,38] Calcification of healing surgical incisions has also been reported in patients with EDS.[39]

Dystrophic calcification has been observed in patients with porphyria cutanea tarda (see Chapter 132).[40,41] Sclerodermoid plaques with dystrophic calcification have occurred on the preauricular area, scalp, neck, and dorsa of the hands. Ulceration with transepidermal elimination of sheets of calcium is also rarely reported. Other genetic disorders in which calcification may occur include Werner syndrome and Rothmund–Thomson syndrome (see Chapter 139).[42,43]

CUTANEOUS NEOPLASMS

Dystrophic calcification occurs in association with a variety of benign and malignant cutaneous neoplasms. Often the neoplasms also show ossification in the surrounding stroma.

Pilomatricomas (see Chapter 119) are the most common cutaneous neoplasms that manifest calcification and ossification. Approximately 75% of pilomatricomas show calcification and 15% to 20% show ossification.[44,45] Ossification usually occurs within the connective tissue adjacent to the shadow cells, probably through metaplasia of fibroblasts into osteoblasts. Activating mutations in the adherens junction protein β-catenin have been identified in some pilomatricomas.[46]

A large number of other neoplasms may be associated with calcification and ossification, including: pilar cyst, basal cell carcinoma, intradermal nevi (probably as a result of inflammation or folliculitis), desmoplastic malignant melanoma, atypical fibroxanthoma, pyogenic granuloma, hemangioma, neurilemmoma, trichoepithelioma, and seborrheic keratoses.[47–51] Mixed tumors (chondroid syringomas) may also show calcification and ossification. However, unlike other neoplasms, the ossification occurs within the tumor via ossification of the chondroid cells, much like endochondral bone formation occurring in the epiphyses of bones.

INFECTIONS

Infectious agents may produce enough cutaneous damage to cause dystrophic calcification. Parasitic infections that may result in calcinosis cutis include onchocerciasis (*Onchocerca volvulus*) and cysticercosis (*Taenia solium*).[52,53] Calcinosis cutis has also been reported as a complication of intrauterine herpes simplex infection.[54]

OTHER

Dystrophic calcification has been reported in a variety of settings where local tissue injury occurs, such as in scarring caused by burns, trauma, neonatal heel sticks (subepidermal calcified nodule), surgery, and keloids.[55–59]

METASTATIC CALCIFICATION

CHRONIC RENAL FAILURE

Metastatic calcification most commonly occurs in chronic renal failure and takes the form of either benign nodular calcification or calciphylaxis. In chronic renal failure, decreased clearance of phosphate results in hyperphosphatemia. In addition, the impaired production of $1,25(OH)_2D_3$ results in a decrease in calcium absorption from the intestine and decreased serum calcium levels. The hypocalcemia results in increased PTH production and secondary hyperparathyroidism. Elevated levels of PTH cause bone resorption and mobilization of calcium and phosphate into the serum, leading to normalization of the serum calcium concentration but marked hyperphosphatemia. If the solubility product of calcium and phosphate is exceeded, metastatic calcification may occur. In benign nodular calcification, the calcifications typically occur at periarticular sites, and their size and number tend to correlate with the degree of hyperphosphatemia. The lesions disappear with normalization of calcium and phosphate levels.

Calciphylaxis is a life-threatening disorder characterized by progressive vascular calcification, soft tissue necrosis, and ischemic necrosis of the skin (see Chapter 151).[60] Clinically, it presents as firm, extremely painful, well-demarcated, violaceous plaques associated with soft tissue necrosis and ulceration (Fig. 138-2). The

Figure 138-2 Calciphylaxis. The lesions develop as violaceous plaques that may progress to necrotic ulcers, as shown in this patient.

lesions may occur anywhere, but the lower extremities are most frequently involved. The mortality rate is estimated to be approximately 80%. Histopathologically, there is medial calcification of small and medium-sized arteries with intimal hyperplasia, primarily in dermal and subcutaneous tissues. Calciphylaxis occurs almost exclusively in patients with a history of chronic renal failure and prolonged secondary hyperparathyroidism. However, there exist rare reports of the occurrence of calciphylaxis in the absence of renal failure.[61] Most of the patients reported are female, and there may be an association with obesity and poor nutritional status.[62,63]

The pathogenesis of calciphylaxis remains controversial. Experiments in a rat model suggested that calciphylaxis may be triggered by exposure to a sensitizing agent (PTH, dihydrotachysterol, or vitamin D) followed by a challenging agent (metal salts, albumin, or corticosteroids).[64] However, the clinical description and histopathology of the animal lesions differ from the human disease. Protein C dysfunction has also been described in a subset of patients with calciphylaxis, but this more likely is a mark for a coagulation defect that predisposes this group to calciphylaxis.[65] More recently, it has been proposed that conversion of vascular smooth muscle cells into osteoblast-like cells is a critical step in the development of progressive vascular calcification as is seen in calciphylaxis. This conversion may be stimulated by phosphates, substances that stimulate inflammation in the vascular wall and bone morphogenic protein (BMP)-2. Other proteins that are currently under study as potential effectors, both positive and negative, are BMP-7, osteoprotegerin, matrix Gla protein, fetuin-A, and phosphatonins.[66]

The current therapy of calciphylaxis involves a multifaceted approach. The calcium-phosphate product should be normalized by methods including: low calcium dialysis, use of phosphate binders that combine calcium acetate and magnesium carbonate, sodium thiosulfate, and parathyroidectomy in those instances where medical management fails.[67] Aggressive management of wound infections and judicious use of debridement may help lower the incidence of sepsis and death in these patients.

HYPERVITAMINOSIS D

Chronic ingestion of vitamin D in supraphysiologic doses (50,000–100,000 units/day) may produce hypervitaminosis D.[68] The initial signs and symptoms of hypervitaminosis D are attributable to hypercalcemia and hypercalciuria, and include weakness, lethargy, headache, nausea, and polyuria. Metastatic calcification may also occur.

MILK–ALKALI SYNDROME

Milk–alkali syndrome is characterized by excessive ingestion of calcium-containing foods or antacids, leading to hypercalcemia.[69] Complications other than the acute manifestations of hypercalcemia include irreversible renal failure, nephrocalcinosis, and subcutaneous calcification, occurring predominantly in periarticular tissues.

TUMORAL CALCINOSIS

Tumoral calcinosis (TC) is a disorder characterized by the deposition of calcific masses around major joints, such as hips, shoulders, elbows, and knees. The masses are intramuscular or subcutaneous and may enlarge to sizes causing significant impairment of joint function. Usually, the overlying skin is normal, but associated ulceration and calcinosis cutis may occur. It generally occurs in otherwise healthy adolescents. Tumoral calcinosis may be either sporadic or familial. The familial type may be associated with hyperphosphatemia or normophosphatemia. Inactivating mutations in either the *GALNT3* or *FGF23* genes may lead to hyperphosphatemic TC.[70–72] *GALNT3* encodes a glycosyltransferase (*N*-acetylgalactosaminyltransferase 3 or ppGalNAc-T3) that initiates mucin-type *O*-glycosylation. It is hypothesized that FGF23, an important regulator of phosphate homeostasis, must be glycosylated by ppGalNAc-T3 to function properly. Normophosphatemic familial TC has been associated with mutations resulting in the absence of SMAD9, an anti-inflammatory protein that has also been suggested to be a tumor suppressor. Surgical excision is the treatment of choice, but phosphate deprivation via dietary restriction and antacids that impair phosphate absorption has met with some success.[73]

OTHER DISORDERS

Other systemic disorders associated with hypercalcemia and/or hyperphosphatemia are reported to cause metastatic calcification. These include neoplasms associated with bony destruction, such as lymphoma, leukemia, multiple myeloma, and metastatic carcinoma.[74–76] Sarcoidosis may also be associated with metastatic calcification.[77]

IDIOPATHIC CALCIFICATION

Calcified nodules characterize idiopathic calcification of the scrotum. The lesions usually appear in otherwise

healthy males and tend to increase in size and number with time.[76] Eventually, they may break down and exude a chalky material. Controversy exists over the etiology of this disorder.[78–81] The largest series of patients to date with calcified nodules of the scrotum ($n = 100$) exhibit a spectrum of histologic findings from clear cut calcification of an epidermal cyst, to inflamed cyst with partial loss of the epithelia lining, to calcium deposits, suggesting that these nodules form from dystrophic calcification of cysts and obliteration of the cyst wall.[82] Excision of the lesions is the treatment of choice, although patients may continue to develop nodules at other sites. Idiopathic calcification of the penis, vulva, and breast has also been reported.[83,84]

Subepidermal calcified nodules appear on the exposed areas of the head and the extremities.[85] They may be congenital or acquired and typically appear as hard, 3- to 10-mm solitary lesions, although multiple lesions may occur. Some investigators believe the lesions represent calcified sweat gland hamartomas.[86]

Reports have described the appearance of milia-like idiopathic calcinosis cutis on the dorsa of hands and forearms of patients with Down syndrome.[87–89] Some of the calcifications are associated with syringomas.

IATROGENIC CALCIFICATION

Cutaneous calcification may be iatrogenic. Calcinosis cutis is a complication of intravenous calcium chloride and calcium gluconate therapy.[90] Calcified nodules may appear at sites of extravasation, probably as a result of an elevated tissue concentration of calcium and tissue damage. Minor trauma and prolonged contact with calcium salts can lead to calcinosis cutis in a variety of settings.[91,92] It has occurred in patients undergoing electroencephalography with saturated calcium chloride electrode paste.[93] Cutaneous calcification of skin graft donor sites after the application of calcium alginate dressings has also been reported.[94] Transient deposits of calcium in the skin and other soft tissues have also been reported after liver transplantation.[95] It is hypothesized that these transient deposits are caused by the large amounts of calcium- and cit-rate-containing blood products used during surgery, combined with metabolic abnormalities in the perioperative period.

PRIMARY OSSIFICATION

Primary ossification of cutaneous and subcutaneous tissues rarely occurs without any underlying tissue abnormality or preexisting calcification. In addition to miliary osteoma of the face, there are three well-described ossifying syndromes[96]: fibrodysplasia ossificans progressiva (FOP), and two GNAS-associated disorders, Albright hereditary osteodystrophy (AHO), and progressive osseous heteroplasia (POH). Other primary ossification disorders reported in the literature, such as plate-like osteoma cutis, isolated osteoma or widespread osteoma, probably are variants of the described ossifying syndromes or represent a group of poorly described primary ossification disorders.

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA

FOP is an autosomal-dominant syndrome characterized by the progressive ossification of deep connective tissues leading to significant morbidity and mortality.[97] Ossification is of the endochondral type, and involvement of the skin occurs as a result of direct extension from underlying tissues. Dysmorphic great toes are a characteristic feature of FOP. Other features include abnormal phalanges of the hands, deafness, baldness, and mental retardation. Point mutations in the activin (*ACVR1*) gene have been identified as the cause of FOP. Most cases represent spontaneous mutations but in a few families parental germ-line mosaicism has been identified.[98] ACVR1 (also known as activin-like kinase 2; ALK2) is a bone morphogenic protein type I receptor and its mutation leads to overactive BMP signaling, leading to ectopic bone formation.

ALBRIGHT HEREDITARY OSTEODYSTROPHY, PROGRESSIVE OSSEOUS HETEROPLASIA, AND PLATE-LIKE OSTEOMA CUTIS

AHO, and POH, are closely related syndromes that are characterized by intramembranous bone formation in skin. Mutations in the gene encoding for the α-subunit of the stimulatory G protein of adenyl cyclase (GNAS1), a negative regulator of bone formation, have been identified in both of these disorders.[96,99–101] In addition, some patients have been described in which features of both disorders are present.[102] Several families have demonstrated an "imprinting" effect; inheritance of an inactivating mutation in GNAS1 from the mother results in pseudohypoparathyroidism type Ia, whereas paternal inheritance leads to POH.[103,104] In addition, different splice variants are expressed solely by maternal or paternal alleles. AHO more commonly arises from maternally inherited mutations but no clear genotype–phenotype correlation has yet been established between these disorders. Those patients described as plate-like osteoma cutis appear to be form frustes of AHO or POH.

AHO is an autosomal dominantly inherited syndrome characterized by the ossification of cutaneous and subcutaneous tissues in childhood. AHO generally follows a limited course, and significant deformity and physical impairment are rare. Patients typically have brachydactyly dimpling over the metacarpophalangeal joints (Albright's sign), obesity, round or moon facies, short stature, and mental retardation. Most patients have a deficient end-organ response to PTH or "pseudohypoparathyroidism" with hypocalcemia, hyperphosphatemia, and elevated levels of PTH. Other patients have "pseudopseudohypoparathyroidism" with normal serum levels of calcium and phosphorus.[93]

POH is characterized by progressive ossification of skin and deep tissues during infancy or childhood.[105,106] Most reported patients are female, although

Figure 138-3 Progressive osseous heteroplasia. The appearance of the skin in progressive osseous heteroplasia can be subtle, but the lesions have a distinctive textural change that feels like rice grains in the skin.

a small number of male patients have also been described. Ossification usually begins in the dermis and progresses to involve deeper tissues, such as muscle, as well as overlying skin. Skin involvement has been described as a papular eruption resembling "rice grains" and having a "gritty" consistency (Fig. 138-3). Unlike AHO or FOP, there are no associated dysmorphic features. Secondary orthopedic problems, such as limb-length discrepancy or ankylosis of the joint, arise if the cutaneous ossification is severe enough to limit motion.

Miliary osteoma cutis of the face most commonly occurs as multiple small, firm nodules on the faces of young women with a history of acne vulgaris. However, there are reports of multiple miliary osteoma cutis in older patients without acne vulgaris or other underlying skin disease.[104]

ACKNOWLEDGMENT

The author thanks John S. Walsh, MD, for his work on this chapter in previous editions.

Chapter 139 :: Hereditary Disorders of Genome Instability and DNA Repair

:: Thomas M. Rünger, John J. DiGiovanna, & Kenneth H. Kraemer

HEREDITARY DISORDERS OF GENOME INSTABILITY AND DNA REPAIR AT A GLANCE

- Genome instability characterizes a large group of inherited disorders with prominent cutaneous abnormalities; many have an increased cancer risk.
- Genome instability is caused by impaired repair and/or maintenance of DNA.
- Xeroderma pigmentosum is a prototype with impaired repair of environmentally induced DNA damage and a greatly increased frequency of sunlight-induced cancer.
- Although these disorders are rare, heterozygotic carriers of affected genes, which may comprise several percent of the general population, may carry an increased cancer risk as well.

Because the genome exerts control for cellular function, maintaining genome stability is important for the continued function of cells, tissues, and organisms. DNA is the carrier of genetic information. Its structure is regularly threatened by damaging agents that include oxidative stress, ultraviolet (UV) and X-radiation, and chemical agents. Although much damage is repaired, failure to maintain genomic integrity may lead to abnormal cell function or cell death. If the cell divides, progeny may accumulate additional damage and this progressive accumulation of damage can lead to malignancy (see Chapter 110).

This chapter describes the relevant skin disorders with genome instability and the underlying defective mechanisms of DNA repair or DNA maintenance (Tables 139-1 and 139-2). All of these exhibit prominent cutaneous abnormalities that involve dermatologists in their diagnosis and management. Most, but not all, are also characterized by an increased risk of malignancies. This demonstrates that the maintenance of genome integrity is of utmost importance for the prevention of malignant transformation. Malignant transformation requires the accumulation of several mutations in specific genes of a single cell. Thus a mutator phenotype is often regarded a prerequisite for carcinogenesis, because without genome instability it would be exceedingly unlikely that all of those mutations occur in a single cell.[1–4] The same genes that are affected in the hereditary genome instability disorders can also confer genome instability to individual cells when impaired through acquired mutations, thereby playing an important role early in spontaneous carcinogenesis.

In addition, although these heritable diseases are rare (of the order of 10^{-5} or 10^{-6}), carriers of the affected genes may comprise several percent of the general population. These individuals are usually free of clinical symptoms, as most of these disorders are characterized by autosomal recessive inheritance. However, epidemiologic studies suggest that heterozygotic carriers may have an increased risk of neoplasia as well.[5,6]

Spontaneous genome instability is present in Bloom syndrome (BS), ataxia telangiectasia, and Fanconi anemia (FA) as manifested by increased chromosome breakage in primary blood or skin cells. On the other hand, genome instability is present in cells from patients with xeroderma pigmentosum (XP) only after exposure to DNA-damaging agents such as UV radiation or other carcinogens such as benzo[*a*]pyrene, which is present in cigarette smoke. In XP, many of the severe disease manifestations such as cancer and corneal scarring leading to blindness are the result of the interplay between genetic risk and environmental exposure. For example, XP patients who avoid UV radiation dramatically reduce or eliminate the probability of developing skin cancer and blindness.

In some of the disorders discussed here, genome instability is caused by an impaired ability to repair damage to DNA introduced by certain physical or chemical agents. Cells are equipped with different DNA repair pathways (reviewed in Chapter 110) that repair different types of DNA damage. The nucleotide excision repair (NER) pathway, which processes bulky DNA lesions, including UV-induced DNA photoproducts, is impaired in XP, Cockayne syndrome (CS), and trichothiodystrophy (TTD). Cells from patients with these conditions are characterized by increased killing and mutation formation following exposure to UV radiation. However, only XP patients have increased cancer risk. The reason for this difference in cancer risk is not known.

Proteins encoded by some of the affected genes in these three disorders are not only involved in DNA repair, but also in transcription and cellular DNA damage responses. Thus, mutations affecting different functions of the same gene (such as nervous system development or immune competence) appear to play a role in various phenotypes that are not directly linked to DNA repair functions and underlie several overlap syndromes between those three conditions (Table 139-3). Multiple clinical phenotypes of DNA repair diseases have been recognized. Defects in many genes have been associated with these clinical phenotypes. Mutations in different DNA repair genes can be associated with the same clinical phenotype. On the other hand, different mutations in one DNA repair gene can be associated with different clinical phenotypes. For example, mutations in the XPD(ERCC2) gene have been associated with the following clinical phenotypes: XP, XP with neurologic abnormalities, the XP-Cockayne syndrome complex (XP/CS), XP/TTD, COFS (cerebro-oculofacio-skeletal syndrome), or CS/TTD. XP variant, which is clinically indistinguishable from XP, is a disorder of DNA damage tolerance. Although normal cells can bypass DNA damage during replication (translesional DNA synthesis), cells from XP-variant patients have a defect in this process. The DNA mismatch repair pathway (see Chapter 110) is affected in hereditary nonpolyposis colon cancer (Lynch syndrome) and its subform, Muir–Torre syndrome. Muir-Torre syndrome has cutaneous features including sebaceous gland tumors. These are reviewed in Chapter 153.

Helicases are proteins that unwind DNA and are required for a multitude of metabolic processes involving DNA, such as transcription, replication, repair, and more. Two genes involved in NER are helicases that are also part of the basal transcription factor, TFIIH. The XPB (ERCC3) gene product unwinds DNA in the 3′ to 5′ direction whereas the XPD (ERCC2) gene product unwinds DNA in the opposite direction. The RecQ family of DNA helicases is highly conserved in evolution from bacteria to humans.[7,8] Of the five known human RecQ family members, three [(1) BLM, (2) WRN, and (3) RECQL4, which cause BS, Werner syndrome (WS), and Rothmund–Thomson syndrome (RTS), respectively] are mutated in distinct clinical disorders associated with chromosomal instability, cancer predisposition, and/or premature aging.[9]

Genetic instability can also result from abnormal telomere maintenance. Telomeres are long nucleotide $(TTAGGG)_n$ repeats that are important for the maintenance of chromosomal integrity.[10] Some telomeric repeats are lost at each cell division and shortened telomere lengths are a feature of aged cells. Accelerated telomere shortening is a hallmark of cells from patients

TABLE 139-1
Clinical Features of Hereditary Disorders of Genome Instability and DNA Repair

	Clinical Features			
Disorder	**Cutaneous**	**Neoplasia**	**Other**	**Inheritance**
Disorders of Genome Instability with Defective DNA Repair				
Xeroderma pigmentosum (XP)	Photosensitivity (blistering on minimal sun exposure in some patients), freckle-like (lentiginous) macules, poikiloderma (hyper- and hypopigmentation, atrophy, telangiectasia), skin cancer	BCC, SCC, melanoma, central nervous system tumors	Sensorineural deafness, progressive neurologic degeneration, primary loss of neurons (some patients)	Autosomal recessive
Cockayne syndrome (CS)	Photosensitivity (burning on sun exposure)	No increased incidence	Typical facial features (deep set eyes, loss of subcutaneous fat), pigmentary retinal degeneration, postnatal growth failure, sensorineural deafness, progressive neurologic degeneration, primary dysmyelination, brain calcifications	Autosomal recessive
Xeroderma pigmentosum/Cockayne syndrome complex (XP/CS)	Photosensitivity (burning on sun exposure), freckle-like (lentiginous) macules, poikiloderma (hyper- and hypopigmentation, atrophy, telangiectasia), skin cancer	BCC, SCC	Neurologic changes of CS	Autosomal recessive
Trichothiodystrophy` (TTD)	Brittle hair, photosensitivity (burning on sun exposure), ichthyosis, collodion membrane, "tiger tail banding" of hair with polarized microscopy	No increased incidence	Congenital cataracts, short stature developmental delay, microcephaly, primary dysmyelination, recurrent infections	Autosomal recessive
Xeroderma pigmentosum/ trichothiodystrophy (XP/TTD)	Clinical features of both TTD and XP including skin cancer	BCC, SCC, melanoma	Clinical features of both TTD and XP	Autosomal recessive
Hereditary nonpolyposis colon cancer (HNPCC)/MUIR–TORRE Syndrome (MTS)	Sebaceous tumors (benign and malignant), keratoacanthomas	Low-grade cancer of the colon, endometrium, stomach, small intestine, hepatobiliary system, upper urethral tract, larynx and ovary; sebaceous carcinoma, BCC with sebaceous differentiation		Autosomal dominant

Other Disorders of Genome Instability				
Bloom syndrome (BS)	Photosensitivity (burning on sun exposure), malar erythema, café-au-lait macules	Most cancer types; in particular leukemia, lymphomas, carcinomas of the breast and gastrointestinal tract	Immune deficiency, growth retardation, unusual facies, male infertility and female subfertility, type II diabetes	Autosomal recessive
Werner syndrome (WS)	Graying of hair, skin atrophy, leg ulcers, melanomas	Sarcomas, thyroid cancer, meningiomas, melanomas (acral lentiginous, and mucous membrane melanomas)	Premature aging (atherosclerosis, diabetes mellitus, osteoporosis, cataracts)	Autosomal recessive
Rothmund–Thomson syndrome (RTS)	Photosensitivity (burning on sun exposure), poikiloderma, alopecia	Osteosarcomas, cutaneous SCC and others	Skeletal abnormalities, growth deficiency, juvenile cataracts, osteoporosis	Autosomal recessive
Fanconi anemia (FA)	Café-au-lait macules	Myeloid leukemia, SCC of head and neck	Aplastic anemia, pancytopenia, growth retardation, thumb and other bone abnormalities	Autosomal recessive
Dyskeratosis congenita	Lacy, reticular pigmentation of neck and upper chest; nail dystrophy; premature gray hair, hyperhidrosis, skin cancer	Mucosal leukoplakia leading to cancer of anus or mouth, Hodgkin disease, pancreatic adenocarcinoma	Stenosis of lacrimal duct, anemia, pancytopenia, immunodeficiency, learning difficulties, deafness, brain calcifications, cerebellar hypoplasia, testicular atrophy, short stature, intrauterine growth retardation, retinopathy	X-linked recessive, autosomal dominant, autosomal recessive
Ataxia telangiectasia (AT)	Telangiectasias	T-cell leukemia, lymphomas	Progressive cerebellar ataxia, immune defects, hypogonadism, increased acute toxicity of therapeutic X-ray	Autosomal recessive
AT-like disorder (ATLD)	Similar to AT	Similar to AT	Similar to AT, but no ocular telangiectasias	Autosomal recessive
Nijmegen breakage syndrome (NBS)	Café-au-lait macule, vitiligo	B- and T-cell lymphomas, rhabdomyosarcoma, neuroblastoma	Immune defects, growth retardation, microcephaly, mental retardation, characteristic facies	Autosomal recessive
Seckel syndrome	Café-au-lait macules	Leukemia	Proportionate dwarfism, microcephaly, mental retardation, characteristic facies (receding forehead, narrow face, large beaked nose, micrognathia), immune deficiency, pancytopenia	Autosomal recessive

TABLE 139-2
Mechanisms of Hereditary Disorders of Genome Instability and DNA Repair

Disorder	Mechanisms		
	Cellular Abnormalities	Affected Gene(s)	Impaired Function
Disorders of Genome Instability with Defective DNA Repair			
Xeroderma pigmentosum (XP)	Increased UV-induced cell killing and mutagenesis	*XPA*, *XPB*, *XPC*, *XPD*, *XPE*, *XPF*, *XPG*, or DNA polymerase η	Nucleotide excision repair: global genome and transcription-coupled DNA repair; translesional DNA synthesis (XP-variant)
Cockayne syndrome (CS)	Increased cell killing and mutagenesis after exposure to UV and ionizing radiation	*CSA* or *CSB*	Nucleotide excision repair: transcription-coupled DNA repair only
Xeroderma pigmentosum/ Cockayne syndrome complex (XP/CS)	Increased UV-induced cell killing and mutagenesis	*XPB*, *XPD*, or *XPG*	Nucleotide excision repair: global genome and transcription-coupled DNA repair
Trichothiodystrophy (TTD)	Increased UV-induced cell killing	*XPB*, *XPD*, *TTD-A*, or *TTDN1*	Nucleotide excision repair: transcription-coupled pathway of nucleotide excision repair
Xeroderma pigmentosum/ trichothiodystrophy (XP/TTD)	Same as XP	*XPD*	Nucleotide excision repair: global genome and transcription-coupled DNA repair
Hereditary nonpolyposis colon cancer (HNPCC)/MUIR–TORRE SYNDROME (MTS)	High level of microsatellite instability in tumors	*hMSH2* (MTS, HNPCC1), *hMLH1* (MTS, HNPCC2), *PMS1* (HNPCC3), *hPMS2* (HNPCC4), *hMSH6* (HNPCC5), *TGFBR2* (HNPCC6), or *hMLH3* (HNPCC7)	Mismatch repair
Other Disorders of Genome Instability			
Bloom syndrome (BS)	Spontaneous chromosome breakage and rearrangements, increased sister chromatid exchanges, quadriradial chromosomes	*BLM*	A RecQ DNA helicase, recombination, replication
Werner syndrome (WS)	Chromosomal instability, accelerated telomere shortening	*WRN*	A RecQ DNA helicase, transcription, DNA repair (DSBR, SSBR, recombination), DNA replication, telomere maintenance
Rothmund–Thomson syndrome (RTS)	Chromosomal instability in response to ionizing radiation	RECQL4 (some patients)	A RecQ DNA helicase
Fanconi anemia (FA)	Increased sensitivity to DNA cross-linking agents	*FANCA*, *FANCB*, *FANCC*, *FANCD1/ BRCA2*, *FANCD2*, *FANCE*, *FANCF*, *FANCG/XRCC9*, *FANCI*, *FANCJ/BACH1/ BRIP1*, *FANCL*, *FANCM*, *FANCN/PALB2*	DNA damage signaling, recombination repair
Dyskeratosis congenita	Shortened telomeres	*DKC1* X-linked; *TERC*, *TERT*, *TINF2*, autosomal dominant; *TERT*, *NOLA3*, *NOLA2* autosomal recessive	Abnormal telomere biology
Ataxia telangiectasia (AT)	Increased spontaneous and X-ray-induced chromosome breakage, increased sensitivity to killing by ionizing radiation, impaired cell cycle arrest and/or apoptosis in response to DNA damage	*ATM*	DNA damage signaling (control of cell cycle, apoptosis), repair of DNA double strand breaks
AT-like disorder (ATLD)	Increased spontaneous and X-ray-induced chromosome breakage, increased sensitivity to killing by ionizing radiation, impaired DNA strand break repair	*LIG4*	DNA ligase 4, strand break repair
Nijmegen breakage syndrome (NBS)	Increased spontaneous and X-ray-induced chromosome breakage, increased sensitivity to killing by ionizing radiation	*NBS1*	Nibrin (p95), which is part of the MRE11–RAD50–NBS1 complex, DNA damage signaling, recombination, DNA double strand break repair, cell cycle checkpoint
Seckel syndrome	Spontaneous and mitomycin C-induced chromosome instability, sensitivity to killing by UV and DNA cross-linking agents	*ATR*	Ataxia telangiectatica- and RAD3-related protein, DNA damage response, cell cycle checkpoints

TABLE 139-3
DNA Repair Disorders and Molecular Defects

Clinical Disorders	Molecular Defects
Xeroderma pigmentosum	XP-C, XP variant, XP-D, XP-A, XP-F, XP-G, XP-E
Xeroderma pigmentosum with neurological Abnormalities	XP-A, XP-D, XP-B
Trichothiodystrophy	XP-D, TTD-A, XP-B, TTDN1
Cockayne syndrome	CS-B, CS-A
Xeroderma pigmentosum/ Cockayne syndrome complex	XP-B, XP-G, XP-D
Xeroderma pigmentosum/ Trichothiodystrophy complex	XP-D
Cerebro-ocular-facial skeletal (COFS) syndrome	CS-B, XP-D

with the cancer-prone disorder dyskeratosis congenita. In about half of dyskeratosis congenita patients, mutations have been found in one out of six genes involved in telomere maintenance.[11]

BASC (*B*RCA1-*a*ssociated genome *s*urveillance *c*omplex) is a multienzyme complex centered around the BRCA1 protein in the nucleus.[12] It contains important DNA damage response proteins including ATM, ATR, the MRE11-RAD50-NBS1 complex, BRCA1, BLM, FANCD2, and MLH1. These proteins physically interact with each other. Genome instability may result from a defect in any of those and cause the genome instability disorders ataxia-telangiectasia (reviewed in Chapter 143), Seckel syndrome, Nijmegen breakage syndrome, hereditary breast cancer, BS, FA, or hereditary colon cancer. BS and FA are reviewed here.

DISORDERS OF DNA REPAIR

XERODERMA PIGMENTOSUM

XP serves as the prototype heritable disease with increased sensitivity to cellular injury.[12–14] XP is an autosomal recessive disease with sun sensitivity, photophobia, early onset of lentigines and freckling, and subsequent neoplastic changes on sun-exposed surfaces. There is cellular hypersensitivity to UV radiation and to certain chemicals in association with abnormal DNA repair. Some of the patients have progressive neurologic degeneration.

FREQUENCY. XP occurs with a frequency of about 1 in 1 million persons in Europe and the United States[15,16] It is relatively more common in areas such as the Middle East where marriage of close relatives is practiced. Patients have been reported worldwide in all races, including whites, Asians, blacks, and Native Americans.

CLINICAL FEATURES

Skin. Approximately one-half the patients with XP have a history of acute sunburn reaction on minimal UV exposure. The other patients tan normally without excessive burning. In all patients, numerous freckle-like hyperpigmented macules (lentigines) appear predominately on sun-exposed skin (Fig. 139-1). The median age of onset of the cutaneous symptoms in XP is between 1 and 2 years (Fig. 139-2).[14] These generally spare sun-protected sites such as the buttocks (see Fig. 139-1D). However, some severely sun-exposed patients may show pigmentary abnormalities in the axillae. Continued sun exposure causes the patient's skin to become dry and parchment-like, with increased pigmentation, hence the name *xeroderma pigmentosum* ("dry pigmented skin"; see Fig. 139-1A). Premalignant actinic keratoses develop at an early age (see Fig. 139-1B). The appearance of sun-exposed skin in children with XP is similar to that occurring in farmers and sailors after many years of extreme sun exposure.

Cancer. Patients with XP younger than 20 years of age have a greater than 10,000-fold increased risk of cutaneous basal cell carcinoma, squamous cell carcinoma, or melanoma.[12,13,16,17] The median age of onset of nonmelanoma skin cancer reported in patients with XP is 8 years. This 50-year reduction in comparison with the general population is an indication of the importance of DNA repair in protection from skin cancer in unaffected individuals (see Fig. 139-2).

Review of the world's literature on XP has revealed a substantial number of cases of oral cavity neoplasms, particularly squamous cell carcinoma of the tip of the tongue, a presumed sun-exposed location. Brain (sarcoma and medulloblastoma), central nervous system (astrocytoma of the spinal cord), lung, uterine, breast, pancreatic, gastric, renal, and testicular tumors and leukemia have been reported in a few patients with XP.[11,12,15,16] Overall, these reports suggest an approximate 10- to 20-fold increase in internal neoplasms in XP.

Eyes. Ocular abnormalities are almost as common as the cutaneous abnormalities and are an important feature of XP (see Fig. 139-1C).[14,18,19] The posterior portion of the eye (retina) is shielded from UV radiation by the anterior portion (lids, cornea, and conjunctiva). Clinical findings are strikingly limited to these anterior, UV-exposed structures. Photophobia is often present and may be associated with prominent conjunctival injection. Schirmer's testing frequently reveals reduced tearing leading to dry eyes. Continued UV exposure of the eye may result in severe keratitis, leading to corneal opacification and vascularization. The lids develop increased pigmentation and loss of lashes. Atrophy of the skin of the lids results in ectropion, entropion, or, in severe cases, complete loss of the lids. Benign conjunctival inflammatory masses or papillomas of the lids may be present. Epithelioma, squamous cell carcinoma, and melanoma of UV-exposed portions of the eye are common. The ocular manifestations may be more severe in black patients.[20]

Figure 139-1 Xeroderma pigmentosum. **A.** Pigmentary changes, atrophy, dryness, and cheilitis in a 16-year-old patient. **B.** Cheek of a 14-year-old patient with pigmented macules of varying size and intensity, actinic keratosis, basal cell carcinoma, and a surgical scar. **C.** Corneal clouding, prominent conjunctival blood vasculature, and loss of lashes. **D.** Myriads of pigmented macules of varying size and intensity and scattered achromic areas on the back, with marked sparing of sun-protected buttocks of a 14-year-old patient.

Neurologic System. Neurologic abnormalities have been reported in approximately 30% of the patients.[13,21] The onset may be early in infancy or, in some patients, delayed until the second decade. The neurologic abnormalities may be mild (e.g., isolated hyporeflexia) or severe, with progressive mental retardation, sensorineural deafness (beginning with high-frequency hearing loss), spasticity, or seizures. The most severe form, known as the *De Sanctis–Cacchione syndrome,* involves the cutaneous and ocular manifestations of classic XP plus additional neurologic and somatic abnormalities, including microcephaly, progressive mental deterioration, low intelligence, hyporeflexia or areflexia, choreoathetosis, ataxia, spasticity, Achilles tendon shortening leading to eventual quadriparesis, dwarfism, and immature sexual development. The complete De Sanctis–Cacchione syndrome has been recognized in very few patients; however, many patients with XP have one or more of its neurologic features. In clinical practice, deep tendon reflex testing and routine audiometry usually can serve as a screen for the presence of XP-associated neurologic abnormalities. In cases where there is clinical evidence of early neurologic abnormalities, a brain magnetic resonance imaging (MRI) may show enlarged ventricles.

The predominant neuropathologic abnormality found at autopsy in patients with neurologic symptoms was loss (or absence) of neurons, particularly in the cerebrum and cerebellum. There is evidence for a primary axonal degeneration in these patients.[20] In a long term follow-up study of 106 XP patients those with neurodegeneration had a younger age at death (29 years) than those without neurodegeneration (37 years).

LABORATORY ABNORMALITIES

Cellular Hypersensitivity. Cultured cells from patients with XP generally grow normally when not exposed to damaging agents. However, the population growth rate or single-cell colony-forming ability is reduced to a greater extent than normal cells after exposure to UV radiation. A range of post-UV colony-forming abilities has been found with fibroblasts from patients, some having extremely low post-UV colony-forming ability and others having nearly normal survival (see Chapter 110).[12,14]

XP fibroblasts are deficient in their ability to repair some UV-damaged viruses or plasmids to a functionally active state.[12,14,20] These host cell reactivation assays have detected an abnormality in every form of XP tested.

UV-irradiated XP fibroblasts are hypermutable compared to normal fibroblasts. This post-UV hypermutability is believed to be the basis of the increased frequency of sunlight-induced somatic mutations that lead to cancer in XP patients.[22]

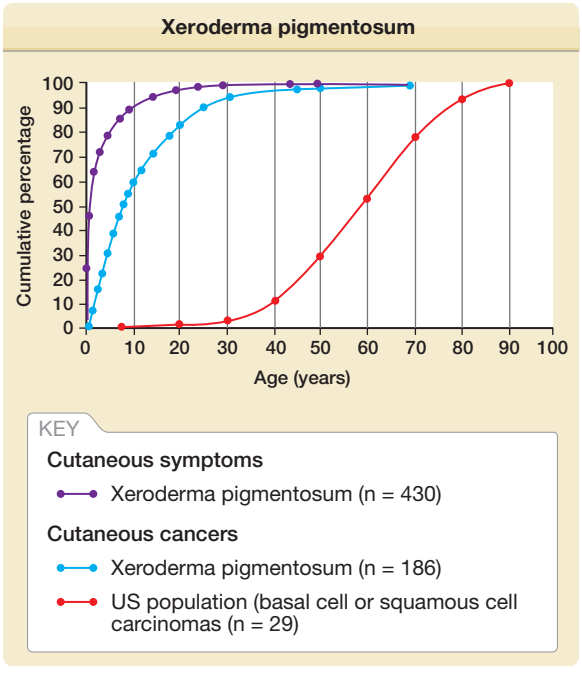

Figure 139-2 Xeroderma pigmentosum. Age at onset of clinical symptoms and skin cancer. Age at onset of cutaneous symptoms (generally sun sensitivity or pigmentation) was reported for 430 patients. Age at first skin cancer was reported for 186 patients and is compared with the age distribution for 29,757 patients with basal cell carcinoma or squamous cell carcinoma in the US general population. There is a 50-year reduction in age of onset of skin cancer in the XP patients compared with the US general population. (From Kraemer KH, Lee MM, Scotto J: Xeroderma pigmentosum. Cutaneous, ocular, and neurologic abnormalities in 830 published cases. *Arch Dermatol* **123**:241, 1987, with permission.)

Chromosome Abnormalities. XP cells generally are found to have a normal karyotype without excessive chromosome breakage or increased sister chromatid exchanges (as seen in BS). However, after exposure to UV radiation, abnormally large increases in chromosome breakage and in sister chromatid exchanges have been observed.[23] The extent of this induced abnormality varies in different patients.

DNA Repair. In 1968, hypersensitivity of cultured XP cells to UV damage was reported by Cleaver[24] to be the result of defective DNA repair. He found defective UV-induced repair replication, indicating a defect in the NER pathway. Most XP cells have a normal response to treatment with X-rays, indicating the specificity of the DNA repair defect.[25] The defective genes for the seven NER-defective forms of XP and the XP variant have been cloned[26] and their functions are being investigated (see Chapter 110).

Complementation Groups. Genetic heterogeneity among the XP DNA repair defects was found by fusing cultured fibroblasts from different patients and defining complementation groups (see Chapter 110). Up to 2011, seven such DNA excision repair-deficient complementation groups have been identified (named XP-A to XP-G) and the corresponding genes have been identified (see Table 139-3).[26] Additional patients with clinical XP but normal NER have been called *XP variants*. Studies of cellular hypersensitivity revealed a slightly increased sensitivity to UV-induced inhibition of cell growth that was potentiated by caffeine. Cells from XP-variant patients have a defect in an error-prone DNA polymerase (pol η) that bypasses unrepaired DNA damage.[27,28]

Prenatal Diagnosis. Prenatal diagnosis has been reported by measuring UV-induced unscheduled DNA synthesis in cultured amniotic fluid cells[29] and by use of DNA diagnosis of trophoblast cells obtained early in pregnancy.[30,31] DNA-based prenatal diagnosis may also be possible in selected cases.[32]

Drug and Chemical Hypersensitivity. A number of DNA-damaging agents other than UV radiation have been found to yield hypersensitive responses with XP cells. These agents include drugs (psoralens, chlorpromazine), cancer chemotherapeutic agents (cisplatin,[33] carmustine), and chemical carcinogens (benzo[*a*]pyrene derivatives). Presumably, these agents induce DNA damage whose repair involves portions of the DNA repair pathways that are defective in XP.[33]

TREATMENT

Management of patients with XP is based on early diagnosis, lifelong protection from UV radiation exposure, and early detection and treatment of neoplasms. Diagnosis rests on recognition of the characteristic clinical features and is confirmed by laboratory tests of cellular hypersensitivity to UV and defective DNA repair (see Chapter 110). Molecular determination of some of the XP disease-causing mutations is offered in a laboratory that is certified for clinical testing (see http://genetests.org for the most recent listing).

Sun Protection. Patients should be educated to protect all body surfaces from UV radiation by wearing protective clothing and UV-absorbing glasses and long hair styles. They should adopt a lifestyle to minimize UV exposure and use sunscreens with high sun protective factor (SPF) ratings (minimum SPF 30) daily. Patients should be examined frequently by a family member who has been instructed in recognition of cutaneous neoplasms. A set of color photographs of the entire skin surface with close-ups of lesions (including a ruler) is often extremely useful to both the patient and the physician in detecting new lesions. A physician should examine patients at frequent intervals (approximately every 3–6 months depending on severity of skin disease). Premalignant lesions such as actinic keratoses may be treated by freezing with liquid nitrogen, or with topical 5-fluorouracil or imiquimod. Photodynamic therapy, using, for example, the topical photosensitizer 5-aminolevulinic acid followed by exposure to blue light, is an effective treatment modality for normal patients with multiple actinic keratoses. There are no data on the safety or efficacy of this treatment in XP patients. *Caution is recommended because an abnormal response to photodynamic therapy or*

other light- or laser-based therapies cannot be excluded in XP cells. Larger areas have been treated with therapeutic dermatome shaving or dermabrasion to remove the more damaged superficial epidermal layers.[34–37] This procedure permits repopulation by relatively UV-shielded cells from the follicles and glands.[38]

Because cells from patients with XP are also hypersensitive to environmental mutagens such as benzo[*a*]pyrene found in cigarette smoke, prudence dictates that patients should be protected against these agents. One of our patients who smoked cigarettes for more than 10 years died of bronchogenic carcinoma of the lungs at age 35 years and another patient who smoked has developed a lung cancer at age 48 years.[39] Thus, we recommend that XP patients refrain from smoking cigarettes and that parents should protect children with XP from being exposed to secondhand smoke.

Cancer. Cutaneous neoplasms are treated in the same manner as in patients who do not have XP. This involves electrodesiccation and curettage, surgical excision, or Mohs micrographic surgery (see Chapters 115 and 244). Because multiple surgical procedures are often necessary, removal of undamaged skin should be minimized. Extremely severe cases have been treated by excision of large portions of the facial surface and grafting with uninvolved skin.[35]

Most patients with XP are not abnormally sensitive to therapeutic X-rays, and XP patients have responded normally to full doses of therapeutic X-radiation for treatment of inoperable neoplasms such as an astrocytoma of the spinal cord,[40] a frontal lobe astrocytoma, or recurrent squamous cell carcinoma in the orbit. However, cultured cells from two XP patients were found to be hypersensitive to X-rays,[41,42] so when X-ray therapy is indicated, an initial small dose is advisable to test for clinical hypersensitivity.

Oral isotretinoin has been shown in a controlled study to be effective in preventing new neoplasms in patients with multiple skin cancers.[43] Because of its toxicity (hepatic, hyperlipidemic, teratogenic, calcification of ligaments and tendons, premature closure of the epiphyses), oral isotretinoin should be reserved for patients with XP who are actively developing large numbers of new skin cancers. We found that the effective dose varies among patients and some patients may respond to doses of oral isotretinoin as low as 0.5 mg/kg/day.

A bacterial DNA repair enzyme, denV T4 endonuclease, in a topical liposome-containing preparation, has been reported to reduce the frequency of new actinic keratoses and basal cell carcinomas in XP patients in one research study.[44] As of 2010, this treatment has not been approved by the U.S. Food and Drug Administration.

A study treating multiple melanoma in-situ lesions with intralesional interferon-α in one XP patient showed localized clearing only of lesions injected with the intralesional interferon-α but not with the control diluent.[45] There are several case reports of XP patients responding to topical treatment with the immune modulator imiquimod (see Chapter 221).[46–49] However, none of these reported long-term follow-up.

Eyes. The eyes should be protected by wearing UV-absorbing glasses with side shields. Methylcellulose eye drops can be used to keep the cornea moist. Corneal transplantation has restored vision in patients with corneal opacity from severe keratitis. However, some of these suffered graft rejection due to neovascularization. Neoplasms of the lids, conjunctiva, and cornea are usually treated surgically.[50–52] We are examining the possibility of using a swab to obtain cytologic specimens from the surface of the eye to determine if early neoplasms can be detected or excluded without the need for performing biopsies.

CLINICAL-LABORATORY CORRELATIONS.

Patients with XP are hypersensitive to UV radiation, as are their cultured cells. Cutaneous and ocular abnormalities are strikingly limited to UV-exposed areas and usually spare such UV-shielded locations as the axillae, buttocks, and retina. The fact that black patients with XP have an increased frequency of skin cancer suggests that a normally functioning DNA repair system provides greater protection against skin cancer than does the natural pigmentation of black skin.

Complementation Groups. At least eight different molecular defects are associated with the clinical abnormalities recognized as XP, as indicated by the existence of seven DNA excision repair-deficient complementation groups (A to G) and the variant form. A discussion of the cloned XP genes and their function can be found in Chapter 110. A Web site listing disease-causing mutations in XP and CS genes has been established at http://xpmutations.org/. There is a complex relationship among the DNA repair genes and clinical disease (see Table 139-3 and see http://genetests.org for review of xeroderma pigmentosum). Multiple NER genes are associated with at least a spectrum of different clinical phenotypes. A clinical phenotype can be associated with defects in each of several genes. Conversely, mutations in one gene can be associated with several different clinical phenotypes. These complex relationships and the roles of DNA repair genes in regulation of transcription and in immune functions are under intense investigation.

Complementation Group A. Complementation group A (see Table 139-3) contains patients with the most severe neurologic and somatic abnormalities (the De Sanctis–Cacchione syndrome) as well as patients with minimal or no neurologic abnormalities.[13] Long-term follow-up of these patients has revealed a relationship between the genotype and the phenotype. Patients with the most severe disease appear to have truncating mutations in both alleles of the *XPA* gene leading to no detectible normal protein. In contrast, patients with minimal neurologic abnormalities have splice-site mutations that permit a small amount of normal messenger RNA (mRNA) to be made. This form is seen in the United States, Europe, and the Middle East. It is the most common form of XP in Japan. Approximately 90% of Japanese XP-A patients have the same single-base-substitution founder mutation.[53] This finding has served as the basis for development of a rapid diagnostic

Figure 139-3 Xeroderma pigmentosum (XP/CS) complex. **A.** 28-year-old patient (XP11BE) in XP complementation group B with cutaneous changes of XP, including pigmentary changes and atrophy. She has a beak-like nose and loss of subcutaneous tissue typical of Cockayne syndrome. **B.** The patient is of short stature (less than 4 ft. tall). Her mother, an obligate heterozygote, is clinically normal.

assay for Japanese XP-A patients (including prenatal diagnosis) using polymerase chain reaction analysis of a small sample of DNA.[37] Heterozygous carriers of this disease-causing mutation who have one mutated allele and one normal allele have been estimated to comprise approximately 1% of the Japanese population.[16]

Complementation Group B. Complementation group B (Fig. 139-3) is composed of five patients in four kindreds who had the cutaneous abnormalities characteristic of XP (including neoplasms) in conjunction with neurologic and ocular abnormalities typical of CS.[13,54] Another family had two adult sisters with XP without CS who had ocular melanomas and were parents of normal children. Surprisingly, a patient with TTD also was found to have a defect in the *XPB* gene.

Complementation Group C. Patients in complementation group C, with rare exceptions, have XP with skin and ocular involvement but without neurologic abnormalities.[13,55–61] This is the most common group in the United States, Europe, and Egypt, but has been found rarely in Japan. Most patients have truncating mutations in both alleles leading to undetectable levels of *XPC* mRNA (due to nonsense-mediated message decay). However, a splice lariat branchpoint mutation resulting in as little as 3% to 5% of normal mRNA resulted in milder clinical symptoms in one family in Turkey.[58] XP-C patients typically do not give a history of severe blistering sunburns on minimal sun exposure and at times are first diagnosed with the appearance of skin cancer in a child. One XP-C patient was reported to be hypersensitive to ionizing radiation[42]; however, correction of the *XPC* gene defect did not correct the cellular ionizing radiation hypersensitivity, suggesting that more than one gene was defective in this patient.

Complementation Group D. Patients in complementation group D have been described with several different clinical phenotypes. They may have cutaneous XP with late onset of neurologic abnormalities in their second decade of life or XP with no neurologic abnormalities.[13,62] Two XP-D patients have been reported with clinical symptoms of both XP and CS. Cells from patients with a photosensitive form of TTD (without XP) also were assigned to the XP complementation group D. Two patients were reported with combined symptoms of both TTD and XP (one patient had a skin cancer and another died of metastatic melanoma) and mutations in the *XPD* gene.[63] Finally, a patient with cerebro-oculo-facio-skeletal (COFS) syndrome had a mutation in the *XPD* gene.[64]

Complementation Group E. Complementation group E was found in one kindred in Europe and several in Japan.[13,65] We have studied adult patients with multiple skin cancer in 3 kindreds in the US and Germany. These patients had no neurologic involvement.[66]

Complementation Group F. Complementation group F patients have been found mainly in Japan.[67,68] Most of these patients have mild clinical symptoms without neurologic abnormalities or skin cancer. However, we recently found two families with adult onset of severe neurodegeneration with mutations in the *XPF* gene. The residual rate of DNA repair is very low (only 10% to 20% of normal).

Complementation Group G. Thirteen patients in XP complementation group G have been identified in the United States, Europe, and Japan (Fig. 139-4).[69] There is a large variation in clinical features among these patients. Several patients with mutations in the

Figure 139-4 Severe and mild xeroderma pigmentosum XP-G patients. **A** and **B.** XP82DC. **C–F.** XP65BE. **A.** Patient XP82DC at 3 years of age has deep-set eyes characteristic of Cockayne syndrome (CS) and irregular lentiginous pigmentation on her face characteristic of XP, indicating XP/CS complex. **B.** Patient XP82DC at 3 years of age has characteristic XP-pigmented lesions on her forearms and dorsa of hands along with thin, translucent skin with readily visible veins. The small size of her hands is apparent in comparison with the hands of her mother. **C.** Patient XP65BE at age 6 months experienced severe sunburn on her face with minimal sun exposure. Erythema and swelling are seen on skin of forehead, cheeks, and periorbital area. **D.** Patient XP65BE at age 9 months shows erythema and peeling of skin of malar area of face after sun exposure. **E.** Patient XP65BE at age 4.5 years shows pigmentary changes on her nose, malar area, and other portions of her face. **F.** Patient XP65BE at 4.5 years shows blistering sunburn on her upper thigh. Note spared area above knee where sunscreen was applied **G.** Patient XP65BE shows minimal pigmentary changes on face and sparing of neck and hand. She used measures to protect her skin from sun exposure. (From Emmert S et al: Relationship of neurologic degeneration to genotype in three xeroderma pigmentosum group G patients. *J Invest Dermatol* **118**:972, 2002, with permission.)

XPG gene had clinical features of both XP and severe CS with cachexia and death in the first decade (see Fig. 139-3). Other patients with different mutations in the same gene had no neurologic abnormalities.

Xeroderma Pigmentosum Variant. XP-variant cells have normal DNA NER and thus do not fall into any of the complementation groups of cells with defective DNA excision repair.[14] However, there is a defect in an error-prone, translesional DNA damage bypass polymerase, pol η (see Chapter 110).[25,27,70] Most XP-variant patients have clinical XP with no neurologic abnormalities.[71] The cutaneous and ocular abnormalities have been severe in some patients and mild in others.

Heterozygotes. XP heterozygotes (parents and some other relatives) are carriers of the gene for XP but are clinically normal. There is limited epidemiologic evidence to indicate that such persons have an increased risk of developing skin cancer.[72] Most tests of cell function or DNA repair yield normal responses with cells from XP heterozygotes.

PATIENT SUPPORT GROUPS

The Xeroderma Pigmentosum Society is an educational, advocacy, and support organization for XP patients and their families: Xeroderma Pigmentosum Society, Inc., Box 4759, Poughkeepsie, NY 12602–4759;

Web site: http://www.xps.org; e-mail: xps@xps.org; telephone: toll-free (877) XPS-CURE (877-977-2873). Another support group is the XP Family Support Group, 8375 Folsom Blvd Suite 201, Sacramento Ca, 95826. Their Web site is http://www.xpfamilysupport.org/. A Web site listing disease-causing mutations in XP and CS genes has been established at http://xpmutations.org/.

COCKAYNE SYNDROME (INCLUDING XERODERMA PIGMENTOSUM–COCKAYNE SYNDROME OVERLAP)

CS is a very rare, autosomal recessive degenerative disease with cutaneous, ocular, neurologic, and somatic abnormalities (see Table 139-1).[73,74] A review published in 1992 described 140 cases reported in the literature.[75]

CLINICAL FEATURES

In 1936, E. A. Cockayne described a syndrome characterized by cachectic dwarfism, deafness, and pigmentary retinal degeneration with a characteristic "salt and pepper" appearance of the retina.[76] The skin had photosensitivity without the excessive pigmentary abnormalities seen in XP. There was marked loss of subcutaneous fat, resulting in a "wizened" appearance with typical "bird-headed" facies and prominent "Mickey Mouse" ears. Other ocular findings included cataracts and optic atrophy.[77] Neurologic abnormalities, in addition to deafness, include peripheral neuropathy, normal pressure hydrocephalus, and microcephaly. Birth weight and early development are usually normal. The disease onset is usually in the second year of life with slowly progressive neurologic degeneration. Intellectual deterioration may be nonuniform, with some functions preserved better than others. A severe infantile form has been described[78,79] as well as a milder form with late onset. COFS syndrome[64,80,81] with microcephaly and severe mental retardation and CAMFAK syndrome of congenital *ca*taracts, *m*icrocephaly, *fa*ilure to thrive, and *k*yphoscoliosis[82] have some similar features. CS is not associated with an increased incidence of neoplasia.

LABORATORY ABNORMALITIES

Clinical laboratory testing often shows sensorineural deafness, neuropathic electromyogram, and slow motor nerve conduction velocity.[13,20,69,75,78,83] The electroencephalogram may be abnormal, and X-ray examination may show thickened skull and microcephaly. Computed tomography may be diagnostically useful in the detection of normal-pressure hydrocephalus and showing calcification of the basal ganglia and other structures (see eFig. 139-4.1 in online edition). MRI of the brain shows atrophy and dysmyelination of the cerebrum and cerebellum. Bone age is usually normal. Height and weight are usually well below the third percentile for the age.

Cellular Hypersensitivity. As with XP, cultured cells (fibroblasts or lymphocytes) from patients with CS are hypersensitive to UV-induced inhibition of growth and colony-forming ability.[13,84] Host cell reactivation of UV-damaged adenovirus or plasmids is reduced, although generally to a lesser extent than in XP. There are two complementation groups (A and B) in CS (see Table 139-3). Patients with defects in CSA or CSB have similar features.[75] A recent report from Europe identified CSA (*ERCC8*) and CSB (*ERCC6*) mutations in 84 kindreds. 62% (52) had mutations in the CSB gene.[85] A patient with COFS syndrome was reported with a defect in CSB[82] and another with a defect in *XPD* (Table 139-3).[57] Molecular determination of some of the CS disease-causing mutations is offered in a laboratory that is certified for clinical testing (see http://genetests.org for the most recent listing).

Prenatal Diagnosis. Prenatal diagnosis of CS has been performed[86] based on the delay in recovery of post-UV RNA synthesis and the increased cell killing by UV radiation.

CLINICAL-LABORATORY CORRELATION.

Patients with defects in CSA or CSB have similar clinical features.[75]

PATIENT SUPPORT GROUP

The Share and Care Cockayne syndrome network (http://cockaynesyndrome.net or http://www.cockayne-syndrome.org) is an educational, advocacy, and support organization for CS patients and their families (Box 570618, Dallas, TX 75357).

XERODERMA PIGMENTOSUM–COCKAYNE SYNDROME COMPLEX

Approximately one dozen patients with CS have been found to have, in addition, clinical features of XP.[19,48,61] These features include freckle-like pigmentation on sun-exposed skin and cutaneous neoplasms (see Fig. 139-4). Cells from these XP/CS patients have reduced DNA excision repair characteristic of XP. Clinically, these patients may be distinguished from XP patients with neurologic abnormalities by the presence of the CS features of pigmentary retinal degeneration, calcification of the basal ganglia, normal-pressure hydrocephalus, and hyperreflexia. Cells from patients with this complex have been found to have mutations in three different XP genes: *XPB*, *XPD*, and *XPG*,[54,59,84] demonstrating that several different genes are implicated in this disorder (see Table 139-3).

TRICHOTHIODYSTROPHY

TTD is a rare autosomal recessive disorder that is characterized by sulfur deficient, brittle hair and includes a broad spectrum of clinical abnormalities that may include photosensitivity, ichthyosis, intellectual impairment, short stature, microcephaly, characteristic facial features (protruding ears, micrognathia), recurrent infections, bilateral cataracts, dystrophic nails, and other features (Fig. 139-5).[85–94] Bone abnormalities include osteosclerosis of the axial skeleton with osteopenia of

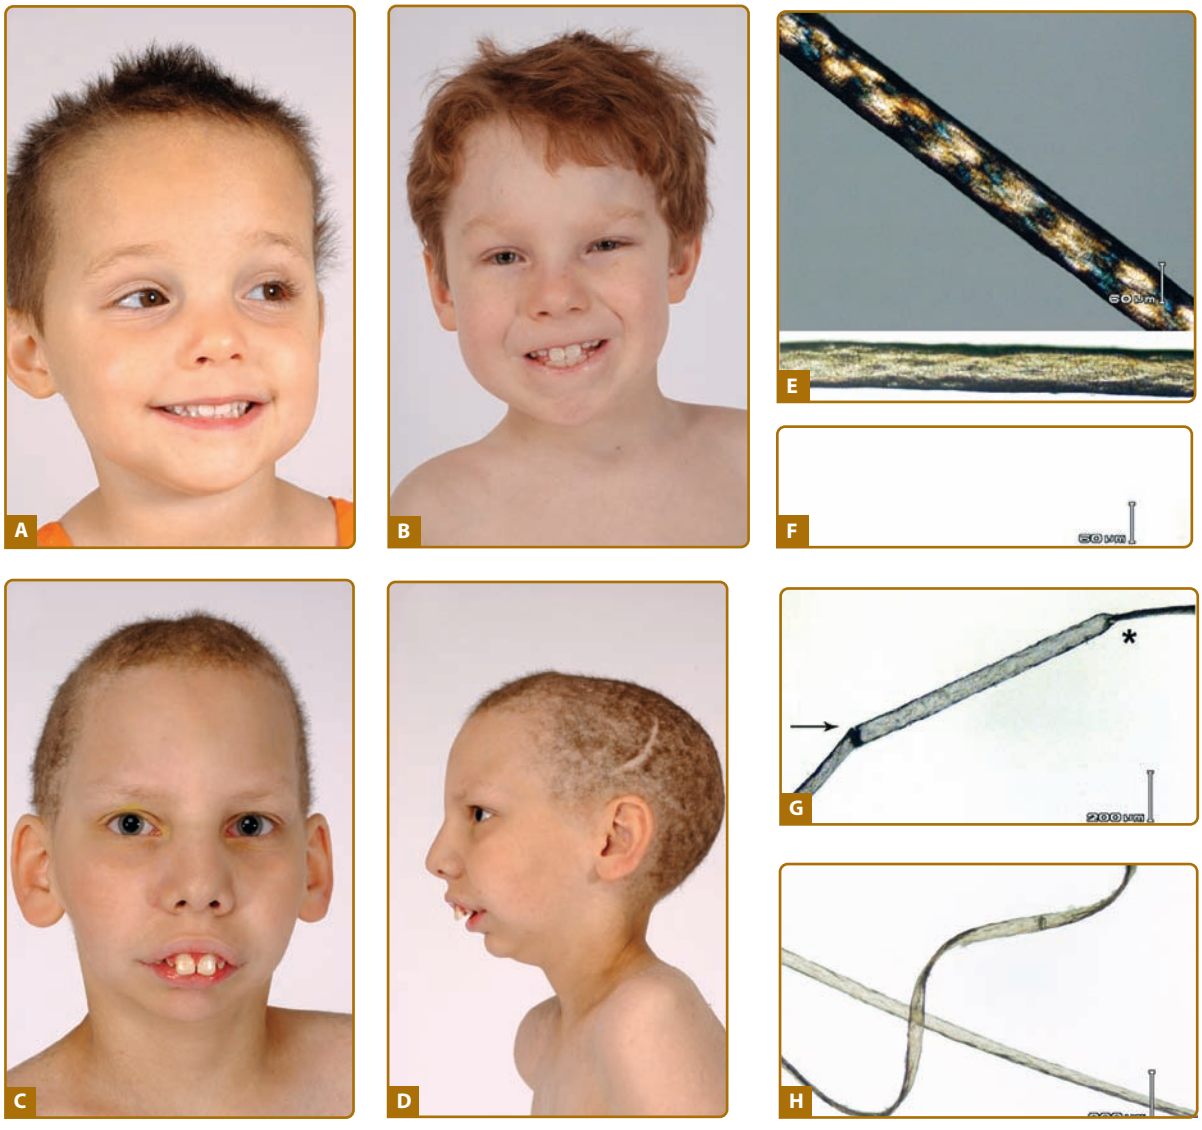

Figure 139-5 Trichothiodystrophy (TTD): clinical and microscopic hair findings. **A.** Three-year-old girl with TTD having short brittle hair that is sparse and broken off at different lengths. She rarely has haircuts except to trim uneven hairs. She has developmental delay. **B.** Seven-year-old boy with TTD with sun sensitivity, congenital cataracts, multiple infections, and developmental delay. In contrast to the patient in **A**, he has long hair. He has a happy engaging personality. **C** and **D.** Severe clinical phenotype: 14-year-old boy with short brittle hair and dysmorphic facies with protruding ears, micrognathia, deep set eyes, head elongation in fronto-occipital plane. He also has ichthyosis, intellectual impairment, short stature, photosensitivity, osteosclerosis, neurologic abnormalities, and recurrent infections. Light microscopy findings: **E.** TTD hairs displaying alternating light and dark "tiger tail" bands using polarizing microscopy. **F.** Irregular, undulating hair shaft with light microscopy **G.** Trichoschisis (*arrow*): clean, transverse cleavage fracture; marked narrowing of shaft diameter (*asterisk*). **H.** Ribboning. (Modified from Liang C et al: Characterization of tiger tail banding and hair shaft abnormalities in trichothiodystrophy. *J Am Acad Dermatol* **52**:224, 2005.)

the limbs. Decreased red blood cell mean corpuscular volume and increased hemoglobin A2 levels mimic β-thalassemia trait. eTable 139-3.1 in online edition lists the clinical findings in one TTD patient, as an example of the diverse findings.[85] Developmental delay may be associated with dysmyelination,[96] a feature similar to CS; however, patients do not have retinal changes of CS. The spectrum of clinical involvement is broad ranging from only hair to severe multisystem abnormalities (Fig. 139-5). TTD encompasses patients who have been described as *Tay syndrome*, *Amish brittle hair syndrome*, *Sabinas brittle hair syndrome*, or *Pollitt syndrome*.

In 1980, Price proposed the term *trichothiodystrophy* [derived from Greek *tricho*: hair; *thio*: sulfur; *dys*: faulty; *trophe*: nourishment] recognizing the hair shaft sulfur deficiency as a marker for this symptom complex.[90] While most TTD patients have short, broken hair (Figs. 139-5A, 139-5C, and 139-5D), some patients have long hair (Fig. 139-5B). Under light microscopy with polarization, TTD hair shafts have a characteristic dark and light banding pattern that gives a "tiger tail" appearance (Fig. 139-5E). In addition, they usually have hair shaft abnormalities including trichoschisis (a clean transverse break through the hair) (Fig. 139-5G),

trichorrhexis nodosa-like defects, and ribboning (Fig. 139-5H).[79,80] Hair shafts are brittle because of a reduction of high-sulfur matrix proteins, and amino acid analysis of the hair demonstrates reduced levels of cysteine and cystine in hair shaft proteins.[97] This is associated with a decrease in the ratio of strong to weak disulfide bonds within the hair shafts.[91] Approximately 50% of TTD patients have clinical photosensitivity that ranges from subtle to severe. However, in contrast to the typical clinical features of XP, patients with TTD do not develop poikilodermatous changes (hyper- and hypopigmentation, telangiectasias, and atrophy) or skin cancer. Rarely, patients may have an overlap syndrome with features of both TTD and XP, with typical hair features of TTD and the pigmentary and skin cancer characteristic of XP (see Table 139-3).[63]

The majority of TTD patients have a defect in *XPD* (*ERCC2*). A few have mutations in *XPB* (*ERCC3*) or *TTDA* (*TFB5*) genes, which are components of the transcription factor TFIIH that regulates both DNA repair and transcription. Some TTD patients have mutations in *TTDN1*, a gene of unknown function.[98] It is believed that mutations that affect the repair function of the NER genes are associated with features of XP, whereas mutations affecting the transcription-related function results in features of TTD.[99]

The diagnosis of TTD is based on examination of hair shafts (Fig. 139-5E–H). TTD hair shafts display tiger tail banding under polarizing microscopy. In addition, they show a spectrum of typical hair shaft abnormalities, including trichoschisis, trichorrhexis nodosa-like fractures, surface irregularities, and ribboning.[88,89] Amino acid analysis of hair shafts can confirm reduced levels of cysteine and cystine (see Chapter 88).

A recent review of the literature identified 112 patients, whose clinical features are detailed in eTable 139-3.2 in online edition. Patients with TTD show a wide spectrum of clinical findings, including abnormal characteristics at birth, pregnancy complications in mothers carrying an affected fetus, ocular abnormalities and infections (eTable 139-3.1 in online edition).[100,101] Clinical features of *p*hotosensitivity, *i*chthyosis, *b*rittle hair, *i*ntellectual impairment, *d*ecreased fertility and *s*hort stature have been used to describe patients with the acronyms *PIBIDS*, *IBIDS*, and *BIDS*. While patients can be found who fit having these features, all of these individuals have additional clinical findings, making these acronyms poor descriptors of the actual disease features. Moreover, more than a third of patients do not fit these acronyms. Because they are misleading they should be abandoned.

Management includes sun protection and varies with the individual clinical features. Patients with developmental delay and intellectual impairment may have dysmyelination as seen on MRI of the brain and may benefit from neurologic and developmental assessment and rehabilitation medicine consultation. Ophthalmologic involvement can include cataracts (which may be congenital), nystagmus, and errors of refraction.[102] A review of the literature identified a high mortality (>20%) in children below the age of 10, with most deaths due to infection. In some patients, recurrent infections have been managed with prophylactic antibiotics or intravenous immunoglobulin. Patients with skeletal abnormalities may benefit from rehabilitation medicine evaluation and support. In addition, a high frequency of complications occur during pregnancies, including intrauterine growth restriction, preeclampsia, preterm delivery, hemolysis-elevated liver enzymes-low platelets (HELLP) syndrome, and abnormal levels of maternal serum screening markers, highlighting the role of DNA repair in normal development.[103] Several our TTD patients in their first or second decade of life have experienced progressive inability to walk over a few year interval resulting from bilateral aseptic necrosis of their hips.

DISORDERS OF GENOME INSTABILITY

BLOOM SYNDROME

BS is a rare, autosomal recessive disorder characterized by growth deficiency, unusual facies, sun-sensitive telangiectatic erythema, immunodeficiency, and predisposition to a variety of different cancers.[7,104] It is most frequent among Ashkenazi Jews.[105] Approximately 250 patients have been recognized.

CLINICAL FEATURES

Facial erythema and telangiectasia superficially resembling lupus erythematosus (Fig. 139-6) are often present within the first few weeks after birth in the malar

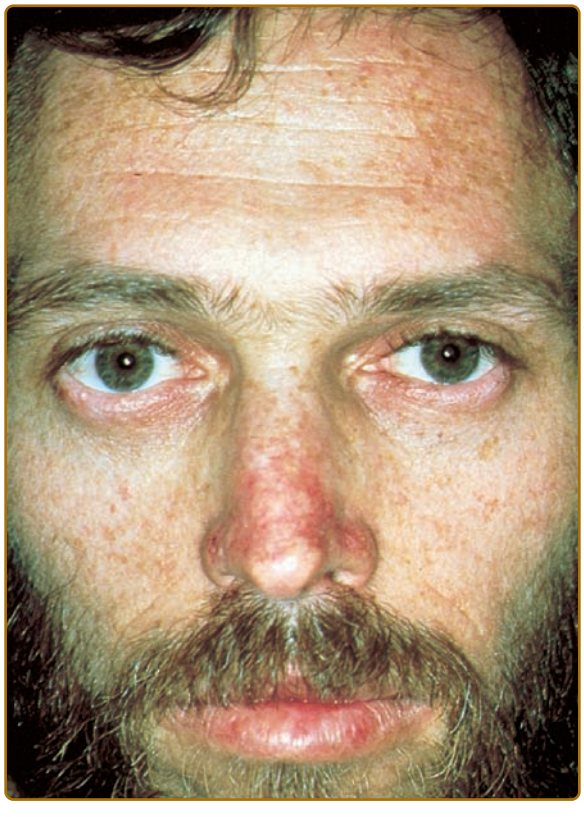

Figure 139-6 Bloom syndrome. Prominent telangiectasia in malar distribution.

area, on the nose, and around the ears.[104] Sun exposure accentuates these abnormalities and may induce bullae, bleeding, and crusting of the lips and eyelids. Café-au-lait spots are common, at times accompanied by adjacent depigmented areas. Patients are well proportioned but small. Adult height is usually under 150 cm. Patients have a long, narrow head with a characteristic facies consisting of a narrow, prominent nose, relatively hypoplastic malar areas, and a receding chin.

Patients with BS are predisposed to multiple infections, as there is immune dysfunction. Fertility is decreased and diabetes mellitus is common. Approximately 20% of patients with BS develop malignancies, comprising a normal spectrum of cancer types, of which one-half occur before age 20 years.[104] Patients usually die before the age of 30 years from either cancer or infection.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES

BS is caused by mutations in *BLM*, which encodes a RecQ helicase.[7,9,105,106,107] BS cells are characterized by an increase in the frequency of spontaneous sister chromatid exchanges (see Chapter 110) and in exchanges between homologous chromosomes. The latter is often visualized by quadriradial chromosomes. These are four-armed chromosomes most likely formed by recombination between two chromosomes (and almost never found in unaffected individuals). These observations demonstrate that BS cells are characterized by hyperrecombination. Although the exact mechanisms of how mutations in the BLM helicase lead to hyperrecombination are still not completely understood, it has been suggested that they are related to defective DNA replication or defective resolution of stalled replication forks. Hyperrecombination may result in an increased frequency of loss of heterozygosity and through that mechanism, in conjunction with increased spontaneous mutation frequency, an increased frequency of malignant transformation. The immune deficiency, characterized by diminished immunoglobulin levels, reduced cellular proliferative response to mitogens, and decreased proliferation in the mixed leukocyte reaction, probably further contributes to the increased cancer risk.

TESTING

The observation of quadriradial chromosomes (observed in 0.5% to 14% of lymphocytes of BS patients) and the approximately tenfold increased frequency of spontaneous sister chromatid exchanges are used to diagnose BS.[108] A founder deletion/insertion mutation in the *BLM* gene was identified in Ashkenazi Jews at a frequency of approximately 1% (BLM^{Ash})[105,109] and can be used for DNA diagnosis of BS patients and carriers among Ashkenazi Jews.[57] Diagnostic testing for BS is offered in a number of laboratories that are certified for clinical testing (see http://genetests.org for the most recent listing).

WERNER SYNDROME (ADULT PROGERIA)

WS is a rare, autosomal recessive disorder, characterized by several features of premature aging and an increased cancer risk. More than 800 patients have been reported.[110] Most of the WS patients are Japanese.

CLINICAL FEATURES

Patients with WS are clinically normal until adolescence, when they do not show the usual growth spurt and start to prematurely develop features and diseases of aging, including graying and thinning of hair, loss of subcutaneous fat, wrinkling of skin, type 2 diabetes, osteoporosis, and cardiovascular disease secondary to atherosclerosis.[111] Often, ophthalmologists are first to make the diagnosis of WS as cataracts develop early.[112] Other features that are not part of the normal aging process are scleroderma-like changes with subcutaneous atrophy, leg ulcers, soft tissue calcifications, and bird-like facies. Although an increased incidence and early onset of cancer is related to aging, the 10:1 ratio between epithelial to mesenchymal cancer seen in a normal aging population is shifted to 1:1 in WS patients, with, for example, sarcomas and melanomas being more frequent.[113] As in the Japanese general population, most of the melanomas are of the acral-lentiginous type or arise from mucous membranes and are therefore not considered to be related to UV-exposure. Thyroid cancer occurs at a younger age in WS patients than in the Japanese general population. Death usually occurs before the age of 50 years due to either myocardial infarction or cancer.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES

WS is caused by a mutation in *WRN*, which encodes a RecQ helicase.[7,114,115] Most mutations of *WRN* result in truncation of the protein, sometimes by only a small amount, with loss of the nuclear targeting sequence. WRN is involved in many metabolic processes of DNA metabolism and *WRN* mutations cause various defects in DNA replication, recombination, base excision repair of oxidative DNA damage, repair of DNA strand breaks, DNA damage signaling, and transcription. Cells from WS patients have a reduced replicative lifespan in culture[116] and show altered telomere structure and length. Genome instability in WS cells is shown by an increased frequency of nonhomologous chromosome exchanges and of large chromosomal deletions.

ROTHMUND–THOMSON SYNDROME

CLINICAL FEATURES

The hallmark of RTS, a rare, autosomal recessive disorder, is poikiloderma with variegated cutaneous pigmentation, atrophy, and telangiectasias beginning in infancy.[117,118] RTS patients are photosensitive and develop prominent erythema and facial swelling on sun exposure early in life, which may be accompanied by blister formation. They often have sparse scalp hair, eyebrows, and eyelashes. Other clinical features include juvenile cataracts, stunted growth, skeletal abnormalities including radial bone defects, and a predisposition for cancer, in particular for osteosarcomas (32% of patients). Five percent of RTS patients also develop nonmelanoma skin cancer.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES

Mutations in the helicase RecQL4 have been identified in a majority of patients with RTS.[119] Cells from RTS patients are characterized by chromosomal instability with trisomy, aneuploidy, and chromosomal rearrangements, suggesting a role of RECQL4 in maintaining chromosome stability.[120,121] RTS cells have also been reported with an increased sensitivity to ionizing radiation with increased formation of chromosome gaps and breaks.[120,121] However, this was not confirmed in other patients, possibly reflecting heterogeneity in this disease.[122] The exact function of the RECQL4 helicase remains unclear.[115,123] Cells from one patient had reduced DNA repair after exposure to UVC.[124] One RTS patient had increased acute toxicity after high-dose radiotherapy after surgery and subsequent palliative chemotherapy. However, another RTS patient was reported to have a normal acute response to radiation therapy for a squamous cell carcinoma of his tongue.[125] He died 2 years later with extensive squamous cell carcinoma in the thorax, but no tumor in the oral cavity.

FANCONI ANEMIA

FA is an autosomal recessive disease characterized by progressive pancytopenia, growth retardation, various congenital abnormalities of the heart, kidney, and limbs, and a predisposition to cancer.[126,127] More than 1,200 patients have been reported to the International Fanconi Anemia Registry.

CLINICAL FEATURES

Cutaneous abnormalities are present in almost 80% of patients (Figs. 139-7A–139-7D).[126,128,129] Hyperpigmentation is present from birth or early childhood and is diffuse and accentuated over the neck, joints, and trunk. Café-au-lait spots and achromic lesions are also present.

Hematopoietic manifestations usually have their onset before age 10 years and most commonly lead pediatricians to make the diagnosis of FA. These consist of a hypocellular bone marrow with progressive decrease in the number of circulating platelets, granulocytes, and erythrocytes. Skeletal malformations are common and often include aplasia or hypoplasia of the thumb, metacarpals, or radius.[130,131] Short stature, renal deformities, strabismus, microphthalmia, hypogonadism, and central nervous system abnormalities, including hyperreflexia and mild mental retardation, are also observed. The frequency of acute myelogenous leukemia has been reported to be elevated 500-fold.[132–135] If patients survive aplastic anemia and/or leukemia (e.g., as a result of bone marrow transplantation), they often develop solid tumors by the fifth decade of life, mostly squamous cell carcinomas of the head and neck and the anogenital area.

GENE DEFECT, PATHOGENESIS, AND LABORATORY ABNORMALITIES

FA is genetically heterogeneous with 13 complementation groups (FANCA to FANCN). All 13 genes have been identified and all of the FA proteins have been shown to act in a common DNA damage response signaling pathway, which also involves *BRCA1* and *BRCA2* (these genes are mutated in hereditary breast cancer; see Chapter 110) and multiple other proteins involved in cellular DNA damage responses.[136–147] Activation of this FA/BRCA pathway is thought to mediate DNA recombination to repair DNA strand breaks and DNA cross-links, generated, for example, by ionizing radiation or DNA cross-linking agents and to facilitate resolution of stalled replication forks.

TESTING

Increased chromosome breakage after exposure to DNA cross-linking agents such as mitomycin C or diepoxybutane is a feature of FA. Central to the FA/BRCA pathway is the monoubiquitination of the FANCD2 protein. The inability of FA cells to ubiquitinate the FANCD2 protein, as shown in Western blots after, for example, exposure to DNA cross-linking agents, is currently used as a screening tool to confirm the diagnosis of FA. Diagnostic testing for FA is offered in a number of laboratories that are certified for clinical testing (see http://genetests.org for the most recent listing).

RESOURCES: THE FANCONI ANEMIA RESEARCH FUND

Patients, physicians, and researchers may obtain information from the Fanconi Anemia Research Fund, Inc. (http://www.fanconi.org) or from Fanconi Canada (http://www.fanconicanada.org).

DYSKERATOSIS CONGENITA

Dyskeratosis congenita, the Zinsser–Cole–Engman syndrome, is an X-linked multisystem disease with cutaneous, mucosal, ocular, gastrointestinal, and hematologic abnormalities and an increased incidence of cancer (see Table 139-1). There are also autosomal dominant and autosomal recessive forms. A Registry at Hammersmith Hospital in London recruited 228 families having 354 affected patients from 40 countries.[148] More than 500 patients have been reported in the literature.[149] Affected females may have either the autosomal dominant or autosomal recessive form.

CLINICAL FEATURES

The most common features are a triad of reticulated hyperpigmentation, dystrophic nails, and mucosal leukoplakia (see Figs. 139-7E–139-7H).[150–152] During the first decade of life, patients develop reticulated poikiloderma of sun-exposed areas, with hyperpigmentation and, occasionally, bullae. Nail dystrophy is present in virtually all patients beginning at approximately age 2–5 years. The nails initially split easily, then develop longitudinal ridging with irregular free edges. Eventually, the nails become smaller, resulting in rudiments remaining. The fingernails are usually involved before the toenails. Other skin abnormalities include atrophic, wrinkled skin over the dorsum of hands and feet and hyperhidrosis and hyperkeratosis of palms and soles with disappearance of dermal ridges (absence of fingerprints).

Leukoplakia may be present in any mucosal site. The oral mucosa is the most frequent, but leukoplakia is also

Figure 139-7 Skin and oral mucous membrane findings in Fanconi anemia (**A–D**) and dyskeratosis congenita (**E–H**). **A–D.** Fanconi anemia. **A.** Congenital absence of thumb. The second finger has been surgically altered to function as a thumb. Keratotic papules are present on the palm. **B.** Oral leukoplakia on right buccal mucosa (*arrow*). **C** and **D.** Dyspigmentation of Fanconi anemia. **C.** Hyperpigmentation of left axilla with discrete hyperpigmented and hypopigmented macules. **D.** Several irregular café-au-lait macules, smaller fine tanned hyperpigmented macules, and dozens of guttate hypopigmented macules in the lower back. **E–H.** Dyskeratosis congenita. **E.** Oral leukoplakia involving the tongue. **F.** Severe atrophy of all fingernails and thickening of the palm. **G.** Longitudinal ridging and dystrophy of several fingernails with dyspigmentation and thickening of the palm. **H.** Poikiloderma showing reticular hypo- and hyperpigmentation of the skin of the neck and chest. (**A–D** modified from Braun M et al: Thrombocytopenia, multiple mucosal squamous cell carcinomas, and dyspigmentation. *J Am Acad Dermatol* **54**:1056, 2006; **E–H** used with permission from Dr. Blanche Alter, NCI, Bethesda, MD.)

found in the urethra, glans penis, vagina, and rectum. Lingual hyperkeratosis may be present. Mucosal surfaces such as the esophagus, urethra, and lacrimal duct may become constricted and stenotic, resulting in dysphagia, dysuria, and epiphora. Multiple dental caries and early loss of teeth are common. Progressive pulmonary disease, including infections and fibrosis (and cirrhosis in some patients) was reported in 19% of affected males.[151] Approximately 20% of the patients had learning difficulties or mental retardation.[151] There have been several reports of intracranial calcifications, especially of the basal ganglia.[153,154] These are also seen in CS.

There is an increased incidence of neoplasia, particularly squamous cell carcinoma of the mouth, rectum, cervix, vagina, esophagus, and skin. A large British kindred had Hodgkin disease and adenocarcinoma of the pancreas.[155] Similar to FA, although hypoplasia is the main abnormality seen in bone marrow, there is a predisposition to both myelodysplasia and acute myeloid leukemia.[151]

The majority (93%) of patients developed bone marrow failure which was the main cause (71%) of early death.[151] Approximately one-half of the patients (21 of 41) developed pancytopenia under the age of 10 years with a hematologic picture similar to FA. Patients have been treated with bone marrow transplantation.[156]

LABORATORY STUDIES

A gene for dyskeratosis congenita (*DKC1*) has been cloned,[148,157,158] which is located on the q28 region of the X

chromosome. The protein, dyskerin, has a nucleolar function, and a role in telomere maintenance and aging.[159–163] Mutations in the *DKC1* gene have been detected in affected patients.[148,164–166] There is also evidence for an autosomal form with affected females[148,151,167,168] having mutations in the *TERC* gene, which is also involved in telomere function. Approximately half of the DC patients have a mutation in a gene in the telomere biology pathway: *DKC1*, *TERC*, *TERT*, *TINF2*, *NOLA2*, and *NOLA3*. Many DC patients have very short telomeres.

TESTING. Diagnostic testing for DC is offered in a number of laboratories that are certified for clinical testing (see http://genetests.org for the most recent listing).

Chapter 140 :: Tuberous Sclerosis Complex

:: Thomas N. Darling

TUBEROUS SCLEROSIS COMPLEX AT A GLANCE

- Autosomal dominant syndrome with variable expressivity.
- Manifested by hamartomatous tumors in multiple organs, including brain (causing seizures), eyes, heart, kidneys, lungs, and skin.
- Skin lesions occur in nearly all individuals and are important for diagnosis.
- Skin lesions include hypomelanotic macules, "confetti" lesions, facial angiofibromas, fibrous facial plaque, shagreen patch, and ungual fibromas.
- Hypomelanotic macules appear at birth or shortly thereafter and are most useful in early diagnosis.
- Although the skin lesions are benign, they may require treatment due to symptoms or disfigurement.

EPIDEMIOLOGY

The incidence of tuberous sclerosis complex (TSC) is as high as 1 in 6,000 live births.[1,2] It occurs with equal frequency in males and females and in different races and ethnicities. Hereditary transmission is evident in approximately one-third of patients. Sporadic disease occurs in about two-thirds of patients, and this is attributed to de novo mutations.[3]

ETIOLOGY AND PATHOGENESIS

TSC is caused by mutations in a tumor suppressor gene, either *TSC1* or *TSC2*.[3] Mutations in *TSC2* are observed in about three-fourths of patients, and even more commonly in de novo cases.[4,5] Patients with mutations in *TSC2* tend to exhibit a more severe phenotype.[4–7]

TSC1 maps to chromosome band 9q34. The 8.6-kb full-length transcript encodes a protein called *hamartin* or TSC1.[8] *TSC2* maps to chromosome band 16p13.3. The 5.5-kb transcript encodes a protein called *tuberin* or TSC2.[9] Immediately adjacent to *TSC2* on chromosome 16 is *PKD1*, the gene mutated in polycystic kidney disease. Some patients with TSC have severe, early-onset renal cystic disease, and most of these patients have a contiguous deletion of *TSC2* and *PKD1*.[10]

Typical of mutations in tumor suppressor genes, the mutations observed in patients with TSC are inactivating mutations located anywhere along the sequence of *TSC1* or *TSC2*. Consistent with Knudson's two-hit hypothesis, most TSC tumors show a second somatic mutation that inactivates the wild-type allele.[11,12] TSC1 and TSC2 form a complex that inhibits signaling through the mammalian target of rapamycin (mTOR) pathway (Fig. 140-1). Loss of TSC1/TSC2 function leads to increased mTOR signaling and increased cell growth. Rapamycin is a drug that inhibits mTOR and may be useful for the treatment of internal tumors in TSC.[13]

CLINICAL FINDINGS

CLINICAL CRITERIA

The diagnosis of TSC is based on clinical criteria categorized as major or minor features (Table 140-1).[14,15] Cutaneous and oral lesions comprise 4 of 11 major features and 3 of 9 minor features. Major features are thought to have a high degree of specificity for TSC, whereas minor features are less specific or substantiated. No single feature is present in all patients, and no feature is specific for TSC. Genetic testing can be

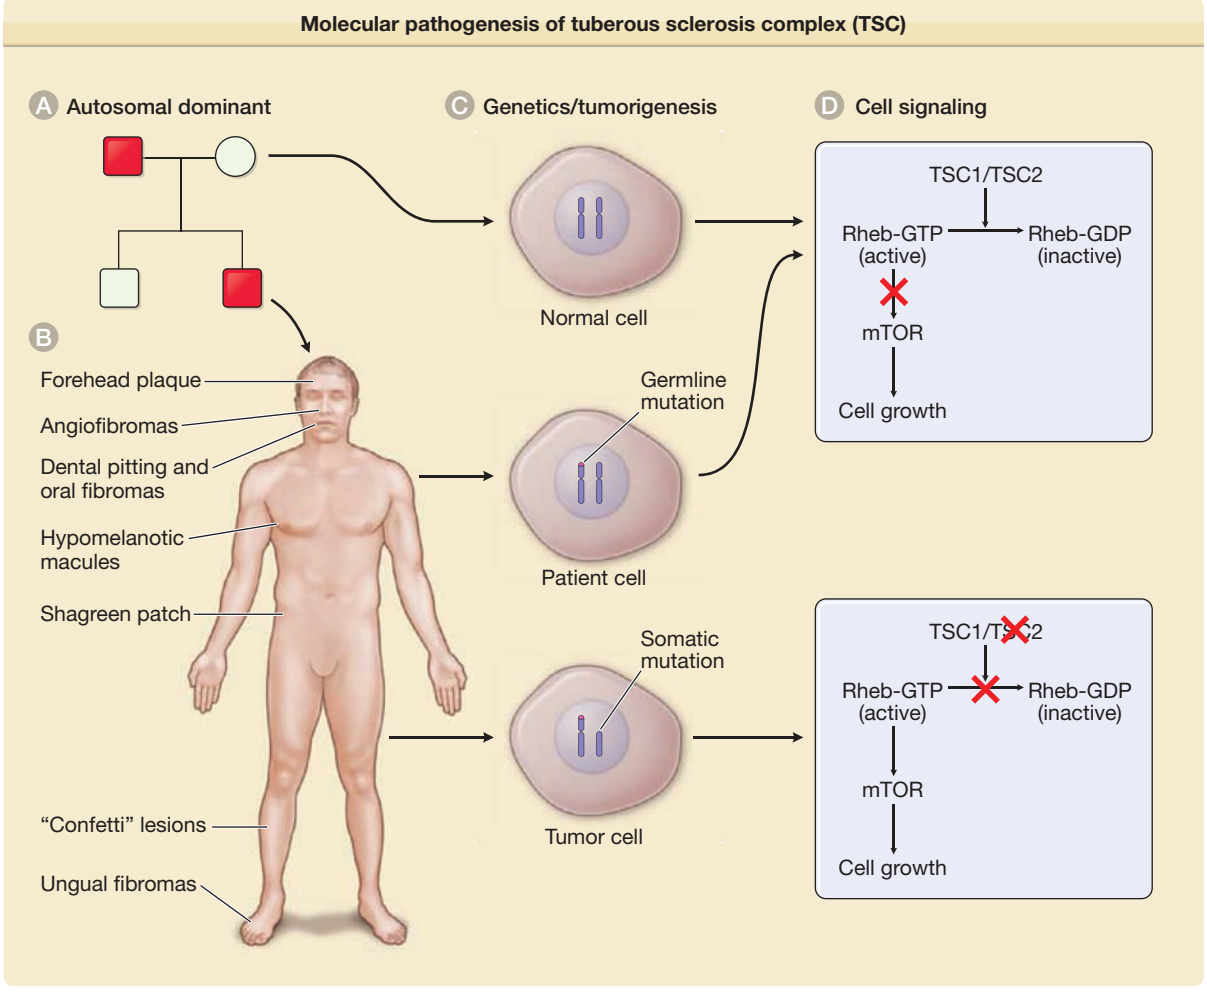

Figure 140-1 Molecular pathogenesis of tuberous sclerosis complex (TSC). **A.** An example is shown in which a mutation in *TSC2* is passed from the father (*red square*) to the son (*red square*), whereas the mother (*white circle*) and another son (*white square*) are unaffected. **B.** Skin lesions are observed in the son at the indicated locations. **C.** A cell from the mother shows two normal alleles for *TSC2 on* chromosome band 16p13.3. A cell from the son shows the *TSC2* mutation inherited from his father. A tumor from the son has this germ-line mutation and a "second-hit" mutation, detectable as loss of heterozygosity at this locus, that inactivates the other allele. **D.** TSC2, in a complex with TSC1, is a guanosine triphosphatase-activating protein, converting active Ras-homolog enriched in brain (Rheb) guanosine triphosphate (GTP) to inactive Rheb guanosine diphosphate (GDP). Rheb GTP activates mammalian target of rapamycin (mTOR), a kinase that increases protein translation and cell growth, so TSC2 normally acts to inhibit cell growth. Loss of TSC2 function in tumors results in increased levels of Rheb GTP, activation of mTOR, and increased cell growth.

TABLE 140-1
Diagnostic Criteria for Tuberous Sclerosis Complex (TSC)

Major Features
- **Facial angiofibromas or forehead plaque**
- **Nontraumatic ungual or periungual fibromas**
- **Hypomelanotic macules (three or more)**
- **Shagreen patch (connective tissue nevus)**
- Multiple retinal nodular hamartomas
- Cortical tuber[a]
- Subependymal nodule
- Subependymal giant cell astrocytomas
- Cardiac rhabdomyoma, single or multiple
- Lymphangiomyomatosis[b]
- Renal angiomyolipomas[b]

Minor Features
- **Multiple randomly distributed pits in dental enamel**
- Hamartomatous rectal polyps[c]
- Bone cysts
- Cerebral white matter migration lines[a,d,e]
- **Gingival fibromas**
- Nonrenal hamartoma[c]
- Retinal achromic patch
- **Confetti skin lesions**
- Multiple renal cysts[c]

[a]When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of TSC.
[b]When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of TSC should be present before a definitive diagnosis is assigned.
[c]Histologic confirmation is suggested.
[d]Radiographic confirmation is sufficient.
[e]One panel member recommended that three or more radial migration lines constitute a major feature.
Note: Cutaneous and oral lesions are in bold.
Definite TSC: Presence of either two major features or one major feature and two minor features.
Probable TSC: Presence of one major feature and one minor feature.
Possible TSC: Presence of either one major feature or two or more minor features.
Adapted from Roach ES, Gomez MR, Northrup H: Tuberous sclerosis complex consensus conference: Revised clinical diagnostic criteria. *J Child Neurol* **13**:624, 1998.

offered and may be important in particular situations (see Section "Molecular Diagnosis").[15]

HISTORY

The medical and family history taking should include questions about seizures, learning disability, behavioral disorders, visual problems, and tumors of the brain, heart, kidneys, lungs, and skin. Determining the ages of onset of skin lesions and their subsequent changes may assist in discriminating TSC skin lesions from similar-appearing non-TSC skin lesions. Many TSC skin lesions are not present at birth, but appear later at ages typical for the lesion.[16] For example, infants show multiple hypomelanotic macules but not angiofibromas or ungual fibromas. Adults may have multiple angiofibromas and ungual fibromas, but hypomelanotic macules may have faded or disappeared.

CUTANEOUS AND ORAL LESIONS

HYPOMELANOTIC MACULES. Hypomelanotic macules (Fig. 140-2) are observed in over 90% of children with TSC.[4,17–21] They are often present at birth or appear within the first few years of life and may fade or disappear in adulthood. The ultraviolet light of a Wood's lamp is used to improve detection, especially in lightly pigmented individuals[22] (Fig. 140-3).

Hypomelanotic macules typically measure 0.5–3.0 cm in diameter. They are off-white and not completely depigmented as in vitiligo.[23] Some are oval at one end and taper to a point at the other. Such lesions are called *ash-leaf spots* because of their resemblance to the leaf of the European mountain ash.[24] They number from 1 to over 20. They can be located anywhere on the body but tend to occur most often on the trunk and buttocks. When located on the scalp, they cause poliosis.[17]

Three or more hypopigmented macules constitutes a major feature for the diagnosis of tuberous sclerosis. One or two, and in rare individuals up to three, hypomelanotic macules occur in 4.7% of the general population.[25] A less common type of hypopigmentation is the "confetti" skin lesion (Fig. 140-4), which is considered a minor feature for diagnosis. It typically occurs on the legs below the knees or on the forearms,

Figure 140-2 Hypomelanotic ash-leaf macules on the lower leg of a child with tuberous sclerosis complex.

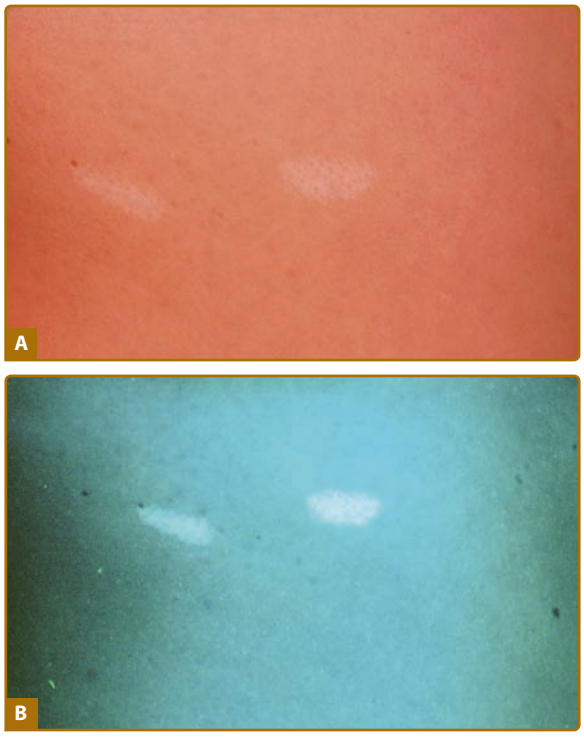

Figure 140-3 **A.** Hypomelanotic macules on the lateral chest of an adult with tuberous sclerosis complex. The macules may be easily overlooked. **B.** Wood's lamp accentuates the macules.

and consists of multiple hypopigmented macules 2–3 mm in diameter.[17,24]

FACIAL ANGIOFIBROMAS. Angiofibromas appear at 2–5 years of age and eventually affect 75% to 90% of patients.[4,17,20,21] These 1–3 mm in diameter pink to red papules have a smooth surface (Fig. 140-5). They may be hyperpigmented, especially in individuals with darker pigmentation. They occur on the central face and are often concentrated in the alar grooves (see eFig. 140-5.1 in online edition), extending symmetrically onto the cheeks and to the nose, nasal opening, and chin, with relative sparing of the upper lip and lateral face. Sometimes lesions occur on the forehead, scalp, or eyelids. They may number from 1 to over 100. Lesions may coalesce to form large nodules, especially in the alar grooves.[17,20,22] Angiofibromas are unilateral in rare cases and may indicate a segmental or mosaic defect.[26–29]

Figure 140-4 Confetti-like hypopigmented macules on the lower leg of an adult with tuberous sclerosis complex.

Figure 140-5 Multiple facial angiofibromas on the nose, cheeks, and chin, with relative sparing of the upper lip as commonly observed in tuberous sclerosis complex.

The development of papules may be preceded by mild erythema that is intensified by emotion or heat. During puberty, angiofibromas may grow in size and number. During adulthood they tend to be stable in size, but redness may gradually diminish.[22]

Angiofibromas must be multiple to be counted as a major feature. A solitary angiofibroma is clinically and histologically indistinguishable from the fibrous papule that occurs sporadically as a single lesion in the general population.[30] Multiple angiofibromas are also observed in multiple endocrine neoplasia type 1,[31–33] and as an unusual finding in Birt–Hogg–Dubé syndrome.[34]

FIBROUS FACIAL PLAQUE. The forehead plaque may be congenital or show gradual development over years.[17,35] It is present in 20% to 40% of patients.[4,17,20] It is an irregular, soft to firm, connective tissue nevus with the color of the normal surrounding skin, red, or hyperpigmented in darkly pigmented individuals

Figure 140-6 The forehead fibrous plaque in tuberous sclerosis complex is often pink-red and has a bumpy surface and irregular outline.

(Fig. 140-6). The plaque can also be found on the scalp, cheeks, and elsewhere on the face and is therefore sometimes referred to as a fibrous facial plaque. The forehead plaque is grouped together with angiofibromas as a major feature for diagnosis.[14]

SHAGREEN PATCH. The shagreen patch is observed in approximately 50% of patients.[4,17,20,21] It may be present in infancy but usually becomes apparent later. It is a firm or rubbery irregular plaque ranging in size from 1 to 10 cm (Fig. 140-7). The surface may appear bumpy with coalescing papules and nodules, or the patch may have the surface appearance of an orange peel. The color may be that of the surrounding skin, or it may be slightly pink or brown. There may be scattered smaller oval papules with or without a larger plaque (see eFig. 140-7.1 in online edition). The most common locations are on the lower back and buttocks; the patch is found less commonly on the thighs.[22]

UNGUAL FIBROMAS. Ungual fibromas, also known as *Koenen's tumors*, usually appear after the first decade and eventually affect up to 88% of adults with TSC.[20] They are more common on the toes than on the fingers.[36]

Ungual fibromas measure 1 mm to 1 cm in diameter. They arise from under the proximal nail fold (periungual fibromas) and under the nail plate (subungual fibromas). Periungual fibromas are red papules and nodules that are firm, pointed, and hyperkeratotic, or soft and rounded (Fig. 140-8). They press on the nail matrix and cause a longitudinal groove, and sometimes a groove forms without an evident papule[20,36] (see eFig. 140-8.1 in online edition). Subungual fibromas can be seen through the nail plate as red or white oval lesions or as red papules emerging from the distal nail plate, causing distal subungual onycholysis (see eFig. 140-8.2 in online edition). In addition to ungual

Figure 140-7 The shagreen patch in tuberous sclerosis complex is a firm, bumpy plaque that is usually located on the lower back.

fibromas, TSC patients may develop "red comets" (subungual red streaks), splinter hemorrhages, and longitudinal leukonychia.[36]

Presence of a nontraumatic ungual fibroma is a major feature for diagnosis of TSC.[14] Solitary lesions (also termed *acral* or *acquired digital fibrokeratomas*) are also observed in the general population, especially after nail trauma.[37] Multiple acral fibromas with a myxoid stroma were reported in one patient with familial retinoblastoma.[38]

OTHER SKIN LESIONS. Molluscum fibrosum pendulum (skin tags) is the name given to multiple fibroepithelial polyps in TSC. These range from soft pedunculated papules to larger firm pedunculated nodules located on the neck, axillae, trunk, and flexures (see eFig. 140-8.3 in online edition). They can be skin colored or hyperpigmented.[17] Skin tags are common in the general population, so these are not useful for diagnosis. Miliary fibromas are patches of multiple minute papules, usually on the neck or trunk that appear like "gooseflesh."[22] Pachydermodactyly

Figure 140-8 Multiple periungual and subungual fibromas on the toes in a patient with tuberous sclerosis complex.

is a benign thickening of the proximal fingers that has been observed in a few patients with TSC.[36,39,40]

DENTAL PITTING. Multiple pits of the dental enamel are observed in up to 100% of TSC patients.[41–44] These pits can be tiny pinpoint lesions or larger crater-like lesions (see eFig. 140-8.4 in online edition). They occur on both deciduous and permanent teeth. The identification of these lesions is enhanced by using a dental plaque stain. Dental pits can also be seen in the general population, albeit with lower prevalence and at lower numbers than in TSC.[41] The presence of multiple dental pits is a minor feature for diagnosis.[14]

ORAL FIBROMAS. Approximately 50% of TSC patients have oral fibromas[20] (see eFig. 140-8.5 in online edition). These sometimes occur in the first decade but are more common in adulthood.[45] They are most common on the gingivae, but also occur on the buccal and labial mucosa, hard palate, and tongue.[45] Some patients have diffuse gingival overgrowth. Gingival overgrowth is a common side effect of anticonvulsants, especially phenytoin and cyclosporine, but gingival overgrowth can be observed in TSC even in patients not treated with anticonvulsants or immunosuppressive agents.[45,46] Gingival fibromas are a minor feature for diagnosis.[14] Oral fibromas in the general population are typically single and form at sites of trauma, usually on the tongue or buccal mucosa.[47]

RELATED PHYSICAL FINDINGS

Tuberous sclerosis can affect almost any organ. Only one-third of patients have the classic triad of seizures, mental retardation, and angiofibromas.

BRAIN. Cerebral lesions include cortical tubers, subependymal nodules, and subependymal giant cell astrocytomas. Cerebral lesions may manifest as seizures, cognitive disability, and behavioral disorders. Seizures occur in approximately 80% of patients, with onset common in the first 2 months and usual by the first 2 years of life. Seizures are most likely infantile spasms but can be all types except pure absence (classic petit mal).[48] Seizures are controlled with antiepileptic drugs. A ketogenic diet can decrease seizures and mTOR inhibitors may also prove to be useful in reducing seizures.[49,50] Epilepsy surgery may be required for seizures intractable to anticonvulsant therapy.[51,52]

Learning disability tends to occur in patients with seizures, but many children with seizures have no obvious neurologic impairment. The extent of mental disability ranges from mild to profound. Individuals with normal intelligence may have specific deficits in attention, executive control, and memory.[53] Behavioral disorders include autism, attention deficit disorder, hyperactivity, aggressive behavior, impulsivity, anxiety, and sleep disorders.[7,53,54]

Subependymal giant cell astrocytomas occur in 6% to 14% of individuals with TSC. They may increase intracranial pressure and cause headache, vomiting, and bilateral papilledema.[55]

HEART. Cardiac rhabdomyomas are observed in 50% to 70% of infants with TSC.[56] These neoplasms are often asymptomatic and spontaneously regress, but they may cause fetal hydrops and stillbirth or heart failure shortly after birth.[57,58] Cardiac rhabdomyomas may cause dysrhythmias, commonly Wolff–Parkinson–White syndrome, noticed in utero or in the first year of life in TSC patients.[57–59]

KIDNEYS. Angiomyolipomas (AMLs) are observed in approximately 75% TSC patients over 10 years of age.[56,60] Additional renal lesions include renal cysts and rarely renal cell carcinoma.[61] Polycystic kidney disease is present in 2% to 3% of patients.[56] Renal lesions can cause renal insufficiency, hypertension, and potentially fatal retroperitoneal hemorrhage. Patients may require selective embolization or partial nephrectomy.[62–65]

LUNGS. Lung involvement in TSC includes lymphangioleiomyomatosis (LAM), multifocal micronodular pneumocyte hyperplasia, and clear cell tumors of the lung. LAM develops in females with TSC during the third or fourth decade of life. Radiographic evidence of LAM was observed in 26% to 40% of adult females with TSC, most of whom had subclinical disease.[66] It may cause spontaneous pneumothorax, chylothorax, dyspnea, cough, and hemoptysis.[67]

EYES. Retinal astrocytic hamartomas are observed in 44% to 87% of patients.[68] The most common type is a slightly raised, smooth, translucent, gray, noncalcified circular or oval lesion with indistinct boundaries. Also common are elevated and opaque multinodular "mulberry" lesions that have calcified, glistening nodules. Retinal astrocytic hamartomas can be similar to retinal lesions in neurofibromatosis type 1 and may appear similar to retinoblastomas. Some patients have vision loss, but blindness is rare.[69] In exceptional cases, enucleation has been required for enlarging retinal astocytomas.[70] TSC patients may also have "punched out" depigmented retinal lesions, which were observed in 39 of 100 patients compared to 6 of 100 controls.[68] Additional eye findings include angiofibromas of the eyelids, colobomas, strabismus, and sector iris depigmentation. Retinal astrocytic hamartomas are a major feature for the diagnosis of TSC.

GASTROINTESTINAL TRACT. Rectal polyps, usually asymptomatic, have been observed in 14 of 18 adults (78%) with TSC.[71] Histologically, they are hamartomas and rarely adenomas. Polyps have also been observed in the upper gastrointestinal tract and colon of TSC patients.[72,73] The presence of hamartomatous rectal polyps is a minor feature for TSC. Hepatic AMLs occur in TSC, typically in association with renal AMLs.[74] They are more common in females than in males with TSC.

OTHER ORGANS

Benign tumors have been found in the spleen, thymus, and thyroid. TSC may also be associated with

pituitary, parathyroid, and islet cell tumors.[75] Arterial stenotic-occlusive disease and arterial aneurysms including aortic and intracranial aneurysms have been observed,[76] Bone lesions in TSC are usually asymptomatic and may be sclerotic (calvaria, pelvis, vertebrae, ribs, and long bones)[77] or cystic (phalanges).[78] In unusual cases, there is localized overgrowth of a digit.[36]

LABORATORY TESTS

SKIN HISTOPATHOLOGIC FINDINGS

Hypomelanotic macules have normal numbers of melanocytes, in contrast to the lesions of vitiligo, in which melanocytes are absent. The melanocytes in hypomelanotic macules have poorly developed dendritic processes, and melanosomes are decreased in numbers, size, and melanization.[23] Angiofibromas contain plump, spindle-shaped, or stellate fibroblastic cells in the dermis among increased numbers of dilated vessels (see eFig. 140-8.6 in online edition). Collagen fibers are oriented in an onionskin pattern around follicles and vessels. The epidermis shows melanocytic hyperplasia and flattening of rete ridges. Periungual fibromas are similar, but with more extensive hyperkeratosis and a variable increase in vascularity (see eFig. 140-8.7 in online edition). The shagreen patch has sclerotic bundles of collagen in the reticular dermis (see eFig. 140-8.8 in online edition). Elastic fibers are typically reduced in amount.

SPECIAL TESTS (INCLUDING IMAGING STUDIES)

Besides dermatologic and ophthalmologic examination, the initial evaluation of a patient suspected to have TSC includes the following: (1) cranial computed tomography (CT) or cranial magnetic resonance imaging (MRI), (2) renal ultrasonography (or MRI or CT), and (3) electrocardiography.[60] In addition, the following tests are recommended for subsets of patients. Electroencephalography is valuable if seizures are suspected and subsequently for seizure management. In children, standardized cognitive and behavioral assessments are indicated at the time of diagnosis, in response to changes in behavior or worsening performance, and at regular intervals tailored to the individual.[53] In adult women, high-resolution chest CT is used to detect LAM. Echocardiography is indicated if the patient exhibits cardiac symptoms.[60]

After diagnosis, the patient should have periodic surveillance for the development of new lesions or changes in existing lesions. Cranial CT or MRI is recommended every 1–3 years in children. This may reveal the presence of a subependymal giant cell astrocytoma, which allows removal before it becomes locally invasive or causes symptoms. Similarly renal ultrasonography is recommended every 1–3 years, depending on clinical suspicion and results of previous examinations. If large or numerous renal tumors are present, renal CT or MRI should be performed. Echocardiography and chest CT are indicated for cardiac and pulmonary symptoms, respectively[60]

Screening of first-degree relatives of a TSC patient begins with examination of the skin, oral mucosa, teeth, and retina. Most affected family members will show TSC lesions with this approach, but additional imaging studies are recommended even in their absence.[60] When results of the physical examination are negative, cranial CT is recommended over MRI because of its lower cost and the lower likelihood of detecting lesions unrelated to TSC. Renal ultrasonography is also recommended. Molecular diagnosis may be useful for individuals in families with a known genetic change.[60]

MOLECULAR DIAGNOSIS

Genetic testing may be useful to confirm diagnosis in individuals not meeting criteria for definite TSC.[60] It can provide additional information for genetic counseling, and it can be used in prenatal diagnosis.[15] Genetic testing may yield false-negative or inconclusive results. Extensive analysis of *TSC1* and *TSC2* fails to identify a mutation in approximately 15% of TSC patients.[4,5] *TSC1* and *TSC2* are large genes, and mutations may occur anywhere along the sequence. Also, sequence analysis does not identify large deletions and must be supplemented by other methods of analysis.[4,5,79] Mutation detection may also be hampered by somatic mosaicism.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses for several major features of TSC are summarized in Boxes 140-1, 140-2, 140-3, and 140-4.

COMPLICATIONS

None of the skin lesions in TSC is prone to malignant degeneration, but the lesions can be a major cosmetic concern for the patient, causing social isolation and difficulties with self-esteem.[80] Angiofibromas, facial plaques, and ungual fibromas can be painful or bleed spontaneously or in response to minor trauma. Ungual fibromas can cause nail dystrophy and eventual loss of the nail. Large facial lesions may obstruct vision or occlude the nasal passages.[81]

PROGNOSIS AND CLINICAL COURSE

Individuals with tuberous sclerosis exhibit decreased overall survival compared with the general population. The causes of premature death include renal failure, intractable seizures, obstructive hydrocephalus, cardiac outflow obstruction, arrhythmia, respiratory failure, pneumothorax, and hemorrhage from an aneurysm or a tumor, especially AMLs.[82,83] Fatal events may

BOX 140-1 DIFFERENTIAL DIAGNOSIS OF HYPOMELANOTIC MACULES

- Polygonal or ash leaf
  - Nevus depigmentosus
  - Piebaldism
  - Vitiligo
  - MEN1 hypomelanotic macules
  - Nevus anemicus
- Confetti
  - Idiopathic guttate hypomelanosis (adults)
  - MEN1 confetti lesions
  - Pityriasis alba
  - Pityriasis lichenoides chronica
- Poliosis
  - Waardenburg syndrome
  - Piebaldism
  - Vitiligo
  - Vogt–Koyanagi–Harada syndrome
  - MEN1 hypomelanotic macules
  - Nevus anemicus
  - Segmental pigment mosaicism

MEN1 = multiple endocrine neoplasia type 1.

occur at any age. Brain and heart tumors may cause death in infancy, whereas lung and kidney tumors are more likely to cause premature death in adulthood. The prognosis for the individual patient depends on disease expressivity. Some individuals have a normal life span with few medical complications.

TREATMENT

When an infant is newly diagnosed with TSC, a major aspect of care is answering questions and addressing the concerns of the family. Unfortunately, many parents report negative experiences because of physician insensitivity and the provision of inaccurate information and inadequate support.[84] Patients should be promptly referred to other specialists and social services as needed, and genetic counseling should be offered. Families should be informed about organizations dedicated to TSC, such as the Tuberous Sclerosis Alliance (http://www.tsalliance.org).

Current treatments for TSC skin tumors are mostly surgical. Angiofibromas have been treated by excision, curettage, chemical peel, cryosurgery, dermabrasion,

BOX 140-2 DIFFERENTIAL DIAGNOSIS OF ANGIOFIBROMAS

- Fibrous papules
- Multiple endocrine neoplasia type 1 angiofibromas
- Birt–Hogg–Dubé angiofibromas
- Trichoepitheliomas
- Fibrofolliculomas/trichodiscomas
- Tricholemmomas
- Syringomas
- Dermal melanocytic nevi
- Acne vulgaris
- Rosacea

BOX 140-3 DIFFERENTIAL DIAGNOSIS OF UNGUAL FIBROMA

Most Likely

- Periungual
  - Acral fibrokeratoma
  - Superficial acral fibromyxoma
  - Epidermoid cyst
  - Pseudomyxoid cyst
  - Wart
  - Pyogenic granuloma
  - Juvenile xanthogranuloma
- Subungual
  - Acral fibrokeratoma
  - Superficial acral fibromyxoma
  - Wart
  - Subungual exostosis
  - Subungual horn
  - Familial retinoblastoma
  - Pyogenic granuloma
  - Onychomycosis
  - Psoriasis

Always Rule Out

- Subungual
  - Squamous cell carcinoma
  - Bowen disease
  - Amelanotic melanoma

BOX 140-4 DIFFERENTIAL DIAGNOSIS OF SHAGREEN PATCH

Most Likely

- Familial cutaneous collagenoma
- Eruptive collagenomas
- Dermatofibrosis lenticularis disseminata (in Buschke–Ollendorf syndrome)

Consider

- Multiple endocrine neoplasia type 1 collagenomas
- Sclerotic fibroma (Cowden syndrome)
- Isolated connective tissue nevus
- Juvenile elastoma
- Nevus elasticus
- Nevus mucinosis (Hunter syndrome)

electrosurgery, and different types of laser procedure.[81,85–89] Multiple sessions using several approaches may be required for optimal results. Potential complications of surgical treatments include infection, hypertrophic scarring, postinflammatory hyperpigmentation, and hypopigmentation. Treated angiofibromas tend to recur over a couple of years, and new lesions may form.[81] Ungual fibromas are usually treated by excision, but these lesions also have a high recurrence rate. Hypomelanotic macules may be temporarily concealed using self-tanning lotions or makeup matched to the person's skin color. The shagreen patch is usually left untreated, but it can be excised. For further details regarding surgical approaches to TSC skin lesions, as well as preoperative and postoperative issues, consult reference nos. 22 and 81.

Clinical trials are in progress to test potential medical therapies for TSC tumors. Oral rapamycin caused regression of subependymal giant cell astrocytomas, decreased the size of renal AMLs, and improved pulmonary function in patients with LAM.[13,90] Several patients showed improvement in angiofibromas while on oral rapamycin,[91,92] but the potential for serious side effects is likely to limit systemic use of rapamycin for these benign skin lesions, especially in children. Application of a topical form of rapamycin has recently been shown in a single case to diminish the size and numbers of angiofibromas while reducing the risks of systemic administration[93] and maintaining efficacy against TSC skin lesions, but surgical approaches continue to be the mainstay of treatment until appropriate studies are done.

GENETIC COUNSELING ISSUES

It is not unusual for a child with TSC to be born to parents who do not carry the diagnosis of TSC. This may represent a de novo mutation, parental mosaicism, or it may indicate that one parent has a very mild form of TSC that has escaped detection. Both parents should be carefully screened as described earlier. If one parent has TSC, there is a 50% chance that subsequent children will inherit the mutation.

If neither parent has TSC, it is possible that there is alternate paternity or undisclosed adoption. Another possibility is that one parent is mosaic for a mutation in TSC1 or TSC2.[94,95] This has profound implications for genetic counseling. Whereas it would be extremely unlikely for parents of a child with a de novo mutation to have another affected child, germ-line mosaicism in one parent greatly increases the risk of having another child with TSC. An estimate of the overall risk that apparently unaffected parents will have a second child with TSC is approximately 2%.[15]

Prenatal testing can be performed on cells obtained by chorionic villus sampling or amniocentesis.[15,96,97] It is also possible to use high-resolution ultrasonography and ultrafast MRI to examine for TSC tumors in the fetus, but the sensitivity of these tests is unknown.[15,98–101] It should be emphasized that TSC is highly variable, even within a family, and that genetic testing does not predict disease severity in offspring. Also, this brief summary does not detail many issues surrounding genetic testing that require utmost thought and sensitivity and consultation with genetics professionals.

:: Robert Listernick & Joel Charrow

NEUROFIBROMATOSIS TYPE 1 AT A GLANCE

- Autosomal dominant condition with incidence of 1 in 3,000 live births.
- Diagnosed clinically if two major features are present (see Table 141-1).
- Cutaneous neurofibromas:
  - Softer than the surrounding connective tissue and protrude just above the skin surface or lie just under the skin with an overlying violaceous hue.
- Subcutaneous neurofibromas:
  - Arise from peripheral nerves, both under the skin and deep in the viscera.
  - Generally much harder.
- Plexiform neurofibromas:
  - Generally present at birth or apparent during the first several years of life.
  - May lead to disfigurement, blindness (secondary to amblyopia, glaucoma, or proptosis), loss of limb function, or organ dysfunction by compression of vital structures.
- Segmental neurofibromatosis type 1 (NF-1):
  - Manifestations of NF-1, usually limited to one area of the body.
  - Occurs as result of a postconceptional mutation in the NF-1 gene, leading to somatic mosaicism.

EPIDEMIOLOGY

The "modern age" of neurofibromatosis began in 1981, with Riccardi's detailed clinical descriptions of the features and natural history of von Recklinghausen disease and the subsequent description of "central neurofibromatosis with bilateral acoustic neuroma." With the availability of gene-based diagnosis, several distinct clinical syndromes have been identified: (1) neurofibromatosis type 1 (NF-1), also known as von Recklinghausen disease; (2) neurofibromatosis type 2 (NF-2), whose cardinal feature is the development of bilateral vestibular schwannomas; (3) segmental or mosaic NF-1; (4) Legius syndrome (*SPRED1* mutation) leading to autosomal dominant transmission of café-au-lait spots, intertriginous freckling and macrocephaly; and (5) schwannomatosis. Both NF-1 and NF-2 occur equally in all ethnic groups. NF-1 occurs at an incidence of 1 in 3,000 live births, whereas NF-2 is much less common with an estimated incidence of 1 in 40,000 live births.

ETIOLOGY AND PATHOGENESIS

GENETICS

NF-1 is inherited in an autosomal dominant fashion. Although the expressivity of NF-1 varies considerably, even among individuals in the same family who are genotypically identical, the disorder is considered to be 100% penetrant. Thus, apparent skipping of NF-1 between generations may be the result of misdiagnosis, nonpaternity, or the occurrence of a new mutation in the grandchild. Although a large number of *NF1* mutations have been described, only two genotype-phenotype correlations have been noted. Individuals who have deletions of the entire NF1 gene have an increased risk of facial dysmorphism, mental retardation, early appearance of neurofibromas, and the presence of plexiform neurofibromas.[1] In addition, individuals who have a specific 3 base pair in-frame deletion in exon 17 of the *NF1* gene may have café-au-lait spots, intertriginous freckling and Lisch nodules, but do not develop cutaneous, subcutaneous or plexiform neurofibromas. neurofibromas. There is evidence that NF-1 is more severe when inherited from the mother rather than from the father.

The gene *NF1* is located on the long arm of chromosome 17, and encodes a protein called neurofibromin. Homozygosity for mutant *NF1* alleles has not been reported, probably because it is a lethal condition.

TABLE 141-1

Diagnostic Criteria for NF-1 (Two or More Required for Diagnosis)

1. Six or more café-au-lait macules over 5 mm in greatest diameter in prepubertal individuals, and over 15 mm in postpubertal individuals
2. Two or more neurofibromas of any type *or* one plexiform neurofibroma
3. Freckling in the axillary or inguinal regions
4. Optic glioma
5. Two or more iris Lisch nodules
6. A distinctive osseous lesion such as sphenoid dysplasia or thinning of long bone cortex with or without pseudarthrosis
7. A first-degree relative (parent, sibling, or offspring) with NF-1 by the above criteria

NF1 has an unusually high mutation rate, estimated at 2.4×10^{-5} to 10×10^{-5} gametes per generation, one of the highest of known inherited disorders.[2] This may reflect the large size of the gene, which spans 350 kb of genomic DNA, and contains 59 exons which encode a peptide containing over 2,800 amino acids. An alternative hypothesis is that there is some structural property of the gene that renders it particularly susceptible to mutation. New mutations account for approximately 50% of cases, and are usually on the paternally inherited allele. In contrast to many other dominant disorders, the frequency of new mutations does not appear to increase with advancing paternal age.

MOLECULAR BIOLOGY

Most *NF1* mutations result in reduced intracellular levels of the *NF1* gene product, neurofibromin; this appears to be sufficient to cause many of the clinical manifestations of the disease. Tumorigenesis, including the development of benign dermal neurofibromas, appears to be dependent on inactivation of the normal *NF1* allele in somatic cells, a process referred to as loss of heterozygosity.[3] Loss of heterozygosity is a critical step in tumorigenesis in many inherited cancer predisposition syndromes (e.g., retinoblastoma, Li-Fraumeni syndrome), and the genes involved are called "tumor suppressor genes." Tumorigenesis is initiated when both copies of the gene cease functioning normally—the first as a result of an inherited mutation, and the second as the result of a second somatic "hit" interfering with the function of the previously normal allele.

Neurofibromin is found in a variety of cell types, including neurons, oligodendrocytes, and nonmyelinating Schwann cells. Considerable evidence has been developed for the role of neurofibromin as a negative regulator of RAS.[4,5] The RAS gene family encodes membrane-associated, guanine nucleotide-binding proteins that are involved in the regulation of cellular proliferation, differentiation, and learning. RAS exists in an active (RAS-GTP) and inactive (RAS-GDP) state. By favoring conversion of RAS from its active state to its inactive state, neurofibromin downregulates the downstream effects of RAS, which include promoting learning, memory, synaptic plasticity, and cell growth and proliferation.[4,6] Mediators of the downstream effects of RAS include mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K), protein kinase B (PKB), and mammalian target of rapamycin (mTOR) kinase. Spred1 also inhibits activation of the MAPK pathway.

Four different forms of neurofibromin exist, resulting from alternate splicing. The type II variant includes a 21 amino acid sequence encoded by exon 23a, while type I does not. This sequence appears to be critical for RAS regulation and learning. In the brain, there are three major isoforms of RAS; K-RAS has been shown to be the primary target of neurofibromin activity.[5] Activation of RAS by neurofibromin stimulates G-protein activity, resulting in activation of adenylyl cyclase. Cyclic AMP and other downstream intermediates appear to play a role in cell growth, learning, and memory. Neurofibromin also associates with microtubules and plays a role in regulating GABA-ergic inhibitory neuronal activity in the hippocampus.[7]

RAS is a membrane-bound protein, and requires farnesylation (addition of a C15 isoprenoid to a cysteine residue near the *C*-terminus) for activity, a process that is catalyzed by farnesyltransferase. Agents that inhibit farnesyltransferase cause general inhibition of the RAS pathway, much as neurofibromin does. Farnesyltransferase inhibitors reverse the proliferative phenotype in *Nf1*-deficient mouse cells, and can reverse spatial learning impairments in a mouse model of *NF1*, by decreasing RAS levels.[6] These observations have prompted investigations into the use of farnesyltransferase inhibitors for the treatment of NF-1-related complications, such as rapidly growing plexiform neurofibromas.

Loss of heterozygosity of the *NF1* gene in Schwann cells has been shown to be the necessary event for the development of discrete neurofibromas.[8] Furthermore, neurofibromin-deficient Schwann cells secrete a substance which stimulates mast cell migration which, in turn, stimulates production of extracellular matrix and angiogenesis.[9] Astrocytes lacking *NF1* expression cannot form optic nerve gliomas on their own; a brain environment heterozygous for *NF1* is necessary for the development of these tumors.[10]

CLINICAL FINDINGS

A consensus development conference was held by the National Institutes of Health in 1987 in order to establish diagnostic criteria to promote better clinical research and care of patients with NF-1.[11] The seven diagnostic features recognized at this conference (Table 141-1), and the recommendation that two or more of these seven features be present before a diagnosis of NF-1 is established, have proven extremely useful and continue to be used without modification 20 years later. Perhaps the one caveat is the identification of a separate autosomal dominant syndrome caused by an inactivating mutation of the gene encoding sprouty-related EVH1 domain-containing protein 1 (*SPRED1*) which leads to the development of café-au-lait spots, intertriginous freckling, and macrocephaly, but none of the other manifestations of NF-1 (Legius syndrome).[12]

CAFÉ-AU-LAIT SPOTS

Café-au-lait spots, which are flat, pigmented macules, are often the first manifestation of NF-1 to appear (Fig. 141-1). Frequently present at birth, they become more numerous as the infant grows; new ones may continue to appear throughout the first decade of life. Once noticed, they tend to grow in size in proportion to the overall growth of the child. Although infrequently found on the face, they may be noted anywhere on the body. The size, shape and contour of café-au-lait spots are of no diagnostic significance, and the oft-quoted adage about smooth-edged café-au-lait spots being more typical of NF-1 rather than McCune–Albright syndrome is incorrect

Figure 141-1 Café-au-lait spots.

(see Section "Differential Diagnosis" and Box 141-1). When café-au-lait spots overlap each other, the area of overlap may be darker than either individual spot. When found within Mongolian spots, they are typically surrounded by a more lightly pigmented halo. Individuals with large numbers of café-au-lait spots do not have "more severe" NF-1, and the location of the macules in no way predicts the location of subsequent neurofibromas.[13]

Café-au-lait spots represent collections of heavily pigmented melanocytes of neural crest origin in the epidermis. Although the cells may contain increased numbers of "giant" melanosomes, or melanin macroglobules, these are not unique to NF-1, and their presence or absence in biopsies is not helpful diagnostically.

The diagnostic criterion for NF-1 is six or more café-au-lait spots greater than 5 mm in diameter in prepubertal individuals or 1.5 cm in adults. Of all children ultimately diagnosed with NF-1, 53% will have six or more café-au-lait spots by age 3 years and 97% by age 6 years.[14]

BOX 141-1 DIFFERENTIAL DIAGNOSIS OF SYNDROMES ASSOCIATED WITH MULTIPLE CAFÉ-AU-LAIT SPOTS

Most Likely

- Neurofibromatosis type-1
- Neurofibromatosis type-2
- Familial café-au-lait spots (consider Legius syndrome)
- LEOPARD syndrome (multiple lentingines syndrome)

Less Likely

- Tuberous sclerosis
- Fanconi anemia
- Multiple endocrine neoplasia type 2B
- Bannayan–Riley–Ruvalcaba syndrome
- McCune–Albright syndrome (polyostotic fibrous dysplasia)
- Bloom syndrome
- Ataxia-telangiectasia

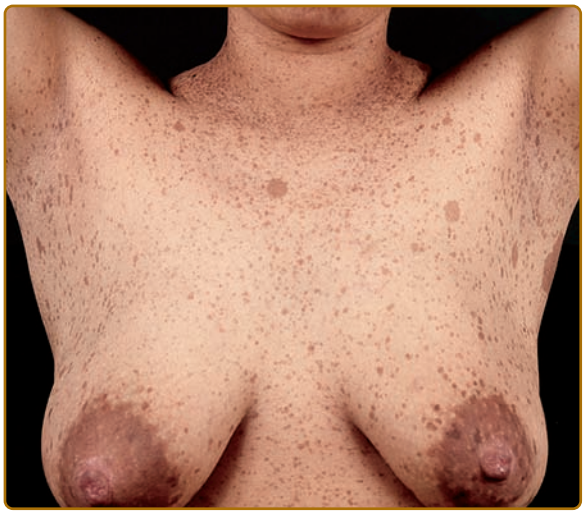

Figure 141-2 Axillary freckling.

INTERTRIGINOUS FRECKLING

Café-au-lait spots smaller than 5 mm are referred to as freckles, and are commonly present in the axillae, inguinal region, and under the breasts (Fig. 141-2). Unlike ordinary freckles in these locations, these lesions are not related to sun exposure, and are considered virtually pathognomonic of NF-1 (Crowe's sign). Of all children ultimately diagnosed with NF-1, 81% will have intertriginous freckling by age 6 years.[14]

DISCRETE NEUROFIBROMAS

Neurofibromas, which consist of Schwann cells, mast cells, fibroblasts, and perineural cells, are benign nerve sheath tumors that appear as discrete masses arising from peripheral nerves.[15] Cutaneous neurofibromas protrude just above the skin surface or lie just under the skin with an overlying violaceous hue (Fig. 141-3). They are softer than the surrounding connective tissue, often creating a "buttonholing" sensation when a finger is rubbed gently over the surface (Fig. 141-4). Subcutaneous neurofibromas that arise from peripheral nerves, both under the skin and deep in the viscera, are generally much harder (Fig. 141-5). If they arise from the dorsal root ganglia, they may grow through neural foramina, compressing the spinal cord, creating a "dumbbell" appearance. Subcutaneous neurofibromas in the neck may feel like a "beaded necklace," often being confused with lymph nodes. While less than 20% of children under 10 years of age have cutaneous

Figure 141-3 Cutaneous neurofibromas with overlying hyperpigmentation.

Figure 141-5 Subcutaneous neurofibroma.

neurofibromas,[14] they generally start appearing after puberty and increase in number as the patient grows older. Women who have NF-1 often comment on the appearance of cutaneous neurofibromas during pregnancy. The majority of adult patients with NF-1 probably have numerous asymptomatic deep neurofibromas involving the dorsal roots and other larger nerves. On occasion, neurofibroma-associated pruritus may be severe enough to require treatment with antihistamines.

PLEXIFORM NEUROFIBROMAS

Plexiform neurofibromas, histologically similar to discrete neurofibromas, are benign peripheral nerve sheath tumors which involve single or multiple nerve fascicles, often arising from branches of major nerves.[16] They may elicit a "wormy" sensation on palpation, as one feels multiple thickened nerve fascicles. Often there is overlying hyperpigmentation ("giant café-au-lait spot") or hypertrichosis (Fig. 141-6). Most plexiform neurofibromas are present at birth or become apparent during the first several years of life. Externally visible plexiform neurofibromas are easily identified and may lead to disfigurement, blindness (secondary to amblyopia, glaucoma, or proptosis), or loss of limb function (eFig. 141-6.1 in online edition, Fig. 141-7, Fig. 141-8). In contrast, thoracic or abdominal plexiform neurofibromas may have no external manifestations but may have equally devastating consequences due to invasion or compression of vital structures (e.g., ureters, bowel, spinal cord, etc.).

The growth rate of plexiform neurofibromas is highly variable. Periods of rapid growth alternating with long periods of quiescence are common. Malignant peripheral nerve sheath tumors, which generally arise from plexiform neurofibromas, may develop silently in deep plexiform neurofibromas and not give rise to symptoms until distant metastases have occurred. While loss of heterozygosity at the NF-1 locus may lead to the formation of benign neurofibromas, the generation of malignant transformation of a benign plexiform

Figure 141-4 Multiple cutaneous neurofibromas.

Figure 141-6 Plexiform neurofibroma with overlying hyperpigmentation and hypertrichosis.

Figure 141-7 Plexiform neurofibroma of left first toe leading to isolated macrodactyly.

neurofibroma may be due to cell cycle regulators beyond the *ras* oncogene. For example, mice which have null mutations in both the Nf-1 and *p53* genes uniformly develop malignant tumors.[17,18] Physicians caring for individuals with NF-1 should be alert to development of a malignancy; plexiform neurofibromas should be biopsied if they exhibit rapid growth or cause significant pain or focal neurologic dysfunction.

OPTIC PATHWAY TUMORS

Approximately 15% of children with NF-1 will develop optic pathway tumors (OPT); however, only half of these patients will ever develop symptoms, giving an overall incidence of *symptomatic* OPT of 7%.[19,20] Recent series of NF-1-associated OPT have identified an approximately 2:1 female predominance of patients, as well as a lower incidence in African-American children. These observations suggest the possibility that either hormonal factors or modifying genes may influence the development of OPT.

The period of greatest risk for the development of symptomatic OPT in NF-1 is during the first 6 years of life. In addition, the development of a symptomatic tumor after age 6 years is extremely unusual.[19,20] Thus, physicians caring for children with NF-1 should be sensitive to the signs and symptoms of OPT in this young age group. Approximately 30% of children with symptomatic OPT will present with the rapid onset of proptosis, with moderate to severe visual loss in the affected eye (eFig. 141-8.1 in online edition). Another 30% of children will have abnormal ophthalmologic examinations, without any visual symptoms, leading to discovery of the tumors. As young children rarely complain of visual loss, even when severe, thorough annual eye examinations are imperative in all young children with NF-1. When present, ophthalmologic signs may include an afferent papillary defect, optic nerve atrophy, papilledema, strabismus, or defects in color vision. Finally, as many as 40% of children who have chiasmal tumors develop precocious puberty. Accelerated linear growth will be the first sign of precocious puberty, underscoring the need for all children with NF-1 to have annual assessments of growth using standard growth charts. Children with chiasmal tumors often have no ophthalmologic symptoms or signs. Early detection of precocious puberty is important as both the accelerated linear growth and the development of secondary sexual characteristics can be can be aborted with the use of a long-acting luteinizing hormone releasing hormone agonist.[21]

Figure 141-8 Plexiform neurofibroma of left lower extremity leading to leg length discrepancy.

LISCH NODULES

Lisch nodules are slightly raised, well-circumscribed melanocytic hamartomas of the iris thought to be virtually pathognomonic of NF-1 (Fig. 141-9). They

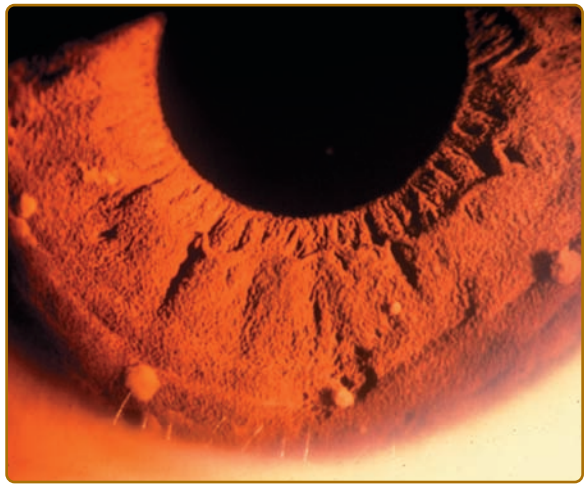

Figure 141-9 Lisch nodules.

are best seen using a slit lamp, which is necessary to distinguish them from the more commonly seen flat iris nevi, which are not associated with NF-1. They do not cause any functional impairment of vision. The frequency with which they are found increases with age; although Lisch nodules are found in over 90% of adults with NF-1, only 30% of children with NF-1 under 6 years of age have them.[14]

DISTINCTIVE OSSEOUS LESIONS

There are two bony lesions distinctive enough to be included in the diagnostic criteria for NF-1. The first, dysplasia of the wing of the sphenoid bone, results in poor formation of the wall and/or floor of the orbit (eFig. 141-9.1 in online edition). This congenital mesodermal dysplasia may be, but is not always, clinically apparent leading to proptosis (from herniation of meninges or brain into the orbit) or enophthalmos.

Dysplasia of a long bone, characterized by congenital thinning and bowing, affects approximately 2% of children with NF-1 (eFig. 141-9.2 in online edition). Although the tibia is most commonly affected, the femur, humerus and other long bones may also be involved. Even when the bone is intact, thinning and bowing produce a visible deformity, and the weakened mechanical properties of the bone predispose to fracture, particularly in the weight bearing bones. Failure of primary union following a fracture results in a "false joint," or pseudarthrosis.[22]

LABORATORY TESTS

Despite the identification of the NF-1 gene and its complete sequencing, the diagnosis of NF-1 remains primarily a clinical one. Although laboratory confirmation of the diagnosis is extremely useful in specific circumstances, in most cases it is unnecessary. Since no common mutations have been identified, molecular diagnosis can only be based on strategies that screen the entire gene for mutations. Several laboratories now offer sequencing of some or all exons and/or mutation scanning with a resulting sensitivity of as high as 95%. This testing is available for both presymptomatic individuals and can be applied to prenatal diagnosis of NF-1 when a mutation has been identified in an affected parent.

Inexperienced clinicians often biopsy cutaneous masses in an effort to confirm the diagnosis of NF-1 in an individual with multiple café-au-lait spots or other stigmata of NF-1. Such procedures are invariably unnecessary as the clinical diagnosis of NF-1 is usually quite straightforward. Biopsy of a plexiform neurofibroma should be reserved for those situations in which the physician wishes to exclude the possibility of a malignancy.

RADIOGRAPHIC EVALUATION

There has been considerable debate regarding the role of screening neuroimaging in the care of asymptomatic children with NF-1. Routine "screening" would be important if it led to early detection of OPT and early initiation of therapy which prevented visual deterioration. A longitudinal study of children with NF-1 failed to identify any tumors in which early detection altered the patient's clinical course.[19] Moreover, targeted screening of very young children with NF-1, the high-risk group for the development of OPT, failed as three children developed symptomatic tumors shortly after having had normal MRI scans. Brainstem tumors in both children and adults with NF-1 are generally more indolent than their counterparts in non-NF-1 individuals, suggesting that routine screening would not be beneficial.[23] Thus, the National Neurofibromatosis Foundation Optic Pathway Task Force has recommended against routine screening neuroimaging of all children with NF-1.[24]). Although there are no comparable longitudinal data for adults regarding the performance of "routine" MRI scans of the head and spinal cord, it seems reasonable to perform such testing only in individuals who have symptoms or signs suggestive of CNS pathology.

Similarly, there is debate as to whether patients with NF-1 should be "screened" for the presence of hidden, internal plexiform neurofibromas; most studies have demonstrated an approximately 30% incidence.[25,26] Newer techniques utilizing whole body MRI scans have been shown to reliably assess the entire tumor burden of individuals with NF-1.[27] As such a strategy incurs great cost without offering any proven benefit in preventing morbidity from plexiform neurofibromas, it is not recommended.[28] However, if current chemotherapeutic trials prove successful in the treatment of rapidly growing tumors, their identification at an early age may become more important.

COMPLICATIONS OF NF-1

SKELETAL COMPLICATIONS

All children with NF-1 should be regularly screened for scoliosis, beginning in early childhood. Scoliosis is the most common skeletal manifestation of NF-1, affecting 10%–30% of patients. Scoliosis is divided into dystrophic and nondystrophic types. Dystrophic scoliosis is the result of primary bone dysplasia, and may present very early in childhood, typically resulting in a sharply angulated curve spanning relatively few vertebral bodies (eFig. 141-9.3 in online edition). It is often accompanied by extreme rotation, scalloping of the posterior margins of the vertebral bodies, vertebral wedging, defective pedicles, and enlargement of the neural foramina and spinal canal.[22] The curvature may progress rapidly, necessitating surgery which may be particularly complicated because of the complex, multiplanar curves, poor quality of bone, potential for nerve root and spinal cord injury, and the presence of intraspinal and extraspinal neurofibromas. The nondystrophic type of scoliosis is more common, and is similar to idiopathic scoliosis in adolescents. Many children can be managed expectantly or with bracing.

Localized regions of bony overgrowth may also occur in children with NF-1 and are often in areas free of neurofibromas. The overgrowth may affect only a single digit or a larger region such as a hand or an extremity, but true hemihypertrophy is unusual. Bony overgrowth may also occur in a region affected by a plexiform neurofibroma.

CANCER

There is little doubt that NF-1 predisposes one to an increased risk for certain cancers. In a Swedish cohort of 212 probands and their affected relatives followed for more than 40 years, malignant neoplasms or central nervous system tumors occurred in 45% of the probands, for a relative risk of 4 compared with that in the general population. However, when the affected relatives of the probands were examined, only the female relatives with NF-1 had an increased risk of neoplasms.[29] This illustrates the tremendous bias inherent in data obtained through hospital records and disease-specific clinics. In reviewing the records of Japan's Children's Cancer Registry, the incidence of NF-1 was 6.45 times the expected estimated rate.[30]

Malignant peripheral nerve sheath tumors almost exclusively arise from preexisting plexiform neurofibromas. Estimates of the lifetime risk for the development of this tumor vary but may be as high as 13%.[31,32] As the outcome of therapy is poor, physicians should be diligently aware of the early symptoms referable to these tumors including a rapidly growing mass or unexplained pain or dysfunction. Although conventional imaging cannot identify malignant tissue within a benign plexiform neurofibroma, newer modalities such as 18-fluorodeoxyglucose positron emission tomography may be useful.[33]

Pheochromocytoma clearly is associated with NF-1 with an incidence potentially as high as 1.4%. In a recent review, the mean age at presentation was 42 years; 84% had solitary adrenal tumors, 9.6% had bilateral adrenal tumors, and 6% had ectopic tumors in the abdominal sympathetic chain, organ of Zuckerkandl, and the bladder.[34] Catecholamine-associated symptoms and hypertension each were present in 61% of the patients; 22% of the patients had neither of these findings. Malignant pheochromocytomas were found in 11.5% of patients, often with distant metastases at presentation. Loss of heterozygosity of the NF-1 gene has been demonstrated both in NF-1-associated and sporadic pheochromocytomas.[35,36]

There is an increased risk of chronic myelomonocytic leukemia and acute lymphoblastic leukemia in children with NF-1. In contrast to the fourfold predominance of lymphocytic leukemia generally seen in childhood, there is a clear excess of cases of myelogenous leukemia in children with NF-1.[37] Homozygous inactivation of the NF-1 gene in the bone marrow cells children with NF-1 and malignant myeloid disorders have been identified, suggesting that the NF-1 gene plays a role in downregulating the growth of immature myeloid cells.[38] Some children with NF-1 also develop juvenile xanthogranulomas, yellowish papules less than 1 cm in diameter that are usually found on the head or trunk (Fig. 141-10) and may be multiple.

Figure 141-10 Multiple juvenile xanthogranulomas on the forehead.

An unusual association between juvenile xanthogranulomas, NF-1, and the development of myeloid leukemias has been reported.[39,40] Although the pathogenesis is obscure, this association also has been observed independent of NF-1. Juvenile xanthogranulomas are yellowish papules less than 1 cm in diameter usually found on the head or trunk (Figure 142-15). Some authors have recommended "screening" blood counts for individuals who have juvenile xanthogranulomas and NF-1. Given that the magnitude of the risk is unknown but certainly extremely small, this recommendation only serves to increase parental anxiety without providing any useful information and is not endorsed by the authors. Rhabdomyosarcoma also occurs more frequently in individuals with NF-1.[41,42] Although a relationship between both neuroblastoma and Wilms tumor and NF-1 has been suggested, there are no strong epidemiologic data linking these tumors with NF-1. Other tumors that appear to occur in excess frequency in adults with NF-1 are somatostatinomas of the duodenum and the ampulla of Vater, and gastrointestinal stromal tumors (GIST). Compared to those tumors seen in non-NF-1 individuals, somatostatinomas in NF-1 rarely arise in the pancreas, are smaller, and generally are not associated with hormonal symptoms (i.e., diabetes, steatorrhea, and gallbladder disease).[43]

VASCULOPATHY

Patients with NF-1 may have a vasculopathy affecting essentially any arterial vessel. Clinical manifestations may include renal artery stenosis with hypertension, cerebral infarcts, bleeding aneurysms, and intermittent claudication of an extremity. This vasculopathy is a developmental problem not related to compression of an arteriole by a neurofibroma, and appears to be acquired after birth, as the appearance of new lesions and the progression of preexisting ones have been described. Characteristic pathologic changes have been described in all layers of the vascular wall which ultimately leads to narrowing of the arterial lumen.[44,45]

The most commonly identified vascular lesion in patients with NF-1 is in the renal artery, leading to renovascular hypertension.[46] Renal artery vasculopathy should be considered in any adult NF-1 patient with hypertension that is not easily controlled with a single antihypertensive medication; all NF-1 children should be evaluated for this complication. Aortography with selective angiography of the renal arteries should be used to confirm the diagnosis. If the blood pressure is uncontrollable using oral antihypertensives, percutaneous transluminal angioplasty can be performed and repeated if initially unsuccessful.

UNIDENTIFIED BRIGHT OBJECTS

Brain magnetic resonance imaging of children with NF-1 frequently demonstrates regions of increased signal intensity on T2-weighted images, referred to as "unidentified bright objects" or UBOs (eFig. 141-10.1 in online edition). UBOs may be found in the internal capsule, basal ganglia, cortex, cerebellar hemispheres, optic tract, or brainstem. They do not enhance and are not associated with compression of surrounding tissue, which distinguish them from neoplasms. UBOs are present in approximately 60% of children with NF-1, but disappear with age, and are uncommon in adults. They are not associated with focal neurologic signs, and are of uncertain significance. Histopathologic studies have shown that the UBOs corresponded to areas of myelin vacuolization with increased water content.[47] Recent studies have found that NF-1 children with UBOs have significantly lower IQ and language scores, significantly impaired visual-motor integration and motor coordination, and are at much greater risk for impaired academic achievement, when compared with NF-1 subjects without UBOs.[48]

INTELLIGENCE AND LEARNING DISABILITIES

Contrary to gross misstatements in the older literature, the mean IQ of patients with NF-1 is only 5–10 points lower than the general population and unaffected siblings.[49] However, learning disabilities, defined as discrepancies between ability (intellect) and performance, are quite common with an estimated prevalence of 30%–60%.[50,51] Although earlier reports suggested there might be a specific "cognitive phenotype" in NF-1 characterized by an excess of visual/perceptual disabilities, more recent studies have demonstrated that verbal deficits (e.g., reading) are at least as common as nonverbal disabilities in individuals with NF-1. These learning disabilities are lifelong and can affect adult functioning. Many children with NF-1 also have poor attention and impulse control, and may be diagnosed with attention deficit hyperactivity disorder, significantly interfering with school performance and learning. Stimulant medications may have a profound beneficial effect on these individuals' ability to succeed academically and professionally.

TREATMENT OF NF-1

Individuals with NF-1 are best cared for within a multidisciplinary clinic, which has access to a wide range of subspecialists. The exact physician composition of the clinic is less important than the ability to obtain expeditious subspecialty consultation. All first-degree relatives should be examined for the cutaneous manifestations of NF-1 and should undergo slit-lamp examination at the first visit to ascertain the presence of Lisch nodules. Yearly visits allow the physician to identify NF-1 complications early while providing counseling and dissemination of information regarding NF-1.[13] Individuals and families can obtain further information from the Web sites of the two national support groups: (1) the Children's Tumor Foundation (www.ctf.org) and (2) Neurofibromatosis, Inc. (www.nfinc.org).

All children with NF-1 who are 6-years-old and younger should have yearly complete ophthalmologic examinations looking for signs of an optic pathway tumor. These should include assessment of visual acuity, color vision, visual fields, fundoscopy, and slit-lamp examination. As almost all optic pathway tumors arise in children in this age group, the frequency of ophthalmologic examinations can be reduced in children over 10 years of age. Yearly measurements of weight and height should be plotted on standardized growth charts, as the earliest indication of precocious puberty may be accelerated linear growth. Blood pressure measurements should be obtained at each visit to look for signs of renovascular hypertension. In addition, the spine should be examined each year for early signs of scoliosis.[13]

CAFÉ-AU-LAIT SPOTS

Café-au-lait spots on the face are unusual in individuals with NF-1. On occasion, they do occur and affected individuals may seek to improve cosmesis. Attempts at removing café-au-lait spots with laser therapy have provided very mixed results. Although total disappearance of the lesion may occur, some studies cite a recurrence rate as high as 67%. While results with use of the Q-switched ruby laser (694 nm) have been mixed, favorable reports in a limited number of cases using either the continuous mode copper vapor laser (511 nm) or the erbium:YAG laser (2,940 nm) have been published.[52,53] Multiple treatments of a single lesion may be more effective.

CUTANEOUS NEUROFIBROMAS

Discrete cutaneous neurofibromas may be removed surgically to improve cosmesis or to prevent local irritation, for example, in the hairline while brushing or on the foot rubbing against the shoe. Deeper neurofibromas may require surgical removal when pushing on vital structures, such as a dorsal root neurofibroma that infiltrates the neural foramen and compresses the spinal cord. Complications of surgery include regrowth of the original tumor and nerve damage. In individuals who have severe pruritus from a large burden of

cutaneous neurofibromas, antihistamines may provide symptomatic relief. Uncontrolled anecdotal case reports have suggested that ketotifen, an antihistamine and mast cell stabilizer, has provided relief from pruritus and pain and prevented the rapid growth of new neurofibromas.[54] Use of the CO_2 laser under general anesthesia to remove hundreds of cutaneous neurofibromas has resulted in markedly increased patients' quality of life and decreased pain and pruritus.[55] The residua of a flat smooth depigmented scar was not felt to be an impediment to such surgery by most patients.

PLEXIFORM NEUROFIBROMAS

Until recently, the treatment of plexiform neurofibromas was limited to surgical debulking either to improve cosmesis or to prevent loss of function (e.g., upper airway obstruction, blindness). Such surgery was highly limited in its efficacy; complete resection was impossible given the highly infiltrative nature of these tumors and tumor regrowth was common. Thus, there has been considerable interest in the development of nontraditional chemotherapy for use against these tumors. Not surprisingly, the design of studies to test the efficacy of such agents is fraught with complications. Plexiform neurofibromas are quite different biologically from more conventional solid neoplasms. Lack of growth following treatment may be part of the natural history of the tumor rather than a true therapeutic response. In addition, tumor burden may be difficult to quantify radiographically; plexiform neurofibromas may "spread" along nerve roots sending out multiple finger-like projections, quite different than a single, solid tumor mass.

Despite the above difficulties, several Phase I and II chemotherapeutic trials are in progress. Preliminary studies utilizing pirfenidone, an antifibrotic agent that decreases proliferation of fibroblasts and collagen matrix synthesis, and a farnesyltransferase inhibitor which downregulates the *ras* oncogene, did not yield promising results. In a recently described case and based on studies of the important role of mast cell c-kit receptor signaling, administration of imatinib to a 3-year-old with an unresectable airway plexiform neurofibroma led to 70% diminution in size during 3 months of therapy.[56] Other newer agents are also currently being studied. These include: (1) AZD2171, which is a potent inhibitor of vascular endothelial growth factor receptor tyrosine kinases; (2) sirolimus, an mTOR pathway inhibitor; (3) PEG interferon-α-2b; and (4) photodynamic therapy. If any of these studies demonstrate potential efficacy, the role of screening imaging to detect "hidden" plexiform neurofibromas would need to be readdressed.

OPTIC PATHWAY TUMORS

Once identified, OPT should be followed by serial MRI and ophthalmologic examinations. Treatment should be initiated only after demonstration of clear radiographic progression or deterioration of vision. The goal of treatment should be preservation of vision while minimizing the side effects of therapy. Chemotherapy with carboplatin and vincristine has proven effective in the management of these tumors.[57] Radiation therapy, while a mainstay of treatment of progressive CNS neoplasms not associated with NF-1, is not appropriate for *NF1*-associated OPTs because of the risk of vasculopathy, second malignancies, and detrimental neurocognitive and endocrinologic side effects in very young children.

RELATED CONDITIONS

NEUROFIBROMATOSIS-2 (NF-2)

NEUROFIBROMATOSIS TYPE 2 AT A GLANCE

- Autosomal dominant disorder with incidence of 1 in 40,000 live births.
- Hallmark is the presence of bilateral vestibular schwannomas.
- At risk for development of multiple meningiomas, schwannomas, gliomas, and neurofibromas throughout neural axis.

NF-2 is an autosomal dominantly inherited condition characterized by bilateral vestibular schwannomas, meningiomas (intracranial, intraspinal, and optic nerve sheath), schwannomas (dorsal roots of the spinal cord, peripheral nerves, and cranial nerves), ependymomas and gliomas of the central nervous system, and juvenile posterior subcapsular cataracts.[58] The estimated birth incidence is 1 in 40,000 live births. While much less common than NF-1, its morbidity is much greater, with patients frequently becoming paralyzed and deaf. The most recent clinical diagnostic criteria have led to increased sensitivity in establishing the diagnosis, particularly in those cases without a positive family history (Table 141-2). Approximately 60% of patients present in adulthood with hearing loss, tinnitus, or loss of balance. The younger the age at presentation, the greater the ultimate severity of the disease. Children are more apt to present with a noneighth nerve tumor such as an optic nerve sheath meningioma. Ophthalmologic findings include juvenile posterior subcapsular cataracts (60%–80% of patients), retinal hamartomas, and optic nerve sheath meningiomas.[58]

Individuals with NF-2 may have several café-au-lait spots, but rarely have more than six; intertriginous freckling is not seen. The characteristic cutaneous lesion of NF-2 is the cutaneous schwannoma (Fig. 141-11). It is a plaque-like, slightly raised lesion with a faint violaceous hue, occasionally with hair. Less commonly,

TABLE 141-2
Manchester Clinical Diagnostic Criteria for NF-2

A patient has the clinical diagnosis of NF-2 if one of the following criteria is present:

A. Bilateral vestibular schwannomas
B. First degree family relative with NF-2 and unilateral vestibular schwannomas or any two[a]: meningioma, schwannoma, glioma, neurofibroma, or posterior subcapsular lenticular opacities
C. Unilateral vestibular schwannoma and any two[a]: meningioma, schwannoma, glioma, neurofibroma, or posterior subcapsular lenticular opacities
D. Multiple meningiomas (two or more) and unilateral vestibular schwannoma and any two[a]: schwannoma, glioma, neurofibroma, cataract

[a]"Any two" refers to two individual tumors or cataract.
From Evans DGR et al: Management of the patient and family with neurofibromatosis 2: A consensus conference statement. *Br J Neurosurg* **19**:5-12, 2005.

cutaneous neurofibromas, indistinguishable from those seen in NF-1, may be found.

NF-2 is caused by mutations in a gene on chromosome 22, which encodes the membrane-related protein merlin, also known as schwannomin. As in NF-1, the *NF-2* gene is a tumor suppressor gene which downregulates cellular growth. The exact cellular pathways by which this control is exerted have yet to be delineated.

SEGMENTAL NF-1

The term "segmental neurofibromatosis" refers to individuals who have manifestations of NF-1, usually café-au-lait macules and neurofibromas, limited to one area of the body.[59] Ruggieri and Huson have proposed use of the term "mosaic localized NF-1" for these individuals, as an acknowledgement that the pathogenesis of this condition is a postconceptional mutation in the NF-1 gene leading to somatic mosaicism.[60] This has been confirmed in a patient in whom the mutant NF-1 allele was present in a mosaic pattern in cultured fibroblasts from a café-au-lait macule and absent in fibroblasts from normal skin.[61]

Figure 141-11 Cutaneous schwannoma.

The vast majority of patients with segmental NF-1 have café-au-lait macules or intertriginous freckling limited to one area of the body (Fig. 141-12). These individuals are at risk for developing complications of NF-1 in the affected area, most commonly neurofibromas. Localized manifestations of NF-1 other than café-au-lait macules, freckling, or cutaneous neurofibromas may also represent examples of somatic mosaicism. There have been numerous reports of isolated plexiform neurofibromas, including one case in which loss of heterozygosity of the NF-1 gene in Schwann cells from the tumor was demonstrated. Since only 50% of cases of tibial pseudarthrosis occur in the context of NF-1, the others may actually represent cases of segmental NF-1. Other examples of segmental NF-1 include a child who had a unilateral optic pathway glioma that acted that acted biologically like an NF-1-associated tumor and individuals with isolated sphenoid bone dysplasia.

Genetic counseling of patients with segmental NF-1 is problematic. Many of these patients are misdiagnosed as having NF-1, leading to unnecessary anxiety and inappropriate genetic counseling. In addition, gonadal mosaicism for NF-1 has been demonstrated; patients with segmental NF-1 have had offspring with complete NF-1.

NF1–NOONAN SYNDROME

It has been recognized that there are individuals who meet the diagnostic criteria for NF-1, yet have many features of Noonan syndrome, which is characterized by hypertelorism, ptosis, downsloping palpebral fissures, low set, posteriorly rotated ears, webbed neck, pectus deformities, and short stature. Over 50% of children with Noonan syndrome have cardiovascular disease, most commonly pulmonary valve stenosis. Noonan's syndrome is caused by mutations in the gene *PTPN11* in 50% of cases. Mutations in several other genes (*KRAS*, *SOS1*, *BRAF*, *MEK1*, *MEK2*, *HRAS* and *RAF1*) have also been associated with this phenotype. Genetic testing has shown that most individuals with LEOPARD syndrome also have mutations in *PTPN11*. A recent study documented mutations in the NF-1 gene in 16 of 17 unrelated subjects who clinically had the NF-1–Noonan phenotype; no mutations in *PTPN11* were found.[62] Thus, it appears that the vast majority of cases of NF-1–Noonan syndrome are due to mutations in NF-1.

LEGIUS SYNDROME

Families recently have been identified who have autosomal dominant transmission of café-au-lait spots, intertriginous freckling, and macrocephaly without any other manifestations of NF-1, including neurofibromas, in whom no NF-1 mutation was detected. Further genetic studies of these individuals revealed

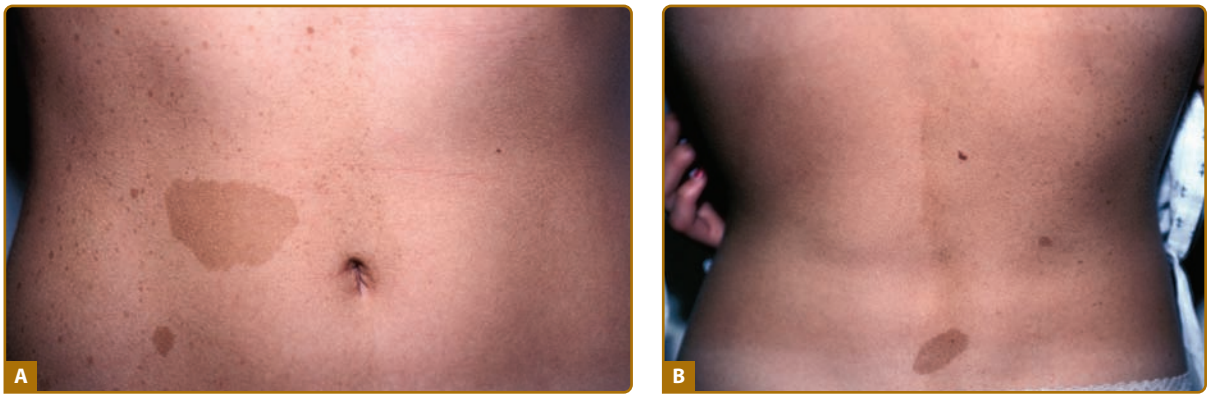

Figure 141-12 **A** and **B.** Segmental NF-1. Note café-au-lait spots and freckling limited to one side of body.

mutations in *SPRED1*, a gene that negatively regulates the mitogen-activated protein kinase (MAPK) pathway. None of these individuals has discrete neurofibromas, plexiform neurofibromas, Lisch nodules, optic pathway tumors, or NF-1-specific bony abnormalities.[12] The frequency of cognitive deficits in these individuals is, as yet, unknown. Genetic testing for *SPRED1* mutations is available in individuals suspected of having Legius syndrome in whom NF-1 gene testing has failed to detect a mutation.

SCHWANNOMATOSIS

It had been noted for some time that there are patients who develop multiple schwannomas but who fail to develop other manifestations of NF-2, particularly vestibular schwannomas.[63,64] Patients with this condition, now called schwannomatosis, develop multiple painful schwannomas within peripheral nerves and paraspinal nerve roots. The tumors most often start appearing during the second and third decades of life. Surgery of individual lesions is often necessary to treat intractable pain. In contrast to NF-2, individuals with schwannomatosis have a normal life span. Before making a diagnosis of schwannomatosis, it is extremely important to exclude the possibility of NF-2 by both genetic testing and performing an MRI scan to look for vestibular schwannomas. Germ-line mutations in *SMARCB1/INI1*, another tumor-suppressor gene previously implicated in the development of rhabdoid tumors in infants and young children, have been identified as the cause of a large number of the familial cases of schwannomatosis.[65]

Chapter 142 :: Ectodermal Dysplasias

:: Alanna F. Bree, Nnenna Agim, & Virginia P. Sybert

ECTODERMAL DYSPLASIAS AT A GLANCE

- A group of inherited disorders characterized by developmental abnormalities in two or more ectodermal structures.
- These include hair, teeth, nails, and sebaceous and sweat glands.
- There may be abnormalities in nonectodermal structures and functions.
- Distinction is based on clinical features, mode of inheritance, and molecular findings.
- Clinically distinct disorders may be due to different mutations in the same gene (allelic heterogeneity), and clinically similar conditions may be due to mutations in different genes (locus heterogeneity).

The ectodermal dysplasias (EDs) are a group of inherited disorders that share in common developmental defects involving at least two of the major structures classically held to derive from the embryonic ectoderm—hair, teeth, nails, and sweat glands. Freire-Maia and Pinheiro[1] published an exhaustive review and classification system for these disorders using a numeric system of 1 (hair), 2 (teeth), 3 (nail), and 4 (sweat glands) for characterization. This system has little use in practice, although it did allow for a rational approach to a previously chaotic field. Freire-Maia and Pinheiro laid claim to more than 150 ectodermal disorders in their most recent compilation.[2] Several other classification schemes have been suggested. Each has limited clinical application but can help in ordering thinking about these disorders.[3,4] In an attempt to move to a more useful and unified system, an international classification conference was convened in 2008 to initiate this process which is still ongoing.[5]

This chapter covers only the more common of these conditions and those in which ectodermal defects are likely to bring them to a dermatologist for diagnosis and medical attention. Fig. 142-1 is an algorithm showing the approach to the diagnosis of EDs. The first step in the algorithm for making a specific diagnosis of an ED is to determine the presence of sweating (hidrotic) or absence of sweating (hypohidrotic/anhidrotic). The involvement of other ectodermal structures and of nonectodermally derived tissues provides further branching points in a diagnostic hierarchy. Mode of inheritance may differ within a seemingly uniform diagnostic group, and care must be taken in evaluating family members before providing recurrence risks.

Within the last few years, causal genes have been identified for many of the EDs. Given continuing discoveries, the reader is directed to the following resources: http://www3.ncbi.nlm.nih.gov/Omim (Online Catalog of Mendelian Inheritance in Humans) and http://www.ncbi.nlm.nih.gov/sites/GeneTests (an up-to-date listing of laboratories offering molecular testing). The National Foundation for Ectodermal Dysplasias (http://www.nfed.org) is a lay support group that has numerous informative pamphlets for families and physicians, as well as a strong advocacy program for dental care, insurance coverage, and research.

HYPOHIDROTIC ECTODERMAL DYSPLASIA [ANHIDROTIC ECTODERMAL DYSPLASIA, CHRIST–SIEMENS–TOURAINE SYNDROME; OMIM #305100]

HISTORICAL ASPECTS

One of the earliest descriptions of hypohidrotic ectodermal dysplasia involving male first cousins and their grandmother with sparse hair, missing teeth and dry skin was described in 1848 by Thurnam.[6] Darwin described this condition in his writings from 1875.

EPIDEMIOLOGY

X-linked hypohidrotic ED (XLHED) occurs in all racial groups and is thought to have an incidence at birth of anywhere from 1 in 5,000–17,000 births.[7] Accurate prevalence and incidence data are not available.

ETIOLOGY, PATHOGENESIS, AND GENETICS

XLHED results from alterations in the gene *ectodysplasin* (*EDA*, *EDA1*, *HED*) located at Xq12-13.[8] It codes for a transmembrane protein, ectodysplasin, which is composed of 391 amino acids and has alternative splicing forms, the significance of which is not known. A multitude of mutations in this gene causing XLHED have been identified. There does not appear to be a correlation between the nature of the mutation and the clinical features[9] (i.e., to date, there have been no phenotype–genotype correlations). Interfamilial and intrafamilial variation occurs to a mild degree.

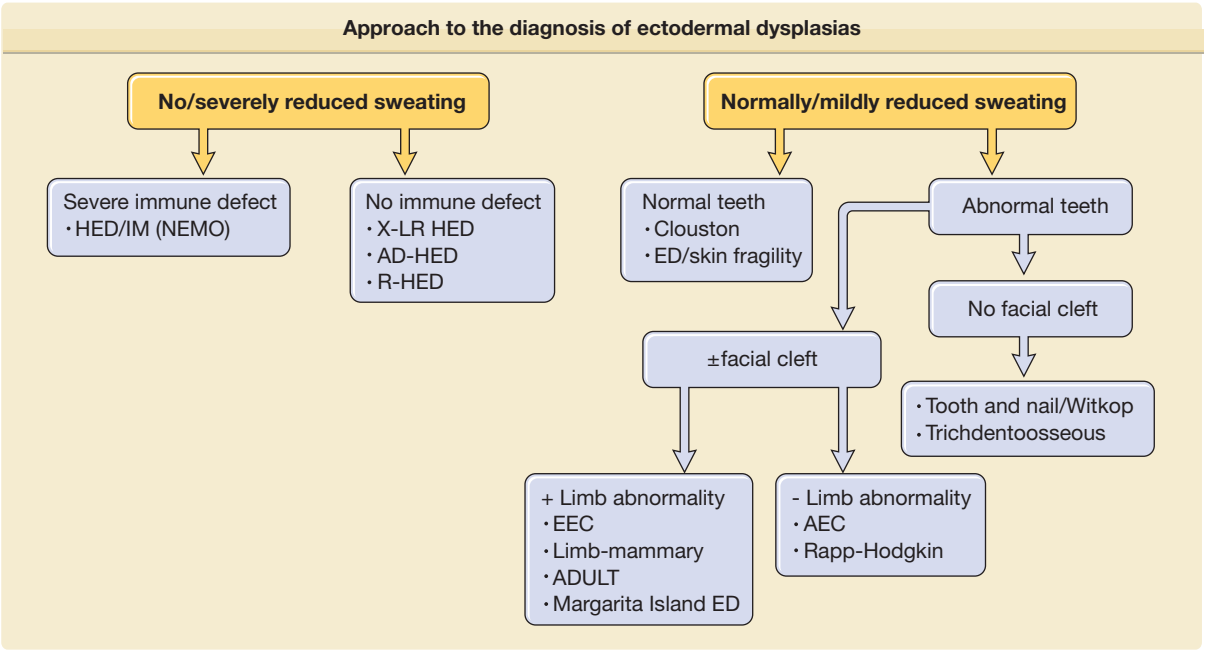

Figure 142-1 Approach to the diagnosis of ectodermal dysplasias. AD = autosomal dominant; ADULT = *a*cro-*d*ermato-*u*n-gual-/acrimal-*t*ooth syndrome; AEC = *a*nkyloblepharon filiforme adnatum–*e*ctodermal dysplasia–*c*left palate syndrome; AR = autosomal recessive; ED = ectodermal dysplasia; EEC = ectrodactyly–ED–cleft lip/palate syndrome; HED = hypohidrotic ectodermal dysplasia; IM = immune defects; X-LR = X-linked recessive.

Ectodysplasin belongs to the tumor necrosis factor family and plays a role in regulation of the formation of ectodermal structures. It forms trimers and is expressed in keratinocytes, the outer root sheath of hair follicles, and sweat glands. It localizes to the lateral and apical surfaces of cells.

As is typical of X-linked recessive disorders, expression is full blown in affected males, and carrier females may express none, some, or all of the features of the disorder, often in a patchy distribution. Between 60% and 80% of carrier females express some clinical signs of the disorder; the most frequent are patchy hypotrichosis and hypodontia. The disorder can be inherited from a carrier mother or occur in an affected individual as the result of a de novo mutation. Approximately 70% of affected males inherited the mutation from a carrier mother.

Mutations in an autosomal gene, *EDAR*, mapped to 2q11-q13, have been implicated in an autosomal dominant form of hypohidrotic ectodermal dysplasia (HED; OMIM #129490) and in an autosomal recessive form (OMIM #224900)[10] that are clinically similar to XLHED. Both these entities are much rarer. EDAR acts as a receptor for ectodysplasin. Mutations in yet another gene, *EDARADD*, have been identified recently in autosomal recessive HED and autosomal dominant HED.[11,12] EDARADD is an intracellular adaptor protein that assists in transmitting the signal from the activated EDA receptor to the nucleus of the cell. Individuals with autosomal dominant HED appear to have a milder defect in the ability to sweat.

Certain mutations in the X-linked *NEMO* gene, which causes incontinentia pigmenti (IP) in females, have been shown to result in HED and immune defects in males (see Chapter 143).[13,14]

CLINICAL MANIFESTATIONS

DERMATOLOGIC. Affected males may present at birth with a collodion membrane or with marked scaling of the skin,[15] similar to congenital ichthyosis. Scalp hair is usually sparse, fine, and blonde. It may thicken and darken at puberty, and secondary sexual hair is typically normal. Other body hair is usually sparse or absent.

The ability to sweat is significantly compromised, and most affected males have marked heat intolerance. Sweat pores are usually undetectable on physical examination, and fingerprint ridges are effaced. The inability to sweat adequately in response to environmental heat results in an elevation of core temperature and bouts of unexplained high fevers, usually leading to an extensive workup for infectious disease, malignancy, or autoimmune disease before the correct diagnosis is recognized. In an older series of patients, mental retardation was reported as a feature of XLHED. Currently, this is believed to have been due to damage from prolonged high fevers and seizures and not to be an intrinsic feature of the disorder.[16]

The nails are usually normal; reports of thin, fragile nails are not convincing.[17] Periorbital wrinkling and hyperpigmentation are typical and often present at birth (Figs. 142-2A–142-2C). Eczema affects more than two-thirds of affected males and is often difficult to manage. Hyperplasia of sebaceous glands,

Figure 142-2 Hypohidrotic ectodermal dysplasia. **A.** Newborn with periorbital wrinkling, beaked nose. Diagnosis would not be suspected unless there were a positive family history. **B.** Peg-shaped teeth; fine periorbital wrinkling can be appreciated. **C.** Two unrelated males with X-linked hypohidrotic ectodermal dysplasia; adult is wearing dentures; periorbital wrinkling and hyperpigmentation are evident. (Used with permission from the National Foundation for Ectodermal Dysplasias.)

particularly on the face, can develop over time and appear as small, pearly, flesh-colored to white papules that may resemble milia.

SYSTEMIC ASSOCIATIONS. Hypodontia, oligodontia, or anodontia are invariable features of XLHED in affected males. Hypoplastic gum ridges in an affected infant can be an early clue to the diagnosis of the disorder. Teeth that do erupt are usually peg-shaped and small (see Fig. 142-2B). The facies of the disorder are characterized by frontal bossing and a depressed midface with a saddle nose and full, everted lips. Otolaryngologic manifestations include thick nasal secretions and impaction, ozena, sinusitis, recurrent upper respiratory tract infections and pneumonias, decreased saliva production, hoarse voice, and an increased frequency of asthma. The increased frequency of respiratory tract infections has been attributed to hypoplastic or absent mucus secreting glands in the bronchial tree.[18] Gastroesophageal reflux and feeding difficulties may be a problem in infancy. The basis for this is unknown. Preliminary studies suggest that there may be failure to thrive in infancy and early childhood in as many as 20% to 40% of affected boys, with catch-up growth seen later.[19] Although several reviews have suggested that infant mortality may be increased, unbiased confirmatory data are lacking.

Female carriers for XLHED may be affected as severely as males or show few, if any, signs of the disorder (Fig. 142-3). Heat intolerance, if present, is usually mild; adult carrier women comment that they do not sweat much or that they do not like very warm weather, but it is unusual for a female to experience fever due to inability to sweat. Typically, a few teeth

Figure 142-3 Hypohidrotic ectodermal dysplasia. **A.** Female carrier of X-linked hypohidrotic ectodermal dysplasia with her affected son. **B.** Two sisters with X-linked hypohidrotic ectodermal dysplasia manifesting to different degrees. Note periorbital hyperpigmentation, full everted lips, and sculpted noses. (From Sybert VP *Genetic Skin Disorders.* New York, Oxford University Press, 1997.)

may be peg-shaped or missing and scalp hair may be patchy or thin. Careful examination of the skin of carrier females often reveals a diminution in or patchy distribution of sweat pores. This sometimes can be appreciated readily just by magnification of fingertip pads or may require more sophisticated sweat testing.

VARIANTS. As noted in Section "Etiology, Pathogenesis, and Genetics," the autosomal dominant and autosomal recessive forms of HED are similar, although the autosomal dominant form may be milder. The X-linked form is by far the most common and always should be the diagnosis of default in a sporadic case.

HISTOPATHOLOGY

The epidermis is thinned and flattened. There is a reduction in the number of sebaceous glands and hair follicles. Eccrine glands are absent or incompletely developed. Histologic evaluation of the skin is usually not necessary.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(Box 142-1)

The scaling skin at birth may result in a misdiagnosis of congenital ichthyosis. Repeated bouts of fever may be thought to have an infectious source. The diagnosis of HED is recognized readily when expected, such as when an at-risk male is born into a family in which the disorder is known to segregate. Examination for sweat pores and a Panorex view of the jaw leads quickly to the correct diagnosis. Absence of eccrine structures in skin biopsies of the scalp and/or palmar region may help confirm a diagnosis,[20] but are rarely necessary. In an isolated, fully expressing female, the autosomal dominant and recessive forms of HED need to be considered. Family history is mandatory, and mothers

BOX 142-1 DIFFERENTIAL DIAGNOSIS OF SOME DIAGNOSTIC FEATURES OF ECTODERMAL DYSPLASIAS

- Collodion membrane
  - Lamellar exfoliation of the newborn
  - Neutral lipid storage disease
  - Autosomal recessive congenital ichthyosis
    - Nonbullous congenital ichthyosiform erythroderma
    - Lamellar ichthyosis
  - Trichothiodystrophy
  - Storage diseases (e.g., Gaucher)
  - Chondrodysplasia punctata
- Ankyloblepharon filiforme adnatum (AFA)
  - Lethal popliteal pterygium syndrome
  - Popliteal pterygium syndrome
  - Isolated AFA
  - AFA and cleft palate
- Hypodontia
  - Isolated hypodontia
  - Incontinentia pigmenti
- Skin fragility/erosions
  - Epidermolysis bullosa disorders
  - Incontinentia pigmenti
  - Acrodermatitis enteropathica
  - Plakophilin/ectodermal dysplasia
  - Congenital erythropoietic porphyria
  - LOGIC (*l*aryngeal and *o*cular *g*ranulation tissue *i*n children from the Indian subcontinent)
- Atrophic streaks
  - Incontinentia pigmenti—stage 4
  - MIDAS (*mi*crophthalmia, *d*ermal *a*plasia, and *s*clerocornea)
  - Focal dermal hypoplasia

always should be examined fully to detect mild manifestations of the X-linked form. Molecular testing may be helpful but is not indicated for clinical diagnosis in most instances. Referral to a pediatric dermatologist may be helpful if the diagnosis is in question.

TREATMENT

Maintenance of cool ambient temperatures is vital to prevent hyperpyrexia. Most children do well with simple measures, such as wet T-shirts, air conditioning in home and school, wet headbands, etc. Occasionally, cooling vests allow a broader range of participation in sports and vigorous physical activity in warm climates.

Dental restoration is of primary importance, and early implementation of dentures and ultimate use of dental implants are mainstays of treatment.

Management of otolaryngologic complications, asthma, and recurrent infections needs to be individualized. The eczema may be quite refractory to care.

> The National Foundation for Ectodermal Dysplasias (http://www.nfed.org) has several pamphlets for individuals and professionals dealing with diagnosis and treatment.

Although infancy and childhood are complicated by many problems, most individuals with HED lead adult lives that allow them to function successfully in society. Heat intolerance seems to decrease due to the development of some ability to sweat in adolescence or to the development of common sense and adaptation of lifestyle, or both.

Recombinant ectodysplasin protein injections of pregnant affected (*Tabby*) mice led to permanent rescue of the phenotypic features in the offspring.[21] Further, early postnatal injections were also shown to ameliorate the developmental defects. Similar results have been seen in affected canine models who were infused with recombinant ectodysplasin protein in the postnatal period, with resultant normalization of teeth, lacrimation and sweating ability, as well as decreased eye and respiratory infections.[22,23] These developments in animal models have been encouraging and human trials are planned. An international patient registry has been established by the NFED to facilitate these clinical trials.

HIDROTIC ECTODERMAL DYSPLASIA (CLOUSTON SYNDROME; OMIM #129500)

EPIDEMIOLOGY

Hidrotic ED was first described in a French–Canadian kindred.[24] It has been reported in other ethnic groups, but the majority of affected individuals can trace their ancestry back to an original French–Canadian settler.

ETIOLOGY, PATHOGENESIS, AND GENETICS

Hidrotic ED is autosomal dominant with variable expression (the degree of severity can vary within and between families). Males and females are affected in equal numbers and to equal degree. The gene maps to the centromeric region of the long arm of chromosome 13.

The disorder is caused by mutations in a connexin gene, *GJB6* or *connexin-30*.[25] Different mutations in the same gene are responsible for a form of nonsyndromic autosomal dominant deafness and at least one patient with *k*eratitis-*i*chthyosis-*d*eafness (KID syndrome) (see Chapter 49). Other connexin genes show similar variability in mutation: disease correlations [e.g., mutations in *connexin-31* (*GJB3*)] can cause either erythrokeratodermia variabilis (see Chapter 49) or late-onset autosomal deafness.

CLINICAL MANIFESTATIONS

The scalp hair is wiry, brittle, and pale, and there is often patchy alopecia (Fig. 142-4A). This progresses in adult life and may lead to total alopecia. Body and facial hair are affected. The nails may be milky white in infancy and early childhood, gradually thickening and becoming dystrophic. The nail plates in adults are thick, short, and slow growing. They separate distally from the nail bed (see Fig. 142-4C), and may cause pain. Anonychia has been reported. Not all the nails are necessarily affected to the same degree. Progressive palmar/plantar hyperkeratosis is common (see Fig. 142-4B). In contrast to HED, sweating is normal, as are the teeth. Oral leukoplakia has been reported. Conjunctivitis and blepharitis, possibly due to poor function of sparse eyelashes, are common.

HISTOPATHOLOGY

The thickened palms and soles show orthohyperkeratosis with a normal granular layer. On electron microscopy, an increase in the number of desmosomes in the cells of the stratum corneum is found. The hair shows nonspecific changes.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(See Box 142-1)

The diagnosis is straightforward. The involvement of nails and hair and palmar/plantar thickening, in the absence of other signs of ED, are reasonably specific. Other palmar/plantar hyperkeratoses do not have similar hair changes. Orofacial clefting differentiates other forms of autosomal dominant hidrotic ED, such as ankyloblepharon–ED–cleft palate (AEC) syndrome or Rapp–Hodgkin syndrome. Although the nail changes are similar to those of pachyonychia congenita, the hair changes are distinctive.

Figure 142-4 Hidrotic ectodermal dysplasia (Clouston syndrome). **A.** Patchy alopecia in adult. Coarseness of hair can be appreciated. **B.** Palmar hyperkeratosis. **C.** Nail dystrophy.

TREATMENT

Occasionally, ablation of the nail matrix is necessary for relief of pain. Wigs may provide cosmetic benefit. Treatment of the thickened palms and soles is not specific and minimally successful.

ANKYLOBLEPHARON FILIFORME ADNATUM–ECTODERMAL DYSPLASIA–CLEFT PALATE SYNDROME (HAY–WELLS SYNDROME; OMIM #106260) (INCLUDES RAPP–HODGKIN SYNDROME; OMIM #129400)

EPIDEMIOLOGY

Described first in 1976,[26] Hay–Wells syndrome has been found in ethnically and geographically disparate families. Described in 1968, Rapp–Hodgkin syndrome, with many clinical similarities to Hay–Wells syndrome, was once thought to be a distinct clinical entity. More recently, it has become evident that Rapp–Hodgkin syndrome is allelic to Hay–Wells syndrome.[27–30] Although there are some clinical differences, the genotype–phenotype correlations are limited at best and it is reasonable to consider these disorders to be the same.

ETIOLOGY, PATHOGENESIS, AND GENETICS

The disorder is caused by mutations in the tumor-suppressor gene *p63*, a gene that has been implicated in the pathogenesis of ectrodactyly–ED–cleft lip/palate (EEC) syndrome, limb–mammary syndrome, *a*cro-*d*ermato-*u*ngual-*l*acrimal-*t*ooth (ADULT) syndrome, and other autosomal dominant forms of ED. Mutations that cause EEC and AEC cluster in different regions of the gene.[31,32] AEC syndrome is an autosomal dominant disorder with complete penetrance and variable expression.

CLINICAL FEATURES

DERMATOLOGIC. Eighty percent to 90% of affected infants present at birth with shiny red, cracking, peeling skin, and superficial erosions, similar to the appearance of a collodion membrane (Fig. 142-5A).[17] This sheds within a few weeks, and the skin underneath is dry and thin. The scalp is almost invariably affected by recurrent erosions, and many individuals are plagued by a chronic erosive dermatitis with abnormal granulation tissue on the scalp (see Figs. 142-5B and 142-5C).[33] Recurrent bacterial infection of the scalp is common. Patchy alopecia is the rule, and the scalp hair that is present is often wiry, coarse, and light in color with an uncombable hair appearance. Sparseness to absence of body hair is typical. Dyspigmentation, both hypo- and hyperpigmentation, can be quite striking and is seen universally in affected patients.[34,35] Ankyloblepharon

Figure 142-5 Ankyloblepharon filiforme adnatum–ectodermal dysplasia–cleft palate (Hay–Wells) syndrome. **A.** Newborn with peeling collodion membrane. **B.** Scalp erosions. **C.** Mild ankyloblepharon, blepharitis, midfacial hypoplasia, repair cleft lip, and abnormal granulation tissue on scalp. **D.** Fine strands of tissue (ankyloblepharon filiforme adnatum) between eyelids.

filiforme adnatum (AFA)—strands of skin between the eyelids—is seen in approximately 70% of affected infants (see Fig. 142-5D). These may tear spontaneously prior to birth, minimally involve the lateral eyelids or require surgical lysis. Lacrimal duct atresia or obstruction is common. The nails may be normal, hyperconvex and thickened, absent, or partially dystrophic, and all changes can be found in a single individual. Effaced dermatoglyphics and palmoplantar erosive changes are also quite common. Sweating may be normal, although most affected individuals describe subjective heat intolerance. Supernumerary nipples and ectopic breast tissue are seen occasionally, as is mild cutaneous syndactyly of toes two and three. More prominent limb defects, including ectrodactyly, have recently been observed.[36,37]

In Rapp–Hodgkin, hypohidrosis usually without episodes of frank hyperpyrexia, abnormal hair with pili torti or pili trianguli et canaliculi and progressive balding, along with nail dystrophy, similar to Hay–Wells, are seen.[38,39] The face in Rapp–Hodgkin syndrome is striking, with a short nasal columella and maxillary hypoplasia, thin upper lip, and full lower lip (Figs. 142-6A and 142-6B). The nails are thick and short, worsening with age (see Fig. 142-6C). The teeth may be conical and prone to caries (see Fig. 142-6D). The lacrimal puncta are aplastic in almost one-third of affected individuals. Scalp involvement with breakdown and granulation tissue formation appears to be far less common in patients with Rapp–Hodgkin than in AEC syndrome, and AFA is rare.

SYSTEMIC ASSOCIATIONS. Cleft palate, with or without cleft lip, occurs in 80% to 100% of reported cases, with some cases displaying submucosal clefts alone.[40] There is typically hypodontia with missing or misshapen teeth, and maxillary hypoplasia is also common.[41] Malformed auricles have been described in some. Recurrent otitis media and secondary conductive hearing loss are common and may be consequence of the cleft palate. Hypospadias has been described in several affected males with AEC syndrome. In Rapp–Hodgkin, hypospadias has been reported in two-fifths of affected males; labial hypoplasia and absence of the opening of the vagina have been reported in a single female. These features are also reminiscent of the EEC syndrome.

Figure 142-6 Rapp–Hodgkin syndrome. **A.** Affected infant at 5 months. **B.** Fine, blond, sparse hair; beginnings of nail changes on middle finger of right hand. (Used with permission from the National Foundation for Ectodermal Dysplasias.) **C.** Abnormal nails in same patient as (**A**), at age four-and-half years with thickened and friable nail plates. (From Sybert VP: *Genetic Skin Disorders*. New York, Oxford University Press, 1997.) **D.** Abnormal dentition, missing teeth, and peg teeth.

HISTOPATHOLOGY

Consistent histopathologic changes include mild epidermal atrophy, focal orthokeratosis, prominent superficial vascular plexus, and pigment incontinence with melanophages.[42] Electron microscopy of hairs shows a defective cuticular structure, atrophy and loss of melanin, along with structural abnormalities including pili torti and pili trianguli et canaliculi. There is a decrease in the keratins of the basal and suprabasal layers of the epidermis and disorganized keratin filaments in the stratum corneum.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(See Box 142-1)

Among the autosomal dominant EDs associated with clefting, EEC syndrome is characterized by bony hand and foot abnormalities not typically seen in AEC and also lacks the ankyloblepharon. The peeling, eroded skin of the newborn can lead to misdiagnosis of epidermolysis bullosa or congenital ichthyosis. AFA can occur in the absence of syndromic associations, and strands of tissue between the eyelids have been seen in several forms of arthrogryposis, in association with chromosomal aneuploidy, and in CHANDS (*c*urly *h*air, *a*nkyloblepharon, and *n*ail *d*ysplasia *s*yndrome), an autosomal recessive form of ED.

TREATMENT AND PROGNOSIS

Light emollients should be used until the collodion membrane sheds. Ankyloblepharon may require surgical lysis. Ongoing ocular hygiene is important. Vigorous and meticulous but gentle scalp care with prompt treatment of infection is extremely important. Grafting of skin to the scalp has not proven successful in most instances. Clefting requires a team approach for repair and follow-up for secondary issues, such as feeding difficulties, speech defects, orthodontia, and ear infections.

ECTRODACTYLY ECTODERMAL DYSPLASIA–CLEFT LIP/PALATE (EEC) SYNDROME; SPLIT HAND–SPLIT FOOT–ECTODERMAL DYSPLASIA–CLEFT LIP/PALATE SYNDROME (OMIM #604292)

HISTORICAL ASPECTS AND EPIDEMIOLOGY

EEC syndrome is an ED classified as a multiple congenital anomaly syndrome because it has major involvement of structures other than those derived ectodermally. EEC syndrome has occurred in all racial groups worldwide.

ETIOLOGY, PATHOGENESIS, AND GENETICS

Mutations in *p63*, a tumor-suppressor gene mapped to 3q27, have been found in most, but not all, individuals with EEC syndrome.[43] The gene is expressed widely, including in the basal cells of proliferating epithelial tissues. Mutations in the same gene cause some cases of isolated split hand–split foot disease, limb–mammary syndrome, the ADULT (OMIM #103285) syndrome, and Hay–Wells/Rapp–Hodgkin syndrome. There appear to be some genotype–phenotype correlations.[44] The majority of alterations identified thus far in Hay–Wells syndrome have been missense mutations in the sterile α motif domain of p63; in EEC syndrome, the majority of mutations result in single-amino-acid substitutions in the DNA-binding domain of p63.[19] Similar mutations in the DNA-binding domain are also found in the split hand–split foot malformation.[45] Frameshift mutations in *p63* cause limb–mammary syndrome, in which ectodermal structures other than the mammary gland often, but not always, appear normal. Among three unrelated families with ADULT syndrome, all shared the same point mutation in *p63*.[46]

EEC syndrome is an autosomal dominant disorder with variable expression and reduced penetrance. Intrafamilial and interfamilial differences in severity are common.

CLINICAL MANIFESTATIONS

DERMATOLOGIC. The ED may be quite mild. The hair is usually blond, coarse, and dry. It may be sparse and slow growing. Axillary and pubic hair also may be affected. The nails are dystrophic in approximately four-fifths of individuals with transverse ridging, pitting, and slow growth. Dry skin and thickening of the palms and soles can occur. Sweating is usually normal.

SYSTEMIC ASSOCIATIONS. The major distinguishing feature of EEC syndrome is ectrodactyly—abnormal development of the median rays of the hands and feet (Figs. 142-7A–142-7C). The feet are involved more frequently than the hands, and there may be asymmetry of involvement (see Figs. 142-7A–142-7C).

Cleft palate, with or without cleft lip, occurs in 70% to 100% depending on the series.[47,48] Hypodontia and premature loss of secondary teeth and the dental abnormalities associated with clefting are found in most affected individuals. Lacrimal gland abnormalities are common. Secondary conductive hearing loss is frequent. Genitourinary abnormalities that include hydronephrosis, and structural renal or genital malformations affect one-third or more of persons with EEC syndrome. Although mental retardation has been reported, it is not believed to be an inherent feature of the disorder.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Among disorders with limb defects that need to be considered in the differential diagnosis of EEC syndrome are the odontotrichomelic syndrome (OMIM #273400), in which there are severe absence deformities of the limbs, and aplasia cutis congenita with limb defects (Adams–Oliver syndrome, OMIM #100300), which does not have clefting or ectodermal defects other than absence of skin. Cutis marmorata telangiectatica congenita (see Chapter 107) has been described in some individuals with Adams–Oliver syndrome. Other EDs with clefting include Hay–Wells syndrome, and limb–mammary syndrome, all of which, in at least some families, appear to be allelic to EEC syndrome. Ectrodactyly with cleft palate without ED (OMIM #129830) also may be a distinct entity. There appear to be some families with EEC in whom linkage studies have suggested other causal genes located at different chromosomal loci. These genes have not yet been identified, but Dlx protein regulation by *p63* may play an important role in the development of limb abnormalities. Prenatal diagnosis by ultrasound for detection of limb abnormalities is unreliable; molecular testing may prove useful in some families.

TREATMENT

As for other EDs with orofacial clefting and ophthalmologic involvement, management requires a team approach. Similarly, treatment for the limb defects must be individualized. Renal ultrasound and a high index of suspicion for urinary tract problems are appropriate and warranted.

TOOTH AND NAIL SYNDROME (WITKOP SYNDROME; HYPODONTIA WITH NAIL DYSGENESIS; OMIM #189500)

HISTORICAL ASPECTS AND EPIDEMIOLOGY

The earliest case was reported by Witkop in 1965 when he described a pedigree demonstrating autosomal

Figure 142-7 Ectrodactyly–ectodermal dysplasia–clefting syndrome. **A.** Hands of an affected adult. **B.** Hands and feet of affected infant. **C** and **D.** Feet and hands of parent of infant in (**B**) demonstrating variability of expression both among limbs and between family members. Note the nail dystrophy in the mildly affected mother, especially evident on the thumbs.

dominant inheritance.[49] Along with Hudson, he later went on to describe 23 cases in six families in 1975. All demonstrated hypoplastic nails and hypodontia; the latter manifested as failure of permanent teeth to erupt.[50]

ETIOLOGY, PATHOGENESIS, AND GENETICS

A nonsense mutation in *MSX1*, a gene expressed in the developing teeth and nail beds in mice, has been found in one family with Witkop syndrome.[51,52] Other mutations in *MSX1* have been associated with isolated tooth agenesis or tooth agenesis with cleft palate. Tooth and nail syndrome is autosomal dominant, with variable expression and intrafamilial variability.

CLINICAL MANIFESTATIONS

DERMATOLOGIC. The nails are thin, small, and friable and may show koilonychia at birth. Toenails are usually more severely involved than fingernails (Fig. 142-8B). Nail changes improve with age and may

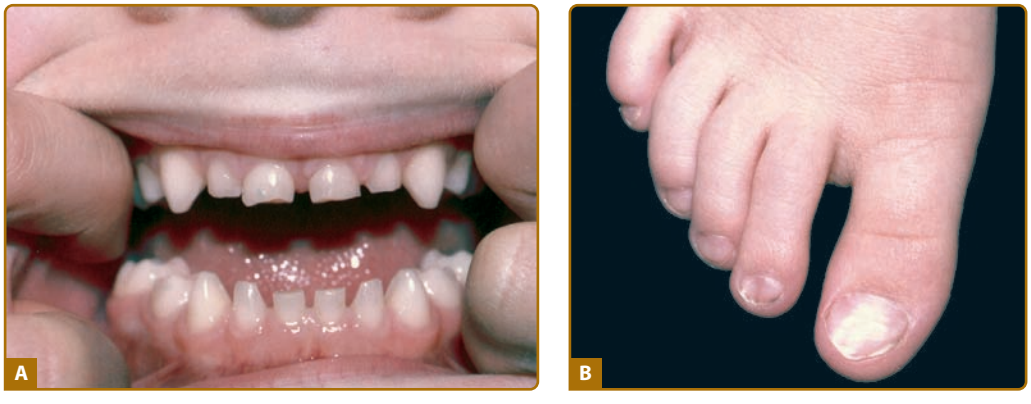

Figure 142-8 Tooth–nail syndrome. **A.** Primary teeth still in place; failure of adult teeth to erupt. **B.** Dystrophic toenails with flattening of nail plates.

be unappreciated in affected adults. A few individuals have reported thin, fine hair.

SYSTEMIC ASSOCIATIONS. The primary teeth usually are unaffected, although they may be small. The secondary teeth may fail to erupt, and there can be partial or total absence (see Fig. 142-8A). The mandibular incisors, second molars, and maxillary canines are missing most often. No other ectodermal structures are affected.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

This is an easy condition to miss. The nail changes may be subtle. The tooth abnormalities may be mild enough to escape detection by a physician. The lack of associated features, either dermatologic or systemic, readily distinguish Witkop syndrome from other EDs. There is a presumed autosomal recessive disorder characterized by taurodontia (teeth with an elongated body and pulp chamber and short roots), absent teeth, sparse hair, and hypoplastic nails that appears similar.

TREATMENT AND PROGNOSIS

The nails usually require no treatment. Restorative dentistry is important.

FOCAL DERMAL HYPOPLASIA OF GOLTZ (OMIM #305600)

EPIDEMIOLOGY

Focal dermal hypoplasia of Goltz (FDH), first described in 1934, received its name from a report by Goltz and coauthors[53] of three patients. Subsequently, there have been over 200 case reports published.

ETIOLOGY, PATHOGENESIS, AND GENETICS

Focal dermal hypoplasia is an X-linked dominant disorder, usually lethal in males. Case reports of males with the condition are believed to be due to mosaicism for postzygotic mutations (as is true for incontinentia pigmenti); the presence of some normal cells allows survival in the male. The mutated gene is *PORCN*, the human homolog of the porcupine gene in *Drosophila*. *PORCN* is thought to be important for palmitoylation and secretion of Wnt protein, a key regulator of the development of skin and bone.[54,55]

CLINICAL MANIFESTATIONS

DERMATOLOGIC. The skin changes of FDH are the primary diagnostic features with considerable phenotypic variability. There is linear, punctate, streaky cribriform atrophy (Fig. 142-9) with telangiectasia. The cribriform atrophy is marked by tiny ice pick-like depressions in the skin. These are distributed along the lines of Blaschko. Areas of thinned to absent dermis are irregularly distributed and the resultant herniations of fat appear as yellow–pink excrescences on the skin surface (see Fig. 142-9C). These are easily depressed. Papillomas that may be fleshy or vascular develop throughout life and favor the perigenital, perioral, intertriginous, and mucosal surfaces. Other dermatologic features include patchy alopecia, brittle or sparse hair, and palmar and plantar hyperkeratoses. Some individuals have had hyperhidrosis and some have had aplasia cutis congenita.

SYSTEMIC ASSOCIATIONS. The other organ systems most frequently involved in FDH are the skeletal, central nervous system, teeth, and eyes. Microphthalmia and coloboma are common and the diagnosis of FDH should prompt a full ophthalmologic evaluation. Oligodontia, tooth dysplasia, and enamel defects are common. The skeletal abnormalities are too numerous to list; the more common are vertical banding of the bones (osteopathia striata), syndactyly (both cutaneous and bony), asymmetry, and short stature. Mental retardation has been reported in approximately 15% of cases. Defects in other organ systems have been described in a minority of cases, including cardiac defects, abdominal wall defects, and renal malformations. It is not certain that these are inherent features of FDH.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

(See Box 142-1)

The diagnosis of FDH is relatively straightforward. Cribriform atrophy has been described in X-linked dominant Conradi–Hünermann syndrome (chondrodysplasia punctata), but ichthyosis is not a feature of FDH, and fat herniation is not part of Conradi–Hünermann. The streaky distribution of the atrophic lesions of IP is similar, as are the other system malformations, but the blistering, hyperkeratosis, and hyperpigmentation of IP are not found in FDH. In microphthalmia and linear skin defects/microphthalmia, dermal aplasia, sclerocornea, the skin defects are limited to the head and neck; there is atrophy and scarring of the skin more similar to aplasia cutis congenita and not dermal atrophy alone. The disorders do share similar ocular abnormalities.

TREATMENT AND PROGNOSIS

There is no specific treatment for the dermatologic and systemic features of FDH. Papillomas can be excised if they interfere with function. Use of vascular lasers to decrease the erythema of telangiectatic areas may have cosmetic benefit. As with most X-linked dominant disorders, clinical involvement varies considerably, and the range in severity is marked. This makes prognostic counseling difficult early in infancy, and usually it is wiser to counsel patience and reassurance until the

Figure 142-9 Focal dermal hypoplasia of Goltz. **A.** Streaky and patchy involvement in the newborn. Note similarity to the distribution of lesions in incontinentia pigmenti. **B** and **C.** Same girl at age 2 showing atrophy and fat herniation. **D.** Now a young adult, erythema and atrophy, with dryness and scale, predominate. (From Sybert VP: *Genetic Skin Disorders.* New York, Oxford University Press, 1997.)

extent to which there is systemic involvement becomes clear. It is important to inquire about the family history of lost pregnancies (a distorted male–female ratio in offspring and increased pregnancy loss are clues to the mother being a carrier). Both mothers and fathers should be examined carefully; fathers may have subtle features, and, presumably, represent individuals with postzygotic mutations for the *FDH* gene.

Chapter 143 :: Genetic Immunodeficiency Diseases

:: Ramsay L. Fuleihan & Amy S. Paller

GENETIC IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases are inherited disorders of the immune system that result in an increased susceptibility to infection and an increased morbidity and mortality. Many of these genetic immunodeficiency diseases may be associated with a variety of cutaneous abnormalities, and recognition of these clinical features may allow an early diagnosis of primary immunodeficiency. Cutaneous abnormalities may include cutaneous infections, atopic- or seborrheic-like dermatitis, macular erythemas, alopecia, poor wound healing, purpura, petechiae, telangiectasias, pigmentary dilution, cutaneous granulomas, extensive warts, angioedema, and lupus-like changes (Table 143-1). Other clinical features often include failure to thrive, visceral infection, autoimmune disorders, connective tissue/rheumatologic diseases, allergic reactions, and neoplasias.

CLINICAL FINDINGS

Immunodeficiency should be suspected when patients have recurrent infections of increased duration or severity, particularly with unusual organisms. Incomplete clearing of infections, unexpected or severe complications of infection, or poor response to antibiotics may be associated.[1] Affected infants often grow poorly (failure to thrive). The most common noncutaneous abnormalities are infections, diarrhea, vomiting, hepatosplenomegaly, arthritis, adenopathy or paucity of lymph nodes/tonsils, and hematologic abnormalities.

The classification of genetic immunodeficiency disorders includes (1) antibody deficiencies, (2) cellular deficiencies, (3) combined antibody and cellular deficiencies, (4) disorders of phagocytosis and cell killing, and (5) complement defects. The characteristic clinical signs of each group suggest that proper classification and laboratory tests may be used to confirm the diagnosis. The laboratory testing and clinical patterns of illness associated with each group of immunodeficiency disorders that allow their differential diagnosis are outlined in Table 143-2 and Fig. 143-1. The most important disorder in the differential diagnosis of all genetic immunodeficiency disorders is human immunodeficiency virus (HIV) infection. In addition to the lack of HIV antigen as detected by polymerase chain reaction in patients with genetic immunodeficiency, other features help to differentiate the disorders. Patients with HIV infection tend to show an inverted CD4/CD8 ratio and hypergammaglobulinemia, in contrast to the hypogammaglobulinemia of many patients with genetic immunodeficiency.

ANTIBODY DEFICIENCY DISORDERS

AGAMMAGLOBULINEMIA

X-LINKED AGAMMAGLOBULINEMIA AT A GLANCE

- Synonym: Bruton disease.
- Early-onset, recurrent bacterial infections.
- Absent or barely detectable tonsillar and cervical lymph node tissue.
- Profound hypogammaglobulinemia and decreased or absent peripheral B cells.

EPIDEMIOLOGY. Agammaglobulinemia results from gene defects that prevent the assembly of a full B cell antigen receptor. X-linked agammaglobulinemia (XLA) is the most common cause of agammaglobulinemia and results from defects in a cytoplasmic tyrosine

TABLE 143-1
Manifestations of Genetic Immunodeficiencies

Cutaneous Manifestations	Associated Immunodeficiency	Cutaneous Manifestations	Associated Immunodeficiency
■ Angioedema	Hereditary angioedema	■ Mucocutaneous telangiectasias	Ataxia-telangiectasia
■ Atopic-like dermatitis	IgA deficiency/IgM deficiency Chronic granulomatous disease Common variable immunodeficiency Elevated IgM with hypogammaglobulinemia Ectodermal dysplasia with immunodeficiency Hyperimmunoglobulinemia E syndrome Severe combined immunodeficiency Wiskott–Aldrich syndrome X-linked agammaglobulinemia	■ Petechiae and/or purpura	Chédiak–Higashi syndrome Griscelli syndrome Wiskott–Aldrich syndrome
		■ Pigmentary dilution/silvery hair	Chédiak–Higashi syndrome Griscelli syndrome IgA deficiency
		■ Pyoderma gangrenosum-like ulcerations	Chédiak–Higashi syndrome Chronic granulomatous disease Hyperimmunoglobulinemia E syndrome Leukocyte adhesion deficiency
■ Cutaneous abscesses	Chronic granulomatous disease Hyperimmunoglobulinemia E syndrome Leukocyte adhesion deficiency	■ Seborrheic-like or exfoliative dermatitis	X-linked hypogammaglobulinemia Ataxia-telangiectasia "Leiner" phenotype: complement deficiency or dysfunction Severe combined immunodeficiency X-linked agammaglobulinemia
■ Cutaneous granulomas	Ataxia-telangiectasia Chronic granulomatous disease Chronic mucocutaneous candidiasis Common variable immunodeficiency Severe combined immunodeficiency, especially TAP2 deficiency X-linked hypogammaglobulinemia	■ Warts, extensive	Common variable immunodeficiency Elevated IgM with hypogammaglobulinemia Epidermodysplasia verruciformis (see Chapter 196) IgM deficiency Severe combined immunodeficiency after transplantation (mutations in *IL2RG* or *JAK3*) WHIM syndrome
■ Cutaneous candidal infection	Chronic mucocutaneous candidiasis DiGeorge syndrome Hyperimmunoglobulinemia E syndrome Severe combined immunodeficiency especially TAP2 deficiency		
■ Eosinophilic folliculitis, infantile	Hyperimmunoglobulinemia E syndrome		
■ Graft-versus-host disease	DiGeorge syndrome Severe combined immunodeficiency		
■ Lupus-like cutaneous change	IgA deficiency Chronic granulomatous disease, autosomal recessive Chronic granulomatous disease, X-linked carrier Common variable immunodeficiency Complement deficiency, early components Elevated IgM with hypogammaglobulinemia		

Ig = immunoglobulin; TAP = transporter associated with antigen processing or transporter, ATP-binding cassette; WHIM = warts, hypogammaglobulinemia, infections, myelokathexis.

kinase, Bruton's tyrosine kinase (BTK). XLA is inherited in an X-linked fashion, and approximately 50% of affected boys have a family history of the disorder.[2] Autosomal recessive agammaglobulinemia affects males and females equally and results from defects in the genes that encode for components of the pre-B cell and B cell receptors or in BLNK, a scaffold protein that assembles signaling molecules associated with the pre-B cell and B cell receptor.[23]

CLINICAL FINDINGS. Agammaglobulinemia is characterized by recurrent pyogenic infections that often begin between 3 and 18 months after birth, concurrent with the waning of maternal immunoglobulins (Ig). These patients have absent or barely detectable tonsils and cervical lymph nodes.[5] Skin infections, especially furunculosis and impetigo, occur in 28% of patients and often surround body orifices. An atopic-like eczematous eruption that fails to improve with Ig therapy has

TABLE 143-2
Patterns Associated with Primary Immune Deficiency

Disorder	Infection	Other
Antibody	Sinopulmonary (pyogenic bacteria) Gastrointestinal (enterovirus, *Giardia*) Normal handling of fungal and viral infections (exception is enterovirus)	Autoimmune disease (autoantibodies, inflammatory bowel disease) Minimal growth retardation Paucity of lymphoid tissue
Cellular	Low-grade or opportunistic infections Pneumonia (pyogenic bacteria, *Pneumocystis*, viruses) Gastrointestinal (viruses) Skin, mucous membranes (fungi)	Growth retardation Graft-versus-host disease Fatal infections from live vaccines Malignancy
Phagocytosis and cell killing	Skin, reticuloendothelial system (*Staphylococcus*, enteric bacteria, *Aspergillus*, *Mycobacteria*)	Ulcerative stomatitis
Complement	Alternative, late components Sepsis/blood-borne (*Streptococci*, *Pneumococci*, *Neisseria*)	Early components Autoimmune disease (systemic lupus erythematosus, glomerulonephritis) C1 esterase inhibitor deficiency Angioedema

been described in many affected children. Pyoderma gangrenosum and noninfectious cutaneous granulomas have been reported. Childhood exanthematous disorders are handled appropriately, but the infections may recur, owing to a failure to develop specific antibodies.

Recurrent otitis, sinusitis, bronchitis, and pneumonia are the earliest infectious manifestations and usually are caused by *Pneumococci*, *Staphylococci*, or *Haemophilus*. Untreated pulmonary infections may lead to progressive bronchiectasis and chronic pulmonary disease, seen in 45% of XLA patients over the age of 10.[6] Patients can also suffer from chronic enteroviral infections and hearing loss from repeated otitis and sinusitis infections. Other common bacterial infections include conjunctivitis, osteomyelitis, septic arthritis, and meningitis. Protracted diarrhea may be due to infection, particularly with *Giardia*, *Salmonella*, *Campylobacter*, or *Cryptosporidium* spp. Three virus groups cause problems: (1) enterovirus, (2) hepatitis B virus, and (3) rotavirus. Patients have developed paralysis after administration of the live polio vaccine. A rheumatoid-like arthritis, characterized by chronic inflammation and swelling of the large joints, may develop in as many as one-third to one-half of boys with XLA and is often due to mycoplasmal infection (*Ureaplasma urealyticum*). Disseminated echovirus infection has caused meningoencephalitis and a dermatomyositis-like disorder with brawny edema, induration of the muscles with accompanying weakness, muscle contractures, and poikiloderma.

The diagnosis of agammaglobulinemia is made by serum concentrations of IgG, IgA, and IgM that are far below the 95% confidence limits for appropriate controls (usually less than 100 mg/dL total Ig) and by the virtual absence of B cells in the peripheral circulation (<1% of normal). Identification of a defect in one of the known genetic causes of agammaglobulinemia confirms the diagnosis and allows for genetic counseling and prenatal diagnosis.

TREATMENT, PROGNOSIS, AND CLINICAL COURSE. Early Ig replacement, intravenously (IVIG) or subcutaneously, and antibiotic use markedly reduces the risk of infections, although it may not be helpful in diminishing the risk and morbidity of chronic lung disease or chronic enterovirus infection.

COMMON VARIABLE IMMUNODEFICIENCY

COMMON VARIABLE IMMUNODEFICIENCY AT A GLANCE

- Heterogeneous group of disorders in which both antibody deficiency and abnormalities of T cells may be found.
- Most common underlying gene defect in transmembrane activator, calcium modulator, and cyclophilin ligand interactor, which also can lead to IgA deficiency.
- May manifest during childhood, but average of onset is almost at 30 years of age.
- Variable severity of autoimmune and infectious complications.

CLINICAL FINDINGS. CVI commonly presents in young adults, but 25% of cases are diagnosed before the age of 21 years.[9] Patients have infections similar to those in patients with XLA, particularly sinopulmonary infections, but are less susceptible to enteroviral infections and more susceptible to *Giardia* infections.

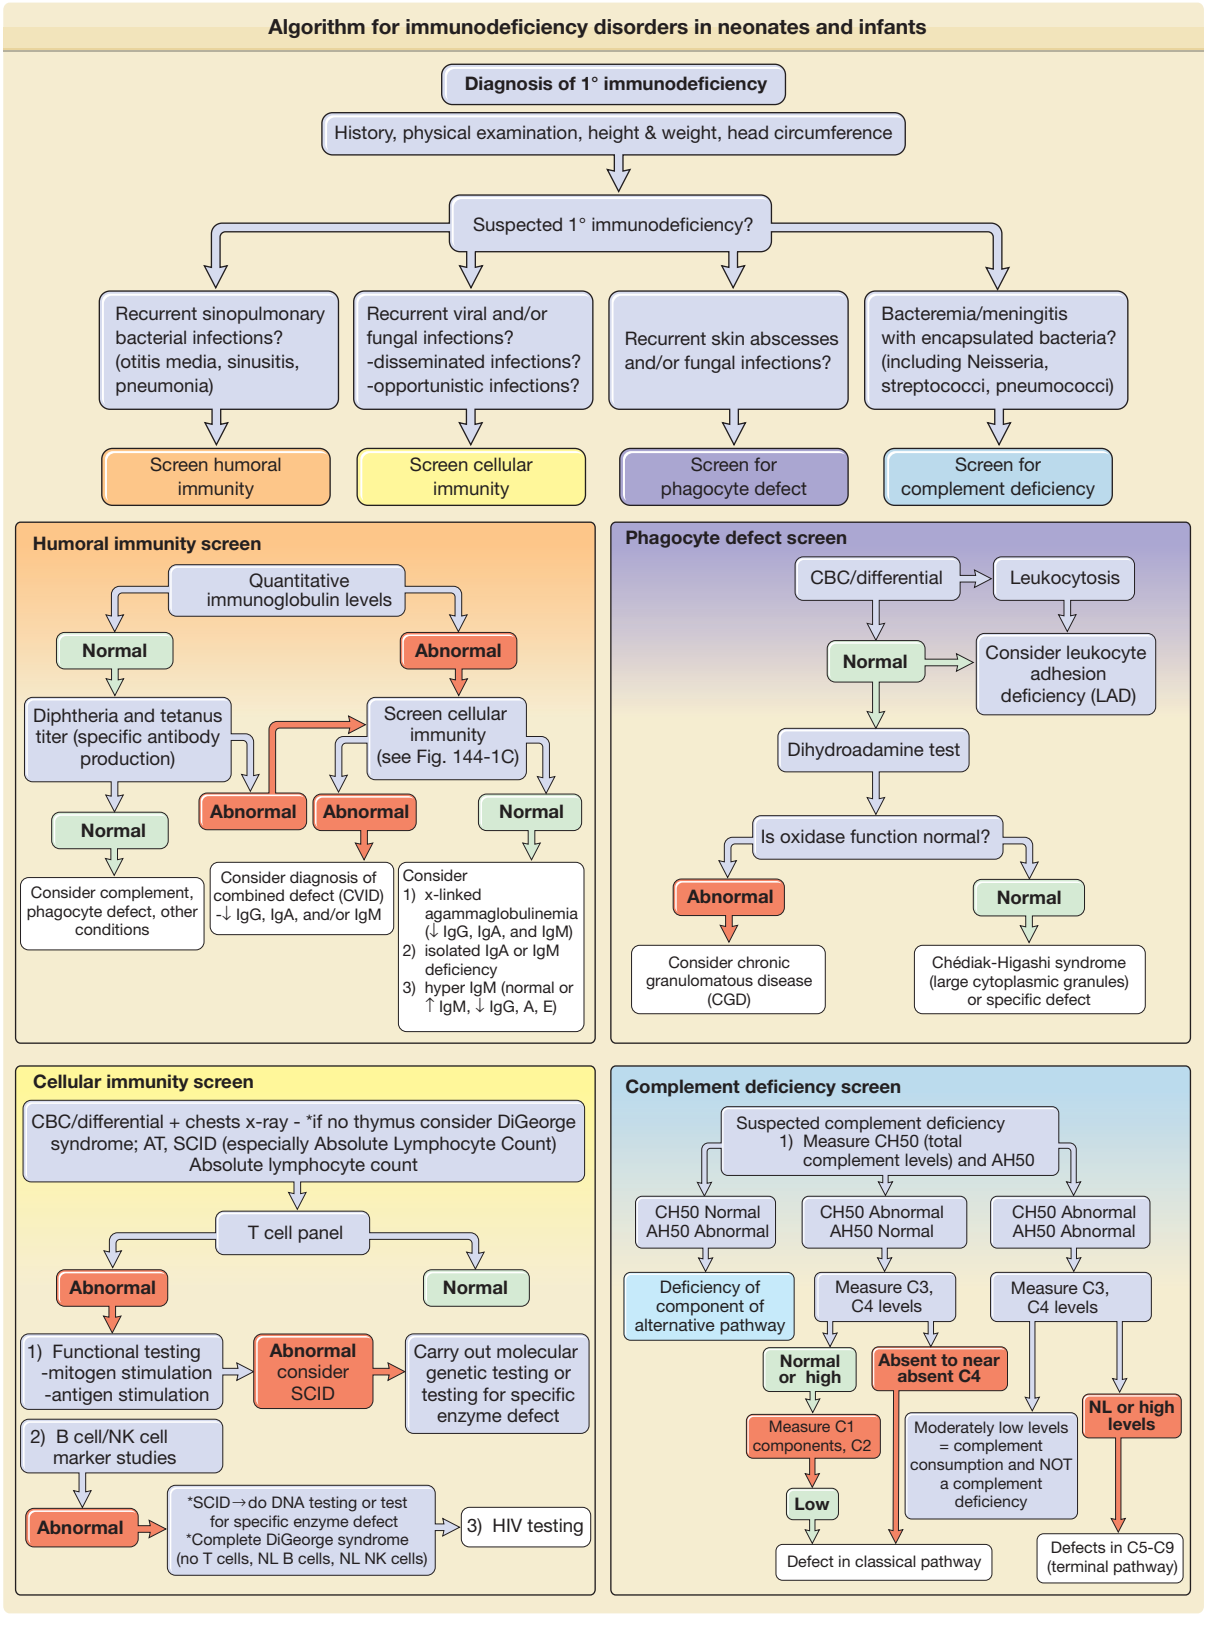

Figure 143-1 A–C. Algorithm for immunodeficiency disorders in neonates and infants. If the clinical presentation is concerning for severe combined immunodeficiency (SCID), this is a medical emergency and patient needs immediate referral to an immunologist. AT = ataxia-telangiectasia; CBC = complete blood cell count; CVID = common variable immunodeficiency; HIV = human immunodeficiency virus; Ig = immunoglobulin; NK cell = natural killer cell; NL = normal; ↓ = decreased; ↑ = increased.

Figure 143-2 Noncaseating granulomas on the legs of a child with common variable immunodeficiency. Cultures and special stains showed no organisms.

Many patients with CVI have liver disease and gastrointestinal (GI) disease, causing malabsorption syndromes. Noncaseating granulomas of skin (Fig. 143-2), lungs, liver, and spleen have been reported. Caseating granulomas of the skin and viscera, although rare, have also been described.[11,12] Extensive warts can be a major problem in individuals with CVI (Fig. 143-3). Lymphoid tissues often are enlarged, and splenomegaly with hypersplenism is found in 25% of patients. Autoimmune disorders are especially frequent (11% to 22%),[9,13] particularly autoimmune thrombocytopenia, autoimmune hemolytic anemia, rheumatoid arthritis, sicca syndrome, and pernicious anemia. Alopecia areata and lupus also have been described. In 10% to 20% of patients, at least one family member is also immunodeficient, particularly with CVI or IgA deficiency.[14] The incidence of lymphoreticular malignancy and gastric carcinoma are markedly increased, particularly in the fifth and sixth decades of life.[15]

Figure 143-3 The dorsal aspect of the hands were covered with recalcitrant verrucae vulgaris in this girl with common variable immunodeficiency.

SELECTIVE IMMUNOGLOBULIN DISORDERS

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY AT A GLANCE

- IgA deficiency is usually asymptomatic; only 10% to 15% of affected individuals demonstrate clinical manifestations, especially bacterial sinopulmonary infections and autoimmune disorders.

CELLULAR DEFICIENCIES

CHRONIC MUCOCUTANEOUS CANDIDIASIS

CHRONIC MUCOCUTANEOUS CANDIDIASIS AT A GLANCE

- A heterogeneous group of disorders with altered immune responses selective to *Candida*.
- Recurrent, progressive candidal infections of the skin, nails, and mucous membranes.
- May be associated with the later development of endocrinopathy [APECED, *a*utoimmune *p*oly*e*ndocrinopathy-*c*andidiasis-*e*ctodermal *d*ystrophy].

EPIDEMIOLOGY. Several clinical subtypes of chronic mucocutaneous candidiasis (CMC) have been defined (Table 143-3). They have varied clinical manifestations, variable immunodeficiency, and different forms of genetic inheritance. Patients with CMC may have childhood or mature onset, familial, or sporadic occurrence, and CMC may be present with or without endocrinopathy. Patients with *a*utoimmune *p*oly*e*ndocrinopathy-*c*andidiasis-*e*ctodermal *d*ystrophy (APECED or autoimmune polyendocrine syndrome or APS, type 1) often have affected siblings. APECED and other familial forms of CMC are autosomal recessive. Autosomal dominant inheritance is seen in patients with associated keratitis.

CLINICAL FINDINGS. Patients with CMC have recurrent, progressive infections of the skin, nails, and

TABLE 143-3
Classification of Patients with Chronic Mucocutaneous Candidiasis[a]

CMC Type	Inheritance/ Gene Defect	Onset	Clinical Features	Associated Disorders	NonCandidal Infections
Chronic oral candidiasis	No known genetic defect	Middle-aged or elderly women	Candidiasis of tongue and buccal mucosa No esophageal, skin, or nail involvement	Fe^{2+} deficiency	No
Familial chronic mucocutaneous candidiasis	Autosomal recessive and autosomal dominant Males and females are equally affected	Early childhood, often before age 2 years	Oral candidiasis Limited skin and nail involvement	No endocrinopathies	Yes
Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome	Autosomal recessive Mutations in the *AIRE* (autoimmune regulator) gene on 21q22.3 More common in the Finnish population, Iranian Jews, and Sardinians Rarely, dominant form with *AIRE* mutations or mapped to chromosome 2p	Candidal infections before age 5 years Endocrine abnormalities between 10 and 15 years of age	Oral and diaper area candidiasis more often than skin and nail involvement Endocrinopathies and autoimmune disorders	*Most common endocrinopathies*: Hypoparathyroidism Hypoadrenalism *Other associated disorders*: Thyroid disease Primary hypogonadism Hepatitis Malabsorption Pernicious anemia Alopecia areata Vitiligo *Ectodermal manifestations:* Dental enamel hypoplasia Pitted nail dystrophy Keratoconjunctivitis Myasthenia gravis Hypogammaglobulinemia	Yes
CMC with thymoma	No known genetic basis	Adult onset	Mucous membrane and cutaneous candidiasis	Malignant/benign thymomas Aplastic anemia Myasthenia gravis Hypogammaglobulinemia	No
Chronic localized candidiasis (candida granuloma)	No known genetic basis Males and females are equally affected	Early childhood, often before age 5 years	Thick, adherent candidal crusts on the scalp and face Oral candidiasis	None	Yes
CMC with keratitis	Autosomal dominant	Early childhood	Candidiasis of the oral cavity, diaper area	Keratoconjunctivitis Alopecia Endocrine abnormalities	Yes

CMC = chronic mucocutaneous candidiasis.
[a]Chronic candidal infections have been described in patients with DiGeorge, hyperimmunoglobulinemia E, severe combined immunodeficiency, ectrodactyly-ectodermal dysplasia-clefting, and keratitis-ichthyosis-deafness syndromes; multiple carboxylase deficiency; and acrodermatitis enteropathica.

mucous membranes most commonly due to *Candida albicans*.[33,37] Depending on the subtype, the clinical presentation ranges from recurrent, recalcitrant thrush (Fig. 143-4) to mild erythematous scaling plaques (see eFig. 143-4.1 in online edition) with a few dystrophic nails to severe generalized, crusted granulomatous plaques (Fig. 143-5). The cutaneous plaques occur most commonly in intertriginous areas, periorificial sites, and the scalp, but they may be generalized. The nails are thickened, brittle, and discolored, and the paronychial areas are often erythematous, swollen, and tender. Scalp infections may lead to scarring and alopecia. Although the oral mucosa is the most frequent site of mucosal alteration, esophageal, genital, and laryngeal mucosae may be affected. Strictures may be formed by candidal infection at these mucosal sites. Scrapings and cultures from cutaneous or mucosal lesions demonstrate candidal organisms.

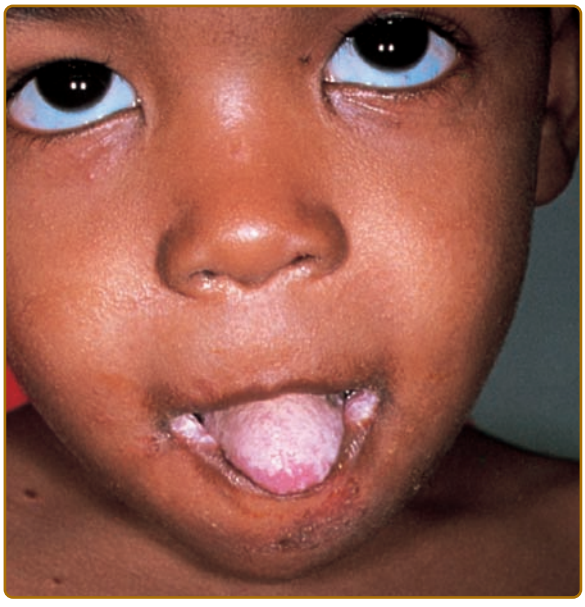

Figure 143-4 Recurrent thrush and candidal cheilitis in a boy with mucocutaneous candidiasis.

Patients with CMC rarely develop systemic candidiasis, but 50% may develop recurrent or severe infections due to other organisms. In one study, 81% of patients with early-onset CMC also had infections with bacteria, fungi, and parasites, including bacterial septicemia.[33] Concomitant dermatophyte infections may occur.

In patients with APECED, the candidal infections tend to begin by 5 years of age, although the endocrinologic dysfunction may not be apparent until 12–13 years of age (see Fig. 143-5). The most commonly associated endocrinopathies are hypoparathyroidism (88%) and hypoadrenocorticism (60%). One-third of patients have candidiasis, hypoparathyroidism, and defective adrenal function. Other associated endocrinopathies or autoimmune disorders include gonadal insufficiency (45%), alopecia areata (20%), pernicious anemia (16%), thyroid abnormalities (12%), chronic active hepatitis or juvenile cirrhosis (9%), vitiligo, diabetes mellitus, and hypopituitarism. Chronic diarrhea and malabsorption have been reported in 25% of patients and usually are associated with hypoparathyroidism. Some affected patients also have pulmonary fibrosis, dental enamel hypoplasia, and keratoconjunctivitis. The "ectodermal dysplasia" features are likely to be secondary to the candidal infections or autoimmunity.[37] Patients with APECED often have autoimmune antibodies, including antithyroglobulin, antimicrosomal, antiadrenal, and antimelanocyte antibodies, and rheumatoid factor. Autoantibodies also have been found in patients with CMC who do not have clinical endocrinologic disease.

Figure 143-5 This 3-year-old child with hypothyroidism had oral thrush, intertriginous candidiasis, verrucous crusting on the scalp and face, and candidal onychomycosis. The warty growths shown in the photograph consisted of dried pus and serum, and grew only *Candida albicans*.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT. Candidal lesions in patients with CMC generally respond to systemically administered azole antifungal agents (itraconazole, fluconazole) or terbinafine.[38] Ketoconazole is no longer used because of the risk of hepatitis. Patients who are resistant usually respond to amphotericin B with or without flucytosine. Cutaneous granulomas often are less responsive despite clearance of infection. Recurrences are common, and the antifungal agents must be used intermittently. The drugs have no effect on the abnormal cell-mediated immunity. All patients with CMC should have an annual endocrine evaluation and patients with documented endocrinopathy or a family history of APECED should be monitored more closely. Patients who have a history of infections other than candidal should have further evaluation of their immune status.

CARTILAGE–HAIR HYPOPLASIA SYNDROME

CARTILAGE–HAIR HYPOPLASIA SYNDROME AT A GLANCE

- Synonym: metaphyseal chondrodysplasia McKusick type.
- Autosomal recessive disorder, common in Amish and Finnish populations.
- Mutations in the RNA component of a ribonucleoprotein endoribonuclease, leading to defective cell-mediated and humoral immunity.
- Characterized by fine, sparse hypopigmented hair, short-limbed dwarfism.
- Supportive treatment with appropriate antibiotic use, bone marrow transplant corrects immune deficiency but not dermis or cartilage.

COMBINED ANTIBODY AND T-CELL DEFICIENCY

HYPERIMMUNOGLOBULIN M SYNDROME

HYPERIMMUNOGLOBULIN M SYNDROME AT A GLANCE

- Most cases of hyperimmunoglobulin M syndrome have the X-linked recessive form with deficiency of CD40 ligand; common clinical features are recurrent sinopulmonary and gastrointestinal infections, oral ulcerations, and verrucae.
- Autosomal recessive hyperimmunoglobulin M syndrome, except CD40 deficiency, does not have a susceptibility to opportunistic infections and have lymphoid hyperplasia.

WISKOTT–ALDRICH SYNDROME

WISKOTT–ALDRICH SYNDROME AT A GLANCE

- X-linked recessive.
- Mutations in Wiskott–Aldrich syndrome protein gene.
- Recalcitrant dermatitis.
- Recurrent pyogenic infections.
- Hemorrhage due to thrombocytopenia and platelet dysfunction.
- Therapy: bone marrow stem cell transplantation.

EPIDEMIOLOGY. Wiskott–Aldrich syndrome (WAS) is an X-linked recessive disorder with an incidence of approximately 4 per million male births.[75]

PATHOGENESIS. The defective gene is *WASP,* mapped to Xp11.22–11.23, which encodes WASp, a hematopoietic specific cytoplasmic protein that functions in signaling and cytoskeletal organization. WASp couples signals arising at the cell membrane with reorganization of the cellular cytoskeleton, resulting in cellular activation and promotion of cell motility. Mutations in WASp affect organization of the immunologic synapse and T-cell activation, T and B lymphocyte migration, and initiation of the primary antibody response.[76] There is a strong phenotype–genotype correlation; classic WAS occurs when WASp is absent or truncated, while X-linked thrombocytopenia occurs when mutated WASp is expressed.[77] The atopic dermatitis is likely associated with the observed skewing of $CD4^+$ T cell differentiation towards Th2 cells with suppression of Th1 and regulatory T cells (Treg) differentiation.[78] Given the expression of WASp on epidermal Langerhans cells, abnormal interactions of Langerhans cells with T cells and ability of Langerhans cells to move to the lymph node after antigen stimulation may be involved as well.

WAS patients have decreased function and number of both T- and B-lymphocytes, beginning in the first years of life.[79] The lymphocytes of patients with WAS lack microvilli formed by actin bundles, resulting in defective chemotaxis and, in some patients, there is decreased expression of sialoglycoproteins (e.g., CD43 and others) on lymphocytes and platelets. Defects in humoral immunity include abnormal serum Ig and decreased antibody response to polysaccharide antigens. WAS patients also have defects in NK cell cytotoxicity, dendritic cell migration, and activation, and impaired macrophage chemotaxis.[76]

CLINICAL FINDINGS. The classic triad of WAS is (1) hemorrhage due to thrombocytopenia and platelet dysfunction, (2) recurrent pyogenic infections, and (3) recalcitrant dermatitis, but this triad appears in only 25% of patients.[80] The bleeding diathesis is the most common manifestation of mutations in WAS, present in 84% of patients[79] and often manifests initially during the first weeks or months of life with bloody diarrhea. Epistaxis, hematemesis, hematuria, mucocutaneous petechiae, and intracranial hemorrhage also may occur. Recurrent bacterial infections begin in infancy as levels of placentally transmitted maternal antibodies diminish. These infections include furunculosis, conjunctivitis, otitis media and otitis externa, pansinusitis, pneumonia, meningitis, and septicemia. Infections with encapsulated bacteria such as *Pneumococcus*, *Haemophilus influenzae*, and *Neisseria meningitidis* predominate. Patients are also susceptible to infections due to herpes and other viruses and to *Pneumocystis jiroveci*.

The atopic dermatitis associated with WAS, which occurs in approximately 80% of patients,[75] usually develops during the first few months of life and may be quite severe. The face, scalp, and flexural areas are the most severely involved, although patients commonly have widespread involvement with progressive lichenification. The eruption may be more exfoliative than that of atopic dermatitis in individuals without WAS, and excoriated areas frequently have serosanguineous crusts (Fig. 143-6). Secondary bacterial infection of eczematous lesions is common, as are eczema herpeticum (see eFig. 143-6.1 in online edition) and molluscum contagiosum. IgE-mediated allergic problems, such as urticaria, food allergies, and asthma, are seen in addition to the atopic dermatitis.

As many as 40% of patients with WAS develop an autoimmune disorder.[81] The most common are vasculitis (particularly involving the skin, GI tract, brain, and heart) in 20% of patients, autoimmune

Figure 143-6 Severe atopic dermatitis in a boy with Wiskott–Aldrich syndrome. Note the serosanguineous crusting.

hemolytic anemia in 14%, and IgA nephropathy in up to 10% of patients.[82] Other immune-mediated cutaneous manifestations are angioedema, dermatomyositis, pyoderma gangrenosum, and erythema nodosum.[81] Hepatosplenomegaly is common, and lymphadenopathy, transient arthritis, and joint effusions are present occasionally.

The thrombocytopenia of WAS is persistent, and platelet counts may range from 1,000 to 80,000 platelets per µL. A platelet count of <70,000 is required for formal diagnostic criteria. The platelets are small, and platelet aggregation is defective. Levels of IgM and sometimes, IgG, are low, and isohemagglutinins are absent. IgA, IgE, and IgD levels usually are elevated. Eosinophilia, leukopenia, and lymphopenia are also seen. Delayed hypersensitivity skin-test reactivity is diminished, and patients fail to respond to polysaccharide antigens. WASp can be detected by flow cytometry using intracellular staining with an antibody to WASp and sequencing of the *WASP* gene can confirm the diagnosis of WAS or X-linked thrombocytopenia, which results also from mutations in the *WASP* gene that do not affect immune function.[76] Mutation analysis allows for prenatal diagnosis.[83]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT. Therapeutic interventions allow some patients with WAS to survive into adulthood; however, a significant proportion die before the age of 10 years due to infections secondary to hemorrhage, malignancies, or the complications of transplantation.[75,84,85] Thirteen percent of patients with WAS develop lymphoreticular malignancies,[80] especially non-Hodgkin lymphoma, with a predominance of extranodal and brain involvement. Development of autoimmune hemolytic anemia is a poor prognostic factor and associated with the development of lymphoid malignancies; overall 25% of patients with autoimmunity develop a malignancy.[82] Ten percent of patients die from these malignancies, usually as adolescents or young adults.

Appropriate antibiotics, immunizations, and transfusions of platelets and plasma decrease the risk of fatal infections and hemorrhage. Ig replacement therapy is useful in some patients. Splenectomy has been advocated to ameliorate the bleeding abnormality in patients with recurrent severe hemorrhage, but this procedure increases the risk of infection from encapsulated bacterial organisms. Bone marrow or stem cell transplantation is the treatment of choice for patients with recurrent problems, especially significant autoimmunity. Full engraftment results in normal platelet number and function, normal immunologic status, and clearance of the dermatitis (T lymphocyte engraftment). The 5-year survival rate with HLA-matched sibling donors is 87%.[80] Topical glucocorticoid preparations and Ig replacement may improve the dermatitis, and chronic administration of oral acyclovir is appropriate for patients with recurrent eczema herpeticum.

SEVERE COMBINED IMMUNODEFICIENCY

SEVERE COMBINED IMMUNODEFICIENCY AT A GLANCE

- Heterogeneous group of X-linked and autosomal recessive disorders with deficient cell-mediated and humoral immunity.
- Failure to thrive in early infancy; diarrhea; recurrent mucocutaneous candidiasis, bacterial and viral infections; risk of graft-versus-host disease.
- Transplantation may prevent death during infancy.

CLINICAL FINDINGS. Infants with SCID usually fail to gain weight by 3–6 months of age, following the onset of recurrent sinopulmonary and skin infections. Persistent mucocutaneous candidiasis is often present at the time of diagnosis, and systemic candidal infections occur occasionally. Patients with SCID also may have chronic diarrhea and malabsorption caused by viral infections. *P. jiroveci* pneumonia (PCP) is often a presenting feature. Although bacterial infections usually respond to systemic antibiotics, viral infections tend to be fatal. Infants with SCID lack palpable lymphoid tissue despite recurrent infections.

In addition to cutaneous bacterial and candidal infections, the most common cutaneous eruptions are morbilliform or resemble seborrheic dermatitis. In some infants with SCID, biopsy sections show GVHD (see Chapter 28). GVHD may result from in utero exposure to maternal lymphocytes, from transfusion with nonirradiated blood products, or may follow

TABLE 143-4
Subtypes of Severe Combined Immunodeficiency

Lymphocyte Profile	Disorder	Gene	Gene Product Function
T–/B–/NK–	ADA deficiency[a,b] PNP deficiency	*ADA* *PNP*	Enzyme necessary for detoxification of metabolic products of the purine salvage pathway that cause lymphocytes to undergo apoptosis Enzyme necessary for detoxification of metabolic products of the purine salvage pathway that cause lymphocytes to undergo apoptosis: located downstream from ADA
T–/B–/NK+	RAG 1 or 2[c] Artemis deficiency[d,e] LIG4 syndrome[e,93]	*RAG1/RAG2* *Artemis* *LIG4*	Required for somatic V, D, and J rearrangements during Band T-cell development Required for DNA repair during somatic V, D, and J rearrangements during B- and T-cell development Ligase required for ATP-dependent repair of double-stranded DNA
T–/B+/NK–	X-linked severe combined immunodeficiency[a,f] Janus protein kinase deficiency[f]	*IL2RG* *JAK3*	Common γ chain of IL-2, -4, -7,-9,-15, and -21 Tyrosine kinase; primary signal transducer from common γ chain
T–/B+/NK+	IL-7 receptor (IL-7R) deficiency T-cell receptor/CD3 complex deficiency CD45 deficiency[92] Winged helix nude deficiency	*IL7R* *CD3δ* and *CD3ε* *PTPRC* *WHN*	α Chain of IL-7 receptor Facilitates expression of T-cell receptor/CD3 complex; block at pre-T-cell receptor stage of development Phosphatase that regulates immune cell signaling Defect in thymic development. Other Defects in T Cell Development			
$CD4^+$ $CD8^-$ /B+/NK+	CD8 deficiency[94] ZAP-70 deficiency MHC class I deficiency/ TAP deficiency (bare lymphocyte syndrome I)	*CD8A* *ZAP-70* *TAP1* *TAP2*	Promotes survival and differentiation of activated T cells to memory $CD8^+$ T cells Signaling tyrosine kinase Transporter associated with antigen processing, transports peptides to assemble the class I molecule, dysregulated NK cells
$CD4^{low}$ $CD8^+$ /B+/NK+	MHC class II deficiency (bare lymphocyte syndrome II)	*CIITA* *RFXB* *RFX5* *RFXAP*	Defects in the transactivating factors of MHC II molecules, nonfunctional CD4 T cells if present
T+/B+/NK+	T-cell receptor/CD3 complex deficiency	*CD3γ*	Chain facilitates expression of T-cell receptor/CD3 complex

ADA = adenosine deaminase; ATP = adenosine triphosphate; IL = interleukin; MHC = major histocompatibility complex; NK = natural killer cell; PNP = purine nucleoside phosphorylase; RAG = recombination activating gene; TAP = transporter associated with antigen processing.
[a]Most common severe combined immunodeficiency defects. X-linked severe combined immunodeficiency accounts for approximately 50% of patients. Adenosine deaminase deficiency accounts for approximately 20% of patients.
[b]Eighty-five percent to 90% of patients present in infancy with severe immunodeficiency; one-half have skeletal deformities, neurologic symptoms, behavior problems, and decreased IQ.
[c]Deletions/frameshift mutations of *RAG1 /RAG2* genes result in severe combined immunodeficiency phenotype. Less severe mutations result in Omenn syndrome, clinically distinct from other forms of severe combined immunodeficiency. Mutations in other genes may lead to the Omenn phenotype and immunodeficiency.
[d]Common genetic defect seen in Athabascan-speaking Native Americans, the defect is called *SCIDA* in this population. Gene frequency may be as high as 2%. These patients have a higher incidence of oral/genital ulcers.
[e]Both *Artemis* and *LIG4* mutations lead to hypersensitivity to irradiation.
[f]Highest risk of human papillomavirus infections after transplantation may reflect a persistent abnormality in expression on keratinocytes despite transplantation.[195]

transplantation. Patients with GVHD most commonly present acutely with morbilliform erythema, papular dermatitis, or diffuse erythroderma. The face, neck, palms, and soles are usually affected initially, before the eruption becomes generalized. Severe cases are complicated by diffuse bullae or toxic epidermal necrolysis. The clinical presentation of GVHD from maternal engraftment (without transplantation) is indistinguishable from the clinical presentation of GVHD from transplantation, but histopathologic features differ.[98] Biopsy sections from GVHD secondary to maternal engraftment show psoriasiform hyperplasia with parakeratosis and variable spongiosis in contrast to the vacuolar interface pattern observed in conventional

GVHD.[98] Overall, 83% of SCID patients with maternal engraftment develop skin manifestations.[98] Oral and genital ulcerations are also seen in SCID, particularly in Athabascan-speaking American Indian children with a defect in the *Artemis* gene.[99] Patients with Omenn syndrome show erythroderma, hepatosplenomegaly and lymphadenopathy with eosinophilia and increased IgE production. B cells tend to be undetectable, and T cells, although often increased in number, are nonfunctional. Recently, Omenn syndrome has been shown to be a phenotype with several underlying genetic bases. Most patients have RAG1/RAG2 mutations, but the phenotype of Omenn syndrome has been described in patients with mutations in Artemis and IL7R.[100–102] Two individuals with CHH and another with complete DGS also showed features of Omenn syndrome.[103–104]

ECTODERMAL DYSPLASIA WITH IMMUNODEFICIENCY

ECTODERMAL DYSPLASIA WITH IMMUNODEFICIENCY AT A GLANCE

- Mutations in nuclear factor κB essential modulator, leading to abnormal nuclear factor κB signaling.
- Characteristic facies of hypohidrotic ectodermal dysplasia.
- Often severe immunodeficiency; bacterial, atypical mycobacterial, and viral infections are common.
- Therapy: transplantation.

EPIDEMIOLOGY. X-linked recessive transmission is most common with an estimated incidence of 1:250,000 live male births.[108] An autosomal dominant form of ectodermal dysplasia with immunodeficiency has also been described.[109]

ETIOLOGY AND PATHOGENESIS. Several genetic disorders result from gene mutations in NEMO and lead to abnormal nuclear factor κB (NF-κB) signaling (see Section "Hypohidrotic Ectodermal Dysplasia" in Chapter 142, and Section "Incontinentia Pigmenti" in Chapter 73). One of these, hypohidrotic ectodermal dysplasia with immunodeficiency, results from hypomorphic mutations in the *NEMO* gene [also called *ectodermal dysplasia, anhidrotic, with immunodeficiency* (EDA-ID), or *hyperimmunoglobulinemia M, immunodeficiency, X-linked with ectodermal dysplasia*]. NF-κB is recognized as a DNA-binding factor,[110] and its ability to transcribe genes is regulated by a cytoplasmic inhibitor, IKB. NF-κB signaling affects inflammation, apoptosis, development, and immunity.[111,112] NF-κB activation requires phosphorylation of IKB by IKB kinase (IKK). IKK is composed of two catalytic components (IKKα and IKKβ) and a regulatory subunit, IKKγ or NEMO. NEMO has no catalytic function, but is the structural scaffold that supports the IKK complex.[111] When NEMO is absent or defective, no functional IKK complex is formed and, as a result, NF-κB cannot translocate to the nucleus and activate gene transcription.

The hypomorphic mutations that cause EDA-ID allow early survival in males, in contrast to the large deletions in *NEMO* (usually of exons 4 to 10) that lead to incontinentia pigmenti in carrier females and fetal death in affected males (see Chapter 73). Female carriers of hypomorphic *NEMO* mutations often show mild features of incontinentia pigmenti, but may also express an incontinentia pigmenti phenotype with transient immunodeficiency.[113] In boys with hypomorphic mutations of *NEMO*, the ectodermal dysplasia phenotype results from impaired NF-κB signaling.[114] Immunodeficiency results from impaired NF-κB activation in response to Toll-like receptor (TRL), interleukin-1 receptor and tumor necrosis factor (TNF) α receptor signaling.[115] Gain of function mutations in IκBα, the component of the inhibitor of NF-κB that is phosphorylated by IKK, lead to an autosomal dominant form of ectodermal dysplasia with a distinct immunologic phenotype,[114] characterized by a profound T-cell deficiency,[109] but normal natural killer (NK) cytotoxicity and responses to *Mycobacteria*. Mutations in *NEMO* have also been reported that cause immunodeficiency without the ectodermal dysplasia phenotype.[116]

CLINICAL FINDINGS. Affected patients present with classic characteristics of hypohidrotic ectodermal dysplasia (Fig. 143-7). These include the characteristic

Figure 143-7 Ectodermal dysplasia with immunodeficiency gene mutation. This boy with a hypomorphic mutation in *NEMO* showed failure to thrive, slightly exfoliative dermatitis, and the typical facial features of hypohidrotic ectodermal dysplasia. Note the small chin, the "pouty" lower lip, thin upper lip, small pinched nose with malar hypoplasia. His mother had a pigmented streak following a line of Blaschko, typical of that seen in incontinentia pigmenti. (Used with permission from Dr. Anthony Mancini.)

facies, hypotrichosis or atrichia, hypohidrosis (leading to heat intolerance), hypodontia or anodontia with conical incisors, and associated dermatitis (see Chapter 142).[66,108,116–118] A subset of patients has associated osteopetrosis and lymphedema in association with severe immunodeficiency. Boys with immunodeficiency from *NEMO* mutations without the features of hypohidrotic ectodermal dysplasia have also been described.[119] In a recent analysis of 72 patients with *NEMO* mutations, only 77% had ectodermal dysplasia.[120] Bacterial infections early in infancy are common, particularly sepsis, pneumonia, otitis, sinusitis, and lymphadenitis. Recurrent pneumonias may lead to bronchiectasis. Common pathogens include *Streptococcus pneumoniae*, *H. influenzae*, *Klebsiella*, *Salmonella*, and *Pseudomonas.* Infections with atypical *Mycobacteria* and viruses, including cytomegalovirus (systemic and GI involvement), herpes simplex virus, molluscum contagiosum, human papillomavirus, and *Pneumocystis carinii,* are also reported.[66,108,117]

The immunodeficiency is often severe, but its characteristics are variable with an apparent genotype–phenotype correlation that can be further identified by in vitro reconstitution of the mutations.[119] Immune dysfunction includes impaired B-cell class switching with hypogammaglobulinemia (and often increased levels of IgM and/or IgA), impaired specific antibody production (particularly to polysaccharide antigens), deficient NK cell cytotoxicity, poor cytokine production in response to CD40 signaling and autoinflammation, especially of the gut.[108,118,120] Biopsy of skin may show evidence of keratinocyte apoptosis, reflecting the dysfunction in NF-κB signaling, and must be differentiated from GVHD.

TREATMENT AND PROGNOSIS. There is an increased mortality with 36% of patients dying at a mean age of 6.4 years.[120] Therapy is guided by the patient's clinical and immunologic phenotype. Ectodermal dysplasia is treated supportively (see Chapter 142). Patients with impaired antibody production may benefit from Ig replacement. All infections (bacterial and viral) should be treated aggressively with the appropriate antibiotics/antivirals. Prophylaxis for both *P. jiroveci* and *Mycobacterium avium-intracellulare* should be considered.[108] Stem cell transplantation may lead to immune reconstitution.[121] The mothers and sisters of these patients should be offered genetic testing for the *NEMO* mutation and counseling.

ATAXIA-TELANGIECTASIA

EPIDEMIOLOGY. Ataxia-telangiectasia [AT; Online Mendelian Inheritance in Man (OMIM) #208900], also called *Louis–Bar syndrome*, is an autosomal recessive disorder with an incidence of approximately 1:40,000 and a carrier rate of up to 1%. Carriers have an increased risk of breast cancer, hematologic malignancies,[122] and ischemic heart disease, with a reduced life expectancy of approximately 8 years.[123] These heterozygotes show an increased risk of chromosomal breaks after exposure to irradiation in vitro, suggesting that mammograms in known carriers of AT are contraindicated.

ATAXIA-TELANGIECTASIA AT A GLANCE

- Autosomal recessive disorder with mutations in *ataxia-telangiectasia mutated (ATM).*
- Early onset of ataxia with progressive neurologic deterioration; conjunctival. telangiectasia first appears in preschool years in most patients.
- Sinopulmonary infections, lymphoreticular neoplasia.
- Deficiency of IgA, IgE, IgG_2, IgG_4; variable manifestations of T-cell deficiency; high levels α-fetoprotein; chromosomal breaks; sensitive to irradiation.

CLINICAL FINDINGS. Characteristic oculocutaneous telangiectasias begin near the ocular canthi and progress across the bulbar conjunctivae (Fig. 143-8). These telangiectasias usually appear when patients are 3–6 years of age; rarely have they been described at earlier ages. Cutaneous telangiectasias subsequently may develop on the malar prominences, ears, eyelids, anterior chest, and popliteal and antecubital fossae, and the dorsal aspects of the hands and feet (Fig. 143-9). The telangiectasias may be subtle and resemble fine petechiae, especially in the flexural areas. The development of telangiectasias may be related to sun exposure, because ocular, but not cutaneous, telangiectasias develop in affected dark-skinned children. The development of telangiectasias may relate, at least in part, to the sensitivity of some AT strains to ultraviolet (UV) light.[127]

Progeric changes of the skin, including xerosis and gray hair, occur in 90% of patients.[128] During adolescence, the facial skin may become progressively more atrophic and sclerotic, causing a mask-like appearance. Occasionally, the ears, arms, and hands also become sclerodermatous. The hair may be diffusely gray by

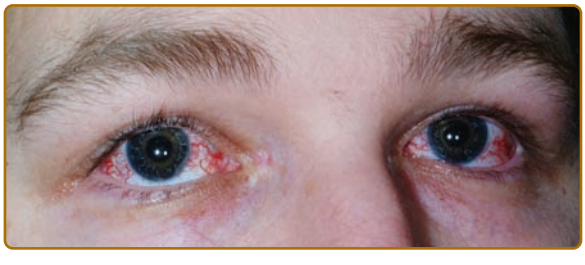

Figure 143-8 Bulbar conjunctival telangiectasias in a patient with ataxia-telangiectasia.

Figure 143-9 Ataxia-telangiectasia. Telangiectasias inside and on the helix.

Figure 143-10 Noninfectious granulomatous dermatitis of a patient with ataxia-telangiectasia. These persistent lesions tend to ulcerate, but often respond to injections of triamcinolone acetonide.

adolescence, and subcutaneous fat is generally lost in childhood. Recurrent severe impetigo often develops. Seborrheic dermatitis occurs in many patients, and the associated blepharitis may lead to a diagnosis of blepharoconjunctivitis rather than ocular telangiectasia. Mottled hyper- and hypopigmentation commonly occur and, together with the telangiectasias and atrophy, can resemble the poikiloderma of radiodermatitis, actinic damage, or scleroderma. Other pigmentary changes include café-au-lait spots that may be found in a dermatomal distribution,[129] multiple ephelides, and vitiligo. Hypertrichosis of the arms and legs, alopecia areata, multiple warts, atopic dermatitis, keratosis pilaris, nummular eczema, and acanthosis nigricans have also been described in association with AT. Among the most common cutaneous manifestations are noninfectious cutaneous granulomas (Fig. 143-10).[129] These persistent, atrophic, and often ulcerative lesions are often mistaken for other granulomatous processes, including sarcoidosis, necrobiosis lipoidica diabeticorum, granuloma annulare, and granulomatous dermatitis.

Usually, the progressive cerebellar ataxia first becomes apparent during infancy (median age, 1.2-years-old) with swaying of the head and trunk and apraxia of eye movements, often years before skin or conjunctival abnormalities develop. In childhood, dysarthric speech, drooling, choreoathetosis, and myoclonic jerks become prominent. The diagnosis of AT is usually made at a median age of 7 years, after appearance of the mucocutaneous telangiectasia. Patients usually require a wheelchair by their teenage years.

Recurrent bacterial and viral sinopulmonary infections occur in up to 80% of patients; these are the most common cause of death, which is usually from bronchiectasis and respiratory failure. Approximately 75% of patients with AT may have growth retardation and endocrine disorders, especially ovarian agenesis or testicular hypoplasia and insulin-resistant diabetes.

Neoplasia occurs in 40% of surviving adolescents or young adults, although lymphoid malignancy has been described as the presenting sign during infancy. Most common are lymphomas (especially B cell; 200-fold increased risk) and leukemia (especially T-cell chronic lymphocytic; 70-fold increased risk).[130,131] Basal cell carcinomas have been reported in young adults.

Patients with AT tend to have both humoral and cellular immunologic abnormalities. Serum IgA and IgE are absent or deficient in 70 and up to 80% of patients, respectively. Circulating anti-IgA antibodies are common in AT patients with IgA deficiency. Approximately 60% of patients have selective IgG_2 and IgG_4 deficiencies. Defective cell-mediated immunity is found in 70% of patients, particularly lymphopenia and deficient in vitro responses to antigens and mitogens[132]; T cells bearing γ/δ receptors are increased in number, while $CD4^+$ T cells tend to be reduced.

Virtually all patients have elevated levels of α-fetoprotein (which is particularly significant after 2 years of age), and many have detectable carcinoembryonic antigen. Patients with AT often have elevated hepatic transaminases (40% to 50%), and glucose intolerance. DNA is exquisitely sensitive to X-irradiation, and patients also show an increased rate of telomere shortening. Spontaneous chromosomal abnormalities (fragments, breaks, gaps, and translocations) occur 2–18 times more frequently in patients with AT than in

normal individuals and mainly involve chromosomes 2, 7, and 14. Rearrangements of chromosomes 7 and 14, and especially 14:14 translocations, seem to predict the development of lymphoreticular malignancy including leukemia. The thymus is absent or hypoplastic, and the spleen may be reduced in size.

Among techniques to confirm diagnosis are an elevated serum α-fetoprotein level in children older than 8 months of age, analysis of radio-resistant DNA synthesis (which demonstrates an abnormal S phase checkpoint), radiosensitivity testing with the colony survival assay, immunoblotting for the ATM protein, assessment of ATM kinase activity, and molecular genetic testing.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT. Therapy for AT is supportive and includes administration of antibiotics for infection, physiotherapy for pulmonary bronchiectasis, physical therapy to prevent contractures in patients with neurologic dysfunction, and sunscreens and sun avoidance to diminish actinic-like changes. Patients should be aggressively screened for malignancy, especially after the first decade of life. Intralesional injections of triamcinolone have helped to promote healing of the painful associated ulcerations, although the lesions do not clear completely with treatment. Autopsy findings indicate that approximately 50% of the patients die from pulmonary disease, the most common cause of death. Lymphoreticular malignancies, including lymphoid leukemia, are the second most common cause of death (15% of patients with AT). The remaining patients tend to die of both pulmonary disease and malignancy. Therapeutic radiation and radiomimetic chemotherapeutic agents, especially bleomycin, may lead to extensive tissue necrosis. The administration of small doses of other chemotherapeutic drugs and low-dose, fractionated radiation is the least harmful means of managing these malignancies. In a small subset of patients with milder AT, treatment with aminoglycosides increased ATM gene function.[133] Death usually occurs by late childhood or early adolescence; the oldest surviving patient died at the age of 50 years. Prenatal diagnosis is currently best achieved by DNA analysis.

DISORDERS OF PHAGOCYTOSIS AND CELL KILLING

Patients with defects in phagocyte function or cell killing typically present during infancy or childhood with recurrent, unusual, and/or difficult to clear bacterial infections. Infections commonly seen include those of skin or mucosa, lung, lymph nodes, deep tissue abscesses, or childhood periodontitis. The most distinctive disorders of phagocytosis and cell killing are chronic granulomatous disease (CGD), leukocyte adhesion deficiencies, hyperimmunoglobulinemia E syndrome (HIES), and the silvery hair syndromes with immunodeficiency.[134] However, several disorders with neutropenia, neutrophil dysfunction, or cytokine dysfunction also lead to a decreased ability to engulf and/or kill organisms. These are reviewed in Table 143-5.

CHRONIC GRANULOMATOUS DISEASE

CHRONIC GRANULOMATOUS DISEASE AT A GLANCE

- Group of disorders in which defective production of reactive oxygen intermediates impairs intracellular killing of microorganisms.
- X-linked or autosomal recessive.
- Mutations in genes that encode components of nicotinamide adenine dinucleotide phosphate oxidase system.
- Pneumonias, lymphadenopathy, hepatosplenomegaly, and skin infections.
- Granulomas, most commonly of lungs and liver.

EPIDEMIOLOGY. CGD is a heterogeneous group of X-linked and autosomal recessive disorders. Ninety percent of patients with the disorder are male, and the overall incidence is 1 in 200,000 to 250,000 persons. X-linked disease with deficiency of $gp91^{phox}$ occurs in 70% of affected individuals with signs and symptoms manifesting in the first year of life. Individuals with autosomal recessive disease (30%) present later in life with milder signs and symptoms; 56% of these patients have a deficiency of $p47^{phox}$ and deficiencies in $p22^{phox}$ and $p67^{phox}$ account for the remaining cases.[135]

PATHOGENESIS. CGD is caused by defects in the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, the enzyme complex responsible for the generation of superoxide.[136] Normal bactericidal activity after phagocytosis requires the NADPH oxidase system, which consists of NADPH, an unusual phagocyte cytochrome b (b_{558}), and cytosolic proteins. In patients with CGD, this membrane-associated NADPH oxidase system fails to produce superoxide and other toxic oxygen metabolites. Until recently, it was thought that the oxidative metabolites themselves were solely responsible for killing intracellular organisms. A new paradigm for NADPH oxidase-mediated microbial killing suggests that the oxidative molecules act as intracellular signaling molecules, activating the release of primary granule proteins neutrophil elastase and cathepsin G inside the phagocytic vacuole that in turn are necessary to kill microbes.[137] Evidence supports a dual role for NADPH oxidase, as oxidative metabolites have direct microbicidal effects.[138] and activate other microbicidal pathways.

TABLE 143-5
Other Disorders of Phagocytosis or Cell Killing

Disorder	Genetics	Gene	Functional Consequence	Clinical Findings
Neutropenia				
Cyclic neutropenia	AD	*ELA2*	Defects in neutrophil elastase	Cycles of neutropenia and monocytopenia, about every 3 week. Oral ulcers and fever when low.
Severe congenital neutropenia	AD AD	*ELA1* *GF11*	Defects in neutrophil elastase lead to abnormal neutrophil trafficking Repressor of elastase transcription leads to accumulation of elastase	Neutropenia, myelodysplastic syndrome, and acute myelogenous leukemia. Neutropenia and lymphopenia. Myeloid progenitors in circulation.
Shwachman–Diamond syndrome (SBDS)	AR	*SBDS*	SBDS protein participates in metabolism of ribosomal RNA	Pancytopenia with myelodysplastic syndrome and acute myelogenous leukemia. Pancreatic insufficiency. Chondrodysplasia.
WHIM[160]	AD	*CXCR4*	Receptor regulates development and migration of neutrophils; affects viral entry into cells	Chronic cutaneous and cervical warts, antibiotic-responsive bacterial sinopulmonary infections; often low Ig levels, peripheral neutropenia in the face of bone marrow hypercellularity (myelokathexis), and distinctive neutrophil morphology.
Cytokine Defects				
	AR	*IL12B*	Absence of component of IL-12 and IL-23 that stimulates IFN-γ production	Severe mycobacterial infections. Disseminated Bacille Calmette-Guérin after vaccination. Severe *Salmonella* infections.
	AR	*IL12RB1*	β1 chain of IL-12 and IL-23 receptors	
	AR, AD	*IFNGR1*	Affects ligand binding to IFN-γ receptor	
	AR	*IFNR2*	Affects IFN-γ receptor signaling	
	AR, AD	*STAT1*	Affects transcription in IFN receptor signaling	Also severe viral infections.
	AR	*STAT5B*	As in Stat1, but also growth hormone receptor signaling	Also growth hormone insensitivity.
Defects of Killing				
Myeloperoxidase deficiency	AR	*MPO*	Myeloperoxidase required for bacterial killing	Especially *Staphylococcus aureus* and candidal infections. May be asymptomatic.
Specific granule deficiency	AR	*C/EBPE*	C/EBPε transcription factor required for granulocyte differentiation	Recurrent bacterial infections. Neutrophils with two lobes.

AD = autosomal dominant; AR = autosomal recessive; IFN = interferon; IL = interleukin; WHIM = warts, hypoimmunoglobulinemia, infections, myelokathexis.

In X-linked kindreds the *CYBB* gene encoding the gp91^{phox} (phagocyte oxidase) subunit of cytochrome b_{558} is mutated. Patients with autosomal recessive CGD are deficient in NADPH oxidase cytosolic factors (p47^{phox} or p67^{phox}); occasionally, the p22^{phox} (γ subunit of cytochrome b_{558}), which contains a docking site for p47^{phox}, is deficient. It is thought that cytochrome b_{558} is the membrane attachment site for these cytosolic factors that translocate from the cytosol to the plasma membrane, assembling oxidase components to allow activation of the NADPH oxidase.

The types of microbial organisms that cause infections in patients with CGD require intracellular killing and are usually catalase-positive. Only five organisms are responsible for the overwhelming majority of infections in CGD in North America and Europe: (1) *Staphylococcus aureus*, (2) *Serratia marcescens*, (3) *Burkholderia cepacia*, (4) *Nocardia* spp., and (5) *Aspergillus* spp.[136] The intense humoral and granulomatous responses of CGD are thought to be compensatory in the robust but ineffectual response to organisms.

CLINICAL FINDINGS. Pyodermas with associated regional lymphadenopathy and dermatitis, especially around the nares and ears, usually occur during infancy and sometimes even in affected neonates. Staphylococcal abscesses are found in 40% of patients, particularly of the perianal area. Purulent inflammatory reactions may develop at sites of lymph node drainage or minor cutaneous trauma and heal slowly with scarring. Patients with CGD often develop chronic inflammatory granulomas, most commonly of the lungs and liver. Cutaneous granulomas are nodular and often necrotic. Granulomas can occlude vital structures, especially of

the GI and genitourinary systems. Intraoral ulcerations resembling aphthous stomatitis, chronic gingivitis, perioral ulcers, scalp folliculitis, and seborrheic dermatitis have also been described in many patients. Female carriers for X-linked CGD do not have the increased risk of infections but may have cutaneous lesions of discoid or systemic lupus erythematosus (SLE), Jessner lymphocytic infiltration of the skin, aphthous stomatitis, granulomatous cheilitis, photosensitivity, and/or Raynaud phenomenon.[139]

The lymph nodes, lungs, liver, spleen, and GI tract are the most frequent areas of noncutaneous involvement. Suppurative lymphadenitis with abscess and fistula formation usually affects cervical nodes. Pneumonia occurs in almost all affected children and may lead to abscess formation, cavitation, and empyema. Hepatosplenomegaly has been reported in 80% to 90% of patients; more than 30% of patients develop hepatic abscesses, and staphylococcal liver abscesses are almost pathognomonic to CGD.

Patients with bacterial and *Nocardia* spp. infections tend to be symptomatic and frequently have leukocytosis, anemia, and elevated sedimentation rate. In contrast, lack of fever, normal erythrocyte sedimentation rate, and few symptoms are more common in *Aspergillus* spp. infections. Thus, laboratory values within normal limits do not rule out infection in a CGD patient. Patients show an increased erythrocyte sedimentation rate, hypergammaglobulinemia, leukocytosis, and mild anemia; other immune function tests are otherwise usually normal.

The diagnosis of CGD is made on the basis of assays that rely on superoxide production. The dihydrorhodamine flow cytometry-based test is currently favored and can readily identify patients or carriers of X-linked disease[140]; the ferricytochrome c reduction assay is another quantitative measure of the respiratory burst. The screening test for CGD is the nitroblue tetrazolium (NBT) reduction assay, in which the yellow NBT becomes insoluble, oxidized form (blue formazan) when precipitated with normal oxidative metabolism. Quantitative NBT tests and chemiluminescence assays also may be performed. Immunoblot analysis confirms the absence of the glycoprotein 91^{phox} ($gp91^{phox}$) component; because deficiency of one component of cytochrome b_{558} leads to absence of the other, sequencing of the *gp91*^{phox} or *p22*^{phox} gene is necessary if absence is noted by immunoblot analysis. Immunoblots that show the absence of $p47^{phox}$ or $p67^{phox}$ can be diagnostic.

Biopsy of cutaneous granulomas shows histiocytic infiltrates associated with foreign body giant cells and accumulation of neutrophils with necrosis. Although the histopathologic features of lupus erythematosus-like skin lesions in CGD patients and carriers may resemble those of lupus patients, immunofluorescence examination of lesional skin is usually negative.

PROGNOSIS, CLINICAL COURSE, AND TREATMENT.

Patients with X-linked CGD, $p22^{phox}$ CGD and $p67^{phox}$ CGD tend to have a more severe clinical course compared to patients with $p47^{phox}$ CGD. The mean age of diagnosis of X-linked CGD is 3 years of age, and of autosomal recessive forms 8 years of age. More than 90% of patients with non-$p47^{phox}$ CGD have undetectable levels of superoxide production.[136] Some patients will develop severe infections as early as infancy while others will unexpectedly develop a serious infection typical of CGD later during childhood.

Small foci of localized inflammation may not be associated with fever and may be difficult to detect without vigorous investigation of the lungs, liver, and bones by routine screening radiographs, scans, or ultrasound. Cultures should be performed to identify the infectious agent, and invasive procedures may be necessary to obtain adequate tissue samples. Patients with evidence of infection should be treated empirically with broadspectrum parenteral antibiotics that cover *S. aureus* as well as Gram-negative organisms. Intravenous therapy should be continued for at least 10–14 days, followed by a several-week course of oral antibiotics. Surgical interventions (drainage, debridement) may be required for deeper infections (Table 143-6 Trimethoprim/sulfamethoxazole therapy

TABLE 143-6
Treatment of Chronic Granulomatous Disease

Treatment	Indication	Dose
Trimethoprim-sulfamethoxazole[a] (dicloxacillin if allergic)	Bacterial infections	5 mg/kg/day divided bid
Itraconazole[a]	Fungal infections	100 mg/day if <50 kg; 200 mg/day if >50 kg
Interferon-γ[a]	Infections	50 μg/m^2 subcutaneous 3×/week
Leukocyte transfusion	Life-threatening infections	
Bone marrow transplantation	Life-threatening infections	
Systemic glucocorticoids	Granulomas, particularly if obstructive	
Debridement/drainage/surgical intervention	Abscesses (particularly liver)	

[a]Regardless of genetic subgroup, the current recommendation is to use prophylaxis with trimethoprim-sulfamethoxazole, itraconazole, and interferon-γ.[136]

decreases the incidence of bacterial infection without increasing the incidence of fungal infection. Itraconazole is an effective agent for prophylaxis for fungal infections.[141] Prophylactic IFN-γ has been shown to decrease the number and severity of infections without increasing the incidence of chronic inflammatory complications in both X-linked and autosomal recessive CGD.[142] Use of IFN-γ is not accompanied by any measurable improvement in NADPH oxidase activity; its clinical benefit is related to enhanced phagocyte function and killing by nonoxidative mechanisms.[143] Leukocyte transfusions have been used for rapidly progressive, life-threatening infections. A recent study shows a survival rate of 90% after stem cell transplantation[144] and, therefore, this procedure should be considered for patient with matched related or unrelated donors and for those that have severe, life-threatening infections despite appropriate medical care. Systemic glucocorticoids have been helpful for patients with obstructive visceral granulomas. Prenatal diagnosis has been performed by the NBT slide test and now can be based on molecular analysis.

The prophylactic administration of antibiotics and IFN-γ has reduced the mortality of CGD to about 2% per patient-year for autosomal CGD and 5% for X-linked CGD.[135] The most common causes of death are pneumonia and/or sepsis due to *Aspergillus* or *B. cepacia*.

LEUKOCYTE ADHESION DEFICIENCIES

LEUKOCYTE ADHESION DEFICIENCY AT A GLANCE

- Group of three autosomal recessive and one autosomal dominant disorders.
- Gingivitis and periodontitis.
- Poor wound healing; delayed separation of the umbilical stump and development of pyoderma gangrenosum-like necrotic ulcerations after wounding.
- Life-threatening bacterial and fungal infections.

HYPERIMMUNOGLOBULINEMIA E SYNDROME

EPIDEMIOLOGY. HIES is rare (incidence 1 in 10^6).[148] It is found equally in males and females. Most cases are sporadic or consistent with an autosomal dominant inheritance. Autosomal recessive inheritance has also been described, but patients show different associated features.

HYPERIMMUNOGLOBULINEMIA E SYNDROME AT A GLANCE

- Synonyms: Job syndrome, Buckley syndrome, hyperimmunoglobulin E recurrent infection syndrome.
- Most cases are sporadic or show autosomal dominant inheritance with variable penetrance.
- Classic triad: (1) recurrent staphylococcal skin abscesses, (2) pneumonia with pneumatocele formation, and (3) high serum levels of IgE.
- Other common features are the atopic dermatitis, scoliosis, fractures, and dental abnormalities.
- Sporadic and autosomal dominant cases suffer from a multisystem disorder, affecting the skin, soft tissues, skeletal system, and dentition. Autosomal recessive cases have severe viral infections, lack skeletal and dental involvement, and develop severe neurologic complications.

ETIOLOGY AND PATHOGENESIS. Three different gene defects have been identified in HIES. The most common is a dominant negative mutation in signal transducer and activator of transcription 3 (STAT3)[149,150] and is associated with a severe reduction of Th17 cells.[151] STAT3 signals downstream of IL-6, which together with TGF-β is important for the development of Th17 cells. Autosomal recessive HIES has been shown to result from mutation in *TYK2* in a single patient[152] and with defects in the dedicator of cytokinesis 8 (*DOCK8*), which encodes for a protein that is implicated in the regulation of the actin cytoskeleton.[153,154] In all three types of HIES, there is an absence of Th17 cells, demonstrating the role of this T cell differentiation pathway in immunity to bacterial and fungal organisms. The pathogenesis of other features of HIES is not well known, but probably related to the lack of response or absence of Th17 cells and the resultant cytokine abnormalities.

CLINICAL FINDINGS. The clinical presentation of individual patients with HIES may vary greatly. The neonatal or infantile rash of HIES is often a papulopustular eruption with prominent crusting distributed on the scalp, face, neck, axillae, and diaper area. The most consistent finding on skin biopsy is an eosinophilic spongiotic dermatitis, sometimes centered in the dermal follicles.[155] In other infants, early candidal infections of the skin, mucosae, and nails and/or infantile atopic dermatitis are alternative presentations; in patients with the eosinophilic papulopustules, the

Figure 143-11 Coarse facial features, atopic dermatitis furuncles, and a cold abscess at the glabella in a boy with hyperimmunoglobulinemia E syndrome.

atopic dermatitis commonly follows later in infancy. Superinfection of the dermatitis with *S. aureus* is very common,[156] and patients show high levels of anti-staphylococcal IgE antibodies. Staphylococcal skin infections include impetigo, furunculosis, paronychia, cellulitis, and characteristic "cold" abscesses (see Fig. 143-11) that do not demonstrate the anticipated degree of erythema, warmth, and purulence. The abscesses occur most commonly on the head and neck and in intertriginous areas.

Pulmonary bacterial pneumonia, abscesses, and empyema are the most frequent systemic infections and may result in pneumatoceles that serve as the nidus for bacterial or fungal superinfection. The most common infecting organisms are *S. aureus* and *H. influenzae*. Other than pneumonias, deep-seated infections, bacteremia, and sepsis are rare.[148]

Facial and skeletal abnormalities are common. Patients develop progressive coarsening of facial features (see Fig. 143-11), probably reflecting the skeletal defects, but the recurrent facial pustulation and lichenification from dermatitis may contribute. Distinctive facial features, including prominent forehead, a broad nasal bridge, and wide nasal tip are universally present by the age of 16 years. Dental anomalies include retention of primary teeth and lack of eruption of secondary teeth. Osteopenia is common, and 57% of patients have had at least three pathologic fractures, especially of the long bones, ribs, and pelvis. Scoliosis occurs in 63% of adult patients and hyperextensibility of joints in 68% of patients.[148]

By definition, serum IgE levels must be elevated, but normal levels of IgE increase markedly during childhood. Levels of >2,000 IU/mL are seen in adolescents and adults; considerably lower levels during infancy are seen, given that the upper limit of normal in infants <1-year-old is 12.7 IU/mL and by 5 years of age is 47.1 IU/mL; an IgE level tenfold above the 95th percentile for age is required for diagnosis. Eosinophilia of at least two standard deviations above normal (usually above 700 cells/μL) is also a clinical manifestation. The total white blood cell count is typically normal and often fails to elevate in the setting of acute infection. The most common clinical features and laboratory values of patients with sporadic or autosomal dominant HIES are summarized in Table 143-7.

TABLE 143-7
Characteristics of Hyperimmunoglobulinemia E Syndrome[131]

	Incidence (%)
Immune System	
■ Dermatitis	100
■ Skin abscesses	87
■ Recurrent pneumonia (three or more, proved by X-ray)	87
■ Pneumatoceles	77
■ Mucocutaneous candidiasis	83
Skeletal System	
■ Characteristic fades	83
■ Wide nose	65
■ Failure of dental exfoliation (>three teeth)	72
■ Hyperextensibility	68
■ Recurrent pathologic fractures	57
■ Scoliosis (>10°)	63
Laboratory Values	
■ IgE >2,000 IU/mL or >10 times the age-specific norm	97
■ Eosinophilia (>two standard deviations above the norm)	93

Autosomal recessive disease is characterized by recurrent bacterial and viral infections, autoimmunity and devastating neurologic complications that are often fatal in childhood (see Fig. 143-12). Patients with autosomal recessive HIES show no tendency to form pneumatoceles and have no skeletal or dental abnormalities.[157] Eosinophilia tends to be more severe (e.g., 17,500/μL).[148] These patients have a global defect in T cell activation, which may explain their susceptibility to viral infections (including herpes and molluscum) in addition to bacterial and fungal infections.[154]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT. Given the lack of correlation between serum levels of IgE, eosinophilia, and the susceptibility to severe infections, the clinical course is difficult to predict. Patients with autosomal recessive HIES have a more severe course related to the neurologic complications.[157]

Antistaphylococcal antibiotics are effective for most cutaneous infections in patients with HIE, and oral triazole antifungals treat the mucocutaneous candidiasis. The prophylactic use of antistaphylococcal antibiotics markedly reduces the incidence of skin

Figure 143-12 This boy with autosomal recessive HIES due to a *DOCK8* mutation shows extensive molluscum contagiosum infection on the neck. (Used with permission form Dr. I. Barlan.)

abscesses and pneumonia. The cutaneous and pulmonary abscesses often require incision and drainage and may require partial lung resections. IVIG therapy has been used successfully. IVIG may influence IgE levels due to an increased Ig catabolism or neutralization of the IgE.[148] Ascorbic acid and cimetidine have decreased the number of infections and the chemotactic defect in some patients. Isotretinoin has been reported to eliminate the recurrent staphylococcal abscesses in an isolated patient without any change in immunologic status. Cyclosporine A has also been used with good clinical and laboratory response.[158,159] IFN-γ has shown inconsistent effects on IgE levels and infection susceptibility. Bone marrow transplant has been attempted in typical autosomal dominant HIES with limited success.

WHIM SYNDROME

WHIM (*w*arts, *h*ypogammaglobulinemia, *i*nfections, *m*yelokathexis) syndrome is an immunodeficiency that is characterized by neutropenia, hypogammaglobulinemia, and a susceptibility to infection by human papilloma virus. The disorder results from defects in the chemokine receptor gene *CXCR4*,[160] and thus mature neutrophils are not able to exit the bone marrow (myelokathexis). The susceptibility to human papilloma virus infections suggests an important role for CXCR4 in immunity to this virus.

SILVERY HAIR SYNDROMES: CHÉDIAK–HIGASHI AND GRISCELLI SYNDROMES

The silvery hair syndromes comprise a group of autosomal recessive disorders in which a peculiar metallic sheen to hair and often skin is noted (see also Chapter 73). Of these, Chédiak–Higashi and Griscelli (type 2) syndromes have associated immunodeficiency (Table 143-8). Another syndrome with silvery hair, Elejalde syndrome, does not have associated immunodeficiency and may be allelic with the myosin 5a-deficient form of Griscelli syndrome (GS), with severe associated CNS dysfunction.

CHÉDIAK–HIGASHI SYNDROME

CHÉDIAK–HIGASHI SYNDROME AT A GLANCE

- Autosomal recessive disorder of vesicle trafficking that results in giant organelles, including melanosomes, leukocyte granules, and platelet-dense granules.
- Mutations in *LYST*.
- Silvery hair, often hyperpigmentation on nose and ears, and a variable degree of photophobia and nystagmus.
- Recurrent pyogenic infections and a mild bleeding diathesis.
- An "accelerated phase" with pancytopenia and organomegaly due to lymphohistiocytic infiltration (fatal without hematopoietic stem cell transplantation).
- Progressive neurologic deterioration.
- Therapy: transplantation.

Epidemiology. Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disorder. Parental consanguinity is often reported, and there are approximately 300 reported cases worldwide.

Etiology and Pathogenesis. CHS is caused by mutations in the *LYST* gene, located on chromosome lq42, which encodes a protein required for the final steps of vesicle trafficking and secretion.[161,162] The *LYST* gene is expressed in lysosomes and other secretory organelles (melanosomes, cytolytic granules, and platelet dense granules). Characteristic giant granules are thought to result from altered granule maturation and fusion.[163] Enlarged melanosomes are unable to be transferred to keratinocytes. NK cells and cytotoxic T lymphocytes do not release proteolytic enzymes necessary for target cell killing. Cytotoxic T lymphocyte-associated antigen is trapped in abnormally large vesicles rather than on the cell surface and thus may be unable to regulate T-cell activation, increasing the risk of lymphoproliferative disease.[164] Platelet dense granules are delayed in secretion of storage pools required for normal coagulation. Diminished chemotaxis of neutrophils and monocytes and delayed intracellular microorganism killing are often associated.

Clinical Findings. Patients usually first show manifestations during infancy or early childhood. Pigment abnormalities occur in 75% of patients, particularly the

TABLE 143-8
Characteristics of Griscelli and Chédiak–Higashi Syndromes

	Griscelli (GS1)	Griscelli (GS2)	Griscelli (GS3)	Chédiak–Higashi
Gene defect/protein	*MYO5A*/myosin5a.	*RAB27A*/Rab27a.	a. *Slac2-a/mlph.* b. *MYO5A* F-exon deletion.	LYST/lysosomal transport protein.
Functional consequence	Intracellular organelle transport and neurotransmitter secretion; interacts with Slac2-a/mlph.	GTPase for organelle movement and transfer. Essential for T and NK lymphocyte cytotoxic granule release and target cell death. Interacts with Slac2-a/mlph.	Interacts with both myosin 5a and Rab27 to form a protein complex essential for melanosome movement to melanocytes.	Protein required for final steps of membrane fusion and vesicle trafficking.
Tissue expression	Brain. Not in cytotoxic cells.	Cytotoxic cells. Not in brain.	Slac2-a/mlph is not in cytotoxic cells.	
Clinical features	Silvery metallic hair. Mild skin pigment dilution. Onset of neurologic disorder in infancy.	Silvery metallic hair. Mild skin pigment dilution. Severe immune disorder with hemophagocytic syndrome. Neurologic symptoms are associated with hemophagocytic syndrome and central nervous system infiltration.	Silvery metallic hair.	Silvery metallic hair and skin. Recurrent infections. Bleeding tendencies. Progressive neurologic defects. Immune disorder with hemophagocytic syndrome.
Immune defects	None	T and NK cell function; hypogammaglobulinemia.	None	T and NK cell function, diminished neutrophil chemotaxis and bactericidal activity.
Hair mount	Large, uneven clusters of pigment.	Same as GS1.	Same as GS1.	Granular, evenly distributed pigment.
Skin light microscopy	Pigmentary dilution in keratinocytes, accumulation of melanosomes in melanocytes.	Same as GS1.	Same as GS1.	Pigmentary dilution in both keratinocytes and melanocytes.
Skin electron microscopy	Mature melanosomes filling epidermal melanocytes.	Same as GS1.	Same as GS1.	Reduced numbers of giant melanosomes.
Leukocyte granules	None	None	None	Large, cytoplasmic.

GTPase = guanosine triphosphatase; mlph = melanophilin; NK = natural killer.

silver sheen to the hair (Fig. 143-13A). Ocular hypopigmentation may cause photophobia, and strabismus and nystagmus are common. Visual acuity does not tend to be reduced. The skin is typically fair, but dark slate-colored areas of pigmentation and diffuse speckled hypopigmentation may be seen in the sun-exposed skin of dark-skinned individuals.[165]

Infections can be observed in the newborn period and continue through the lifetime of the patient. Infections most commonly involve the skin, lungs, and respiratory tract where microbes such as *S. aureus*, *Streptococcus pyogenes*, and *Pneumococcus* are prevalent. Deep ulcerations resembling pyoderma gangrenosum have been described.

Neurologic manifestations include muscle weakness, cranial and peripheral neuropathy and progressive neurologic deterioration. CHS patients have also been observed to exhibit a mild coagulation defect. Patients bruise easily, manifest petechiae, and have some mucosal bleeding, although platelet numbers remain normal.

The finding of large cytoplasmic granules in blood leukocytes is highly diagnostic. Hair shafts have evenly distributed small pigment granules (see Fig. 143-13B), in contrast to the irregular, large pigmentary clumping of GS (see Fig. 143-13C). Skin biopsy shows pigmentary dilution in both melanocytes and keratinocytes and electron microscopy reveals giant melanosomes.

Prognosis, Clinical Course, and Treatment.

Hemophagocytic syndrome, an accelerated phase of the disease that resembles lymphoma, occurs by late childhood. Hemophagocytic syndrome is characterized by widespread visceral infiltration by atypical lymphoid and histiocytic cells. This lymphoma-like stage is precipitated by viruses, particularly by EBV

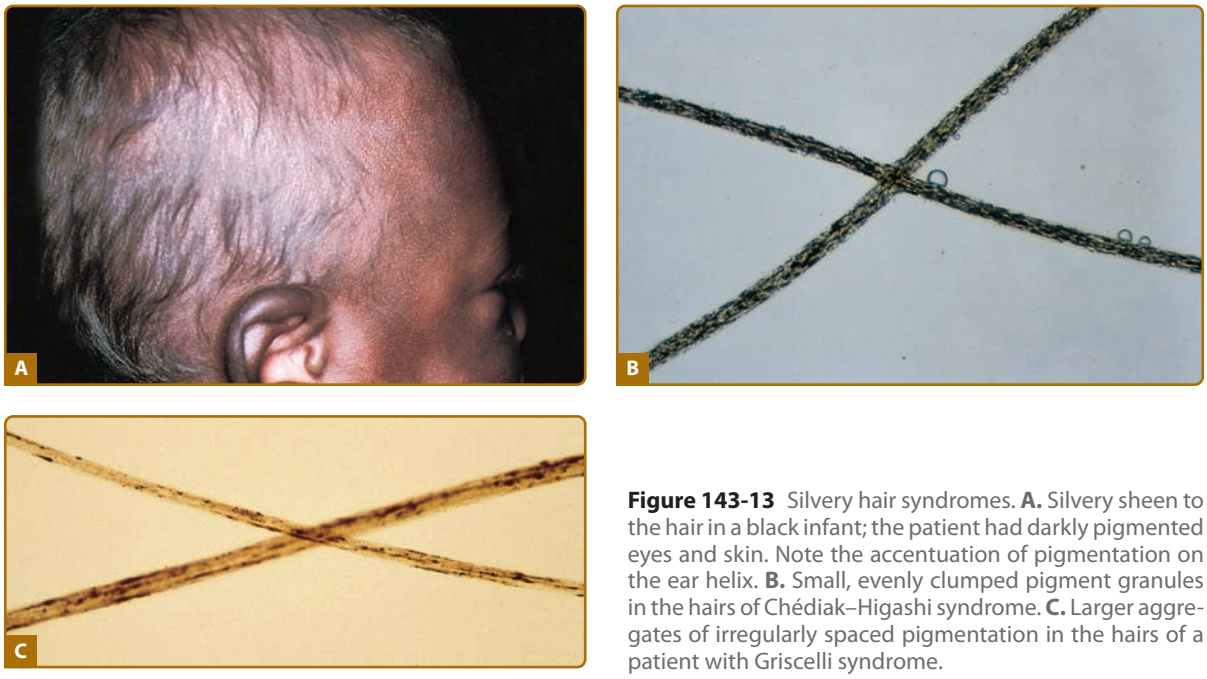

Figure 143-13 Silvery hair syndromes. **A.** Silvery sheen to the hair in a black infant; the patient had darkly pigmented eyes and skin. Note the accentuation of pigmentation on the ear helix. **B.** Small, evenly clumped pigment granules in the hairs of Chédiak–Higashi syndrome. **C.** Larger aggregates of irregularly spaced pigmentation in the hairs of a patient with Griscelli syndrome.

infection. Hepatosplenomegaly lymphadenopathy pancytopenia, jaundice, fever, a leukemia-like gingivitis, and pseudomembranous sloughing of the buccal mucosa are common features.

The hemophagocytic syndrome associated with lymphohistiocytic proliferation of silvery hair syndromes needs to be distinguished from massive lymphoproliferation in other immunodeficiency disorders, particularly X-linked lymphoproliferative disorder (see Section "Antibody Deficiency Disorders"), familial hemophagocytic lymphohistiocytosis, autoimmune lymphoproliferative syndrome, and immunodeficiency due to mutations in the IL-2R. *Familial hemophagocytic lymphohistiocytosis* is a group of autosomal recessive disorders with hemophagocytosis and absence of NK cell cytotoxicity that tends to be fatal without early stem cell transplantation.[166] The condition can result either from mutations in the gene that encodes perforin, which is a critical intracellular granule protein of NK cells and cytotoxic T lymphocytes, or in *UNC13D*, which encodes Munc 13–4, a protein that allows secretion of cytolytic granules. Mutations in several genes can lead to autosomal recessive or dominant autoimmune lymphoproliferative syndrome, also known as Canale–Smith syndrome.[102,167] These include the genes that encode Fas or CD95 (*TNFRSF6*), the cell surface apoptosis receptor, and its ligand (*TNFSF6*), and the caspase proteins 8 and 10, proteases in the cascade leading to apoptosis. This group of disorders features autoimmune disorders (cytopenias, leukocytoclastic vasculitis, lupus erythematosus) and an increased risk of lymphoma, and is associated with increased numbers of circulating $CD4^-$/$CD8^-$ α/β T cells. Immunodeficiency with extensive lymphocytic infiltration of viscera is also a manifestation of autosomal recessive mutations in the α chain of the interleukin-2 receptor.[168] Patients demonstrate bacterial, viral, and fungal infections because of early apoptosis of the developing thymic T lymphocytes.

The mean age of death for patients with Chédiak–Higashi syndrome is 6 years, usually from overwhelming infection or hemorrhage during the lymphoma-like accelerated phase. Prenatal diagnosis has been achieved by examination of hair from fetal scalp biopsies and of leukocytes from fetal blood samples.

The treatment of choice for patients with Chédiak–Higashi syndrome is early transplantation, which corrects the immunologic status but does not affect the pigment abnormality nor inhibit the development of neurologic disorders that grow increasingly worse with age. Acyclovir, high-dose intravenous γ-globulin, vincristine, cyclosporine, and prednisone have been used to control the accelerated phase, but it is usually fatal. Ascorbic acid corrects the microtubular defects in vitro but has no clinical ameliorative effects.[169] Interferon has been demonstrated by some authors to partially restore NK cell function.[170]

GRISCELLI SYNDROME

GRISCELLI SYNDROME AT A GLANCE

- Autosomal recessive group of disorders.
- Mutations in *MYO5A* (more neurologic), *RAB27A* (hemophagocytosis), or *Slac-2a*.
- Silvery hair is a hallmark.
- Hemophagocytosis often precipitated by Epstein–Barr virus infection.
- Treatment: transplantation.

Epidemiology. The majority of affected patients with this autosomal recessive disorder are of Mediterranean or Middle Eastern origin and born into consanguineous families.

Etiology and Pathogenesis. Mutations in three genes may underlie GS. GS1 is caused by a mutation in the *MYO5A* gene that encodes myosin 5a, a motor protein responsible for intracellular organelle transport. *MYO5A* is abundantly expressed in brain tissue and is important for neurotransmitter secretion. It is not expressed in cytotoxic cells. GS2 is caused by a mutation in the *RAB27A* gene, which encodes Rab27a, a guanosine triphosphatase protein involved in the function of the intracellular-regulated secretory pathway. It is essential for T and NK lymphocyte cytotoxic granule release and cell death. This defective cytotoxic activity most likely leads to the uncontrolled activation of lymphocytes and macrophages in the hemophagocytic syndrome. Both *MYO5A* and *RAB27A* have been mapped to chromosome 15q21.1.[171] A third type of Griscelli syndrome (GS3) is the result of a homozygous missense mutation in *Slac2-a/mlph* (melanophilin, mlph) or a deletion of the *MYO5A* F-exon. Melanophilin (also not expressed in cytotoxic cells) encodes a member of the Rab effector family and interacts with both myosin 5a (through the F-exon) and *RAB27A* to form a triprotein complex essential for the capture and local transport of melanosomes to the melanocytes (Fig. 143-14).[171,172] All three genetic subtypes share the inability to construct this complex for melanosome transport, thus leading to the characteristic pigmentary abnormality of GS.

Clinical Findings. The pigmentary dilution of GS is often limited to the hair, characterized by a silver-gray sheen with a few cases of skin involvement. The hair shaft shows large uneven clusters of pigment (see Fig. 143-13C) and the skin shows pigmentary dilution in keratinocytes but accumulation of melanosomes in melanocytes. Electron microscopy reveals numerous stage IV melanosomes in epidermal melanocytes. In contrast to Chédiak–Higashi syndrome, smears of leukocytes do not show giant granules. The additional clinical features present in each subtype are dependent on the function and tissue expression of the defective protein. Patients with GS1 have a primary neurologic disorder that presents in infancy with hypotonia and developmental delay. Severe immune disorder characterized by hemophagocytic syndrome or an "accelerated phase of the disease" is seen in GS2. Hemophagocytic syndrome is characterized by infiltration of various organ systems by activated lymphocytes and macrophages. It develops at mean age of 36 months, and often is precipitated by a virus, particularly EBV. Patients have fever, hepatosplenomegaly, neurologic impairment, coagulopathy, and pancytopenia.[173] Patients with GS3 present solely with the pigmentary abnormalities.

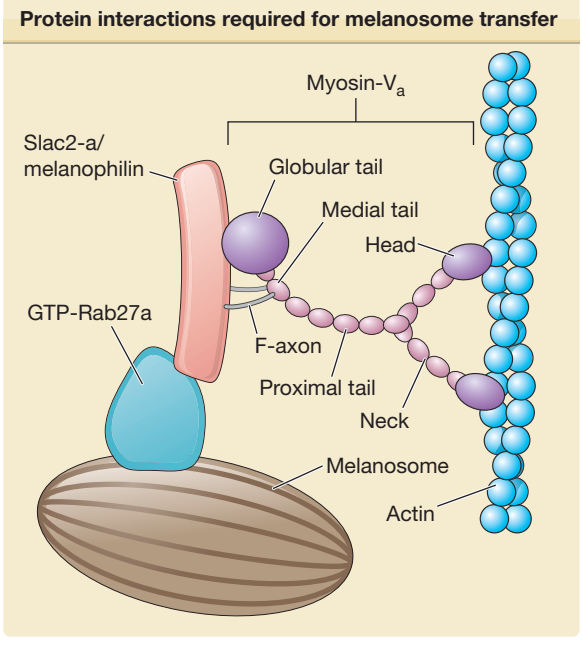

Figure 143-14 Protein interactions required for melanosome transfer. GTP = guanosine triphosphate. [Adapted from Menasche G et al: Griscelli syndrome restricted to hypopigmentation results from a melanophilin defect (GS3) or a MYO5A F-exon deletion (GS1). *J Clin Invest* **112**:450, 2003.]

Prognosis, Clinical Course, and Treatment. GS has been uniformly fatal but now can be reversed by successful hematopoietic stem cell transplantation. Eighty-five percent of patients with GS2 have mutations in the *RAB27A* gene that lead to early protein truncation. They have the most severe form of the disease with early development of hemophagocytic syndrome and rapid progression. The median survival from the onset of the accelerated phase to death in these patients is 5 months. Most patients die by 5 years of age secondary to progressive CNS disease or recurrent infections.[173] Missense mutations in the *RAB27A* gene show a milder phenotype with later age of hemophagocytic syndrome onset and a good response to chemotherapy treatment.[174] Patients with GS1 do not develop hemophagocytic syndrome. Prenatal diagnosis has been achieved by examination of hair from fetal scalp biopsies and DNA from leukocytes of fetal blood samples.[175]

COMPLEMENT DEFICIENCY DISORDERS

COMPLEMENT DEFICIENCY DISORDERS AT A GLANCE

- Deficiency or dysfunction of early complement components is associated with autoimmune disorders, particularly systemic lupus erythematosus.
- Deficiency or dysfunction of early complement components leads to risk of infections caused by encapsulated bacteria.
- Deficiency of late complement components markedly increases susceptibility to neisserial infections.

TABLE 143-9
Clinical Manifestations of Hereditary Deficiency or Dysfunction of Complement Components

Manifestation	Component	Pathway	Associations
Infection	C1q, C1r, C1s, C4, C2	Classical	Autoimmune disorders, especially SLE Increased encapsulated bacterial infections
	Mannan-binding lectin	Lectin	Pyogenic infections in neonates and children (SLE)
	Factors H, I	Inhibitors, alternative	Recurrent pyogenic infections (C3 depletion)
	Properdin	Stabilizer, alternative	Fulminant neisserial infections
	CR3	Receptor for iC3b	Leukocyte adhesion defect (see LAD type 1)
	C5–C9	Terminal (membrane attack complex)	Recurrent neisserial infections; milder with C9 deficiency
Autoimmune disorders	C1, C4, C2	Classical	Autoimmune disorders, especially SLE Increased encapsulated bacterial infections
	Mannan-binding lectin	Lectin	Pyogenic infections in neonates and children SLE
Exfoliative erythroderma	C3, C5	Shared, terminal	Failure to thrive, diarrhea, infections
Angioedema	C1 esterase inhibitor	Inhibitor, classical	Angioedema
Renal disease and/or hemolysis	Factor H	Inhibitor, alternative	Glomerulonephritis, atypical hemolytic uremic syndrome
	Decay accelerating factor (CD59)	Inhibitor, alternative	Hemolysis, thrombosis
	Membrane cofactor protein (CD46)	Inhibitor, alternative	Atypical hemolytic uremic syndrome
	C3	Shared	Membranoproliferative glomerulonephritis, severe bacterial infections

LAD = leukocyte adhesion deficiency; SLE = systemic lupus erythematosus.

HEREDITARY ANGIOEDEMA

HAE is almost always inherited in an autosomal dominant fashion with a spontaneous mutation rate of 25% (for clinical features and management, see Chapter 38).[190] It occurs in 1 in 150,000 persons and has no racial or ethnic predilection. Seventy-five percent of patients report a positive family history. There are three types of HAE. Type I is characterized by low antigenic levels of C1 INH and affects 85% of patients, whereas the remainder of patients have Type II, with low functional levels but normal/high antigenic levels of C1 INH.[191] A third type of HAE does not show a deficiency of C1 INH.[192] This type of HAE was previously thought to only affect women, although recently a family was described in which three male family members were affected.[193] One family has been identified in which the disease is transmitted as an autosomal recessive trait due to a mutation in the promoter region of the gene.[194]

SECTION 25

Skin Manifestations of Bone Marrow or Blood Chemistry Disorders

Chapter 144 :: Hematologic Diseases

:: Warren W. Piette

HEMATOLOGIC DISEASES AT A GLANCE

- Mucocutaneous changes (i.e., pallor, jaundice, flushing, erythema, and cyanosis) often predict underlying hematologic pathology.
- Anemia is best differentiated by mean corpuscular volume value.
- Megaloblastic anemia of vitamin B_{12} deficiency is distinguished from folate deficiency by lack of neurologic signs in folate deficiency.
- Carcinoid tumor results in flushing, typically for 10 minutes or less; in comparison, flushing from mastocytosis lasts 30 minutes or more.
- Polycythemia vera presents with acrocyanosis, aquagenic pruritus, urticaria, Sweet syndrome, and purpura.
- The morphologic diagnosis of purpura begins with three Ps: (1) is the lesion *p*urpuric, (2) is it *p*rimary, and (3) is it *p*alpable?
- Leukemia cutis is a localized or disseminated skin infiltration by leukemic cells. It is a sign of dissemination or systemic disease or relapsing leukemia.

Hematology includes the study of blood and blood-forming tissues. Given the number and variety of hematologic disorders, it is not surprising that mucocutaneous manifestations of hematologic disorders are common. Many hematologic malignancies and pseudomalignancies can involve the skin through atypical cell infiltration (specific lesions), and some of these may present preferentially in the skin. These conditions, such as leukemias and lymphomas, plasma cell dyscrasias including myeloma, and Langerhans and non-Langerhans histiocytoses, are discussed in other chapters. Likewise, complications of chemotherapy, radiotherapy, cytokine use, or marrow transplantation are discussed elsewhere.

The first section of this chapter is directed toward the differential diagnosis of purpura with an emphasis on those subsets of purpura with important underlying hematologic abnormalities. The second major section of this chapter is directed toward nonspecific (nontumor-containing) findings that may be associated with hematologic disorders. Although the ready availability of laboratory testing has made early recognition of such conditions as anemia and polycythemia much less dependent on physical findings, cutaneous associations still may aid in the diagnosis of a hematologic condition or complicate its management. A comprehensive listing of these associations is presented in Table 144-1.

Selected associations are covered in more detail in the text.

HEMOSTASIS AND THE DIFFERENTIAL DIAGNOSIS OF PURPURA

HEMOSTASIS

Hemostasis can be defined as the arrest of bleeding, and has two phases, primary and secondary, though research findings are blurring the compartmentalization of this process.[65] Primary hemostasis depends both on the vasoconstriction of the injured vessel and on formation of a platelet plug at the injury site. It is usually sufficient for focal microcirculatory injury repair. Larger defects or injury in larger cutaneous vessels require secondary hemostasis to reinforce the platelet plug.

Primary hemostasis is characterized by vascular contraction, platelet adhesion and activation, and subsequent development of a plug at the site of vessel injury. Vascular contraction leads to slowing of the blood flow, so the platelets can adhere to the injured site and diminish blood loss.[66] Secondary hemostasis promotes vascular integrity when primary hemostasis is insufficient and when larger vessels are involved. This phase maintains vasoconstriction through the secretion of prostaglandins, thromboxane, and serotonin. It also solidifies

TABLE 144-1
Cutaneous Findings with Hematologic Associations[1,2]

Pigmentary Changes

- Generalized hyperpigmentation
  - POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, *s*kin lesions)[3,4]
    - Hyperpigmentation, 93%–98%; apparent skin thickening, 77%–85%; hypertrichosis, 78%–81%; peripheral edema, ~90%; digital clubbing, 56%; white fingernails; verrucous angiomata, telangiectasia
  - Hemochromatosis may have bronze or grayish pigmentation of the skin
  - Megaloblastic anemia of vitamin B_{12} or folate deficiency
  - Fanconi anemia[5,6]
    - Begins age 4–10 years with skin or hematologic presentation
    - Generalized hyperpigmentation, especially lower trunk, flexures, neck, 85%
    - Scattered darker and lighter macules within hyperpigmented areas
    - Progressive hypoplastic anemia with pancytopenia
    - Death from leukemia, other neoplasms, or infections 2–5 years after onset
- Dyskeratosis congenita[7]
  - Nail dystrophy, beginning 5–13 years of age
  - Fine reticulate gray-brown hyperpigmentation, especially neck, thighs, and trunk
  - Atrophic skin with telangiectasis
  - Oral leukoplakia
  - Mucocutaneous carcinomas, occasional pancreatic carcinoma, Hodgkin disease
  - Frequent blood dyscrasias, aplasias, refractory anemias, pancytopenias
- Localized hyperpigmentation
  - Hypermelanosis and hemosiderosis may develop on the lower legs in hemolytic anemia, may develop focally in vitamin B_{12} or folate deficiency
  - Porphyria cutanea tarda, variegate porphyria, erythropoietic porphyria, occasionally hereditary coproporphyria cause hyperpigmentation, primarily in sun-exposed areas (see Chapter 132)
  - Adult Gaucher disease[8]
  - Brown chloasma-like macules on face, neck, and hands
  - Symmetric hyperpigmentation of lower legs
- Niemann–Pick disease[9,10]
  - Indurated discolored patches, especially on checks, café-au-lait spots
  - Mongolian on skin and oral mucosa
- Generalized hypopigmentation
  - Chédiak–Higashi (see "Recurrent cutaneous infections")[11,12]
  - Hermansky–Pudlak[11]
    - White, red, or brown hair; cream-gray to light normal skin
    - Blue–gray to brown iris
    - Platelet bleeding diathesis
    - Ceroid-like deposits in reticuloendothelial system, gastrointestinal tract, lung, and kidney that lead to pulmonary interstitial fibrosis, nephritis, granulomatous colitis
- Localized hypopigmentation
  - POEMS syndrome (see "Generalized hyperpigmentation")
  - Pernicious anemia with vitiligo
  - Vitamin B_{12} deficiency associated with poikilodermatous hypopigmentation
  - Anemia of autoimmune hypothyroidism may be associated with vitiligo
  - Porphyria cutanea tarda, variegate porphyria, erythropoietic porphyria, usually in areas of scarring

Recurrent Cutaneous Infections

- Neutropenia
  - Severe neutropenia (counts of 500/μL usually associated with fever, erythema without pus, painful ulcers). Causes include congenital and cyclic neutropenia; leukemia, lymphoma; marrow toxicity, failure, infiltration; and immune and autoimmune neutropenias.
- Functional leukocyte defects (counts may be low, normal, or elevated; defects identified in adherence, chemotactic response, phagocytosis, and killing)[85,86]
  - Chédiak–Higashi syndrome
    - Autosomal recessive
    - Defect in cytoplasmic granule function
    - Fair skin, light blond or silvery hair, and pale retina; translucent irises due to abnormal melanosomes
    - Large neutrophil inclusion on Wright-stained blood smear
    - Usually die in childhood

(continued)

TABLE 144-1
Cutaneous Findings with Hematologic Associations (Continued)

Recurrent Cutaneous Infections (Continued)

- Griscelli syndrome[13] (see Chapter 143)
  - Pigmentary dilution with silvery-gray hair
  - Autosomal recessive
  - Hypogammaglobulinemia, defective cell-mediated immunity
  - Neutropenia, thrombocytopenia, lymphohistiocytosis, hepatosplenomegaly
  - Neurologic deterioration
- Chronic granulomatous disease of childhood (see Chapter 143)
  - Leukocytes ingest bacteria normally but fail to kill them because of defects in H_2O_2 and oxygen radical production
  - Multiple types, most X-linked; overall sex ration, male-female 6:1
  - Skin lesions eczematous and purulent initially, transition to chronic cutaneous granulomas
  - Catalase-positive microbes (e.g., *Staphylococcus aureus*, *Salmonella*, *Aspergillus*) can multiply intracellularly, whereas catalase-negative microbes (e.g., pneumococci or streptococci) that generate their own H_2O_2 are killed
  - Nitroblue tetrazolium dye helpful in diagnosis
  - X-linked carriers may develop lupus-like skin lesions, aphthous stomatitis, or granulomatous cheilitis
- Myeloperoxidase deficiency
  - Autosomal recessive affecting neutrophils but not eosinophils
  - Functional impairment not severe
  - Occasional difficulty with pyogenic infections, persistent fungal infection more common
- Membrane and cytoskeletal defects (see Chapter 143)
  - Leukocyte adherence disorders due to congenital lack of defect or some component of CD11/CD18 surface glycoproteins (Chapter 143)
    - Neutrophils unable to adhere firmly to surfaces or complement-opsonized microorganisms
    - Possible persistent leukocytosis
    - Failure to develop much neutrophil response at inflammatory or infectious sites
  - Cytoskeletal defect in polymerizable actin[14]
    - Similar presentation to leukocyte adherence defects, but with normal CD11/CD8 but impaired motility
  - Complement abnormalities
    - C3 deficiency, C3b inactivator deficiency
    - Hyperimmunoglobulin E (IgE) syndrome
    - Job and Buckley syndromes are subsets
    - Elevated IgE, defective neutrophil chemotaxis
    - No clear relationship between IgE levels and neutrophil motility defect
    - Cold abscesses
  - Leiner disease
    - Severe seborrheic dermatitis
    - Diarrhea, failure to thrive
    - Gram-negative bacterial and candidal infection during infancy
  - Wiskott–Aldrich syndrome[15]
    - X-linked defect in WAS gene, WAS protein (WASp), less severe defect leads to chronic/intermittent X-linked thrombocytopenia or X-linked neutropenia
    - Thrombocytopenia, small but dysfunctional platelets, hemorrhage
    - Eczema
    - Recurrent infections: initially bacteria such as *Pneumococcus*, *Haemophilus influenzae*, *Neisseria meningitidis*; over time, T-cell function deteriorates and patient becomes susceptible to opportunistic viral, bacterial, and fungal infections
    - Immunologic abnormalities and lymphoreticular malignancies
    - CD43, a ligand for intercellular adhesion molecule-1, is defective; however, probably not primary defect because CD43 gene is on chromosome 16, not X
  - Persistent or extensive herpes simplex or recurrent or disseminated herpes zoster suggest underlying immune defect or hematologic malignancy

Neutrophilic Cutaneous Reactions

- Acute febrile neutrophilic dermatosis (Sweet syndrome): less than 10% of reported patients have heme association, usually acute myelogenous leukemia, myeloproliferative disorder, myelodysplastic syndrome, multiple myeloma, or monoclonal gammopathy
- Pyoderma gangrenosum: often atypical or bullous–hematologic association similar to those in Sweet syndrome
- Antineutrophil cytoplasmic autoantibody (ANCA)-positive neutrophilic dermatosis
- Polymorphic disease with monoclonal IgA ANCA[16]
- Erythema elevatum diutinum (see "Vascular disorders and coagulopathies")
- Leukocytoclastic vasculitis (see "Vascular disorders and coagulopathies")

TABLE 144-1
Cutaneous Findings with Hematologic Associations (Continued)

Vesiculobullous Disease

- Pemphigus vulgaris: lymphoproliferative diseases[2,17]
- Paraneoplastic pemphigus: lymphoproliferative diseases, thymoma[18]
- Acquired immunobullous disease with skin fragility: Waldenström macroglobulinemia[19]
- Linear IgA dermatosis: associations include Hodgkin lymphoma, non-Hodgkin lymphoma, polycythemia vera, chronic lymphocytic leukemia, plasmacytoma[20]
- IgA pemphigus: occasional monoclonal gammopathy or myeloma, most often IgA
- Subcorneal pustular dermatosis: IgG or IgA monoclonal gammopathy or myeloma[3,4]
- Dermatitis herpetiformis: frequent polyclonal IgA gammopathy, occasional myeloma, lymphomas, angioimmunoblastic lymphadenopathy
- Porphyria cutanea tarda, variegate porphyria, hereditary coproporphyria, and erythropoietic porphyria (see "Pruritus, prurigo, and burning," and "Generalized hyperpigmentation")
- Bullous mastocytoma, bullous urticaria pigmentosa of infancy[21]
- Hypereosinophilic syndrome can induce vesiculobullous lesions[22]
- Skin cancers
- Basal cell and squamous cell carcinoma increased in non-Hodgkin lymphoma and chronic lymphocytic leukemia (CLL)[23]
- Kaposi sarcoma increased in lymphoma, CLL, some immune deficiencies

Vascular Disorders and Coagulopathies

- Vasculitis
  - Usually cutaneous leukocytoclastic vasculitis (including urticarial vasculitis) and polyarteritis nodosa; ~5% of patients with vasculitis have an underlying malignancy[24]; lymphoproliferative disease most common, especially hairy cell leukemia, other hematologic associations include cryoglobulinemia, Hodgkin disease, non-Hodgkin lymphoma, myelodysplastic syndrome, chronic myelogenous leukemia, and multiple myeloma[2,25]
  - Erythema elevatum diutinum: gammopathy or myeloma, frequently IgA[3,4]
  - Urticaria and angioedema
    - Lymphoproliferative disease, sometimes with decreased C1-esterase inhibitor function[3,4]
    - Cryoglobulinemia; can also cause cold-induced urticaria[3,4]
    - Lymphocytic vasculitis: angioblastic lymphadenopathy, non-Hodgkin lymphoma, CLL[26]
    - Vasculitis panniculitis: children, non-Hodgkin lymphoma[27]
    - Hypereosinophilic syndrome[22]
- Vasculopathies and altered vascular reactivity
  - Flushing, erythroderma
  - Plethora, ruddy cyanosis
  - Erythema annulare centrifugum: lymphoma, "malignant histiocytosis," hypereosinophilic syndrome[28]
  - Erythralgia/erythromelalgia[29,30]
    - Polycythemia vera, essential thrombocytopenia; less commonly myelofibrosis, chronic myelogenous leukemia, cryoglobulinemia
  - Raynaud phenomenon
    - Waldenström macroglobulinemia[4]
    - Cryoglobulinemia[4]
  - Livedo reticularis[31,32]
    - Plasma cell dyscrasias with hyperviscosity, cryoglobulinemia, or cold agglutinin disease, macroglobulinemia[33]
    - Hyperleukocytosis
    - Polycythemia vera, thrombocythemia[34] (for the following, see also Tables 144-3–144-5)
    - Antiphospholipid antibody, lupus anticoagulant[35,36]
    - Hereditary protein C deficiency[37]
    - Antithrombin III deficiency[37]
    - Heparin-associated thrombocytopenia[38]
  - Acral cyanosis
    - Coumadin or other anticoagulant-enhanced tendency for cholesterol embolization: blue toe syndrome
    - Polycythemia vera, thrombocythemia, rarely with myeloblast leukostasis syndrome of chronic myelogenous leukemia[39]
    - Cryoglobulinemia[4,40]
    - Cold agglutinins[4,33]
    - Crystal globulin vasculopathy: multiple meloma[41,42]
- Vascular changes
  - POEMS syndrome: telangiectasias or angiomas
- AESOP syndrome: adenopathy with extensive skin patch (telangiectasia) overlying an osseous plasmacytoma; may have POEMS at curable stage[43]
  - Langerhans cell histiocytosis: telangiectasias, petechial hemorrhage
  - Telangiectasia macularis eruptive perstans variant of urticaria pigmentosa[44]

(continued)

TABLE 144-1
Cutaneous Findings with Hematologic Associations (Continued)

Vascular Disorders and Coagulopathies (Continued)
- Bleeding or coagulopathy secondary to dysproteinemia[4,45]
  - Mucocutaneous hemorrhage
    - Hyperviscosity syndrome, usually Waldenström macroglobulinemia, occasionally myeloma, cryoglobulinemia
    - Abnormal platelet function from dysproteinemias
    - Clotting factor deficiencies or inhibitors: factor V or VIII with IgM or IgA[36]; factor VII with IgG[46]; factor X adsorptive depletion in amyloidosis[42]
    - Low-grade disseminated intravascular coagulation with protein C dysfunction secondary to IgG gammopathy

Cutaneous Deposition/Induration/Altered Texture[3,4]
- AL (light-chain related) systemic amyloidosis: papules, plaques, nodules, bullae, sclerotic plaques, urticaria-pigmentosa-like lesions, alopecia, macroglossia; occurs with idiopathic or disease-associated monoclonal gammopathies
- Nodular cutaneous amyloidosis: local monoclonal plasma cell infiltrate; atrophic outpouchings of abdominal skin[47]
- Storage papule disease (translucent, often crusted or purpuric centers, buttocks and lower extremities): Waldenström macroglobulinemia[48]
- Cutaneous swelling associated with crystalline protein deposition: myeloma[49]
- Follicular spicules of the nose: multiple myeloma, cryglobulinemia[50]
- Scleromyxedema variant of lichen myxedematosus: usually IgGγ gammopathy[51]
- Scleroderma: usually IgG monoclonal gammopathy, occasionally myeloma
- Niemann-Pick: waxy induration with transient xanthomas overlying enlarged lymph nodes[9,52]
- Thickened, doughy, skin of diffuse cutaneous mastocytosis[53]
- Anetoderma: cutaneous plasmacytoma, benign lymphoid hyperplasia[54]

Xanthomas[3,4]
- Necrobiotic xanthogranuloma with paraproteinemia
  - Usually periorbital xanthoma, typically ulcerative
  - Leukopenia
  - Monoclonal gammopathy or multiple myeloma
- Xanthoma disseminatum—occasional association with monoclonal gammopathy, multiple myeloma, Waldenström macroglobulinemia
- Generalized plane xanthomatosis
  - Multiple myeloma, monoclonal gammopathies, leukemias
  - Xanthomas and café-au-lait spots: juvenile chronic granulocytic leukemia
  - Eruptive or tuberous xanthomas rarely reports with dysproteinemias

Cutaneous Sarcoidal or Histiocytic Tissue Reactions
- Cutaneous sarcoidal reactions: lymphoma {Warkentin, 1906 #72}
- Multicentric reticulohistiocytosis: lymphoproliferative disorders[55]

Epidermal Changes
- Acquired ichthyosis: lymphoproliferative malignancies, primarily Hodgkin disease[56]
- Sign of Lesser-Trélat: lymphomas comprise one-fifth of cases[57]

Hypertrichosis
- Porphyria cutanea tarda, erythropoietic porphyria

Pruritus, Prurigo, and Burning
- Severe itching occurs in 1%–11% of patients with Hodgkin disease even in the absence of any visible skin lesions; occasional complication of non-Hodgkin lymphoma and leukemia[2]
- Mycosis fungoides, Sézary syndrome, or other lymphomas with skin involvement may also present as itching
- Eosinophilic folliculitis after marrow transplant or chemotherapy for heme malignancies[58]
- Aquagenic pruritus: polycythemia vera, hypereosinophilic syndrome, myelodysplastic syndrome, juvenile xanthogranuloma[59]
- Hypereosinophilic syndrome: pruritic, erythematous papules or nodules, and angioedematous or urticarial plaques common[22]
- Mastocytosis: pruritic and usually pigmented papules or diffuse pruritius[60]
- Erythropoietic protoporphyria: pruritus and burning within minutes of sun exposure; may develop urticaria, edema, erythema, purpura
- Angioimmunoblastic lymphadenopathy/lymphoma: macular and popular eruptions, petechial, purpuric, nodular, ulcerative, and erythrodermic eruptions described[61,62]

Ulcerations
- Nonmalignant red blood cell disorders and leg ulcers
  - α or β thalassemias
  - Hemoglobin (Hb) SS, Hb-S-β thal Hb SC
  - Hereditary spherocytosis and elliptocytosis
  - Paroxysmal nocturnal hemoglobinuria

TABLE 144-1
Cutaneous Findings with Hematologic Associations (Continued)

Ulcerations (Continued)
- Cutaneous lesions of leukemia, lymphoma, and some histiocytoses may ulcerate
- Lymphomatoid papulosis
- Polycythemia vera and essential thrombocytopenia
- Kaposi sarcoma
- Reactive hemophagocytic syndrome
- Angioimmunoblastic lymphadenopathy
- Necrobiotic xanthogranuloma with paraproteinemia, xanthoma disseminatum
- Sweet syndrome
- Cryoglobulinemia
- Hypereosinophilic syndrome, especially mucosal ulcerations and erosions[63]
- Protein C deficiency, inherited and acquired (including Coumadin necrosis, some disseminated intravascular coagulation)
- Heparin necrosis
- Antiphospholipid antibody syndrome
- Neutropenic and immune deficiency-related infections
- Chédiak–Higashi: pyoderma gangrenosum or pyoderma gangrenosum-like ulcers[64]
- Leukocyte adhesion deficiency
- Chronic granulomatous disease
- Hyperimmunoglobulinemia E
- Felty syndrome
- Acute myelogenous leukemia

the platelet plug formed during primary hemostasis, through a series of clotting cascade pathways.

Because of the rich and highly visible nature of the skin microcirculation, and because of the very dynamic alterations of cutaneous blood flow (e.g., increasing to promote heat exchange, decreasing dramatically in shock states) as well as hydrostatic pressure variations by anatomic site and body position, the skin can be a very early and sensitive locale for signs of hemostatic alterations and coagulopathy. In nondisease states, the blood participates in an ongoing homeostatic balance between site-specific hemostasis or clot formation, clot extension inhibition, and clot lysis at the appropriate stage of injury repair. The platelet and coagulation cascade participate in clot formation, the antithrombin III and thrombomodulin/protein C/protein S systems in clot inhibition, and the plasminogen/plasmin system in clot lysis.

DIFFERENTIAL DIAGNOSIS OF PURPURA

The bedside dissection of the likely differential diagnosis of purpura can be summarized by five Ps: are lesions **p**urpuric, **p**rimary, **p**alpable, and what is their **p**attern and **p**lacement? For a lesion to qualify as purpuric, it must have a color that is compatible with hemorrhage—usually some shade of red, blue, or purple, but sometimes yellow–brown, green, or black—and at least some of this color must persist on compression of the skin. If the vessels are compressible, and if the color is due to mobile red cells within the vessels, then the skin color should completely blanch on compression, and no hemorrhage is clinically evident. False-positive results occur if the lesions contain tortuous vessels that kink on compression, or if compression is incomplete. Extravasated cells are not free to move, and therefore color persists on compression. It is important not only to determine the persistence of some color on compression, but also to assess in early lesions the proportion of erythema to hemorrhage. Complete blanching is a nonpurpuric lesion, but may be the physical presentation of mild urticarial vasculitis with clinically nonevident hemorrhage. Significant partial blanching of early lesions suggests an inflammatory etiology of the purpuric process. No detectable color change suggests no inflammatory component, and is characteristic of simple hemorrhage and most microvascular occlusive lesions.

Purpura may be primary or secondary in etiology. Hemorrhage may occur in inflammatory syndromes such as cellulitis, psoriasis, stasis dermatitis, or eczema, and these should be considered secondary purpura syndromes. In these and similar settings, the hemorrhage is generally secondary to nonvessel-directed inflammation increasing vascular permeability, and usually hydrostatic pressure increasing the likelihood of incidental red cell extravasation in areas of dependency.

Palpability rarely reflects the amount of cutaneous hemorrhage except for very large and deep focal cutaneous hemorrhage, resulting in a hematoma typically localizing in or below the fat layer of skin. Upward movement of the hemorrhage may occasionally result in an overlying ecchymosis. Most simple hemorrhage in the skin is nonpalpable. Instead, palpability typically results from protein-rich edema secondary to inflammation or microvascular ischemia with vascular and tissue injury. While the presence of palpability should exclude simple hemorrhage as a pathogenesis, the absence of palpability does not exclude inflammatory or occlusive hemorrhagic etiologies.

Many approaches to the differential diagnosis of purpura begin with pathophysiologic mechanisms.

TABLE 144-2
Purpura Number and Distribution Patterns and Their Clinical Relevance

Distribution/ Number Pattern	Distribution	Number of Lesions	Most Common Etiologies
Dependent	Gravity-dependent increasing density of lesions	Few to few 100s	Platelet-dependent hemostatic failure Immune-complex vasculitis
Minor Trauma-Prone areas	Extensor surface of arms, lateral thighs, anterior lower legs	One to a dozen	Extensor arm only suggests actinic purpura; multiple areas suggest minor trauma ecchymosis differential in Table 144-3
Multigeneralized			
Multigeneralized with round lesions	Generalized eruption	Many 100s	Usually drug or viral eruptions
Multigeneralized with retiform lesions	Widespread eruption	Few to Fifty	Sepsis-related microvascular occlusion/ purpura fulminans
Pauci-random	Random localization	Few	Nonimmune complex vasculitis, especially ANCA +; Systemic microvascular occlusive disease
Acral			
Acral: erythema multiforme type	Involves hands and feet, with or without a more generalized distribution	Few on hands/ feet, may have many more if accompanied by a generalized eruption	Usually drug or viral eruption, especially recurrent HSV eruptions
Acral: cold-localized type	Hands, feet, nasal tip, ears	Few	Cold-occlusion phenomena
Acral: hypotensive,	Digital gangrene, or retiform purpura on hands and/or feet	Few	Shock, usually in association with vasoconstrictor administration and sepsis-related coagulopathy
Acral: feet with livedo reticularis extending proximally	Livedo reticularis of legs often prominent early, expect few distal retiform purpura lesions[3]	Few purpura lesions	Cholesterol embolus, can be mimicked by antiphospholipid antibody syndrome
Acral: wedge-shaped	Distal, usually one limb or digit	One wedge-shaped lesion	Arterial occlusion

However, pathophysiology is usually what the physician is attempting to ascertain, and the diagnostic process begins with clinical clues. Some of the most important clinical information available from the bedside examination is lesional number, distribution, and morphology. Exploration of the differential diagnosis can begin with helpful patterns of lesional number and distribution are listed in Table 144-2.

The initial diagnostic considerations based on these patterns should then be combined with information gleaned from the lesional morphologic differential diagnosis (Tables 144-3, 144-4, and 144-5; Fig. 144-1).

The goal of the history and examination is to develop a narrow differential diagnosis or testable clinical hypothesis as to the etiology of purpura in a particular patient, and to order or review the appropriate laboratory studies that may prove or disprove suspected pathophysiologies. While the differential diagnosis of purpura could easily include hundreds of possible etiologies, the diagnostic process can be powerfully refined if one is able to determine clinically whether the early primary purpuric lesions is likely due to simple hemorrhage, inflammatory hemorrhage, or ischemia/occlusion.[67,68,73] In concert with the number and distribution, lesional morphology is critical in facilitating this determination. Simple hemorrhage not severe enough to produce hematoma presents as nonpalpable (macular), nonblanchable purpura, and usually is either primarily petechial or ecchymotic, each pattern having its own differential composition (Tables 144-3, Figs. 144-2 and 144-3). Partially blanchable purpura, often palpable, is the expected clinical manifestation of inflammatory hemorrhage, including but not limited to necrotizing vasculitis (Table 143-4). If early lesions are both partially blanchable and retiform, the differential diagnosis is further narrowed (Fig. 144-4). Finally, if early lesions are retiform with minimal to no blanchable component, microvascular occlusion becomes the likely differential category, always with the caveat that some occlusive syndromes may be accompanied by inflammation when lesions are large and deep, and two vasculitides in particular [granulomatosis with polyangiitis (Wegener's) and microscopic polyangiitis] may present with purpura lesions which show no clinical evidence of inflammation.

TABLE 144-3
Partial Differential Diagnosis of Nonpalpable, Nonretiform Purpura by Size of Lesion[67–70]

- Petechiae: ≤4 mm
- Platelets <50,000/μL, usually <10,000/uL
  - Immune thrombocytopenia
  - Thrombotic thrombocytopenic purpura
  - Disseminated intravascular coagulation
  - Acquired thrombocytopenia (including drug-related)
    - Peripheral destruction (especially quinine)
    - Marrow failure
    - Marrow infiltration, fibrosis, failure
  - Abnormal platelet function
    - Congenital/hereditary platelet function defects
    - Acquired platelet function defects
      - Aspirin, nonsteroidal anti-inflammatory drugs
      - Renal or hepatic insufficiency
      - Gammopathy
      - Myeloproliferative thrombocytosis
- Nonplatelet etiologies
  - Minimally inflammatory conditions
    - Chronic pigmented purpura
    - Waldenström hypergammaglobulinemic purpura
  - Intravascular pressure increase
    - Valsalva-like spikes (nondependent); repetitive vomiting, coughing, childbirth
    - Relatively fixed increased pressure: ligature, strangulation, stasis
    - Trauma: usually linear arrangement
- Midsize macules: 5–10 mm (indeterminate hemorrhage)
  - Waldenström hypergammaglobulinemic purpura
  - Immunocompromised patients with sepsis
- Ecchymoses: ≥1 cm
  - Procoagulant defect and minor trauma
    - Anticoagulant use
    - Vitamin K deficiency
    - Disseminated intravascular coagulation
    - Hepatic diagnosis, poor factor synthesis
    - Platelet abnormality and minor trauma
      - Thrombocytopenia (always <50K, usually <10K)
      - Inherited platelet dysfunction, esp von Willebrand disease
      - Acquired platelet dysfunction (aspirin, uremis, liver disease, gammopathies)
  - Poor dermal vessel support and minor trauma
    - Actinic (senile) purpura
    - Glucocorticoid treatment, topical/systemic
    - Vitamin C deficiency—scurvy
    - Systemic amyloidosis (mostly light chain-related amyloidosis)
    - Ehlers–Danlos syndrome (some types)
    - Pseudoxanthoma elasticum
    - Other pathophysiology
    - Major trauma
    - Waldenström hypergammaglobulinemic purpura

The differential diagnosis of minimal inflammatory retiform purpura, with these caveats, is listed in Table 143-5.

NONPALPABLE, NONBLANCHABLE PETECHIAE (<4 mm)

Palpable or partially blanching petechiae do not fit in this category; such lesions should instead prompt consideration of the differential diagnosis of classical palpable purpura. Nonpalpable petechial hemorrhage is typically the dominant type of hemorrhage resulting from problems in platelet number, always below 50,000/mm, and almost always below 10,000/mm (Table 144-3). In patients with immune thrombocytopenia, either idiopathic or alloimmune, the marrow is healthy, and platelet production is increased, leading to larger and more effective platelets. In such instances, spontaneous formation of petechiae is often minimal, even when platelet numbers are below 5,000. However, when thrombocytopenia is due to marrow failure (medications, especially chemotherapy, radiation exposure, marrow infiltration from leukemia, lymphoma, or other neoplasms), the platelets in circulation are often small, old, and poorly functional, and

TABLE 144-4

Partial Differential Diagnosis of Palpable or Retiform Purpura with Prominent Early Erythema by Lesion, Shape, and Degree of Erythema[67,68,71,72]

Classical Palpable Purpura (Round, Port-Wine Color, Partially Blanchable Early)

Morphology of early lesion: prominent erythema with palpable purpura suggests inflammatory hemorrhage

- Leukocytoclastic vasculitis and immune complex disease (lesions usually cluster in dependent areas)
  - Small vessels only
    - Idiopathic, infection-, drug, or malignancy-associated immunoglobulin G (IgG) or IgM complexes
    - Idiopathic IgA complexes (Henoch-Schönlein purpura, or IgA idiopathic with drugs, infection, or malignancy
    - Subacute bacterial endocarditis—hands
    - Waldenström hypergammaglobulinemia
    - Urticarial vasculitis—often random localization
    - Pustular vasculitis—often random localization
  - Small and medium-size cutaneous vessels may be involved
    - Mixed cryoglobulinemia
    - Rheumatic vasculitis (lupus erythematosus, dermatomyositis, rheumatoid arthritis)
- Leukocytoclastic vasculitis and pauci-immune vasculitis (lesions usually localize randomly)
  - Antineutrophil cytoplasmic antibodies (ANCA)-associated
    - Granulomatosis with polyangiitis (Wegener's)
    - Microscopic polyangiitis
    - Churg-Strauss rarely
  - Other
    - Erythema elevatum diutinum—hands/feet/elbows/buttocks
    - Sweet syndrome (rarely vasculitic)
- Not leukocytoclastic (lesions usually localize randomly)
  - Small vessels only
    - Erythema multiforme—acral early
    - Pityriasis lichenoides et varioliformis acuta (PLEVA)
    - Chronic pigmented purpura—often legs
    - Waldenström hypergammaglobulinemia—usually dependent
    - Urticarial lymphocytic "vasculitis"
- Classic target lesion
  - Usually erythema multiforme—expect acral and mucosal involvement, as well as elsewhere

Inflammatory Retiform Purpura

Morphology of early lesion: prominent erythema with retiform purpura suggests subset of inflammatory hemorrhage (and, rarely, ischemic syndromes)

- Leukocytoclastic vasculitis and immune complex disease (lesions usually cluster in dependent areas)
  - Small vessels only
    - IgA (Henoch-Schönlein purpura) vasculitis
  - Small and medium-sized cutaneous vessels may be involved
    - Mixed cryoglobulinemia
    - Rheumatic vasculitides
- Leukocytoclastic vasculitis, dermal and subcutaneous vessels, pauci-immune
  - ANCA-associated—random location
    - Granulomatosis with polyangiitis (Wegener's)
    - Microscopic polyangiitis
    - Churg-Strauss
  - ANCA-negative syndromes
    - Benign cutaneous polyarteritis nodosa, often legs
- Nonvasculitic
  - Usually lower leg
    - Livedoid vasculitis
  - Usually fingers/toes
    - Chilblains (pernio)
- Usually random location
  - Pyoderma gangrenosum
  - Sweet syndrome/atypical pyoderma gangrenosum

TABLE 144-5

Differential Diagnosis of Palpable or Retiform Purpura with Minimal Early Erythema by Lesion, Shape, and Degree of Erythema[68,73]

Morphology of early lesion: minimal erythema with retiform purpura or with necrosis suggests occlusion with ischemic hemorrhage or infarction.

- Platelet plugs
  - Heparin necrosis (distant or injection sites)
  - Myeloproliferative thrombosis
  - Paroxysmal nocturnal hemoglobinuria
  - Thrombotic thrombocytopenic purpura (plugs mainly visceral vessels, skin lesions usually simple hemorrhage)
- Cold-related gelling or agglutination (lesions localize to acral, cold-exposed areas)
  - Cryoglobulinemia, usually monoclonal
  - Cryofibrinogenemia (often incidental finding in ill patients)
  - Cold agglutinins (rarely occlusive, usually hemolytic)
- Embolization or crystal deposition (lesions localize to dependent or acral areas)
  - Cholesterol emboli
  - Oxalate crystal deposition
  - Both usually have extensive livedo
  - Hypereosinophilic syndrome
- Embolus from atrial myxoma, septic, or marantic endocarditis
  - Crystal globulin vasculopathy
- Systemic changes in coagulation control
  - Coumarin necrosis (altered protein C function)
  - Disseminated intravascular coagulation with severe protein C deficiency or dysfunction: sepsis-related purpura fulminans
- Postinfectious purpura fulminans (usually children, following varicella and/or streptococcal infection, due to antibody inhibition of protein S)
  - Homozygous protein C or S deficiency: neonatal purpura fulminans
  - Antiphospholipid antibody/lupus coagulant
- Local changes in coagulation control
  - Idiopathic livedo reticularis with CVA (Sneddon syndrome): may show only livedo without purpura
  - Livedoid vasculitis atrophie blanche: rarely retiform
  - Malignant atrophic papulosis: never retiform, in skin limited syndromes should suspect antiphospholipid antibody syndrome
- Occlusion caused by organisms growing in vessel and vessel walls (usually immunocompromised host)
  - Vessel-invasive fungus (*Mucor*, *Aspergillus*, *Cephalosporium*, *Rhizopus*, etc.)
  - Ecthyma gangrenosum (*Pseudomonas*)
  - Disseminated strongyloidiasis
  - Lucio phenomenon in leprosy
- Cell occlusion syndromes: typically ulcerative but nonretiform
  - Hemoglobinopathy occlusion (sickle cell, severe thalassemia): probably role for sticky reticulocyte syndrome; Hg S-related disease adds complication of sickling, rigid membrane abnormalities.
  - Typically ulcerative but usually non-retiform
  - Intravascular lymphomas
- Uncertain pathophysiology
  - Cutaneous calciphylaxis
  - Reperfusion necrosis
  - Interferon injection
  - *Loxosceles* spider bite

hemorrhage may occur despite platelet counts many thousands higher than in the immune thrombocytopenias. Drug-related thrombocytopenia can be due to several different mechanisms, including immune, destructive, and cytotoxic.[69]

IMMUNE THROMBOCYTOPENIAS. Idiopathic thrombocytopenic purpura (ITP) is a common bleeding disorder in children caused by autoantibodies against platelet surface antigens, especially glycoproteins IIb/IIIa and Ib. It presents with increased immunoglobulin (Ig) M, IgG, and IgA autoantibodies with decreased platelet surface antigens (CD41, CD61, and CD42b).[74,75] Patients are usually asymptomatic with mostly petechiae and a few ecchymoses found on their physical examination. Oral blood blisters with gastrointestinal or mucocutaneous bleeding can also occur and are referred to as *wet purpura*. As in ITP, immunothrombocytopenic purpura can be associated with recent viral illness and vaccination.[76] Alloimmune thrombocytopenic purpura occurs when alloantibodies against human platelets form during blood or platelet transfusion, or maternal–fetal blood exchange, leading to posttransfusion purpura and fetal and neonatal alloimmune thrombocytopenia, respectively.[46] CD109 is a protein expressed on platelets, T lymphocytes, and endothelial cells. Antibodies against HPA-1, HPA-5, and HPA-15 on $CD109^+$ cells should be sought.

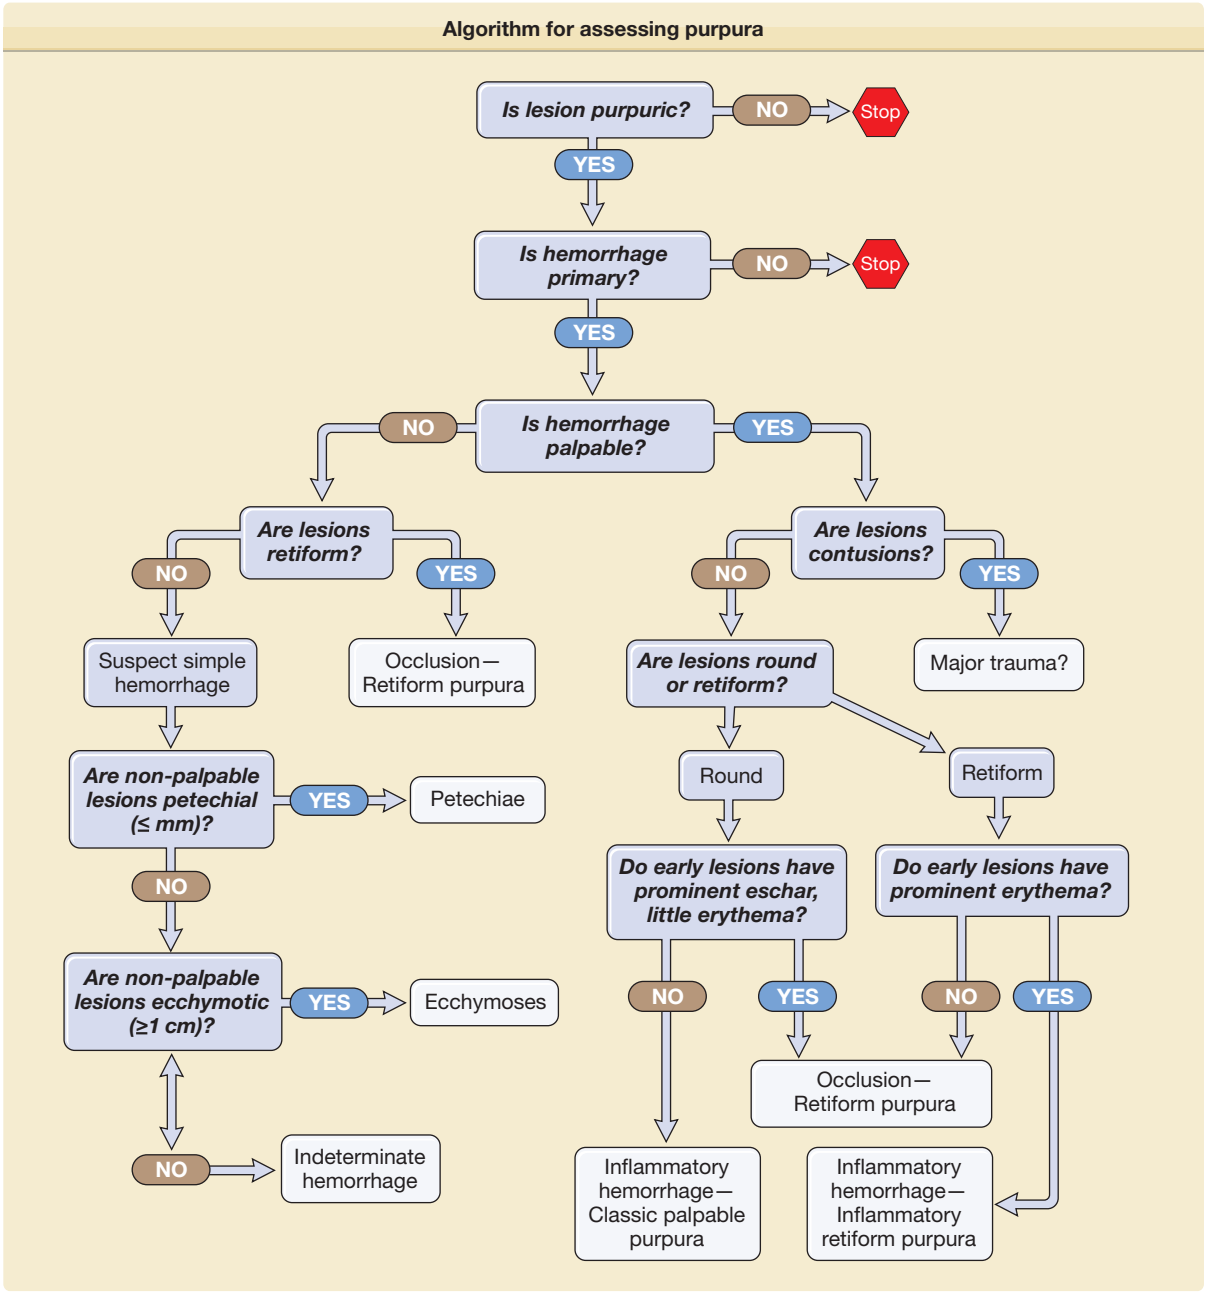

Figure 144-1 Algorithm for assessing purpura.

Unique localization of petechial hemorrhage may result from intravascular pressure spikes. For example, vigorous Valsalva maneuver-like actions from crying in children, vigorous retching, or bearing down during childbirth may result in petechial hemorrhage above the clavicles. A ligature, blood pressure cuff, or attempted strangulation may result in hemorrhage in the affected venous drainage area.

Chronic pigmented purpuras, especially Schamberg type, may mimic simple petechial hemorrhage in the legs, despite histologic evidence of mild nonvasculitic hemorrhage such lesions. Clinically, the inflammation may not be evident, but clues to this diagnosis consist of a tendency of pigmented purpura and petechiae to cluster, leaving an orange–brown pigmentation in affected areas. The pigmented purpuric dermatoses are discussed in detail in Chapter 168.

THROMBOTIC THROMBOCYTOPENIC PURPURA/THROMBOTIC MICROANGIOPATHIES.

Thrombotic thrombocytopenic purpura (TTP) is most commonly seen in adults, whereas hemolytic-uremic syndrome (HUS) is more frequent in children.[77] TTP can result from pregnancy, cancer, drugs (chemotherapeutic-bevacizumab, and immunosuppressives—cyclosporine/tacrolimus, oral contraceptives, ticlopidine, and quinine), bone marrow transplantation, and autoimmune diseases. The most common pathogenesis

Figure 144-2 Nonpalpable ecchymoses in a patient on chronic oral glucocorticoid therapy. Note the rectangular and linear lesions that suggest the minor trauma component; the distal lesion shows that the ecchymosis surrounds a linear traumatic injury. (From Piette W: Myeloma, paraproteinemias, and the skin. *Med Clin North Am* **70**:155, 1986, with permission.)

is from antibodies, which interfere with the function of ADAMTS13. The result is improper cleavage of von Willebrand factor (VWF) and platelet-fibrin thrombotic microangiopathy.[78,79] Patients have increased levels of LDH with associated schistocytes, helmet cells, and megakaryocytes; clinical signs include fever, renal (especially in HUS), and central nervous system (headache, seizures, hemiparesis, disorientation) abnormalities. Despite clear evidence of visceral vessel occlusion from platelet plugging, the mechanism of petechial hemorrhage in TTP is far from clear. Occlusive disease was reported in a small series of mucous membrane lesions, but biopsies of cutaneous lesions are not reported, and the morphology of these lesions is more in keeping with simple hemorrhage. Deficiency of ADAMTS13 has been shown in familial TTP (congenital TTP, Upshaw–Schulman syndrome). The treatment of choice is fresh frozen plasma/plasmapheresis. Acquired functional deficiency of ADAMTS13 is known to occur in several other settings, most commonly with lupus and other

Figure 144-3 Classic palpable purpura on the leg of a patient with immunoglobulin A vasculitis. Partial blanching of an early lesion on compression supports the clinical impression of inflammatory hemorrhage.

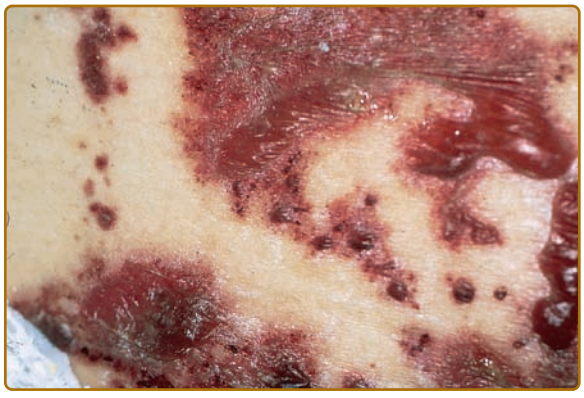

Figure 144-4 Inflammatory retiform palpable purpura in a patient with immunoglobulin A vasculitis. The initial erythematous phase is still present but fading in these lesions, and bullae have formed.

autoimmune diseases.[80] HUS is commonly caused by Shiga toxin, producing Gram-negative bacilli, especially *Escherichia coli* O157:H7 infection. It presents with bloody diarrhea and hemorrhagic colitis, and usually causes oliguric or anuric renal failure. Cutaneous lesions are not seen. Diarrhea-negative or atypical HUS is not associated with Shiga toxin-producing organisms, and occurs without an obvious predisposing condition. Preeclampsia-HELLP (hemolysis, elevated liver enzymes, low platelets) is another thrombotic microangiopathy that can mimic TTP/HUS syndromes.

TTP typically presents as round nonpalpable petechial hemorrhage, in contrast to the typical cutaneous presentation of heparin-induced thrombocytopenia (HIT), in which the retiform morphology of purpura is consistent with platelet-related occlusion of the cutaneous microvasculature. The platelet aggregation is triggered by an antibody, which recognizes antigenic sites on both heparin and platelet factor 4 on the platelet surface. Treatment of heparin necrosis typically involved anticoagulation with coumarin, but this treatment may worsen the vascular occlusion, leading to limb necrosis.[81] Worldwide, three accepted drugs are used in the treatment of patients with HIT: (1) danaparoid (not available in the United States), (2) recombinant hirudin (lepirudin), and (3) argatroban.[79]

NONPALPABLE, NONBLANCHABLE ECCHYMOSES (>1 cm)

The cutaneous lesions associated with scurvy are characterized by purpura that surrounds corkscrew hairs on the lower extremities (see Chapter 130), but nonspecific hemorrhage is more typical. True senile purpura is uncommon, and is usually the misdiagnosis for solar damage in poorly pigmented, often elderly individuals. Solar purpura usually occurs on the extensor surfaces of the forearms and results from the photoinduced loss of cutaneous elasticity and weakened dermal capillary support. Erythrocyte (RBC) extravasation occurs with minor trauma to the hands and other sites (see Chapter 109). Ecchymotic hemorrhage

after minor trauma generally results from procoagulant defects, poor dermal vessel support, or Waldenstrom hypergammaglobulinemic purpura (on the legs) (Table 144-3, Fig. 144-2).

PARTIALLY BLANCHING ROUND PURPURA (CLASSICAL PALPABLE PURPURA) AND PARTIALLY BLANCHING RETIFORM PURPURA

Lesions of inflammatory hemorrhage are round, partially blanching, and palpable, and most commonly represent leukocytoclastic or necrotizing vasculitis. The differential diagnosis of this morphologic presentation is listed in Table 144-4 (Fig. 144-3).

When purpura is *retiform* in configuration, but also associated with prominent early partial blanching, the potential causes of the inflammatory hemorrhage are more limited (Table 144-4, Figs. 144-4 and 144-5, inflammatory retiform purpura). Given the lesional number and distribution, a highly probable clinical hypothesis can be formulated. However, four occlusive syndromes may occasionally present with a few, large, indurated plaques of early inflammation of the dermis and subcutaneous tissue surrounding retiform purpura or eschar. These include: (1) antiphospholipid antibody syndrome; (2) warfarin necrosis; (3) heparin necrosis; and (4) cutaneous calciphylaxis. Among inflammatory causes of hemorrhage/vasculitis, only benign cutaneous polyarteritis nodosa is likely to cause such large necrotic thick plaques with early inflammation.

NONBLANCHING RETIFORM PURPURA

The differential diagnosis of cutaneous microvascular occlusion is extensive, and differs considerably from the usual list of causes of venous thrombosis and pulmonary emboli. Underlying causes can be organized by pathophysiology into eight categories, as shown in Table 144-5 (Figs. 144-6–144-8, nonblanching retiform purpura). Of note, although early lesions of cutaneous vasculitis typically blanch partially, occasionally patients with granulomatosis with polyangiitis (Wegener's) and microscopic polyangiitis may present with necrotic or retiform lesions without discernible erythema. Discussion of all occlusive syndromes is beyond the space limitations of this chapter, but two syndromes merit discussion because of frequent confusion in their use and definition: (1) disseminated intravascular coagulation (DIC) and (2) purpura fulminans. A newly recognized vasculopathy thought secondary to levamisole used to cut illicit cocaine typically presents with nonblanching retiform purpura and necrosis, typically involving ears and trunk or extremities (Fig. 144-8).[82,83] Though associated with both antineutrophil cytoplasmic antibodies

Figure 144-6 Disseminated intravascular coagulation and sepsis, with presumed sepsis-associated protein C depletion leading to purpura fulminans. Extensive geographic areas of cutaneous infarction with hemorrhage involving the face, breast, and extremities; although the patient looked alert, she died within several days. This catastrophic event followed sepsis after abdominal surgery.

Figure 144-5 Noninflammatory retiform palpable purpura on the thigh in a patient with disseminated intravascular coagulation secondary to sepsis, and sepsis-associated protein C depletion leading to purpura fulminans None of the lesional color faded on compression. The biopsy showed multiple dermal vessels occluded by clot without inflammation.

Figure 144-7 Cocaine/levamisole associated noninflammatory retiform purpura. This syndrome associated with cocaine use is most consistent with a levamisole-induced antiphospholipid antibody-related vascular occlusion syndrome, and on biopsy of early lesions in this case showed noninflammatory occlusion.

Figure 144-8 Leukemia cutis. Hundreds of tan-pink papules and a nodule on the trunk of a female with acute myelogenous leukemia arose during a 1-week interval. Per se, these lesions are "nonspecific" and do not represent a diagnosis; but when such an eruption is seen, one should perform a peripheral blood count and a biopsy.

and antiphospholipid antibodies, and both vasculitic and thrombotic histologic findings are reported, early lesional findings seem most consistent with thrombotic vasculopathy, with secondary vasculitic changes (personal observation, author).

DISSEMINATED INTRAVASCULAR COAGULATION.

DIC is not a disease, but rather always secondary to an underlying disorder. The disorders most commonly associated with DIC are listed in Table 144-6.

DIC is characterized by systemic activation of coagulation, insufficiently controlled by natural anticoagulant mechanisms, in concert with clot lysis, leading to the intravascular deposition of fibrin in the (micro) vasculature and the simultaneous consumption of coagulation factors and platelets.[84] In addition to evidence of clot formation, DIC is also defined by prolonged prothrombin and partial thromboplastin times (PT and PTT) as well as depleted fibrinogen. Elevated fibrin degradation products or d-dimers typically provide evidence of active clot lysis, although increased plasma soluble fibrin may be more specific. This combination can result in three clinical scenarios: (1) no clinical evidence of thrombosis or hemorrhage; (2) clinically evident thrombosis; or (3) simple bleeding into skin or tissues, including at from puncture sites. The pathogenetic pathways that play a role in the development of thrombosis include tissue factor-dependent activation of coagulation, defective physiologic anticoagulant pathways (such as the antithrombin system and the protein C system), and impaired fibrinolysis, caused by elevated levels of plasminogen activator inhibitor type 1.[85] Therapeutic strategies are based on the pathogenesis of DIC (trauma, burns, postsurgical, sepsis). These include administration of anticoagulants and strategies to restore physiologic anticoagulant pathways (such as activated protein C concentrate or antithrombin III.[84])

PURPURA FULMINANS.

Purpura fulminans is a severe skin disorder typically associated with DIC that was first reported in children and infants.[86] This term has been used by some to describe widespread cutaneous hemorrhage of any type in seriously ill patients. However, use of the term is best limited to neonatal, sepsis-related, and postinfectious syndromes associated with histologic evidence of small vessel thrombi, typically with clinical lesions of nonblanching retiform purpura or eschar.[68,73]

TABLE 144-6
Clinical Conditions Associated with Disseminated Intravascular Coagulation

- Sepsis/severe infection (any microorganism)
- Trauma (e.g., polytrauma, neurotrauma, fat embolism)
- Organ destruction (e.g., severe pancreatitis)
- Malignancy
  - Solid tumors
  - Myeloproliferative/lymphoproliferative malignancies
- Obstetric calamities
  - Amniotic fluid embolism
  - Abruptio placentae
- Vascular abnormalities
  - Kasabach–Merritt syndrome
  - Large vascular aneurysms
- Severe hepatic failure
- Severe toxic or immunologic reactions
  - Snake bites
  - Recreational drugs
  - Transfusion reactions
  - Transplant rejection

Purpura fulminans occurs in three clinical settings: (1) in relation to acute sepsis, (2) after infection, and (3) in neonates. Catastrophic antiphospholipid antibody syndrome is a mimic. In acute sepsis-associated or secondary purpura fulminans, the related overwhelming infection is most commonly meningococcal (see Chapter 181), but may be caused by many other Gram-positive and Gram-negative organisms. Patients are hypotensive with reduced peripheral perfusion, contributing to the skin necrosis on distal extremities and elsewhere (Fig. 144-6). Sometimes, skin necrosis occurs in a patchy distribution. Postinfectious purpura fulminans can manifest within 10 days of an antecedent illness, most commonly following streptococcal and/or varicella infections in children. Neonatal purpura fulminans is most often seen in association with homozygous protein C deficiency, in which massive intravascular thrombosis and abdominal wall gangrene can also develop.[87]

OTHER CUTANEOUS SIGNS AND SYMPTOMS ASSOCIATED WITH HEMATOLOGIC DISEASES

PALLOR

Pallor of the mucocutaneous tissue is observed most readily in the palms, nail beds, face, and conjunctivae. In these areas, the microvascular bed is visible through the skin. Pallor is the result of lowered hemoglobin content. Among the multiple causes for pallor are acute and chronic hemorrhage, emotion, drugs (i.e., vasopressors), cold, shock, and pathophysiologic adjustments that lead to anemia. Cutaneous edema can also produce pallor. Successful treatment of the underlying etiology corrects the pallor as well.

ANEMIA. The definition of anemia depends on the patient's age and sex. The palmar creases are a good indicator of the severity of anemia. Unless the hemoglobin level drops below 7 g/dL, palmar creases appear pink.[88] Constitutional signs and symptoms of anemia include malaise, fatigue, dizziness, postural hypotension, dyspnea on exertion, and tachycardia.

Anemias may be classified based on RBC volume as microcytic, normocytic, and macrocytic.[89] Review of the blood smear may also reveal distinctive morphologic red cell changes, such as targeting, spherocytosis, red cell fragmentation, or poikilocytosis, which narrow the diagnostic possibilities. Laboratory evaluation should be based on the suspicion of the underlying cause of anemia. In addition to complete blood count with white blood cell differential and red cell morphology, iron studies (iron, total iron blood count, percent saturation of iron), ferritin, B_{12}, lactate dehydrogenase (LDH), haptoglobin, folate levels, platelet and reticulocyte counts may be warranted based on initial laboratory evaluation.

MICROCYTIC ANEMIAS. Microcytic anemias are most often due to (1) iron deficiency, (2) anemia of chronic disease, (3) autoimmune hemolytic anemias, or (4) thalassemias. Of these, the first two are by far the most common.

IRON DEFICIENCY. Sixty percent to 70% of the body stores of iron are in the RBCs in the form of hemoglobin.[90] Heme-containing proteins are essential for metabolic processes in virtually all cells.[91] Hemoglobin, myoglobin, and the cytochromes are heme-containing proteins and enzymes. The average life of an erythrocyte is 120 days, after which it is phagocytized by macrophages of the liver, spleen, and bone marrow. The iron is then stored in the form of ferritin to be recycled.

Iron deficiency anemia can result from increased iron demand in the setting of inadequate iron stores. This is most commonly seen during pregnancy, because increased blood volume is necessary for fetal growth and development.

Symptoms of iron deficiency include fatigue, headache, tinnitus, irritability, paresthesias, burning sensations of the tongue, akathisia (restless leg syndrome), and pica (the craving to eat substances such as dirt, clay, ice, laundry starch, salt, or cardboard).[90] The physical findings of anemia in their approximate order of frequency include: pallor, glossitis (smooth red tongue), stomatitis, and angular cheilitis.[68] Skin dryness and coarsening, brittle nails, and fine, dry hair may also occur. Blue sclerae and koilonychias (spooning of nails) are rare. Retinal hemorrhages or exudates may develop with severe anemia (hemoglobin <5 g/dL), and iron deficiency may accelerate proliferative retinopathy in diabetics. Generalized fatigue often disrupts the patient's ability to focus on daily activities at work, home, and school, resulting in poor performance.[92]

Anemia of chronic disease is a common finding in chronically ill patients. Associated laboratory features somewhat mimic those of iron deficiency anemia with mild microcytosis and low serum iron, but with normal (i.e., not elevated) serum iron-binding capacity and transferrin. In some cases, bone marrow biopsy to stain for iron stores may be required to assess iron status.[91] This form of anemia appears to result from altered recycling of iron in chronic diseases states, and is not repaired by iron replacement. Appropriate diagnosis is important before beginning iron supplementation for microcytic anemia, since iron supplementation may worsen iron storage overload in patients with thalassemia.

Treatment of iron deficiency anemia requires replacing lost iron and maintaining the daily iron dietary requirement. The recommended daily dose for treatment of iron deficiency is between 150 to 200 mg/day of elemental iron (325 mg ferrous sulfate = 65 mg of elemental iron), usually continued until the hemoglobin reaches a normal value.[52]

MACROCYTIC ANEMIA. Megaloblastic anemia is classified as a macrocytic anemia characterized by enlarged erythroid precursor cells. There are numerous etiologies for macrocytic anemia; folate and cobalamin (vitamin B_{12}) deficiency are the most common. Folate and vitamin B_{12} deficiencies are distinguishable by their noncutaneous clinical presentations (see below),

but not by hematologic findings. Their deficiency leads to impaired purine and pyrimidine synthesis, preventing normal DNA replication. The macrocytic cells are a result of nuclear-cytoplasmic asynchronization.

Vitamin B_{12} is found only in meat and dairy products, making vegetarians prone to deficiency.[93] In nonvegetarian populations (especially of Scandinavia, Turkey, and Israel), vitamin B_{12} deficiency is caused by a rare genetic disorder of malabsorption, the Imerslund–Grasbeck syndrome. Pernicious anemia (PA) is the most common cause of vitamin B_{12} deficiency. It is an autoimmune disorder that attacks intrinsic factor in the ileum, which is essential to absorb vitamin B_{12}. The second cause of PA, chronic atrophic gastritis, results in autoantibodies against gastric parietal cells, which produce intrinsic factor.

Folate is found in animal products and in green leafy vegetables. Its deficiency is usually attributed to dietary inadequacy, alcohol abuse, malabsorption, and drugs that interfere with folate metabolism, i.e., methotrexate, phenytoin, trimethoprim. The demand for folate by the placenta and fetus usually doubles. Therefore, it is now standard care to give prophylactic folic acid supplements to all pregnant women to reduce the risk of neural tube defects in newborns.[94] Exfoliative skin disease and hemolysis can also lead to folate deficiency due to increased demand. Hereditary folate malabsorption results in impaired folate transport in the gastrointestinal tract and the blood–brain barrier.

Clinical findings of megaloblastic anemia develop slowly and vary, depending on the level of hemoglobin concentration and the etiology. The commonly shared signs and symptoms are malaise, fatigue, palpitation, glossitis, shortness of breath, and light-headedness. Mild jaundice can also be seen when ineffective erythropoiesis leads to hyperbilirubinemia and this, combined with anemic pallor, may lead to a characteristic lemon-yellow skin color. Hyperpigmentation is common in vitamin B_{12}- and folate-deficient patients, especially skin types III–VI. Patients with PA may also develop vitiligo or Hashimoto thyroiditis.[95] Hyperpigmentation is a common cutaneous manifestation of vitamin B_{12} deficiency.[96] The hyperpigmentation is usually prominent on the knuckles of the hands and feet, especially in darkly pigmented individuals.[97]

Neurologic findings in vitamin B_{12} deficiency, but not folate deficiency, help to clinically distinguish between the two causes of megaloblastic anemia.[93,94] Memory loss, dementia, tremor, Lhermitte's sign, irritability, atrophic glossitis, and neuropathy may occur. Specifically, patients with vitamin B_{12} deficiency develop subacute combined degeneration of the dorsal and lateral spinal columns—paresthesia (initial presentation), loss of vibration and position sense, shuffling gait, ataxia, spasticity, and paraplegia. The signs are symmetric in presentation and affect the lower extremities more than the upper extremities.

Typically, patients with folate deficiency are malnourished and often have diarrhea. Patients with alcoholism are prone to folate deficiency. Another distinguishing marker is that vitamin B_{12} deficiency takes many years to occur, given the large liver stores. Folate deficiency, on the other hand, can occur in a few months.

Correcting the underlying etiology usually resolves the anemia and reverses the signs and symptoms. Vitamin B_{12} is best administered parenterally. Prophylactic folic acid supplementation of 400 µg/day is recommended for all women of childbearing age. In folate-deficient patients, 1–5 mg/day of oral folic acid is recommended with subsequent maintenance therapy.

ANEMIA OF ENDOCRINE DISORDERS. Panhypopituitarism, hypothyroidism, and Addison disease are the most common endocrine disorders in association with anemia, although anemia may occur in hyperthyroidism and gonadal disease as well (see Chapter 151).

FLUSHING

DIFFERENTIAL DIAGNOSIS. Flushing occurs as a result of cutaneous vasodilation, and when associated with sweating is mediated through the sympathetic cholinergic fibers (Box 144-1; see Chapter 151).

POLYCYTHEMIA VERA

The hallmark cutaneous finding of polycythemia vera (PV) is ruddy cyanosis and plethora. Other skin findings are aquagenic pruritus, neutrophilic dermatosis, pyoderma gangrenosum, and purpura. Acrocyanosis is seen in conditions with elevated hemoglobin levels, but deoxygenated blood through the dilated vessels in the skin. Increased red cell mass is either a direct result of compensation for hypoxia or from primary disorders such as PV. These changes lead to an increase in

BOX 144-1 DIFFERENTIAL DIAGNOSIS OF FLUSHING

- Toxins: scombroid poisoning, drugs—ethanol, calcium channel blockers
- Rosacea
- Malignant carcinoid
- Mastocytosis
- Frey syndrome
- Fever
- Benign cutaneous flushing (blushing, exercise, temperature changes, spicy foods)
- Climacteric flushing (hot flashes)
- Chromaffin tumor
- Anaphylaxis
- Renal cell cancer
- Vasoactive intestinal polypeptide tumor
- Medullary carcinoma of thyroid
- Polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes
- Neurologic diseases (brain tumors, migraine headache, orthostatic hypotension, Parkinson)

POLYCYTHEMIA VERA AT A GLANCE

- Myeloproliferative disorder that involves all cell lines, with dominant erythropoietin proliferation and, subsequently, increased plasma volume and hematocrit.
- Presents with acrocyanosis, aquagenic pruritus, urticaria, and Sweet syndrome.
- Diagnostic criteria are (1) elevated red cell mass, (2) normal arterial O_2, and (3) splenomegaly.
- Treatment: concomitant therapy of aspirin and phlebotomy, cytoreductive therapy with hydroxyurea; narrowband ultraviolet B phototherapy for pruritus.

blood viscosity and vascular volume, resulting in a hypercoagulable state, especially when associated with thrombocytosis, and occasionally paradoxical hemorrhage from platelet dysfunction.[98]

Other symptoms are headache, paresthesia, and erythromelalgia. Erythromelalgia is a syndrome of altered acral responses, resulting in erythema and burning pain, especially when triggered by touching a warm object.[99] In myeloproliferative diseases, this syndrome is most probably secondary to platelet abnormalities, and may result in microvascular occlusion and necrotic lesions in affected areas. The catastrophic symptoms include large vessel arterial cerebrovascular (stroke) or cardiovascular (myocardial infarction) events, and peripheral arterial occlusion. PV has an unusually high incidence of portal and hepatic vein thrombosis (Budd–Chiari syndrome), lower extremity deep venous thrombosis, leg ulcers, Raynaud phenomenon, and pulmonary emboli. Bleeding manifestation is assumed to be a direct cause of dysfunctional platelets or von Willebrand disease. Defective primary hemostasis manifests with ecchymosis, menorrhagia, epistaxis, gingival hemorrhage, and, less frequently, gastrointestinal hemorrhage. Risk factors for PV are age (more than 60 years of age), history of thrombosis, cardiovascular risk factors (hypertension, smoking, hypercholesterolemia, diabetes), hereditary and acquired thrombophilic states (congenital deficiency of anticoagulants: antithrombin III, protein C and S; genetic mutation in factor V Leiden, prothrombin G20210A, or methylenetetrahydrofolate reductase), and acquired conditions (anticardiolipin antibodies and/or lupus anticoagulants).[98]

Diagnosis of PV has been greatly simplified in most cases by the ability to test for the *JAK2617F* mutation present in 95% of all patients.[100]

There is no specific therapy for PV. Treatment is directed toward preventing thrombohemorrhagic episodes and progression to myelofibrosis or leukemia. Aspirin may be of minor help in preventing thrombosis. Those not benefiting symptomatically from aspirin usually require platelet cytoreduction, (hydroxyurea, busulfan, radioactive phosphorus, chlorambucil, interferon) or anagrelide to inhibit platelet function. Phlebotomy is useful in controlling red cell mass, but may exacerbate thrombocytosis or leukocytosis.[100]

CYANOSIS

Cyanosis refers to discoloration of the mucocutaneous tissue that results in a blue or purple tinge, particularly in the peripheral tissues such as lips, ears, and nail beds. *Central cyanosis* refers specifically to the lingual and sublingual regions, and is more reflective of reduced hemoglobin in the blood; in peripheral cyanosis (skin, hands, feet, earlobes, etc.), the cause is often vasoconstriction. Cyanosis may be difficult to detect and is often missed on physical examination. Many factors, including natural skin pigment, thickness of the skin, and blood flowing through the cutaneous capillaries, determine the degree of cyanosis.

Cyanosis is detectable when at least 5 g of deoxygenated hemoglobin are circulating in the capillary blood, which correlates with an arterial concentration of deoxygenated hemoglobin of 3.4 g/dL. A patient with severe anemia of less than 7 g/dL Hg may never manifest cyanosis because they may become fatally hypoxic long before they reach 5 g/dL of desaturated hemoglobin, whereas a patient with PV frequently manifests ruddy cyanosis because the total increased hemoglobin content of their blood allows adequate oxygenation of tissue despite reaching the 5g/dL level at which the cyanosis becomes clinically evident (Box 144-2). Fluorescent light is best for detecting cyanosis. The diagnostic workup for a complete assessment of cyanosis includes complete blood cell count, arterial blood gas, pulse oximetry, partial arterial pressure of oxygen (PaO_2) level, and arterial oxygen saturation. If cyanosis is positional, an intracardiac mass must be considered.[24]

BOX 144-2 DIFFERENTIAL DIAGNOSIS OF CYANOSIS

- Deoxyhemoglobin
  - Acquired and inherited methemoglobinemia
  - Sulfhemoglobinemia
  - Low oxygen-affinity hemoglobin
- Abnormal hemoglobin
  - Congenital heart defects
  - Transposition of the great vessels
  - Tetralogy of Fallot
  - Ebstein's anomaly
- Arteriovenous fistulae, e.g., in Osler–Weber–Rendu syndrome or dyskeratosis congenital.
- Disorders of the central nervous system, respiratory system, musculoskeletal and circulatory systems can disrupt the oxygen supply to the tissues.

The causes of cyanosis are broad, but best if characterized into two groups: (1) disorders involving deoxygenated hemoglobin and (2) disorders of abnormal hemoglobin.[101,102] The latter includes acquired and inherited methemoglobinemia, sulfhemoglobinemia, and low oxygen-affinity hemoglobin. Methemoglobinemia causes clinically discernible cyanosis when the absolute level of methemoglobin exceeds 1.5 g/dL; this correlates with approximately 10%–15% methemoglobin. Offending agents are nitrates (found in drinking water, drugs, and food), topical anesthetic agents (lidocaine, benzocaine, and prilocaine), drugs (i.e., dapsone, phenazopyridine, sulfamethoxazole), and aniline dyes. Congenital methemoglobinemia is caused by deficiency in nicotinamide adenine dinucleotide (reduced form)–cytochrome b_5 reductase.[103] Treatment of choice for methemoglobinemia is intravenous methylene blue. Methylene blue should not be administered to patients with glucose-6-phosphate dehydrogenase deficiency. [104] If methylene blue is contraindicated, ascorbic acid can be given. RBC exchange transfusion has also been reported to be an effective treatment in symptomatic methemoglobinemic patients with coexistent glucose-6-phosphate dehydrogenase deficiency (see Chapter 225).

Sulfhemoglobin in concentrations greater than 0.5 g/dL in capillary blood also causes cyanosis, and cannot be reversed. Medications (especially sulfonamides, phenacetin, acetanilide, and phenazopyridine are the usual causes, but this condition has occurred independent of drug use in association with chronic constipation and purging. Offending agents in cases of acquired methemoglobinemia should be discontinued. No other therapy may be required. But if the patient is symptomatic, methylene blue, 1–2 mg/kg over 5 minutes, provides an artificial electron acceptor for the reduction of methemoglobin via the NADPH-dependent pathway. Response is usually rapid; the dose can be repeated in 1 hour, but frequently this is unnecessary. Caution should be exercised to avoid an overdose because large (more than 7 mg/kg) cumulative doses have been reported to cause dyspnea, chest pain, and hemolysis. Because co-oximetry detects methylene blue as methemoglobin, it cannot be used to monitor methemoglobin levels after treatment with methylene blue; however, the specific Evelyn-Malloy method allows for the discrimination of methemoglobin from methylene blue. Sulfhemoglobinemia occurs as sulfur binds to hemoglobin, resulting in irreversible deoxyhemogobinemia. It produces cyanosis at levels of only 0.5-g/dL capillary blood. Etiologies are drugs (sulfonamides, phenacetin, acetanilide, and phenazopyridine), constipation, and purging.

Low oxygen hemoglobin affinity occurs at altitude of 5,000 m (16,000 ft) or higher and can cause hypoxemia severe enough to result in cyanosis. Emotion, cold exposure, Raynaud phenomenon, and cryoglobulins (cold agglutinins) are some nonhematologic causes of peripheral cyanosis.

Disorders involving deoxygenated hemoglobin include congenital heart defects in the newborn (i.e., transposition of the great vessels, tetralogy of Fallot, and Ebstein's anomaly). X-linked dyskeratosis congenita presents with abnormal pigmentation, telangiectasias, nail dystrophy, leukoplakia; rarely, arteriovenous fistulas with central cyanosis occur. Arteriovenous fistulas are a feature of Osler–Weber–Rendu syndrome as well. Other disorders of the central nervous system, respiratory tract, and musculoskeletal and circulatory systems can also disrupt the oxygen supply to the tissues.

JAUNDICE

JAUNDICE AND EXTRAMEDULLARY HEMATOPOIESIS AT A GLANCE

- Jaundice is detectable when bilirubin levels are approximately 51 M (3.0 mg/dL) under nonfluorescent lighting, especially in the sclerae and sublingual region
- Differential diagnosis of jaundice: carotenemia causes yellow pigment in palms, soles, forehead, and nasolabial folds; quinacrine leads to yellowing of skin, but not sclera.
- Extramedullary hematopoiesis: cutaneous lesions include nodules ulcers, erythematous papules, violaceous plaques, and diffusely erythematous induration; biopsy confirms diagnosis but underlying cause needs to be determined.

Jaundice (icterus) refers to the yellowish discoloration of the skin, caused by elevated bilirubin levels. The discoloration is a direct result of the bile pigment that stains the skin, suggesting an abnormality in bilirubin clearance or increased production due to hepatobiliary disease (see Chapter 150) or a hemolytic disorder. Kernicterus or permanent damage to the neonatal brain associated with hyperbilirubinemia is a serious risk.

INFILTRATIVE LESIONS

EXTRAMEDULLARY HEMATOPOIESIS. Synthesis of blood elements outside the bone marrow usually takes place in the spleen and liver but can also affect the skin. The dermis is a normal site of hematopoiesis during early fetal development. Cutaneous lesions of extramedullary hematopoiesis include nodules (can be sclerosing), ulcers, erythematous papules, violaceous plaques, and diffusely erythematous induration. Neonates with dermal hematopoiesis present as blueberry muffin babies with dark blue-colored to violaceous nodules. In neonates, the causes are erythroblastosis fetalis, chromosomal abnormalities, infections, congenital hemolytic anemia, thalassemia, and twin-to-twin transfusion.[105] Older individuals may show dermal hematopoiesis from hemolytic anemias, myeloproliferative syndromes such as chronic idiopathic myelofibrosis and

PV, thalassemia, and osteoporosis. The histologic findings are intradermal proliferation of immature granulocytes, megakaryocytes, and erythroid and myeloid precursor cells.

LEUKEMIA CUTIS. Leukemia cutis (LC) is a localized or disseminated skin infiltration by leukemic cells. It is usually a sign of dissemination of systemic disease or relapse of existing leukemia. Reported incidence varies from less than 5%–40%, depending on the type of leukemia, both acute and chronic, including the leukemic phase of non-Hodgkin lymphoma and hairy cell leukemias. It most commonly occurs with acute monocytic leukemia (AML-M5) and acute myelomonocytic leukemia (AML-M4).

Pattern of presentation of skin lesions in LC is variable and may have features that overlap with other (inflammatory) eruptions. Most common lesions are small (2–5 mm) papules (Figs. 144-9 and 144-10), nodules (Fig. 144-11), or plaques. LC lesions are usually somewhat more pink, violaceous, or darker than normal skin, always palpable, indurated, firm, or guttate psoriasiform or lymphomatoid papulosis-like lesions, but usually not tender. They are localized or disseminated; usually on trunk (Fig. 144-9), extremities, and face (Fig. 144-10), but may occur at any site. They may be hemorrhagic when associated with thrombocytopenia or may ulcerate. Erythroderma may (rarely) occur. Leukemic gingival infiltration (hypertrophy) occurs with acute monocytic leukemia. Similar lesion morphologies occur with different types of leukemia or specific types of leukemia may present with a variety of morphologies.

Inflammatory disorders occurring in patients with leukemia are modified by the participation of leukemic cells in the infiltrate, resulting in unusual presentations of such disorders (e.g., psoriasis with hemorrhage or erosions/ulcerations). Also, there are a number of cutaneous inflammatory diseases that may be associated with leukemia: Sweet syndrome (see Chapter 32), bullous pyoderma gangrenosum (see Chapter 33), urticaria (see Chapter 38), and necrotizing vasculitis (see Chapter 163).

Figure 144-9 Leukemia cutis. Multiple skin-colored and erythematous papules in a 38-year-old febrile woman that had erupted approximately 1 week before this picture was taken. The patient had acute myelogenous leukemia.

Figure 144-10 Leukemia cutis: chloroma. Large, ulcerated, green-hued tumors (chloromas) in the inguinal and perineal regions of a female with acute myelogenous leukemia; similar lesions were also present in the axillae and on the tongue.

Systemic symptoms are those associated with hematologic malignancy. Not infrequently, cutaneous manifestation may be the initial presenting symptom and may contribute importantly to the diagnosis.

The diagnosis is made by suspicion and verified by skin biopsy, immunophenotyping, and B- or T-cell receptor rearrangement studies. Hematologic studies with complete analysis of bone marrow aspirate and peripheral blood smear are then needed to make the diagnosis. If cutaneous findings precede any systemic disease, careful assessment of peripheral blood smears and bone marrow biopsies must be made.

The prognosis of LC is directly related to the prognosis for systemic disease. Therapy is usually directed at the leukemia itself.

Chapter 145 :: Cutaneous Lymphoma

:: Marc Beyer & Wolfram Sterry

CUTANEOUS LYMPHOMA AT A GLANCE

- Second most common group of extranodal lymphomas; estimated annual incidence is 1 in 100,000.
- Clonal proliferations of neoplastic T or B lymphocytes, and rarely of natural killer cells or plasmacytoid dendritic cells, arising in mid and late adulthood.
- Clinical behavior and prognosis are completely different from those of histologically similar systemic lymphomas.
- Most common form of cutaneous lymphoma is mycosis fungoides (MF), a cutaneous T-cell lymphoma, which is categorized as patch, plaque, or tumor stage. Related features include severe pruritus, alopecia, palmoplantar hyperkeratosis, and bacterial superinfection
- Histologically the patch/plaque stage of MF is characterized by an epidermotropic band-like infiltrate of neoplastic T lymphocytes with hyperconvoluted cerebriform nuclei involving the upper dermis variably with exocytosis and formation of intraepidermal Pautrier's microabscesses. The tumor stage consists of a dermal nodular infiltrate sparing the epidermis.

INTRODUCTION

Cutaneous lymphomas (CLs) represent clonal proliferations of neoplastic T or B lymphocytes and rarely of natural killer (NK) cells or—for historical reasons—plasmacytoid dendritic cells. CLs have been recognized as a heterogeneous group with distinct variability in clinical presentation, histopathology, immunophenotyping, and prognosis.

Primary CLs often show a completely different clinical behavior and prognosis than do histologically similar systemic lymphomas, which may involve the skin secondarily. Therefore, primary CLs require different approaches to treatment. For this reason, a consensus classification has been created based on both the European Organisation for Research and Treatment of Cancer (EORTC) classification for primary CLs and the World Health Organization (WHO) classification for tumors of hematopoietic and lymphoid tissues. This first common classification (WHO-EORTC)[1] categorizes the entities according to lineage and then according to a combination of morphology, immunophenotype, genetic features, and clinical syndromes (Box 145-1) and constituted the basis for the classification of CLs in the new WHO classification 2008.[2] This chapter discusses the most frequent cutaneous T-cell lymphomas (CTCLs)—mycosis fungoides (MF), Sézary syndrome (SS), primary cutaneous anaplastic large-cell lymphoma (cALCL), and lymphomatoid papulosis (LyP)—and the most frequent cutaneous B-cell lymphomas (CBCLs)—primary cutaneous follicle center lymphoma (PCFCL), primary cutaneous marginal zone lymphoma (PCMZL), and primary cutaneous diffuse large B-cell lymphoma (PCLBCL), leg type. These seven types of cutaneous lymphoma represent nearly 90% of all CLs.[3] Rare entities occurring primarily in the skin are also described.

EPIDEMIOLOGY

CLs represent the second most common group of extranodal lymphomas after the primary gastrointestinal lymphomas.[4] The annual incidence is estimated to be 1 per 100,000.[5]

PRIMARY CUTANEOUS T-CELL LYMPHOMAS

CTCLs are non-Hodgkin lymphomas characterized by a dominant skin-homing T-cell clone. They represent

BOX 145-1 WHO-EORTC CLASSIFICATION OF PRIMARY CUTANEOUS LYMPHOMAS

CUTANEOUS T-CELL AND NK-CELL LYMPHOMAS

- Mycosis fungoides
- Mycosis fungoides variants and subtypes
  - Folliculotropic mycosis fungoides
  - Pagetoid reticulosis
  - Granulomatous slack skin
- Sézary syndrome
- Adult T-cell leukemia/lymphoma
- Primary cutaneous CD30-positive lymphoproliferative disorders
  - Primary cutaneous anaplastic large-cell lymphoma
  - Lymphomatoid papulosis
- Subcutaneous panniculitis-like T-cell lymphoma
- Extra-nodal NK/T-cell lymphoma, nasal type
- Primary cutaneous peripheral T-cell lymphoma, unspecified
  - Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma (provisional)
  - Cutaneous γ/δ T-cell lymphoma (provisional)
  - Primary cutaneous $CD4^+$ small or medium-sized pleomorphic T-cell lymphoma (provisional)

CUTANEOUS B-CELL LYMPHOMAS

- Primary cutaneous marginal zone B-cell lymphoma
- Primary cutaneous follicle center lymphoma
- Primary cutaneous diffuse large B-cell lymphoma, leg type
- Primary cutaneous diffuse large B-cell lymphoma, other
  - Intravascular large B-cell lymphoma (provisional)
- Precursor hematologic neoplasm
- $CD4^+/CD56^+$ hematodermic neoplasm (blastic NK-cell lymphoma)

NK = natural killer; WHO-EORTC = World Health Organization and European Organisation for Research and Treatment of Cancer.

approximately 80% of all CLs. The most common forms (approximately 65% of CTCL) are MF and SS, with an annual incidence of five new cases per million people. After MF and SS, the primary cutaneous $CD30^+$ lymphoproliferative disorders comprising LyP and cALCL represent the second most common group of CTCLs (approximately 27%).

ETIOLOGY

For many years, CTCLs were thought of as a disease of long-term antigen stimulation in which an initial inflammatory response in the epidermis leads to T-cell proliferation and, finally, to the emergence of a malignant clone.[6] Despite much effort to identify such an antigen, the etiology remains unknown.

ENDOGENOUS FACTORS

Due to the above-mentioned hypothesis of antigen stimulation several studies have analyzed the HLA background of affected individuals. Two independent studies showed an association of distinct HLA class II molecules and MF or SS, i.e., the alleles HLA-DRB1*11 and DQB1*03 are significantly overrepresented in these patients.[7,8]

EXOGENOUS FACTORS

A viral etiology for CTCLs was an attractive hypothesis given the cutaneous similarities to adult T-cell lymphoma/leukemia, which is associated with human T-cell lymphotrophic virus type 1 (HTLV-1) infection (see Chapter 197). The results of studies to determine an association between CTCL and HTLV-1 are contradictory. Although few studies reported detection of HTLV-1 or -2 sequences by polymerase chain reaction (PCR) analysis in peripheral blood mononuclear cells (PBMCs) or skin biopsies of CTCL patients,[9,10] most reports of American and European populations repeatedly failed to demonstrate an association of MF with HTLV-1 infection by PCR, Southern blot, and reverse transcriptase assays.[11–13] These data suggest that HTLV-1 does not play an important role in the etiology of CTCLs, and that the only reason to screen patients for antibodies is suspicion that the diagnosis is adult T-cell lymphoma/leukemia rather than MF. Epstein-Barr virus (EBV) has also been proposed as a causative pathogen.[14] Given its association with other lymphoproliferative disorders and lymphomas, such as Burkitt lymphoma, this seemed logical. Several studies have shown that EBV is detectable only in a minor percentage of CTCL lesions. In these studies, EBV detection was related to a poor prognosis and its presence is more likely related to immunosuppression caused by either the disease or the therapy, than to etiology of CTCL.[15] However, a strong association of EBV and a rare cutaneous lymphoproliferative disease with a hydroa vacciniforme-like appearance, which occurs mostly in people of Asian origin has been observed.[16]

Bacterial infections have also been implicated in the etiology of CTCLs.[17] Of special interest has been the hypothesis that superantigens from *Staphylococcus aureus* may be responsible for chronic antigenic stimulation.[18] In several studies, *S. aureus* has been detected in a high percentage on the skin of CTCL patients with a high tumor burden, while patients in early stage disease did not show significant differences to control groups.[19,20] Though these studies conclusively demonstrated the involvement of *S. aureus* in disease exacerbation and clinical improvement following antibiotic treatment, the missing difference in *S. aureus* colonization of early stages of CTCL and control groups questions the involvement of *S. aureus* or superantigens produced by these bacteria in initiation of CTCLs.

Besides infectious pathogens, it has also been suggested that environmental and occupational risk factors play a causative role in CTCL, because an indolent dermatitis often precedes the diagnosis. Exposure to carcinogens in the work environment could provide the suspected long-term antigenic stimulation for the initiation of the clonal expansion. In epidemiologic studies,[21,22] several occupations like glass formers, potters, or paper and wood industry workers have been associated with a higher risk for development of MF. However, neither are the results of the different studies consistent nor could a common denominator like exposure to known carcinogens be identified. With regard to chronic antigenic stimulation by occupational contact allergens it has to be taken into account that MF arises typically on body areas like the lateral trunk, which are protected by clothing during working time. Also other environmental risk factors, like consumption of alcohol, smoking, or exposure to ultraviolet (UV) radiation, were not consistently observed in association with an increased risk for CTCLs.

PATHOGENESIS

The clinical entities encompassed by the term *cutaneous T-cell lymphoma*s share several components: the epidermal and/or dermal microenvironment, a clonal T-cell population, and a modulated antitumor response.[23,24] It has to be kept in mind that due to the rare occurrence of CTCLs in general and of the less prevalent subtypes in particular, nearly all of the knowledge on pathogenetic events has arisen from studies on specimens from MF and SS patients.

The basis for CTCLs as a malignancy confined to the skin, at least in the initial stages of the disease, is the expression of skin-specific homing receptors on the malignant T-cell clone. Skin-homing T cells can be distinguished from other T cells by a unique cell surface receptor called *cutaneous lymphocyte-associated antigen* (CLA). CLA is an inducible posttranslational carbohydrate modification of the ubiquitously expressed T-cell surface protein, P-selectin glycoprotein ligand 1 by α(1,3)-fucosyltransferase and is expressed on 30% of memory T cells in the peripheral blood.[25] It has been shown that induction of CLA expression on T cells occurs during the transition from naive to memory T cells and is mediated by dendritic cells isolated from peripheral skin draining lymph nodes.[26] CLA-positive cells have the ability to home to the skin by binding to E-selectin, which is expressed on endothelial cells of dermal postcapillary venules and is superinduced during cutaneous inflammation. As T cells in CTCLs express CLA and CD45RO, a memory T-cell marker, it is though that CTCLs arise from skin homing memory T cells. However, as CLA expression is strongly detectable in skin biopsies from both MF and inflammatory dermatoses, it cannot be used for the distinction of malignant and reactive T cells or malignant from inflammatory skin conditions.[27] In addition to CLA, expression of the chemokine receptors CCR4 and CXCR3 has been implicated in homing of the malignant cells to the epidermis and dermis. Furthermore, the respective ligands, i.e., the chemokines CCL17 and CCL22 have been found in skin lesions of CTCLs.[28] Interestingly, diminished expression of these skin homing receptors seems to be associated with more aggressive disease, i.e., large cell transformation, tumor formation. and dissemination of tumor cells into the blood or lymph nodes.[29,30]

Besides chemokines that attract the T cells into the skin, cytokines play an important role in the pathogenesis of CTCLs. Because of the memory phenotype of the tumor cells the cytokines interleukin 7 (IL-7) and IL-15, which are necessary for long-term survival and basal homeostatic proliferation of CD4 memory T cells, are of special interest.[31] In vitro studies and immunohistochemical analyses on skin biopsy specimens from lesions of MF demonstrate the presence of IL-15 and IL-7 and their capacity to prolong survival of a cell line derived from a SS patient in vitro, probably by an upregulation of the antiapoptotic protein bcl-2. As source of these cytokines both keratinocytes and the tumor cells themselves have been discussed.[32,33]

Direct genetic analysis of the clonal T cells and the identification of pathogenetically relevant genes in CTCLs have been hampered by the difficult differentiation of malignant and reactive lymphocytes in skin specimens on the one hand and by a large variety of reported genetic alterations on the other. The basis for the latter phenomenon is a chromosomal instability in tumor cells of patients with CTCLs, which has been described repeatedly.[34] In the last years, the application of large-scale genome analysis by comparative genomic hybridization and array technologies has elucidated the genetic basis for established pathogenetic factors and disclosed several new pathways, which are of central importance in the pathogenesis of CTCLs. These studies were conducted on samples with high tumor load from MF (skin biopsy specimens from tumors) and SS (PBMCs) patients, and also demonstrated considerable differences of these two entities in regard to genetic abnormalities.[35] The most consistent results were obtained for chromosomal and transcriptional gains affecting the proto oncogene *MYC* and loss of the tumor suppressor gene *TP53*, a combination for which it is shown to induce genetic instability by disrupting cell cycle control and apoptosis.[36] Furthermore, gains of genes important for the generation of survival signals, for example, the cytokine IL-7, the IL-2 receptor or transcription factors like STAT3/5, as well as alterations in members of the NFκB pathway, have been described.[37] In addition to gains, losses of well-known tumor suppressor genes, for example, *CDKN2A* (p16), were detected.[38]

Loss of Fas expression on tumor cells is of special importance as the Fas receptor/Fas ligand (FasL) pathway is involved in activation induced cell death of physiologically activated T cells. Loss of Fas has been linked to escape from the antitumoral immune response in diverse cancer entities.[39] Fas receptor and FasL are transmembrane proteins of the tumor necrosis factor family and are expressed on cells of lymphoid and myeloid lineage. On binding of the Fas ligand to Fas, a cascade of events is initiated that finally leads to apoptosis.

Aberrations of the Fas/FasL pathway have been studied in CTCLs. Immunohistochemical studies of Fas

expression in skin biopsy specimens from MF lesions demonstrated loss of Fas expression the in tumor stage, while expression was clearly detectable in early patch and plaques stage.[40] In addition to the loss of Fas expression on the cell surface, upregulation of intracellular proteins like cFLIP, which inhibit Fas-initiated apoptosis has been shown in CTCL cells.[41] Thus, downregulation or loss of Fas expression as well as disturbance of intracellular pathways activated by death receptors may counteract proapoptotic signals given to the tumor cells by antitumoral immune cells, finally resulting in immune escape of the tumor cells in CTCLs.

In conclusion, specific mechanisms for all features that have been proposed to be necessary for the evolution of tumor cells,[42] like evasion of apoptosis, generation of growth or survival signals and insensitivity to antigrowth signals, mechanism of tissue homing and metastasis have nowadays been demonstrated in CTCL cells.

Finally CTCLs exhibit a modulated antitumor response. It is well established that patients with CTCLs have variable production and response to T helper 1 and 2 (Th1, Th2) cytokines. Early studies that measured the messenger RNA (mRNA) levels of Th1 and Th2 cytokines showed that, at any stage of disease, mRNA of the Th2 cytokines interleukin 4 and 5 (IL-4, IL-5), could be found, with the persistence of Th2 cytokine mRNA in skin more frequent in the tumor stage. Correlation of the amount of the Th2 cytokine IL-10, which has immunosuppressive functions, and disease stage in CTCLs has been described.[43] The decline in interferon (IFN)-γ and predominance in Th2 cytokines, which is accompanied by a decreasing number of circulating dendritic cells in the blood, might be responsible for the loss of immunosurveillance, which allows CTCL to progress. Lesions of CTCLs often have a $CD8^+$ T-cell component. Although they were once thought to be innocent bystanders in the epidermis, data have now defined the responsibility of $CD8^+$ T cells in the antitumor response. The first insight into defects in the integrity of normal T-cell function in patients with advanced stages of CTCLs came from the observation of patients who had been treated with extracorporeal photochemotherapy (ECP).[44] Responding patients had significantly lower CD4/CD8 T-cell ratios and higher absolute numbers of $CD8^+$ T cells in their peripheral blood at the outset of treatment than did nonresponders. In general, skin biopsy specimens of MF lesions in early stages (T1 and T2) harbor a higher proportion of $CD8^+$ cells than lesions in advanced stages. Improved long-term prognosis was correlated with the presence of these $CD8^+$ tumor-infiltrating lymphocytes (TIL) in MF.[45] It is now believed that these $CD8^+$ cytotoxic T cells play an important part in the pathogenesis of CTCLs, mainly in mediating an antitumor response.

An interesting hypothesis pursued during the recent years, proposes that the malignant T cells themselves exhibit properties of regulatory T cells (T regs) and thereby are able to modulate the antitumoral immune response.[46] However, the results of studies enumerating T regs in CTCL biopsy specimens were inconsistent. These conflicting results may be due to the fact that both a decrease of T regs as well as an increase of CD25-negative T regs, which then are phenotypically identical with the malignant clone, can be observed in SS.[47]

MYCOSIS FUNGOIDES

DEFINITION. MF is the most frequent disease among CTCLs, usually arising in mid-to-late adulthood (median age at diagnosis, 55–60 years) with a male predominance of 2:1.

CLINICAL FINDINGS

Skin Signs. Clinically, MF is categorized as being in the patch, plaque, or tumor stage, but patients may simultaneously have more than one type of lesion. In early patch-stage MF (Figs. 145-1 and 145-2), there are single or multiple erythematous, scaly macules and patches that vary in size and are usually well defined. The color of the lesions may vary from orange to a dusky violet–red. The distribution classically favors nonsun-exposed sites, with the "bathing trunk" and intertriginous areas predominant early in the course of the disease. The eruption may be intensely pruritic or asymptomatic and occasionally may be transitory, disappearing spontaneously without scarring. Diagnosis at this stage may be difficult. Often a patient will recall a preceding "chronic dermatitis" for 10–20 years that may have been considered to be therapeutically resistant contact dermatitis, atopic dermatitis, psoriasis, or eczema. In any patient with a dermatosis that is refractory to the usual modalities of treatment, multiple biopsy specimens should be taken to pursue a diagnosis.

Patches may last for months or years before progressing to the plaque stage (Fig. 145-3), or plaques may arise de novo. Plaques appear as sharply demarcated, scaly,

Figure 145-1 Patch lesions of mycosis fungoides in typical locations on the lateral trunk.

Figure 145-2 Large patch lesions of mycosis fungoides surrounding areas of uninvolved skin.

Figure 145-4 Multiple patches and plaques of mycosis fungoides on the lateral trunk. In this patient the plaques developed rapidly and partially show central necrosis.

elevated lesions that are dusky red to violaceous and variably indurated (Figs. 145-3 and 145-4). Lesions in this stage may regress spontaneously or may coalesce to form large plaques with annular, arcuate, or serpiginous borders, and may clear centrally with disease activity remaining at the periphery of the lesion. There may be purpuric hyperpigmentation or hypopigmentation and poikiloderma.

Tumors may occur anywhere on the body, but have a predilection for the face (Figs. 145-5 and 145-6) and body folds: axillae, groin, antecubital fossae, and, in women, the inframammary area. These may occur in preexisting plaques or patches of MF, which coincides with an extension of these lesions in the vertical dimension (Fig. 145-3). At this point, the neoplastic cells behave in a biologically more aggressive manner, with pronounced tumor cell accumulation that leads to the clinical appearance of an expanding dermal nodule (see Fig. 145-6). De novo occurrence suggests metastatic spread by cells of a malignant T-cell clone. The nodules are reddish brown or purplish red and smooth surfaced, but they often ulcerate and may become secondarily infected. Growth rate is variable.

Figure 145-3 Polymorphic nature of mycosis fungoides. Patches and a plaques with a developing nodule on the left buttock.

Figure 145-5 Leonine facies characterized by infiltrated plaques and tumors of cutaneous T-cell lymphoma.

Figure 145-6 Tumor lesions of mycosis fungoides on the right arm, which are partially eroded and ulcerated.

Patients with tumors tend to have a more aggressive form of the disease than patients with patch and plaque disease.

Erythroderma (Fig. 145-7A) may start de novo or develop in MF. The nomenclature for erythrodermic phases of CTCL varies. It has been proposed that erythroderma be defined as the involvement of 80% of body surface area with lesions of ill-defined borders and that patients with a history of preexisting MF be defined as having a separate syndrome of "erythrodermic MF."

The skin is diffusely bright red with readily apparent scaling, but there may be characteristic islands of uninvolved skin, termed *nappes claires* (Fig. 145-2). There may be sparing of the areas of skin that are frequently folded, such as the abdomen and antecubital and axillary areas. This sparing produces a finding often called the *deck chair* or *folded luggage* sign. Some patients with the erythrodermic form of CTCL develop tumors.

Other Symptoms. Patients may complain of fever, chills, weight loss, malaise, insomnia secondary to the overwhelming pruritus, and poor body temperature homeostasis. There may be hyperkeratosis, scaling and fissuring of the palms and soles, alopecia, ectropion, nail dystrophy, and ankle edema, with the integument being shiny and hidebound. These changes result in pain on walking and extreme difficulty with tasks requiring manual dexterity. Such patients experience severe restrictions by the extent and localization of their skin manifestations. Pruritus is often intense, which results in excoriation, exudation, and secondary infection that may dominate the clinical picture.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of MF is summarized in Box 145-2.

HISTOPATHOLOGY.

In the patch, plaque, and also in the erythrodermic stage, there is a band-like infiltrate in the upper dermis composed of reactive T cells and neoplastic T lymphocytes, which are characterized by hyperconvoluted cerebriform nuclei. The neoplastic T cells show an epidermotropism with formation of intraepidermal Pautrier's microabscesses (Figs. 145-8 and 145-9). In the tumor stage, a nodular infiltrate in the dermis is found, and the epidermal component is much less pronounced (Fig. 145-10). Immunohistologically, the malignant cells express a mature peripheral T-cell ($CD4^+$) phenotype. Partial loss of pan-T-cell antigens

Figure 145-7 Sézary syndrome patient with erythroderma (**A**), palmar fissuring (**B**), and plantar hyperkeratosis (**C**).

BOX 145-2 DIFFERENTIAL DIAGNOSIS OF MYCOSIS FUNGOIDES

PATCH/PLAQUE STAGE

- "Chronic dermatitis"
- Psoriasis
- Contact dermatitis
- Eczema
- Tinea corporis

TUMOR STAGE

- B-cell lymphoma
- Carcinoma cutis
- Sarcoidosis
- Deep fungal infection
- Atypical mycobacterial infection
- Leprosy
- Leishmaniasis

ERYTHRODERMA

- Pityriasis rubra pilaris
- Psoriasis
- Atopic dermatitis
- Drug eruption
- Seborrheic dermatitis

such as CD7 and CD3 may be a feature of MF but is not pathognomonic of the disease. Analysis of T-cell receptor genes (TCR) typically shows a clonal rearrangement as demonstrated by PCR or Southern blot techniques.

TREATMENT AND PROGNOSIS. Treatment should be stage-adapted and alleviate symptoms (see Sections "Staging of Cutaneous T-Cell Lymphomas" and "Principles of Treatment of Cutaneous T-Cell Lymphoma"). The prognosis depends on the type and extent of skin involvement (plaques, tumors, or erythroderma), the presence of lymph node involvement, and the presence of visceral disease. Overall, patients

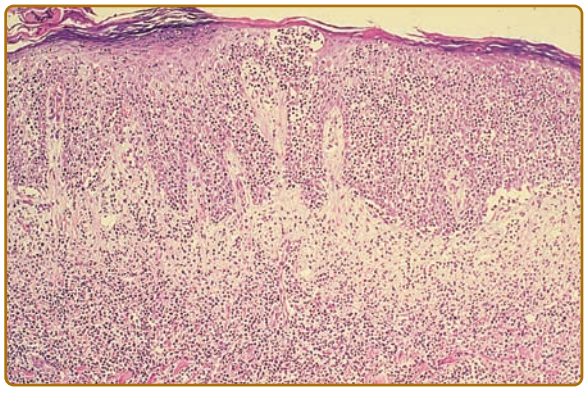

Figure 145-8 Dense mononuclear cell infiltrate extending from the papillary dermis into the epidermis. The epidermis is completely permeated by these cells, which form a Pautrier's abscess.

with MF limited to the skin have a 5-year survival rate of 80%–100%. In contrast, patients with lymph node involvement show a 5-year survival rate of 40%.

MYCOSIS FUNGOIDES VARIANTS

FOLLICULOTROPIC MYCOSIS FUNGOIDES. Folliculotropic MF represents a distinct variant of MF characterized by preferential involvement of the head and neck by folliculotropic T-cell infiltrates, with or without mucinous degeneration of the hair follicles (Fig. 145-11B). Previously, this variant was called *follicular mucinosis* or *alopecia mucinosa*. Folliculotropic MF affects mostly adults and is rarely observed in children and adolescents. Patients may have grouped follicular papules (see Fig. 145-11A), acneiform lesions, indurated plaques, and sometimes tumors, which usually involve the head and neck region. The occurrence of hair loss within the lesions, most conspicuous on the eyebrows, an intense pruritus, and secondary bacterial infections is common.

HYPOPIGMENTED MYCOSIS FUNGOIDES. Patients with dark skin develop hypopigmented MF,

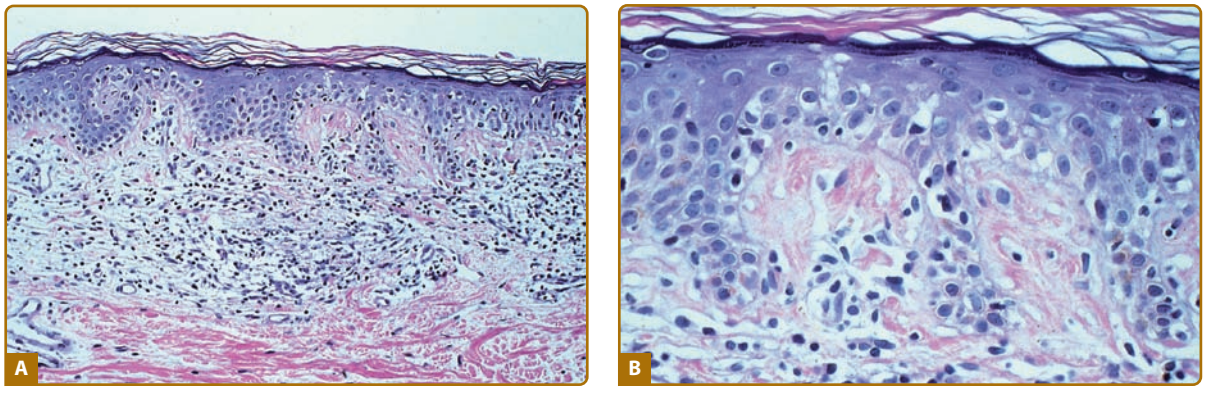

Figure 145-9 Patch stage of mycosis fungoides. **A.** Single atypical mononuclear cells in epidermis with sparse superficial perivascular infiltrate in the papillary dermis. (Hematoxylin and eosin-stained section.) **B.** High-power view of atypical cells in epidermis of same section.

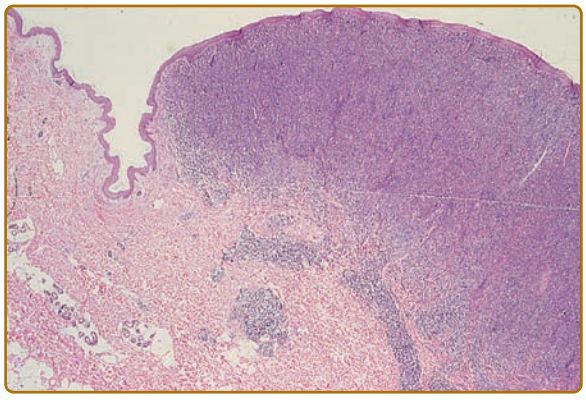

Figure 145-10 Low-power view of a mycosis fungoides tumor. The dense infiltrate extends deep into the dermis.

a variant of patch MF. In darker skinned individuals, this may be the most common presentation of the disease. Patients respond to therapy by repigmentation, and the reappearance of hypopigmented lesions often indicates a relapse.

PAGETOID RETICULOSIS. Pagetoid reticulosis (Woringer–Kolopp disease) is a distinct variant of MF that is characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic cells. Patients present with a solitary psoriasiform or hyperkeratotic patch or plaque, which is usually localized on the extremities (Fig. 145-12) and is slowly progressive. Unlike in classic MF, extracutaneous dissemination has not been observed.

In the past, the term pagetoid reticulosis also included a disseminated form (called Ketron–Goodman type). As this type usually shows a more aggressive behavior, it is now classified as an aggressive primary cutaneous epidermotropic $CD8^+$ T-cell lymphoma (see Section "Primary Cutaneous Aggressive Epidermotropic $CD8^+$ T-Cell Lymphoma").

GRANULOMATOUS SLACK SKIN. Granulomatous slack skin is a rare subtype of MF characterized by localized areas of bulky folding of the skin, with a predilection for the axillae and groins (Fig. 145-13).

Figure 145-12 Pagetoid reticulosis. Hyperkeratotic plaque localized on the lower leg of a male patient.

Light microscopy reveals a dense granulomatous infiltrate in the entire dermis. In addition to small atypical cells with cerebriform nuclei, macrophages and multinucleated giant cells occur and loss of elastic fibers is observed. The neoplastic cells express a $CD3^+$ $CD4^+$ $CD8^-$ phenotype.[48]

SÉZARY SYNDROME

DEFINITION. SS is characterized by the triad of diffuse erythroderma, generalized lymphadenopathy, and circulating malignant T cells with cerebriform nuclei, the so-called *Sézary cells*.

CLINICAL FINDINGS. The erythroderma is often accompanied by severe scaling or fissuring of the palms and soles (see Fig. 145-7A–C), alopecia, and

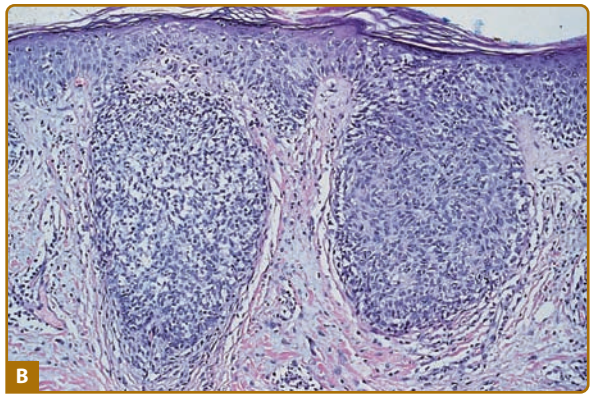

Figure 145-11 **A.** Folliculotropic mycosis fungoides. Note follicular localization and resulting hair loss. **B.** Outer root sheath of hair follicle is disrupted by T cells and mucin deposition, which leads to small cystic spaces.

Figure 145-13 Granulomatous slack skin. Note skinfolds due to secondary elastolysis.

onychodystrophy and may be associated with marked exfoliation, edema, and lichenification and an intense pruritus.

LABORATORY FINDINGS. SS demonstrates histologic features similar to those of MF, but repeated biopsies may be necessary as specimens often show nondiagnostic findings. Therefore, several diagnostic criteria for the blood involvement proposed by the International Society for Cutaneous Lymphoma—including an absolute Sézary cell count in the peripheral blood of at least 1,000 cells/mm^3 detected by light microscopic examination of a blood smear, or an increased CD4/CD8 ratio of more than 10 measured by fluorescence-activated cell-sorting analysis, or evidence of a circulating T-cell clone detected by cytogenetic methods—were included in the WHO–EORTC classification.[1] Patients lacking the atypia on the peripheral blood smear or the corroborating evidence are considered to have erythrodermic CTCL.[49]

TREATMENT AND PROGNOSIS. Compared with patients with patch- or plaque-stage MF, patients with SS have a markedly decreased 5-year survival rate of 24%. By the time the SS appears, there is very little normal immunity left. Indeed, SS patients often die because of infectious complications.[50]

PRIMARY CUTANEOUS CD30$^+$ LYMPHOPROLIFERATIVE DISORDERS

Primary cutaneous CD30$^+$ lymphoproliferative disorders consist of LyP and cALCL. Both entities are now recognized to form the ends of a spectrum, which includes borderline cases that, on histomorphologic grounds alone, cannot be clearly assigned to LyP or cALCL.

LYMPHOMATOID PAPULOSIS

Definition. LyP was first described by Macaulay in 1968. It is an uncommon chronic disorder (incidence of 1.2–1.9 cases in 1,000,000) characterized by recurrent self-healing crops of papules and papulonodules.

Clinical Findings. Disseminated recurrent self-healing papules and papulonodules occur that may become necrotic in the center (Fig. 145-14) and often erupt over a period of months or several years. The lesions typically involve the trunk and extremities, and lesions in various stages of evolution may be present concurrently.

Histopathology. LyP shows a highly variable histologic picture that closely mimics that of malignant lymphoma. Three major histologic types, designated as *A*, *B*, and *C*, have been recognized.[51] Types A and C are characterized by the presence of large atypical blasts, including mononucleated and binucleated or multinucleated cells resembling Reed–Sternberg cells characteristic of Hodgkin lymphoma. The atypical blasts express one or more T-cell antigens as well as the lymphoid activation antigen CD30 (Fig. 145-15). Although in type A these cells are embedded in a dense inflammatory background consisting of histiocytes, small lymphocytes, neutrophils, and/or eosinophils, in type C they form large sheets closely simulating cALCL. LyP type B is composed of small-to-medium-sized CD30-negative T cells showing epidermotropism and thus closely resembles classic MF. Importantly, different histologic types of LyP can be present in one patient, because the histologic picture also correlates with the age of the individual lesion.

Treatment and Prognosis. Because a curative therapy is not available and none of the available treatment modalities affects the natural course of the disease, the short-term benefits of active treatment should be balanced carefully against the potential side effects. Low-dose methotrexate (5–20 mg/week) is the most effective therapy to suppress the development of new skin lesions. Treatment with psoralen plus ultraviolet A light (PUVA) has been reported to yield beneficial effects but duration of response is often short-lived after discontinuation of treatment. Therefore, in patients with few, nonscarring lesions, long-term follow-up without active treatment should be considered.[52]

In general, LyP shows a benign clinical course and a favorable 10-year survival rate of nearly 100%. However, in a proportion of patients, estimated at 10%–20% of cases, LyP can precede, coexist with, or follow malignant lymphoma, especially MF, Hodgkin lymphoma, or nodal anaplastic large cell lymphoma. In many of these cases, the same clonal TCR rearrangements have been found in the LyP as well as in the associated lymphoma. In the majority of LyP cases, despite the sometimes extremely long course of the disease, there is no evolution of a secondary lymphoma.

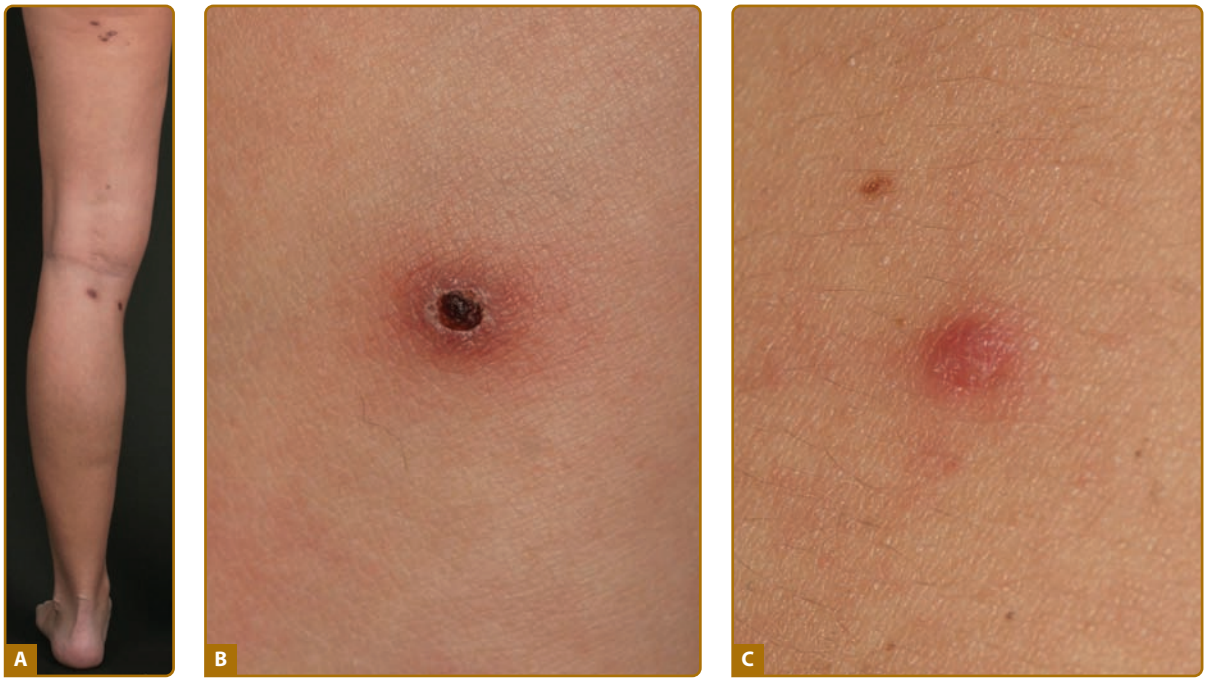

Figure 145-14 Lymphomatoid papulosis. **A.** Papular skin lesions on the right leg. The lesions may appear disseminated and grouped. **B.** Lymphomatoid papulosis papulonecrotic lesion. **C.** Lymphomatoid papulosis erythematous papulonodule.

CUTANEOUS ANAPLASTIC LARGE CELL LYMPHOMA

Definition. The cutaneous lymphoma cALCL is characterized by large tumor cells, of which the majority express the CD30 antigen, with no evidence or history of MF or another type of primary CTCL. Regardless of the morphology of the tumor cells (anaplastic, immunoblastic, or pleomorphic large cells), the clinical presentation and behavior are identical.

Clinical Findings. $CD30^+$ cutaneous large-cell lymphomas occur in adults and rarely in children and adolescents, with a male–female ratio of 1.5:1. The clinical picture is characterized by the solitary or locoregional occurrence of reddish to brownish nodules and tumors, which frequently ulcerate (Fig. 145-16A). Although secondary involvement of the regional lymph nodes is observed in roughly 10% of the patients, it is not necessarily associated with an unfavorable prognosis.

Histopathology. A nodular or diffuse nonepidermotropic infiltrate of large cells is seen in the dermis (see Fig. 145-16B). In the majority of cases, the neoplastic cells show an anaplastic morphology with oval or irregularly shaped nuclei, prominent nucleoli, and an abundant cytoplasm. Less commonly, a pleomorphic or immunoblastic appearance is observed. Atypical mitotic figures are frequent. In the periphery of the lesions, inflammatory cells (lymphocytes, eosinophils, and neutrophils) are present, sometimes imitating the histologic picture seen in LyP.

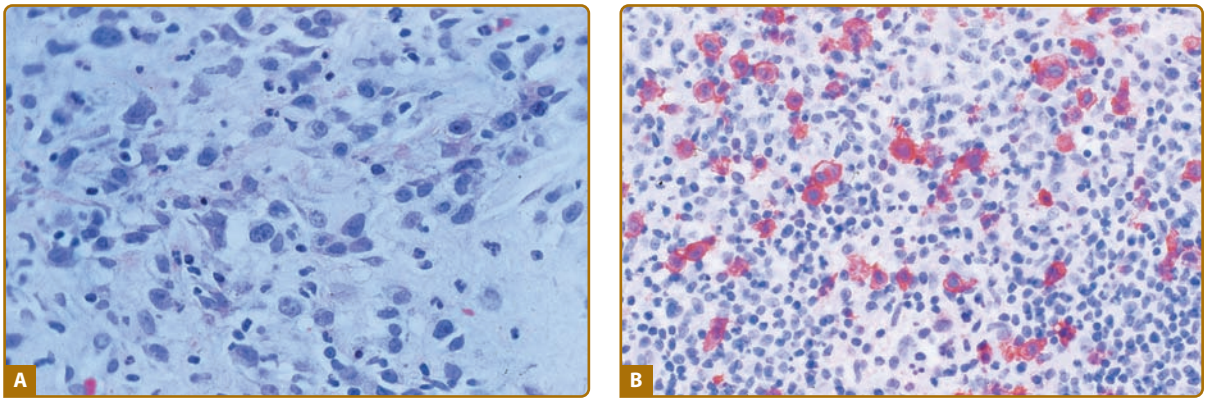

Figure 145-15 **A.** Lymphomatoid papulosis. Dermal infiltrate contains several large lymphoid cells with nuclei showing evenly dispersed chromatin and variably prominent nucleoli (so-called *type A cells*). **B.** Type A with large $CD30^+$ T cells (*red*) among admixed inflammatory cells.

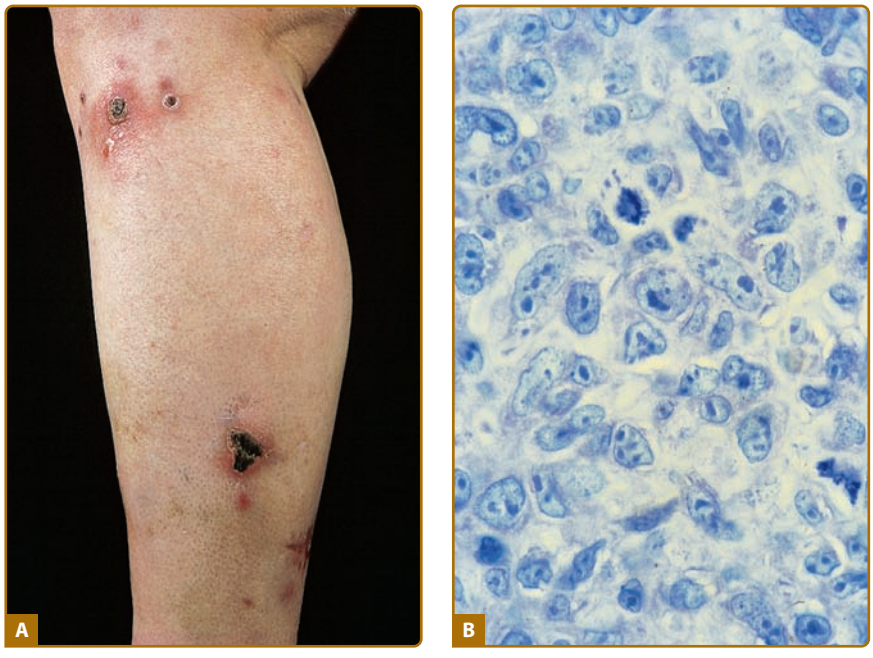

Figure 145-16 Primary cutaneous anaplastic large-cell lymphoma. **A.** Localized nodules, some with ulcerations. **B.** Pleomorphic large-cell lymphoma T-cell infiltrate.

By definition, at least 75% of the large cells are CD30$^+$. In addition, they express a CD4$^+$ phenotype with variable loss of pan-T-cell antigens such as CD2, CD3, and CD5. Cases with CD8$^+$ neoplastic cells occur rarely. Unlike nodal CD30$^+$ lymphomas, CD30$^+$ large-cell lymphomas of the skin test negative for CD15 and epithelial membrane antigen, and expression of the anaplastic lymphoma kinase ALK is also absent in most cases of cALCL. Clonal TCR rearrangements are detected in most cases.[53]

For diagnosis clinicopathologic correlation is crucial. The histologic picture may suggest LyP, but lesions of CD30$^+$ cutaneous large cell lymphoma are clinically larger and localized, and they usually do not tend to disappear spontaneously.

Treatment and Prognosis. In cases of solitary or localized skin lesions, excision or radiotherapy is the treatment of choice. Successful treatment with PUVA in combination with IFN-α has been reported. If skin lesions are generalized systemic therapy with methotrexate (20 mg/week) is preferred and in the case of extracutaneous dissemination multiagent chemotherapy should be considered. A chimeric monoclonal anti-CD30-antibody has shwon promising results in phase II study in CD30$^+$ CTCL.[54] In contrast to extracutaneous large-cell lymphomas, CD30$^+$ cutaneous large-cell lymphomas of the skin have a favorable prognosis, with a disease-related 5-year survival rate of 90%.

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

DEFINITION. Subcutaneous panniculitis-like T-cell lymphoma (SPTL) is defined as a cytotoxic T-cell lymphoma characterized by the presence of primarily subcutaneous infiltrates of small, medium-sized, or large pleomorphic αβ T cells and many macrophages, predominantly affecting the legs and occasionally complicated by a hemophagocytic syndrome. Subcutaneous lymphomas with a γ/δ phenotype of the TCR show a more aggressive course and are nowadays classified within the cutaneous γδ T-cell lymphomas.

CLINICAL FINDINGS. SPTL is characterized by subcutaneous nodules and plaques, which usually involve the extremities and the trunk, less commonly the face. Patients may present with B symptoms, i.e., weight loss, fever, and fatigue.

HISTOPATHOLOGY. Histologic examination shows subcutaneous infiltrates simulating a lobular panniculitis. Infiltrates contain a mixture of neoplastic pleomorphic cells of various sizes and macrophages. Rimming of individual fat cells by neoplastic T cells is a helpful diagnostic feature. Immunophenotyping shows that the neoplastic cells express CD3, CD8, CD45RO, T cell-restricted intracellular antigen 1 (TIA-1), perforin, granzyme B, and the TCR α/β. The neoplastic T cells show a clonal TCR gene rearrangement.

TREATMENT AND PROGNOSIS. The optimal therapy has not been defined so far and patients have been treated with immunosuppressive agents like prednisone or multiagent chemotherapy. However, the prognosis of the SPTL with a TCRα/β-phenotype seems to be favorable with a 5-year survival rate of 85% and therefore justifies an initial treatment approach with corticosteroids alone.[55]

EXTRANODAL NATURAL KILLER/ T-CELL LYMPHOMA, NASAL TYPE

DEFINITION. Extranodal NK/T-cell lymphoma, nasal type, is a lymphoma that is nearly always EBV-positive. The tumor cells are small, medium, or large, and usually have an NK-cell or, more rarely, a cytotoxic T-cell phenotype. The skin is the second most common site of presentation after the nasal cavity.[1]

CLINICAL FINDINGS. Extranodal NK/T-cell lymphoma either affects the naso-oropharynx, which leads to destruction of the nasal region (formerly described as *lethal midline granuloma*) or manifests in skin, subcutis, lungs, viscera, and testes. Skin lesions enclose subcutaneous tumors, erythematous plaques, ulcers, or an exanthematous eruption with macules and papules. The clinical course is often aggravated by a hemophagocytic syndrome with pancytopenia.

HISTOPATHOLOGY. This type of lymphoma shows dense infiltrates involving the dermis and, often, the subcutis. Epidermotropism may be present. Prominent angiocentricity and angiodestruction are often accompanied by extensive necrosis. Immunophenotypically, the neoplastic cells express CD56, and cytotoxic proteins (TIA-1, granzyme B, perforin) and are characteristically positive for EBV. While they show positivity for CD3ε in the cytoplasm, they lack CD3 on the surface.

TREATMENT AND PROGNOSIS. Even with aggressive chemotherapy, the disease is often lethal within months.[56] A study of the EORTC cutaneous lymphoma group suggested that bone marrow transplantation may be the treatment of choice.[57]

PROVISIONAL ENTITIES OF CUTANEOUS T-CELL LYMPHOMA

In addition to the diseases discussed in the preceding sections, a number of provisional entities are included in the WHO-EORTC classification system. These primary CTCLs display characteristic histologic features, but no distinct clinical presentation and/or outcome has been defined so far.

PLEOMORPHIC SMALL- OR MEDIUM-SIZED CUTANEOUS T-CELL LYMPHOMA

Definition. A neoplastic proliferation of pleomorphic, small- or medium-sized T cells in the skin without any clinical signs of classic MF defines the pleomorphic, small- or medium-sized CTCL.

Clinical Findings. Patients have one or several red-purplish papules or nodules with a predilection for the head and neck area.[58] Because histologic differentiation from MF and MF-associated follicular mucinosis can raise problems, the absence of patches and plaques in pleomorphic small- or medium-sized CTCL is the decisive criterion.

Histopathology. Histologically, a dense, diffuse or nodular infiltrate containing small- to medium-sized pleomorphic cells is observed within the dermis and, sometimes, the subcutis. Epidermotropism may be present. The neoplastic cells express a T-helper cell phenotype with frequent loss of pan-T-cell markers. Demonstration of an aberrant phenotype and of T-cell clonality, as well as predominance of pleomorphic T cells in the infiltrate, serve as useful criteria for the exclusion of pseudolymphomas, which often show an identical histologic pattern. MF is excluded by the absence of a dominant cerebriform tumor cell population.[59] In cases of CD8 expression these tumors show a more aggressive clinical course and are grouped within the primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma.

Therapy and Prognosis. Solitary lesions are often excised for diagnostic purposes. If excision is not possible or lesions are localized, radiotherapy is the preferred mode of treatment. PUVA therapy, possibly in combination with IFN-α, is useful in cases with disseminated lesions.

A 5-year survival rate of between 60% and 90% is reported for this type of lymphoma.

PRIMARY CUTANEOUS AGGRESSIVE EPIDERMOTROPIC $CD8^+$ T-CELL LYMPHOMA

Definition. Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma is a CTCL characterized by a proliferation of $CD8^+$ cytotoxic T cells that exhibit a strong epidermotropism and an aggressive clinical behavior. Differentiation from other types of CTCL expressing a $CD8^+$ cytotoxic T-cell phenotype, as observed in pagetoid reticulosis and rare cases of MF, LyP, and cALCL, is based on the clinical presentation and clinical behavior.

Clinical Findings. Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma presents with hyperkeratotic patches and plaques, or by papules and tumors. A metastatic spread to unusual sites such as the lung, testis, central nervous system, and oral cavity, but not to the lymph nodes is often observed.

Histopathology. Histologically, band-like infiltrates consisting of pleomorphic lymphocytes or immunoblasts are observed, displaying a diffuse infiltration of the epidermis with variable degrees of spongiosis, intraepidermal blistering, and necrosis. The neoplastic cells express the Ki67 antigen at a high frequency and are positive for CD3, CD8, CD45RA, and TIA, whereas CD2 and CD5 are frequently lost. Expression of TIA identifies these lymphomas derived from a cytotoxic T-cell subset.

Treatment and Prognosis. Even with multiagent chemotherapy the disease shows an aggressive course, and median survival is 32 months.

CUTANEOUS γ/δ T-CELL LYMPHOMA

Definition. Cutaneous γ/δ T-cell lymphoma encompasses the peripheral T-cell lymphomas with a clonal

proliferation of mature, activated γ/δ T cells with a cytotoxic phenotype. This group includes cases previously termed *subcutaneous panniculitis-like T-cell lymphoma with a γ/δ phenotype*.[1]

Clinical Findings. Patients have disseminated ulceronecrotic nodules or tumors, particularly on the extremities, but other sites may be affected as well. Involvement of mucosal and other extranodal sites is frequent, but involvement of lymph nodes, spleen, or bone marrow is uncommon. A hemophagocytic syndrome may occur.

Histopathology. Histologically, three major patterns of involvement can be present in the skin: epidermotropic, dermal, and subcutaneous. The neoplastic cells are generally medium-to-large with coarsely clumped chromatin. Large blastic cells with vesicular nuclei and prominent nucleoli are infrequent. Apoptosis and necrosis are common, often with vessel invasion. Immunohistologically the tumor cells have a $\beta F1^-$, $CD3^+$, $CD2^+$, $CD5^-$, $CD7^{+/-}$, $CD56^+$ phenotype with strong expression of cytotoxic proteins. Most cases lack both CD4 and CD8, although CD8 may be expressed in some cases. In frozen sections, the cells are strongly positive for TCR δ (antibody testing is not available for paraffin sections). If only paraffin sections are available, the absence of βF1 may be used to conclude a γ/δ origin.

Treatment and Prognosis. Most patients have aggressive disease resistant to multiagent chemotherapy and/or radiation therapy. Median survival is 15 months.

PRIMARY CUTANEOUS PERIPHERAL T-CELL LYMPHOMA, UNSPECIFIED

Definition. PTL, unspecified, is a diagnosis of exclusion of any of the above-characterized subtypes of CTCL.

Clinical Features. Usually adult patients, present with solitary, localized, or generalized nodules or tumors without predilection for specific locations.

Histopathology. The infiltrate is nodular or diffuse and shows varying numbers of medium-sized and at least 30% large-sized pleomorphic or immunoblast-like T cells. Epidermotropism is unusual. Immunohistologically, the cells are in general CD4-positive but otherwise demonstrate a variable loss of pan-T-cell antigens.

Treatment and Prognosis. The 5-year survival rate is less than 20% and therefore multiagent chemotherapy is the treatment of choice.

STAGING OF CUTANEOUS T-CELL LYMPHOMAS

After the diagnosis of a cutaneous T-cell lymphoma has been established, appropriate staging investigations are obligatory to exclude secondary involvement of the skin by an extracutaneous lymphoma and to determine the extent of disease. The first classification and staging system of CTCLs has been published in 1979 by the MF cooperative group. In the meantime, it has been recognized that this staging system does not apply to

TABLE 145-1
Staging System for Mycosis Fungoides and Sézary Syndrome

Stage	T (Tumor)	N (Lymph Node)	M (Metastases)	B (Blood)
IA	T1	N0	M0	B0 or B1
IB	T2	N0	M0	B0 or B1
IIA	T1 or T2	N1 or N2	M0	B0 or B1
IIB	T3	N0-2	M0	B0 or B1
III	T4	N0-2	M0	B0 or B1
IIIA	T4	N0-2	M0	B0
IIIB	T4	N0-2	M0	B1
IVA1	T1–T4	N0-2	M0	B2
IVA2	T1–T4	N3	M0	B0–2
IVB	T1–T4	N0–N3	M1	B0–2

T1 = patch/plaque ≤10% of body surface; T2 = patch/plaque ≥10% of body surface; T3 = skin tumor(s); T4= erythroderma; N0 = normal nodes; N1 = palpable nodes without clear histologic evidence of lymphoma [for N1 and N2, "a" or "b" may be added for either no (a) or detection (b) of a T cell clone by Southern blot or PCR analysis]; N2 = palpable nodes, histologic evidence of lymphoma, node architecture preserved; N3 = palpable nodes with histologic evidence of lymphoma, effacement of node architecture; M0 = no visceral involvement; M1 = histologically confirmed visceral involvement. B0 = ≤5% Sézary cells (for B0 and B1, "a" or "b" may be added for either no (a) or detection (b) of a T cell clone by Southern blot or PCR analysis); B1 = >5% Sézary cells but either less than 1.0 K/microL absolute Sézary cells or absence of a clonal rearrangement of the TCR or both; clonal rearrangement of the TCR in the blood and either 1.0 K/microL or more Sézary cells or one of the following two: (1) increased $CD4^+$ or $CD3^+$ cells with CD4/CD8 of ten or more or (2) increase in $CD4^+$ cells with an abnormal phenotype (>40% $CD4^+/CD7^-$ or >30% $CD4^+/CD26^-$).

all entities of CTCLs listed in the current WHO classification. Furthermore, the Ann Arbor system, commonly used for staging of nodal non-Hodgkin lymphomas, is not suitable for all entities of CTCLs. Because of these facts and new data on prognostic factors, both revisions of the staging and classification for MF and SS and a TNM classification system for CLs other than MF and SS have been proposed by the EORTC and the International Society for CLs in the recent years.[60,61] It has to be mentioned that staging according to the TNM system has been proven to be useful to choose an appropriate therapy for patients with MF and SS, but data correlating results of the TNM staging and prognosis are missing for some entities of CTCLs. Staging examination for all entities of CTCLs include examination of the entire skin, chest radiography, and ultrasonography of abdominal organs and peripheral lymph nodes (cervical, axillary, and inguinal). Blood investigations should include complete blood cell count, clinical chemistry with liver enyzmes, kidney function tests and lactate dehydrogenase level, as well as T-cell clonality. Staging may be completed by computed tomographic scan and/or histologic and molecular (TCR rearrangement) investigations of suspicious lymph nodes and/or visceral organs. Staging examination should be repeated at relapse or progression of disease. A bone marrow examination is only recommended at a B2 blood rating (Table 145-1) or unexplained hematological abnormalities. However, this procedure is not of direct clinical relevance, as detection of atypical cells in the bone marrow has not been shown to be an independent prognostic factor.

The aforementioned investigations allow for classification according to the tumor, lymph node, metastases (TNM) system (Table 145-1 and Box 145-3). Although the prognostic value and applicability of TNM staging for different CTCLs is controversial, the TNM scheme directs the decision-making process toward an appropriate therapeutic regimen for most CTCLs.

PRINCIPLES OF TREATMENT OF CUTANEOUS T-CELL LYMPHOMA

Every successful strategy in managing CTCL with generalized skin lesions begins with goals, tumor-burden assessments, questionnaires, and a timetable. The primary goals of therapy are to achieve a remission, improve the quality of life, to prolong life, and if possible to cure. The chronic disease course of the most prevalent CTCL subtypes MF and SS, makes surrogate markers necessary, and tumor burden is still the best surrogate marker for survival. Additionally, measures of symptoms like pruritus or quality of life assessments are commonly used. Currently, skin scores provide a measure of objective responses to therapy, and questionnaires guide the assessment of subjective responses to therapy. It has not been shown that reducing disease in a patient from T3 to T1 is accompanied by any benefit in survival, yet it is also recognized that cure is unattainable unless the patient is first in remission with a skin score of 0 by whatever skin scoring system is used. Thus, remission is the first step toward achieving a cure.

BOX 145-3 STAGING SYSTEM FOR CUTANEOUS LYMPHOMAS OTHER THAN MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

T (TUMOR)

- T1: solitary skin involvement
  - T1a: a solitary lesion <5-cm diameter
  - T1b: a solitary lesion >5-cm diameter
- T2: regional skin involvement: multiple lesions limited to one body region or two contiguous body regions[a]
  - T2a: all-disease-encompassing in a <15-cm diameter circular area
  - T2b: all-disease-encompassing in a >15- and <30-cm diameter circular area
  - T2c: all-disease-encompassing in a >30-cm diameter circular area
- T3: generalized skin involvement
  - T3a: multiple lesions involving 2 noncontiguous body regions
  - T3b: multiple lesions involving ≥3 body regions

N (LYMPH NODE)

- N0: No clinical or pathologic lymph node involvement
- N1: Involvement of one peripheral lymph node region[b] that drains an area of current or prior skin involvement
- N2: Involvement of two or more peripheral lymph node regions[b] or involvement of any lymph node region that does not drain an area of current or prior skin involvement
- N3: Involvement of central lymph nodes

M (METASTASES)

- M0: No evidence of extracutaneous nonlymph node disease
- M1: Extracutaneous nonlymph node disease present

[a]Definition of body regions.[61]
[b]Definition of lymph node regions is consistent with the Ann Arbor system: Peripheral sites: antecubital, cervical, supraclavicular, axillary, inguinal-femoral, and popliteal. Central sites: mediastinal, pulmonary hilar, paraortic, iliac.

A few principles help guide therapy strategies.[62] Excellent long-term results have been reported with the localized treatment of localized disease. More widespread disease requires total skin or systemic therapy. However, it is not known at what percentage of skin surface involvement it becomes imperative to treat the entire skin. Once remission is achieved, maintenance therapy has a role in preventing relapse. Because many patients will undergo treatments that span decades, it is also important to minimize exposure to therapies

that have cumulative toxicities on keratinocytes (i.e., mutagens) or the bone marrow.

With these principles in mind, one can approach the treatment of a given patient based on the patient's individual presentation. The clinical presentation of the patient can be matched up with a successful therapy modality for both the remission-induction phase of therapy and the maintenance phase. For patients with several types of lesions, priority is given to those further down in Table 145-1. For example, a patient with both patches and tumors would be approached as a patient with tumors until those lesions are cleared.

The therapies used to treat a patient with CTCL can best be categorized into skin-directed therapies, biologic response modifiers (BRMs), cytotoxic therapies, and combination therapies. Within each category, the individual modalities have unique properties that are discussed in the following sections in the context of how these modalities are used.

UNILESIONAL/LOCALIZED CUTANEOUS T-CELL LYMPHOMAS: SKIN-DIRECTED THERAPY.

The modalities considered for inducing a remission of unilesional/localized disease depend on the type and localization of the lesion as well as on the specific entity.

Distinct demarcated nodules as they are commonly seen in small- or medium-sized CTCL and $CD30^+$ lymphoproliferations are best treated by excision or spot X-ray therapy. Patches and plaques can be approached with spot X-ray therapy, but also with topical chemotherapy with carmustine (BCNU), and topical retinoid therapy with bexarotene due to their superficial flat appearance.

Spot radiotherapy is the most reliable and rapid method of inducing a remission of solitary or localized lesions. Radiotherapy is widely available, and most lesions, no matter where they occur on the body (e.g., eyelid, buttock crease, ear), can be treated with this modality. There are no compliance problems, with each treatment session conducted by a professional radiotherapist. The immediate toxicity is minimal, but the long-term toxic effects of radiation dermatitis and cutaneous malignancy encourage conservative use of this modality.

The limitations of topical BCNU therapy are the systemic toxicity from absorption of the chemotherapeutic agent and local irritation. As a result, topical BCNU is used primarily for a limited body surface area. The initial protocols for BCNU administration called for an alcohol-based solution kept in the refrigerator. However, ointment-based protocols are now more common. BCNU can be easily made up in 10-mg/100 g or 20-mg/100 g ointments with a petrolatum base. Patients typically apply BCNU ointment at night and wash it off in the morning. Locally, a dose-related irritation and/or hyperpigmentation may appear over the 8–20 weeks needed to clear lesions. Monitoring includes performing complete blood cell counts every 2 weeks to check for marrow suppression. The cumulative toxicity of BCNU is primarily structural damage with skin thinning and telangiectasias. The patient must be reliable and adherent to the regimen for this therapy to succeed.[63]

The limitations of topical bexarotene gel are also due primarily to dose-related irritant effects. Hence, bexarotene gel is typically used for lesions on less than 15% of body surface area, as was the case in most of the patients in the pivotal trial that led to its approval.[64] The gel is commercially available in a 1-% formulation, so that dose intensity is varied by changing the frequency of application. Patients typically initiate therapy with nightly lesional applications of bexarotene gel. After a week, the frequency is increased to twice daily, and the patient has to be made aware of the possibility of an irritant dermatitis at the site of the lesions. Complete clearance of lesions will usually occur after 12–16 weeks of therapy. Irritant responses can be managed by decreasing the frequency of application.[65] Successful topical bexarotene therapy also requires a patient who adheres to the treatment regimen and is willing to put up with the irritant properties of this synthetical retinoid.

DISSEMINATED SKIN-LIMITED DISEASE.

Cutaneous T-cells recirculate through the vascular system and are capable of patrolling the entire skin. When CTCL lesions are scattered, the most successful treatment strategies are those that treat the entire skin so as to extend the antilymphoma effect to the entire range of the cutaneous T cell. Recirculating CTCL cells are detectable even in limited disease, and such recirculating cells are capable to induce disease recurrences. These cells provide some of the rationale for the use of maintenance therapy after a complete response has been achieved in the management of patients with disseminated patch/plaque disease. Due to the variation in biological behavior, the therapy of disseminated disease differs markedly in CTCLs. The total skin treatment modalities most commonly used as first-line therapy against disseminated patch/plaque disease of MF are phototherapies, topical chemotherapy, and total skin electron-beam radiotherapy. However, $CD8^+$ epidermotropic CTCL or blastic plasmacytoid dendritic cell neoplasm (BPDCN), also presenting with plaque disease show a much more aggressive course and polychemotherapy is the treatment of choice. Furthermore widespread disease of $CD30^+$ lymphoproliferations responds well to low-dose methotrexate therapy in most instances.

Phototherapies. PUVA (see Chapter 238) can produce a definite clinical response and complete remissions of long duration in patients with patch/plaque CTCL. PUVA therapy requires regular treatments, initially three to four times a week, for up to 3 months or until remission occurs. The follow-up of a patient receiving PUVA for CTCL includes an assessment to be sure there is some mild degree of phototoxicity. Otherwise, dosing of either the psoralen or the UVA light may be insufficient. Risks of the treatment include possible induction of cutaneous epithelial neoplasms and cataract formation. Therefore, all patients should be observed closely and checked regularly for the development of skin cancer. In addition, patients are advised to protect their eyes for 12 hours after PUVA therapy and to have annual ophthalmologic examinations. These precautions should be enforced early, because PUVA is

a therapy that may continue for years as a maintenance treatment. Even after poor responses to conventional therapy, patients have experienced complete clearing of the skin with PUVA.[66] However, maintenance therapy may be needed, as shown by the prolongation of clinical remission with continued PUVA.[67] For this reason, a gradual taper of therapy from thrice weekly to one session every 2–4 weeks after the patient has achieved a stable remission is typical. Combination of PUVA with IFN-α reduces the total UV dose necessary to induce a remission and prolongs the duration of remission.

UVB and narrow-band UVB light are both effective in treating CTCL. These phototherapies are more convenient for patients, although their efficacy, especially for plaque disease, may not be as great as that of PUVA. Patch-stage MF can often be completely cleared with UVB or narrowband UVB light. A complete response can typically be induced with three to five treatment sessions per week for a duration of 2–3 months. After a complete response has occurred, phototherapy can be continued on a maintenance schedule, initially once a week. The immediate adverse effects are primarily phototoxicity; the long-term toxicity is an increased risk for cutaneous malignancy.

Total Skin Topical Chemotherapy. Total skin topical chemotherapy consists of nitrogen mustard (mechlorethamine hydrochloride) applied as either an ointment or a freshly prepared aqueous solution. As an initial dose, 10 mg of the drug is dissolved in approximately 50 mL of tap water. The entire amount is then applied to the whole body surface by the patient. The patient should wear protective plastic gloves while applying the solution. A delayed hypersensitivity reaction may complicate treatment, and it is possible to desensitize patients, although their confidence in the therapy may be compromised. Ointment-based mechlorethamine, typically 10 mg/100 g strength, may be less sensitizing and is shelf stable for a long period. Other side effects from mechlorethamine hydrochloride therapy, besides hypersensitivity reactions and primary irritant reactions, include the development of second cutaneous malignancies and hypo- as well as hyperpigmentation. This therapy is relatively easy for the patient to use at home, but daily whole-body application is required for maintenance therapy once remission is induced.

Total Skin Radiation Therapy. The radiosensitivity of CLs has been therapeutically exploited by the administration of total skin electron-beam radiation. Because electrons penetrate only to the upper dermis, electron-beam therapy may be used without systemic effect. The limited penetration of the electrons is advantageous because it spares the mucous membranes, bone marrow, gastrointestinal tract, and other vital internal organs. Only those portions of the skin that are directly exposed to the beam are irradiated. Therefore, the palms, soles, scalp, axillae, and perineum may need separate exposures to ensure total body treatment. The eyelids are routinely covered with lead eye shields to protect the cornea and lens from the effects of radiation. If the eyelids are involved, 5-mm-thick contact lenses are worn between the lid and cornea within the conjunctival sac. Nail shields may also be used to prevent anonychia.

Whole body electron-beam irradiation brings about complete remission in 80%–95% of patients. The relapse rate is highest in the later stages of CTCL, i.e., in those patients with tumors, lymphadenopathy, and visceral involvement. Patients with limited plaque disease were found to have the highest relapse-free rate (42% at 10 years). Most relapses occurred within the first year after completion of therapy, and relapses were very rare 3 years or more after completion of therapy. The median disease-free interval was longer than 3 years in the limited plaque group, approximately 1 year for patients with generalized plaque or erythrodermic disease, and less than 6 months for patients with cutaneous tumors. The total dose of radiation is important. A dose of 30 cGy (3,000 rad) or more gives higher complete remission rates and disease-free survival than do lower doses. The major disadvantages are that this type of therapy must be provided at a specialized center and up to 3 months are required for complete treatment.

Local side effects include alopecia, atrophy of sweat glands and skin generally, radiodermatitis, and edema. When the total dose is highly fractionated, these complications are minimized and often avoided. The question is, what is the maximum radiation tolerance of the skin? When the highly fractionated approach is used, patients can receive a second course of electron-beam therapy of 36 cGy (3,600 rad) to reinduce a remission. As the total radiation dose increases, so does the risk of squamous cell carcinoma and radiodermatitis. Small-field or spot orthovoltage radiotherapy using soft X-rays (60–100 kV with half-value layers of 1–1.5 mm Al) fractionated to doses of 0.75–5 cGy (75–500 rad) and total doses of 8–15 cGy (800–1,500 rad) will adequately eliminate most lesions.

In many patients, a second or even third complete course of total skin electron-beam radiation can be safely given. The strategy of administering electron-beam radiation for repeat courses requires the use of a highly fractionated dose of 1 Gy per dose.

Maintenance Therapy and Topical Steroid Therapy. The concept of treating normal skin evolved from the clinical experiences with skin-directed therapies. There are two components to this approach: the treatment of normal skin during remission-induction skin-directed therapy and the treatment of normal skin during the remission–maintenance phase. Topical chemotherapy, PUVA, and total skin electron-beam radiation all involve the exposure of normal skin as an integral component of their success in achieving remission. This success reflects the ability of the therapy to interrupt the critical skin-based phase of the life cycle of a recirculating CTCL cell. Once a remission has been achieved, normal skin can be maintained with lower doses and frequencies of the therapies used to clear it. Maintenance therapies have been described with PUVA, total skin application of nitrogen mustard, ECP, and IFN. The most commonly used maintenance therapy is PUVA (see Chapter 238)

or UVB irradiation (see Chapter 237). As a maintenance therapy, PUVA is initially administered at once-weekly intervals until 1 year has passed. At this point, the schedule is changed to every other week for another year, to every third week for the following year, and finally to every fourth week for 2 years. At this point, the patient should have been in remission for 5 years. Consideration should be given to stopping therapy at this point. A cure is defined as freedom from disease for 8 years off all therapy. This definition arose from the experience with nitrogen mustard treatment and total skin electron-beam radiotherapy showing that after a patient achieves a remission-off therapy of 5–8 years, late relapse is extremely rare. This would imply that malignant cutaneous T cells recirculate without causing lesions for up to 5 years. With 5 years of intermittent PUVA, it is less likely that one of these cells will survive, but it is still possible. After therapy has been discontinued, patients should not be considered cured unless they remain clear of disease for 8 years.

The management of suspected relapse often includes the use of topical glucocorticoids and reflects the critical role this modality can play in the treatment of suspicious lesions. Early in the course of CTCL and in a recurrence of the disease in a patient in remission, the T-cell activation process can be blunted by the aggressive use of topical glucocorticoids. Indeed, most patients have a history of using these agents before a firm diagnosis is made. A regimen for treating early lesions of MF is twice-daily applications of a class I topical glucocorticoid for 8 weeks. This regimen is one of the first-line modalities for suspected relapse, and it can help identify which patients need to undergo a 4-week "wash-out" before repeat biopsies are performed.

ERYTHRODERMA. In erythrodermic CTCLs, immune dysfunctions and inflammatory processes initiated by the malignant cells result in total skin redness, scaling, and discomfort. It is not surprising that immune-based therapies take the forefront in the management of these disorders. The three major BRMs used in the treatment of erythrodermic CTCLs are (1) oral retinoids, (2) ECP via an intravenous route, and (3) subcutaneous injections of IFN-α. In the clinical trials of these agents, patients have undergone monotherapy for what has usually been heavily pretreated refractory disease. In practice, these treatments are often used as first-line monotherapy in erythroderma, and other agents are incorporated for combination therapies if the response is incomplete. With these agents, partial responses are more common than complete responses. Thus, if the goal is remission, combination therapy is used more commonly than monotherapy. If the goal is palliation, monotherapy with a BRM is often sufficient. The BRMs differ in terms of their administration, side effects, interactions with other therapy modalities, and availability.

Retinoid Therapy. The first-generation retinoids such as isotretinoin have an effect on CTCL. The synthetic retinoid bexarotene binds the retinoid X receptor with high selectivity, whereas the other available retinoids have less specific binding patterns. In the monotherapy trials, bexarotene was dosed at 300 mg/m^2. Responses were seen in patients in all stages of the disease: plaques, erythroderma, and tumors. Responses paralleled the secondary end points: decreases in overall body surface area involved and in overall tumor aggregate area, and improvement in pruritus. Erythrodermic patients may experience increased desquamation during the first few weeks of oral bexarotene therapy. Improvement typically starts by week 12 of therapy.[68]

Although there appeared to be a dose-response relationship with respect to efficacy, the higher dosages were also associated with a higher rate of adverse events and dose-limiting toxicities, of these hyperlipidemia/hypercholesterolemia and neutropenia were most common. Elevations in lipid levels occurred rapidly, within 2–4 weeks, and were associated with serious, but reversible, pancreatitis. Monitoring of lipids and the use of lipid-lowering drugs were helpful in controlling the lipid levels.[69] Dosage reduction of bexarotene capsules was also required in some patients. Drug interactions of oral bexarotene with gemfibrozil and warfarin have been observed.

Patients started on bexarotene therapy develop central hypothyroidism with low levels of thyroid-stimulating hormone and free thyroxine within weeks of starting the medication. Symptoms of hypothyroidism may be subtle and include feeling fatigued and feeling cold, which may wrongly be attributed to the disease itself. Supplementation with levothyroxine while patients are taking bexarotene alleviates the symptoms and improves tolerance of treatment. The condition is reversible within weeks of stopping therapy. There is no immunosuppression with bexarotene therapy. Patients taking bexarotene typically have monthly monitoring visits to follow lipid, liver, and thyroid parameters.

Extracorporeal Photochemotherapy. (See Chapter 238). ECP involves the treatment of a portion of a patient's lymphocyte compartment with 8-methoxypsoralen in the presence of UVA light, followed by reinfusion of these cells. The treatment is performed via an intravenous line that feeds into an UVA-radiation device, and the procedure typically requires the patient to remain recumbent for 3 hours. Treatments are conducted on two consecutive days every 4 weeks. Erythrodermic CTCLs can be managed with ECP monotherapy, but treatment of other disease stages with monotherapy has not been rigorously studied. In a multicenter study involving erythrodermic CTCL patients, approximately one-fourth had a complete response, one-fourth had no response, and the remainder had partial responses. However, it is clear that even a partial response can improve the quality of life of these patients. Improvement sometimes began as early as 6 weeks into therapy, but some patients did not show complete lesion clearance until 12 months after starting therapy. There were occasional temporary responses immediately after a 2-day cycle of therapy. On average, after 4–6 months there was typically a gradual and permanent decrease in erythema, scaling, and pruritus. Patients often notice more subtle changes, such as the return of body hair,

loss of rigors, and a return of the ability to sweat. Partial responses may also decrease the morbidity these patients experience in terms of infectious complications. More heavily involved and inflamed skin is more readily colonized, providing both a reservoir and access point for microbes to invade the host. Thus, cutaneous improvement can also minimize complications of CTCLs.

The clinical experiences with ECP for erythrodermic MF and SS suggest that the therapeutic response may well be based in the immune system. One feature is that when less than 5% of the malignant lymphocyte pool is photoinactivated with 8-methoxypsoralen and UVA light, clinical responses can be seen, with more than 95% of the malignant lymphocytes disappearing over time. It also appears that most immunocompetent patients respond. Patients who were heavily pretreated, with longer disease durations, were less responsive. Also, patients with normal or only slightly decreased $CD8^+$ lymphocyte levels were responsive to ECP. In one study, total skin electron-beam radiotherapy was combined with ECP in patients with T3 and T4 disease. Comparison of patients receiving skin-directed radiotherapy plus BRM with historic controls who underwent electron-beam radiotherapy at the same institution demonstrated the impact of ECP, because patients in the skin-directed therapy plus BRM group showed significantly longer survival.[70]

Interferon-α Therapy. The most-studied IFN has been IFN-α, but clinical trials have also been done with IFN-β and IFN-γ in the treatment of CTCLs. The initial studies using IFN-α as monotherapy showed rates of complete responses that varied from 10%–27% with treatment durations of less than 6 months.[71] Again, the heterogeneity of the disease and the pretreatments patients undergo affect outcomes and make comparisons with other modalities impossible. IFN-α is typically started at 3 million units (MU), three times a week, and can be increased to a maximally tolerated dose, typically in the range of 9 MU/day. As with the other BRMs, the response to IFN is gradual, and 3–6 months are needed to determine the maximal response. After patients achieve a maximal response, IFN dosage can be lowered to a maintenance level of 1 MU daily.[72]

All IFNs have similar toxicities. Initially IFN therapy is complicated by a flu-like illness that is characterized by fever, headache, myalgia, and fatigue. As this wears off, patients are often left with a slight feeling of chronic fatigue. The long-term toxicity that causes most concern is neurologic: depression, neuropathy, dementia, and myelopathy. Autoimmune phenomena, such as thyreoiditis, may occur. Furthermore, toxic effects of the liver and bone marrow may occur. Monitoring of IFN therapy includes blood counts and urinanalysis along with questionnaires assessing the impact on the patient's quality of life.

Other BRMs. *$DAB_{389}IL$-2* (Denileukin Difititox, Ontak®) is a recombinant cytotoxic fusion protein composed of the receptor binding domain of IL-2 and a mutated diphtheria toxin (DT) molecule. After binding to the IL-2-receptor, which is expressed on activated lymphocytes and monocytes as well as CTCL cells, and after internalization of DAB_{389}IL-2, the DT fragment becomes active and inhibits the protein synthesis leading to cell death. DAB_{389}IL-2 is administered intravenously and has shown efficacy in a phase III trial in CTCL patients with an overall clinical response rate of 30%. Side effects are generally mild, but few patients suffered from allergic reactions or a capillary-leak syndrome.[73]

Alemtuzumab is a humanized monoclonal IgG antibody binding to CD52, which is expressed on monocytes, granulocytes, and normal and malignant lymphocytes. In a phase II trial efficiency, including complete remissions, but also fatal infectious complications were seen in patients with therapy refractory advanced MF/SS.[74] Efficiency has also been shown with lower doses and s.c. application resulting in less administration-related and infectious complications.[75] Because of the side effects, alemtuzumab should be reserved for patients with advanced MF/SS disease who did not respond to previous systemic therapies.

Vorinostat: The first histone deacetylase inhibitor (HDACI) approved by the FDA was vorinostat for the treatment of therapy refractory CTCL. The increased histone acetylation by HDACI favors transcription of genes involved in cell differentiation, cell cycle arrest, and apoptosis. In a phase II trial, mostly partial remissions and a decrease in pruritus were seen in CTCL patients refractive to previous therapies. Common adverse events of HDACI were fatigue, nausea, and thrombocytopenia.[76]

PRIMARY CUTANEOUS B-CELL LYMPHOMAS

Primary CBCLs are B lymphocyte-derived malignancies that develop in the skin without extracutaneous involvement at the time of diagnosis. CBCLs comprise approximately 20% of all CLs. The primary cutaneous marginal zone B-cell lymphoma (PCMZL) and the PCFCL are indolent subtypes, whereas the diffuse large B-cell lymphoma, leg type (PCLBCL, leg type) has an intermediate to aggressive clinical behavior. These three entities [i.e., (1) PCMZL, (2) PCFCL, and (3) PCLBCL] together comprise 97% of the CBCL.

ETIOLOGY

As for CTCL an infectious trigger has been hypothesized to be involved in the etiology of CBCL. A strong association of gastric extranodal marginal zone lymphomas (MZL) and Helicobacter pylori infection is well known. In a minority of PCMZL from European patients but not in American or Asian patients *Borrelia burgdorferi* has been detected. It has recently been hypothesized that two different types of PCMZL exist: one that is phenotypically related to gastric MZL, triggered by *B. burgdorferi* infection, while the majority of PCMZL is not. A viral agent, in particular Hepatitis C virus, has also been suspected to be of relevance in the etiology of CBCL, but the results of the studies were contradictory.

PATHOGENESIS

Because of the rarity of the CBCL subtypes, studies investigating pathogenetic events in CBCL have been mainly conducted on small series of cases. However, in the recent years considerable progress has been made.

A phenomenon called aberrant somatic hypermutation (SHM) that has been previously reported in nodal B cell lymphomas has been detected in all three main types of CBCL.[77,78] This term describes the activity of the enzyme activation induced deaminase, which contributes to the process of affinity maturation of immunoglobulins (Ig) by SHM, in regions of the genome that do not encode Ig genes. If this process occurs in oncogene-containing gene loci, in association with the loss of the physiologically high-fidelity DNA repair mechanisms, tumorigenic mutations may occur and contribute to lymphomagenesis.[79]

Furthermore, genetic investigations demonstrated distinct differences of CBCL subtypes. A genetic basis for differentiation of histological akin PCFCL with a diffuse growth pattern of large cells and PCLBCL, leg type, was shown. The gene expression profiles, of these entities were consistent either with germinal center B cells for PCFCL or with activated B cells for PCLBCL, leg type.[80] Alike results were found in a study focusing on pro- and antiapoptotic genes. While PCLBCL, leg type with a poor prognosis had a genetic profile called *activate apoptosis cascade*, PCFCL and cases of PCLBCL, leg type with a favorable prognosis had a high expression level for genes that are associated with an antitumoral cytotoxic immune response.[81] These findings also give an explanation the more favorable prognosis of PCFCL compared to PCLBCL, leg type.

Furthermore, PCMZL were found to arise in a different pathogenetic background than extranodal MZL. The main differences were the high percentage of CXCR3-negative PCMZL, which also, in contrast to other extranodal MZL, exhibited an Ig class switch and a Th2 cytokine milieu.[82] How this relates to the presence of plasmacytoid DCs in PCMZL, which were also found in cutaneous pseudolymphomas, but not in DLBCL and only rarely in PCFCL, has to be investigated in the future.[83]

PRIMARY CUTANEOUS FOLLICLE-CENTER LYMPHOMA

DEFINITION. PCFCL can be defined as a neoplasm of clonal centrocytes (small and large cleaved follicle center cells) and centroblasts (large follicle center cells with prominent nucleoli) with or without formation of follicles.

CLINICAL FINDINGS. Patients with PCFCL present with nonscaling solitary or grouped papules, plaques or tumors. Patients with PCFCL have a median age of 58 years at diagnosis and men are nearly two times more often affected than women.[84] Occasionally, an annular erythema can be observed in the surrounding area (Fig. 145-17A). A typical finding is the occurrence of lesions in a circumscribed area of the head and neck region or the trunk but rarely on the legs.

HISTOPATHOLOGY. The typical histologic finding in PCFCL is a nodular or diffuse infiltrate with sparing of the epidermis. In the initial lesion a mixture of centrocytes, few centroblasts, and many reactive T cells is present that creates a follicular growth pattern or remnants of follicles with a network of $CD21^+$ follicular dendritic cells (fDC). In parallel with progression of the tumor, the number and size of neoplastic B lymphocytes increases and the infiltrate is more diffuse with scattered fDC. In persisting lesions large follicle center cells (centrocytes and centroblasts) dominate (see Fig. 145-17B). The abnormal follicles show a reduced or even absent mantle zone, lack tingible body macrophages, and contain malignant $bcl\text{-}6^+$ follicle center cells. The typical immunophenotype of the neoplastic cells is $CD20^+$

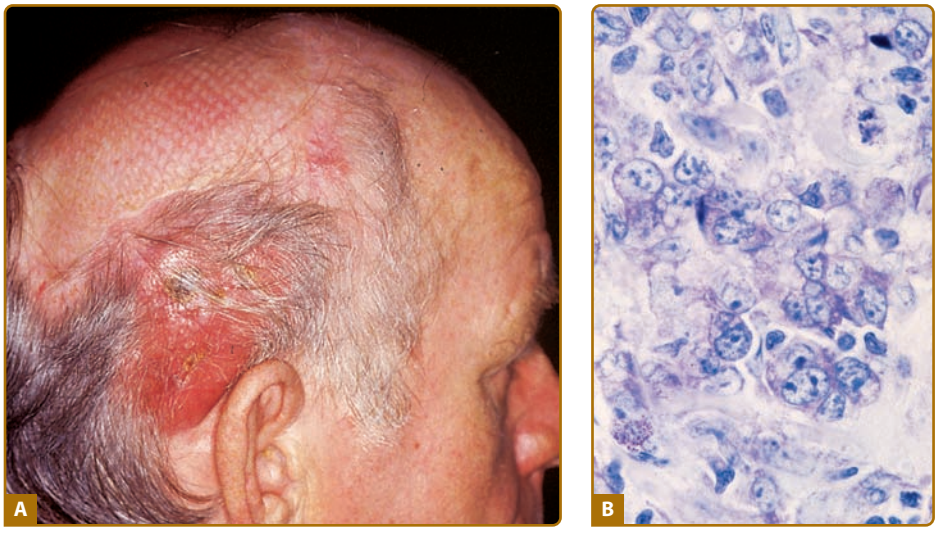

Figure 145-17 Primary cutaneous follicle center lymphoma. **A.** Tumor in the head area surrounded by erythema. **B.** The cellular infiltrate consists of a mixture of centrocytes, a number of centroblasts, and reactive T cells.

CD79a$^+$. Expression of CD10 is found only in infiltrates with a follicular pattern. Unlike in nodular follicular lymphomas, the t(14;18) translocation is not present. Bcl-2 protein may be detectable in few cases but only in a minority of tumor cells and in a weak-staining intensity. Therefore, detection of bcl-2 in the majority of tumor cells is indicative of a secondary cutaneous involvement of a systemic lymphoma. A clonal rearrangement of the variable part of the immunoglobulin heavy chain gene is detected in 60%–80% of cases.[85]

TREATMENT AND PROGNOSIS. Radiotherapy is the preferred mode of treatment; solitary lesions may also be excised. Immune therapies such as administration of IFN-α or monoclonal antibodies against CD20 may be beneficial in cases with disseminated lesions. Chemotherapy should be considered only in rare cases where more generalized skin lesions are present. With an estimated 5-year survival rate of 97%, the follicle center cell lymphoma is classified as an indolent type of primary CBCL. In untreated patients, the skin lesions increase in size over the years, but extracutaneous dissemination is uncommon.

PRIMARY CUTANEOUS MARGINAL-ZONE B-CELL LYMPHOMA

DEFINITION. PCMZL is an indolent B cell lymphoma composed of small B-lymphocytes, marginal zone cells, lymphoplasmacytoid cells, and plasma cells, which are initially localized in the marginal zone of a follicular center. In the current WHO classification, it is classified within the extranodal marginal zone lymphoma of Mucosa-associated lymphatic tissue. In a subgroup of PCMZL, *B. burgdorferi* is thought to have an etiologic role.

CLINICAL FINDINGS. PCMZLs are seen most commonly on the upper extremities or the trunk and occur at a median age of 55 years; they predominate in females. Patients have small red to violaceous papules, plaques, or nodules that, in contrast to the lesions of PCFCL, frequently occur in multiple locations. PCMZL accounts for 25% of primary CBCLs.

HISTOPATHOLOGY. Histologic analysis of well-developed lesions shows dense nodular or diffuse infiltrates with sparing of the epidermis. The infiltrate is composed of marginal zone cells, small to medium-sized cells with indented nuclei, lymphoplasmacytoid cells and plasma cells. The marginal zone cells are found in the periphery of reactive germinal centers, the atypical plasma cells in the periphery of the infiltrate. Monotypic expression of immunoglobulin light chains can be observed in approximately 75%–85% of cases. Importantly, the number of neoplastic cells within the infiltrate is variable and may be very low and is often accompanied by a substantial number of reactive T cells.

The typical immunophenotype is CD20$^+$ CD79a$^+$ CD5$^-$ CD10$^-$ and bcl-2$^+$, bcl-6$^-$. An immunoglobulin light chain restriction can frequently be found. Monoclonal immunoglobulin gene rearrangement can be demonstrated by molecular genetic methods such as PCR or Southern blotting.

TREATMENT AND PROGNOSIS. In case of detection of *B. burgdorferi*, a systemic antibiotic treatment should be given first. Otherwise radiotherapy or excision is the treatment of choice for solitary tumors. However, in most cases PCMZL present with multifocal lesions and systemic therapy is mandatory. Chlorambucil and rituximab have been used with success and a good safety profile.[86,87] For relapsing disease immune agents such as IFN-α may be administered subcutaneously or intralesionally. In the absence of symptoms a watch and wait strategy can be followed. The disease has an indolent course with an excellent prognosis, and the 5-year survival rate is nearly 100%. However, local recurrences are frequently observed. Extracutaneous involvement is extremely rare.

PRIMARY CUTANEOUS DIFFUSE LARGE B-CELL LYMPHOMA, LEG TYPE

DEFINITION. PCLBCL, leg type has been identified as a distinct clinical entity because of its perceived poor outcome compared with the indolent subtypes described above. This entity shows an intermediate and in some patients aggressive clinical course and is defined by tumors composed of large B cells that presents in the overwhelming majority of cases on the legs, but can also arise at other locations. It has been shown that the majority of patients with PCLBCL, leg type have aberrations on chromosome 9p21 and that loss of this region, which contains the *CDKN2A* gene is associated with a worse prognosis.[88]

CLINICAL FINDINGS. PCLBCL, leg type affects elderly patients (over 65 years), with a predominance in females. Typically, patients have solitary or clustered bluish erythematous plaques and tumors located on one or, sometimes, both legs (Fig. 145-18A). Ulceration is common and sometimes leads to the misdiagnosis of an ulcer due to chronic venous insufficiency.

HISTOPATHOLOGY. The diffuse infiltrate spares the epidermis and often extends into the subcutaneous tissue. Monotonous populations or confluent sheets of centroblasts and immunoblasts with a high mitotic rate are admixed with few reactive T cells (see Fig. 145-18B). The neoplastic B-lymphocytes express CD20, CD79a, multiple myeloma-1/IFN regulatory factor-4 (MUM-1/IRF4), and the bcl-2 molecule. Staining for bcl-6 gives positive results in most cases, whereas results for CD10 are negative. A clonal immunoglobulin rearrangement is detected in most cases.

TREATMENT AND PROGNOSIS. This tumor belongs to the intermediate aggressive group of CBCLs. Patients develop rapidly growing painless lesions, which initially disseminate along the lymph vessels. The tumor can involve the regional lymph nodes and progress to extracutaneous involvement. In cases of solitary or localized skin lesions, radiotherapy may be

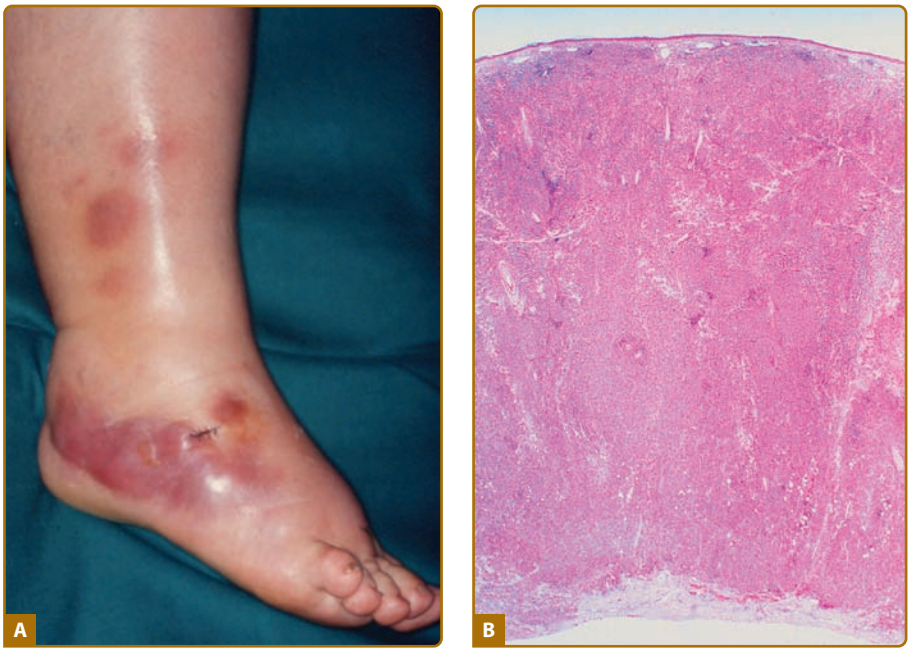

Figure 145-18 Primary cutaneous diffuse large B-cell lymphoma, leg type. **A.** Nodules and tumors on the right leg. **B.** Histology shows a diffuse infiltrate of large B cells with centroblasts, large centrocytes, and numerous immunoblasts.

undertaken; in all other cases and when progression is observed, multiagent chemotherapy in combination with an immunotherapy agent {e.g., CHOP [*c*yclophosphamide, *h*ydroxydaunomycin, *O*ncovin (vincristine), *p*rednisone] plus anti-CD20 antibody treatment} should be administered. An unfavorable prognosis is reported, with a 5-year-survival rate of 55%.

PRIMARY CUTANEOUS DIFFUSE LARGE B CELL LYMPHOMA, OTHER

This term covers diffuse large cell B cell lymphomas, which do not belong to PCLBCL, leg type, or PCFCL. These cases may represent a skin manifestation of systemic lymphomas. T cell/histocyte rich B-cell lymphomas with skin lesions only are also included; these cases show, in contrast to their nodal counterparts, an excellent prognosis.

INTRAVASCULAR CUTANEOUS B-CELL LYMPHOMA. Intravascular cutaneous B-cell lymphoma is characterized by clusters of large neoplastic B cells within dermal and subcutaneous blood vessels. Occasionally, slight extravascular infiltrates of atypical cells are observed. Clinically, red to bluish, indurated plaques occur on the legs or trunk. Sometimes, a panniculitis-like pattern can be seen. Multiagent chemotherapy is the preferred mode of treatment.

STAGING OF CUTANEOUS B-CELL LYMPHOMA

Staging of cutaneous B-cell lymphoma includes examination of the entire integument, a complete blood cell count, blood chemistry including lactate dehydrogenase level, and if indicated a serum electrophoresis to exclude a monoclonal gammopathy and/or flow cytometry on peripheral blood. In endemic regions, *Borrelia* serologic testing and PCR of skin biopsy specimens should be performed. Imaging studies include a contrast-enhanced CT scan with or without positron emission tomography, for chest, abdomen, and pelvis, and if lesions arose on the head and neck area, of the neck. Staging is completed by a bone marrow biopsy.[89] Although the necessity of a bone marrow biopsy has been questioned for MZL appearing in the skin, a definite diagnosis of PCMZL can not be made without a complete staging procedure.[90] With the results of the staging examinations patients can be classified according to a proposal of the ISCL/EORTC. While the T stage is not of prognostic significance for PCMZL and PCFCL, for PCLBCL, leg type an increasing T stage seems to be prognostically relevant.[91]

PRINCIPLES OF TREATMENT OF CUTANEOUS B-CELL LYMPHOMA

Treatment of primary CBCLs should be adapted to the favorable prognosis of these entities, in particular of PCFCL and PCMZL. Because no curative regimen has been defined so far, therapy depends on the entity and the dissemination of the cutaneous lesions. In the case of solitary lesions, complete excision of the tumor is the treatment of choice. Alternatively or in the case of few localized lesions local irradiation (single dose of 3–4 Gy; total dose of 30–40 Gy) by X-ray or electron beam is effective. When this regimen is used, long-lasting remissions can be achieved.

Systemic treatment is recommended for disseminated PCMZL or PCFCL with chlorambucil or anti-CD20 antibodies, respectively. For recurrence of indolent CBCLs with disseminated lesions a wait and see-strategy in conjunction with treatment of symptomatic lesions may be followed.

Systemic treatment regimens are recommended in cases of PCLBCL, leg type, and in PCFCL with localization on the legs, as these PCFCL have a worse prognosis or when secondary extracutaneous manifestations are present. Polychemotherapy (six cycles of CHOP, COP), in combination with an anti-CD20 antibody is recommended. In patients, that would not tolerate such an aggressive treatment local radiotherapy or rituximab monotherapy may be considered.

PRECURSOR NEOPLASMS

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

DEFINITION. In the WHO-EORTC classification $CD4^+/CD56^+$ hematodermic neoplasm was included for the first time as a clinically aggressive neoplasm with a high incidence of cutaneous involvement and risk of leukemic dissemination. The blastic cytologic appearance and CD56 expression initially suggested an NK precursor origin. More recent studies suggested derivation from a plasmacytoid dendritic cell precursor and therefore this entity is classified as BPDCN.

CLINICAL FINDINGS. BPDCN commonly presents in the skin as solitary or multiple nodules or tumors (Fig. 145-19) with or without concurrent extracutaneous manifestations. Approximately 50% of patients have nodal or bone marrow involvement at presentation. Most patients who have only skin lesions when they first come for treatment rapidly develop involvement of bone marrow, peripheral blood, lymph nodes, and extranodal sites.

HISTOPATHOLOGY. The typical findings are diffuse monomorphous infiltrates of medium-sized cells separated by a grenz zone from the epidermis. Perivascular patchy infiltrates and an Indian file pattern are observed occasionally. Angiotropism is uncommon. The neoplastic cells express CD4, CD43, and CD56, as well as TCL1. Tests for the lineage markers CD20, CD3, or other markers like CD30, TIA1, granzyme B give negative results. The cells further express CD123 and blood dendritic cell antigen 2, both of which support a relationship to plasmacytoid dendritic cells. *TCR* genes are in germline configuration. Tumor cells test negative for EBV.

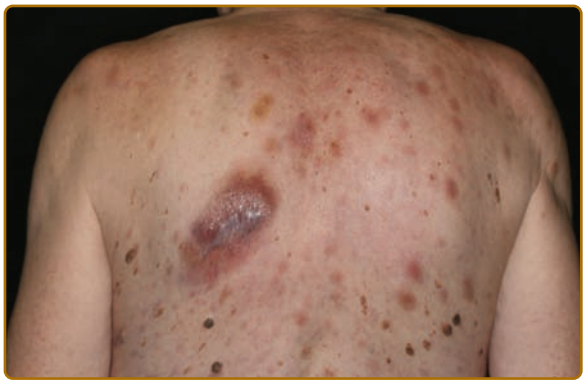

Figure 145-19 Blastic plasmacytoid dendritic cell neoplasm. Multiple lesions on the back. The large tumor was the initial site of manifestation (centrally located is the scar of a biopsy), the multiple small lesions developed in a short period of time.

TREATMENT AND PROGNOSIS. BPDCN is associated with a highly aggressive clinical course and thus a poor prognosis (median survival of 14 months). Although systemic chemotherapy is the first choice for treatment of this disease, the results are often disappointing. Studies suggest that patients can best be treated with regimens used to treat acute myeloid leukemias, including bone marrow transplantation.

PREVENTION. Not applicable.

Chapter 146 :: Inflammatory Diseases That Simulate Lymphomas: Cutaneous Pseudolymphomas

:: Gary S. Wood

CUTANEOUS PSEUDOLYMPHOMAS AT A GLANCE

- A diverse group of skin disorders characterized by dense lymphoid infiltrates mimicking various types of cutaneous lymphomas.
- Two major immunologic categories: (1) mixed B and T cell (cutaneous lymphoid hyperplasia, Kimura disease, angiolymphoid hyperplasia with eosinophilia, Castleman disease) and (2) T cell (pseudomycosis fungoides, lymphomatoid contact dermatitis, Jessner's lymphocytic infiltration of the skin).
- Most are idiopathic but some are reactions to foreign antigens introduced locally or systemically.
- Usually present as violaceous, solitary, or localized papules, plaques, or nodules.
- Some cases harbor occult dominant lymphoid clones; occasional cases progress to overt cutaneous lymphomas.

Cutaneous pseudolymphoma is a term used to describe skin lesions that bear a clinical and/or histopathologic resemblance to lymphoma. Over the years, a wide variety of designations have been included in this category. Some of these represent outdated synonyms, some refer to variants of the same entity, and some are misnomers for diseases now recognized to be true lymphomas. The relevant entities that are discussed in this and other chapters can be organized into several distinct disorders based on their lymphoid subset composition, pattern of cutaneous infiltration, and associated clinical findings (Table 146-1).

CUTANEOUS LYMPHOID HYPERPLASIA

EPIDEMIOLOGY

Cutaneous lymphoid hyperplasia (CLH) has a worldwide distribution and affects all races and ethnic groups. It occurs in both adults and children. Females are more commonly affected than males.

ETIOLOGY AND PATHOGENESIS

CLH is characterized by a relatively dense lymphoid infiltrate, centered in the reticular dermis, which is usually B-cell rich and may resemble lymphoma clinically and/or histopathologically. Many terms are used to refer to this type of pseudolymphoma, including *Spiegler–Fendt sarcoid*, *lymphocytoma cutis*, *lymphadenosis benigna cutis*, and *cutaneous lymphoplasia*. *Cutaneous lymphoid hyperplasia* is the preferred term because it accurately describes the underlying pathophysiology of the lesion and is unlikely to be confused with terms used to describe various forms of cutaneous lymphoma.[1–6]

In most cases, CLH is idiopathic; however, some lesions are associated with exposure to foreign antigens from arthropods (bites, stings, infestations), infections (herpes zoster, *Borrelia burgdorferi*, *Helicobacter pylori*), tattoos, acupuncture, trauma, gold jewelry, vaccinations, hyposensitization injections, or medications (Figs. 146-1–146-4).[1–9] Medications that may induce CLH include phenytoin, carbamazepine, phenobarbital, β blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, allopurinol, d-penicillamine, penicillin, mexiletine chloride, cyclosporine, and agents that inhibit binding of histamine to H_1, H_2, or H_{1c} receptors. These drugs include conventional H_1 and H_2 antagonists, as well as tricyclic and nontricyclic antidepressants and phenothiazines.[10] It has been proposed

TABLE 146-1
Classification of Cutaneous Pseudolymphomas

Clinicopathologic Subtype	Predominant Lymphoid Subset(s)	Predominant Localization	Major Associated Findings
Cutaneous lymphoid hyperplasia	B and T cell	Reticular dermis	—
Kimura disease	B and T cell	Subcutis	Lymphadenopathy
Angiolymphoid hyperplasia with eosinophilia	B and T cell	Reticular dermis	Eosinophilia
Castleman disease	B and T cell	Subcutis	Lymphadenopathy, POEMS syndrome
Pseudomycosis fungoides	T cell	Papillary dermis and epidermis	—
Lymphomatoid contact dermatitis	T cell	Papillary dermis and epidermis	Contact allergen
Lymphocytic infiltration of the skin (Jessner's)	T cell	Perivascular and periadnexal dermis	—

POEMS = polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

that, rather than being the target of an immune response themselves, these latter agents may alter lymphocyte reactivity in a way that promotes a CLH response to other antigens in some individuals.[11,12]

CLINICAL FINDINGS

APPROACH TO THE PATIENT. Although the details of the workup for individual patients will vary with the specific type of pseudolymphoma being considered, certain data are generally important for establishing the correct diagnosis, identifying potential causative factors, and ruling out an underlying lymphoma. The clinical history taking should elicit information about the duration and symptomatology of lesions; the nature and pace of clinical progression; past treatment; local or systemic exposure to foreign antigens, including medications; and personal or family history of other lymphoproliferative disorders. It should also include a review of systems focusing on so-called *lymphoma B symptoms*, such as fever of unknown origin, unexplained weight loss, night sweats, fatigue, and malaise. A general physical examination is important, with special attention to the type and distribution of skin lesions and to the status of peripheral lymph nodes, liver, and spleen. A complete blood count with differential review, general chemistry panel, and a chest radiograph are screening tests that help to exclude

Figure 146-4 Cutaneous lymphoid hyperplasia. Lymphomatoid drug reaction manifest as a generalized papulonodular eruption in a patient who was taking various neuroleptics.

extracutaneous involvement. Lesional skin biopsy is an essential part of the diagnostic evaluation. The use of topical and systemic glucocorticoids should be discontinued approximately 4 weeks before biopsy if possible, because these agents can attenuate lymphoid infiltrates and thereby confound their interpretation. Skin specimens should be large enough and deep enough to ensure representative sampling and to provide adequate tissue for routine histopathologic, immunohistologic, and molecular biologic studies. As with squamoproliferative skin lesions, the most diagnostic areas within cutaneous lymphoid infiltrates are often their deepest portions (Fig. 146-5). For cost-effectiveness, one can often perform these biopsy studies in a sequential fashion, proceeding to the next test only if a firm diagnosis cannot be made based on the results of preceding analyses. However, rigorous characterization of a pseudolymphomatous infiltrate requires the full complement of these assays. If there is only a solitary lesion, it is generally best to obtain all biopsy material at one time, because inflammatory changes induced by the initial biopsy may interfere with the interpretation of subsequent specimens from the same locale.

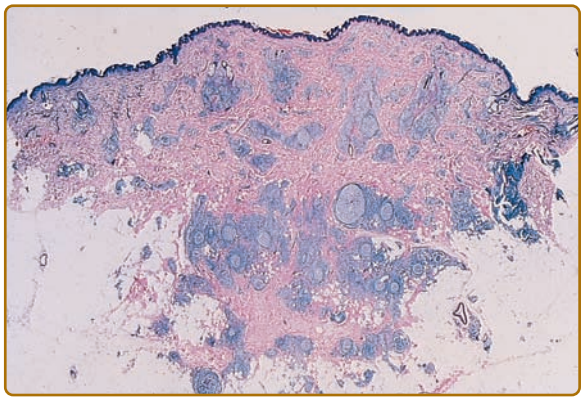

Figure 146-5 Cutaneous lymphoid hyperplasia. Infiltrate is wedge shaped and tapers out in its deeper portions. Note reactive lymphoid follicles containing pale germinal centers.

In the event that there is still uncertainty as to whether the lymphoid infiltrate represents a pseudolymphoma or a lymphoma, additional workup can be helpful. This includes computed tomographic scans of the chest, abdomen, and pelvis, as well as bone marrow aspiration and biopsy. Biopsy can be performed on abnormally enlarged lymph nodes identified by physical examination or radiography and the specimens evaluated as described in the preceding paragraph for skin lesions. It is possible for patients with atypical cutaneous B-cell infiltrates manifesting as only one or a few skin lesions to have an otherwise unremarkable workup until radiographic scans of deep lymph nodes or bone marrow sampling demonstrates advanced-stage B-cell lymphoma with minor skin involvement.

HISTORY. There may be a history of contact with an etiologically relevant foreign antigen; however, the majority of CLH cases are idiopathic. Lesions may be pruritic or asymptomatic. Occasionally, they may be slightly tender.[13]

CUTANEOUS LESIONS. CLH presents most commonly as a solitary nodule, but it can also appear as a localized array of nodules, plaques, or papules. Generalized forms occur rarely. The head, neck, extremities, breasts, and genitalia are common sites (see Figs. 146-1–146-4). Lesions have a doughy to firm consistency and range from red–brown to violaceous in color. Lesions secondary to arthropod bites can be pruritic, ulcerated, or crusted. Occasionally, reactive lymphadenopathy may be present in the area of regional lymphatic drainage.[13,14]

Hydantoin-associated pseudolymphoma syndrome is caused by anticonvulsant drugs such as phenytoin. This syndrome is characterized by fever, lymphadenopathy, hepatosplenomegaly, arthralgia, eosinophilia, and generalized cutaneous macules and papules or, rarely, nodules.[4,6] Nodules may contain aggregates of large lymphoid cells that raise concern for lymphoma; however, both B and T cells are polyclonal. Subcutaneous lymph nodes may exhibit reactive follicular hyperplasia or atypical features suggestive of lymphoma. The macular and papular lesions of this syndrome share histopathologic features with those of hypersensitivity reactions to other drugs.

Acral pseudolymphomatous angiokeratoma of children presents as a unilateral eruption of angiomatous papules on the extremities.[15] There is a dense lymphoid infiltrate associated with histiocytes, plasma cells, and prominent, thickened capillaries.[16] This disorder is probably a variant of CLH secondary to arthropod bites.

Large cell lymphocytoma, originally reported as a cutaneous pseudolymphoma, most likely represents a mixed cell or large cell form of primary cutaneous B-cell lymphoma (CBCL).[5]

LABORATORY TESTS

HISTOPATHOLOGY. Histopathologic examination of CLH lesions reveals a dense, nodular or diffuse lymphoid infiltrate that is concentrated in the reticular

Figure 146-6 Cutaneous lymphoid hyperplasia. Nodular scabies. Patchy dense infiltrate composed of small lymphocytes, histiocytes, eosinophils, and plasma cells.

dermis (see Figs. 146-5 and 146-6). It tends to be top heavy and to taper out in the lower dermis, although more widespread dermal infiltration with extension into the subcutis can sometimes be seen. In most cases, the epidermis is normal and separated from the underlying infiltrate by a narrow grenz zone of uninvolved papillary dermis. Occasionally, the epidermis may exhibit variable degrees of hyperkeratosis, parakeratosis, acanthosis, dyskeratosis, spongiosis, and basal vacuolar degeneration. Arthropod-induced reactions may show prominent epidermal hyperplasia or ulceration. Rarely, retained mouth parts may be seen associated with foreign-body granulomatous reactions. The dermal infiltrate is composed primarily of small mature lymphocytes, with a minor component of large lymphoid cells containing large, pale vesicular nuclei with small nucleoli (Fig. 146-7). Fewer than half of cases exhibit well-defined reactive lymphoid follicles discernible in routinely stained sections (see Figs. 146-5 and 146-8). These B-cell follicles may be either primary or secondary. The former are composed of homogeneous small lymphocytes, whereas the latter are compartmentalized into a peripheral mantle zone of small lymphocytes surrounding a germinal center composed of a heterogeneous mixture of small and large lymphoid cells with cleaved and noncleaved nuclei known as *centrocytes* and *centroblasts.* Germinal centers contain $CD4^+$ T-follicular helper cells characterized by expression of PD-1, Bcl-6, and CXCL13.[17] Also present in germinal centers are tingible-body macrophages, so named because they contain phagocytized debris from apoptotic lymphoid

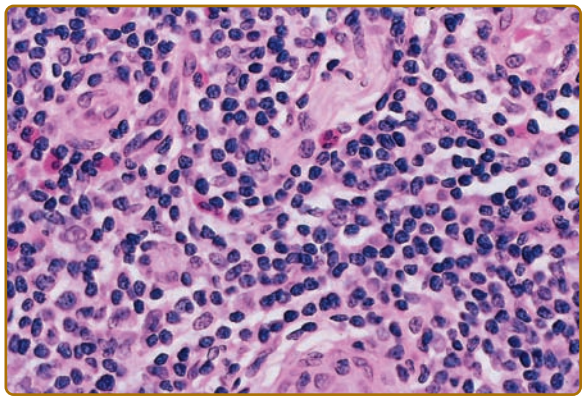

Figure 146-7 Cutaneous lymphoid hyperplasia. Infiltrate consists predominantly of small lymphocytes with an admixture of large lymphoid cells, histiocytes, and eosinophils.

cells. Mitotic figures may be numerous within germinal centers but are usually uncommon elsewhere in the infiltrate. Various types of histiocytes, including macrophages, dermal dendritic cells, and Langerhans cells, are scattered throughout the infiltrate in variable proportions. Capillary hyperplasia and endothelial swelling are often present. Other cells are sometimes admixed, including plasma cells, eosinophils, mast cells, neutrophils, and histiocytic giant cells. The first two are particularly common in arthropod-induced reactions such as nodular scabies (see Fig. 146-6).[13,14]

In the less common T-cell CLH, there are only rare B cells.[4–6,18–20] Lesions may be idiopathic or secondary to drugs or arthropod bites. Sparse to moderate epidermotropism by atypical lymphoid cells may be seen. The dermal infiltrate has a nodular or diffuse pattern and may contain cerebriform cells, immunoblasts, and histiocytes mixed with a preponderance of small mature lymphocytes. The histiocytes are sometimes numerous enough to impart a vaguely granulomatous appearance.[18] The author has seen one such case presenting as multiple nodules on the trunk and extremities that was associated with rheumatoid arthritis and eventuated in T-cell lymphoma.

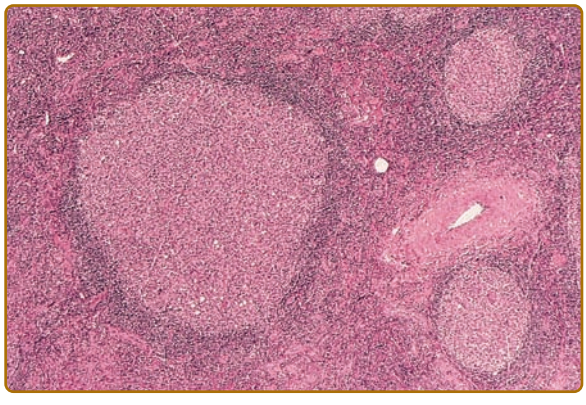

Figure 146-8 Cutaneous lymphoid hyperplasia. Lymphoid follicles in the dermis contain pale germinal centers surrounded by darker mantle zones.

SPECIAL TESTS. CLH is just one special case of extranodal lymphoid hyperplasia that may occur in a variety of organ systems. In their most well-developed form, these extranodal reactions recreate the immunoarchitectural features of reactive follicular lymphoid hyperplasia occurring in lymphoid tissues. CLH is generally a mixed B-cell/T-cell disorder. B cells may be organized into primary or secondary lymphoid follicles, simple clusters devoid of the follicular dendritic cell network seen in B-cell follicles, or may be randomly scattered throughout the infiltrate (Fig. 146-9). A defining immunophenotypic feature of CLH is that the small, nongerminal center B cells and plasma cells are polytypic; i.e., instead of restriction to only one type of immunoglobulin light chain, there is a mixture of κ-positive and λ-positive cells.[21–23] The follicular dendritic cell networks in lymphoid follicles coexpress both immunoglobulin light chains because of the polytypic nature of the immunoglobulins bound to these networks (Fig. 146-10). The larger germinal center B cells are also polytypic but generally have very low levels of immunoglobulin expression, which is obscured by the more intense staining of the follicular dendritic cell networks in which they are enmeshed.[24] Consistent with their role as a site of antigen selection and apoptosis, reactive germinal centers test negative for the bcl-2 oncoprotein.[5]

Some researchers classify CLH into follicular and diffuse variants based on the identification of lymphoid follicles in routinely stained sections. This distinction is probably not relevant biologically, because most of the apparently diffuse cases also exhibit B-cell follicles when examined immunohistologically. T cells are also present in all cases of CLH. They are found in small numbers within lymphoid follicles, for example, T follicular helper cells, but are concentrated mainly between follicles, constituting an interfollicular T-cell domain. This imparts an overall compartmentalization of B and T cells in CLH lesions. The $CD4^+$ T-cell subset

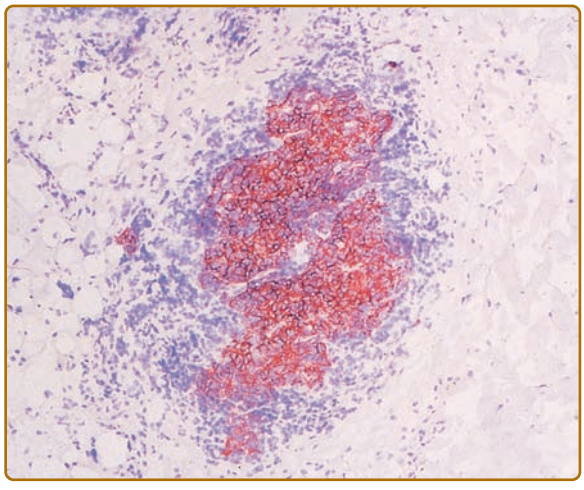

Figure 146-9 Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains B cells (*blue*) enmeshed in a network of follicular dendritic cells (*red*). Frozen section immunoperoxidase-stained using the antidendritic reticulum cell monoclonal antibody.

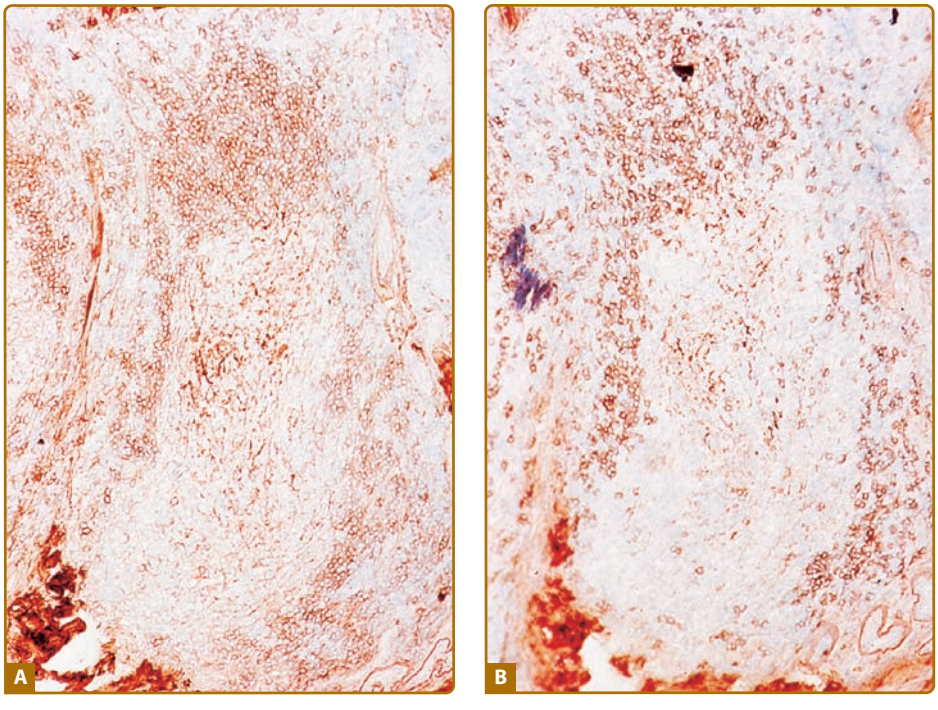

Figure 146-10 Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains a germinal center surrounded by a mantle zone composed of a mixture of B cells that express either κ-immunoglobulin light chain (**A**) or λ-immunoglobulin light chain (**B**). Note that the central follicular dendritic cell network stains positive for both light chains because polytypic immunoglobulins are bound to its surface.

predominates over the CD8$^+$ subset. There is a normal pattern of T-cell antigen expression except that CD7 may be moderately deficient at times, being expressed by only 20% to 40% of T cells. Germinal center B cells, mantle zone B cells, interfollicular B cells, and plasma cells also express the same complement of cell surface differentiation antigens expressed by their counterparts in reactive lymphoid tissues.

Unlike in most nodal follicular B-cell lymphomas (Chapter 145), the t(14;18) translocation, which results in inappropriate expression of the bcl-2 oncoprotein, is absent in CLH.[5,25–27] Molecular biologic studies show that 5% to 33% of CLH cases defined by clinicopathologic and immunohistologic criteria contain occult dominant immunoglobulin gene rearrangements, which indicate the presence of a dominant B-cell clone.[5,28–32] These cases, known as *clonal CLH*, have progressed in some cases to overt B-cell lymphoma exhibiting the same dominant B-cell clone. These findings support the view that CLH, clonal CLH, and primary CBCL exist as points along a continuum of cutaneous B-cell lymphoproliferative disorders. Progression across this spectrum of disease clearly occurs in some cases, most likely as the result of serial mutations within the dominant B-cell clone. This implies that patients with persistent CLH require regular monitoring for the development of lymphoma.[22] Clonal T-cell receptor gene rearrangements have also been detected in up to one-third of CLH cases.[28,33] This may represent an expanded reactive T-cell clone within the CLH infiltrate. Evidence for this has been observed in CLH related to human immunodeficiency virus infection.[34] Other possibilities include a low-grade T-cell lymphoma such as the CD4$^+$ small/medium pleomorphic type[17,35] or an evolving B-cell lymphoma bearing T-cell receptor gene rearrangements.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of CLH includes all of the conditions listed in Box 146-1. Many of these entities, such as granuloma faciale, Merkel cell tumor, histiocytomas, granulomas, and metastatic carcinoma, are readily distinguished from CLH by their histopathologic features.

A principal challenge in the differential diagnosis of CLH is its distinction from CBCL of either the diffuse or follicular types (see Chapter 145).[4–6,27,36] The most common variant of CBCL is diffuse large cell lymphoma, which is readily distinguished from follicular CLH on the basis of its diffuse architecture and monomorphous large cell composition. Differentiating follicular CLH from follicular CBCL can be difficult. Follicular CBCL tends to be more bottom heavy with adnexal infiltration and lymphoid follicles lacking the cellular heterogeneity, zonation, and macrophages typical of reactive follicles. Immunophenotyping shows that neoplastic B-cell follicles are either monotypic or immunoglobulin negative.[18–20] Cases involving cutaneous lymphoid infiltrates that are hard to classify or that contain a dominant lymphoid clone often benefit from a staging workup as described in Section "Approach to the Patient." In those instances representing lymphoma, workup will sometimes reveal extracutaneous involvement, and biopsy specimens from these lesions may be easier to diagnose as lymphoma. Staging also provides useful prognostic data and is essential for appropriate management of patients with overt lymphoma.

CLH must also be distinguished from other disorders with prominent lymphocytic infiltrates such as chronic lymphocytic leukemia, deep figurate erythemas, polymorphous light eruption, discoid lupus erythematosus, and Jessner's lymphocytic infiltration of the skin. All of these disorders tend to produce perivascular, and sometimes periadnexal, infiltrates whose density is far lower than that of the nodular or diffuse infiltrates typical of CLH. With the exception of chronic lymphocytic leukemia, these are all T-cell disorders. Chronic lymphocytic leukemia is a B-cell disorder that exhibits monotypic immunoglobulin and CD5 expression and involves the blood and bone marrow. CLH lesions rich in plasma cells must be distinguished from the lesions of secondary syphilis, plasmacytoma, myeloma, and immunocytoma. The infiltrate in secondary syphilis is generally richer in plasma cells or histiocytes than in small lymphocytes and is associated with epidermal hyperplasia, an interface inflammatory component, and positive results on serologic tests. The plasma cells in plasmacytoma and myeloma are monotypic and tend to exhibit mitotic figures, atypia, immaturity, and multinucleated forms. Monotypic immunoglobulin is also present in the tumor cells of primary cutaneous immunocytoma. This B-cell neoplasm is also known as *marginal zone lymphoma*, *mucosa-associated lymphoid tissue (MALT)-type lymphoma*, and *low-grade skin-associated lymphoid tissue (SALT) B-cell lymphoma*.[5,27,37]

BOX 146-1 DIFFERENTIAL DIAGNOSIS OF CUTANEOUS LYMPHOID HYPERPLASIA

Most Likely
- Chronic cutaneous lupus erythematosus
- Jessner's lymphocytic infiltration of the skin
- Granuloma faciale

Consider
- Polymorphous light eruption
- Drug eruption
- Angiolymphoid hyperplasia with eosinophilia
- Deep figurate erythemas
- Metastatic carcinoma
- Merkel cell carcinoma
- Secondary syphilis
- Histiocytomas
- Infectious and inflammatory granulomas

Always Rule Out
- Cutaneous B-cell lymphoma
- Cutaneous CD4$^+$ small/medium pleomorphic T-cell lymphoma
- Leukemia cutis

It is composed of varying proportions of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and marginal zone-like B cells. The latter have monocytoid features with a halo of cytoplasm visible around their nuclei. These cells often surround clusters of small lymphocytes, imparting a "reverse reactive follicle" appearance with smaller cells centrally and the larger monocytoid cells peripherally.

Other disorders that can contain dense cutaneous infiltrates of both T cells and B cells include (1) lymphomatoid keratosis,[38] (2) pseudolymphomatous folliculitis,[39] (3) systemic immunoglobulin IgG4-related plasmacytic syndrome (SIPS),[40,41] and (4) $CD4^+$ small/medium pleomorphic T-cell lymphoma.[17,35] The first three are readily distinguished from classic CLH on clinicopathological grounds. Although it can mimic CLH clinically and contain abundant B cells and plasma cells, $CD4^+$ small/medium pleomorphic T-cell lymphoma is recognized by its predominance of $CD4^+$ atypical lymphoid cells, frequent dominant T-cell clonality, paucity of reactive lymphoid follicles, and T-follicular helper cell phenotype.

It should be noted that typical reactive lymphoid follicles with germinal centers are not specific for CLH. They can be seen in some lymphomas (e.g., marginal zone lymphoma), Kimura disease, angiolymphoid hyperplasia with eosinophilia, Castleman disease, inflammatory pseudotumor of the skin, and morphea and as part of the host response to tumors such as basal cell carcinoma. The broad histopathologic differential diagnosis of CLH also includes histiocytoses, especially Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy; see Chapter 148), as well as so-called *small round cell tumors* such as Merkel cell carcinoma (see Chapter 120), oat cell carcinoma, neuroblastoma, and Ewing sarcoma.

Differentiation between T-cell CLH and T-cell lymphomas relies on the fact that most cases of mycosis fungoides exhibit marked epidermotropism, and most nonmycosis fungoides cutaneous T-cell lymphomas are diffuse large cell types, although a pleomorphic small/medium cell type occurs rarely as discussed above. Many T-cell lymphomas show loss of one or more T-cell antigens, and most have monoclonal T-cell receptor gene rearrangements. Progression to T-cell lymphoma has been reported in occasional patients with T-cell CLH.[19,20]

COMPLICATIONS

One of the most challenging issues concerning cutaneous pseudolymphomas has been the nature of their relationship to true lymphomas. Many patients with CBCL have a history of prior diagnosis of biopsy specimens as CLH or atypical CLH. Patients with disorders such as lymphomatoid papulosis, lymphomatoid granulomatosis, and angioimmunoblastic lymphadenopathy with dysproteinemia have an increased risk of developing various forms of overt lymphoma.[5,6,27,37] The advent of molecular biologic methods for determining B-cell or T-cell clonality by analyzing immunoglobulin or T-cell receptor gene rearrangements, respectively, has provided important insights into the relationship between pseudolymphomas and lymphomas.[5,6,27] It appears that many forms of cutaneous pseudolymphoma represent the benign end of a lymphoproliferative continuum eventuating in true lymphoma at its malignant extreme. In between lies a spectrum of intermediate disorders that are often difficult to classify unless one conceptualizes the disorders along such a continuum. In some cases, such as the CLH–CBCL spectrum, lesions range from polyclonal CLH at the benign extreme, through an intermediate form known as clonal CLH, to overt CBCL at the malignant extreme. In other instances, such as the lymphomatoid papulosis–$CD30^+$ lymphoma spectrum, dominant clonality is already present in most cases at the clinically benign end of the spectrum. The most compelling evidence for the validity of this concept of a continuum is that case studies verify that the same dominant lymphoid clone is involved in the clonal pseudolymphomatous precursor and the subsequent overt lymphoma when they arise in the same individual. This relationship between overt neoplasia and clonal precursor lesions is not unique to cutaneous pseudolymphomas. It is also seen in the connection between other forms of extranodal lymphoid hyperplasia and overt lymphoma and in the relationship between monoclonal gammopathy of uncertain significance (formerly termed *benign monoclonal gammopathy*) and subsequent B-cell malignancies.

The concept of a spectrum for cutaneous pseudolymphomas and associated lymphomas has several important implications for the diagnosis, management, and pathogenesis of these disorders. First, because some cases will exhibit lesions at an intermediate point along the lymphoproliferative continuum, they may be difficult to classify neatly into a specific disease entity. It is probably more important to recognize that they belong to a particular disease spectrum, because it is the spectrum that is often the most relevant factor for determining optimal therapy as well as the magnitude and nature of the subsequent lymphoma risk. Second, because many patients with cutaneous pseudolymphomas are at increased risk for a clonally related lymphoma, they should have regular clinical follow-up, and all reasonable attempts should be made to eradicate or suppress their disease. Third, patients with pseudolymphomas probably have underlying abnormalities in the regulation of lymphoid proliferation and/or clearance (e.g., via apoptosis). Clonal evolution and concomitant clinical disease progression are likely to occur through a sequence of somatic mutations that act through these mechanisms to confer progressively increasing autonomy to the dominant lymphoid clone. Elucidating these pathogenetic mechanisms will be important not only for developing novel therapies for cutaneous pseudolymphomas but also for improving the treatment of analogous lymphoproliferative disorders occurring in other organ systems.

PROGNOSIS AND CLINICAL COURSE

CLH lesions may resolve spontaneously or persist indefinitely. Nodular scabies (see Figs. 146-3 and 146-6)

is a well-recognized form of persistent CLH. Solitary lesions sometimes regress after biopsy or may be eradicated by excision. Those lesions that are secondary to drug use usually regress when the offending agent is withdrawn.

TREATMENT

CLH related to infection with *Borrelia burgdorferi* (lymphocytoma cutis; see Chapter 187) responds to antibiotic therapy with cephalosporins, as do some cases of idiopathic CLH. Glucocorticoids (topical, intralesional, systemic), cryotherapy, antimalarials, minocycline, and radiation therapy have all been used with variable success (Box 146-2). The latter is particularly effective but is usually regarded as a treatment of last resort. Laser therapy and photodynamic therapy have also been beneficial in some cases.[43,44] Local or distant recurrence can arise after any of these treatments. Cases of atypical CLH that cannot be distinguished from lymphoma are usually treated as localized lymphoma after staging rules out extracutaneous disease. Treatment typically involves local radiation therapy, which may be preceded by excision of the lesion.

PREVENTION

The principal preventive strategy is to avoid contact with, or ingestion of, agents known to induce CLH in those patients with a relevant clinical history. Examples include anticonvulsant medications, arthropods, gold jewelry, and hair dyes.[45–49]

BOX 146-2 TREATMENT OF CUTANEOUS LYMPHOID HYPERPLASIA

FIRST LINE

- Excision
- Topical corticosteroids (mid-to-high potency twice daily)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)
- Systemic antibiotics (e.g., minocycline 50–100 mg PO twice daily; cephalexin 500 mg PO twice daily)
- Topical tacrolimus[42]

SECOND LINE

- Cryotherapy
- δ-Aminolevulinic acid photodynamic therapy
- Laser therapy (e.g., pulsed dye laser)
- Hydroxychloroquine (200 mg PO twice daily)
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)
- Local radiation therapy

KIMURA DISEASE AND ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA

EPIDEMIOLOGY

The skin lesions of Kimura disease and angiolymphoid hyperplasia with eosinophilia (AHLE) most commonly affect young to middle-aged adults. Kimura disease is more common in Asian men, whereas AHLE is more common in women.[50–53]

ETIOLOGY AND PATHOGENESIS

It is possible that Kimura disease represents a florid, subcutaneously deep-seated form of the same basic pathogenetic process that gives rise to classic dermal CLH. Most favor the concept that Kimura disease and AHLE are distinct clinicopathologic entities despite some clinicopathologic overlap.[54–56] The terms *epithelioid hemangioma* and *pseudopyogenic granuloma* have been used as synonyms for AHLE. Some regard AHLE essentially as a malformation of blood vessels caused by an underlying arteriovenous shunt. They consider the CLH-like aspects of the lesional infiltrate to be a secondary feature. There is also evidence of lymphatic vessel proliferation in AHLE.[52] Compared with the lesions of Kimura disease, AHLE lesions tend to be smaller (Fig. 146-11) and more superficial (centered in the dermis rather than the subcutis) and exhibit a more prominent vascular hyperplasia, characterized by small blood vessels lined by plump endothelial cells with abundant cytoplasm and sometimes atypical nuclei (see Fig. 146-11). In addition, there is often evidence of arteriovenous anastomoses, the lymphoid infiltrate is less extensive, secondary lymphoid follicles are present in only a minority of cases, and lymphadenopathy is usually absent. Patients with both AHLE and Kimura disease have been shown to harbor dominant clonal T-cell populations in some cases.

CLINICAL FINDINGS

Kimura disease presents as solitary or multiple nodules up to 10 cm in diameter centered in the subcutis, most commonly involving the head and neck.[54–56] Peripheral eosinophilia and regional lymphadenopathy are characteristic. AHLE tends to present with multiple smaller, more superficial intradermal papulonodules that are typically unilateral. Salivary glands, lymph nodes, and other cutaneous sites can also be affected in either disorder, although such locations are more typical of Kimura disease.

Histopathologically, the dermis and/or subcutis exhibit hyperplasia of small blood vessels lined by plump endothelial cells similar to those present in the high endothelial venules of lymphoid tissues. These venules are a major point of lymphocyte trafficking between the blood and the paracortical T-cell domain

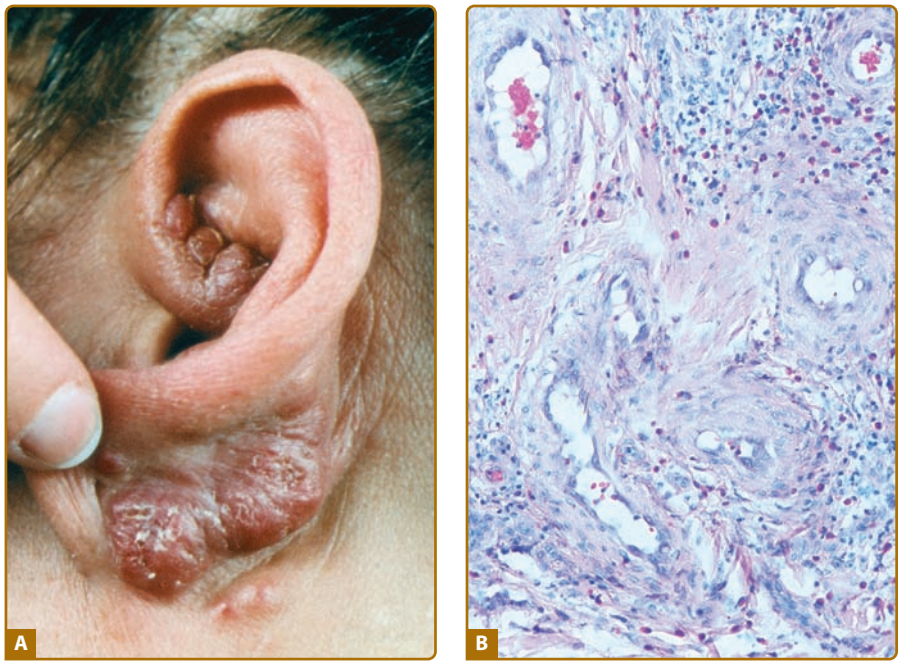

Figure 146-11 Angiolymphoid hyperplasia with eosinophilia. **A.** Clinically, there are soft, confluent papular lesions typically located in the auricular region. **B.** Histologically, blood vessels are lined by plump endothelial cells protruding into the lumen; there is vascular hyperplasia with thickened vascular walls lymphocytic infiltrates, and prominent eosinophilia.

of lymph nodes. Surrounding these hyperplastic vessels is a dense infiltrate composed of small lymphocytes, plasma cells, histiocytes, and eosinophils. The latter are typically prominent but may be absent in some cases. There are usually multiple secondary lymphoid follicles with prominent germinal centers, particularly in the subcutaneous lesions. In general, lesions are more superficial and the vascular features are more prominent in AHLE, whereas lesions are deeper and the lymphoid features are more prominent in Kimura disease.[50,51,57]

DIFFERENTIAL DIAGNOSIS

Kimura disease, which generally forms deeper, larger lesions, needs to be distinguished from CBCL, sinus histiocytosis with massive lymphadenopathy, soft tissue tumors, and subcutaneous deposits of metastatic carcinoma (Box 146-3). AHLE, which has smaller, more superficial lesions, should be differentiated from CLH, CBCL, hemangioma, angiosarcoma, pyogenic granuloma, nodular Kaposi sarcoma, bacillary angiomatosis, and bartonellosis. Many of these entities have distinctive histopathologic features. The distinguishing features of CLH and CBCL have been discussed earlier (see Section "Differential Diagnosis" under "Cutaneous Lymphoid Hyperplasia").

COMPLICATIONS

Kimura disease has been associated with lichen amyloidosis and renal disorders such as nephrotic syndrome.[58]

PROGNOSIS AND CLINICAL COURSE

Some cases, such as those associated with dominant T-cell clonality, have exhibited a chronic clinical course marked by multiple recurrences and resistance to treatment.

BOX 146-3 DIFFERENTIAL DIAGNOSIS OF KIMURA DISEASE AND ANGIOLYMPHOID HYPERPLASIA (AHLE)

Most Likely
- Cutaneous lymphoid hyperplasia (both)
- Sinus histiocytosis with massive lymphadenopathy (both)
- Pyogenic granuloma (AHLE)
- Hemangioma (AHLE)

Consider
- Soft tissue tumors (both)
- Angiosarcoma (AHLE)
- Kaposi sarcoma (AHLE)
- Bacillary angiomatosis (AHLE)
- Bartonellosis (AHLE)

Always Rule Out
- Cutaneous B-cell lymphoma and other lymphomas (both)
- Metastatic carcinoma (both)

BOX 146-4 TREATMENT OF KIMURA DISEASE AND ANGIOLYMPHOID HYPERPLASIA (AHLE)

FIRST LINE

- Excision
- Topical corticosteroids (high potency twice daily)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)

SECOND LINE

- Topical tacrolimus ointment (twice daily)
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)
- Cyclosporine [microemulsion (Neoral) 2.5–4 mg/kg/day total dose divided into twice daily PO doses; use the minimum]
- Local radiation therapy
- Vinblastine (15 mg/week IV; one report of extensive AHLE lesions treated successfully)
- Photodynamic therapy (AHLE)
- Ultralong pulse dye laser (AHLE)
- Radiofrequency ablation and sclerotherapy (AHLE)
- Isotretinoin (0.5 mg/kg/day) (AHLE)
- Rituximab (375 mg/m^2/week × 4 weeks) (Kimura disease)

TREATMENT

The treatment of Kimura disease and AHLE is not well established because of the rarity of the disorders. Many approaches have been tried in only a limited number of cases. The most common and distinctive therapies are listed in Box 146-4. Topical treatments are used mainly for AHLE. Local radiation therapy has been reported to be superior to surgery and corticosteroids for treatment of Kimura disease.[51,58–60]

CASTLEMAN DISEASE

EPIDEMIOLOGY

Castleman disease is also known as *angiofollicular lymphoid hyperplasia* or *giant lymph node hyperplasia*.[61–64] Four subtypes are recognized: (1) hyaline-vascular, (2) plasma cell, (3) HHV-8-associated, and (4) multicentric, not otherwise specified.[65] The hyaline vascular variant is more common in younger patients, the HHV-8 variant occurs among the immunosuppressed and the other variants tend to occur in older individuals.

ETIOLOGY AND PATHOGENESIS

Castleman disease is a polyclonal lymphoproliferative disorder of undetermined etiology. The hyaline-vascular type might involve abnormalities of follicular dendritic cells or vascular endothelial growth factor (VEGF). Epstein–Barr virus (EBV) has been detected in 20/20 cases in Taiwan.[66] Studies of multicentric Castleman disease demonstrate increased levels of lesional and circulating interleukins 1β and 6, which suggests that cytokine abnormalities may be pathogenic and mediate the systemic manifestations of POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes).[67,68] Castleman disease occurring in the setting of human immunodeficiency virus infection or other immunosuppression is associated with human herpesvirus type 8,[69,70] which has also been detected in Kaposi sarcoma (see Chapter 128) and primary effusion lymphomas.

CLINICAL FINDINGS

CUTANEOUS LESIONS. Castleman disease most often presents as an isolated mediastinal mass, although a multicentric form of the disease also exists. Lesions can be nodal and/or extranodal. Rarely, it may present as solitary or multiple, subcutaneous or cutaneous tumors in various locations.

RELATED PHYSICAL FINDINGS. The plasma cell variant can be associated with polyneuropathy, organomegaly, endocrinopathy, the presence of M protein, hyperpigmentation, and hypertrichosis (POEMS syndrome).[68,71]

LABORATORY TESTS

Three histopathologic variants of Castleman disease exist. The more common hyaline vascular variant exhibits small, concentrically whorled, lymphoid follicles surrounded by small lymphocytes arranged in a concentric, onionskin pattern. An extensive proliferation of capillaries is present between follicles. The rarer plasma cell variant exhibits large, hyperplastic secondary lymphoid follicles associated with a highly vascular interfollicular zone rich in plasma cells. An intermediate form has also been reported.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cutaneous and subcutaneous Castleman disease includes eosinophil-poor AHLE, Kimura disease, plasmacytoma, myeloma, sinus histiocytosis with massive lymphadenopathy, CLH, angioimmunoblastic T-cell lymphoma, and follicular types of CBCL (Box 146-5). All of these diseases lack the characteristic features of the lymphoid follicles seen in the two histopathologic variants of Castleman disease. These disorders also lack prominent vascular hyperplasia except for AHLE and Kimura disease, whose characteristic endothelial cells aid in their recognition, and angioimmunoblastic T-cell lymphoma, which contains large clonal atypical T cells. Plasmacytoma and

BOX 146-5 DIFFERENTIAL DIAGNOSIS OF CASTLEMAN DISEASE

Most Likely
- Cutaneous lymphoid hyperplasia

Consider
- Angiolymphoid hyperplasia with eosinophilia
- Kimura disease
- Plasmacytoma
- Sinus histiocytosis with massive lymphadenopathy

Always Rule Out
- Cutaneous B-cell lymphoma
- Myeloma
- Nonmycosis fungoides cutaneous T-cell lymphoma

myeloma contain dense sheets of atypical plasma cells and differ in their associated clinical findings. CLH is usually centered in the dermis rather than the subcutis. Most cutaneous lymphomas have a diffuse, monomorphous appearance. The rare follicular types of CBCL have distinctive features, as summarized earlier in Section "Differential Diagnosis" under "Cutaneous Lymphoid Hyperplasia." Sinus histiocytosis with massive lymphadenopathy is rich in $S100^+$ histiocytes that exhibit emperipolesis (intact lymphocytes within their cytoplasm).

COMPLICATIONS

Castleman disease has been associated with paraneoplastic pemphigus, plane xanthomas, vasculitis, and peliosis hepatis.[72,73] Lymphomas and follicular dendritic cell sarcomas can develop in the setting of Castleman disease.

PROGNOSIS AND CLINICAL COURSE

The clinical course is usually favorable for patients with localized and extranodal lesions.

TREATMENT

Surgical excision is effective therapy for localized Castleman disease. Radiation therapy, chemotherapy, and immunotherapy have been used to treat multicentric variants (Box 146-6).[74,75]

BOX 146-6 TREATMENT OF CASTLEMAN DISEASE

FIRST LINE
- Excision

SECOND LINE
- Radiation therapy
- Chemotherapy
- Rituximab +/– chemotherapy or thalidomide
- Anti-IL6 or anti-IL6R antibody
- Bortezomib

PSEUDOMYCOSIS FUNGOIDES

EPIDEMIOLOGY

Eruptions mimicking mycosis fungoides occur typically in adults. Both genders can be affected.

ETIOLOGY AND PATHOGENESIS

Pseudo-T-cell lymphomas with a band-like or mycosis fungoides-like histopathologic pattern may arise spontaneously or may occur as a T-cell infiltrate coexisting with B-cell chronic lymphocytic leukemia, as a rare variant of the eruption of lymphocyte recovery (which occurs in the setting of leukocyte reconstitution after iatrogenic marrow aplasia), or in association with ingestion of various drugs, including hydantoins, carbamazepine, propyl valerate, imatinib mesylate, and dexchlorpheniramine maleate and other antihistamines.[4–6,10,12,56,76]

CLINICAL FINDINGS

HISTORY. There may be a history of an associated disease or medication. Lesions may be pruritic or asymptomatic.

CUTANEOUS LESIONS. The lesions present clinically as one or a few plaques on the trunk or extremities. Occasionally, several plaques or a Sézary-like syndrome develops.

LABORATORY TESTS

Histopathologically, there is a papillary dermal, band-like infiltrate containing mostly small and medium-sized atypical lymphocytes with clefted and cerebriform nuclei. Moderate numbers of histiocytes are admixed, but eosinophils and plasma cells are rare. The dermal–epidermal junction is obscured, and there is no grenz zone. The overlying epidermis may be hyperplastic and/or may contain a sparse to moderate atypical lymphoid infiltrate; however, compared with mycosis fungoides, epidermotropism is typically far less prominent and Pautrier's microabscess-like cell aggregates are rare. Most cases contain polyclonal T cells, although occasional cases exhibit dominant T-cell clonality.[10,77]

DIFFERENTIAL DIAGNOSIS

The differentiation of these pseudolymphomas from mycosis fungoides is aided by their tendency toward

minimal epidermotropism in many cases, the small number of lesions, their tendency to be polyclonal, and their resolution after discontinuation of an inducing drug and/or local therapy.

Lichenoid drug eruptions caused by agents such as gold, thiazides, and antimalarials may also bear a histopathologic resemblance to atrophic forms of large plaque parapsoriasis and overt mycosis fungoides when they result in a band-like dermal lymphoid infiltrate that involves an atrophic epidermis. As in mycosis fungoides, eosinophils and plasma cells may also be present. However, these lesions lack lymphoid atypia, exhibit the clinical features of typical lichenoid drug rashes, and regress eventually after discontinuation of the causative agent. Poikilodermatous skin lesions of collagen vascular diseases and genodermatoses are distinguished from mycosis fungoides by their associated clinical and laboratory findings; by sparser infiltrates lacking atypia; and, for collagen vascular diseases, by dermal mucin, thickened epidermal basement membranes, and characteristic epidermal alterations. Lymphomatoid keratosis is a solitary keratotic lesion that contains a mixture of T cells and B cells, both of which can be epidermotropic. Chronic radiodermatitis may resemble poikilodermatous mycosis fungoides clinically but is distinguished by clinical history, sparse infiltrate, keratinocyte atypia, dermal fibrosis, and loss of adnexa. Some cases of secondary syphilis may also mimic mycosis fungoides, showing a dense, band-like, upper dermal infiltrate that obscures the dermal–epidermal junction and invades a nonspongiotic epidermis. However, the infiltrate contains more plasma cells and fewer lymphocytes than expected in mycosis fungoides; there is no lymphoid atypia; there may be neutrophils in the epidermis; and there is a deep perivascular extension of the infiltrate that is unusual in mycosis fungoides except in the tumor phase. Furthermore, the patient's history, the clinical appearance of the lesions, serologic testing, and response to antibiotic therapy will facilitate the correct diagnosis (Box 146-7).

Three other disorders that may mimic mycosis fungoides/Sézary syndrome clinically and/or pathologically are (1) follicular mucinosis, (2) lymphomatoid contact dermatitis, and (3) actinic reticuloid. Because of their distinctive features, each is discussed separately in this text.

COMPLICATIONS

Severe pseudomycosis fungoides eruptions such as erythrodermas may be associated with serious complications common to other forms of generalized exfoliative dermatitis, including local skin infection, sepsis, disrupted barrier function, and cardiovascular imbalance.

PROGNOSIS AND CLINICAL COURSE

Prognosis depends heavily on the clinical context and the ability to remedy the underlying cause of the pseudomycosis fungoides lesions. If this can be accomplished, then the lesions generally regress, although lichenoid infiltrates may require many months to resolve.

BOX 146-7 DIFFERENTIAL DIAGNOSIS OF PSEUDOMYCOSIS FUNGOIDES

Most Likely
- Lichenoid drug eruption
- Psoriasis
- Tinea corporis

Consider
- Dermatomyositis
- Subacute cutaneous lupus erythematosus
- Pityriasis rubra pilaris
- Secondary syphilis
- Chronic radiodermatitis
- Genodermatoses with poikiloderma
- Alopecia mucinosa
- Actinic reticuloid
- Noncutaneous T-cell lymphoma erythrodermas

Always Rule Out
- Mycosis fungoides
- Large plaque parapsoriasis
- Associated drug ingestion
- Associated iatrogenic marrow aplasia
- Associated B-cell chronic lymphocytic leukemia

TREATMENT

When the disorder is drug induced, identification and withdrawal of the offending agent is the principal therapy (Box 146-8). Corticosteroids (topical or systemic) and various forms of phototherapy may also be beneficial in hastening the resolution of skin lesions. Excision can be effective for isolated or sparse lesions. When pseudomycosis fungoides is associated with a

BOX 146-8 TREATMENT OF PSEUDOMYCOSIS FUNGOIDES

FIRST LINE
- Drug discontinuation (when drug induced)
- Treatment of underlying disorder (when associated with a specific disease)
- Topical corticosteroids
- UVB and narrowband UVB phototherapy
- Psoralen plus UVA phototherapy

SECOND LINE
- Systemic corticosteroids (60/40/20 mg PO taper, 5 days each)

specific disease, treatment should be directed at that underlying disorder.

PREVENTION

Strategies for prevention are similar to those described for treatment.

LYMPHOMATOID CONTACT DERMATITIS

EPIDEMIOLOGY

Lymphomatoid contact dermatitis has been observed in adults of both genders.

ETIOLOGY AND PATHOGENESIS

Lymphomatoid contact dermatitis was described originally in four patients with persistent allergic contact dermatitis proven by patch testing.[78] Responsible allergens include phosphorus sesquisulfide, *para*-tertiary butyl phenol formaldehyde resin, ethylenediamine dihydrochloride, *N*-isopropyl-*N*′-phenyl-p-phenylenediamine (IPPD), benzydamine hydrochloride, teak wood, cobalt naphthenate, gold, nickel, and *para*-phenylenediamine.[79–86] The clinical and histopathologic changes in the lesions are said to resemble those of mycosis fungoides.

CLINICAL FINDINGS

HISTORY. Skin lesions are generally pruritic. Patients may be aware of the offending contact allergen.

CUTANEOUS LESIONS. Clinically, lymphomatoid contact dermatitis is characterized by generalized red, scaly papules and plaques that may become confluent (Fig. 146-12) with resultant exfoliative erythroderma.

Figure 146-12 Lymphomatoid contact dermatitis. Erythematous papules and plaques on the forehead. Patch test with local anesthetics gave positive results.

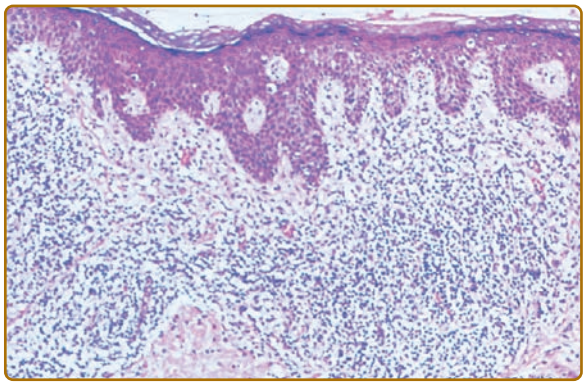

Figure 146-13 Lymphomatoid contact dermatitis. Dense band-like infiltrate in the upper part of the dermis and spongiotic foci in the epidermis ("spongiotic simulator" of mycosis fungoides).

LABORATORY TESTS

Results of patch tests for a variety of common allergens, such as ethylenediamine dihydrochloride, may be positive.

Histopathologically, lymphomatoid contact dermatitis exhibits a superficial lymphocytic dermatitis that contains foci of spongiosis simulating the appearance of cutaneous T-cell lymphomas. It must be differentiated from mycosis fungoides (Fig. 146-13), usually on the basis of changes within the epidermis; specifically, in mycosis fungoides more atypical lymphocytes have a tendency to form Pautrier's microabscesses. Frequently, there is edema in the papillary dermis in lymphomatoid contact dermatitis, a finding that is usually absent in mycosis fungoides. Immunohistopathologic investigations indicate that lymphomatoid contact dermatitis represents a T-cell pseudolymphoma. Examination of the cells in the infiltrate by electron microscopy reveals many atypical lymphocytes with cerebriform nuclei like those in mycosis fungoides.

DIFFERENTIAL DIAGNOSIS

Concern for mycosis fungoides is based mainly on the histopathologic features of the lesions. Recognition of the contact allergen is central to the correct diagnosis, aided by the microscopic distinctions noted in the preceding section. Other causes of spongiotic dermatitis and, in severe cases, erythroderma should also be considered (Box 146-9).

COMPLICATIONS

Although in rare cases lymphomatoid contact dermatitis has been reported to evolve into lymphoma, it is possible that those patients had lymphoma from the outset.

BOX 146-9 DIFFERENTIAL DIAGNOSIS OF LYMPHOMATOID CONTACT DERMATITIS

Most Likely
- Conventional allergic contact dermatitis
- Irritant contact dermatitis

Consider
- Drug eruption
- Psoriasis
- Tinea corporis
- Noncutaneous T-cell lymphoma erythrodermas (when extensive)

Always Rule Out
- Mycosis fungoides and Sézary syndrome
- Large plaque parapsoriasis

PROGNOSIS AND CLINICAL COURSE

Avoidance of the responsible allergens leads to eventual resolution of the condition in most cases.

TREATMENT

A thorough search for the offending antigen by way of patch testing is necessary if the process of lymphomatoid contact dermatitis is to be interrupted. Topical application of glucocorticoids is beneficial (Box 146-10).

PREVENTION

The only relevant preventive measure for lymphomatoid contact dermatitis is avoidance of known causes.[78–80,86–91]

LYMPHOCYTIC INFILTRATION OF THE SKIN

EPIDEMIOLOGY

The vast majority of cases of lymphocytic infiltration of the skin (LIS) occur in middle-aged adults, with a roughly equal gender ratio. Children have been affected rarely. There is also a rare familial variant.[92]

BOX 146-10 TREATMENT OF LYMPHOMATOID CONTACT DERMATITIS

FIRST LINE
- Elimination of responsible allergen
- Topical corticosteroids

SECOND LINE
- Topical tacrolimus or pimecrolimus

ETIOLOGY AND PATHOGENESIS

The etiology of LIS is unknown. Some regard it as a distinct disease, whereas retrospective studies have allowed some authors to reclassify many cases as dermal variants of lupus erythematosus or, less commonly, CLH, polymorphous light eruption or other dermatoses.[93,94] Some of the CLH-like cases have been associated with *B. burgdorferi* in Europe. One case appeared due to hydroquinone, suggesting that dermal delayed-type hypersensitivity reactions can be an etiology.[95] Photoexacerbation occurs in a minority of patients according to some observers. Immunologic investigations have shown decreased natural killer cell function as well as elevation in circulating immune complexes, the levels of which were reported to parallel disease activity.[96] Skin lesions known as *arcuate dermal erythema* may arise in female carriers of chronic granulomatous disease. These lesions resemble LIS clinically and microscopically.

CLINICAL FINDINGS

HISTORY. Skin lesions are typically asymptomatic.

CUTANEOUS LESIONS. LIS, which was first described by Jessner and Kanof,[97] presents as one or more erythematous plaques or nodules, generally localized to only one or a few sites on the face, neck, upper trunk, or arms.[98,99] Pustules, pruritus, and epidermal alterations are absent. In contrast to discoid lupus lesions, LIS lesions show no epidermal atrophy or follicular plugging.

LABORATORY TESTS

Histopathologic examination reveals a superficial and deep, perivascular and variably periadnexal infiltrate of small mature lymphocytes, often with a minor admixture of histiocytes, plasmacytoid monocytes, and plasma cells. Lymphoid follicles and eosinophils are absent. The epidermis is unremarkable. Results of direct immunofluorescence studies are negative or nonspecific. Immunohistologic studies have demonstrated a predominantly HLA-DR$^-$ Leu-8$^+$ T-cell infiltrate with some B cells and histiocytes admixed. In contrast, most of the T cells in discoid lupus are HLA-DR$^+$ Leu-8$^-$.[100–102] Immunopathologic studies have shown a predominance of CD8$^+$ T cells within lesional infiltrates. Initial studies indicate that the infiltrate lacks dominant clonality.[5,103,104]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of LIS includes chronic cutaneous lupus erythematosus, polymorphous light eruption, CLH, lymphocytic lymphoma and leukemia, deep figurate erythemas such as erythema chronicum migrans, granuloma faciale, and reticular erythematous

BOX 146-11 DIFFERENTIAL DIAGNOSIS OF LYMPHOCYTIC INFILTRATION OF THE SKIN

Most Likely

- Chronic cutaneous lupus erythematosus
- Cutaneous lymphoid hyperplasia
- Polymorphous light eruption

Consider

- Granuloma faciale
- Infectious and inflammatory granulomas
- Erythema chronicum migrans
- Other deep figurate erythemas
- Reticular erythematous mucinosis

Always Rule Out

- Cutaneous B-cell lymphoma
- Leukemia cutis (especially B-cell chronic lymphocytic leukemia)

BOX 146-12 TREATMENT OF LYMPHOCYTIC INFILTRATION OF THE SKIN

FIRST LINE

- Topical corticosteroids
- Topical tacrolimus and pimecrolimus
- Photoprotection (if historically relevant)
- Intralesional corticosteroids (5–40 mg/mL, 1 mL monthly)

SECOND LINE

- Hydroxychloroquine (100–200 mg PO twice daily)
- Systemic corticosteroids (60/40/20 mg PO daily taper, 5 days each; if effective, then as needed)
- Auranofin (3 mg PO twice daily)
- Acitretin (25–50 mg PO daily)
- Thalidomide (100 mg PO daily)
- Pulsed-dye laser (595 nm)

mucinosis (Box 146-11). In considering differential diagnostic features, keep in mind that some authors regard both LIS and reticular erythematous mucinosis to be misdiagnosed lupus erythematosus, CLH, or other miscellaneous disorders.[93,94] Discoid lupus generally exhibits epidermal changes, an interface inflammatory component, and a lupus band on direct immunofluorescence. The tumid variant of discoid lupus is typified by abundant dermal mucin and subtle alterations at the dermal–epidermal interface. These changes are not seen in LIS. Antinuclear antibody (ANA) panel results and erythrocyte sedimentation rate are also normal in most cases; however, positive ANAs have been reported in some patients leading to reclassification of their disease as lupus. Polymorphous light eruption exhibits papillary dermal edema, which is absent in LIS. CLH contains nodular or diffuse, dermal lymphoid infiltrates that are much denser than the predominantly perivascular infiltrate of LIS. Furthermore, LIS lacks reactive B-cell follicles. Well-differentiated or small lymphocytic lymphoma/leukemia is usually a monoclonal B-cell process, and there is a peripheral lymphocytosis in the leukemic form of the disease. These findings are absent in LIS. In erythema chronicum migrans and some cases of CLH, there is serologic evidence of active infection with *B. burgdorferi*, whereas this is rarely seen in LIS except when there has been suspicion of misdiagnosis of CLH as LIS.[94] Granuloma faciale is rich in neutrophils and eosinophils that are not features of LIS. Reticular erythematous mucinosis has a reticulated clinical appearance, favors the trunk rather than the head and neck, and shows bipolar fibroblasts. These are not features of LIS.

COMPLICATIONS

Postinflammatory pigmentary alterations and corticosteroid-associated skin atrophy may complicate the clinical course of LIS, especially in cosmetically sensitive locations.

PROGNOSIS AND CLINICAL COURSE

LIS has a chronic course and may show periods of spontaneous remission and eventual resolution. Lesions may recur at their original sites or elsewhere. Some patients have subsequently developed features typical of lupus erythematosus.[93,94]

TREATMENT

LIS may respond favorably to topical or intralesional glucocorticoids, calcineurin inhibitors, antimalarials, pulsed-dye laser or thalidomide; however, a persistent, indurated variant has been described that may require systemic glucocorticoid therapy to achieve remission[105] (Box 146-12).

PREVENTION

Photoprotection may be helpful in those cases with a history of photoexacerbation.

Chapter 147 :: Cutaneous Langerhans Cell Histiocytosis

:: Carlo Gelmetti

LANGERHANS CELL HISTIOCYTOSIS AT A GLANCE

- A group of rare disorders that are considered reactive but have a broad spectrum of severity.
- The reactive vs. neoplastic nature of the disease is debated. A clonal origin for the cells of Langerhans cell histiocytosis (LCH) in genetically predisposed patients is the most probable hypothesis.
- Histopathologic features consist of a dense infiltrate of histiocytes with a strong epidermotropism. The unifying element is the typical "LCH cell"—a histiocyte with an irregular vesiculated, often reniform nucleus and an abundant, slightly eosinophilic cytoplasm. These cells test are positive for S100 protein, CD1a, and CD207, and contain cytoplasmic Langerhans granules.
- Cutaneous lesions vary from papules to vesicles, pustules, nodules, and ulcers.
- The course of LCH ranges from localized self-healing forms to generalized and fatal cases.
- The most common sites of involvement are the head, trunk, and skin folds.
- Mucosal lesions are usually ulcerated nodules involving mainly gingival and genital regions.
- Associated manifestations include diabetes insipidus and exophthalmos.
- Systemic lesions may affect bones, lungs, bone marrow, liver, spleen, and lymph nodes.
- Aggressive forms may be treated successfully with vinblastine and other drugs.

INTRODUCTION

The term "histiocytoses" identifies a group of diseases that have in common the proliferation of cells of the mononuclear phagocyte system, including dendritic cells.

Histiocytes, formally connective tissue macrophages, and dendritic cells constitute two of the major types of nonlymphoid mononuclear cells and are involved in immune and nonimmune inflammatory responses. Both cells arise in the bone marrow from pluripotential stem cells, but follow different paths of differentiation (Fig. 147-1). The macrophage, detectable by CD68, is a monocyte in the peripheral blood and a macrophage in tissue. It may differentiate into a number of different giant cells, including foreign body, epithelioid, Touton, and Langhans types.

Dendritic cells are antigen-presenting cells that interact with T cells. The prototype of dendritic cell in the skin is the Langerhans cell (LC). First described by Paul Langerhans in 1868 as a neuronal cell, the LC was first linked to antigen presentation during the 1940s. Precursor cells to the LCs migrate from the dermis into the epidermis where they complete differentiation. LCs have long cytoplasmic projections and a large almost kidney-shaped nucleus. Electron microscopy reveals the characteristic cytoplasmic organelle, the Langerhans or Birbeck granule, a tennis racket-shaped structure that is involved in pinocytosis and receptor-mediated endocytosis. Langerin (CD207), a receptor that permits internalization of antigen into Birbeck granules and presentation of antigen at the cell surface, is the most specific marker for LCs. LCs are also S100- and CD1a-positive. Once LCs have contacted antigen, they move via the lymphatics to the T-cell zones of the regional lymph nodes where they are designated interdigitating reticulum cells. There LCs present antigen to naive T-cells, activating them to proliferate if the antigen is recognized. Indeterminate cells are most likely immature Langerhans cells that lack Birbeck granules. Dermal dendritic cells are perivascular cells that are also capable of antigen uptake and presentation. Dermal macrophages can be identified in the normal dermis but their number increases during inflammation.

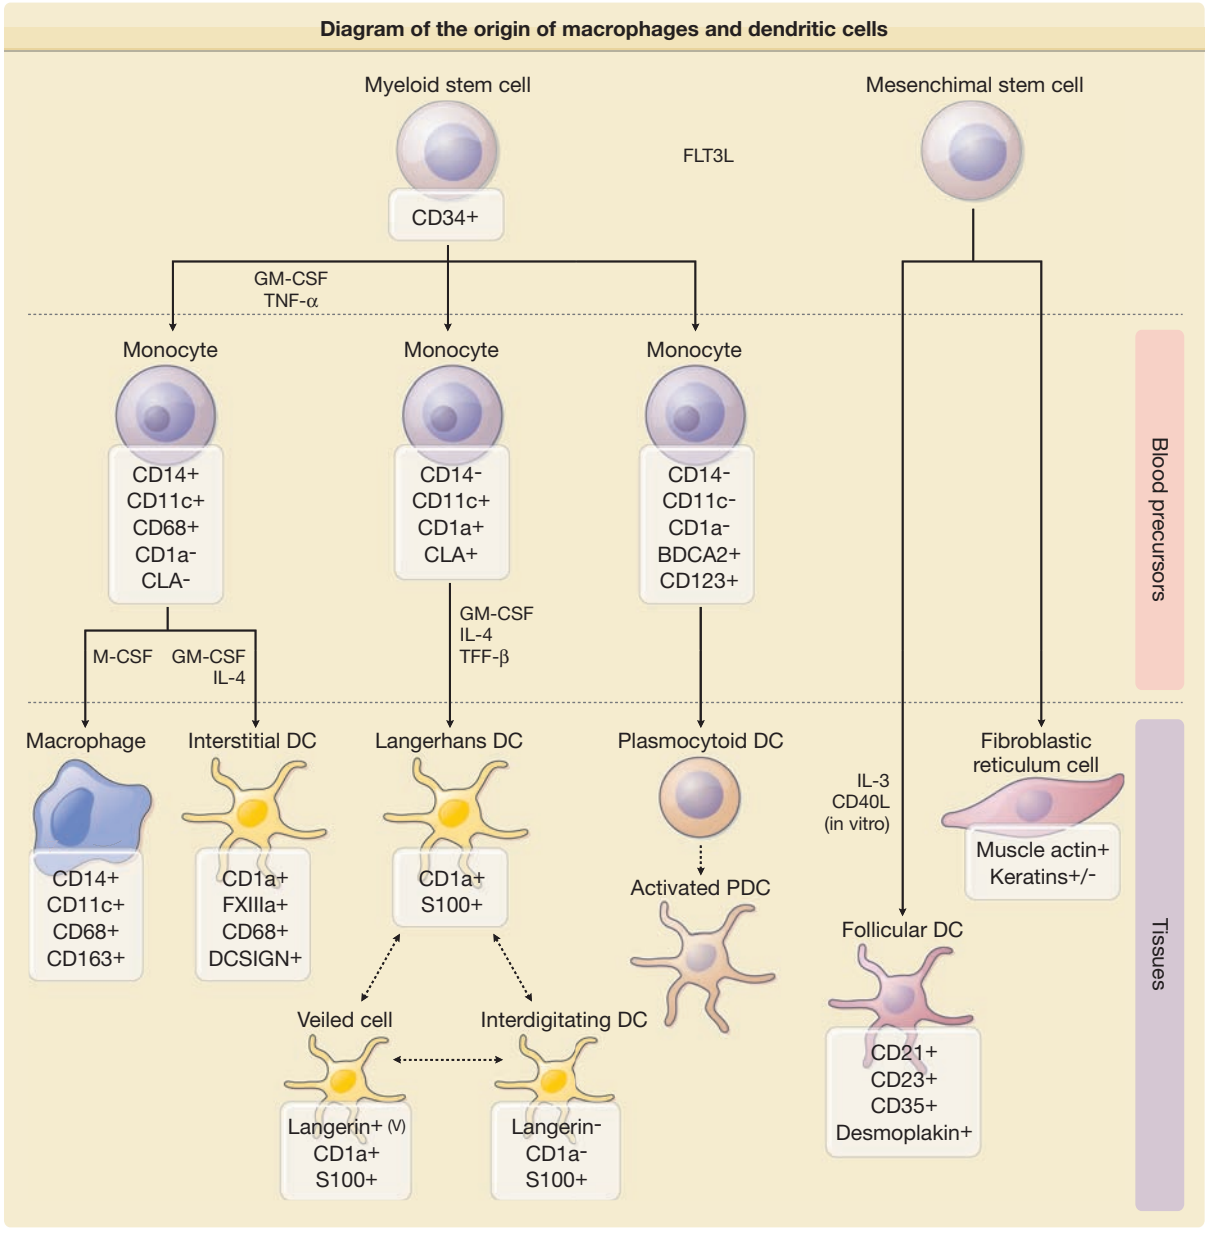

Figure 147-1 Schematic diagram of the origin of macrophages and dendritic cells. Both macrophages and dendritic cells (antigen presenting cells) are derived from a common bone marrow precursor. In contrast, follicular dendritic cells are thought to be of nonhematopoietic origin. +, most, if not all, cells positive; –, all cells negative, +/–, a minority of cells positive; v, variable intensity. (Adapted from Jaffe R et al: Histiocytic and dendritic cell neoplasms, introduction. In: *WHO Classification of Tumors of Haematopoietic and Lympoid Tissues*, edited by SH Swerdlow et al. Geneva, Lyon, WHO Press, 2008.)

Dermal macrophages, dermal dendritic cells, and Langerhans cells have a common bone marrow precursor, explaining why there are so many overlapping functions and markers.[1]

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is characterized by aberrant proliferation of the LCs. Lichtenstein grouped Letterer–Siwe disease, Hand–Schüller–Christian disease, and eosinophilic granuloma of bone as "histiocytosis X" in 1953, based on finding abnormal histiocytes in these three related disorders. During the ensuing decade, Basset and Nezelof investigated novel intracellular granules in the lesional histiocytes and recognized them to be identical to those described in normal LCs. The term *Langerhans cell histiocytosis (LCH)* is now preferred to "histiocytosis X".[2]

EPIDEMIOLOGY

The prevalence of LCH is internationally estimated to be from 4.0 to 5.4 per million population, but these

numbers may be low because of failure to recognize the organ and skin involvement in many patients. In children, the annual incidence is estimated at 0.5 per 100,000 children in the United States and at 4 per million worldwide.[3] The male–female ratio is 2:1. The disease can occur in individuals of any age and can also be congenital, but is most common in children aged 1–3 years.

ETIOLOGY AND PATHOGENESIS

Histiocytoses are caused by a dysregulated proliferation or activation of dendritic cells or macrophages, both belonging to the mononuclear phagocyte system. Despite the improved knowledge of the classification of histiocytic disorders and the establishment of guidelines for diagnosis, treatment, and follow-up provided by the Histiocyte Society, the etiology and pathogenesis of most of these diseases are poorly understood, partially because of the lack of reliable animal models.[4]

The pathogenesis of LCH remains a mystery despite numerous investigative efforts. In addition to genetic factors, infectious agents (especially viruses), and cellular and immune system dysfunction, including abnormalities of lymphocytes and cytokines (interleukin 1α, interleukin 10), cellular adhesion molecules, and a combination of these, have been implicated. The role of genetics is not well defined. Although LCH has been reported in both monozygotic and dizygotic twins, the relative rarity of the familial occurrence does not favor a significant hereditary influence.

The reactive versus neoplastic nature of LCH cells is also debated. Although clonality has been demonstrated in all forms of LCH, this does not mean that the process is histologically and biologically malignant. The following features substantiate the reactive hypothesis: (1) LCH cells are highly differentiated, (2) histologically the granulomatous lesions resemble those seen in infections or foreign-body reactions, and (3) lesions may spontaneously regress. These pathogenic steps have been suggested: (1) viruses induce activation of histiocytes, (2) immunologic mechanisms produce the pathologic Langerhans cell phenotype, and (3) a cytokine-mediated storm results in LCH lesions. Many viruses (human herpesvirus 6, cytomegalovirus, adenovirus, and parvovirus) are suspected to play an etiologic role, but none has been proven to be responsible for the disease.

In contrast, the following observations support a clonal neoplastic origin of LCH: (1) bone marrow derivation and clonality of LCH cells, (2) the existence of familial cases of LCH, (3) findings of chromosomal instability with an abnormality on chromosome 7 and of p53 protein in LCH, and (4) cooccurrence of LCH and a myelodysplastic marrow. Two possible explanations have been proposed for the association between LCH and myelodysplasia. The first is that the marrow dysplastic features are secondary to the infiltration of the marrow by LCH cells induced by cytokines and do not represent elements of a true myelodysplastic syndrome. A second possibility is that the abnormal marrow cells are related to the clonal LCH cells and are part of the disease process, for example, myelodysplastic cells could be arising from the same clonal cell, an anomalous pluripotent dendritic (stem) cell line. This possibility raises the issue of whether LCH could be considered a "myeloid dendritic stem cell disorder." These findings also suggest a genetic predisposition in LCH and stimulate the search for potential candidate genes in LCH. Figure 147-1 illustrates the histiocyte developmental pathway according to Jaffe et al.[5]

CLINICAL FINDINGS

CLASSIFICATION

LCH is a disorder with a broad spectrum of forms: it can be local, asymptomatic with an indolent course, limited to an isolated bone lesion, or systemic and aggressive involving multiple organs and producing significant symptoms. Thus, the clinical manifestations depend on the site of the lesions and the systems involved. Historically, LCH has been described under various names: Letterer–Siwe disease is the prototype of the acute, disseminated, multisystemic form that usually appears in infants or newborns. Its course, if the disease is untreated, is fatal; Hand–Schüller–Christian disease is the chronic, progressive, multifocal form, commonly beginning in childhood; eosinophilic granuloma is the localized, benign form; and Hashimoto–Pritzker disease represents the benign, self-healing variant of LCH, usually present at birth or during the first few days of life. In 1997, experts of the Reclassification Working Group of the Histiocyte Society advocated the disuse of the eponyms. They recommended the use of the term *Langerhans cell histiocytosis* only and the stratification of patients based on the extent of disease. The classification system for histiocytosis defined by the Histiocyte Society is shown in Table 147-1. At present, it seems realistic to describe LCH as a continuum as in Fig. 147-2, because every patient is unique with regard to the type, number, and location of lesions.

Although the historical terminology can be maintained for didactic purposes, it is more important to distinguish the forms with systemic involvement that require systemic management (multisystemic LCH) from those with localized lesions and the best prognosis that can be treated with a topical medication or observational approach (single-system LCH) or that are "self-healing" (Fig. 147-3).

The Writing Group of the Histiocyte Society proposed a guideline identifying confidence levels for the diagnosis of class I histiocytosis (LCH). These criteria were as follows: (1) presumptive diagnosis—light morphologic characteristics; (2) designated diagnosis—light morphologic features plus two or more supplemental positive results to stains for adenosine triphosphatase, S100 protein, α-D-mannosidase, and peanut lectin; (3) definitive diagnosis—light morphologic characteristics plus Birbeck granules in the lesional cell visible with electron microscopy and/or positive results on staining for CD1a antigen on the lesional cell.

Current immunostaining techniques allow the definitive diagnosis of LCH from just paraffin-embed-

TABLE 147-1
Classification of Langerhans-Cell Histiocytosis (LCH)[6,7]

Single-system Disease	
Localized (single site)	Monostotic bone involvement[a] Isolated skin involvement Solitary lymph node involvement
Multiple site	Polyostotic bone involvement[a] Multifocal bone disease (two or more different bones) Multiple lymph node involvement
Multisystem Disease	
Low-risk group	Disseminated disease with involvement of low-risk organs (skin, bone, lymph node, pituitary)
High-risk group	Disseminated disease with involvement of one or more of the high-risk organs (hematopoietic system, lungs, liver, and spleen)

[a]CNS-risk lesions: involvement of facial bones, sinuses, the maxilla, or anterior or middle cranial fossa (temporal, mastoid, sphenoidal, ethmoidal, zygomatic, orbital bones) with intracranial tumor extension. Not included are vault lesions.

ded tissue, which avoids the need for sophisticated and expensive methods such as electron microscopy. Because the location and diffusion of the lesions have a significant influence on the course of the disease and its prognosis, various classification schemes assign scores for each organ and system involved. The former classification of LCH into three or four disease categories is no longer used. The present system attempts to evaluate the extent of involvement and its relationship to prognosis. The former classification of LCH into three or four disease categories is no longer used. The present system attempts to evaluate the extent of involvement and its relationship to prognosis.

CUTANEOUS LESIONS

Cutaneous manifestations are very common in LCH and may represent the earliest sign of the disease. The typical lesion is a small translucent papule, 1–2 mm in diameter, slightly raised, rose-yellow (Figs. 147-4A and 147-4B), and usually located on the trunk (see Figs. 147-4A and 147-4B) and scalp. The lesions frequently show scaling (see Fig. 147-4A) and may become crusted and ulcerated (see Figs. 147-4B and 147-4C). Vesicles and pustules may occur, simulating eczema, miliaria, scabies, and varicella. This is an especially common presentation during the neonatal period (first month of life). The presence of purpura is a poor prognostic sign. Hashimoto–Pritzker disease has traditionally been characterized by the eruption of multiple or solitary elevated, firm, red–brown nodules (Fig. 147-5A) or flesh-red lesions similar to infantile angiomas; late papulonodular lesions may show elevated borders and ulcerate easily. These lesions can grow in size and number in the first few weeks of life, and some may become quite large. They then form brown crusts, which are shed and occasionally leave whitish atrophic scars after spontaneous resolution. Since the original description of the papulonodular lesions, it is clear that small reddish-brown crusted papules that may resemble chickenpox are also a common manifestation of

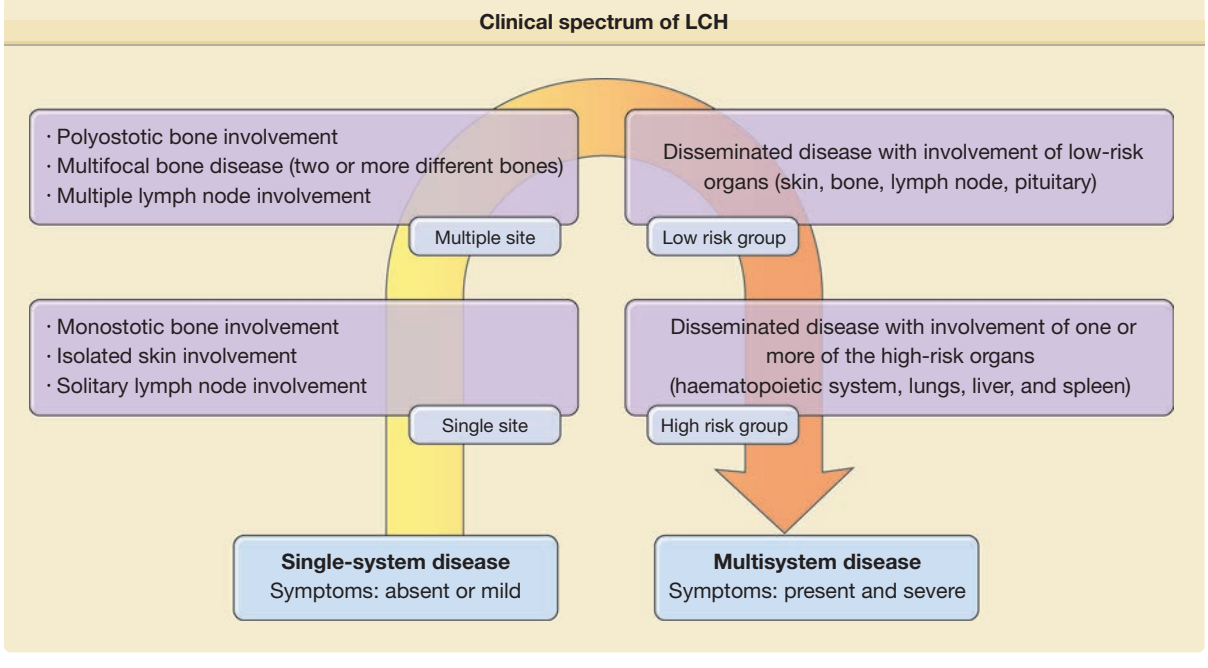

Figure 147-2 Clinical spectrum of LCH. Any single patient affected by LCH can be situated in a given point of the arrow.

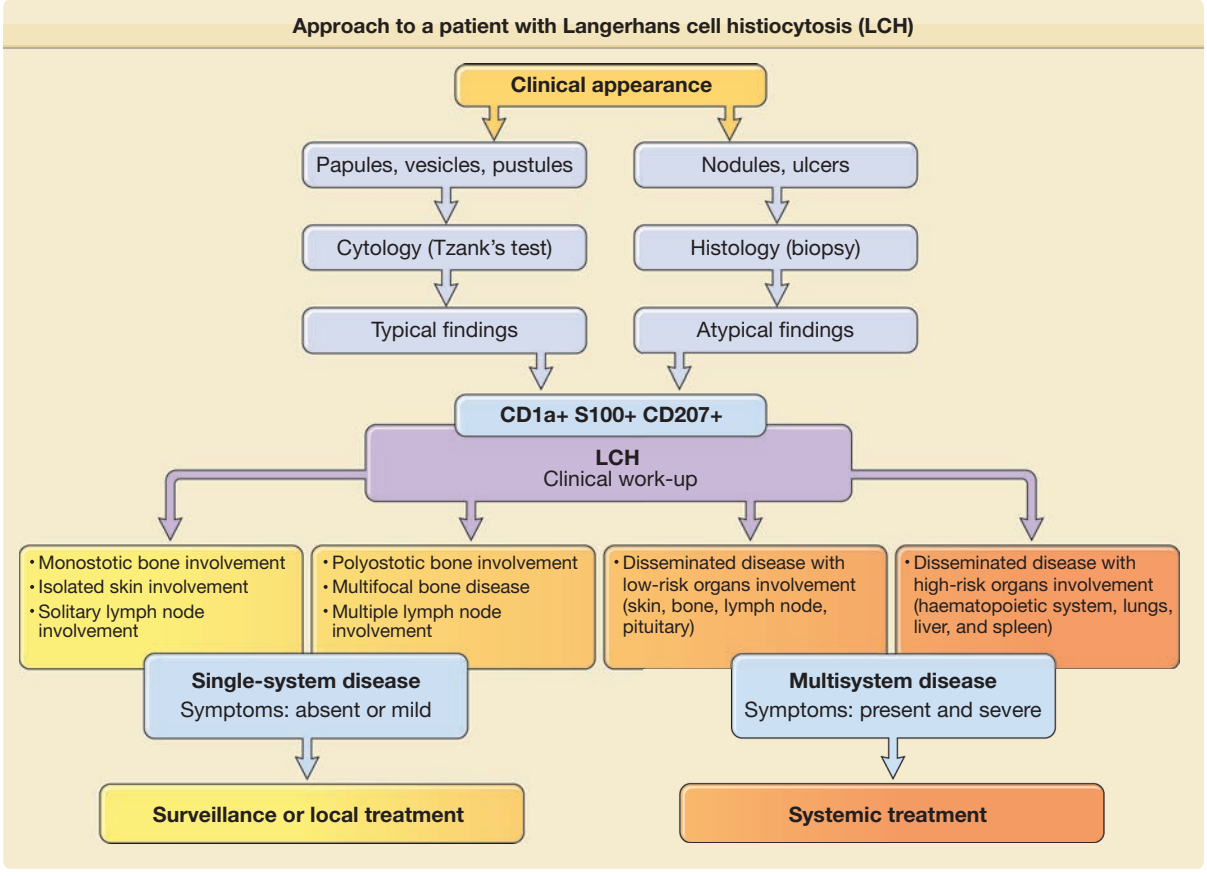

Figure 147-3 Approach to the patient with Langerhans cells histiocytosis.

"self-healing Langerhans cell histocytosis," with spontaneous clearance by 2–3 months of age (see Fig. 147-5B). Presentation with extensive, erosive, superficial lesions suggestive of congenital bullous epidermolysis has also been described.[8]

Cutaneous lesions may appear rapidly in successive crops. The lesions tend to merge on the scalp, mimicking seborrheic dermatitis or folliculitis, and leading to alopecia, and on the folds (retroauricular, axillary, and genital), mimicking intertrigo. Occasionally, the lesions merge into plaques on the medial aspect of the chest (Fig. 147-6), the midback, and temporoparietal regions, and may become xanthomatous.

Mucous membrane lesions are commonly noduloulcerative and mainly involve the perioral area and gingiva (Fig. 147-7) and the perigenital or perianal regions (Fig. 147-8). Oral manifestations may be the first sign of LCH: nonspecific pain, aphthae, gingival bleeding, candidiasis, ulceration with loosening of the teeth, and premature eruption of the teeth can be observed.

Nail changes include fragile lamina, paronychia, subungual pustules, nail fold destruction, onycholysis, subungual hyperkeratosis, longitudinal grooving, and pigmented and purpuric striae of the nail bed (Fig. 147-9). These features are considered to be unfavorable prognostic signs. Cutaneous manifestations in elderly patients (Fig. 147-10) are similar to those seen in children.

RELATED PHYSICAL FINDINGS

Malaise, weight loss, failure to thrive, nausea, myalgia, arthralgia, and fever are frequently present in aggressive forms. Bone lesions are the most frequent manifestations of LCH (80% of cases), and bone involvement alone is seen in 50% to 60% of cases. The bones that are most commonly involved by LCH are the skull, femur, mandible, pelvis, and spine. Cervical LCH lesions often extend to paravertebral soft tissue, epidural space, pedicles, and even to the endplate and lamina.[9] The lesions of the skull most often involve the temporoparietal region, in which infiltrates lead to limited osteolytic foci that merge to form typical "map" lesions (Fig. 147-11). Because osteolysis of the lower maxillary bones is also frequent, the teeth appear to be floating in the mouth in X-rays. Mastoid involvement is common and often symptomatic. Bone involvement can be shown by computed tomography (CT) or gadolinium-enhanced magnetic resonance imaging (MRI) and can lead to organ dysfunction such as diabetes insipidus and growth retardation. Retro-ocular bone involvement is responsible for exophthalmos. In addition, flat bones, vertebral bones, and long bones

Figure 147-4 Extensive Langerhans cell histiocytosis. **A.** Abdominal area of infant with multiple yellowish erythematous papules covered by scale or crust. **B.** Infant with multiple ulcerated skin lesions on the trunk. **C.** Severe disease with confluent erosive and crusted lesions forming ulcers; distension of the abdomen reflects hepatosplenomegaly.

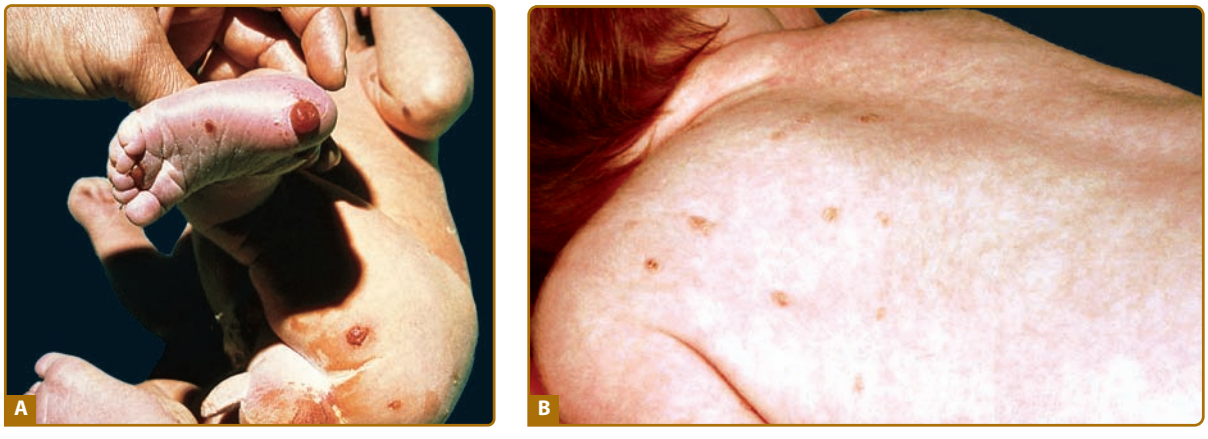

Figure 147-5 **A.** Congenital "self-healing" reticulohistiocytosis (also called self-regressive cutaneous LCH and formerly Hashimoto–Pritzker disease). Multiple disseminated, elevated, firm red–brown or dark red nodules (multiple form) present at birth. (From Bonifazi L et al: Congenital self-healing histiocytosis. *Arch Dermatol* **118**:267, 1982, with permission.) **B.** Resolving crusted reddish brown papules of congenital self-healing Langerhans cell histiocytosis with chickenpox-like lesions.

can be involved. Osteolytic lesions, either asymptomatic or accompanied by pain and functional impairment, are generally multiple and appear gradually. At times, lesions may cause a significant periosteal reaction. Extension to the adjacent tissues (e.g., muscles) can produce symptoms, which may be unrelated to the bone involvement. The onset can be insidious, and the osseous lesion can be single and may go undetected until spontaneous fracture or destruction of an organ occurs. When the lesions become symptomatic, there is localized pain, tenderness, soft tissue swelling, deformation, fracture or medullar compression (vertebra plana), or premature teeth loss.

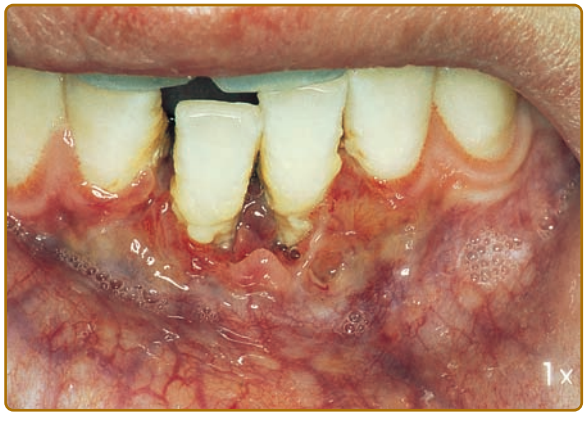

Figure 147-7 Extensive Langerhans cell histiocytosis. Infiltrating lesions of the gingival tissue which frequently leads to loss of teeth.

Figure 147-8 Restricted Langerhans cell histiocytosis. Noduloulcerative lesions in the vulva and on the perianal area. These lesions, although rare, are as unique as the bone lesions.

Bone marrow involvement, which is rare and generally occurs late in aggressive forms of LCH, is characterized by the presence of numerous histiocytic cells. When thrombocytopenia, leukopenia, and anemia occur, death is almost certain.

Conventional radiography and MRI can both be used in the diagnosis of bone LCH lesions, but MRI has an advantage in the detection of muscle involvement. In addition, isotopic bone scanning can be used for multiple lesions, and scintigraphy and fluorodeoxyglucose positron emission tomography can identify active osseous lesions. Isolated bone lesions, typically with bevelled margins and without sclerosis, have the best prognosis, whereas bone lesions with multisystem involvement predict a more problematic course.

Figure 147-9 Extensive Langerhans cell histiocytosis. All nails, save one, show purpuric linear lesions of the nail bed. Nail changes are considered an unfavorable prognostic sign.

Figure 147-10 Extensive Langerhans cell histiocytosis in an 81-year-old woman. The diffuse papuloscaling and papulocrusted lesions on the trunk are similar to those seen in early childhood. Systemic involvement consists of hepatosplenomegaly and pulmonary lesions. (From Caputo R et al: Mucocutaneous expressions of Langerhans cell histiocytosis in adults. *Eur J Dermatol* **13**:481, 1994, with permission.)

Pulmonary involvement may be asymptomatic but can also cause death. Pulmonary lesions are more often problematic in elderly patients and are quite frequent (12% to 23% of patients). Functional signs consist of dyspnea, tachypnea with rib retraction, cough, cyanosis, and thoracic pain. Other signs include mediastinal compression and pneumothorax caused by bulla

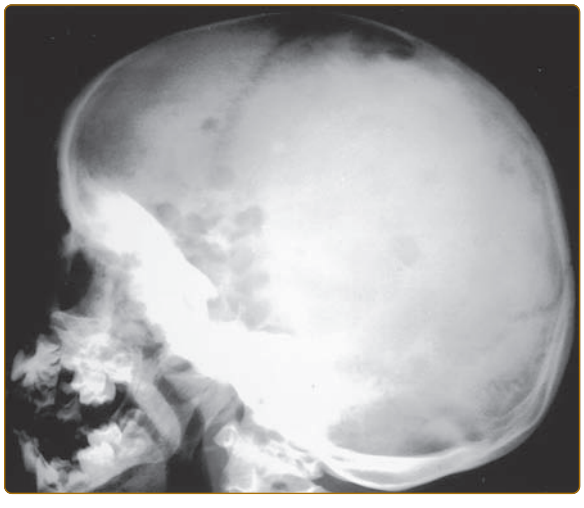

Figure 147-11 Extensive Langerhans cell histiocytosis. Radiograph of the skull shows well-circumscribed osteolytic areas with a typical "map" appearance.

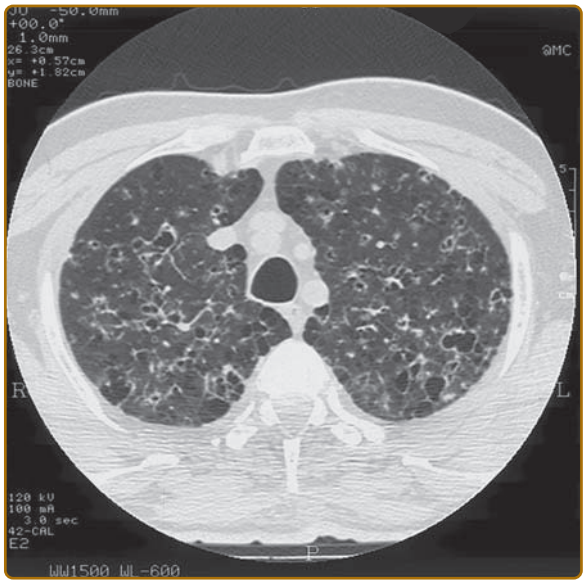

Figure 147-12 Extensive Langerhans cell histiocytosis. Bilateral involvement of the lungs characterized by multiple cystic cavities (honeycomb appearance). (Used with permission from E. De Juli, MD.)

formation. In chest radiographs, the lungs may show a classic "honeycomb" appearance (Fig. 147-12) or a micronodular pattern. Pulmonary function tests may reveal restrictive lung disease with decreased pulmonary volume. The diagnosis of LCH can be made if more than 5% of the cells in specimens obtained by bronchoalveolar lavage are Langerhans cells as indicated by immunostaining or electron microscopic examination. Involvement of the liver and spleen is quite frequent (15% to 50% of patients). Hepatic lesions may evolve to severe fibrosis, biliary cirrhosis, and liver failure. Hepatosplenomegaly, often due to portal infiltration by Langerhans cells or Kupffer cell hyperplasia, is never the initial sign of the disease but is a frequent complication and is a prognostically unfavorable sign, particularly when accompanied by jaundice and ascites. Splenomegaly may increase the severity of thrombocytopenia.

LCH may manifest orally with single or multiple lesions of the alveolar or basal bone, ulcerated mucosal lesions accompanied by adenopathy and/or periodontal lesions. The latter show gingival inflammation, bleeding, recession, necrosis, odontalgia, dental hypermobility, and premature loss of teeth. The principal differential diagnoses include advanced periodontal disease or a periapical process of dental or periodontal origin.[10] Gastrointestinal tract involvement in LCH is rare (~1%–2% of the patients) but, when present, tends to manifest at a very young age. Symptoms are nonspecific and are due to mucosal infiltration.[11] LCH may manifest as hematochezia, constipation, or diarrhea leading to protein-losing enteropathy and can range in severity from mild to life threatening.[12] The gastrointestinal symptoms can be preceded by or associated with the characteristic cutaneous lesions in the majority of the patients.

Although conventional radiographs may show either dilated or stenotic segments, the specific diagnosis can be made by only endoscopic biopsy. Since most of gut biopsies demonstrated histologic evidence of LCH, even in patients who were not experiencing gastrointestinal symptoms, endoscopic assessment of both the upper (gastroduodenal) and lower (distal colon) gastrointestinal tract should be considered with multiple mucosal biopsies in the initial LCH-staging studies in patients with no other evidence of systemic disease. Since patients with gastrointestinal tract involvement of LCH have poor outcome, they should be treated as a multisystemic disease irrespective of the patient's clinical status.

Lymphadenopathy is rarely prominent but has been noted in 25% to 75% of fatal cases. Cervical lymph nodes are the most often affected. The nodes are only rarely symptomatic, but if massive, they may damage the surrounding structures. For example, enlargement of the nodes surrounding the respiratory tract may provoke cough, dyspnea, or cyanosis. Suppuration and chronic drainage can also occur.

Diabetes insipidus is present in more than 50% of cases and occurs more often in patients with involvement of the skull and the orbits. It should be evaluated by water deprivation testing and measurement of urinary levels of arginine vasopressin. Diabetes insipidus is easily controlled by vasopressin therapy. Although diabetes insipidus is an obvious marker of skull invasion, it is not considered a prognostically unfavorable symptom. Growth retardation in children can be due to anterior pituitary involvement leading to growth hormone deficiency; however, it is more commonly caused by chemotherapy, systemic steroids, malabsorption, and general malaise. Other endocrine organs, such as the pancreas, thymus, and gonads can also be affected.

Exophthalmos is present in only 10% to 30% of cases. It may be unilateral or bilateral and is due to retroocular bone infiltration by Langerhans cells. Mastoid involvement mimics an infectious mastoiditis and leads to chronic otitis media, otorrhea, and also deafness caused by the extension of the disease to the middle ear.

CNS involvement by LCH is probably not as uncommon as believed in the past. Moreover, the clinical picture is very heterogeneous and may develop years after the initial diagnosis of LCH with mild symptoms as subtle behavioral disturbances or learning difficulties.[13] Besides growth retardation (in children), signs may include cranial nerve deficit, blurred vision, tremors, dysarthria, ataxia, reflex abnormalities, spastic paraplegia or tetraplegia, progressive intellectual deficit, headaches, psychosis, and hydrocephalus. Other signs, such as seizures and those related to increased intracranial pressure, are rare and depend on the site and size of the lesion. Cerebellar manifestations may appear as a first sign, followed by signs of involvement of the paraventricular cerebral white matter. CT or MRI may reveal tumor lesions as a sign of primary invasion or secondary atrophic or demyelinating lesions. Yet other patients are free of neurologic symptoms despite typical MRI changes.

T- and B-cell counts and T-cell subset analysis for immunologic evaluation
Urinalysis including urine osmolality testing[a]

[a]Every 6 months, or every month if indicator for currently involved system.

Hypogonadotropic hypogonadism,[14] chronic erosive oligoarthritis of large joints,[15] and a high incidence of hearing loss[16] have also been reported. An association between LCH and acute myeloid leukemia has been recorded in a few series.[17]

LABORATORY TESTS

The recommended laboratory evaluations for a patient with LCH are shown in Table 147-2. Other investigations that should be carried out in LCH are listed in Table 147-3.

IMAGING STUDIES

Diagnostic imaging, from plain films to axial high-resolution CT and gadolinium-enhanced MRI, plays a major role in the diagnosis and management of LCH. The most common intracranial manifestation in LCH is hypothalamic pituitary region infiltration in 10% to 15% of patients with LCH and is associated with diabetes insipidus or anterior pituitary hormone deficiency. The second-most common CNS finding is neurodegenerative LCH, characterized by bilateral symmetric lesions in the dentate nucleus of the cerebellum or basal ganglia of variable signal intensity on MRI. By conventional MRI, using T1- and T2-weighted sequences, the classical pattern of neurodegeneration in LCH is represented by bilateral T2-hyperintense and T1-hypointense, noncontrast-enhancing signal alterations and discrete T1-hyperintense calcifications.[18] Susceptibility-weighted imaging (SWI), a newly developed MRI sequence, is more sensitive for intraparenchymal calcifications and hemorrhages. SWI may reveal areas of tissue injury, for example, certain gray matter structures, like the substantia nigra, that go undetected on conventional MRI.[19]

As already noted, bone involvement can be investigated using isotopic bone scans to reveal multiple lesions and fluorodeoxyglucose positron emission tomography

TABLE 147-3
Procedural Investigations for Langerhans Cell Histiocytosis

Specific Investigation	Indication
Skin biopsy or cytology	Mandatory to determine diagnosis
Weight and height	To determine general health
Chest radiography[a]	To determine respiratory system involvement
Abdominal ultrasonography[a]	To determine gastrointestinal involvement
Endoscopy and biopsy	To investigate malabsorption
Bone marrow biopsy	To evaluate cause of anemia, leukopenia, thrombocytopenia
Liver biopsy	To determine specific infiltration and involvement
Pulmonary function tests	To investigate tachypnea; to assess before chemotherapy
Bronchoalveolar lavage	To determine specific infiltration
Lung biopsy	To exclude opportunistic infection
Brain magnetic resonance imaging	To evaluate neurologic, visual, endocrine anomalies
Endocrine evaluation	
Growth hormone level	To determine cause of short stature, hypothalamic syndrome
Thyroid-stimulating hormone level	To investigate galactorrhea, precocious puberty
Otorhinolaryngologic evaluation, audiogram	To evaluate auricular discharge, deafness
Bone scans, skeletal survey, or fluorodeoxyglucose positron emission tomography	To assess bone involvement
Urine osmolality after water deprivation	To investigate diabetes insipidus

[a]Every 6 months, or every month if indicator for currently involved system.

to identify active osseous lesions. These techniques may allow the precise visualization of lesions in potentially dangerous bony locations such as the skull and the spine. In the thorax, reticulonodular shadowing and honeycombing of the lung with preserved lung volume is typically revealed.

HISTOPATHOLOGIC, IMMUNOHISTOCHEMICAL, AND ULTRASTRUCTURAL EVALUATION

The pathologic features of LCH provide the unifying aspect for the entire continuum of LCH disorders. The common histologic element of the different lesions is the typical "LCH cell," a cell easily identified and differentiated from the nonspecific elements of the infiltrate by its size and configuration. This cell is approximately four to five times larger than small lymphocytes, has an irregular and vesiculated nucleus, is often reniform (kidney shaped), and has abundant, slightly eosinophilic cytoplasm (Figs. 147-13–147-15). The histologic patterns observed in LCH are of three types: (1) proliferative, (2) granulomatous, and (3) xanthomatous. A proliferative reaction is seen in early papules. It consists of an extensive epidermotropic, lichenoid infiltration of LCH cells in the upper dermis. The epidermis soon becomes compressed, thinned, invaded, and even destroyed (see Fig. 147-13). In the upper dermis, LCH cells are typically separated by edema, whereas in the lower dermis their cell membranes coalesce. In the deep dermis, the infiltrate is often localized around vessels and may invade the hypodermis. A few mitotic figures are occasionally found. Cytologic examination of LCH cells is easily accomplished by scraping early papules. The granulomatous reaction (see Fig. 147-14) consists of an aggregation of LCH cells with some multinucleated histiocytes and a varying number of eosinophils, generally in clusters. Neutrophils, lymphocytes, and plasma cells may also be present in the infiltrate. This type of reaction is seen in the chronic stages of the disease. The xanthomatous reaction is encountered mainly in what was formerly called HSC and consists of numerous foam cells intermingled with LCH cells and eosinophils (see Fig. 147-15). Multinucleated giant cells are frequently seen. They are mainly of the foreign-body type but occasionally may have the appearance of Touton giant cells. Lipid accumulation is considered to be a late secondary phenomenon. These different types of histologic reactions may be

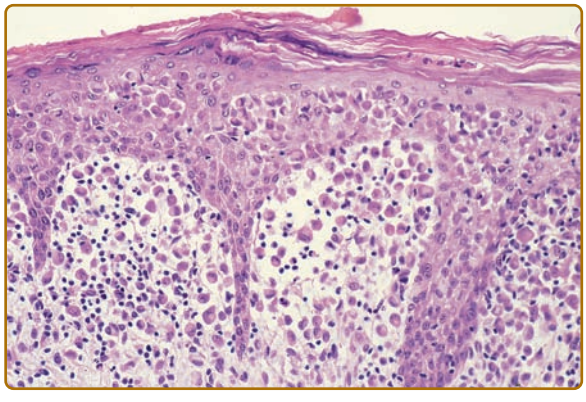

Figure 147-13 Langerhans cell histiocytosis (LCH). Proliferative reaction. A pure LCH cell infiltrate invades and destroys the epidermis.

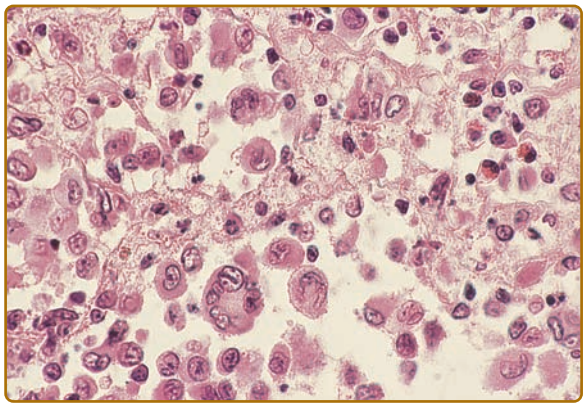

Figure 147-14 Langerhans cell histiocytosis (LCH). The granulomatous reaction consists of an aggregation of LCH cells with some multinucleated histiocytes and varying numbers of eosinophils, neutrophils, lymphocytes, and plasma cells. This type of reaction is seen in the chronic stage of the disease.

found simultaneously in the same patient, and the visceral lesions present in LCH show the same three types of reactions observed in the skin.

In historical, nodular Hashimoto–Pritzker disease, the infiltrate appears to consist mostly of large multinucleated giant cells intermingled with typical LCH cells. The cytoplasm of the giant cells is either acidophilic or has a "ground glass" appearance. It is usually localized in the middermis and deep dermis; occasionally, the epidermis may be infiltrated and ulcerated. The LCH cells show the immunophenotype of normal Langerhans cells, expressing high levels of major histocompatibility complex class II molecules, CD1a complex, CD4, CD207 molecules, and S100 protein. Electron microscopic studies show that approximately 50% of the histiocytes of LCH contain Langerhans granules (see eFig. 147-15.1 in online edition).

E-cadherin expression on LCs in lesional skin may be an indicator of a good prognosis and limited disease.

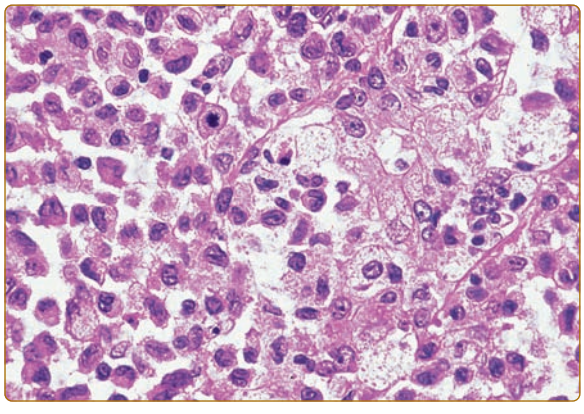

Figure 147-15 Langerhans cell histiocytosis (LCH). The xanthomatous reaction consists of numerous foam cells intermingled with LCH cells and is encountered mainly in the subtype of LCH formerly called Hand–Schüller–Christian disease. Mitotic figures are occasionally seen.

Some authors suggest testing E-cadherin expression on frozen tissue samples because of a lack of sensitivity in the use of paraffin-embedded tissue. Regulator T (Treg) cells have been shown to be numerous in skin lesions of LCH and may be involved in its pathogenesis, but their density does not predict disease evolution.[20]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for LCH is summarized in Boxes 147-1 and 147-2.

COMPLICATIONS

Intercurrent infections, mainly candidiasis and sometimes dermatophytosis, are frequently observed in LCH, especially in LSD. The development of severe pyogenic abscesses has been reported in elderly patients. The results of the progressive destruction of the surrounding tissue by invading histiocytes can therefore be highly variable and multifocal. The association of LCH with malignant neoplasms, particularly solid tumors (lung tumors, celiomesenteric neuroblastoma), malignant lymphomas, or acute leukemia is not unusual. In some of these cases, LCH may be considered as a reactive process associated with malignancy. Neoplasms may also be related to chemotherapy or radiotherapy for LCH. The synchronous occurrence of LCH with leukemia may be interpreted as additional clinical evidence in favor of a common origin of monocytes and Langerhans cells.

PROGNOSIS AND CLINICAL COURSE

Although the presence of numerous lesions, either in the skin or in other tissues, generally indicates an unfavorable course, the evolution of LCH is unpredictable. The prognosis is based on clinical features and is related to the age at onset, the rate of disease progression, and the number of organ systems involved. It is not related to the histopathologic features. In short, an early-onset (under the age of 2 years), extensive disease, and the presence of organ failure are the three main negative prognostic indicators.

Single-system LCH is usually associated with a good prognosis, whereas multisystem LCH may be fatal. However, some patients with multiple lesions have been reported to recover spontaneously. The appearance of xanthomatous lesions in the course of LCH is considered by some authors to be an expression of a shift from a disseminated aggressive form into a progressive chronic form; others believe that these lesions may represent a distinct clinical entity independent of the primary disease. Organ dysfunction (liver, bone marrow, and lung), which occurs in approximately 15% of patients with LCH, is the most important predictor of poor outcome; however, diabetes insipidus is not a poor prognostic indicator. In infants with organ

dysfunction, the mortality rate may be as high as 50% to 65%. The most frequent causes of death are pulmonary and bone marrow dysfunction and intercurrent infections.

It is impossible to attribute significance to any single sign, but jaundice, thrombocytopenia, anemia, hepatic failure, and nail involvement are considered unfavorable prognostic indicators. A favorable prognosis is associated with a small number of lesions, nodular lesions, prompt resolution of lesions, and the involvement of only one organ system (skin or bones). Multisystem LCH carries a better prognosis in adults than in children.

Liver dysfunction is considered present if there is hypoproteinemia not due to protein-losing enteropathy (less than 5.5 mg/dL total protein and/or less than 2.5 g/dL of albumin), edema, ascites, and/or hyperbilirubinemia (total serum bilirubin of more than 1.5 mg/dL). Lung dysfunction is considered present if there is cough, dyspnea or tachypnea, cyanosis, radiologically evident interstitial disease, restrictive lung disease, pneumothorax, or pleural effusion attributable to the disease rather than to infection.[22] The presence of dense areas on radiography alone is not interpreted as evidence of dysfunction. Hematopoietic dysfunction is considered present if there is anemia (less than 10 g/dL hemoglobin) not due to infection or iron deficiency, leukopenia (white blood count of fewer than 4,000/μL), or thrombocytopenia (fewer than 100,000 platelets/μL). The presence of excessive numbers of histiocytes in the marrow aspirate per se is not considered as evidence of dysfunction. Hypercalcemia is also associated with a poor prognosis and is sometimes caused by bone resorption or excess prostaglandin production. Finally, the rapidity and intensity of the clinical response to initial treatment is a good indicator of prognosis.

Hashimoto–Pritzker disease is classically characterized by congenital or neonatal isolated cutaneous involvement (nodules in the historical cases, papules and vesicopustules in other cases) without systemic involvement. Lesions regress spontaneously in weeks to months, with an excellent prognosis. As such, Hashimoto–Pritzker disease is the prototype of self-regressive cutaneous LCH (SR-LCH; also called "self-healing" LCH). However, in the same age group, cutaneous involvement is also the most common presentation of nonself-regressive cutaneous LCH (NSR-LCH). Unfortunately, there are no absolute criteria that can reliably distinguish SR-LCH from NSR-LCH in the neonatal and early infancy periods other than continued follow-up for signs of resolution.

In the recent past, it has been postulated that a higher degree of necrosis and ulceration on physical examination and a denser infiltrate of eosinophils on histopathology would suggest a self-healing process as opposed to a multisystem disease. Despite these differences, patients who were initially diagnosed with single-system LCH (cutaneous involvement only) eventually developed progression of the disease and required systemic treatment.[21]

A recent retrospective survey has reviewed a cohort of 31 patients with a diagnosis of cutaneous LCH in the first 3 months of life and no previous visceral LCH in an attempt to define predictors of disease evolution. While no single item can be a reliable indicator of a good prognosis, a solitary lesion or the tendency to involve the extremities were more common in SR-LCH. Given the marked overlapping features of SR-LCH and NSR-LCH, the term Hashimoto–Pritzker disease should be

  - Psoriasis guttate
  - Dermatitis

avoided. Spontaneous regression of the lesions, the lack of multiorgan involvement, and close long-term follow-up to monitor for progression of the disease are the only ways to definitively diagnose SR-LCH.[22]

TREATMENT

Treatment strategies for LCH are chosen on the basis of the age of the patient, the extent of disease, and the location of lesions (see Fig. 147-3 and the treatment algorithm in eFig. 147-15.2 in online edition).

In single-system disease involving skin or bone, management is nonaggressive. In children with skin involvement only, observation is the best option. Topical drugs, including corticosteroids (also intralesional injections),[23] tacrolimus, and imiquimod,[24] can be used for localized lesions. In adults with skin involvement only, topical treatment with nitrogen mustard may be effective. In one patient with localized LCH, complete clearance was achieved after 12 sessions of narrowband UVB with a cumulative dose 970 mJ/cm^2.[25] Significant improvement has been obtained with conventional psoralen plus UVA light treatment in a considerable number of cases. CO_2 laser therapy has been suggested to treat periorificial eosinophilic granuloma. Systemic glucocorticoids or antimitotic drugs are indicated for limited disease only in resistant cases. The use of thalidomide at a dosage of 100 mg/day for 1 month and then 50 mg/day for 1 or 2 months may induce a remission of skin lesions. Usually, the disease recurs after treatment is stopped. The effect of thalidomide seems to be a result of its immunomodulatory and anti-inflammatory properties. In one case, a complete remission of skin lesions was obtained after oral isotretinoin therapy. The patient was treated with 1.5 mg/kg daily for 8 months and remained free of recurrence and visceral involvement for 5 years. For patients with bone involvement only, surgery (excision or curettage) is the treatment of choice if the lesions are accessible (see eFig. 147-15.3 in online edition). In children, glucocorticoid injections into selected sites may prevent surgical trauma to developing teeth or the growth plate of long bones. In adults, radiotherapy is indicated for involvement of vertebrae, the sella turcica, and weight-bearing bones with risk of spontaneous fracture. In children, radiotherapy must be reserved for cases that fail to respond to other measures to avoid the risk of long-term effects. Recent data indicate that indomethacin at a daily dose of 1–2.5 mg/kg administered for an average of 7.7 months (range, 5–12 months) may effectively treat isolated LCH of bone in children.[26] In the case of multiple bone lesions, monochemotherapy is suggested as with multiorgan involvement.

The management of patients with multisystem disease has several options. Currently, monochemotherapy with vinblastine with or without glucocorticoids is probably the most suitable treatment.[27] Vinblastine is given intravenously at doses of 0.1–0.2 mg/kg (6.5 mg/m^2) once weekly for 1–3 months. Readministration of the alkaloid should be instituted only when new lesions appear. In the event of relapse, retreatment with the same type of monochemotherapy results in complete clearing in 60% of cases. Finally, methylprednisolone (30 mg/kg intravenously on 3 consecutive days) may be the initial therapeutic choice.

Multiagent regimens including vincristine, cyclophosphamide, doxorubicin, and chlorambucil may be considered for patients for whom monochemotherapy is not effective. In refractory and advanced cases of LCH, cyclosporine and interferon-α2, and 2-chlorodeoxyadenosine (2-CdA, cladribine) have been used. cladribine has excellent activity in patients with LCH, even though response is not uniform across all risk groups. Recent literature have shown cladribine as monotherapy has significant activity in patients with disease in nonrisk organs such as bone, but limited activity in refractory risk organ disease. In a large prospective study, the only other factors predictive of response to cladribine were age at cladribine therapy and the time from diagnosis to cladribine therapy. The response to the drug and survival were significantly

better in patients greater than 2 years of age, while the time from diagnosis to cladribine therapy was also significantly different in the responding patients compared to those who failed to respond. The potential serious side effects of cladribine (transient neutropenia, absolute monocytopenia, T-cell suppression, autoimmune hemolytic anemia, and severe skin rashes) call for a careful risk-benefit evaluation in each case. High-risk patients who fail to respond to cladribine have a high-risk of mortality.[27]

A current open pilot study of the Histiocyte Society for patients with refractory LCH is investigating whether the response rate can be improved by the addition of cytosine arabinoside (Ara-C) to cladribine. Allogenic bone marrow transplantation or autotransplantation with CD1a-depleted bone marrow has been successful in some patients. Other approaches, including stem cell transplantation with myeloablative and nonmyeloablative preparative regimes, are also being tested (eFig. 147-15.2 in online edition).

Chapter 148 :: Non-Langerhans Cell Histiocytosis

:: Carlo Gelmetti

NONLANGERHANS CELL HISTIOCYTOSIS AT A GLANCE

- A broad group of disorders characterized by the proliferation of histiocytes involving cells other than Langerhans cells.
- Not rare. Most cases are in infants and run a benign, self-healing course lasting a few years.
- The primary histopathologic feature is a dense, diffuse infiltrate that is less epidermotropic than in Langerhans cell histiocytosis (LCH) and composed of occasionally foamy macrophages intermingled with lymphocytes, plasma cells, eosinophils, and sometimes Touton giant cells.
- In typical cases, histiocytes are $CD68^+$ but $CD1a^-$ and $CD207^-$.
- Most common sites of involvement are the head, trunk, and skin folds, with mucosal lesions rare.
- Systemic manifestations such as ocular involvement, diabetes insipidus, and joint and visceral impairment are rare in juvenile xanthogranuloma, the most common type of non-Langerhans cell histiocytosis (NLCH), but are common in the rarer forms of NLCH.

TABLE 148-1
Disorders Categorized as Non-Langerhans Cell Histiocytosis (with Abbreviations)

Juvenile xanthogranuloma (JXG)
- Papular xanthoma (PX)

Generalized eruptive histiocytosis (GEH)
- Benign cephalic histiocytosis (BCH)

Xanthoma disseminatum (XD)
- Erdheim–Chester disease (ECD)

Multicentric reticulohistiocytosis (MRH)
- Solitary cutaneous reticulohistiocytosis (SRH)
- Diffuse cutaneous reticulohistiocytosis (DRH)

Progressive nodular histiocytosis (PNH)
Necrobiotic xanthogranuloma (NXG)
Sinus histiocytosis with massive lymphadenopathy (SHML)

Note: Major disorders are in bold. The other forms are considered variants of these diseases.

Non-Langerhans cell histiocytosis (NLCH), or class II histiocytosis, represents a broad group of different disorders characterized by the proliferation of histiocytes other than Langerhans cell (LC) (Table 148-1).

In some textbooks, these diseases are gathered under the term: macrophage/dermal dendritic cell disorders. In 2001, Zelger et al suggested a unifying approach to understand this disease group. They identified different types of macrophages in the prototype lesion, juvenile xanthogranuloma, and then used this morphology to subcategorize the diseases.

Clinicopathologic overlap makes it difficult to place some patients exactly into one defined entity, indicating a close relationship between these disorders. While many of these disorders may feature foamy cells, affected patients are normolipemic. In all instances, the etiology and pathogenesis are unknown.[1]

Most of these cells share the same immunophenotypes, but the resulting disorders differ in clinical presentation and course. Although all NLCH disorders are considered reactive with no clinical evidence of malignancy, some forms, as with class I histiocytosis (Langerhans cell histiocytosis or LCH), can be invasive and therefore they are not necessarily biologically benign. Patients have been described who have developed both LCH and an NLCH, particularly, juvenile xanthogranuloma (JXG).

These cases seem to demonstrate a relationship between LCH and NLCH.[2] According to some authors the dendritic cell is the presumed cell of origin of both LCH and NLCH, leading to the shared categorization of these diseases as dendritic cell-related disorders and separated from macrophage-related proliferations such as sinus histiocytosis with massive lymphadenopathy (SHML), also known as Rosai–Dorfman disease. However, the coexistence of LCH and cutaneous SHML has also been reported, further complicating the complex relationships among histiocytic disorders. See Table 147-2 for a list of the recommended laboratory evaluations for a patient with LCH and Table 147-3 for a list of other investigations that should be carried out in LCH.

Several attempts have been made to classify NLCH, but none has been universally accepted.

Although impossible to perfectly correlate histologic features and immunophenotype with either clinical presentation or course of a single disease, one practical classification is infantile versus adult disease. Infantile forms with individual papulonodular lesions tend to be almost all cutaneous and self-healing [e.g., JXG, generalized eruptive histiocytosis (GEH), benign cephalic histiocytosis (BCH)], whereas the adult forms with coalescing plaque-like lesions tend often to be systemic and progressive/aggressive [e.g., Erdheim–Chester disease (ECD); necrobiotic xanthogranuloma (NXG); SHML]. Other rare forms including hereditary progressive mucinous histiocytosis are not discussed. An approach to the patient with NLCH is outlined in Fig. 148-1.

This chapter discusses only disorders of significance to the general dermatologist. Forms that are very rare (e.g., indeterminate cell histiocytosis) or that have been described in a single patient (e.g., fat-storing hamartoma of dermal dendrocytes) are not considered.

EPIDEMIOLOGY

JXG accounts for 80%–90% of cases of NLCH. All of the other NLCHs are rare. The author has encountered almost 300 cases in the past 35 years. There is no sexual or racial predilection. JXG appears within the first year of life in approximately 80% of cases; in 20%–35% of cases, it is congenital. Approximately, 30 adult cases are reported in the literature. There is a slight male predominance among individuals with solitary JXG lesions and a strong male predominance among those with multiple cutaneous lesions. Papular xanthoma (PX), considered a variant of JXG, is a rare disorder; fewer than 20 cases have been described. The onset of PX in children is usually during the first year of life. The disease seems to be more frequent in males. GEH is rare, with approximately 40 cases described, of which 10 were in children. It may start at any age, with reports of onset ranging from 3 months to 58 years. BCH is also rare. Over the past 3 decades, approximately 30 cases have been described, with the same incidence in boys and girls. The age of onset is 5–34 months (mean, 13.5 months). Progressive nodular histiocytosis (PNH) is an exceptional form described in a few children and adults. Xanthoma disseminatum (XD) is rare (approximately 100 published cases) and affects males more frequently than females. The random nature of the disorder does not permit an exact evaluation of either familial involvement or morbidity. In approximately 60% of patients, onset is before age 25 years. ECD is also rare, and only about 60 cases have been described in 70 years. Multicentric reticulohistiocytosis (MRH) is an uncommon disorder but has been observed in more than 100 individuals reported up to

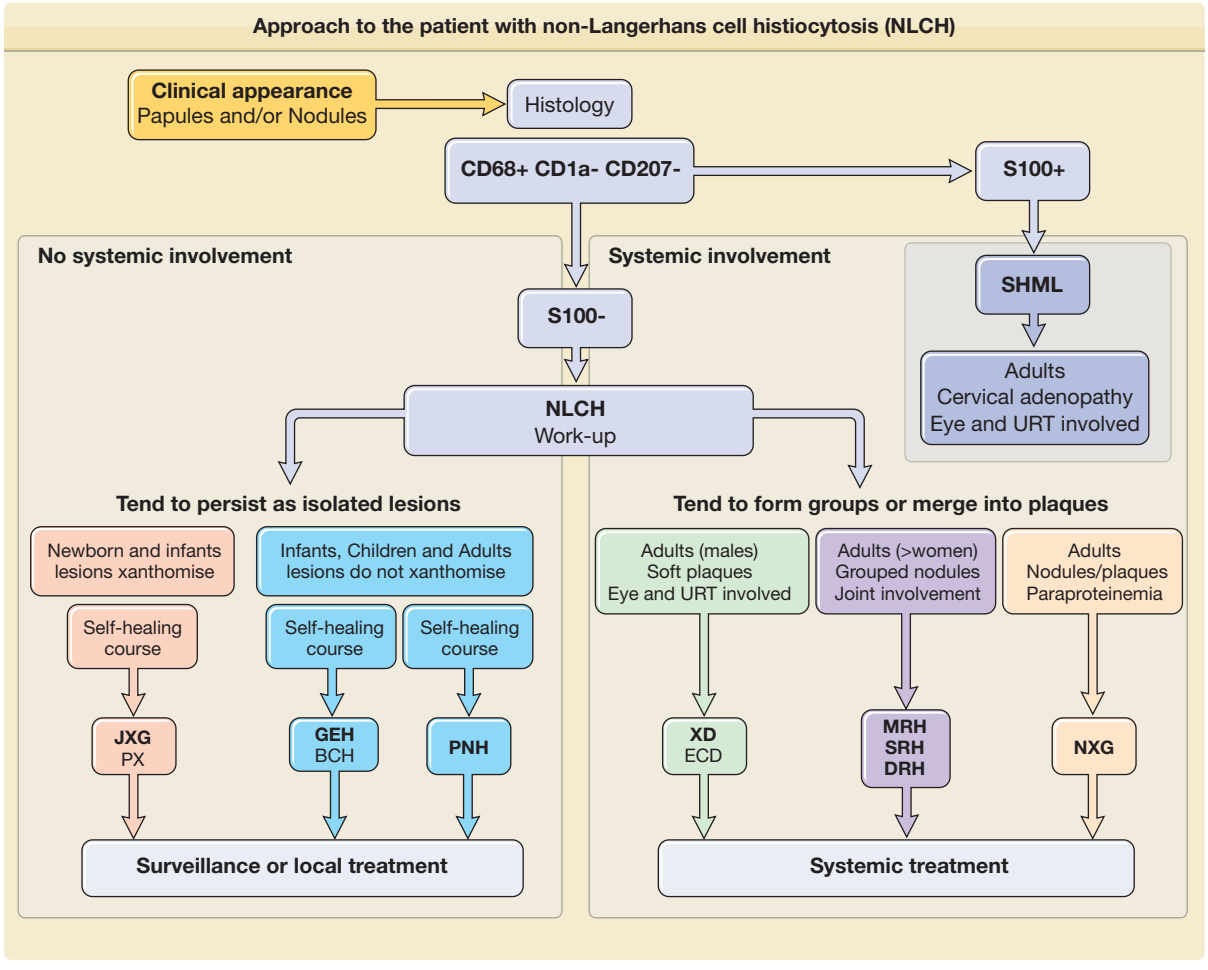

Figure 148-1 Approach to the patient with non-Langerhans cell histiocytosis (NLCH). BCH = benign cephalic histiocytosis; DRH = diffuse cutaneous reticulohistiocytosis; ECD = Erdheim–Chester disease; GEH = generalized eruptive histiocytosis; JXG = juvenile xanthogranuloma; MRH = multicentric reticulohistiocytosis; NXG = necrobiotic xanthogranuloma; PNH = progressive nodular histiocytosis; PX = papular xanthoma; SRH = solitary cutaneous reticulohistiocytosis; SHML = sinus histiocytosis with massive lymphadenopathy; URT = upper respiratory tract; XD = xanthoma disseminatum.

1990, with the purely cutaneous forms seen in more than 50 patients. Caucasians are affected in more than 85% of cases, and women are more frequently affected than men (female–male ratio of 3:1). In general, MRH affects adults 40 years of age, but the disease may appear during adolescence and rarely in childhood (pure cutaneous forms). NXG has been described in approximately 60 cases. The age of onset of NXG ranges from 17 to 85 years, and the disease shows no gender predilection. SHML is also a relatively rare disease; approximately 365 cases have been studied. The disease has a worldwide distribution with increased incidence in blacks from Africa and the West Indies. There is no gender predilection. Any age group may be affected, but 80% of cases occur in the first or second decade of life.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of NLCH is unknown. Virus-induced local immune alternation in the transformation of the NLCH has been postulated since previous studies have suggested that the proliferation of histiocytes is a physiologically appropriate response to viral infection.[3]

MRH may represent an abnormal histiocytic reaction to different stimuli. In forms with solitary lesions, local trauma may play a role, whereas in diffuse forms, the association with internal malignancies and autoimmune diseases suggests an immunologic basis for the initiation of the reaction.

PNH is a progressive disease with no tendency to involute spontaneously. It is thought to entail proliferation of mature spindle-shaped cells and may represent an evolution of another form of NLCH. MRH may evolve from a less developed form of NLCH, such as GEH or adult JXG. It has also been suggested that urokinase released by the activated histiocytes may play a role in the extracellular matrix degradation leading to erosion of cartilage and adjacent bone. The origin and function of the pleomorphic cytoplasmic inclusions that are frequently present in the histiocytes forming the infiltrate in this disease are still debated. They may result from a peculiar kind of endocytosis or from

the expression of an exocytosis phenomenon. These unique granules have already been described in several cases of reticulohistiocytosis, and if their presence is confirmed by subsequent observations, they could represent the ultrastructural marker.

The cause of NXG and its link to paraproteinemia are uncertain. It has been suggested that serum immunoglobulins complexed with lipid become deposited in the skin, eliciting a giant cell foreign-body reaction. Another hypothesis is that the paraproteinemia is the primary phenomenon, and a secondary proliferation of macrophages with receptors for the Fc portion of immunoglobulin G occurs. It has also been proposed that the paraprotein in NXG has functional features of a lipoprotein that may bind to lipoprotein receptors of histiocytes and induce granuloma formation. Mutations in *SLC29A3*, encoding an equilibrative nucleoside transporter (ENT3), have recently been shown to cause both familial histiocytosis syndrome (Faisalabad histiocytosis) and familial SHML.[4]

JUVENILE XANTHOGRANULOMA

CLINICAL FINDINGS

CUTANEOUS LESIONS. JXG is a benign, self-healing disorder that is characterized by asymptomatic yellowish papulonodular lesions of the skin and other organs in the absence of a metabolic disorder. Lesions consist of an infiltrate of histiocytes with a progressively greater degree of lipidation. Two main clinical forms can be distinguished, a papular and a nodular form. In both the lesions are initially orange–red or red–brown but quickly turn yellowish. The papular form (Fig. 148-2) is characterized by numerous (up to 100) firm hemispheric lesions 2–5 mm in diameter. These lesions are irregularly scattered throughout the skin but are located mainly on the upper part of the body. PX is considered to be a form of JXG in which the lesions rapidly become xanthomatous. PX lesions range from 2 to 12 mm and show a generalized distribution with no tendency to merge into plaques. The nodular form (Fig. 148-3) is less frequent and occurs as one or a few lesions. Such nodules are generally round, 10–20 mm in diameter, and translucent, and might show telangiectases on their surface. The term *giant juvenile xanthogranuloma* is applied to lesions larger than 2 cm. Unusual clinical variants have been also reported. The mixed form is characterized by the simultaneous presence of both small and large nodules. The term *juvenile xanthogranuloma en plaque* defines a group of JXG lesions with a tendency to coalesce into a plaque as the only expression of the disease. In one study, 67% of 174 cases involved solitary papular lesions, and an additional 16% showed solitary nodular lesions. Multiple cutaneous lesions were noted in 7% of affected individuals, a solitary extracutaneous lesion in 5%, and multiple cutaneous and visceral-systemic lesions in an additional 5%.

Recently, two new variants have been described. The first was a case with skin lesions consisting of bluish papules and nodules (mimicking a "blueberry muffin baby") located on the head, trunk, and proximal extremities. The second, "multiple lichenoid JXG," was characterized by hundreds of discrete papules.[5]

Figure 148-2 Juvenile xanthogranuloma. Papular form.

Figure 148-3 Juvenile xanthogranuloma. Nodular form.

RELATED PHYSICAL FINDINGS. Ocular involvement is the most typical extracutaneous manifestation. It may precede or follow the cutaneous lesions. Approximately 0.4% of cases exhibit ocular manifestations, usually unilateral.[6] Lesions may affect the orbit, iris, ciliary body, cornea, and episclera, and can result in spontaneous hyphema, glaucoma, and blindness. JXG of the uvea is a rare disease that usually responds to systemic steroids or low-dose radiotherapy; aggressive cases can be treated with chlorambucil.[7] Therefore, the importance of ocular screening in patients with JXG, especially those with periocular lesions, should be emphasized. However, it is important to realize that the absence of skin lesions should not rule out JXG because skin lesions can often regress spontaneously.

An extremely rare extracutaneous manifestation of the papular variant is central nervous system (CNS) involvement. The nodular form of JXG may occasionally be related to systemic lesions of the lungs, bones, kidneys,[8] pericardium, colon, ovaries, and testes. Juvenile chronic myelogenous leukemia (JMML) has been observed in association with this variant of JXG.

Café-au-lait macules and JXGs occur together in 20% of individuals with papular JXGs and can be considered an excellent marker of neurofibromatosis type 1 (NF-1) (see Chapter 141) during the first years of life, even in the absence at that age of other reliable markers of NF-1. The occurrence of the triad of NF1, JXG, and JMML was first reported case in 1958, but is rare (approximately 20 cases in the literature). However, children with NF1 and JXG have a 20–30-fold higher risk for JMML than patients with NF1 without JXG.[9]

LABORATORY TESTS

No abnormalities in laboratory test results are usually found in JXG except in the very rare cases in which juvenile chronic myeloid leukemia is associated with JXG.

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

Biopsy sections of JXG lesions show a feature that is common to many NLCHs, i.e., a nonepidermotropic histiocytic infiltrate lacking Langerhans granules. Early lesions of JXG are characterized by a monomorphous, nonlipid-containing histiocytic infiltrate that occupies at least the upper half, and sometimes the entire thickness, of the dermis. Mature lesions (Fig. 148-4) contain foam cells, foreign-body giant cells, and Touton giant cells, mainly distributed in the superficial dermis and on the border of the infiltrate. Lymphocytes, eosinophils, and neutrophils are variably associated. Older lesions may show fibrosis. In mature lesions, fat stains yield positive results. The majority of JXG lesional biopsy sections stain positive for CD68/Ki-M1P and factor XIIIa but negative for CD1a and S100 protein. Recently, a 9-month-old boy was clinicopathologically diagnosed as S100-positive JXG. Longitudinal observation revealed that strong S100 reactivity disappeared in parallel with maturation of the lesions within 2 years after the initial diagnosis.[10]

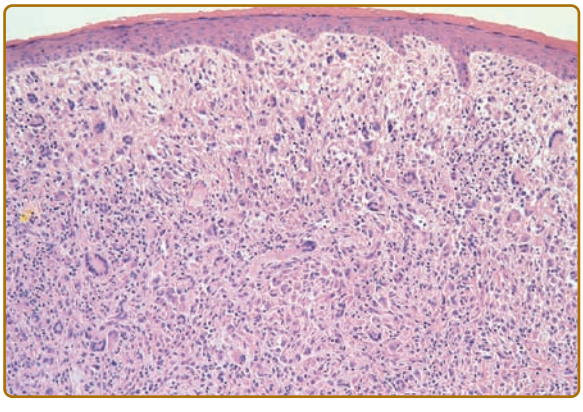

Figure 148-4 Juvenile xanthogranuloma. Histopathologic features. A mature lesion containing foam cells, foreign-body giant cells, and Touton giant cells.

Under the electron microscope, the histiocytes that characterize the early stage of the disease exhibit pleomorphic nuclei, are rich in pseudopods, and contain many elongated and irregular dense bodies. Clusters of comma-shaped bodies can occasionally be observed. In older lesions, there is a predominance of foam cells, the cytoplasm of which is completely filled with lipid vacuoles, cholesterol clefts, and myeloid bodies. Touton giant cells are extremely large and sometimes contain more than ten nuclei. Lipid material fills the periphery, whereas mitochondria and lysosomes predominate at the center.

The lesions of PX are composed almost entirely of foam cells and Touton giant cells. There is no evidence of a primitive histiocytic phase, and inflammatory cells are scarce or absent. Ultrastructurally, the cytoplasm is completely filled with lipid vacuoles without a limiting membrane, myeloid bodies, and lysosomal inclusions. Comma-shaped bodies are not found in these histiocytes.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of JXG is summarized in Box 148-1.

COMPLICATIONS

Eye involvement of a JXG lesion can cause severe secondary glaucoma. Lesions compatible with JXG have

BOX 148-1 DIFFERENTIAL DIAGNOSIS OF JUVENILE XANTHOGRANULOMA

PAPULAR

Most Likely

- Papular xanthoma
- Xanthoma disseminatum
- Tuberous xanthoma (hyperlipemic)
- Sarcoidosis (lichenoid form)
- Papular mastocytosis

Consider

- Benign cephalic histiocytosis
- Generalized eruptive histiocytosis
- Diffuse cutaneous reticulohistiocytosis
- Eruptive Spitz nevi
- Molluscum contagiosum
- Leukemia

NODULAR

Most Likely

- Hashimoto-Pritzker LCH
- Nodular mastocytoma
- Spitz nevus

Consider

- Dermatofibroma
- Solitary cutaneous reticulohistiocytosis
- Giant molluscum contagiosum

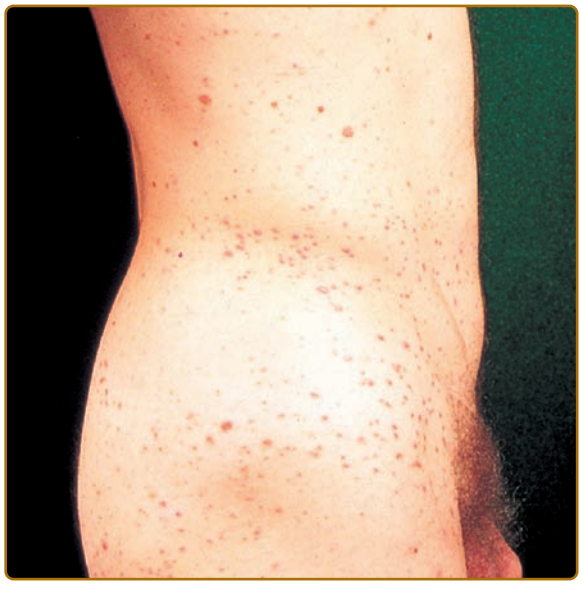

Figure 148-5 Generalized eruptive histiocytosis in an adult.

been described in many other organs as well, including oropharynx, lungs, spleen, liver, testes, heart, pericardium, gut, kidney, pancreas, lymph nodes, bone marrow, and even the CNS, and in rare cases can lead to death.[11] Severe multisystemic JXG in infants is a life-threatening disorder, and thus treatment is often required.[12] Patients may respond to multiagent chemotherapeutic regimens used to treat LCH.

PROGNOSIS AND CLINICAL COURSE

The cutaneous lesions of JXG tend to flatten with time. Each lesion evolves separately; thus, lesions at different stages of development may be seen in the same patient. Both cutaneous and visceral lesions disappear spontaneously, usually within 3–6 years. The patient's general health is not impaired, and physical and mental development is normal. Metabolic disturbances have not been identified. In the absence of associated conditions, prognosis is good. However, it is important to recognize that JXG may herald hematopoietic disorders in children and adults.[13]

GENERALIZED ERUPTIVE HISTIOCYTOSIS

CLINICAL FINDINGS

The skin lesions of GEH consist of an asymptomatic eruption of round or oval papules that are firm, pink or dark red, and range in size from 3 to 10 mm (Fig. 148-5). These lesions appear in successive crops and are usually numerous (in the hundreds). In adults, the lesions are symmetrically distributed and may involve the mucous membranes, whereas in children the lesions are irregularly scattered over the entire body and the mucous membranes are spared.

BCH may evolve into GEH and therefore is now considered a limited form of the latter. BCH manifests as asymptomatic, slightly raised, round or oval, orange–red or red–brown lesions, 2–8 mm in diameter, that are initially localized on the upper part of the face, mainly around the eyelids, forehead, and cheeks (Fig. 148-6). Other lesions subsequently appear over the entire head, the auricles (particularly on the posterior side), the occipital region, and the neck. A few lesions may appear on the shoulders and arms. The number of early lesions varies considerably, from 2 to more than 100, and new ones continue to appear

Figure 148-6 Benign cephalic histiocytosis. Note the distribution on the face (**A**) and also on the neck (**B**).

for many months. GEH and BCH do not, in general, show other features and do not lead to abnormalities in laboratory test results, or have known complications. However, diabetes insipidus has been reported in association with BCH from infiltration of the pituitary stalk, as has been described more commonly in LCH (see Chapter 147) and XD (see Section "Xanthoma Disseminatum").

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

The lesions of GEH (Fig. 148-7) show a dense, monomorphous, nonxanthomatous histiocytic infiltrate in the papillary and midportion of the dermis, with a few lymphocytes. The histiocytes contain a nucleus with scanty chromatin and an abundant light, poorly limited cytoplasm. These cells are often arranged in nests around vessels. Older lesions in children may contain rare foam cells and few multinucleated giant cells with peripheral nuclei. By conventional microscopy, lesions of BCH cannot be distinguished from GEH lesions. In GEH, electron microscopy shows the tumor cells to contain a large number of dense and regularly laminated bodies, often clustered together. Occasionally, worm-like bodies are found. In BCH, many coated vesicles with a diameter ranging from 500–1500 nm are seen in all the histiocytes. Clusters of comma-shaped bodies are present in nearly one-fourth of the histiocytes. The comma-shaped bodies are formed by two electron-dense membranes of approximately 6 nm, separated by a light space of approximately 8 nm. Where the infiltrate is denser, desmosome-like junctions may be observed among the histiocytes.

DIFFERENTIAL DIAGNOSIS

The disorders from which GEH should be differentiated are listed in Box 148-2.

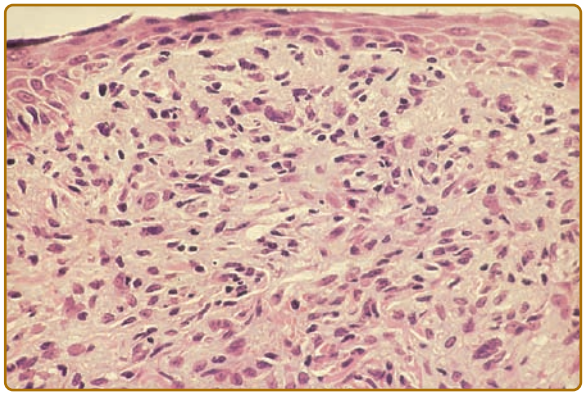

Figure 148-7 Generalized eruptive histiocytosis. Histopathologic features. Dense monomorphous histiocytic infiltrate in the papillary and mid-dermis, intermingled with a few lymphocytes.

BOX 148-2 DIFFERENTIAL DIAGNOSIS OF GENERALIZED ERUPTIVE HISTIOCYTOSIS

Most Likely

- Papular xanthoma
- Xanthoma disseminatum
- Multicentric reticulohistiocytosis
- Indeterminate cell histiocytosis
- Sarcoidosis (lichenoid form)
- Juvenile xanthogranuloma[a]
- Papular mastocytosis[a]

Consider

- Granuloma annulare disseminatum

[a]Children.

PROGNOSIS AND CLINICAL COURSE

In GEH, new crops of lesions may continue to appear for years. Slowly the disease subsides spontaneously without a trace or leaving anetoderma-like macules. Spontaneous regression of lesions occurs months to years after the onset of BCH. Regression of lesions starts characteristically where papules first appeared. The papules begin to flatten, and then, after a short period of hyperpigmentation, the lesions disappear without leaving scars.

PROGRESSIVE NODULAR HISTIOCYTOSIS

CLINICAL FINDINGS

PNH is a histiocytic disorder of skin and mucous membranes with a progressively deforming course. Cutaneous lesions consist of the eruption of hundreds of lesions of two different types: (1) superficial papules and (2) deep nodules. The most common lesions are yellow to orange papules, 2–10 mm in diameter that are randomly scattered over the body without localization in the flexural areas. These lesions may be present in the oral, laryngeal, and conjunctival mucosae. The deep lesions are dermal nodules ranging from 1 to 5 cm, with overlying telangiectasia, mainly located on the trunk. Café-au-lait spots, arthritis, and diabetes insipidus are absent. PNH has been described in a child with a hypothalamic tumor, probably histiocytic. Other patients with PNH have had hepatosplenomegaly, hypothyroidism, hypocholesterolemia, hyperuricemia, and chronic myeloid leukemia, or extensive involvement of pharynx and supraglottic larynx; the link between PNH and these other features is not clear.[14]

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

The histopathologic features of PNH are those of a xanthogranuloma with a predominance of storiform, spindle-shaped histiocytes that are positive for macrophage/dendritic cell line markers (CD68), and negative for CD1a and S100. Electron microscopic examination reveals histiocytes with a large indented nucleus.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for PNH is summarized in Box 148-3.

PROGNOSIS AND CLINICAL COURSE

In PNH, new lesions continue to develop during successive years with no sign of spontaneous involution. Despite the progressive nature of the lesions, patients remain in good health.

XANTHOMA DISSEMINATUM

CLINICAL FINDINGS

CUTANEOUS LESIONS. XD is a rare, benign, normolipemic form of NLCH affecting the skin and mucous membranes. It is frequently associated with diabetes insipidus. The cutaneous manifestations consist of hundreds of papules that are red–brown at first and then become yellowish. They symmetrically involve the eyelids, trunk, face, and proximal extremities and, in flexures and folds, tend quickly to merge, forming soft plaques (Fig. 148-8). ECD is considered a variant of XD that has visceral manifestations and is progressive.

RELATED PHYSICAL FINDINGS. In approximately 50% of cases of XD, xanthomatous lesions may also be observed on the mouth, pharynx, larynx, conjunctiva, and cornea. Symptoms of dyspnea and dysphagia are not uncommon. Vasopressin-sensitive transitory diabetes insipidus may be present, but polyuria and polydipsia are generally mild. Osteolytic lesions have been reported in only a few patients. XD may be associated with multiple myeloma, Waldenström macroglobulinemia, and monoclonal gammopathy. In ECD, the most common sign is chronic bone pain, usually mild and localized in the lower limbs. Extraosseous involvement can affect almost every organ, including the lungs, liver, kidney, heart, and CNS.

Figure 148-8 Xanthoma disseminatum.

BOX 148-3 DIFFERENTIAL DIAGNOSIS OF PROGRESSIVE NODULAR HISTIOCYTOSIS

Most Likely
- Multicentric reticulohistiocytosis
- Papular xanthoma
- Xanthoma disseminatum
- Generalized eruptive histiocytosis
- Sarcoidosis
- Lepromatous leprosy

Consider
- Nodular mastocytoma

LABORATORY TESTS

A normal lipid profile is present in this disease, but slightly elevated levels of serum cholesterol or triglycerides have been found in a few cases. In some cases, multiple myeloma, Waldenström macroglobulinemia, and monoclonal gammopathy have been detected. When lesions affect the CNS, magnetic resonance imaging may show foci of abnormally high signal intensity. In ECD, radiographs show symmetric sclerosis typically affecting the long bones of the lower limbs with involvement of the diaphyseal and metaphyseal regions.

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

In the early stage of XD, biopsy specimens show a mixture of histiocytes, foam cells, and inflammatory cells; later, foam cells predominate and Touton giant cells are frequently present (Fig. 148-9). Siderosis is often observed. The proliferating cells resemble those of JXG

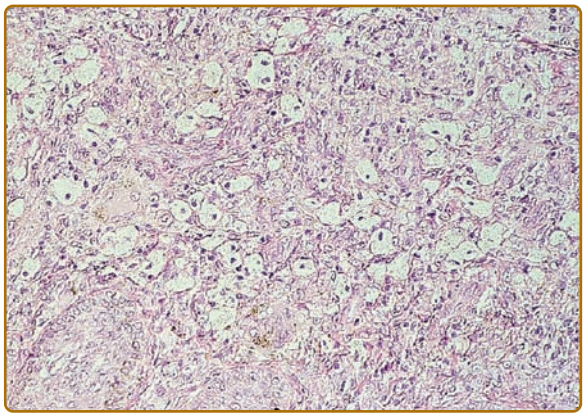

Figure 148-9 Xanthoma disseminatum. Histopathologic features. The lesions are characterized by a mixture of histiocytes, inflammatory cells, and foam cells. Touton giant cells are present.

ultrastructurally, but the plasma membranes of foam cells show many microvilli. Lesional skin sections in ECD show an infiltrate of lipid-laden histiocytes intermingled with Touton giant cells and eosinophils, surrounded by fibrosis.

DIFFERENTIAL DIAGNOSIS

The disorders from which XD should be differentiated are listed in Box 148-4.

COMPLICATIONS

In XD, organ involvement may lead to a variety of complications, particularly conjunctival inflammation and respiratory obstruction. Seizures, diabetes insipidus, and growth retardation have also been described. Chronic bone pain is the hallmark of ECD.

PROGNOSIS AND CLINICAL COURSE

Based on the evolution and prognosis of reported cases, three clinical variants of XD have been distinguished: (1) a self-healing form, (2) a persistent form, and (3) a progressive form (ECD). The persistent form is the most frequent one. Prognosis is usually good, but respiratory tract involvement may lead to dyspnea and dysphagia. Tracheotomy has been required in a few cases. In ECD, the prognosis is poor because of the high risk of visceral involvement, particularly pulmonary fibrosis.

BOX 148-4 DIFFERENTIAL DIAGNOSIS OF XANTHOMA DISSEMINATUM

Most Likely

- Chronic disseminated Langerhans cell histiocytosis
- Tuberous xanthoma (hyperlipemic)
- Papular xanthoma

Consider

- Juvenile xanthogranuloma
- Generalized eruptive histiocytosis
- Multicentric cutaneous reticulohistiocytosis
- Progressive nodular histiocytosis

MULTICENTRIC RETICULOHISTIOCYTOSIS

CLINICAL FINDINGS

CUTANEOUS LESIONS. MRH is characterized by the association of a cutaneous and mucosal eruption with severe arthropathy and other visceral symptoms. The papulonodular lesions range in diameter from a few millimeters to 2 cm and are round, translucent, and yellow-rose or yellow-brown (Figs. 148-10 and 148-11). Grouping of lesions into plaques can give a cobblestone appearance, but lesions are generally scattered and isolated. They do not tend to ulcerate and are pruritic in about one-third of cases. These lesions preferentially affect the fingers (see Fig. 148-10), the palms and backs of the hands, the juxta-articular regions of the limbs, and the head (see Fig. 148-11). Small, scattered lesions may be found on the trunk. Periungual papules (see Fig. 148-10), arranged around the nail folds, resemble "coral beads" and have been noted in approximately 40% of cases. Severe involvement of the face may lead to a leonine facies. Xanthomatous lesions are found in 30% of cases. Periarticular nodules, resembling rheumatoid nodules, may occasionally be seen. Erythematous, photodistributed macules and papules have been observed in approximately 15% of cases and may be confused with dermatomyositis. Nail changes, including brittleness, longitudinal ridging, and atrophy, may occur. Almost 50% of affected patients have specific nodular lesions of the oral, nasal, and pharyngeal mucosae.

Two different subtypes without joint or visceral manifestations have been described: (1) solitary cutaneous

Figure 148-10 Hands of a patient with active skin lesions of multicentric reticulohistiocytosis. Note the periungual array of some of the nodules, resembling "coral beads."

Figure 148-11 Mucocutaneous nodular infiltrate on the perioral and perinasal areas, as well as the oral and nasal mucosae in a patient with multicentric reticulohistiocytosis.

reticulohistiocytosis (or reticulohistiocytoma cutis) and (2) diffuse cutaneous reticulohistiocytosis. Solitary cutaneous reticulohistiocytosis is characterized by a single firm, rapidly growing nodule varying in color from yellow-brown to dark red (Fig. 148-12). Its most common location is the head, but it may be found in almost any cutaneous site. It occurs without evidence of systemic involvement, and its onset may be preceded by trauma. Diffuse cutaneous reticulohistiocytosis is a purely cutaneous form characterized by the eruption of firm, smooth, asymptomatic papulonodular lesions, 3–10 mm in diameter, scattered diffusely over the skin.

Figure 148-12 Solitary cutaneous reticulohistiocytosis.

The color of early lesions is pinkish yellow, whereas older lesions show a red–brown color.

RELATED PHYSICAL FINDINGS. In MRH, severe chronic diffuse polyarthritis with arthralgias is the initial sign of the disease in up to two-thirds of cases. The lesions symmetrically involve the hands (80% of cases), knees (70%), wrists (65%), and less frequently the shoulders, ankles, elbows, hips, feet, and spine. The osteoarticular lesions show a progressive destructive course for 6–8 years and then become stable. Involvement of the muscles (myositis, myotonia, and myoatrophy), cardiopulmonary system (pericarditis, cardiac insufficiency, pleuritis, pulmonary infiltration), eyes (exophthalmos, conjunctival infiltration), gastrointestinal system (gastric ulcer), thyroid gland (thyroid nodules), and submandibular salivary glands have occasionally been reported, but histologic documentation of involvement at these sites is rare. Fever, weight loss, and weakness can be present. The term *familial histiocytic dermatoarthritis* is used to indicate a particular form of MRH characterized by familial occurrence and typical ocular involvement (glaucoma, uveitis, and cataracts). Internal malignancy may be associated in 15%–27% of cases. Solid tumors such as bronchial, breast, gastric, and cervical carcinomas are most common. Lymphomas and myelodysplastic syndromes have been found less frequently, and malignant melanoma has been reported in three cases. Whether MRH can be interpreted as a true paraneoplastic disease is not clear. Whatever the nature of the association, the incidence of internal neoplasia is such that patients who come for treatment of MRH should be investigated for concomitant internal neoplasm. MRH has been described in association with autoimmune diseases, systemic vasculitis, tuberous sclerosis, sclerosing lesions of the leg, and tuberculosis.

LABORATORY TESTS

In MRH, elevated erythrocyte sedimentation rate and anemia have been observed in about half of patients and hypercholesterolemia in one-third of cases. An increase in immunoglobulin G and the presence of cryoglobulinemia and cold agglutinins have occasionally been reported. Rheumatoid factor is usually not detected. Radiographically, the joint lesions of MRH are characterized by bilateral, symmetrical, sharply circumscribed, and rapidly progressive erosions that spread from the margins to the joint surfaces, often with concomitant separation of the bone ends but without subchondral sclerosis.

HISTOPATHOLOGY AND ULTRAMICROSCOPIC FINDINGS

The histologic findings in MRH and its subtypes are identical. Histologically, the early lesions may be composed of histiocytes and lymphocytes, and therefore may be confused with other cutaneous histiocytoses. Older lesions show the presence of numerous large,

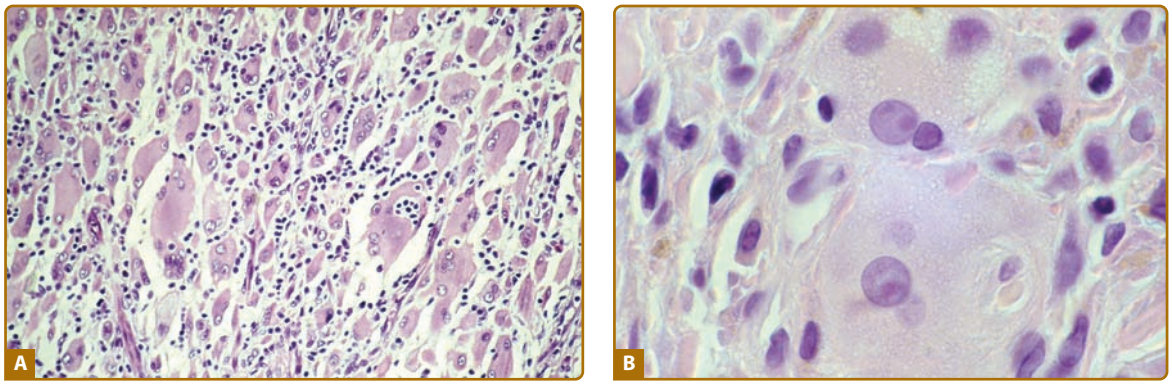

Figure 148-13 Photomicrographs of a lesion of multicentric reticulohistiocytosis. Note the histiocytic infiltrate (**A**) and multinucleated giant cells with aggregated nuclei and ground-glass cytoplasm (**B**).

mononucleated or multinucleated histiocytes with an abundance of eosinophilic, homogeneous cytoplasm containing fine granules that has a ground-glass appearance (Fig. 148-13). The number of giant cells may vary, and the diameter of these cells may reach 100 nm. The nuclei of the multinucleated cells may be arranged haphazardly or they may align along the periphery or cluster in the center. Plasma cells and eosinophils are sometimes present. Fragmentation and clumping of collagen and elastic fibers have been reported. At times, connective tissue and cell phagocytosis may be seen. Histochemically, the granular material in histiocytes and giant cells stains with periodic acid-Schiff after diastase digestion, Sudan black, and scarlet red, which indicates the presence of glycolipids and/or glycoproteins and neutral fat. Dermal proliferation of histiocytes with diffuse cytoplasmic granular cell changes has recently been described.[15]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for MRH is summarized in Box 148-5.

BOX 148-5 DIFFERENTIAL DIAGNOSIS OF MULTICENTRIC RETICULOHISTIOCYTOSIS

Most Likely

- Rheumatoid arthritis
- Dermochondrocorneal dystrophy
- Familial histiocytic dermatoarthrosis
- Lipodermoarthrosis
- Progressive nodular histiocytosis

Consider

- Farber lipogranulomatosis
- Xanthoma disseminatum
- Lipoid proteinosis
- Lepromatous leprosy
- Sarcoidosis
- Self-healing cutaneous mucinosis
- Fibroblastic rheumatism

COMPLICATIONS

Complications occurring in MRH are mainly due to visceral involvement of the disease. Lesions in the upper airway may lead to dysphonia and/or dysphagia. Cardiopulmonary manifestations are more frequently reported and may also be fatal. In addition, bones and all the visceral organs may be affected, which leads to weight loss and pyrexia that complicate the potentially mutilating inflammatory polyarthritis.

PROGNOSIS AND CLINICAL COURSE

The purely cutaneous forms of reticulohistiocytosis may involute spontaneously. It is possible that the diffuse, purely cutaneous form is an early stage of MRH before the appearance of joint and visceral lesions. In MRH, the mucocutaneous course does not parallel the articular course. The mucocutaneous lesions have an unpredictable course and may remit spontaneously. In half of the patients, the osteoarticular manifestations become stable, whereas in the other half, they cause progressive destruction. The prognosis is favorable for cutaneous forms. The prognosis for MRH is related to the severity of the osteoarticular manifestations, the presence of visceral involvement, and underlying neoplasms if present.

To date, no treatment of MRH has been shown to be universally successful; the tendency to use multiple therapies as well as the natural relapsing and remitting nature of the condition makes interpretation of therapeutic response difficult. Recently, leflunomide was successful in one patient and therefore it can be considered a therapeutic option.[16]

NECROBIOTIC XANTHOGRANULOMA

CLINICAL FINDINGS

CUTANEOUS LESIONS. In NXG, early cutaneous lesions consist of indurated papulonodules varying in color from red–orange to violaceous or yellow and involving the dermis and subcutaneous tissue. These

Figure 148-14 Necrobiotic xanthogranuloma on the calf. Note "granulomatous" periphery of the lesion, with central ulceration and necrotic material at the base.

lesions slowly enlarge into plaques with well-demarcated edges, ranging in diameter from a few to 25 cm. There is central atrophy with telangiectasias or areas of ulceration (Fig. 148-14). Most cases are asymptomatic, but pain or a burning sensation may be noted. The lesions are usually multiple and involve, in order of frequency, the face, trunk, and extremities. The periorbital area is the site of predilection and is involved in 85% of cases. The oral mucosa is occasionally involved. Hepatosplenomegaly has been observed in approximately 20% of patients.

RELATED PHYSICAL FINDINGS. NXG may be associated with myeloma, arthropathy, hypertension, neuropathy, neoplastic syndrome, primary biliary cirrhosis, and Graves disease.

LABORATORY TESTS

Ninety percent of patients with NXG have paraproteinemia (immunoglobulin G κ or λ light chains), especially in cases with associated myeloma. Cryoglobulinemia has been found in approximately 40% of cases. Other abnormal laboratory test results may include an elevated sedimentation rate, neutropenia, leukopenia, anemia, and decreased levels of CH50.

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

The histopathologic picture of NXG is characteristic and consists of a granulomatous infiltrate involving the whole dermis and subcutis composed of a mixture of lymphocytes, epithelioid cells, foam cells, and Touton giant cells. Areas of severe, clearly defined necrosis are sharply delineated from the surrounding granuloma. Typically, cholesterol crystals are located within the necrobiotic areas. Numerous, atypical, very large, bizarrely angulated, multinucleated giant cells may be seen adjacent to the areas of necrosis. Dense, well-defined lymphoid nodules, occasionally containing a germinal center, may be present in the dermis or subcutis. Touton cell panniculitis may involve the entire fat lobules. Occasionally, a granulomatous infiltrate may surround some vessels. Ultrastructurally, cells are rich in lipid droplets, cholesterol clefts, and myeloid bodies and are similar to those observed in JXG.

BOX 148-6 DIFFERENTIAL DIAGNOSIS OF NECROBIOTIC XANTHOGRANULOMA

Most Likely

- Granuloma annulare
- Necrobiosis lipoidica
- Xanthoma disseminatum
- Multicentric reticulohistiocytosis

Consider

- Juvenile xanthogranuloma
- Hyperlipemic xanthoma

DIFFERENTIAL DIAGNOSIS

The disorders from which NXG should be differentiated are listed in Box 148-6.

COMPLICATIONS

In NXG, the periorbital involvement may lead to ocular complications such as lagophthalmos, conjunctivitis, keratitis, scleritis, uveitis, corneal ulceration, and even loss of ocular function. Nausea, vomiting, epistaxis, back pain, and Raynaud phenomenon have also been recorded.

PROGNOSIS AND CLINICAL COURSE

NXG has a chronic, often progressive course that is characterized by the appearance of new lesions and ulcerations. The prognosis in given cases is difficult to predict and depends on extracutaneous involvement and the presence of visceral tumors such as multiple myeloma.

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ROSAI–DORFMAN DISEASE)

CLINICAL FINDINGS

CUTANEOUS LESIONS. SHML is a benign, generally self-limited disease confined mainly to cervical

Figure 148-15 Sinus histiocytosis with massive lymphadenopathy.

lymph nodes. Cutaneous manifestations are observed in approximately 10% of patients and are polymorphic (Fig. 148-15). They may occur as yellowish macules and patches, reddish-brown papules, and plaques and nodules that may become eroded or ulcerated. In one patient, firm purple nodules and tumors as large as 10 cm in diameter were noted, but in most instances the lesions are much smaller, multiple, widespread, and asymptomatic. Periocular involvement of SHML can result in lobulated induration of the eyelids. Cutaneous lesions may be the initial manifestation and sole presenting feature of the disease. Massive bilateral cervical lymphadenopathy, usually painless, is the hallmark of the condition. Less commonly, axillary, mediastinal, inguinal, and preauricular lymph nodes may be affected.

RELATED PHYSICAL FINDINGS. SHML is usually accompanied by fever. Extranodal disease occurs in approximately 25% of patients and may be the initial manifestation of the disorder. The extranodal noncutaneous sites most commonly affected are the eye, upper respiratory tract, liver, spleen, testes, skeleton, and nervous system. Involvement of the gastrointestinal tract is rare. An elderly woman with hematochezia was found to have SMLH of the rectum presenting as a rectal mass.

LABORATORY TESTS

SHML is usually accompanied by an elevated erythrocyte sedimentation rate, leukocytosis with neutrophilia, and polyclonal hypergammaglobulinemia. Less frequent findings include moderate anemia (60%), lymphopenia, elevated titers of Epstein–Barr virus, and, in one case, elevated *Klebsiella* antibody titers. Axial postcontrast computed tomography can highlight the lymphadenopathy.

HISTOPATHOLOGIC AND ULTRAMICROSCOPIC FINDINGS

Histopathologically, the skin lesions of SHML are characterized by a diffuse dermal infiltrate composed predominantly of histiocytes with large vesicular nuclei and abundant pale cytoplasm. Some histiocytes are foamy, multinucleated, or both. Histiocytes are sometimes aggregated in clusters resembling lymph node sinuses. Lymphocytes, plasma cells, and polymorphonuclear leukocytes, typically eosinophils, may be intermixed in the infiltrate. Emperipolesis (phagocytosis of leukocytes, especially lymphocytes) is a constant feature. In electron microscopic views, most of the histiocytes are rich in phagosomes and may contain clusters of comma-shaped bodies.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for SHML is summarized in Box 148-7.

COMPLICATIONS

The organs affected by primary extranodal SHML include: skin, soft tissue, nasal cavity and paranasal sinuses, eye (bilateral anterior granulomatous uveitis) and orbit, bone (leading to chronic ankle arthritis), CNS (mimicking neurofibromatosis, meningioma, pachymeningitis), and salivary glands. The digestive system is one of the least common sites of involvement by SHML, and only three pathologically confirmed cases of primary pancreatic SHML have been reported to date.[17] Infections such as HIV and cytomegalovirus (CMV) can act synergistically in a myelosuppressive manner and provide the antigenic and inflammatory context for the development of fatal histiocytic complications.[18]

BOX 148-7 DIFFERENTIAL DIAGNOSIS OF SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY

Most Likely
- Abscesses
- Hodgkin disease
- Tuberculosis

Consider
- Sarcoidosis
- Leukemia
- Acquired immunodeficiency syndrome

PROGNOSIS AND CLINICAL COURSE

In most patients, SHML has a benign course with spontaneous regression over a period of months to years. Usually the extranodal lesions regress first, whereas adenopathy may persist for years. A worse prognosis results mainly from the associated immunologic abnormalities.

TREATMENT

Most forms of NLCH, such as JXG, do not require treatment because the disease is asymptomatic and self-healing. When treatment is necessary, as in XD, ECD, MRH, NXG, or SHML, therapy options are few and treatment is often unsuccessful.

Treatment of XD is usually not helpful. Vasopressin is necessary for the associated diabetes insipidus. Radiotherapy, cryotherapy, corticosteroids, and antiblastic chemotherapy have been attempted with palliative results in the more disfiguring forms.

Therapy for MRH has frequently been disappointing. Anti-inflammatory agents such as aspirin, indomethacin, and pyrazolones have shown little effect. Systemic corticosteroids may be effective on articular lesions, but only for a short period of time. Dexamethasone pulse therapy led to a dramatic response in one case. Azathioprine is of no benefit alone but in association with prednisolone may have a beneficial effect on both skin and joint lesions. Antimitotic agents (mainly cyclophosphamide and chlorambucil) have been reported to induce regression of lesions in only a few patients. Oral methotrexate seems to be the most effective. Etanercept has been used successfully to treat both cutaneous and articular symptoms. Generally, solitary cutaneous lesions are surgically excised.

In NXG, intermittent glucocorticoid treatment can induce a partial response. Low dosages of alkylating agents, such as chlorambucil or melphalan, may lead to remission of the paraproteinemia and skin lesions but do not prevent the evolution to multiple myeloma. Temporary remission of skin lesions has been obtained with radiation therapy and with plasmapheresis.

As a rule, because the vast majority of lesions of SHML heal spontaneously, no treatment is necessary. In rare instances, a space-occupying lesion will interfere with the function of an organ, and then treatment with systemic glucocorticoids or with various chemotherapeutic regimens might be useful.

PREVENTION

At present, because the causes of all of the forms of NCLH are unknown, the possibility of preventing such diseases does not exist. As in LCH, future directions include complete genome hybridization and derivation of a gene expression profile.

Chapter 149 :: Mastocytosis

:: Michael D. Tharp

MASTOCYTOSIS AT A GLANCE

- The hallmark of mastocytosis is a pathologic accumulation of mast cells in tissues.
- Mastocytosis occurs at any age.
- The skin is the most commonly involved organ system.
- Cutaneous findings consist of hyperpigmented macules, papules or nodules, or a diffuse infiltration of the dermis.
- Generally benign in children.
- In adults, most commonly associated with a somatic activating mutation of *c-kit* (codons 816 and 560).
- Cutaneous manifestations may occur alone or in association with systemic disease.
- Related features may be flushing, pruritus, hypotension, nausea, dyspepsia, and diarrhea.
- Most common extracutaneous tissues involved are the bone marrow, liver, spleen, and lymph nodes.
- May be associated with myeloproliferative and myelodysplastic disorders.
- Classification of mastocytosis is critical for prognosis and treatment.

MAST CELLS AT A GLANCE

- Mast cells are derived from pluripotent stem cells.
- Stem cell factor is required for proliferation and survival.
- Mast cells release both pre-formed and generated mediators when activated.

EPIDEMIOLOGY

Mastocytosis represents a group of disorders characterized by an abnormal accumulation of mast cells in one or more organs. While the true incidence of this disease is unknown, most cases are in children, with 60%–80% presenting within the first year of life. Congenital mastocytosis is less common, representing approximately 18%–31% of childhood cases.[1,2] Adult-onset mastocytosis also occurs and is being more commonly recognized with newly established World Health Organization (WHO) criteria for this disease[3] (Tables 149-1 and 149-2). This disorder has no gender preference, and it has been reported in all races.[4] While most patients with mastocytosis have no family history, there are reports of familial cases, including monozygotic twins, some of which were discordant for this disease.[4–6]

PATHOGENESIS

Mast cells arise from the bone marrow as agranular, undifferentiated, $CD34^+$, KIT^+ (CD117) pluripotent progenitor cells. After migrating into tissues, immature mast cells assume their typical granular morphology.[7] KIT is a type III tyrosine kinase receptor product of the proto-oncogene c-*kit* located on chromosome 4q12. This enzyme is expressed on mast cells, as well as melanocytes, primitive hematopoietic stem cells, primordial germ cells, and interstitial cells of Cajal. Cross-linking KIT by its ligand, stem cell factor (SCF), is essential for precursor cells to differentiate into mast cells. The gene for SCF is located on chromosome 12, and encodes a protein that localizes to the cell membrane.[7,8] Membrane-bound and a soluble forms of SCF exist, both of which are capable of inducing KIT activation. Soluble KIT is thought to arise from chymase-induced cleavage of the membrane bound form.[9] SCF is produced by bone marrow stromal cells, fibroblasts, keratinocytes, endothelial cells, as well as reproductive Sertoli and granulosa cells. Mature mast cells require SCF for survival.[8,9] Other cytokines that appear important in regulating mast cell growth and differentiation include interleukin-3 (IL-3), IL-4, IL-6, and IL-9 and IFN-γ. IL-3 shares a number of signal transduction pathways with SCF, but has minimal direct effects on human mast cell proliferation except in early cultures. IL-4 enhances mast cell function when added to mature cultures. IL-6 has been shown to increase mast cell mediator concentration,[10] and IL-9 appears to increase the number of mast cells in culture.[11] In developing mast cells, IFN-γ inhibits mast cell proliferation and influences mast cell phenotype and function.[10]

Mutations in *c-kit* appear to play a central role in some forms of mastocytosis. Somatic mutations in codon 816 of c-*kit*, leading to amino acid substitutions (D816V, D816Y, D816F, and D816H), cause constitutive activation of KIT and continued mast cell growth and development.[12] Mutations in this codon are most common in adults with mastocytosis.[3] An activating mutation in codon 560 (V560G) also has been characterized in some adult patients with mastocytosis, but appears to be much less common.[6,13] Activating mutations in

[a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues*, edited by Jaffe ES et al. Lyon, IARC Press, 2001.

c-kit have been reported in children with mastocytosis as well. Among 50 children with this disorder, 42% had detectable mutations of codon 816 (exon 17), while another 42% had demonstrable activating mutations in the extracellular and transmembrane regions of KIT (exons 8–11). The remaining eight children reported in the study had no detectable *c-kit* mutations.[14] There was no clear correlation between the extent of disease and the presence or absence of *c-kit* mutations among these patients. In another report of 22 children and adults with mastocytosis, 11 adult patients and 4 children had 816 activating mutations. Four other pediatric patients with typical lesions of urticaria pigmentosa (UP) lacked changes in this codon, and in three other children, an inactivating *c-kit* mutation (codon E839K) was detected.[12]

A transgenic mouse model of mastocytosis also has been reported using the human activating D816V *c-kit* mutation.[15] The clinical expression of this disorder ranged from indolent mast cell hyperplasia to invasive mast cell tumors, despite the fact that genetically identical animals expressed the same D816V mutation. It appears from these clinical and investigative observations that *c-kit* activating mutations of codon 816 play an important role in the development of mastocytosis. However, the finding of a varied clinical expression of mastocytosis in an animal model along with that fact that some children with mastocytosis have no *c-kit* mutations or have inactivating *c-kit* mutations strongly suggests that other, yet to be defined, factors influence the full clinical expression of this disease.

TABLE 149-2
Diagnostic Criteria for Systemic Mastocytosis (Major and One Minor or Three Minor Criteria Are Needed)[a]

Major
- Multifocal dense infiltrates of mast cells in bone marrow and/or other extracutaneous organs

Minor
- More than 25% of the mast cells in bone marrow aspirate smears or tissue biopsy sections are spindle shaped or display atypical morphology.
- Detection of a codon 816 c-kit point mutation in blood, bone marrow, or lesional tissue.
- Mast cells in bone marrow, blood, or other lesional tissue expressing CD25 or CD2.
- Baseline total tryptase level greater than 20 ng/mL.

[a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues*, edited by Jaffe ES et al. Lyon IARC Press, 2001.

CLINICAL FINDINGS

CLASSIFICATION

Mastocytosis represents a disease spectrum characterized by a diverse phenotypic expression, along with pathologic and genetic findings that affect prognosis. Table 149-1 represents the WHO classification of mastocytosis.[3] Cutaneous mastocytosis (CM) and indolent SM (ISM) represent the majority of patients with this disease. Most children have CM, which is manifested as UP (Fig. 149-1) or less commonly as mastocytomas (Fig. 149-2) or diffuse CM (Fig. 149-3). SM occurs

Figure 149-1 Urticaria pigmentosa in a child.

mostly in adults, and ISM is the most common form. Criteria for SM are listed in Table 149-2. Systemic mastocytosis with an associated clonal hematologic, nonmast cell lineage disease (SM-AHNMD) appears unique to adults. In this group, examination of the bone marrow and peripheral blood reveals a hematologic abnormality. Hematologic disorders associated with SM-AHNMD include myeloproliferative and myelodysplastic disorders such as polycythemia rubra vera, chronic myeloid leukemia, chronic myelomonocytic leukemia, idiopathic myelofibrosis, chronic eosinophilic leukemia and the hypereosinophilic syndrome, acute and chronic lymphocytic leukemia, and non-Hodgkin and Hodgkin lymphoma. Patients with aggressive SM (ASM)[16] frequently have evidence of impaired liver function, hypersplenism, and/or malabsorption, but they do not have a distinctive hematologic disorder or mast cell leukemia (MCL). Patients with ASM have rapidly increasing mast cell numbers and are difficult to manage medically. MCL is characterized by multiorgan failure, and in bone marrow smears mast cells represent greater than 20% of the nucleated cell population. Mast cells also account for 10% or more of peripheral blood nucleated cells.[17,18] Mast cell sarcomas are rare; they have localized destructive growth, and distant spread is possible. Mast cells in these tumors are highly atypical and immature. Extracutaneous mastocytomas are extremely rare, usually localized to the lung, and consist of mature mast cells.[3,19]

Figure 149-2 Mastocytoma on the sole of a child.

Figure 149- 3 Diffuse cutaneous mastocytosis in a child.

CUTANEOUS LESIONS

UP is the most common skin manifestation of CM; however, the morphology of UP lesions differs significantly between children and adults. UP lesions in children appear as tan to brown papules and less commonly as macules, ranging in size from 1.0 to 2.5 cm in diameter (Fig. 149-1). These lesions may be present at birth or arise during infancy. They frequently appear on the trunk and often spare the central face, scalp, palms, and soles. UP lesions in adults, on the other hand, are reddish-brown macules and papules, usually 0.5 cm or less in diameter (Fig. 149-4). On close lesion inspection, variable hyperpigmentation and fine telangiectasias are detectable. Adult UP lesions are most numerous on the trunk and proximal extremities and appear less frequently on the face, distal extremities, or palms and soles. While adult UP lesions appear and resolve over months in individual patients, their number usually increases over years.[20] UP lesions are seen in most adults with ISM, but are much less common in patients with SM-AHNMD, ASM, or MCL.[3,19,20]

Solitary mastocytomas are tan-brown nodules that occur in approximately 10%–35% of children and frequently appear on the distal extremities (Fig. 149-2).[11] Their onset is generally before 6 months of age.[2]

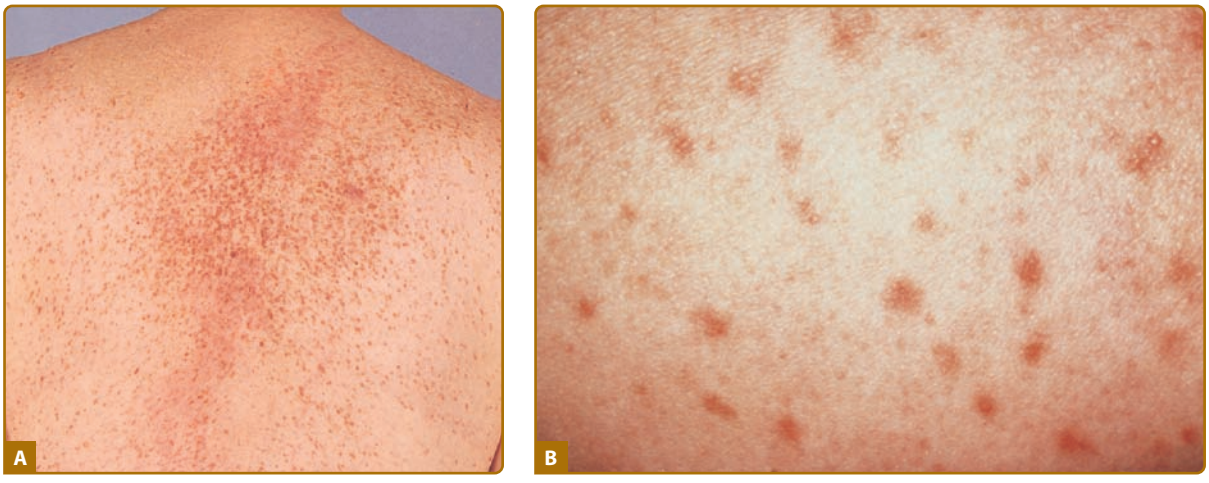

Figure 149-4 Urticaria pigmentosa in an adult with indolent systemic mastocytosis. **A.** Hundreds of lentigo-like macules are seen on the back of this adult. If vigorously rubbed, these lesions will show urtication and become erythematous, raised, and pruritic. **B.** Close-up.

Trauma to mastocytomas has been associated with systemic symptoms such as flushing and hypotension (Fig. 149-1).[2,20]

Scratching or rubbing lesions of CM leads to urtication and erythema known as *Darier's sign*. This reaction is readily demonstrated in childhood UP lesions and mastocytomas, but often is less apparent in adult UP lesions.[20] This likely explanation is that mast cell concentrations in mastocytomas and childhood UP have been reported to be 150-fold and 40-fold greater than normal skin, respectively, whereas the mast cell content of lesional skin in adult mastocytosis patients was only eightfold greater than normal controls.[21]

Diffuse CM (DCM) is seen almost exclusively in infants (Fig. 149-3), although it may persist into adult life. The skin may be thickened with a peau d'orange appearance and yellowish brown discoloration without discrete lesions. Dermographism with formation of hemorrhagic blisters frequently occurs in the first few years of life in patients with DCM, but these blisters often resolve within several years, even though the DCM may persist (Fig. 149-5).[2,20] Telangiectasia macularis eruptiva perstans is rare, and is seen almost exclusively in adults. It appears as telangiectatic macules with irregular borders (Fig. 149-6). Darier's sign and pruritus is variable.[20] Recently, nodular mastocytosis has been described in an adult patient with red–purple lesions infiltrating the axillae and inguinal areas. Mast cells in this rare variant of mastocytosis expressed the V560G *c-kit* mutation.[22]

RELATED CLINICAL FINDINGS

Most children with CM and adults with ISM have few, if any, symptoms. When symptoms do occur, they are due to the release of mast cell mediators, such as histamine, eicosanoids, and cytokines (Table 149-3). Symptoms and signs of mastocytosis may range from pruritus and flushing to abdominal pain, nausea, vomiting and diarrhea, palpitations, dizziness, and syncope. Of interest is the relative absence of pulmonary symptoms in mastocytosis patients. Complaints of fever, night sweats, malaise, weight loss, bone pain, epigastric

TABLE 149-3
Selected Mast Cell Mediators

Mediators	Biologic Effects	Possible Consequences
Preformed		
Histamine	Vasodilation, increased vascular permeability, gastric hypersecretion, bronchoconstriction	Hypotension, flushing, urticaria, abdominal pain; (peptic, colic), nausea, vomiting, diarrhea, malabsorption
Heparin	Anticoagulant, inhibition of platelet aggregation	Prolonged bleeding time
Tryptase	Endothelial cell activation, fibrinogen cleavage, mitogenic for smooth muscle cells	Osteoporosis/osteopenia, disruption of cascade systems (clotting, etc.)
Chymase	Converts angiotensin I to II, lipoprotein degradation	Hypertension
	Cleaves membrane bound stem cell factor	Hyperpigmentation, Skin mast cell accumulation (?)
Newly Synthesized		
Leukotrienes	Increased vascular permeability, bronchoconstriction, vasoconstriction	Bronchospasm, hypotension
Prostaglandins	Vasodilatation, bronchoconstriction	Flushing, urticaria, hypotension
Cytokines		
Stem cell factor	Growth and survival of mast cells, chemotaxis of KIT^+ cells, melanogensis	Mast cell hyperplasia, focal aggregates
Tumor necrosis factor-α	Activation of vascular endothelial cells, cachexia, fatigue	Weight loss, fever, fatigue
Transforming growth factor-β	Enhanced production of connective tissue components	Fibrosis
IL-5	Eosinophil growth factor	Eosinophilia
IL-6	Growth and survival of mast cells	Fever, bone pain, osteoporosis/osteopenia
GM-CSF	Granulocyte and monocyte growth and activation	Eosinophilia

IL = interleukin. GM-CSF = granulocyte/monocyte colony stimulating factor.

distress, and problems with mentation (cognitive disorganization) often signal the presence of SM. Symptoms of mastocytosis can be exacerbated by exercise, heat, or local trauma to skin lesions (childhood UP and mastocytomas). In addition, alcohol, narcotics, salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), polymyxin B, anticholinergics, and some systemic anesthetic agents may induce mast cell mediator release.[19,20,23] Deaths associated with extensive mast cell mediator release are rare.

Noncutaneous disease is extremely uncommon in children, although gastrointestinal (GI) symptoms are the most frequent noncutaneous feature. Gastric hypersecretion due to elevated plasma histamine may cause gastritis and peptic ulcer disease, and present as abdominal pain in both children and adults.[24] Malabsorption with associated diarrhea is limited to a subset of patients with usually more advanced disease. While hepatic disease in adults and children with ISM is rare, hepatic and splenic involvement, including portal hypertension and ascites associated with liver fibrosis, is more common in patients who have SM-AHNMD or ASM.[3,25] Splenomegaly, detected either clinically or by CT scan, has been reported in 50%–60% of adult SM patients.[20,26] However, in two other studies, each with over 140 adult mastocytosis patients, splenomegaly was observed in only 8%–9% of cases.[27,28] Increased numbers of mast cells and eosinophils are frequently observed in the spleen, as are various degrees of fibrosis and hematopoiesis. Lymph node enlargement is uncommon in most mastocytosis patients, but occurs in patients with more advanced systemic disease. Among 58 SM patients, 26% had peripheral lymphadenopathy, whereas 19% had central nodal disease.[29] Anemia, leukopenia, thrombocytopenia, and eosinophilia also may occur in association with systemic disease and suggest SM-AHNMD or ASM.[3,19]

Musculoskeletal pain affects 19%–28% of mastocytosis patients. Skeletal lesions occur more frequently in patients with SM, but are rare in children with this disorder.[2,20] In one large study of 142 adults with mastocytosis, 40% had skeletal involvement.[27] Bony lesions may appear as radio-opacities, radiolucencies, or a mixture of the two. The skull, spine, and pelvis are most commonly involved. In one large study of 58 adult systemic mastocytosis patients, 57% had diffuse bone involvement, whereas only 2% had focal lesions.[30] In patients with severe or advanced disease, pathologic fractures may occur.[19,30]

Neuropsychiatric abnormalities have been reported, and include decreased attention span, memory impairment, headache, and irritability.[31,32] Depression as a consequence of chronic disease or possibly mediated by mast cell mediators may occur.

LABORATORY TESTS

The diagnosis of mastocytosis is established by demonstrating increased numbers of mast cells in one or more organs. For patients with CM, mast cell infiltrates can be detected in a biopsy of lesional skin using special stains, such as toluidine (Fig. 149-7) or Giemsa, or monoclonal antibodies that recognize mast cell tryptase or CD117 (KIT).[20,33] Biopsy specimens of normal-appearing skin from patients with mastocytosis have normal concentrations of mast cells as determined by morphometrics, and thus are not helpful in establishing the diagnosis.[21]

Detection of circulating mast cell mediators and/or their metabolites can offer indirect evidence of mastocytosis, and their measurement may be useful in patients without cutaneous lesions. Two forms (α and β) of mast cell tryptase have been identified.[34] α-tryptase is elevated in patients with SM, with or without acute symptoms, whereas increased levels of β-tryptase can be detected both in mastocytosis patients and in allergic patients experiencing anaphylactic reactions. Total (α and β) serum tryptase levels have been correlated with the extent of mast cell disease. Fifty percent of patients with total serum tryptase levels between 20 and 75 ng/mL had evidence of SM, whereas all patients with levels >75 ng/mL had proven systemic involvement. Total serum tryptase levels of >20 ng/mL are currently considered abnormal and represent one of the minor criteria for SM[3] (Table 149-2). Total serum tryptase levels can provide an estimate of a patient's overall mast cell burden, and thus serial measurements in adults every 6 to 12 months may prove useful in following disease activity.

Determinations of urinary histamine metabolite levels may be worthwhile as a diagnostic test in patients without cutaneous lesions. The major urinary metabolite of histamine, 1,4-methylimidazole acetic acid (MeImAA) is often persistently elevated in SM patients and has been correlated with the extent of mast cell disease.[35] Methylhistamine is next most common urinary histamine metabolite, and can be measured if MeImAA levels are not available in commercial laboratories. Certain foods high in histamine content, such as spinach, eggplant, cheeses (Parmesan, Roquefort, and blue), and red wines, can artificially elevate the levels of urinary histamine and its metabolites, and thus should be avoided during the collection process.

Mast cells can induce bone changes that cause radiographically detectable lesions. Skeletal lesions occur more frequently in adult patients with SM, and are rare in children with this disorder.[2] In one large study of 142 adults with mastocytosis, 40% had skeletal involvement.[27] The proximal long bones, skull, spine, ribs, and pelvis are most commonly affected. Skeletal scintigraphy (bone scan) is more sensitive, but less specific, than routine X-rays for detecting and locating active lesions. Thus, X-rays of the skull, spine, and pelvis serve as a reasonable preliminary test for detecting bone involvement in mastocytosis patients.[19,20]

The bone marrow is often involved in patients with SM, and bone marrow biopsies are indicated for patients suspected of having more advanced (SM-AHNMD, ASM, MCL) disease.[3] In a report of 71 adults with mastocytosis, 90% had increased numbers of spindle-shaped, bone marrow mast cells (BMMCs) with focal perivascular, peritrabecular and/or intertrabecular accumulations.[20] WHO criteria for SM have been defined (Table 149-2), which include the BM findings of multifocal dense mast cell aggregates, atypical mast cell morphology, and the expression of CD2 and/or CD25 by BMMCs. A bone marrow biopsy in childhood-onset disease is not recommended unless there is evidence of systemic involvement as demonstrated by hepatosplenomegaly, lymphadenopathy, and/or unexplained peripheral blood abnormalities. Mast cells in BM biopsies are best identified by immunostaining with antitryptase (Fig. 149-8) or CD117 monoclonal antibodies since decalcification interferes with the effectiveness of metachromatic stains.[3]

Roentgenographic abnormalities of the GI tract fall into three major categories: (1) peptic ulcers;

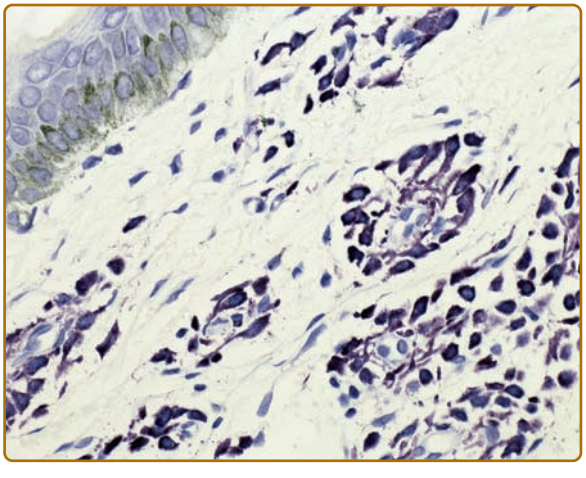

Figure 149-7 Histopathology of urticaria pigmentosa, toluidine blue.

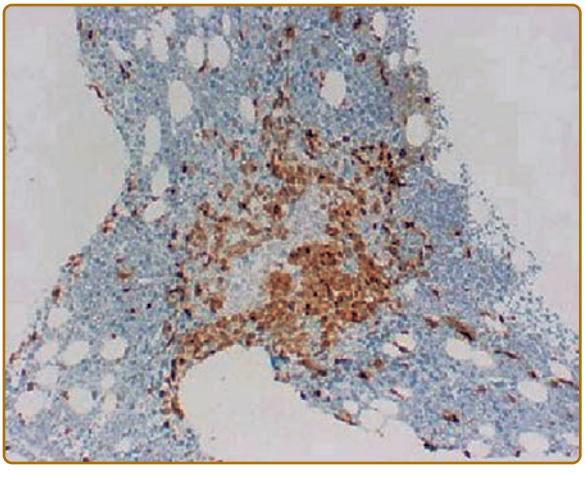

Figure 149-8 Classic mastocytosis bone marrow lesion (100×), tryptase stain.

(2) abnormal mucosal patterns such as mucosal edema, multiple nodular lesions, coarsened mucosal folds, or multiple polyps; and (3) motility disturbances. A biopsy of the GI tract may be indicated for patients in whom the diagnosis of SM is suspected, but who lack skin lesions. Histologic sections of jejunal biopsies show moderate blunting of the villi and may show increased mast cell numbers in association with variable numbers of eosinophils.[19,20]

Despite the infrequency of significant hepatic disease, liver function tests are abnormal in approximately one-half of all patients with extracutaneous disease. Other surrogate markers of mastocytosis are elevated serum IL-6 levels, soluble SCF receptor (CD117), and IL-2 receptor (CD25) levels.[36] The levels of the latter receptors are highly correlated with the severity of bone marrow pathology.[37]

The initial evaluation of a prepubertal child with mastocytosis generally does not require extensive evaluation if the history and physical examination do not indicate the presence of SM. In contrast, the presence of noncutaneous signs and symptoms or disease onset in adolescents or adults necessitates a CBC with differential, liver function test, total serum tryptase level, and skeletal X-rays (see Fig. 149-9 and Table 149-3). Because the presence and type of *c-kit* mutation may predict disease longevity as well as a patient's response to treatment (see Section "Treatment"), determination of *c-kit* mutations in the skin or blood of mastocytosis patients with systemic disease should be considered.

DIFFERENTIAL DIAGNOSIS

Cutaneous lesions of childhood and adult mastocytosis are very characteristic, and thus are rarely confused with other skin disorders. Since UP lesions may urticate, they could initially be mistaken for urticaria. However, individual urticaria lesions last only a few hours and lack the associated hyperpigmentation seen

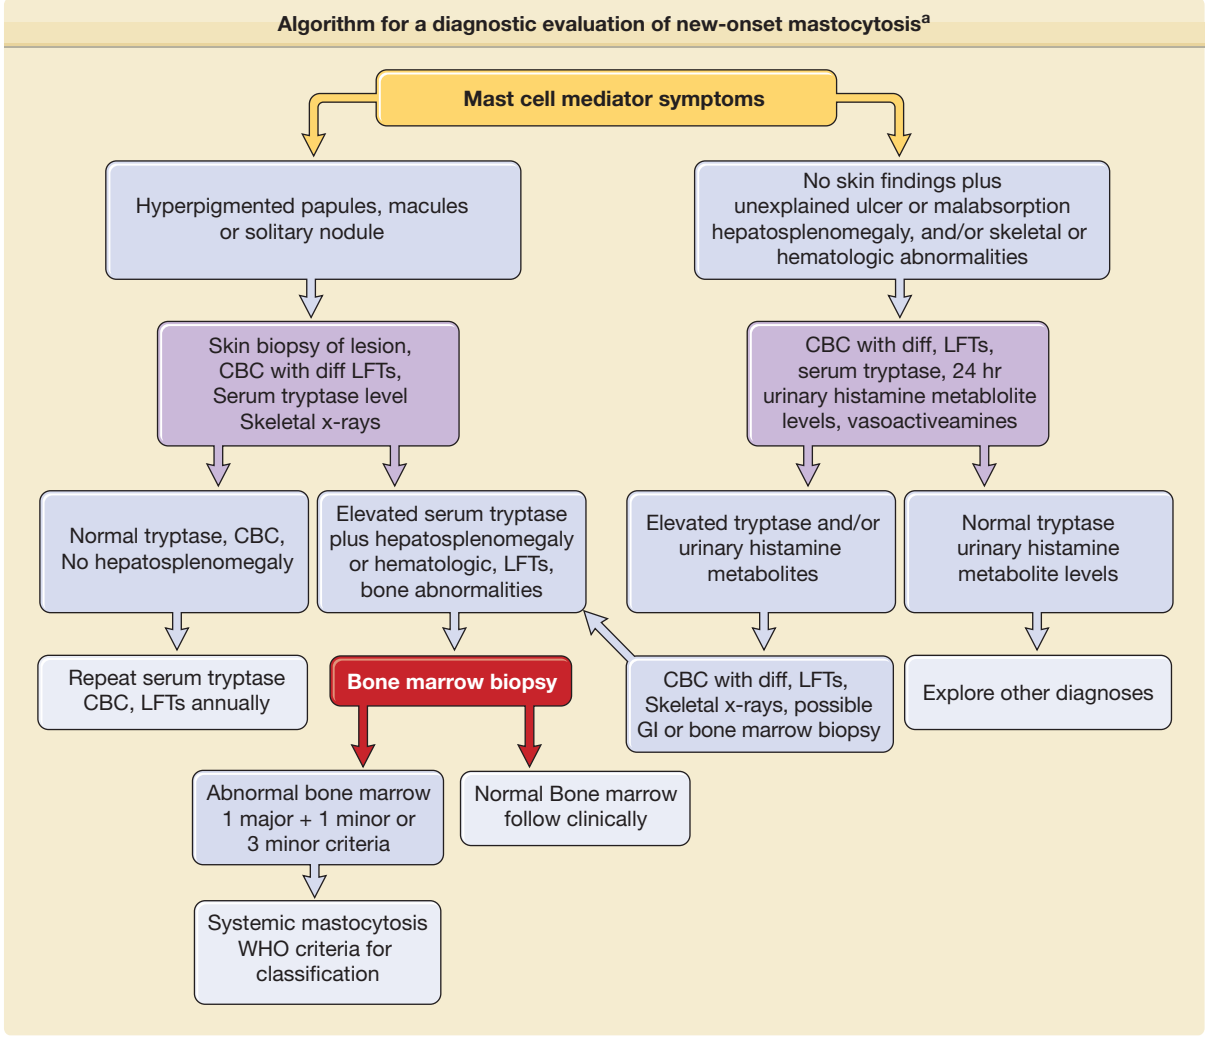

Figure 149-9 Algorithm for a diagnostic evaluation of new-onset mastocytosis (especially in adolescents and adults). CBC = complete blood cell count; Tc = technetium; WHO = World Health Organization. [a]For details of the WHO classification of mastocytosis, see Valent P et al: *World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of the Haematopoietic and Lymphoid Tissues,* edited by Jaffe ES et al. Lyon, IARC Press, 2001.

in UP. Some childhood mastocytosis patients may develop bullae. Therefore, the differential diagnosis for blisters in infants such as bullous impetigo, bullous arthropod bites, linear IgA bullous dermatosis, bullous pemphigoid, epidermolysis bullosa, toxic epidermal necrolysis, and incontinentia pigmenti should be considered. Rarely, nodular scabies lesions have been confused with UP (see Box 149-1). The differential diagnosis of mastocytomas in children includes juvenile xanthogranulomas, Spitz nevi, pseudolymphomas or rarely in resolving lesions, a café au lait macule. Adult UP lesions might initially appear as lentigines or atypical melanocytic nevi; however, they usually have an associated erythema (telangiectasia) not seen in these melanocytic lesions.

Mastocytosis should be suspected in patients without skin lesions if they have symptoms suggesting mast cell mediator release and one or more of the following: peptic ulcer disease or malabsorption, radiographic or ^{99}technetium bone scan abnormalities, hepatomegaly, splenomegaly, lymphadenopathy, and/or peripheral blood abnormalities (Box 149-2). In adults suspected of having SM without cutaneous lesions, the diagnosis of a carcinoid tumor or pheochromocytoma should be considered. Patients with mastocytosis do not excrete increased amounts of 5-hydroxyindoleacetic acid, and patients with carcinoid tumor or pheochromocytoma do not have histologic evidence of mast cell proliferation or elevated serum tryptase levels.[38]

BOX 149-1 DIFFERENTIAL DIAGNOSIS OF CUTANEOUS MAST CELL DISEASE

Most Likely

- Diffuse or localized hyperpigmented papules/macules
  - Urticaria
  - Multiple nevi
  - Langerhans cell histiocytosis
  - Juvenile xanthogranulomas
  - Nodular scabies
  - Café-au-lait spots
  - Multiple cutaneous lentiginosis
  - Postinflammatory hyperpigmentation
- Bullous lesions
  - Linear immunoglobulin A dermatosis
  - Bullous impetigo
  - Epidermolysis bullosa
  - Arthropod bite reaction
  - Toxic epidermal necrolysis
  - Incontinentia pigmenti
- Solitary papule or nodule
  - Congenital nevus
  - Juvenile xanthogranuloma
  - Pseudolymphoma

- Neoplastic/oncologic
  - Hypereosinophilic syndrome
  - Lymphoma
  - Myeloma
  - Histiocytosis
  - Bone tumor metastases

[a]Some forms of mast cell disease may not show cutaneous manifestations. These include aggressive systemic mastocytosis, mast cell leukemia, systemic mastocytosis with an associated clonal hematologic nonmast cell lineage disease, and isolated bone marrow mastocytosis.

PROGNOSIS

Pediatric-onset cutaneous disease has a favorable prognosis with at least 50% of cases of childhood UP resolving by adulthood.[1,16] Furthermore, children born of mothers with ISM reportedly are free of disease.[17] It has been postulated that children with activating *c-kit* mutations may represent the 10%–15% of those whose disease persists into adulthood[2,12]; however, with the recent report of detectable activating *c-kit* mutations in 84% of children with mastocytosis, the prognostic significance of this abnormality is unclear.

Most adults with UP have only CM or ISM and rarely develop more advanced disease. Patients with ISM appear to have a good prognosis with limited potential to progression to more severe forms of SM.[3,19] Older patients with UP who experience fading of their lesions continue to exhibit bone marrow lesions typical of their diagnosis, whether ISM or SM-AHNMD.[18] Patients with SM-AHNMD have a variable course, which is dependent on the prognosis of their hematologic disorder. In patients with ASM, the mean survival is 2–4 years, but the prognosis may improve with

TABLE 149-4
Treatment for Cutaneous Mastocytosis

	Topical	Physical	Systemic
First line	Emollients		$H_1 \pm H_2$ antihistamines
Second line	Topical glucocorticoids Calcineurin inhibitors	Psoralen and ultraviolet A light (adults only) Pulsed dye laser for telangiectasia macularis eruptiva perstans	Leukotriene antagonists Oral cromolyn sodium
Third line		Intralesional corticosteroids or Surgical excision (mastocytoma)	Glucocorticoids

Note: Avoidance of triggering factors such as heat, friction, or drugs.

aggressive symptomatic management. The prognosis for MCL is poor with a mean survival of less than 6 months.[19,28]

TREATMENT

The management of patients with mastocytosis includes counseling patients and care providers as to the features of the disease, avoidance of factors that provoke mast cell mediator release, and management of symptoms associated with these released mediators (Tables 149-4 and 149-5). Mastocytosis patients should be cautioned to avoid potential mast cell degranulating agents such as ingested alcohol, anticholinergic preparations, aspirin and other NSAIDs, narcotics, and polymyxin B sulfate. In addition, heat and friction can induce local or systemic symptoms and should be avoided whenever possible. A number of systemic anesthetic agents, including systemic lidocaine, d-tubocurarine, metocurine, etomidate, thiopental, succinylcholine hydrochloride (suxamethonium chloride), enflurane, and isoflurane, have been directly or indirectly implicated in precipitating symptoms of mastocytosis. Recent reports indicate that fentanyl, sufentanil, remifentanil, paracetamol, midazolam, propofol, ketamine, desflurane, sevoflurane, *cis*-atracurium, pancuronium, and vecuronium bromide, are safe alternative systemic anesthetics for mastocytosis patients. It has been recommended that mastocytosis patients undergoing general anesthesia be monitored postoperatively for 24 hours since delayed anaphylaxis can occur hours after surgery. In contrast to systemic anesthetics, local injections of lidocaine can be used safely in these patients.[23]

There is currently no generally recognized safe and effective mast cell ablative therapy, nor are there effective mast cell stabilizing drugs. Thus, treatment of milder forms of mastocytosis is focused, in great part, on symptomatic relief. In children with asymptomatic mastocytomas or UP lesions, no therapy is needed. Chronic administration of H_1 antihistamines (hydroxyzine, cetirizine, and fexofenadine) is often helpful in reducing pruritus and flushing associated with histamine release.[19] Both ketotifen and azelastine, antihistamines with mast cell-stabilizing properties may help relieve the pruritus and whealing associated with mastocytosis, but neither drug offers a significant advantage over a standard antihistamines.[39] H_2 antihistamines (cimetidine or ranitidine) are most useful in the management of excess gastric acid secretion, but may assist in controlling pruritus, flushing, and wheal formation when administered with an H_1 blocker. If GI symptoms persist with the use of H_2 antihistamines, then proton pump inhibitors may be effective, secondary treatments.[19,20]

TABLE 149-5
Treatment of Noncutaneous Mastocytosis Symptoms

	Gastrointestinal	Cardiovascular	Musculoskeletal	Hematologic
First line	H_2 antihistamines, oral cromolyn (children)	H_1 and H_2 antihistamines Subcutaneous epinephrine (anaphylaxis)	Calcium supplement ± vitamin D supplement	Systemic chemotherapy appropriate for hematologic disorder
Second line	Proton pump inhibitors Leukotriene antagonist Anticholinergics	Glucocorticoids (prophylaxis)	Bisphosphonates Nonsteroidal anti-inflammatory drugs with caution	
Third line	Glucocorticoids		Local radiation to bony lesions	

Note: Cytoreductive therapy is restricted to patients with aggressive variants of mastocytosis (systemic mastocytosis with an associated clonal hematologic nonmast cell lineage disease, aggressive systemic mastocytosis, and mast cell leukemia).

Disodium cromoglycate (cromolyn sodium) inhibits degranulation of mast cells and may have some efficacy in the treatment of mastocytosis, particularly in relieving GI complaints in children.[40] Cromolyn sodium, however, does not lower plasma or urinary histamine levels in patients with mastocytosis. Low-dose aspirin has been used in some patients to reduce flushing, tachycardia, and syncope. However, aspirin must be used with extreme caution, as it may cause vascular collapse in some patients with mastocytosis and exacerbate peptic ulcer disease. Antileukotrienes have proven effective in controlling symptoms of flushing, diarrhea, and abdominal cramping in some mastocytosis patients.[19,20]

Potent topical glucocorticoids under occlusion for 8 h/day for 8–12 weeks reduces the number of UP lesions. However, these lesions eventually recur after discontinuation of therapy within the year.[41,42] Oral glucocorticoids have some efficacy in patients with malabsorption and ascites. After control is achieved, glucocorticoid therapy should be tapered to the lowest effective dose.[17,19] Osteoporosis should be treated with calcium and vitamin D supplementation and, when appropriate, the addition of estrogen replacement or bisphosphonates as determined by monitoring bone density.

Epinephrine should be used to treat episodes of anaphylaxis. Patients with such episodes should carry epinephrine, be prepared to self-administer this drug, and have a plan for emergency management. If subcutaneous epinephrine is insufficient, intensive therapy for vascular collapse should be instituted. Patients with recurrent episodes of anaphylaxis should receive continuous H_1 and H_2 antihistamines to lessen the severity of attacks. Episodes of vascular collapse in mastocytosis patients may be spontaneous, but have also occurred after insect stings or after administration of iodinated contrast media. In the latter case, premedication with corticosteroids and antihistamines is recommended before such procedures.

Methoxypsoralen with ultraviolet A (PUVA) light can relieve pruritus and whealing after 1–2 months of treatment.[43,44] However, pruritus usually recurs within 3–6 months after PUVA is stopped. Pigmentation induced by PUVA also may camouflage lesions of UP in some adult patients; however, this benefit must be weighed against the increased risk of skin cancers associated with long-term treatment.

Cytoreductive therapy should be considered in patients with SM-AHNMD, ASM, or MCL. The risk-benefit must be carefully considered due to the dose-limiting toxicities of the various drugs. IFN-α may be considered for ASM with and without associated hematologic malignancy. In a prospective study, IFN-α was most efficacious in ameliorating the signs and symptoms mast cell disease; however, improvement was only transitory.[45] 2-Chlorodeoxyadenosine has been shown to be efficacious in reducing ascites, mediator-associated symptoms, and BMMC burden in patients with more advance mastocytosis, and appears to be the treatment of choice in this patient group. However, its use is restricted by the associated myelosuppression.[46,47]

Tyrosine kinase inhibitors, such as imatinib mesylate, inhibit growth of neoplastic cells through receptors such as KIT, ABL, and PDGFR tyrosine kinases and have been successful in the treatment of a patient with a transmembrane mutation of KIT at the F522C position.[48,49] Imatinib, however, does not inhibit the growth of mast cells expressing *D816* mutation, and thus is ineffective in the treatment of mastocytosis patients with this KIT abnormality.[50] Disatinib has been demonstrated to inhibit the in vitro growth of mast cell lines expressing D816V; however, this agent has not been effective in reducing the signs or symptoms of mast cell disease in SM patients with this *c-kit* mutation.[51]

Splenectomy may improve survival in patients with ASM that has a poor prognosis.[52] Radiotherapy has been used to treat refractory bone pain in advanced disease.[53] Nonmyeloablative bone marrow transplantation may be considered for gravely ill patients, although a recent report using this therapy in three patients with advanced SM showed no sustained improvement despite inducing a graft-versus-mast cell state.[54]

SECTION 26

Skin Manifestations of Internal Organ Disorders

Chapter 150 :: The Skin and Disorders of the Alimentary Tract, the Hepatobiliary System, the Kidney, and the Cardiopulmonary System

:: Graham A. Johnston & Robin A.C. Graham-Brown

DISORDERS OF THE ALIMENTARY TRACT, THE HEPATOBILIARY SYSTEM, THE KIDNEY AND THE CARDIOPULMONARY SYSTEM AT A GLANCE

- A full physical examination should be part of a full dermatologic assessment.
- It is important to examine the skin in a patient presenting with a systemic problem.
- Look for generalized changes in skin quality first.
- Then examine specific organ systems systematically.
- The majority of causes of jaundice can be found on clinical history and examination.
- In both abdominal pain and gastrointestinal bleeding there can be cutaneous findings that suggest the underlying cause.
- Some cardiopulmonary syndromes have specific dermatologic clues.
- Remember dermatologic drugs as a cause of systemic symptoms.

Diseases of the skin frequently indicate, or associate with, diseases of the alimentary tract, the hepatobiliary system, the kidneys, and the cardiopulmonary system. Just as a full physical examination should be part of a full dermatologic assessment, it is important to examine the skin in a patient presenting with a systemic problem. This chapter is presented in the same order that a physician performing a full physical examination might approach the patient. The cutaneous manifestations that indicate internal disease are discussed for each step of the examination.

GENERAL SKIN CHANGES

ALTERATIONS IN SKIN QUALITY

The presence of pallid, dry, rough, and scaly skin that is usually itchy in patients with malabsorption, chronic renal disease, or chronic hepatic disease is nonspecific. Asteatotic eczema may develop. Some patients itch without any visible abnormality of their skin.

CARDIAC DISEASE

EHLERS–DANLOS SYNDROME. Hyperelastic velvety skin that rebounds to the original position after being stretched, "cigarette-paper" scars, and hyperextensible joints are characteristic of the Ehlers–Danlos syndrome. Mitral and tricuspid prolapse, dilatation of the aorta and pulmonary artery, arterial rupture, myocardial infarction, and emphysema may accompany this syndrome (see Chapter 137).[1]

CUTIS LAXA. Progressive looseness of the skin with pendulous folds and droopy eyelids may be associated with generalized hyperelastosis leading to aortic

dilatation and rupture, congestive heart failure, or cor pulmonale with pulmonary artery stenosis and progressive emphysema (see Chapter 137).

PSEUDOXANTHOMA ELASTICUM. The skin of patients with pseudoxanthoma elasticum (PXE) is thick, lax, and yellowish, especially over the axillae, antecubital area, and neck. Yellow patches may occur on mucous membranes, especially the labia. The alterations in the *ABCC6* gene responsible for PXE may also lead to arteries becoming calcified, the aortic and mitral valves thickened, and cardiovascular symptoms, such as angina pectoris and claudication are frequent symptoms (see Chapter 137).[2]

PROGERIA. In Hutchinson–Gilford syndrome (progeria) and progeroid states such as Werner's syndrome, the skin appears atrophic and tight from a very early age. There is marked loss of subcutaneous tissue, with leg ulceration. Coronary atherosclerosis frequently leads to premature death by myocardial infarction (see Chapter 139).

LIVER DISEASE

Skin changes are very common in chronic liver disease.[3] Hormone-induced changes of the skin include loss of forearm, axillary, and pubic hair in both sexes. Men may experience a decreased rate of growth of facial hair, pectoral alopecia, and a female pubic hair distribution, as well as loss of libido, testicular atrophy, and oligospermia. Striae distensae occur in both men and women (Fig. 150-1). Gynecomastia, together with Dupuytren contracture and swelling of the parotid gland, is associated with cirrhosis.

Many of these changes occur more commonly in those where alcohol is the underlying cause. Patients with chronic alcoholism also develop a "pseudo-Cushing syndrome," even in the absence of liver disease; signs include facial mooning, truncal obesity, and proximal muscle wasting. These changes may regress if the patient discontinues alcohol.

Patients with chronic liver disease often have telangiectatic changes, mainly on light-exposed skin. Numerous tiny telangiectases sometimes give the impression of a diffuse, almost exanthematic redness. They are known as "dollar paper markings" after the small threads visible in paper money held up against the light. They fade on pressure with a glass slide and rarely pulsate.

Figure 150-1 Widespread striae in a 16-year-old boy with chronic active hepatitis.

RENAL DISEASE

The skin of patients with chronic renal failure (CRF) is frequently dry, often with ichthyosis-like scaling,[4] possibly resulting in part from altered vitamin A metabolism.[5] The fluid volume shifts of dialysis may exaggerate this.

COLOR CHANGES

Skin color is altered in CRF. The skin is pale due to anemia and often exhibits a distinctive muddy hue, due to accumulation of carotenoid and nitrogenous pigments (urochromes) in the dermis, although its etiology is complicated and may depend in part on treatment modalities used.[6]

CYANOSIS

An increase in the absolute amount of desaturated (reduced) hemoglobin results in a purple–blue discoloration of the skin. Cyanosis is classified into "central" and "peripheral" types: the terms referring to the level of arterial oxygen saturation rather than the anatomic source of cyanosis. Thus, central cyanosis occurs in states that produce low arterial oxygen saturation, such as congenital heart disease with intracardiac or intrapulmonary right-to-left shunting, or severe lung disease. Peripheral cyanosis develops when there is normal arterial oxygen saturation but reduced blood flow, such as low-output cardiac failure and local vasoconstriction. Pulmonary embolism may result in a combination of central cyanosis and peripheral cyanosis.

Central cyanosis is usually visible on warm areas of the skin like the tongue, oral mucosae, and conjunctivae. Peripheral cyanosis is seen on cooler areas such as the nose, lips, earlobes, and fingertips. In the anemic patient, detection of cyanosis may be impossible because the absolute amount of reduced hemoglobin is not increased. Cyanosis fades when pressure is applied because the coloration is within the blood vessels.

ERYTHEMA

Redness of the skin is caused by an increase in the amount of saturated hemoglobin, an increase in the diameter or actual number of skin capillaries, or a combination of these factors. Edema of the face, arms, and

hands associated with redness and/or cyanosis may indicate obstruction of the superior vena cava due to mediastinal disease.

Primary polycythemia may produce a characteristic "ruddy" complexion but, in secondary disease especially, may also cause a peculiar ruddy cyanosis. This is most pronounced on the tongue, lips, nose, earlobes, conjunctivae, and fingertips. It is due to increased amounts of saturated hemoglobin producing erythema with increased amounts of desaturated hemoglobin producing cyanosis because of the inability of the body to fully oxygenate the increased absolute amounts of hemoglobin. The absence of nail clubbing in polycythemia vera may help differentiate patients with from those patients with cardiopulmonary disease who develop secondary polycythemia. In addition, the hypervolemic state of polycythemia vera is associated with increased stroke volume and may lead to high-output cardiac failure. Pulmonary emboli may result from venous thrombosis secondary to hyperviscosity.

FLUSHING

Paroxysmal intense flushing of the face, neck, chest, and abdomen, often with telangiectases of the face and neck, may occur in patients with carcinoid tumors, systemic mastocytosis, and pheochromocytoma, alone or in Sipple syndrome.

PIGMENTARY CHANGES

In addition to jaundice (see below), both diffuse and circumscribed pigmentary changes may occur in chronic liver disease. A diffuse muddy gray color in patients with long-standing cirrhosis is due to basal cell melanin.

CIRRHOSIS. Melanosis is common in primary biliary cirrhosis (PBC) and may be an early presenting sign. It initially involves exposed areas, but gradually becomes generalized. Blotchy, circumscribed areas of dirty brown pigmentation are also occasionally evident. Accentuation of normal freckling and areolar pigmentation can occur. Localized linear pigmentation may appear in the creases of the fingers and palms. Pigmentation resembling chloasma may localize to the perioral and periorbital areas. Guttate hypomelanosis, a condition in which small white macules, sometimes with a central spider, appear on the skin of the buttocks, back, thighs, and forearms, may occur in cirrhosis and, rarely, in PBC.[7] The yellow and orange lesions of dermal, subcutaneous, and tendon xanthomas and also xanthelasma are common in PBC and can be extensive (see Chapter 135).

HEMOCHROMATOSIS. The generalized metallic gray or bronze-brown color of the skin in hemochromatosis can be striking. There is accentuation in sun-exposed and traumatized skin, and occasionally there is buccal and conjunctival pigmentation.[8]

The etiology and pathogenesis of hyperpigmentation in chronic liver disease remains obscure and varies from disease to disease. The pigmentation in PBC is due predominantly to excess melanin with no stainable iron, while in hemochromatosis, pigmentation results both from the presence of hemosiderin in the skin and excess melanin. After phlebotomy, histologic siderosis and pigmentation decrease, even though melanosis remains histologically.

VITAMIN DEFICIENCY. Pellagra gives rises to lichenified, and often deeply pigmented skin in sun-exposed sites and can develop in patients with alcoholic liver disease. Vitamin B_{12} deficiency causes pigmentation of the distal extremities in a glove and stocking distribution. Diffuse hyperpigmentation occurs in folate deficiency. Kwashiorkor produces generalized depigmentation (see Chapter 130).

JAUNDICE

(Box 150-1)

In jaundice, raised plasma bilirubin produces a generalized coloration of the skin, mucous membranes, and other body tissues varying in hue from faint golden to dark green–yellow. Both jaundice and pigmentation are most prominent in extrahepatic biliary obstruction and in PBC.

Jaundice results from increased cellular or connective tissue binding of bilirubin and its metabolites in the skin. Bilirubin has an affinity for elastin, but circulates almost exclusively as a tightly bound complex with albumin. Eighty-five percent of bilirubin comes from the degradation of heme, the remainder from other heme-containing proteins, such as myoglobin and cytochromes. Jaundice results from an imbalance between tissue production and hepatic clearance of bilirubin.

Tissue-serum equilibration is slow, and so the intensity of clinical jaundice often fails to reflect the concurrent serum bilirubin level. Hyperbilirubinemia may, therefore, antedate the onset of detectable jaundice, and jaundice may persist despite falling or normal serum bilirubin levels. The correlation between skin color and serum pigment levels is especially poor in newborns. The intensity of jaundice and levels of serum bilirubin in patients with biliary atresia, acquired bile duct obstruction, or defective bilirubin conjugation tend to stabilize despite continued pigment production. Congestive cardiac failure may cause hyperbilirubinemia and jaundice secondary to raised intrahepatic pressure.

CLINICAL FEATURES. Clinically detectable jaundice appears when sufficient amounts of bilirubin become tissue bound. Involvement of the sclerae differentiates jaundice from other causes of skin pigmentation, including carotenemia, the yellow skin pigmentation produced by quinacrine and busulfan, and lycopenemia due to the ingestion of tomato juice.

The urine becomes dark yellow and even brown in color as conjugated serum bilirubin rises. Because

BOX 150-1 A FUNCTIONAL CLASSIFICATION OF JAUNDICE

- Unconjugated hyperbilirubinemia
- New and infant
- "Physiologic"—functional hepatic immaturity
- Hemolysis—Rh, ABO, sepsis, drug factors
- Prematurity
- Transient familial hyperbilirubinemia—maternal steroid inhibitors
- Crigler–Najjar syndrome—glucuronyl transferase deficiency (hereditary)
- Adult
- Excess bilirubin production
  - Hemolysis
  - Congenital
  - Acquired
  - Dyserythropoietic—"shunt" hyperbilirubinemia
- Deficient conjugation
- Familial
  - Constitutional hepatic dysfunction (Gilbert syndrome)
  - Crigler–Najjar syndrome type II
- Acquired
  - Posthepatic
  - Associated disease—cardiac, enteric, metabolic
  - Drug-induced
- Diagnostic features
- Serum-conjugated bilirubin less than 15% of total
- Absence of bilirubinuria
- Low to normal urine urobilinogen
- Absence of other liver function disturbances
- Normal morphologic features of liver
- Conjugated hyperbilirubinemia
- Hepatic cell damage
- Acute—viral, toxic, anoxic, metabolic
- Chronic—cirrhosis, metabolic
- Impaired bile excretion
- Extrahepatic obstruction
- Intrahepatic cholestasis—atresia, viral, drugs, hormones, pregnancy, benign recurrent cholestasis
- Familial (defect confined to bilirubin excretion)
- Dubin–Johnson syndrome—excretory defect and cell pigment
- Rotor's syndrome—excretory defect and no pigment
- Diagnostic features
- Serum-conjugated bilirubin more than 15% of total
- Bilirubinuria common
- Urine urobilinogen often elevated
- Other liver functions often abnormal in hepatic cell damage and impaired bile excretion
- Characteristic morphologic abnormalities of liver

most of the brown color of normal feces is due to urobilins derived from degradation of bilirubin in the intestine, the jaundice of impaired bilirubin excretion or bile obstruction is associated with "clay-colored" stools. Ultraviolet radiation enhances degradation of bilirubin; this is the rationale for phototherapy to prevent kernicterus in severe neonatal jaundice.

The jaundice of biliary obstruction resolves after the obstruction is relieved. Jaundice in patients with acute hepatitis resolves spontaneously. The jaundice of chronic liver disease may improve after transplantation. Jaundice in chronic active hepatitis can decrease after glucocorticoid therapy. Neonatal jaundice may respond to phototherapy (see Chapter 237).

PRURITUS

CHOLESTATIC PRURITUS

PATHOGENESIS OF CHOLESTATIC PRURITUS.

One of the most common and distressing symptoms of hepatobiliary disease is pruritus. Although retained cutaneous bile acids have been implicated, there is a poor correlation between the plasma bilirubin and the severity of pruritus. However, the partial relief of itching by bile salt-chelating resins and the disappearance of pruritus when liver cells fail strongly indicates that the liver must manufacture at least one of the contributing agents.

Opiate agonists, such as morphine, induce pruritus. Animal studies show that the intracerebral presence of morphine induces pruritus that is reversed by the opiate antagonist nalaxone,[9] demonstrating that opiate agonists induce itching centrally. In addition, the administration of the opioid antagonist nalmefene to patients with PBC produces a reaction similar to that of opiate withdrawal, and the injection of plasma from patients with PBC into monkeys produces pruritus. Taken together, these studies suggest that opioidergic tone increases in cholestasis.[9] These studies do not, of course, tell us which agent(s) cause the pruritus of cholestasis, nor whether it originates peripherally (e.g., in the liver) or centrally.[10]

CLINICAL FEATURES. Pruritus more commonly occurs in conditions causing cholestasis and ranges from mild and transient to severe and prolonged. Pruritus may be debilitating in patients with PBC, mechanical biliary obstruction, or intrahepatic obstruction. Drugs, especially erythromycin, oral contraceptives, phenothiazines, chlorpropamide, *para*-aminosalicylic acid, and nitrofurantoin, induce cholestasis accompanied by pruritus. Pruritus is the presenting symptom in more than 50% of cases of PBC and may precede jaundice by months or even years. However, in viral hepatitis, itching is frequently missed as an early sign of the disease until it occurs in the later, icteric phase.

Pruritus is usually most marked on the extremities and only rarely involves the neck and face, and genitalia. There is little correlation between the severity of cholestasis and the severity of perceived pruritus: a spontaneous decrease in the intensity of pruritus may signal the development of hepatocellular failure rather

than improvement. Scratching gives only very temporary relief in the pruritus of cholestasis. There may be no visible skin changes except excoriations, although lichenified plaques, nodular prurigo or peforating collagenoses may be seen (see Chapter 69).

MANAGEMENT. Pruritus rapidly decreases when cholestasis secondary to mechanical bile duct obstruction is relieved. Drugs to relieve cholestasis such as ursodeoxycholic acid do not consistently relieve pruritus, nor do the anion exchange resins cholestyramine and cholestipol, which are thought to bind intestinal pruritogens and prevent them making their way to the skin. Neurotransmitter receptor antagonists such as oral nalmefene have been advocated for the pruritus of cholestasis[11] Intravenous naloxone has short-term efficacy[12] as has oral naltrexone.[13] However, while these, together with sedating antihistamines or ultraviolet light can help, long-term results with any approach, including plasmapheresis, charcoal hemoperfusion, and hepatic enzyme inducers (such as rifampicin) have been disappointing.[14]

RENAL PRURITUS

Renal pruritus is a major problem[4] and reported to be as high as 90% in patients undergoing hemodialysis.[15–17]

PATHOGENESIS OF RENAL PRURITUS. Renal pruritus has been thought to be caused by a combination of increased serum histamine, vitamin A, and parathyroid hormone (PTH); mast cell hyperplasia; peripheral polyneuropathy; xerosis.[16,18]; and inflammatory factors.[19] Clinically, the skin may appear normal or demonstrate a variety of lichenified or hyperkeratotic lesions.[20]

MANAGEMENT. Topical moisturizers alleviate pruritus associated with xerotic skin. Topical glucocorticoids and ultraviolet phototherapy[21,22] are often used to suppress inflammation in treated areas. Topical capsaicin depletes substance P from nerve endings, thereby suppressing itch sensation.[23] Gabapentin and the κ-opioid-receptor-agonist nalfurafine have also been found useful.[19] Improving the efficacy of dialysis and/or changing the dialysate concentration may help to alleviate pruritus.[24] Some patients have responded to treatments with intravenous lidocaine, heparin, and cholestyramine.[22] Surgical options include subtotal parathyroidectomy, electric needle stimulation, and renal transplantation. Erythropoietin lowers plasma histamine concentrations with subsequent improvement in pruritus.[25] There are reports of success with oral evening primrose oil,[26] and endocannibinnoids.[27] Thalidomide, pentoxiphylline, and topical tacrolimus ointment may help some patients.[19,28]

ALTERATIONS IN SWEATING

Sweating may be prominent in a number of cardiopulmonary states such as acute myocardial infarction, cardiogenic shock, left ventricular failure, massive pulmonary emboli, and pulmonary edema. Pallor and clamminess/coldness of the extremities and exposed surfaces are also often found. Excessive sweating may suggest pheochromocytoma when associated with hypertension.

The sodium and chloride content of sweat is increased in patients with cystic fibrosis and may lead to an increase in skin wrinkling after immersion, as when bathing.[29]

SKIN CHANGES IN MALIGNANCY

(See also Chapter 153)

Many skin changes occur in association with malignancies.

Dry skin (acquired ichthyosis) with asteatotic dermatitis as well as hyperpigmentation is not uncommon.

DERMATOMYOSITIS

(See Chapter 156)

Adult onset dermatomyositis is associated with underlying malignant disease in a significant minority of cases.[30] Blind CT scans may help uncover occult malignancy in these patients.[31] Pancreatic, gastric, and colorectal cancers are the third most common after bronchogenic and ovarian cancers in Europe and North America. In China, nasopharyngeal carcinoma is common. The rash and myopathy can regress after removal of the tumor.

Interstitial lung disease occurs[32] with bronchiolitis obliterans, subcutaneous emphysema, and spontaneous pneumothorax. Upper pharyngeal weakness can lead to chronic aspiration an, exertional dyspnea can occur because of weakness of the respiratory muscles. Lung disease is associated with anti-Jo-1 antibodies.

ACANTHOSIS NIGRICANS

(See Chapter 151 and 153)

In two-thirds of patients with acanthosis nigricans and cancer, the tumor is gastric. The changes may regress if the tumor, usually an adenocarcinoma of the stomach or bowel, is removed.

HYPERTRICHOSIS LANUGINOSA

Excessive growth of lanugo hair is a rare complication of gastrointestinal cancer.

OTHER SKIN CHANGES IN MALIGNANCY

Diverse cutaneous paraneoplastic syndromes may arise from underlying tumors.[33] They may precede, coincide with, or follow the diagnosis of cancer and usually indicate a poor prognosis. They include

Figure 150-2 Patient with "tripe hands" due to adenocarcinoma of the jejunum.

reactive erythemas, such as erythema gyratum repens and necrolytic migratory erythema; the vascular dermatoses (trousseau syndrome); and papulosquamous disorders, including tripe palms (Fig. 150-2), palmar hyperkeratosis, acquired ichthyosis, pityriasis rotunda, Bazex syndrome, florid cutaneous papillomatosis, the sign of Leser–Trélat, and extramammary Paget disease. Migratory superficial thrombophlebitis occurs in association with neoplasia, particularly carcinoma of the pancreas. Glucagonoma, one of the amine precursor uptake and decarboxylation (APUD) cell tumors, usually arises in the islet cells of the pancreas, and occurs in association with a distinctive necrolytic migratory erythema (see Chapter 153).

Any tumor may metastasize to the skin. The scalp is a common site. Metastases at the umbilicus (Sister Joseph nodules) occur particularly with carcinoma of the stomach, colon, or ovary (Fig. 150-3).

ERYTHRODERMA

(See Chapter 23)

The systemic effects of erythroderma can be considerable. Patients can develop hypothermia, hypoalbuminemia, hypovolemia, secondary sepsis, the initial stages of renal failure, and high-output cardiac failure with secondary effects on hepatic function. Death from sepsis, cardiac failure, adult respiratory distress syndrome, and capillary leak syndrome occur.[34]

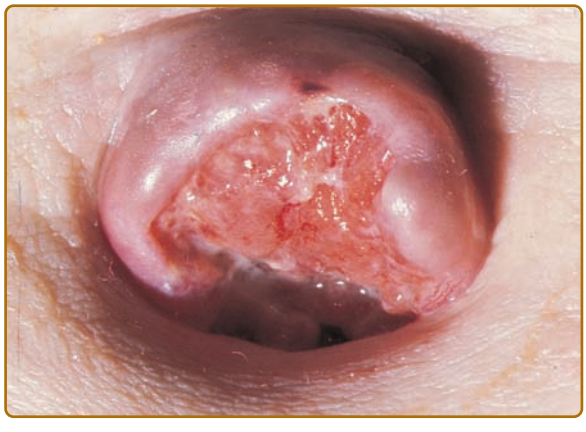

Figure 150-3 Umbilical metastasis (Sister Joseph nodule) from intraabdominal adenocarcinoma.

SPECIFIC ORGAN AND SYSTEM CHANGES

NAILS

(See Chapter 89)

Lindsey, or half-and-half, nails are normal in their distal 50% and white in the proximal 50% and found in CRF.

In malabsorption or malnutrition, nails grow more slowly, become brittle, and may develop fissures.[35,36] Multiple pigmented bands can appear. Koilonychia usually indicates iron deficiency, even without anemia (see below). White nails, thought to be due to selenium deficiency, have occurred with total parenteral nutrition.

Flushing of the nail beds that is synchronous with the heartbeat is a sign of aortic regurgitation called Quincke pulsation.

NAIL CHANGES IN LIVER DISEASE

Nail abnormalities are a less constant physical sign than spider nevi or liver palms. In cirrhosis, however, a number of changes may occur: clubbing, curved nails, thickened nails, longitudinally ridged nails, white nails, watch-glass deformity, flattened nails, white bands, striations, and brittleness.[36]

White nails may occasionally be seen in healthy individuals or in association with systemic disease, including congestive heart failure, diabetes, cryoglobulinemia, Raynaud syndrome, and systemic sclerosis. Intensely white nails (Terry nails) are characteristic of cirrhosis (Fig. 150-4).[37] Thumbs and forefingers are often most affected. The whiteness does not alter with nail growth or with compression of digital vessels and is thought to be due to the opacity of the nail plate itself. The so-called watch-glass deformity may accompany white nails (see Fig. 150-5).

Azure lunulae, a bluish color of the lunular portion of nails, occurs in hepatolenticular degeneration (Wilson disease). Azure lunulae and corneal changes resembling Kayser–Fleischer rings may also be evident in patients with argyria or following treatment with busulfan or antimalarials.[36]

The characteristic nail changes of lichen planus, including longitudinal ridging, pterygium formation, and permanent nail loss, occur both with and without skin changes in PBC (see Section "Cutaneous Manifestations of Primary Biliary Cirrhosis").

Splinter hemorrhages also occur in cirrhosis. Flat or spoon nails are less common in patients with liver disease. The nails are flat or concave, pale in color, and frequently show longitudinal ridging. In hemochromatosis, koilonychia is probably the most common of the nail abnormalities, but it is not related to anemia.[36]

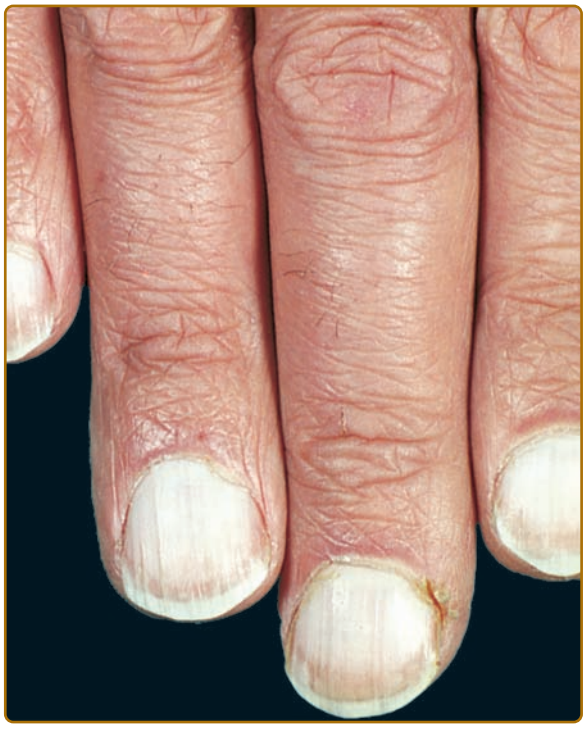

Figure 150-4 Terry's white nails in a patient with cirrhosis.

NAIL CLUBBING

Nail clubbing most commonly occurs in patients with bronchogenic carcinoma, suppurative lung disease, endocarditis, and congenital heart disease, but it may be idiopathic or familial (Fig. 150-6). Clubbing is quite common in all forms of cirrhosis, especially PBC and chronic active hepatitis. Signs include beaking or distal curvature of the nail. There may be loss of the angle between the nail and cuticle. Sponginess or "floating" of the nail when pressure is applied is also characteristic and the size of the terminal tuft may increase.

Anatomically, there is an increased thickness of the nail bed. This is due to edematous infiltration of the soft parts of the terminal segment followed by hyperplasia of the dermal fibrovascular tissue with increased vascularity.[36]

Figure 150-5 Flat white nails with slight convex watchglass deformity, showing a distal pink band in a patient with liver disease.

Figure 150-6 Clubbing of fingernails.

YELLOW NAIL SYNDROME

This is the triad of yellow nails, primary lymphedema, and pleural effusion(s). The characteristics of the nails include thickening, transverse ridging, diminished growth, increased curvature with a "hump," and onycholysis. The lunulae and cuticles may be absent. The color may vary from pale yellow to green (Fig. 150-7). The nail changes are secondary to congenitally hypoplastic lymphatics,[38] leading to lymphedema, which is characteristically slowly progressive and somewhat

Figure 150-7 Yellow nail syndrome. There is thickening, increased curvature, and yellowish discoloration of all fingernails. This patient had lymphedema of the extremities and bronchiectasis with multiple recurrent respiratory infections.

asymmetric, with induration and hyperkeratosis extending to the thighs. Periodic lymphangitis is frequent and may contribute to the swelling.

Respiratory findings include sinusitis, bronchiectasis, and pleural effusions. Patients may have frequent upper respiratory infections, and pneumonia. The appearance of pulmonary features and lymphedema may be late and lymphoma or sarcoma have been reported.

FINGERS

ERYTHROMELALGIA

(See also Chapter 173)

Erythromelalgia (labile hyperthermia) is a chronic clinical syndrome that is characterized by recurrent attacks of burning pain in the hands and/or feet with redness and warmth.[39] There may be swelling that extends to the elbows and knees. Erythromelalgia may be primary or secondary to a disorder such as atherosclerosis, hypertension, and polycythemia. Symptoms are thought to be caused by vascular dysfunction including arteriovenous shunting and reduced capillary perfusion with subsequent tissue hypoxemia.[40] Management includes analgesia, controlling secondary and underlying factors, and use of drugs such as aspirin and calcium channel blockers.[41] A possible role for high-dose oral magnesium has been proposed[42] and the use of a combination gel of 1% amitriptyline and 0.5% ketamine used to treat refractory erythromelalgia pain.[43]

HANDS

HYPERTROPHIC OSTEOARTHROPATHY. Clubbing is often a feature of hypertrophic osteoarthropathy (HOA) but there is also associated arthralgia and/or arthritis of the fingers, wrists, knees, and ankles. There is a painful periostitis with subperiosteal new bone formation on X-ray. There may be pitting edema, shiny skin, increased sweating, and paronychial thickening. HOA is most often secondary to malignant tumors of the chest.

Pachydermoperiostosis, a primary form of HOA, is frequently familial with an onset around puberty, and has a number of cutaneous manifestations. Distinctive thickening and furrowing of the skin of the scalp, forehead, and cheeks may create leonine facies. Other features include excessive sweating and dermatitis, especially of the hands and feet, severe seborrhea of the scalp and face. Familial clubbing alone may also be found and may represent a partial expression of this syndrome. Thyroid acropachy (Chapter 151) may mimic osteoarthropathy but is most often painless.

REFLEX SYMPATHETIC DYSTROPHY

The shoulder–hand syndrome is a painful periarthritis or adhesive capsulitis of the shoulder ("frozen shoulder"), usually on the left side, associated with erythema, increased sweating, shiny induration, edema, tenderness, pain, and immobility of the ipsilateral hand. Reduction of finger flexion, loss of movement, temperature changes, sensory disturbances, and, hair/nail growth changes have been reported.[44] Neurotrophic ulcerations of the fingers and thickening of the palmar aponeurosis with nodules and/or Dupuytren contracture may be late sequelae.[45] Predisposing conditions include arterial embolization, cerebrovascular accidents, and protective disuse of the arms for any reason.[46]

PALMS

PALMAR ERYTHEMA. There are two clinical forms of palmar erythema. In the first (Fig. 150-8), there is an exaggeration of normal mottling; the hands are warm and bright red, especially on the palm, the dorsae of the hands, the fingers, and the nail bases. In the second, there is well-demarcated redness of the hypothenar eminence that gradually spreads to the fingertips and then to other areas of the palm. The soles of the feet may show similar changes. The mottling blanches on pressure and flushes synchronously with the pulse rate under a glass slide. Patients may complain of throbbing or tingling. Often termed "liver palms" these changes also occur in pregnancy and thyrotoxicosis. In cirrhosis, though, atrophy of the muscles of the thenar and hypothenar eminence may coexist. This is of myogenic rather than neurogenic origin.[47]

Figure 150-8 Palmar erythema showing the characteristic blotchy redness.

FACE

SPIDER NEVUS. The spider nevus, or spider angioma, is the most representative and classic vascular lesion of chronic liver disease. Clinically, it has a central arteriole from which numerous small, twisted vessels radiate (Fig. 150-9). Spider nevi range in size from a pinhead to 2 cm. Larger lesions can be seen to pulsate when pressed with a glass slide. Pressure over the central arteriole causes blanching of the whole lesion. Spider nevi are characterized by the abnormal permanent dilatation of end vessels. Histologically, spider nevi consist of a central ascending arteriole ending in a thin-walled ampulla beneath the epidermis from which small arterial branches radiate outward into the papillary dermis.[3]

Spider nevi are most common on the face, neck, and upper part of the chest (i.e., over the region drained by the superior vena cava; see Fig. 150-9). They may be seen in 15% of healthy adults and not infrequently in children, where they tend to affect the hands and fingers. They may appear in large numbers during pregnancy, but usually disappear after parturition. They may also be seen in thyrotoxicosis or due to oral contraceptives.

In liver disease, spider nevi usually persist but can regress with improvement of the underlying condition. Spider nevi are more common in patients with alcoholic cirrhosis than in those with viral or idiopathic cirrhosis. In alcoholic cirrhosis, they are associated with the presence of esophageal varicosities, and their presence may be a useful predictive marker for the future risk of esophageal bleeds.[48]

Vascular spider nevi and palmar erythema (see above) are generally attributed to estrogen excess, particularly because they also occur during pregnancy and because estrogens have an enlarging, dilating effect on the spiral arterioles of the endometrium. This would also explain spider nevi in men receiving estrogen therapy for prostatic cancer. However, in addition to higher plasma estradiol:testosterone ratios, patients with nonalcoholic cirrhosis have been shown to have higher substance P levels than healthy controls.[49] Vascular endothelial growth factor (VEGF) may also have an etiopathogenic role.[50] In alcoholic cirrhosis, the presence of alcoholism and elevated serum bilirubin are both important predictors of the presence of spider nevi.[51]

Figure 150-9 Spider nevi in a patient with cirrhosis.

EYES

Corkscrew scleral vessels (tortuous small arteries that traverse the margins of the ocular sclerae) can develop in patients with chronic liver disease.

MOUTH AND ESOPHAGUS

DYSPHAGIA. When dermatologic diseases extend into the pharynx and esophagus, dysphagia may occur. Cutaneous and oral infections are discussed elsewhere. Symptoms resulting from infections of the esophagus occur in patients taking oral or inhaled glucocorticoids or in those who have an immunodeficiency. *Candida albicans* is the most frequent pathogen, although opportunistic bacteria and viruses can also be responsible.

Extensive esophageal involvement with blisters, erosions, and strictures can occur in hereditary epidermolysis bullosa particularly in the recessive dystrophic and junctional forms (see Chapter 62).[52] The acquired immunobullous disorders can affect mucosae. Dysphagia is most troublesome in cicatricial pemphigoid where half of patients have pharyngeal involvement and up to 13% esophageal involvement (see Chapter 57).[53]

Esophageal lichen planus has been reported only in women, typically middle-aged with oral involvement (see Chapter 26). Therapeutic dilatation can lead to a Koebner-like exacerbation of the stricture.[54] Esophageal involvement also occurs in Darier disease, sometimes in association with esophageal carcinoma (see Chapter 51),[55] and in acanthosis nigricans. The mucosae may be extensively involved in Stevens–Johnson syndrome and toxic epidermal necrolysis (see Chapters 39 and 40).

In Behçet syndrome (see Chapter 166), which should always be considered in a patient with three episodes of oral ulceration in a 12-month period, isolated mucosal ulcers can occur at any point along the gastrointestinal tract.[56] A typical site is the ileocecal region. Oral ulceration can sometimes be difficult to distinguish from the mouth ulceration associated with Crohn disease.

In Plummer–Vinson (Paterson–Kelly) syndrome, a postcricoid web is associated with koilonychia, angular stomatitis, a sore tongue, and, usually, iron deficiency. Up to 10% of patients with a postcricoid web develop carcinoma at the site. The form of tylosis in which 95% of patients develop esophageal cancer is exceedingly rare.[57]

Up to 90% of patients with systemic sclerosis have gastrointestinal involvement, but this is subclinical in one-third (see Chapter 157). Dyspepsia due to gastroparesis is common; decreased peristalsis, esophageal dilation, and stricture formation occur. Gastric antral vascular ectasia is a rare manifestation that may cause significant bleeding.[58] In dermatomyositis and polymyositis, decreased esophageal motility and difficulty swallowing are indications for urgent systemic treatment with high-dose glucocorticoids and immunosuppressive drugs (see Chapter 156). Vasculitic ulcers in the mouth and pharynx may occur in systemic lupus erythematosus (see Chapter 155).

EARS

EARLOBE CREASE. The presence of a diagonally positioned skin crease along the earlobe, either unilateral or bilateral, suggests an increased risk for coronary artery disease (CAD) in men under 60 years of age.[59]

RELAPSING POLYCHONDRITIS

(See Chapter 159)

Relapsing polychondritis is characterized by inflammation and destruction of cartilage and connective tissues, including those of the cardiopulmonary system. It is idiopathic but frequently associated with other immunologic disorders such as systemic lupus erytematosus (SLE). Auricular chondritis with pain, swelling, and redness of the pinna but complete sparing of the lobes is characteristic. Respiratory tract involvement may begin with hoarseness or tenderness of the anterior trachea. Degeneration of the laryngeal, tracheal, and/or bronchial rings may lead to progressive insufficiency or to sudden collapse. Cardiac involvement includes degeneration of the aortic ring with valvular insufficiency and aneurysmal dilatation. "Floppy" mitral valve syndrome also occurs. Pericardial and myocardial abnormalities have been reported.

HAIR

(See Chapter 88)

Malnutrition causes hair to grow more slowly, fall out more easily, and become gray. The hair root diameter and the proportion of anagen hairs decrease. Lanugo hair may develop. Kwashiorkor, a form of protein–energy malnutrition, causes hair to become hypopigmented, varying from red–yellow to white, and curly. There may be alternating bands of pale and dark hair.[35] Total parenteral nutrition has been associated with hair loss and pigmentation of remaining hair. Type 2 vitamin D-dependent rickets is associated with alopecia totalis.

MALE BALDING

Frontoparietal male pattern baldness is more prevalent in men admitted with nonfatal myocardial infarction.[59] Vertex hair loss may be more strongly associated with cardiovascular risk factors, such as hypertension and hypercholesterolemia.[60]

THE CARDIOVASCULAR SYSTEM

(Box 150-2)

Cardiac output frequently increases in patients with cirrhosis, and total peripheral resistance may decrease.

BOX 150-2 DISEASES WITH BOTH CUTANEOUS AND CARDIAC INVOLVEMENT

- Joint and connective tissue diseases
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Reactive arthritis
- Behçet disease
- Systemic scleroderma
- Dermatomyositis
- Rheumatic fever
- Ehlers–Danlos syndrome
- Cutis laxa
- Marfan syndrome
- Periarteritis nodosa
- Multicentric reticulohistiocytosis
- Metabolic diseases
- Hemochromatosis
- Amyloidosis
- Fabry disease
- Carcinoid tumors
- Myxedema
- Hyperlipidemias
- Hyperthyroidism
- Nevoid or genetic disorders
- Progressive lentigines (Moynahan syndrome)
- Watson syndrome
- Neurofibromatosis
- Tuberous sclerosis
- LEOPARD syndrome
- NAME/LAMB/Carney complex
- Danoff syndrome
- Infectious diseases
- Varicella
- Gonococcemia
- Subacute and acute bacterial endocarditis
- Chagas disease
- Diphtheria
- Miscellaneous (protozoal, viral, rickettsial, and bacterial infections)
- Diseases of uncertain etiology
- Sarcoidosis
- Whipple disease
- Kawasaki disease
- Degos disease

CORONARY HEART DISEASE

FAMILIAL HYPERLIPIDEMIA. The familial hyperlipidemias comprise a group of metabolic disorders with elevated plasma cholesterol and/or triglycerides, associated with a high incidence of CAD. Xanthelasmata and cutaneous xanthomata are important clinical features (see Chapter 135).

CARDIOMYOPATHY

NAXOS DISEASE. This is an autosomal recessive mutation in desmoplakin, a desmosomal protein important in cell adhesion.[61] Generalized striate keratodermas are seen, particularly on the palmoplantar epidermis, with woolly hair and dilated left ventricular cardiomyopathy leading to arrhythmias, heart failure, and early sudden death (see Chapter 50).

ATRIAL MYXOMA

Atrial myxomas, the most common primary tumors of the heart, are benign hamartomatous intracardiac tumors. The cardiopulmonary findings include, in order of frequency, congestive heart failure, mitral murmur, chest pain, pulmonary edema, and pulmonary emboli. Additionally, valvular insufficiency, constrictive pericarditis, conduction blocks, and arrhythmias may occur. Variable murmurs can be an important clue. Other systemic findings include fever, cachexia, arthralgia, clubbing, hypergammaglobulinemia, and leukocytosis.

The cutaneous manifestations of atrial myxomas may be dramatic. In addition to biphasic digital color changes on cold exposure, skin lesions may simulate collagen vascular disease or vasculitis with tender, violaceous, nonblanching, annular, and serpiginous lesions of the digital pads, as well as splinter hemorrhages presenting as a systemic vasculitis or infective endocarditis. Characteristic pruritic, erythematous papules as well as cyanosis and ecchymosis of the extremities may also occur. Histologically myxomatous emboli with large pale cytoplasm and stellate nuclei may be found among occluded blood vessels. Mucocutaneous pigmented lesions, including lentigines (Fig. 150-10), melanocytic nevi, and dermal myxomatous nodules, have been described (NAME/LAMB/Carney Complex).[62]

LEOPARD SYNDROME

Multiple lentigines syndrome is an autosomal dominant disorder comprising lentigines; electrocardiogram conduction defects; ocular hypertelorism; pulmonary stenosis; abnormalities of genitalia; retardation of growth and sensorineural deafness. Electrocardiographic features include axis deviation; prolonged P–R interval, bundle branch block, and complete heart block. Hypertrophic cardiomyopathy appears to be the most common anatomic abnormality. Subaortic stenosis is the most common valvular lesion.

Figure 150-10 Lentiginous lesions in the atrial myxoma syndrome complex. This child has the LAMB syndrome.

SUBACUTE BACTERIAL ENDOCARDITIS

(See also Chapter 181)

The cutaneous manifestations of bacterial endocarditis include Osler nodes, Janeway lesions, subungual splinter hemorrhages, cutaneous purpura and petechiae, and conjunctival petechiae (Roth spots).

Petechiae are the commonest manifestation with small, red, or violaceous nonblanching macules especially on the heels, shoulders, and legs.

Osler nodes and Janeway lesions may both present as erythematous or hemorrhagic macules, papules, or nodules (Fig. 150-11). However, while Osler nodes are exquisitely painful, tender, and located distally on the digital tufts, Janeway lesions are nontender and located proximally on the palms and soles. Histologically, Osler nodes are a perivasculitis or necrotizing

Figure 150-11 Osler nodes (*arrows*).

vasculitis *without* microabscess formation or other evidence of infection or emboli whereas Janeway lesions have been described as a vasculitis *with* microabscess formation. Both are found in patients with other conditions, particularly systemic lupus erythematosus, gonococcemia, hemolytic anemia, and typhoid fever.

COLLAGEN VASCULAR DISEASE AND THE HEART

SYSTEMIC LUPUS ERYTEMATOSUS. (See Chapter 155). Pericarditis may be more common in patients with drug-induced lupus or photosensitive discoid lesions. Myocarditis is often undiagnosed and may be associated with prolonged P–R intervals, heart block, and arrhythmias. Valvular heart disease in patients with SLE, most often of the Libman–Sacks type, is frequently associated with antiphospholipid antibodies.[63] Diastolic murmurs may occur with mitral stenosis or aortic insufficiency but the onset of a new diastolic murmur should provoke a search for subacute infective endocarditis. Splinter hemorrhages, Osler nodes, Janeway lesions, and Roth spots may occur in SLE per se without infection. SLE is associated with complete heart block in newborns because of placental transfer of maternal antibodies, especially the anti-Ro antibody.[64] The newborn infants of patients with SLE or of clinically normal but Ro-antibody-positive mothers may also have distinctive evanescent eruptions, including prominent telangiectasia and periorbital erythema.[65]

SYSTEMIC SCLEROSIS. (See Chapter 157). Acute or chronic pericarditis is an important feature of systemic sclerosis. Pericardial effusions may be occult, and constrictive pericarditis and tamponade may occur. Additionally, small-vessel involvement of the myocardium may lead to fibrosis.[66] Fibrosis of the conduction system may cause arrhythmias and sudden death.

THE RESPIRATORY SYSTEM

PULMONARY ARTERIOVENOUS FISTULAS

Pulmonary arteriovenous fistulas are congenital abnormalities of capillary development that may not become clinically apparent until late adolescence. Osler–Weber–Rendu disease[67] is an autosomal dominant trait, characterized clinically by punctate, linear, or spider-like telangiectasias of the skin, especially on the upper body, oral and nasal mucous membranes, and nail beds (Fig. 150-12). Radiating arms about an elevated punctum are the most characteristic feature, especially on the lips and tongue. They are distinguished from spider nevi in that they do not pulsate. Recurrent epistaxis, often beginning in childhood or adolescence, is the most frequent presenting symptom. The liver, gastrointestinal, and central nervous system can be involved (see below) and recurrent hemorrhage

Figure 150-12 Osler–Rendu–Weber disease. Note the punctate and splinter-like telangiectasia on the lips and tongue.

may result. Bleeding may be enhanced by associated disorders such as von Willebrand disease. In those with an arteriovenous fistula of the lungs pulmonary bruits accentuated by inspiration can be heard.

In cirrhosis, arteriovenous shunting may occur within the lungs (the hepatopulmonary syndrome),[68] liver, and extremities. These arteriovenous malformations, including spider nevi, may regress after transplantation.[69]

LARVA MIGRANS

(See Chapter 207)

Cutaneous larva migrans, may cause mild respiratory symptoms and be associated with transient pulmonary infiltrates and a peripheral eosinophilia (Löffler syndrome). Visceral larva migrans, or toxocariasis, may lead to granulomatous involvement of the liver, lungs, heart, muscle, brain, and eyes. Marked eosinophilia, hyperglobulinemia, pneumonitis with wheezing, recurrent bronchitis, fever, and tender hepatomegaly frequently occur. Skin lesions may present as patchy urticaria or erythematous papular eruptions.

FAT EMBOLISM SYNDROME

Petechiae, respiratory insufficiency, and cerebral dysfunction after long bone fracture are termed the *fat embolism syndrome*. Petechiae alone after fractures should suggest this diagnosis. The petechiae are most common on the neck, axillae, shoulders, chest, and conjunctivae. They often appear before other manifestations on the second or third day after injury, and appear in crops. When widespread, they herald more significant cerebral and pulmonary dysfunction. Histologically, fat globules are present within dermal and pulmonary vessels. Respiratory involvement includes

cyanosis, hemoptysis and pulmonary edema. Jaundice and thrombocytopenia may occur.[70]

LIPOID PROTEINOSIS (HYALINOSIS CUTIS ET MUCOSAE)

(See Chapter 137)

Skin changes include confluent, waxy papules, plaques, and scarring, particularly on the face. The tongue is enlarged. Oropharyngeal and laryngeal mucous membranes are usually affected early in the course of the disease, during infancy or childhood. Laryngeal infiltration may present early on as hoarseness, and may progress to obstruction and respiratory insufficiency. The trachea and main stem bronchus may be thickened and studded with warty projections.

MULTICENTRIC RETICULOHISTIOCYTOSIS

(See Chapter 148)

Multicentric reticulohistiocytosis is an uncommon disorder presenting with characteristic mucocutaneous lesions consisting of deeply set, firm, small papules in association with a deforming arthritis, fever, malaise, weight loss, and myopathy. Neurofibroma-like, soft, sessile, larger lesions have been reported, as has an association with malignancy.[71] Cardiopulmonary complications include pleural effusions, pulmonary infarctions, pericarditis, angina pectoris, myocardial infarction, and congestive heart failure.

SARCOIDOSIS

(See Chapter 152)

Cardiac involvement in sarcoidosis may be occult and results from myocardial or conduction system granulomata. Ventricular arrhythmias and conduction disturbances present as palpitations and syncope. Congestive heart failure and chest pain occur as do cardiomyopathy or cor pulmonale. The prognosis for patients with cardiac involvement is unfavorable. Sarcoidosis affecting the pulmonary system is relatively common in association with lupus pernio: involvement of the hilar nodes, bronchi, and/or alveoli may result in obstructive and/or restrictive dysfunction and respiratory failure.[72] Indwelling vascular catheters can, rarely, disintegrate and embolise into small pulmonary vessels and lymphatics, causing granulomatous changes and dyspnoeic symptoms. These lesions have also been reported in the skin.[73]

AMYLOIDOSIS

(See Chapter 133)

Systemic amyloidosis may cause waxy induration of the skin, with hemorrhagic skin changes on stroking (pinch purpura). Amyloid deposition within the vessels is found in clinically normal skin in up to 50% of patients.

Cutaneous involvement occurs most often in the primary and myeloma-associated types, and therefore serves as a marker for cardiopulmonary involvement. Congestive heart failure with cardiomegaly or a restrictive cardiomyopathy occurs. Pathologically, there is infiltration of the endocardium, myocardium, pericardium, valves, and coronary vessels.[74] Senile amyloidosis may also affect the heart but is often asymptomatic.

Respiratory tract involvement is also commonest in primary and myeloma-associated types. Macroglossia may impede respiration, the larynx and trachea may become infiltrated, causing stridor and bronchial and parenchymal involvement cause asthma-like symptoms.

LYMPHOMATOID GRANULOMATOSIS

(See Chapter 145)

Lymphomatoid granulomatosis is a rare angiocentric and angiodestructive, Epstein–Barr virus-associated B cell lymphoproliferative disorder, varying from an indolent process to an aggressive large cell lymphoma. The skin is the extrapulmonary organ most commonly involved. The disease also affects the lungs,[75] heart, central nervous system, and kidneys. Although many patients remain asymptomatic, cough, dyspnea, and chest pain may occur. Chest X-rays show transient infiltrates which may progress to nodules that cavitate and cause profuse hemoptysis.

COLLAGEN VASCULAR DISEASE AND THE LUNGS

The pulmonary complications of the various collagen vascular diseases may sometimes be associated with a specific cutaneous sign or constellation of features.

RHEUMATOID ARTHRITIS. (See Chapter 160). Extra-articular manifestations of rheumatoid arthritis, especially in the lungs, appear to correlate with subcutaneous nodules and vasculitic skin lesions. Skin lesions are also associated with high-titer rheumatoid factor, hypocomplementemia, cryoimmunoglobulinemia, and hypereosinophilia. These occur more commonly in men with long-standing disease, but may not correlate with current arthritis activity. The pulmonary symptoms include cough and hemoptysis.

SYSTEMIC LUPUS ERYTHEMATOSUS. (See Chapter 155). Pleuritis may be present half of patients with SLE and pleural effusions also occur. Parenchymal lung involvement in SLE is usually a result of secondary factors such as infections or pulmonary emboli. Primary lung involvement in SLE may be classified as (1) diffuse interstitial pneumonitis, (2) acute pneumonitis, (3) intrapulmonary hemorrhage, (4) diaphragm dysfunction with decreased lung volume, (5) pulmonary hypertension with cor pulmonale, and (6) fibrosing alveolitis.[76]

SYSTEMIC SCLEROSIS. (See Chapter 157). Raynaud phenomenon, telangiectases, and dilated and distorted

capillary loops of the nails are cutaneous clues. Exertional dyspnea chronic, nonproductive cough, and pleuritic chest pain indicate lung involvement.[77] Pulmonary hypertension with cor pulmonale and congestive heart failure may develop independently of parenchymal disease. Esophageal dysmotility causing aspiration pneumonia is associated with a higher incidence of interstitial lung disease.[64]

THE GASTROINTESTINAL SYSTEM

On examining the abdomen in patients with cirrhosis portal-systemic collateral vessels may be seen and are a clue to the existence of portal hypertension. Often, the umbilical vein is dilated and visible in the epigastrium, an occurrence more common than the well recognized, but rare, caput medusae.

GASTROINTESTINAL BLEEDING

Hematemesis, melena, or passing of fresh blood in the stools are signs of gastrointestinal bleeding (Box 150-3). The characteristic picture of hereditary hemorrhagic telangiectasia is of a familial pattern of epistaxis with telangiectases on mucosal surfaces (see Fig. 150-12) and arteriovenous malformations in multiple organs.[67] Hemorrhage from the gut, usually from the stomach or duodenum, occurs in up to 40% of patients and at an average age of 55 years.

Most cases of blue rubber bleb nevus syndrome are sporadic, but there are some autosomal dominant pedigrees. The gastrointestinal venous malformations look and feel as their name suggests and project into the gut lumen, particularly the small intestine. In contrast to cutaneous lesions, they bleed easily, causing chronic anemia and, less commonly, acute hemorrhage (see Chapter 172).[78]

In the autosomal dominant vascular type of the Ehlers–Danlos syndrome rupture of the bowel, often involving the sigmoid colon, accounts for one-quarter of all complications and 8% of all deaths.[1] Diverticula, and hernias, may also occur (see Chapter 137).

Gastrointestinal bleeding, usually from the stomach, is an important complication of PXE.[2] This may be the first clinical manifestation of the disease (see Chapter 137).

The gut, particularly the small intestine, is a common site for Kaposi sarcoma. While involvement is commonly asymptomatic, severe bleeding may occur (see Chapter 128).

Gastrointestinal bleeding in a patient with a dermatologic disease may also be due to drug therapy. The systemic administration of glucocorticoids commonly causes dyspepsia but may, more significantly, result in gastric erosions, ulceration, and hemorrhage. Methotrexate may cause enteritis, gastrointestinal ulceration, and hemorrhage.

BOX 150-3 SKIN ABNORMALITIES IN PATIENTS WITH GASTROINTESTINAL BLEEDING

- Congenital malformations of blood vessels
- Hereditary hemorrhagic telangiectasia
- Blue rubber bleb nevi
- Inherited defects of connective tissue
- Ehlers–Danlos syndrome
- Pseudoxanthoma elasticum
- Kaposi sarcoma
- Vasculitis
- Polyposis
- Ulcerative colitis and Crohn's disease
- Gastrointestinal tumors
- Drugs used to treat skin disease

ABDOMINAL PAIN

(Box 150-4)

Involvement of the sensory roots of the vertebrae T6–L1 in herpes zoster may produce abdominal pain even before skin lesions appear. Occasionally, herpes zoster in the distribution of S2, S3, and S4 is associated with perineal pain and disturbances of urination and defecation.

Acute attacks of urticaria or angioedema may present as abdominal pain. Edema of the bowel wall and mucosal thickening, often in association with free peritoneal fluid, is evident ultrasonographically—an aid to

BOX 150-4 SKIN ABNORMALITIES IN PATIENTS WITH ABDOMINAL PAIN

- Herpes zoster
- Angioedema
- Porphyria
- Fabry disease
- Vasculitis
- Henoch–Schönlein purpura
- Collagen vascular diseases
- Malignant atrophic papulosis
- Polyposis
- Gardner's syndrome
- Peutz–Jeghers syndrome
- Cronkhite-Canada syndrome
- Neurofibromatosis
- Ulcerative colitis
- Inflammatory bowel disease: ulcerative colitis and Crohn's disease
- Pancreatitis
- Gastrointestinal tumors
- Metastases
- Dermatomyositis
- Acanthosis nigricans
- Hypertrichosis lanuginosa

avoiding unnecessary surgery.[79] This is especially true in hereditary angioedema where colicky abdominal pain and life-threatening laryngeal edema occur and require treatment with injection of purified C1 inhibitor concentrate.[80]

It is only in the rare variegate porphyria that skin involvement and attacks of abdominal pain coexist (see Chapter 132). The skin shows changes identical to those in porphyria cutanea tarda (PCT). Pregnancy or drugs such as estrogen and griseofulvin may precipitate acute attacks. Although the detection of urinary uroporphyrin and fecal protoporphyrin indicates the diagnosis, plasma fluorescence with emission maxima at 626 nm is faster, easier and more sensitive it revealing the condition even in patients who are in remission.[81]

One-third of patients with systemic mastocytosis have gastrointestinal involvement. Symptoms include vomiting, abdominal pain, malabsorption, diarrhea, peptic ulceration, and gastrointestinal bleeding. Patients with more aggressive disease may develop hepatosplenomegaly with ascites and lymphadenopathy.[82–85]

ANGIOKERATOMA CORPORIS DIFFUSUM AND ANDERSON–FABRY DISEASE. Angiokeratoma corporis diffusum is the cutaneous marker for several inherited lysosomal disorders, due to deficiency of a number of enzymes, notably α-galactosidase A (the cause in Anderson–Fabry disease) (see Chapter 136). Signs include severe, painful neuropathy; progressive renal, cardiovascular, and cerebrovascular dysfunction. Gastrointestinal symptoms include abdominal pain and diarrhea. The diagnosis may be missed without the skin signs. Angiokeratomas may not appear until adolescence and, even then, can be subtle. Assay of α-galactosidase A is possible not only in established cases, but also before birth, and female carriers often identifiable. Treatment with intravenous infusions of α-galactosidase A is safe and efficacious.[86]

VASCULITIS. (See Chapter 163). Henoch–Schönlein purpura is palpable, especially on the legs and buttocks, and may occur in conjunction with joint swelling. Up to 76% of patients have gastrointestinal involvement, ranging from colicky abdominal pain, nausea, and vomiting to bloody diarrhea, intussusception, and pancreatitis. Renal involvement is common, especially in patients with bloody stools.[87] Upper gastrointestinal endoscopy reveals multiple raised erythematous lesions or ulceration that resolves after systemic treatment with glucocorticoids.[88]

Malignant atrophic papulosis is an idiopathic, systemic, obliterative vasculopathy (see Chapter 171). The characteristic skin lesions are recurrent crops of porcelain-white atrophic papules with an elevated erythematous border. These may have been present for years with no other apparent disease although gut vessels are involved in half of the cases.[89] Clinically bleeding, abdominal pain, diarrhea, malabsorption, and bowel perforation with peritonitis occur.

POLYPOSIS. True polyps are rare except in the colon and rectum. Polyp-like lesions that are hamartomatous or inflammatory occur in all parts of the gut. The term *hamartoma* implies a nonneoplastic tumor composed of tissue elements normally present in that organ. The hamartomatous polyposis syndromes (e.g., Peutz–Jeghers, Cronkhite-Canada) should be distinguished from the adenomatous polyposis syndromes (e.g., Gardner). In many of these syndromes, hamartomatous polyps of the gastrointestinal tract coexist with adenomas, and adenomas may develop within hamartomatous polyps contributing to the frequent occurrence of adenocarcinoma in most of these syndromes.[90]

Gardner syndrome is an autosomal dominant disorder characterized by cutaneous cysts and premalignant adenomatous polyps, particularly in the colorectum. Duodenal and hepatic carcinoma can also occur. The cutaneous lesions frequently predate the gastrointestinal lesions and include solitary or multiple epidermoid cysts, fibromas, lipomas, pilomatricomas, facial osteomas, and distinctive ocular lesions.[91]

Peutz–Jeghers syndrome is autosomal dominant and characterized by small darkly pigmented macules around the mouth, on the lips, buccal mucosa, and digits. A histologically unique type of hamartomatous polyp occurs, mainly in the small intestine, which predisposes to recurrent intussusception. Bleeding is relatively rare, but up to 2% of patients develop adenocarcinoma of the stomach, duodenum, and colon.[90] There is also an increased risk of malignancy in general.[92]

In *Cronkhite-Canada syndrome*, there is patchy alopecia and characteristic, nail changes.[90] Inflammatory polyps are present in the stomach and bowel, and abdominal pains with a severe protein-losing enteropathy are common.

Both ulcerative colitis and Crohn disease present with abdominal pain, gastrointestinal bleeding, or diarrhea. *Ulcerative colitis* predisposes to carcinoma of the colon. The skin complications of the two diseases are similar, although some occur with different frequencies. Up to one-half of patients with pyoderma gangrenosum may have inflammatory bowel disease, although only 12% of patients with ulcerative colitis and 2% of patients with Crohn disease will develop the condition (see Chapter 33).[93] The severity and extent of ulceration in pyoderma gangrenosum may be linked to the activity of the underlying disease, and pyoderma gangrenosum can heal with effective treatment of the underlying bowel disease. Erythema nodosum is well recognized.

Oral granulomatous nodules are common in *Crohn disease*, where they may coalesce to give a "cobblestone" appearance. Crohn disease is one cause of granulomatous cheilitis, which may predate bowel disease by several years. Granulomas may also occur in the perineum, at colostomy and ileostomy sites, and in association with scars, sinuses, and fistulas. Very rarely, granulomas occur at sites not contiguous with the bowel, such as the trunk and limbs: the so-called "metastatic" cutaneous Crohn disease.[94] Aphthous ulcers may be a presenting feature. Bruising of

the skin around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign) are well-known features of acute pancreatitis, but occur in less than 3% of cases.[95] Chronic pancreatitis may cause tender, subcutaneous nodular areas of fat necrosis that may ulcerate (see Chapter 70).

DIARRHEA AND MALABSORPTION

(Box 150-5)

Gastric bypass surgery or reduction with jejunoileal and jejunocolic anastomoses is used to treat morbid obesity. Dryness of the skin, hair loss, recurrent fever, arthralgia, and inflammatory and vasculitic skin lesions have been reported post operatively. "Bowel bypass syndrome without bowel bypass" is recognized as the same constellation of symptoms, but with other gastrointestinal disorders.[96]

CUTANEOUS EFFECTS OF MALABSORPTION OF SPECIFIC NUTRIENTS. Vitamin deficiency can follow intestinal surgery, pancreatic disease, malabsorption syndromes, and malnutrition, including that associated with alcoholism (see Chapter 130).[35]

- Vitamin A deficiency causes xerotic wrinkled skin covered with fine scales, occasionally accompanied by deep erosions (dermomalacia).
- Deficiency of vitamin B_3 causes pellagra with its triad of diarrhea, dermatitis, and dementia.
- Vitamin B_{12} (cyanocobalamin) deficiency is common in ileal malabsorption syndromes such as pancreatic disease. There is a symmetric "glove and stocking" hyperpigmentation, but a lemon yellow pallor to the skin elsewhere.
- Vitamin C deficiency classically causes follicular keratoses, hemorrhage, and corkscrew hairs.
- Malabsorption of vitamin K occurs in obstructive jaundice and leads to impaired coagulation, resulting in cutaneous hemorrhage with ecchymoses and purpura.
- A diffuse hyperpigmentation, cheilitis, and perineal ulceration or dermatitis can occur in folic acid deficiency states. Theoretically, drugs used for dermatologic diseases such as methotrexate, a folate antagonist, can exacerbate folic acid deficiency.
- Iron deficiency presents with angular stomatitis, smooth painful tongue, and fragile/brittle nails, which have longitudinal ridging and lamellation. In marked iron deficiency anemia koilonychia, a spoonlike convexity of the nails, develops. Hair changes include diffuse scalp alopecia with brittle, split hairs. All take a long time to resolve on replacement therapy.
- Zinc deficiency can result from acrodermatitis enteropathica, malabsorption, or a lack of zinc in long-term parenteral nutrition. Acrodermatitis enteropathica usually presents at weaning or in very early infancy with dermatitic or vesicobullous lesions of the hands, on the feet, and around the mouth and anus, together with progressive alopecia and "failure to thrive."

BOX 150-5 MALABSORPTION AND SKIN DISEASE

- Skin changes due to malabsorption
- Nonspecific
- Acquired ichthyosis and pruritus
- Hair and nail changes
- Hyperpigmentation
- Skin texture and elasticity
- Eczematous and psoriatic rashes
- Jejunoileal and jejunocolic anastomoses
- Specific nutrients
- Zinc
- Essential fatty acids
- Vitamins
- Malabsorption due to skin disease
- Dermatogenic enteropathy
- Collagen vascular disease
- Dermatitis herpetiformis and celiac disease

MALABSORPTION DUE TO SKIN DISEASE

Malabsorption can result from poor intestinal peristalsis in systemic sclerosis or chronic obliteration of mesenteric vessels in polyarteritis and other forms of vasculitis. In systemic sclerosis, 8% of patients develop malabsorption or recurrent intestinal pseudo-obstruction, usually within 3 years of disease onset.[66,97] Vasculopathy interferes with peristalsis and leads to malabsorption by allowing bacterial colonization higher up the bowel than is usual.

Small bowel tumors produce a variety of hormones and vasoactive amines of which the best characterized is serotonin. The most common tumors are in the appendix, rectum, and ileum, where they are usually multiple. Episodic flushing, wheezing, or diarrhea does not occur until the vasoactive amines reach the systemic circulation. Therefore, flushing usually indicates metastasis to the lymph nodes or liver or a primary tumor at a different site (e.g., lung or ovary).[98,99]

THE HEPATOBILIARY SYSTEM

Skin lesions occurring in association with liver disease are usually not specific to a particular disease. The most florid cutaneous lesions appear in patients with chronic active hepatitis or alcoholic liver disease, but may also occur in physiologic states such as spider nevi in pregnant women. There may be no visible skin changes in patients with severe liver disease and, conversely, dramatic cutaneous manifestations may develop in those with minimal hepatic dysfunction.

HEPATITIS AND THE SKIN

Cutaneous striae may appear in patients with chronic hepatitis, whatever the underlying cause and even before glucocorticoid therapy (see Fig. 150-1). Pyoderma gangrenosum, urticaria, vasculitis, acne, scleroderma, and splinter nail hemorrhages occur, depending on the underlying cause of the hepatitis.

The clinical features of infection with the different hepatotrophic viruses that cause *acute* viral hepatitis are similar. In the preicteric phase, malaise, lethargy, nausea, and abdominal pain occur. A discrete, transient, maculopapular, urticarial, or petechial rash may develop, together with arthritis or arthralgia. These symptoms may worsen with the appearance of jaundice, dark urine, and pale stools. Malaise and fatigue may persist for some time after resolution of the disease.

HEPATITIS A. Transmission of hepatitis A virus takes place via the fecal–oral route. Although relapses occur, hepatitis A does not progress to chronic hepatitis.

HEPATITIS B. Hepatitis B virus (HBV) is transmitted by percutaneous and permucosal routes. It is endemic in many countries, and health care professionals are at risk. A recombinant DNA vaccine is available, but has been associated with cutaneous side effects.[100–102] Five percent of HBV-infected subjects become carriers, and 90% of infants born of infected mothers develop chronic infection.

There are four main cutaneous associations of hepatitis B: (1) a serum sickness-like syndrome, (2) cryoglobulinemia, (3) polyarteritis nodosa, and (4) papular acrodermatitis of childhood. The serum sickness-like syndrome occurs in approximately 10% of patients in the preicteric phase of acute hepatitis B infection. Urticaria may be the predominant or sole feature, but is usually accompanied by a low-grade fever, arthralgia of the peripheral joints, proteinuria, and hematuria. There may be vasculitis.

Both HBV and hepatitis C virus (HCV) infection are associated with cryoglobulinemia although HCV infection is more common. Mixed cryoglobulinemia in HCV infection is usually of type III,[103] and the cryoglobulinemia may indicate the presence of active viral replication.[104] Patients develop recurrent purpura, acrocyanosis, arthralgia, lymphadenopathy, peripheral neuropathy, and hepatosplenomegaly. Renal involvement is common. Histopathologically, there is a necrotizing vasculitis (see Chapter 169).[104]

Polyarteritis nodosa can occur in the acute phase of HBV infection, or it may not present for several years. Circulating immune complexes containing hepatitis B surface antigen (HBsAg) and immunoglobulin occur. Leukocytoclastic vasculitis may develop.

Papular acrodermatitis (Gianotti–Crosti syndrome) (see Chapter 192) usually affects children. The appearance of monomorphic, flat-topped, erythematous papules on the face and limbs is characteristic. This eruption is self-limiting and asymptomatic in most, but may be accompanied by lymphadenopathy.[105] Other infectious agents and immunizations have been implicated in papular acrodermatitis.[106] Sweet syndrome has recently been reported with both acute[107] and chronic HBV infection.

HEPATITIS C. The majority of cases of posttransfusion hepatitis have been due to HCV infection, but screening has reduced the number of new cases dramatically. Cutaneous manifestations of acute and chronic HCV infection include leukocytoclastic vasculitis, usually due to cryoglobulinemia (see above); cutaneous necrosis[104] pruritus[108]; acquired angioedema[109] PCT; erythema nodosum; urticaria; erythema multiforme; and polyarteritis nodosa.[110]

Lichen planus occurs more commonly in patients infected with HCV,[111] although studies disagree on the incidence.[112] There is an increased frequency of the HLA-DR6 allele in Italian patients with HCV-associated oral lichen planus,[113,114] suggesting that host factors may play a part in this association.

Treating psoriasis in patients with hepatits C poses particular problems, partly because systemic therapies for psoriasis may be more hazardous but also because interferon α, which is frequently used in such patients, may exacerbate psoriasis.[115]

DISORDERS OF BOTH SKIN AND LIVER

(Box 150-6)

BOX 150-6 DISEASES WITH BOTH CUTANEOUS AND HEPATIC INVOLVEMENT

- Argininosuccinic aciduria
- Dermatomyositis
- Drug reactions
- Eruptive neonatal angiomatosis
- Graft-versus-host disease
- Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease)
- Histiocytoses
- Immunodeficiency states
- Mastocytosis
- Mucocutaneous lymph node syndrome (Kawasaki disease)
- Porphyrias
- Porphyria cutanea tarda
- Variegate porphyria
- Erythropoietic (erythrohepatic) porphyria
- Hereditary coproporphyria
- Sarcoidosis
- Syphilis
- Systemic lupus erythematosus
- Tuberous sclerosis
- Vinyl chloride disease

Argininosuccinic aciduria is a rare autosomal recessive disorder characterized by ataxia, seizures, severe mental retardation, hepatomegaly with liver dysfunction, and brittle hair. Dermatomyositis may be the presenting sign of a primary[116] or secondary hepatic tumour. In eruptive neonatal angiomatosis, multiple angiomas may occur anywhere on the skin surface; in addition, vascular lesions may occur in internal organs, including the liver. Both acute and chronic phases of graft-versus-host reactions may have prominent effects on both skin and liver, most commonly in patients receiving bone marrow transplants. In hereditary hemorrhagic telangiectasia, arteriovenous fistulas can cause shunting, and "cirrhosis" (i.e., multiple small telangiectatic hepatic vessels) occurs.[67] Several of the histiocytoses, including Langerhans cell histiocytosis and malignant histiocytosis, may involve both skin and liver. Immunodeficiency states may result in multiple infections of skin and liver. Examples include congenital disorders (e.g., ataxia telangiectasia, Chediak–Higashi syndrome, chronic granulomatous disease) and acquired disorders (e.g., AIDS).

Hepatomegaly occurs in systemic mastocytosis.[82–85] In Kawasaki disease, children may develop upper abdominal pain associated with hepatobiliary changes, nonspecific elevation of liver enzyme levels due to vasculitic changes, or bile duct inflammation.[117] Sarcoidal infiltration of the liver may accompany the cutaneous signs of sarcoidosis. Hepatic granulomas may also occur in tuberculosis, glandular fever, and syphilis, or as a side effect of drugs such as phenylbutazone, allopurinol, and the sulfonamides. True syphilitic hepatitis is rare but may present with pruritus and cholestatic jaundice.

Patients with systemic lupus erythematosus can have abnormal liver tests.[118] The most common cause is drug-induced hepatitis. Thrombotic conditions, including Budd–Chiari syndrome and veno-occlusive disease, occur with or without lupus anticoagulant. Rare abnormalities include nodular regenerative hyperplasia, perihepatitis, and hepatic or splenic rupture. Autoimmune hepatitis, PBC,[119] granulomatous hepatitis, cryptococcal infection, porphyria, or idiopathic portal hypertension[120] may also occur.

Cholestatic hepatitis occurs as a rare complication of Stevens–Johnson syndrome and has been reported to precede the skin signs.[121]

Angiomyolipomas are frequently seen on ultrasound examination of the livers of patients with tuberous sclerosis but are usually asymptomatic. Liver function abnormalities are common in patients with vinyl chloride disease and may be associated with hepatosplenomegaly, cirrhosis, and, rarely, angiosarcoma.

CUTANEOUS MANIFESTATIONS OF PRIMARY BILIARY CIRRHOSIS. The basis for a diagnosis of PBC is a clinical picture of a middle-aged female with jaundice and pruritus, cholestatic liver function tests, antimitochondrial antibodies, and histologic changes in the liver of inflammatory duct destruction with fibrosis and cirrhosis. Severe itching may antedate other features of biliary cirrhosis by months or years.

The combination of the CREST syndrome (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) and PBC occurs more often than would be expected by chance and has been termed Raynold syndrome. Patients have a higher incidence of anticentromere antibodies (especially the antiprotein C isotype) and Sjögren syndrome.[122]

Lichen planus has a well-recognized association with PBC and may occur in either the presence or the absence of penicillamine treatment for PBC,[123] and isolated nail involvement has been described.[124] The skin lesions can resolve following liver transplantation.[125] Cutaneous xanthomas also occur with PBC. Rarely, both lichenoid and xanthomatous changes appear in the same lesion.[126]

EFFECTS OF SKIN DISEASE ON THE LIVER

Several systemic complications occur as a consequence of skin disease, and some of them reflect abnormalities of hepatic function.

EXTENSIVE LOSS OF SKIN. Patients may lose large areas of skin because of thermal burns, immunobullous disease, or toxic epidermal necrolysis. In experimental animal models, extensive thermal injury results in a halving of the hepatic arterial blood flow.[127] Postburn sepsis amplifies this injury and induces portal hypertension.[128] This may in turn account for a gut barrier dysfunction (the so-called "dermatogenic enteropathy"), but research has not convincingly demonstrated this relationship in humans with extensive skin disease.

PSORIASIS. The high incidence of abnormalities of the liver architecture in patients with psoriasis has been attributed to alcohol misuse. Psoriasis is more common than expected in alcoholic cirrhosis than in cirrhosis due to other causes.[8,129] Those who misuse alcohol are said to have a unique, acral, distribution of psoriasis.[8] Alcohol appears not only to trigger psoriasis, especially in men, but also to influence the course of the disease, as heavy drinkers have more severe, extensive, inflamed disease. Patients who decrease alcohol consumption may decrease the extent of their disease and increase their response to treatment.[129]

DERMATITIS HERPETIFORMIS. Results of liver function tests are sometimes abnormal in patients with dermatitis herpetiformis[130] and can also occur secondary to treatment or as a result of associated conditions.[131]

SKIN CANCER. Primary cutaneous neoplasms, including melanoma, squamous cell carcinoma, Merkel cell tumor, and Kaposi sarcoma, occasionally metastasize to the liver.

TABLE 150-1
Hepatotoxic Drugs Used in the Treatment of Skin Diseases

Drug	Indication	Side Effect
Azathioprine	Bullous disorders, dermatomyositis	Raised liver enzymes
Cyclosporin	Psoriasis, dermatitis	Raised liver enzymes
Cyproterone acetate	Hirsutism and virilization	May worsen preexisting dysfunction
Danazol	Hereditary angioedema	May worsen preexisting dysfunction and porphyria
Dapsone	Dermatitis herpetiformis, erythema elevatum diutinum, granuloma faciale, and others	May cause dapsone syndrome (rash, eosinophilia fever hepatitis). Avoid in porphyria
Griseofulvin	Fungal infections	May worsen preexisting liver disease
Ketoconazole	Fungal infections	Raised liver enzymes and hepatitis
Methotrexate	Psoriasis, sarcoidosis	Cirrhosis
Minocycline	Acne	Hepatitis
Retinoids	Acne, psoriasis, disorders of keratinization	Elevated liver enzymes, increases hepatotoxicity of methotrexate
Stanozolol	Hereditary angioedema	May worsen preexisting dysfunction and porphyria
Terbinafine	Fungal infections	Hepatitis

HEPATOTOXIC EFFECTS OF DRUGS USED IN THE TREATMENT OF SKIN DISEASE

Several drugs used in managing patients with skin disease are hepatotoxic (Table 150-1). Many others, such as antimalarials or terbinafine, warrant caution in patients with hepatic impairment.

Patients who have psoriasis and who are undergoing long-term treatment with methotrexate are at risk of liver fibrosis and cirrhosis, especially if their total doses exceed 1.5 g, and/or if there is a history of alcohol misuse, impaired renal function, diabetes, and obesity. The definitive diagnosis of fibrosis is histologic but the morbidity of liver biopsy can be as high as 10%, and the mortality up to 0.1%.[133] Reducing the risk factors and careful monitoring probably reduces the need for invasive investigation considerably,[132] especially if more sophisticated screening methods are used. In hepatic fibrosis, the synthesis of predominantly type III collagen is increased, and the amino-terminal propeptide of type III procollagen (PIIINP) is cleaved off and released into the circulation.[134,135] Because it is now possible to measure serum PIIINP levels accurately, this test has become a valuable noninvasive marker of active hepatic fibrogenesis during methotrexate treatment of psoriasis.[136] Thus, the number of liver biopsies taken in patients with normal serial serum PIIINP levels can be reduced to a minimum.[137] Another technique that may prove useful is transient elastography, which has already been used for monitoring patients with Crohn disease.[138] Some preliminary work in methotrexate-treated psoriatics has been reported,[139] but further studies are required.[140]

THE RENAL SYSTEM

The cutaneous manifestations of renal disease are primarily encountered in patients with CRF. In contrast, only two skin changes—edema and uremic frost—occur in acute renal failure (ARF). Edema is a particular feature of ARF with nephrotic syndrome. Uremic frost results from eccrine deposition of urea crystals on the skin surface of individuals with severe uremia. It is now rare because of the wide availability of acute hemodialysis.

CALCIFICATION

Metastatic calcification of the skin in CRF results from secondary or tertiary hyperparathyroidism. Abnormally elevated levels of PTH may trigger deposition of crystalline calcium pyrophosphate in the dermis, subcutaneous fat, or arterial walls.[141] Vascular calcification is common in patients with long-term CRF, and is seldom symptomatic. Occasionally, however, calcified vessels may thrombose acutely, resulting in a syndrome that has been called *calciphylaxis*. This acute thrombosis produces livedoid areas that are excruciatingly painful due to ischemia, and quickly become hemorrhagic and ulcerate (Fig. 150-13). Calciphylaxis is associated with a high mortality, particularly when the skin of the trunk is involved.[141] PTH is usually markedly elevated. The serum calcium and

Figure 150-13 Calciphylaxis. (Used with permission from Suzanne N. Granados, MD.)

phosphate levels, and the calcium-phosphate product, are frequently only minimally elevated and may be normal. Treatment of calciphylaxis includes analgesia debridement of gangrenous tissue, and parathyroidectomy.[141,142]

In addition to vascular calcification and calciphylaxis, nodular calcification may occur in the skin and fat of patients with CRF. These calcium deposits are identical to calcinosis cutis in other disorders, such as tumoral calcinosis or CREST syndrome. The involved skin may ulcerate, but this process occurs in a subacute fashion, without livedo or ischemic pain.

BULLOUS DISEASE OF HEMODIALYSIS

PCT has been described in patients with CRF undergoing hemodialysis.[143] Although the etiology of this phenomenon is still unclear, inadequate clearance of plasma-bound porphyria precursors by urine excretion or hemodialysis[144] may lead to porphyrin deposition in the skin manifested clinically as photosensitivity and subepidermal bullae.[143–147] Patients undergoing hemodialysis may also produce or be exposed to compounds that alter normal heme synthesis.

Bullous dermatosis of dialysis or pseudoporphyria may occur in up to a fifth of patients undergoing hemodialysis.[143,145,147] This condition is often clinically indistinguishable from PCT with marked skin fragility and blister formation on sun-exposed skin (see Chapter 132). However, hypertrichosis is less common, and plasma porphyrin levels are typically normal.[143,145] Pseudoporphyria may also occur in some patients taking tetracycline, nabumetone, nalidixic acid, furosemide, and phenytoin.[143]

When treating PCT or pseudoporphyria, phlebotomy can reduce iron levels in the liver, allowing new hepatic uroporphyrinogen decarboxylase to be formed.[148] However, patients with end-stage renal disease often have significant anemia and cannot tolerate phlebotomy. Intravenous erythropoietin[147] may both lower total body iron stores and support phlebotomy as needed.[146,148] Chloroquine effectively clears porphyrins from the liver. In patients with CRF, however, porphyrins may not be effectively cleared by hemodialysis or excreted in the urine.[147] Deferoxamine may lower serum porphyrin levels in some patients.[146] Others may require renal transplantation to obtain complete resolution of symptoms.[146]

ACQUIRED PERFORATING DERMATOSES

Acquired perforating dermatosis can occur in association with CRF and diabetes mellitus (see Chapter 69)[149] This condition occurs in up to 10% of patients undergoing hemodialysis[150,151] and appears to be distinct from the four primary perforating disorders elastosis perforans serpiginosa, Kyrle disease, perforating folliculitis, and reactive perforating collagenosis.[152] Clinically, patients develop hyperkeratotic papules with a central crust-filled crater on the trunk and extensor surfaces, often in a linear distribution.[150] Simultaneous transepidermal elimination of both collagen and elastic fibers has been detected.[151]

Proposed mechanisms for the etiology of this process include diabetic microangiopathy, dysregulation of vitamin A or vitamin D metabolism, abnormality of collagen or elastic fibers, or inflammation and connective tissue degradation caused by dermal deposition of substances such as uric acid and calcium pyrophosphate.[153] Many authorities regard this entity as a response to trauma caused by scratching in chronic renal pruritus. Successful treatment depends on addressing the underlying etiology of pruritus. Topical and intralesional glucocorticoids, topical and systemic retinoids, cryotherapy, and ultraviolet light may be useful.[150,151]

NEPHROGENIC FIBROSING DERMOPATHY

Nephrogenic fibrosing dermopathy (NFD),[154] resembling scleromyxedema in some of its aspects,[155] largely occured in patients with end stage renal disease, most of whom were on hemodialysis. NFD also has been described in a few patients with ARF. Clinically, patients progressively develop erythematous, sclerotic dermal plaques on the arms and legs, with sparing of the head and neck. Pruritus is a common feature. The histopathology of NFD similarly resembles that of scleromyxedema, with proliferation of fibroblasts in the dermis and subcutaneous septae, accompanied by increased dermal and septal collagen and mucin.[156] It is now clear that NFD is closely linked to the use of gadolinium contrast in magnetic resonance procedures.[157]

LOWER LIMBS

In acquired clotting defects, such as thrombocytopenia and vascular fragility, purpuric lesions, ranging from pinpoint-sized spots to large ecchymoses, occur. They may be transient and recurrent, and they are sometimes accompanied by follicular hyperkeratosis.[3]

CHOLESTEROL EMBOLI

In patients with advanced atherosclerosis of the abdominal aorta, cholesterol crystals may microembolize to the lower extremities, particularly after invasive vascular procedures or surgery (see Chapter 173). The pulses may remain normal. Patients complain of pain in the legs, buttocks, and low back, as well as myalgia, restless legs, and abdominal symptoms. Livedo reticularis may affect the lower abdomen and back, buttocks, and legs. Ulcers on the legs and feet, surrounded by an erythematous or violaceous halo and a small scab, may be present. Digital cyanosis and gangrene may simulate necrotizing vasculitis (Fig. 150-14). Indurated plaques and nodules are firm, violaceous, painful, and necrotic in the center. Deep skin biopsy of areas of livedo reticularis or adjacent to nodules or ulceration reveal occlusions of arterioles by multinucleated foreign-body giant cells and fibrosis surrounding biconvex, needle-shaped clefts corresponding to the cholesterol crystal microemboli.[158]

POSTBYPASS SKIN CHANGES

Coronary artery bypass surgery is commonly performed using the superficial veins of the legs as donor-graft sites. Dermatitis has been reported to occur along the saphenous vein graft scars on the medial aspect of the legs 2–6 months after surgery. Patients have no history of venous stasis, thrombophlebitis, ankle edema, or skin disease. Examination reveals a reddish-brown, scaling and fissured dermatitis along the distal part of a well-healed saphenous vein graft scar. The dermatitis responds to topical steroids but recurrence is usual and most patients require continued treatment. The cause may be due to postoperative thrombophlebitis and stasis dermatitis.

Recurrent cellulitis may develop in the healed vein graft many months after surgery. Erythema may extend along the entire vein graft site, accompanied by pain and tenderness. Swelling may be significant. Beta-hemolytic streptococcus has been isolated. The presence of tinea pedis has been reported and patients should be assessed and treated prior to surgery.

:: Andrea A. Kalus, Andy J. Chien, & John E. Olerud

DIABETES MELLITUS

DIABETES MELLITUS AT A GLANCE

- The incidence of diabetes in America is increasing steadily with the epidemic of obesity.
- Eleven percent of health care expenditures in America are diabetes related.
- Metabolic abnormalities in glucose and insulin relate directly to diabetic thick skin, limited joint mobility, eruptive xanthomas, and acanthosis nigricans.
- Neuropathy, vasculopathy, and immune dysfunction associated with diabetes contribute directly to lower extremity ulcers and certain cutaneous infections.
- Diabetes-associated skin conditions without a known pathogenesis include: necrobiosis lipoidica, granuloma annulare, diabetic dermopathy, acquired perforating dermatosis, and bullosis diabeticorum.

EPIDEMIOLOGY

Diabetes mellitus (DM) is a major cause of morbidity and mortality in the United States. More than 24 million Americans have the disease[1], and approximately 11% ($92 billion) of all health care expenditures in the United States were directly attributable to the medical care of diabetes in 2002.[2] Men and women diagnosed with diabetes at age 40 years are expected to lose 12 and 14 life-years, respectively.[3] Major studies have shown that tight glycemic control decreases microvascular disease, i.e., retinopathy, neuropathy, nephropathy, however, coronary vascular disease, the major contributor to morbidity and mortality in patients with diabetes, showed no benefit from intensive glycemic control for patients with a known 10-year duration of diabetes. In one large randomized controlled trial with about a third of patients with known coronary artery disease, intensive glycemic control was, in fact, associated with an increase in mortality. Newly diagnosed type 2 diabetes appears to have long-term benefit from similar degrees of tight control.[4] New guidelines for glycemic control (HbA1c <7%) attempt to balance this body of evidence. The data and guidelines have been recently reviewed.[5] Tight glycemic control may have a beneficial effect on a subset of skin-related, diabetes-associated disorders, but evidence is generally lacking.

Diabetes is characterized by a state of relative or complete insulin deficiency, leading to gross defects in glucose, fat, and protein metabolism. In type 1 diabetes (formerly insulin-dependent DM), an insufficiency of insulin occurs through a gradual, immune mediated destruction of β islet cells in the pancreas, marked by autoantibodies. In type 2 diabetes (formerly noninsulin-dependent DM), chronic hyperglycemia occurs mainly through end-organ insulin resistance followed by a progressive decrease in pancreatic insulin release associated with aging. A fasting blood glucose level of ≥126 mg/dL or a random value of ≥200 mg/dL on two separate occasions confirms the diagnosis of diabetes. Diabetes may also now be diagnosed with an HbA1c level ≥6.5%. A genetic predisposition and a strong association with obesity exist in type 2 diabetes. In both types of diabetes, abnormalities of insulin and elevated blood glucose levels lead to metabolic, vascular, neuropathic, and immunologic abnormalities. Affected organs include the cardiovascular, renal, and nervous systems, the eyes, and the skin.

ETIOLOGY AND PATHOGENESIS

Nearly all patients with diabetes have cutaneous findings related to their condition, including those listed in Box 151-1. Some diabetes-associated skin conditions are a direct result of the related metabolic changes such as hyperglycemia and hyperlipidemia. Progressive damage to the vascular, neurologic, or immune systems also contributes significantly to skin manifestations. The mechanisms for other diabetes-associated skin conditions remain unknown.

Hyperglycemia leads to nonenzymatic glycosylation (NEG) of various structural and regulatory proteins, including collagen. Although NEG occurs normally with aging, the process is greatly accelerated in diabetes.[6,7] NEG leads to the formation of advanced glycation end products (AGEs) that are responsible for decreases in both acid solubility and enzymatic digestion of cutaneous collagen. Disorders such as diabetic thick skin and limited joint mobility (LJM) are thought to result directly from accumulation of AGEs.[8] Studies show that the degree of cutaneous AGEs correlates strongly with retinopathy, nephropathy, and other microvascular complications of diabetes.[9]

Derangements of immunoregulatory mechanisms also occur in diabetes. Hyperglycemia and ketoacidosis diminish chemotaxis, phagocytosis, and

BOX 151-1 APPROACH TO PATIENT WITH DIABETES

CUTANEOUS FINDINGS IN DIABETES

- Acanthosis nigricans
- Limited joint mobility and scleroderma-like syndrome
- Scleredema diabeticorum
- Eruptive xanthomas
- Bacterial infections (streptococcal, malignant external otitis, necrotizing fasciitis)
- Fungal infections (candidal, onychomycosis, mucormycosis)
- Foot ulcers
- Necrobiosis lipoidica
- Granuloma annulare
- Diabetic dermopathy
- Acquired perforating disorders
- Bullosis diabeticorum

RELATED FEATURES IN DIABETES

- Retinopathy
- Nephropathy
- Neuropathy
- Cardiovascular disease
- Peripheral vascular disease
- Hyperlipidemia
- Hypertension

DIAGNOSIS

- In the absence of symptoms, the diagnosis must be confirmed by two separate abnormal tests, fasting blood glucose of ≥126 mg/dL or random value of ≥200 mg/dL.
- Hemoglobin A1C is increasingly being used in conjunction with fasting plasma glucose for the diagnosis of diabetes mellitus.

MANAGEMENT

- Diet and exercise.
- Referral to primary care provider or endocrinologist for medical management with either oral hypoglycemic agents or insulin.
- Always perform a foot examination.
- Address modifiable risk factors.

bactericidal ability of white blood cells.[10] Historically, infections were a major cause of death in the diabetic patient. This has changed dramatically with improved glucose control and antibiotic use. Despite these improvements, certain infections, such as malignant external otitis, necrotizing soft tissue infections, and the devastating disease of mucormycosis, occur more frequently in patients with diabetes.[11]

Metabolic abnormalities, including hyperinsulinemia, as is seen in early insulin-resistant type 2 diabetes, can contribute to cutaneous manifestations as well. The action of insulin on the insulin-like growth factor-1 (IGF1) receptor appears to mediate the abnormal epidermal proliferation and resulting phenotype of acanthosis nigricans.[12] Dysregulated lipid metabolism occurs with diabetes-associated insulin deficiency. The activity of lipoprotein lipase (LPL) is directly dependent on insulin,[13] making insulin central to the processing of triglyceride-rich chylomicrons and very-low-density lipoproteins. In insulin-deficient diabetic patients, defective lipid processing can lead to massive hypertriglyceridemia, manifesting in the skin as eruptive xanthomas. Naturally, disorders of lipid processing also play an integral role in the vasculopathies of diabetes.

Macro- and microangiopathy contribute significantly to the cutaneous complications of diabetes. In patients with diabetes, there is increased "leakiness" or vessel wall permeability, decreased vascular responsiveness to sympathetic innervation, and less ability to respond to thermal and hypoxemic stress.[10] In combination with arteriosclerosis of large vessels, these microvascular abnormalities contribute to the formation of diabetic ulcers. In addition, a loss of cutaneous sensory innervation occurs with diabetes, predisposing patients to infection and injury. The loss of neuroinflammatory cell signaling plays a causal role in nonhealing, lower extremity ulcers.[14] Patients with diabetes who lack lower extremity vibratory perception have a 15.5-fold increased probability of leg amputation.[15]

The cutaneous disorders associated with DM are characterized in the following section by disorders with evidence for metabolic, vascular, neurologic, or immunologic pathogenesis induced by glucose and insulin abnormalities and by disorders associated with diabetes, but without a clear pathogenesis (see below).

CUTANEOUS DISORDERS OF DIABETES MELLITUS ASSOCIATED WITH METABOLIC, VASCULAR, NEUROLOGIC, OR IMMUNOLOGIC ABNORMALITIES

ACANTHOSIS NIGRICANS

EPIDEMIOLOGY. Acanthosis nigricans is probably the most readily recognized skin manifestation of diabetes. Acanthosis nigricans is common in the general population, and most cases are linked to obesity and insulin resistance. In some cases, increased androgen production is also identified.[16,17] Drug-related and idiopathic acanthosis nigricans or familial acanthosis nigricans have been reported.[18] In general, though, acanthosis nigricans should be considered a prognostic indicator for developing type 2 diabetes.[19] The prevalence of acanthosis nigricans varies among different ethnic groups. In one study, despite similar obesity rates, the prevalence was lower in whites (0.5%)

and Hispanics (5%) than in African-American children (13%).[17] This finding suggests a possible genetic predisposition or increased sensitivity of the skin to hyperinsulinemia among certain populations.[19] Although historical data have emphasized the relationship between acanthosis nigricans and malignancy, a true association is rare. Only when the onset is particularly rapid, the clinical findings are florid, or in the nonobese or nondiabetic adult with acanthosis nigricans is an evaluation for malignancy beyond routine age appropriate screening warranted. In one author's experience with seeing more than 12,000 patients with cancer, only two developed acanthosis nigricans.[20]

ETIOLOGY AND PATHOGENESIS. Advances are taking place in understanding the pathogenesis of acanthosis nigricans. Insulin clearly plays a central role in the presentation of acanthosis nigricans. In a subset of women with hyperandrogenism and insulin resistance with acanthosis nigricans, loss of function mutations in the insulin receptor or anti-insulin receptor antibodies can be found (type A and type B syndrome).[21] It is postulated that excess growth factor stimulation in the skin causes the aberrant proliferation of keratinocytes and fibroblasts that results in the phenotype of acanthosis nigricans.[16] In states of insulin resistance and hyperinsulinemia, acanthosis nigricans may result from excess insulin binding to IGF1 receptors on keratinocytes and fibroblasts.[12] IGF1 receptors are expressed on basal keratinocytes and are upregulated in proliferative conditions.[22] Studies show that high concentrations of insulin stimulate fibroblast proliferation through IGF1 receptors in vitro.[23] Other members of the tyrosine kinase receptor family, including the epidermal growth factor receptor and the fibroblast growth factor receptor, have been implicated in acanthosis nigricans. Several genetic syndromes [Crouzon and SADDAN (severe achondroplasia with developmental delay and acanthosis nigricans)] with mutations in fibroblast growth factor receptor 3 result in acanthosis nigricans in the absence of hyperinsulinemia or obesity, implicating this growth factor receptor in the pathogenesis of acanthosis nigricans.[22] In several reports of acanthosis nigricans associated with malignancy, evidence suggests that transforming growth factor-β released from the tumor cells may stimulate keratinocyte proliferation via the epidermal growth factor receptors.[24,25] Support for the role of different growth factors in the pathogenesis of acanthosis nigricans continues to accrue.

In addition to the direct effects of hyperinsulinemia on keratinocytes, insulin also appears to augment androgen levels in women. High insulin levels stimulate the production of ovarian androgens and ovarian hypertrophy with cystic changes.[21] Although associated with elevated androgen levels, the acanthosis nigricans in women with polycystic ovarian syndrome (PCOS) does not respond reliably to antiandrogen therapy, implicating the relative importance of hyperinsulinemia over hyperandrogenism in acanthosis nigricans. Several drugs have also been reported to cause acanthosis nigricans, including systemic glucocorticoids, nicotinic acid, and estrogens such as diethylstilbestrol.[16]

Figure 151-1 Acanthosis nigricans involving the neck.

CLINICAL FINDINGS: CUTANEOUS LESIONS. Clinically, acanthosis nigricans presents as brown to gray-black papillomatous cutaneous thickening in the flexural areas, including the posterolateral neck, axillae, groin, and abdominal folds. The distribution is usually symmetric. The affected skin has a dirty, velvety texture. In some cases, oral, esophageal, pharyngeal, laryngeal, conjunctival, and anogenital mucosal surfaces may be involved. In general, however, the back of the neck is the most consistently and severely affected area[19] (Fig. 151-1). The development of superimposed acrochordons in involved areas is well described (Fig. 151-2). In particularly florid cases, involvement on the back of the hands over the knuckles and even on the palms can be seen. When the palms are involved, the rugated appearance of the palmar surface has been called *tripe palms* and is usually associated with acanthosis nigricans seen in the

Figure 151-2 Acanthosis nigricans involving the axilla with numerous acrochordons.

setting of malignancy. In the majority of cases, the most important factor in diagnosing acanthosis nigricans is recognizing the usually associated hyperinsulinemia, which is a known risk factor for type 2 diabetes and the metabolic syndrome.

The histopathology of clinical lesions demonstrates papillomatosis and hyperkeratosis but minimal acanthosis. Hyperpigmentation of the basal layer has been variably demonstrated and the brown color of the lesions is attributed to the hyperkeratosis by most.[26,27]

TREATMENT. Treatment of acanthosis nigricans is generally ineffective. Topical treatment with calcipotriol,[28] salicylic acid, urea, systemic, and topical retinoids have all been used with anecdotal success.[29] When identifiable, treatment of the underlying cause may be beneficial. Improvement or resolution does occur with weight loss in some obese patients.[12,16] Medications that improve insulin sensitivity, such as metformin, have a theoretic benefit. Removal of an offending medication generally results in clearance of the skin.[30] In patients with acanthosis nigricans in association with malignancy, there is usually improvement following treatment of the underlying malignancy. The skin finding may present before or after the diagnosis of malignancy is made. When it is associated with malignancy, a tumor of intraabdominal origin, usually gastric, is seen in the majority of cases.[31] It has been repeatedly described that patients' skin improves with chemotherapy and remits with recurrences.

DIABETIC THICK SKIN

Several specific syndromes are associated with localized thickening of the skin in diabetes. The common underlying pathogenesis involves biochemical alterations in dermal collagen and mucopolysaccharides. The clinical syndromes are a result of increased deposition and improper degradation of these constituents, likely related to the formation of AGEs.

LIMITED JOINT MOBILITY AND SCLERODERMA-LIKE SYNDROME

Diabetic LJM, or cheiroarthropathy, presents as tightness and thickening of the skin and periarticular connective tissue of the fingers, resulting in a painless loss of joint mobility. Initial involvement of the distal interphalangeal joints of the fifth digit usually progresses proximally to involve all fingers. Larger joints of the elbow, knee, and foot may be affected. The actual joint space, however, remains uninvolved, so that LJM is not a true arthropathy. This disorder is characterized by the "prayer sign," which is an inability to approximate the palmar surfaces and interphalangeal joint spaces with the hands pressed together and fingers separated (Fig. 151-3). In addition to joint contractures, the skin may appear thickened, waxy, and smooth with apparent loss of adnexa, resembling skin changes in scleroderma.

Thirty to fifty percent of adult patients with type 1 diabetes have LJM, and it is common in type 2 diabetes as well. LJM is associated with increased duration of diabetes and poor glucose control.[32,33] One longitudinal prospective study showed a 2.5-fold increase in the risk of LJM for every unit increase in the glycosylated hemoglobin.[33] In addition, it appears that LJM may be correlated with the presence of microvascular disease.[34]

Figure 151-3 Limited joint mobility in a 31-year-old male patient with type 1 diabetes mellitus. The patient is unable to approximate the palmar surface of the proximal and distal interphalangeal joints with palms pressed together (known as the *"prayer sign"*). **A.** Ulnar view; only fingertips are approximated. **B.** Radial view; straining to press palms together.

Most important, the evidence indicates that intensive insulin therapy is central in prevention and, possibly, treatment of LJM and scleroderma-like syndrome. Long-term tight glycemic control leads to decreased skin AGEs,[9] and tight glycemic control is associated with delayed onset and severity of LJM.[33] On the basis of improvements in diabetes management, a fourfold reduction in the frequency of LJM over the last 20 years was reported.[35] Treatment for LJM is difficult and should focus on tight control of blood sugar as well as physical therapy to preserve active range of motion.

Although the scleroderma-like skin changes can occur independently, they often occur together with LJM in patients with diabetes. The scleroderma-like syndrome is not associated with systemic sclerosis but does correlate with the duration of diabetes, the severity of joint contractures, and retinopathy.[36] It seems likely that the historical description of "diabetic hand syndrome" represents a combination of LJM and the scleroderma-like syndrome.

SCLEREDEMA DIABETICORUM

(See Chapter 158)

Recognized in 1970 as a syndrome,[37,38] scleredema of diabetes (scleredema diabeticorum) presents with the insidious onset of painless, symmetric induration and thickening of the skin on the upper back and neck. Spreading to the face, shoulders, and anterior torso may occur. The skin retains a nonpitting, woody, *peau d'orange* quality. Identical changes occur with postinfectious scleredema, usually associated with streptococcal pharyngitis. In scleredema associated with infection, however, the onset is often sudden, and the symptoms usually remit over time. Scleredema diabeticorum affects 2.5%–14% of patients with diabetes.[39,40] Scleredema diabeticorum is a disease of long-standing diabetes associated with obesity. Most patients have type 2 diabetes. This disorder has not been reported in children.

The pathogenesis of scleredema diabeticorum is postulated to be unregulated production of extracellular matrix molecules by fibroblasts, leading to thickened collagen bundles and increased deposition of glycosaminoglycans (GAGs, mainly hyaluronic acid). Studies using in vitro fibroblast analysis from involved skin have variably demonstrated increased synthesis of GAGs and type I collagen.[41] However, most of these reports involved nondiabetic patients with paraproteinemia and are based on small numbers of cases.

Patients with scleredema diabeticorum may experience decreased sensation to pain and light touch over the affected areas and difficulties with upper extremity and neck range of motion. Extreme cases may result in full loss of range of motion. Unlike in LJM and scleroderma-like syndrome, the presence of scleredema does not correlate with retinopathy, nephropathy, neuropathy, or principal vascular disease.[39] However, no large-scale prospective studies have been done. Most patients with scleredema diabeticorum become insulin dependent are difficult to treat, and have multiple complications of diabetes.[41] Treatment for scleredema diabeticorum is usually unsuccessful. Case reports describe treatment with radiotherapy, low-dose methotrexate, bath psoralen and ultraviolet A light (PUVA), extracorporeal photopheresis, factor XIII, and prostaglandin E_1.[38,42,43] Weight reduction and physical therapy to preserve range of motion may be useful.

ERUPTIVE XANTHOMAS

(See Chapter 135)

Eruptive xanthomas present clinically as 1- to 4-mm, reddish-yellow papules on the buttocks and extensor surfaces of the extremities (Fig. 151-4). The lesions occur in crops and may coalesce into plaques over time. Although eruptive xanthomas are generally asymptomatic, there is often underlying severe hypertriglyceridemia (>1,000 mg/dL) and potentially undiagnosed diabetes. Histologic and biochemical studies show that lipoproteins (mainly chylomicrons) in the blood permeate cutaneous vessel walls and accumulate in macrophages in the dermis.[44] Initially, triglycerides predominate in the skin lesions but, because triglycerides are mobilized more easily than cholesterol, the lesions contain progressively more cholesterol as they resolve.[44] Whether this mechanism plays a role in the atherosclerosis of large arteries is unknown.

Insulin is an important regulator of LPL activity. The degree of enzymatic dysfunction and subsequent clearing of serum triglycerides is proportionate to the amount of insulin deficiency and hyperglycemia.[13] Clearance of plasma lipoproteins depends on adequate insulin.[45] In uncontrolled diabetes, this inability to metabolize and clear triglyceride-rich chylomicrons and very-low-density lipoproteins can lead to plasma triglyceride levels in the thousands. Uncontrolled diabetes is a common cause of massive hypertriglyceridemia.

In addition to eruptive xanthomas, triglyceride levels above 4,000 may cause lipemia retinalis. On funduscopic examination, lipemia retinalis appears as pale pink to white retinal arterioles and venules.

Figure 151-4 Eruptive xanthomas appear as yellow–orange papules and plaques on a male patient with type 2 diabetes mellitus. (Used with permission from Greg Raugi, MD.)

The fundus may have a milky hue. Untreated, severe hypertriglyceridemia may also present clinically with abdominal pain, hepatosplenomegaly, pancreatitis, or dyspnea from decreased pulmonary diffusing capacity and abnormal hemoglobin oxygen affinity.[46] Treatment of hypertriglyceridemia involves strict dietary fat restrictions and control of the underlying diabetes. LPL activity returns to normal after treatment with long-term insulin or oral glucose-lowering agents.[13] The eruptive xanthomas respond rapidly and usually resolve completely in 6–8 weeks.[47]

CUTANEOUS INFECTIONS

In diabetic patients, there is not strong evidence for an increased susceptibility to infections in general, but several skin infections do occur more commonly, with greater severity, or with a greater risk for complications in patients with DM. Joshi et al have reviewed this subject.[11]

There is extensive research on the pathogenesis of immune dysfunction in diabetes. Although some studies could not detect defects at the cellular level,[48] other studies show that leukocyte chemotaxis, adherence, and phagocytosis are impaired in patients with diabetes, especially during hyperglycemia and diabetic acidosis.[49] Further studies show that cutaneous T-cell function and response to antigen challenge are also decreased in diabetes.[11] Some of the skin infections which occur more commonly or more severely in diabetic patients are shown in Table 151-1.

DIABETIC ULCERS

EPIDEMIOLOGY. Foot ulcers are a significant problem for patients with diabetes, occurring in 15%–25% of diabetic patients.[50] Patients with diabetes have an estimated increased risk of lower extremity amputation that is 10–30 times greater than the general population. Lower extremity ulcers were the proximal cause of amputation in 67 of 80 patients (84%) in a study by Pecoraro et al.[51] In diabetic patients with foot ulcers, 14%–24% will eventually undergo amputation.[52] The attributable cost of treating a diabetic foot ulcer, excluding the cost of amputation, was estimated to be $28,000 in a 1999 US study.[53]

ETIOLOGY AND PATHOGENESIS. Many of the factors previously described in this chapter contribute to the pathogenesis of diabetic ulcers. Peripheral neuropathy, pressure, and trauma are felt to play prominent roles in the development of diabetic ulcers. Neuropathy (associated with uncontrolled hyperglycemia) is one of the major predictors of diabetic ulcers.[15] Patients with diabetes also suffer the loss of cutaneous sensory nerves.[54] The subsequent diminished neuroinflammatory signaling via neuropeptides to keratinocytes, fibroblasts, endothelial cells, and inflammatory cells may adversely affect wound healing.[55] Excessive plantar pressure develops from foot deformities (Charcot arthropathy), as a result of LJM related to NEG, and from callus formation. Ill-fitting shoes and socks were the most common reasons for foot ulcers in a study of 314 diabetic patients with ulcers.[56] By wearing running shoes, patients with diabetes had a measurable reduction of calluses in one study.[57] Callus formation is a sign of excess friction and often precedes foot ulcers. Once an ulcer develops, peripheral vascular disease and intrinsic wound healing disturbances contribute to adverse outcomes. Known factors associated with foot ulceration in the setting of diabetes include previous foot ulceration, prior lower extremity amputation, long duration of diabetes (>10 years), impaired visual acuity, onychomycosis, and poor glycemic control. Boyko and colleagues have recently published a prediction model for foot ulceration based on the relative contributions of these factors.[58]

CLINICAL FINDINGS. Callus formation precedes necrosis and breakdown of tissue over bony prominences of feet, usually on great toe and sole, over first and/or second metacarpophalangeal joints. Ulcers are surrounded by a ring of callus and may extend to underlying joint and bone (Fig. 151-5). Complications are soft tissue infection and osteomyelitis.

TABLE 151-1
Infections More Common or Severe in Diabetes

Bacteria	Fungal and Yeast
▪ Invasive Group B Strep	▪ Candida
▪ Invasive Group A Strep	▪ Dermatophyte
▪ Malignant external otitis	▪ Rhinocerebral Mucormycosis
▪ Necrotizing fasciitis	

Figure 151-5 "Diabetic foot." Two larger ulcers overlying the first right and second left metacarpophalangeal joints in a 56-year-old man with diabetes of 20 years' duration. There is significant sensory neuropathy and peripheral vascular disease.

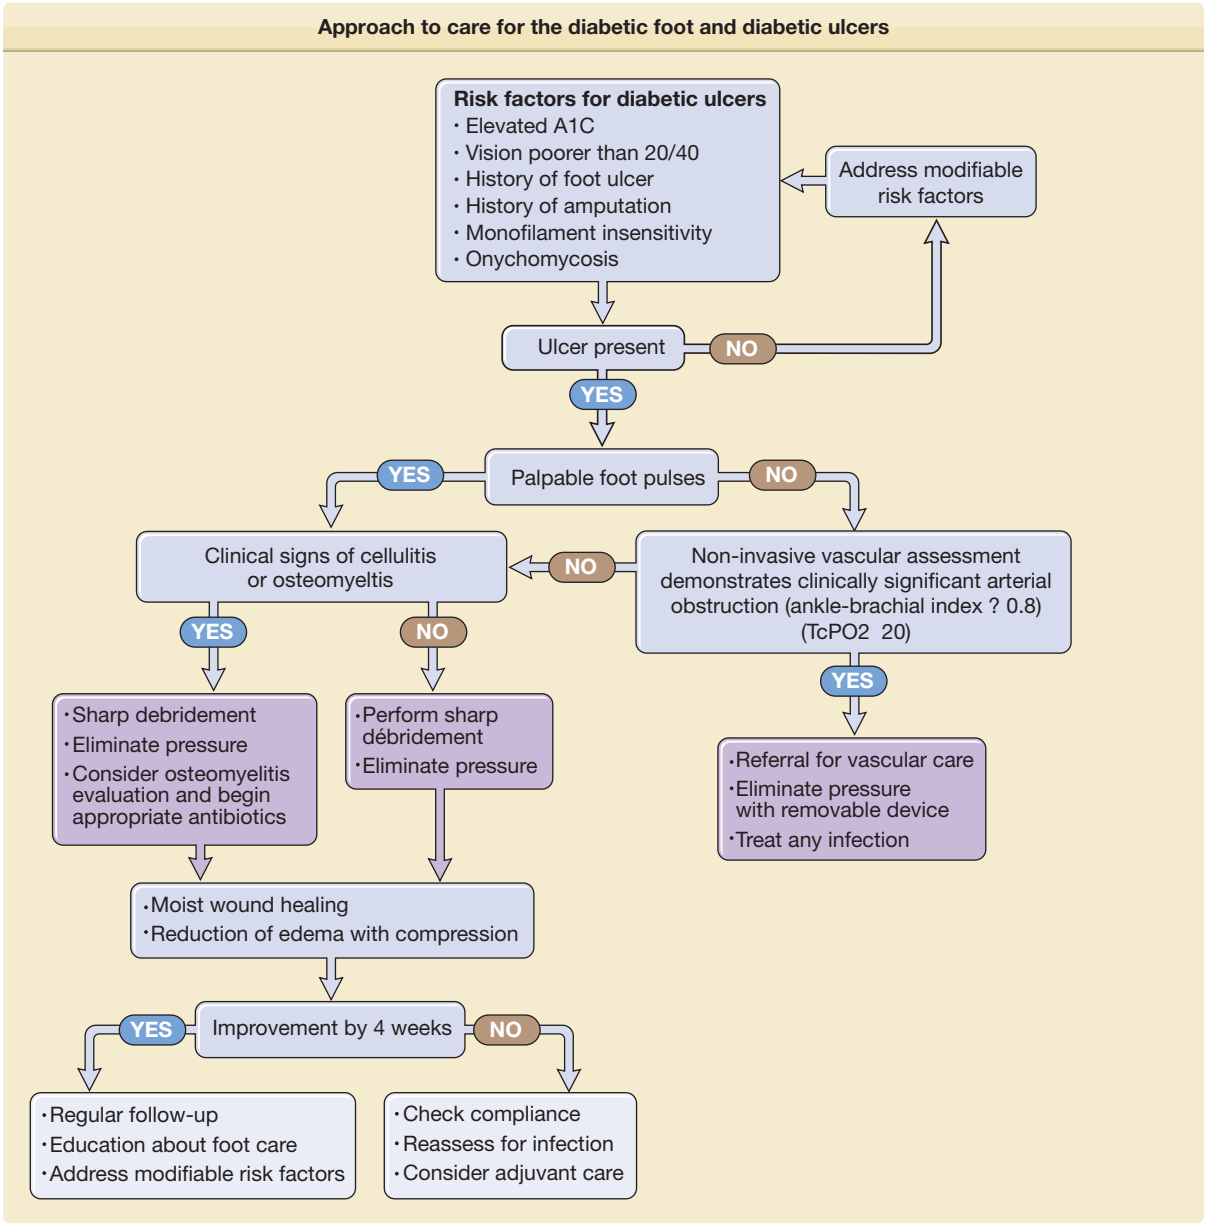

Figure 151-6 Approach to the care of the diabetic foot and diabetic ulcers. A1C = hemoglobin A1C; $TcPO_2$ = transcutaneous oxygen tension.[178]

TREATMENT. Treatment of diabetic ulcers requires modification of factors that contribute to ulcer formation, for example, stasis dermatitis, leg edema, and skin infection. Standard therapy for neuropathic diabetic ulcers includes debridement, off-loading (often nonweight bearing), moist wound care, and protective dressings (Fig. 151-6).

There has been substantial interest in developing adjunctive therapies for diabetic ulcers, including growth factors and skin-replacement products, but data have not supported their use as a replacement for standard wound care. Recombinant platelet-derived growth factor for the topical treatment of diabetic foot ulcers demonstrates a modest benefit if used with adequate off-loading, debridement, and control of infection.[59] A large multicenter, clinical trial of a bilayered living skin equivalent[60] showed 56% healing at 12 weeks as compared with 38% healing for standard care. The most favorable published results for a monolayered living skin equivalent and platelet-derived growth factor show roughly comparable improvement in healing to that reported for bilayered living skin equivalents when each is compared with standard care or placebo.[60] These technologies await definitive analysis of cost effectiveness compared with standard older approaches. While studies available do not support the routine use of these biologic approaches they may have a role in the treatment of large ulcers (>2 cm) or ulcers poorly responsive to standard therapy. A recent meta-analysis makes the points that typically a higher percentage of ulcers heal during a 12-week study period with biologic products, but analysis of cost effectiveness is made difficult by

differences in study designs, short duration of studies, different cost structures, the absence of quality of life measures and pharmaceutical funding of the primary studies and analysis.[61]

PREVENTION. Ulcer prevention is the most important intervention physicians and other health care professionals can provide for diabetic patients. An excellent review of ulcer prevention was published by Singh et al.[50] Optimizing glycemic control is well supported to prevent the neuropathy that is so intimately associated with foot ulceration. In a recent study, the risk of a foot ulcer increased in nearly direct proportion to every 1% increase in hemoglobin A1C.[58] Foot examination should be part of every patient visit if diabetes is on the problem list. Failure to perceive touch by a Semmes-Weinstein 10-g monofilament means a patient lacks protective sensation in the foot tested. If tinea pedis is present, it should be treated to prevent the associated skin barrier disruption. Smoking cessation should be encouraged. Patients should be counseled about the importance of daily foot care (Box 151-2).

Specialized ulcer care teams have published impressive results on the prevention and healing of ulcers.[62] This multidisciplinary team approach is becoming more important in the treatment of diabetic ulcers in large population centers. Patients with a history of ulceration are at high risk for reulceration (34% at 1 year, 61% at 3 years, and 70% at 5 years).[56] Intensifying education (formal foot care classes) and prevention efforts in this group along with lifelong surveillance is required.

BOX 151-2 GENERAL FOOT CARE GUIDELINES FOR PATIENTS WITH DIABETES

- Examine feet every day, including areas between the toes.
- Regular washing of feet with careful drying, especially between the toes.
- Water temperature should always be less than 37°C (98.6°F) and checked first with the hand rather than the foot.
- Barefoot walking in- or outdoors and wearing of shoes without socks is discouraged.
- Daily inspection and palpation of the inside of the shoes for irregular surfaces or foreign objects.
- If vision is impaired, patients should not try to treat their feet (e.g., nails) by themselves.
- Emollients should be used for dry skin but not between the toes.
- Change stockings daily.
- Wearing of stockings with seams inside out or preferably without any seams at all.
- Nails should be cut straight across.
- Corns and calluses should not be cut by patients but by a health care provider.
- The patient must ensure that the feet are examined regularly by a health care provider.
- The patient should seek early health care attention for any blister, cut, scratch, sore, ingrown toenail, or dermatitis.

DISORDERS ASSOCIATED WITH DIABETES MELLITUS BUT OF UNKNOWN PATHOGENESIS

NECROBIOSIS LIPOIDICA

EPIDEMIOLOGY AND PATHOGENESIS. Coined by Urbach in 1932 as *necrobiosis lipoidica diabeticorum*, this disorder was named after characteristic histologic findings and was first described in patients with diabetes. Because not all patients have concurrent diabetes, the shortened term, *necrobiosis lipoidica* (NL) is preferred. Epidemiologic data show that the mean age of onset is around 30 years, with women representing three times more cases than men.[63] The most often quoted statistics concerning the association of NL with diabetes are from a 1966 retrospective study at the Mayo Clinic. Of 171 patients with NL, two-thirds had diabetes at diagnosis, and another 5%–10% had glucose tolerance abnormalities.[63] However, in a 1999 study of 65 patients with NL, only 11% had diabetes after 15 years of follow-up.[64] Conversely, the prevalence of NL has been found to be only 0.3%–3.0% in patients with diabetes.[63] Although lacking full concordance, NL definitely has a strong association with diabetes and remains a valid marker of the disease. The pathogenesis of this skin disease is unclear. Many etiologic mechanisms have been proposed and reviewed.[65] Evidence suggests that the degree of hyperglycemia and diabetic control does not correlate with the presence of NL.[66]

CLINICAL FINDINGS: CUTANEOUS LESIONS. Classically, NL presents with one to several sharply demarcated yellow–brown plaques on the anterior pretibial region (Fig. 151-7). The lesions have a violaceous, irregular border that may be raised and indurated. Initially, NL often presents as red–brown papules and nodules that may mimic sarcoid or granuloma annulare (GA). Over time, the lesions flatten, and a central yellow or orange area becomes atrophic, and commonly telangiectasias are visible, taking on the characteristic "glazed-porcelain" sheen. Aside from the shins, other sites of predilection include ankles, calves, thighs, and feet. Fifteen percent of patients develop lesions on the upper extremities and trunk that tend to be more papulonodular. Although pain and pruritus have been reported, most lesions are asymptomatic. Anesthesia of the plaques does occur.[67]

The clinical course is often indolent, with spontaneous remission in less than 20% of cases.[10] Over time, the plaques tend to stabilize, and formation of

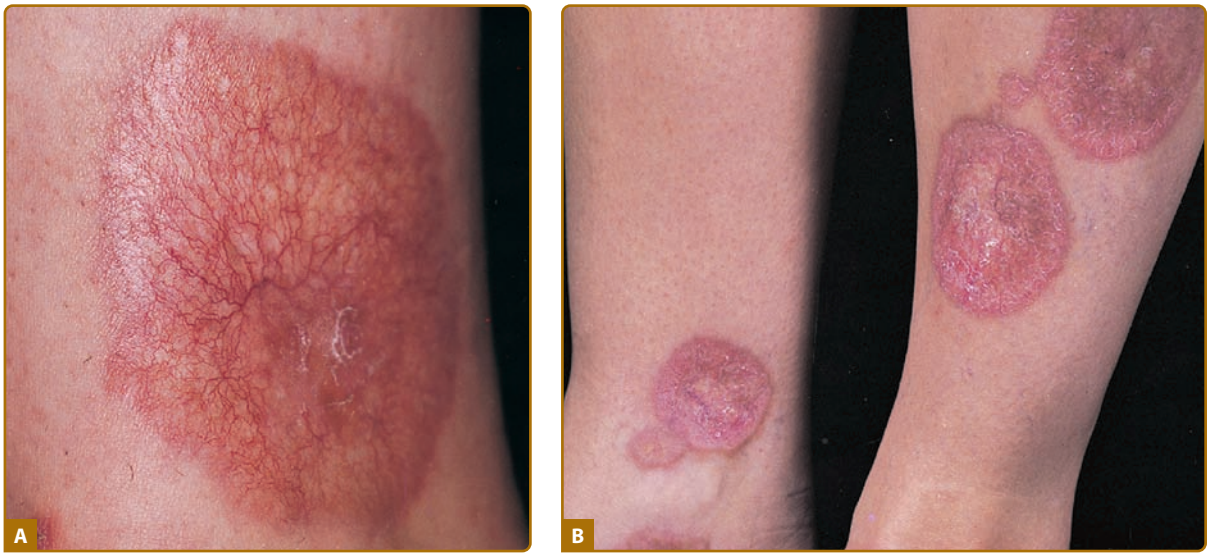

Figure 151-7 Necrobiosis lipoidica. **A.** A single orange plaque with atrophy of the overlying epidermis and arborizing telangiectasias is seen on the lower leg of a juvenile with diabetes mellitus; the crust marks an area of early ulceration. **B.** Older lesions with striking central atrophy involving both the dermis and epidermis.

new lesions tapers off. However, the possibility of ulceration, a poor spontaneous remission rate, and cosmetic concerns lead patients to seek treatment. Ulceration, the most serious complication, occurs in approximately 13%–35% of cases on the legs.[63,65] A few cases of squamous cell carcinoma arising in chronic ulcerative lesions of NL have been reported.[68] Multiple reports document the association of NL with GA and sarcoidosis.[69]

TREATMENT. Treatment for NL is disappointing. At this time, only case reports and small, uncontrolled trials provide the basis for treatment decisions. Early application of potent topical glucocorticoids might slow progression.[65] Although some authors[63] report improvement with intralesional injection of glucocorticoids to the active border, the risk of ulceration with this treatment modality should be considered. A few case reports and one series of six patients[70] showed benefit with short-term systemic glucocorticoids. Aspirin and dipyridamole have produced variable results.[65] Anecdotal reports exist that support the use of topical retinoids and topical PUVA. Treatment with fumaric acid esters in 18 patients was reported to improve lesions clinically and histologically.[71]

Given the generally benign nature of the lesions, physicians should consider the adage "do no harm." Focus should be on prevention of ulcers. When ulceration occurs in patients with NL, the same wound care principles apply as for all diabetic ulcers. Healing of ulcerated lesions with cyclosporine has been demonstrated in several patients.[72] Surgical excision down to fascia and split-thickness skin grafting remain as the last resort for very recalcitrant ulcers in NL.[73]

GRANULOMA ANNULARE

(See Chapter 44)

EPIDEMIOLOGY AND PATHOGENESIS. The association of GA with diabetes is weaker than that of NL. Although most patients with GA are in good health, without underlying systemic illness, an association with diabetes is supported in the literature. Dabski and Winkelmann[74] found diabetes in 10% of 1,353 patients with localized GA and 21% of 100 patients with generalized GA. An additional small retrospective case-control study showed an increased prevalence of diabetes among patients with GA (18%) as compared with the prevalence in age-matched controls (8%).[75] Furthermore, there is an impression that diabetes is found more frequently in patients with adult onset GA and in those with generalized or perforating GA, and that these patients tend to experience a more chronic, relapsing course of GA. The pathogenesis is unclear.

CLINICAL FINDINGS AND TREATMENT. Clinical findings and treatment of GA are discussed in Chapter 44.

DIABETIC DERMOPATHY

ETIOLOGY AND PATHOGENESIS. Atrophic skin lesions of the lower extremity, or shin spots, were first characterized and proposed as a cutaneous marker for diabetes in 1964.[76] Shortly after, Binkley coined the term *diabetic "dermopathy"* to correlate the pathologic changes with those of retinopathy, nephropathy, and neuropathy[77] Since that time, controversy has existed about the disorder's etiology, specificity for diabetes, and association with other microangiopathic complications of diabetes.

The prevalence of shin spots in ambulatory patients with diabetes varies. In a population-based study from Sweden, diabetic dermopathy was found in 33% of patients with type 1 diabetes and in 39% of patients with type 2 diabetes, compared with 2% of controls.[78]

In other studies, the prevalence rate for individuals without diabetes ranges from 1.5% for healthy medical students to 20% for a group of nondiabetic endocrine patients.[79] Diabetic dermopathy occurs more often in patients with an increased duration of diabetes and is more frequent in men.[79]

It is likely that the lesions are related to antecedent trauma. Lithner[80] induced diabetic dermopathy on the legs of diabetic patients with heat and cold injury, whereas nondiabetic control subjects healed without residual change. When questioned, most patients think that the changes are caused by injury, but they are often unable to detail preceding trauma.

CLINICAL FINDINGS, DIAGNOSIS, AND TREATMENT. Diabetic dermopathy presents as small (<1 cm), atrophic, pink to brown, scar-like macules on the pretibial areas (Fig. 151-8). The lesions are asymptomatic and clear within 1–2 years with slight residual atrophy or hypopigmentation.[77] The appearance of new lesions gives the sense that the pigmentation and atrophy are persistent.

An association seems to exist between diabetic dermopathy and the more serious complications of diabetes. In a study of 173 patients with diabetes, the incidence of shin spots correlated with the duration of diabetes and the presence of retinopathy, nephropathy, and neuropathy.[81] Diabetic dermopathy does not, however, correlate with obesity or hypertension in patients with diabetes.[79] No treatment is necessary for the individual atrophic tibial lesions. They are asymptomatic and are not directly associated with an increase in morbidity.

ACQUIRED PERFORATING DISORDERS

(See Chapter 69)

The acquired perforating disorders comprise an overlapping group of disorders characterized by transepidermal elimination or "spitting" of altered dermal constituents. Included in this group are Kyrle disease, reactive perforating collagenosis, perforating folliculitis, and elastosis perforans serpiginosa.[82] These disorders and their treatment[83] are fully described in Chapter 69.

Figure 151-8 Diabetic dermopathy with hyperpigmented macules on the anterior lower legs.

Clinically, these lesions appear as pruritic, keratotic papules mainly on the extensor surfaces of the extremities. Papules and nodules with a perforating component may also occur on the trunk and face. Many are follicular and contain a prominent central keratotic plug. The papules may be grouped, or coalesce to form verrucous plaques. Treatment for the perforating disorders is usually unsuccessful. Retinoic acid, topical glucocorticoids, and PUVA are partially successful.[83]

BULLOSIS DIABETICORUM

ETIOLOGY AND PATHOGENESIS. The abrupt, spontaneous development of blisters on the lower extremities without other demonstrable cause is a rare characteristic skin manifestation of diabetes. The pathogenesis of diabetic bullae is unknown. Patients with bullosis diabeticorum (BD) do not have a history of antecedent trauma or infection. One study found a decreased threshold to suction-induced blister formation in patients with diabetes.[84] Reduced suction blister time is also observed with increasing age in nondiabetic subjects.[85] Although a history of antecedent trauma is not elicited, this finding suggests a role of increased skin fragility in diabetic bullae. Perhaps the formation of AGEs leads to increased fragility.

CLINICAL FINDINGS, DIAGNOSIS, AND TREATMENT. BD is characterized by the abrupt onset of bullae on the lower extremities, usually the toes, feet, and shins, arising in normal skin. Occasionally, the distal upper extremities are involved. The blisters are usually painless and not pruritic. Healing occurs within 2–5 weeks and rarely leaves scarring. The condition may recur as successive crops of bullae over many years. Studies of affected individuals excluded other blistering skin disorders, and revealed no abnormalities of porphyrin metabolism.[84] Histopathologic examination of the bullae shows an inconsistent level of separation varying from intraepidermal to subepidermal.[85] No immunopathologic features are consistently observed (Box 151-3).

BOX 151-3 DIFFERENTIAL DIAGNOSIS AND EVALUATION OF BULLOSIS DIABETICORUM

DIFFERENTIAL DIAGNOSIS

- Bullous impetigo
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Porphyria cutanea tarda
- Bullous erythema multiforme
- Insect bite reaction

LABORATORY TESTS

- Skin biopsy for histology and immunofluorescence
- Bacterial cultures
- Screening for porphyrins

BD runs a benign course without involvement of large body surface areas. The only serious complication is that of secondary infection, which should be managed with culture and appropriate antibiotics if suspected. Otherwise, therapy is supportive. The real importance of this disorder is that of correct diagnosis because several of the blistering skin diseases have a high rate of morbidity and require potentially toxic systemic treatments. Even a negative workup is important. The patient should be educated, reassured, and good wound care implemented.

OBESITY AND THE METABOLIC SYNDROME

EPIDEMIOLOGY. Obesity is characterized by excess fat mass and defined according to the body mass index (BMI, kg/m^2), a calculation based on weight and height [BMI = body weight (in kg) ÷ square of stature (height in meters)]. BMI is correlated with body fat and the WHO defines overweight as a BMI of >25 and obesity as >30 kg/m^2. For Americans the risk of becoming overweight or obese in adulthood is high. As part of the National Health and Nutrition Examination Survey (NHANES) in 2003–2004, 17.1% of children and adolescents were overweight and 32.2% of adults were obese. Approximately 30% of nonhispanic white adults were obese as were 45.0% of nonhispanic black adults and 36.8% of Mexican American. It was also noted that obesity increased in the adult population with age.[86]

ETIOLOGY AND PATHOGENESIS. Contributing factors to obesity are nutritional choices, activity and exercise, medications, and rarely one of several endocrine disorders. In the setting of nutrient excess and weight gain, numerous comorbid factors occur that may contribute to further weight gain by increasing energy intake or decreasing energy expenditure. These include, inflammation and insulin resistance, depression and emotional eating, degenerative joint disease, obstructive sleep apnea, gonadal dysfunction, vitamin D deficiency, among others. Familial studies suggest a strong genetic basis for human obesity. The genetics of obesity are complex, though most human obesity is likely polygenic, multiple single genes have been identified as key regulators of body adiposity. Three of these genes [(1) leptin, (2) pro-opiomelanocortin (*POMC*), and (3) agouti-related protein (*AGRP*)] with dermatologic relevance are discussed in detail below.

The hormone leptin is secreted by adipose tissue in proportion to total body fat. Leptin regulates energy homeostasis, neuroendocrine function, and metabolism.[87] Rare cases in humans have shown that leptin deficiency causes extreme obesity, hyperphagia, diabetes, neuroendocrine abnormalities, and infertility, all of which can be reversed by administration of exogenous leptin. However, most obese humans are leptin resistant, have high circulating levels of leptin and pharmacological leptin administration has not proven to be a successful weight-loss strategy. Leptin resistance appears to be at the hypothalamic leptin receptor or downstream.[87] Congenital and acquired forms of lipoatrophy (HIV or HAART associated) are characterized by low leptin levels and metabolic abnormalities including insulin resistance, hyperlipidemia, and fatty liver. Leptin treatment in these patients can improve insulin resistance, lipid abnormalities, and fat distribution.[88,89]

Leptin stimulates the hypothalamic melanocortin pathway including hypothalamic neurons expressing POMC. Cleavage of POMC results in peptide agonists for all five homologous melanocortin receptors. The melanocortin 1 receptor (MC1R) is expressed on melanocytes and mutations in MC1R are known to cause red hair and fair skin.[90] Inactivating mutations in MC4R and to a lesser degree MC3R are associated with obesity. Studies estimate that inactivating mutations in MCR4 account for up to 6% of all severe cases of early onset obesity. Further emphasizing the importance of the POMC pathway is the finding that homozygous loss of function of POMC (complete POMC deficiency) produces obesity, pale skin, and red hair.[91]

AGRP is an endogenous hypothalamic melanocortin receptor antagonist, which causes obesity when overexpressed. Though studies have found high serum AGRP levels in obese men,[92] the role of AGRP in common obesity is unclear. The gene is closely related to *agouti*, a skin pigmentation gene, which causes yellow coat color and obesity when overexpressed in mice.

The hormonal regulation of obesity is similarly complex and several gut hormones are likely involved in the regulation of food intake. The gastric derived, appetite stimulating hormone ghrelin impacts obesity and diabetes by modulating body weight, insulin secretion, and gastric motility.[93] Serum ghrelin levels rise before meals and are thought to promote food intake. Sharp rises are seen in states of starvation and after weight loss in obesity. This likely contributes to weight regain. Interestingly, postgastric bypass surgery patients have altered ghrelin secretion and this may be one of the reasons for the long-term success of this surgical treatment for obesity.[94] Ghrelin receptors are located in the pituitary and hypothalamus and stimulate growth hormone (GH1) release and regulate energy expenditure[93] (see Fig. 151-15). Several ghrelin antagonists are in development for the treatment of obesity, metabolic syndrome, and diabetes.

CLINICAL FINDINGS. Physiologic changes in the skin related to obesity include alterations in epidermal barrier function,[95,96] increased sweating along with larger skin folds, increased skin surface pH in intertriginous areas,[97] poor lymphatic drainage (eFig. 151-8.1 in online edition), impaired wound healing in animal models,[98] and impaired responsiveness of the microvasculature.[99] Several reviews regarding obesity and dermatology have been published.[100,101] The cutaneous disorders seen in obesity are listed in Box 151-4. Detailed discussion of findings and treatments for these disorders are found in the appropriate sections of the text.

It is now well recognized that the presence of abdominal—central rather than subcutaneous—obesity (more than just increased BMI) is associated with insulin resistance, hyperlipidemia, hypertension, and vascular inflammation (Box 151-5). The coexistence of

these disorders increases the risk for diabetes and cardiovascular disease and has been called the metabolic syndrome. It is not clear that the metabolic syndrome confers risk beyond that of the individual components but because the traits co-occur, those with one trait are likely to have others. The most important therapy is weight reduction and exercise along with adequate control of cardiac risk factors.

The cornerstones of treatment for overweight and obesity are dietary changes, increased physical activity, and behavioral modification. In high-risk patients with comorbid conditions, pharmacologic therapy (sibutramine or orlistat) can be considered as an additional intervention. In clinically severe obesity, surgical therapies may be appropriate. All successful patients will require long-term nutritional adjustments that reduce caloric intake. The role of liposuction in weight loss has been studied and despite the removal of a large volume of subcutaneous adipose tissue there was no improvement seen in the metabolic risk factors associated with obesity.[102,103]

BOX 151-5 DEFINITION OF THE METABOLIC SYNDROME (ANY THREE OF FIVE TRAITS)

1. Abdominal Obesity
2. Serum triglycerides ≥150 mg/dl (or drug treatment for elevated triglycerides)
3. Serum HDL cholesterol <40 mg/dl in men and <50 mg/dl in women (or drug treatment for low HDL-C)
4. Blood pressure ≥130/85 (or drug treatment for elevated blood pressure)
5. Fasting plasma glucose ≥100 mg/dl (or drug treatment for elevated blood glucose)

THYROID DISEASE

THYROID DISEASE AT A GLANCE

- The most common cause of hyperthyroidism is Graves disease, characterized by the triad of autoimmune thyroid disease, eye disease, and thyroid dermopathy (pretibial myxedema).
- Toxic multinodular goiter is another cause of hyperthyroidism that should be considered, particularly in elderly individuals.
- Serious signs of thyrotoxicosis include atrial fibrillation and fever.
- Hashimoto thyroiditis and thyroid ablation for treatment of hyperthyroidism are the two most common causes of hypothyroidism.
- The best screening test for thyroid disease is thyrotropin (TSH), which is elevated in hypothyroidism and depressed or absent in hyperthyroidism.

EPIDEMIOLOGY. Worldwide estimates of the prevalence of goiter (enlargement of the thyroid gland) range from 200 to 800 million affected people. The majority of these worldwide cases are secondary to iodine deficiency. However, in industrialized countries where salt is routinely iodized, the main causes of goiter are autoimmune thyroiditis and nodular thyroid disease. The overall incidence of hyperthyroidism in the US population is estimated at approximately 1%, but may be four to five times higher in older women.[104] Graves disease accounts for 60%–80% of all cases of hyperthyroidism and was first described by Caleb Parry in 1825 (and later by Robert Graves in 1835) as an association between goiter, palpitations, and exophthalmos.[105] Although the incidence of Graves disease is similar between whites and Asians, it appears to be

lower in blacks.[105] *Toxic adenoma* and *toxic multinodular goiter* refer to the hyperplastic growth of thyroid tissue that is functioning independent of TSH regulation, resulting in increased levels of thyroid hormone. Toxic multinodular goiter has been reported to be more common in areas of low iodine intake, particularly in patients older than the age of 50 years.[106] Population-based screening with laboratory testing found hypothyroidism in 4.6% of the US population, although >90% of individuals with tests consistent with hypothyroidism were normal clinically.[104]

The majority of thyroid disease is acquired, but thyroid disease can also be congenital. Congenital hypothyroidism is the most common treatable cause of mental retardation, and occurs in up to 1 in 3,000 neonates worldwide due to either an absent or anatomically defective gland, inborn errors of thyroid metabolism, or iodine deficiency.[107] Congenital hyperthyroidism is much less common, and although 0.2% of pregnant women have Graves disease, only about 1% of the resultant neonates will have hyperthyroidism, with most cases resulting from the transfer of maternal thyroid-activating autoantibodies.[108]

ETIOLOGY AND PATHOGENESIS.

The metabolic regulation of every cell in the body relies on thyroid hormones, which is synthesized primarily in the thyroid gland. Hyperthyroidism (also known as *thyrotoxicosis*) results from the excess levels of thyroid hormones with resultant hypermetabolism, whereas hypothyroidism (or myxedema) is characterized by hypometabolism secondary to diminished levels of thyroid hormone. Thyroid hormones act on target tissues by activating cytoplasmic receptors that subsequently translocate to the nucleus and activate specific thyroid-responsive genes.[109] Thyroid hormone synthesis is heavily dependent on iodine and, consequently, changes in iodine intake can result in both hyperthyroidism and hypothyroidism.

Synthesis of thyroid hormone is regulated by the pituitary via release of TSH in response to hypothalamic release of thyrotropin-releasing hormone (TRH). TSH acts on the thyroid gland by binding a G-protein-coupled receptor (TSHR) to trigger thyroid hormone synthesis and release. Aberrant activation of TSHR is thought to underlie the hyperthyroidism seen in Graves disease, where almost all patients have long-acting thyroid-stimulator autoantibodies that bind and activate TSHR.[110] Release of TSH is, in turn, stimulated by TRH, which also acts via a G-protein-coupled receptor. Administration of recombinant TRH followed by measurement of the response in TSH levels provides a useful test for distinguishing whether hypothyroid disease results from dysfunction of the hypothalamic–pituitary axis or the thyroid gland. Levels of TSH and TRH are both tightly controlled by circulating levels of thyroxine (T_4) and triiodothyronine (T_3), which provide feedback regulation (eFig. 151-8.2 in online edition). Persistent stimulation of the thyroid leads to the hypertrophy of the gland, known as *goiter*.

The great majority of thyroid hormone in the blood is bound by plasma proteins, including thyroid-binding globulin, which is the major determinant of protein binding, and to a lesser extent transthyretin (formerly called *prealbumin*) and albumin. A variety of medical conditions (Box 151-6) and medications can alter levels of thyroid hormone-binding proteins or peripheral conversion of T_4 to T_3 (which is responsible for most of thyroid hormone's effects), and subsequently alter the tissue availability of thyroid hormone independent of changes in thyroid hormone synthesis. Thyroid hormone levels can be affected by a variety of medications, including several that are prescribed by dermatologists (Box 151-7).[111]

BOX 151-6 MEDICAL CONDITIONS THAT CAN AFFECT THYROID HORMONE LEVELS

Increased thyroid-binding globulin
- Pregnancy
- Infectious/chronic active hepatitis
- Biliary cirrhosis
- Acute intermittent porphyria

Decreased thyroid-binding globulin
- Chronic liver disease
- Severe systemic illness
- Active acromegaly
- Nephrosis

Decreased peripheral conversion of thyroxine to triiodothyronine
- Fasting/malnutrition
- Systemic illness
- Physical trauma
- Postoperative state

Hyperthyroidism can be broadly classified into two categories: (1) high radioiodine (radioactive iodine) uptake and (2) low radioiodine uptake. The presence of high radioiodine uptake indicates increased synthesis of thyroid hormone, while diminished or absent radioiodine uptake suggests either an extrathyroidal source of thyroid hormone or the destruction of thyroid tissue with concomitant release of preformed thyroid hormone into the circulation. Evidence suggests that genetic predisposition as well as environmental factors, including infection, may play a role in the pathogenesis of autoimmune thyroid disease.[112] In the case of toxic adenoma, molecular studies have identified a high prevalence of TSHR mutations, resulting in a receptor that triggers thyroid hormone synthesis in the absence of bound TSH.[113]

Although some of the cutaneous findings seen in hyperthyroidism are indirect consequences of thyroid hormone's actions on other tissues, most of the skin manifestations of thyroid disease result from the direct effects of thyroid hormones on the keratinized epithelium of the epidermis, hair, and nails as well as effects on stromal cells in the dermis. Thyroid hormones are essential for optimal epidermal proliferation both in vitro and in vivo.[114] Thyroid hormones regulate genes

BOX 151-7 MEDICATIONS AFFECTING THYROID HORMONE LEVELS

Drugs that affect thyroid hormone secretion
- Lithium (decreases secretion)
- Iodide (can increase or decrease secretion)
- Amiodarone (can increase or decrease secretion)

Drugs that increase serum thyroid-binding globulin concentrations
- Estrogens/tamoxifen
- Heroin/methadone
- Fluorouracil

Drugs that decrease serum thyroid-binding globulin concentrations
- Androgens
- Anabolic steroids
- Slow-release nicotinic acid
- Glucocorticoids

Drugs that increase hepatic metabolism of thyroid hormone
- Phenobarbital
- Rifampin
- Phenytoin
- Carbamazepine

Drugs that decrease deiodination of thyroxine to triiodothyronine
- Propylthiouracil (used to treat hyperthyroidism)
- Amiodarone
- β Blockers
- Glucocorticoids
- Certain radiographic contrast dyes

Drugs that decrease thyrotropin
- Bexarotene

Adapted from Surks MI, Sievert R: Drugs and thyroid function. *N Engl J Med* **333**:1688, 1995.

involved in keratinocyte proliferation and also stimulate the expression of certain keratins.[114]

Approximately 95% of cases of hypothyroidism are thought to arise from defects in the thyroid gland itself, whereas the remaining cases result from defects in the hypothalamic–pituitary axis. Ironically, the most common cause of hypothyroidism without a goiter is the surgical or radioiodine-induced ablation of the thyroid gland for the treatment of Graves thyrotoxicosis. Cretinism occurs with untreated congenital hypothyroidism and does not have a goiter. The most common cause of hypothyroidism with a goiter in North America is Hashimoto thyroiditis. Less common causes of hypothyroidism include inherited defects in hormone synthesis or the ingestion of drugs that inhibit hormone synthesis, such as lithium or aspirin. Bexarotene, a retinoid-X-receptor agonist (see Chapter 228) used to treat cutaneous T-cell lymphoma, causes a central hypothyroidism with a decrease in TSH, followed by low levels of T_3 and T_4.[115] In rare cases, hypothyroidism can occur from decreased secretion of TSH, such as with pituitary failure, a tumor of the pituitary region, or postpartum pituitary necrosis (Sheehan syndrome). Inadequate secretion of TRH by the hypothalamus is another very rare cause of hypothyroidism.

CLINICAL FINDINGS

CUTANEOUS MANIFESTATIONS OF HYPERTHYROIDISM

(Box 151-8) Signs and symptoms of hyperthyroidism and hypothyroidism are variably present and summarized in Table 151-2. The skin changes of hyperthyroidism have been likened to infant's skin and described as soft, warm, and velvety in texture. Pruritus can be a manifestation of thyroid disease, and laboratory screening for thyroid disease is often included in working up patients experiencing diffuse pruritus with no obvious rash. Scalp hair in hyperthyroid patients is described as soft and fine, and in certain

BOX 151-8 APPROACH TO PATIENT WITH HYPERTHYROIDISM

CUTANEOUS FINDINGS IN HYPERTHYROIDISM
- Soft, velvety, infant-like skin
- Thyroid dermopathy
- Soft, fine with diffuse nonscarring alopecia
- Facial flushing
- Palmar erythema
- Hyperpigmentation
- Plummer's nails
- Thyroid acropachy
- Hyperpigmentation

RELATED FEATURES
- Hyperhidrosis
- Atrial fibrillation
- Ophthalmopathy
- Goiter
- High-output cardiac failure
- "Thyroid storm"

DIAGNOSIS
- Best initial test is serum thyrotropin
- Other tests include serum free triiodothyronine, thyroxine, and antithyroid antibodies
- Radioactive iodine uptake and imaging

MANAGEMENT
- Appropriate surgical and endocrine consultation
- Propanolol for symptomatic treatment
- Propylthiouracil to inhibit thyroid hormone metabolism
- Methimazole to inhibit thyroid hormone synthesis
- Radioiodine ablation of the thyroid gland

TABLE 151-2
Symptoms, Clinical Findings, and Complications of Thyroid Disease

Symptoms, Clinical Findings, and Complications of Hyperthyroidism	Symptoms, Clinical Findings, and Complications of Hypothyroidism
Symptoms ■ Unintentional weight loss ■ Heat intolerance/sweating ■ Palpitations ■ Agitation/emotional lability ■ Multiple daily loose stools ■ Pruritus ■ Weakness ■ Oligomenorrhea in women Clinical Findings and Complications ■ Goiter ■ Tachycardia ■ Atrial fibrillation ■ High-output cardiac failure ■ Fine tremor ■ Hot sweaty extremities ■ Ophthalmopathy ■ Agitation/confusion ■ Muscle weakness/wasting ■ "Thyroid storm" with fever, confusion, dehydration, and eventual death, if untreated	Symptoms ■ Unexplained weight gain ■ Fatigue ■ Cold intolerance ■ Constipation ■ Dry skin ■ Muscle weakness ■ Carpal tunnel syndrome ■ Hoarseness ■ Decreased body temperature ■ Facial swelling ■ Menorrhagia in women Clinical Findings and Complications ■ Goiter ■ Cold, doughy skin ■ Bradycardia ■ Facial and finger swelling ■ Slowed relaxation of deep tendon reflexes ■ Hair loss/lateral eyebrow loss ■ Pericardial effusion ■ Myocardial infarction or congestive heart failure with aggressive thyroid hormone replacement ■ Coma and death without treatment

cases may be accompanied by a diffuse nonscarring alopecia analogous to telogen effluvium. Patients with hyperthyroidism frequently have nail changes that are commonly described as soft, shiny, and brittle nails with an increased rate of growth. A small percentage of patients with hyperthyroidism will have Plummer's nails, which exhibit a concave shape with distal onycholysis (see Chapter 89). Plummer's nails can also be found in a variety of other conditions and are not pathognomonic for hyperthyroidism. Vitiligo appears to be overrepresented in patients with Graves disease, but not in patients with other forms of hyperthyroidism. Vitiligo may often predate the diagnosis of thyroid disease and does not improve with the treatment of the hyperthyroidism (see Chapter 74).

Thyroid dermopathy is most commonly seen with Graves disease but has been reported in hypothyroid patients as well. Pretibial thyroid dermopathy (in the past referred to as *pretibial myxedema*) is a classic manifestation of hyperthyroidism and Graves disease (Fig. 151-11). The term *thyroid dermopathy* is used in this chapter because the lesions can occur at any site on the body, are not limited to the pretibial region, and the name does not suggest myxedema as a cause.[116] Although there are reports of hyperthyroid patients who have presented with thyroid dermopathy as their initial finding, thyroid dermopathy is usually a later manifestation of thyroid disease. Almost all patients with thyroid dermopathy also have thyroid ophthalmopathy, another late manifestation of hyperthyroidism.[117] The clinical appearance of thyroid dermopathy can be quite varied. Classically, thyroid dermopathy occurs bilaterally as painless nonpitting nodules and plaques with variable coloring and a waxy, indurated texture (Fig. 151-9). The distribution can range from very circumscribed to diffuse, but by far the most common location is on the extensor surfaces of the legs.[117] Some cases can exhibit a peau d'orange appearance as well. An extreme form of diffuse thyroid dermopathy has been termed the *elephantiasic* variant, which occurs in less than 1% of patients with Graves disease and is characterized by progressive thickening and gray-black hyperpigmentation of the pretibial skin accompanied by a woody, firm edema with nodule formation. The exact pathophysiology underlying thyroid dermopathy is still unclear.[116] Biopsies of thyroid dermopathy reveal a thickened dermis with splayed collagen fibrils and abundant mucin, usually hyaluronic acid, in the interstitial space.

The increased amounts of hyaluronic acid in the dermis and the subcutis have led the hypothesis that fibroblasts or other cells in the dermis may be

Figure 151-9 Hyperthyroidism with thyroid dermopathy in a classic location on the anterior shins. Note that infiltrated plaques extend to the calf and are partially hyperkeratotic. An isolated nodule is also present on the dorsum of the foot.

synthesizing increased levels of GAGs secondary to stimulation by activating autoantibodies. However, antibodies that bind TSHR on fibroblasts can be seen in patients with and without thyroid dermopathy, indicating that other determinants are likely involved. The presence of dependent edema in the lower extremities may also contribute somehow to either the fibroblast stimulation or hyaluronic acid accumulation, and thus account for the tendency of thyroid dermopathy to occur in this anatomic site.

Thyroid acropachy refers to digital clubbing, soft-tissue swelling of the hands and feet, and the presence of characteristic periosteal reactions.[116] This very rare clinical finding is also associated with thyroid dermopathy and exophthalmos, and almost always presents after the diagnosis and treatment of hyperthyroidism (eFig. 151-9.1 in online edition). Like thyroid dermopathy, thyroid acropachy has also been reported in hypothyroid conditions. Clubbing occurs most frequently on the first, second, and fifth metacarpals, the proximal phalanges of the hand, and the first metatarsal and proximal phalanges of the feet.[116] The radiologic findings are characterized by a lamellar periosteal reaction of the hands or wrists, with long bones only rarely involved. Because increased osteoblastic activity has been observed in the diaphyseal parts of small bones, the use of bone scan has been suggested as a sensitive way to aid in diagnosis.[118] The mechanisms underlying thyroid acropachy remain unknown, although interestingly, a large case series identified a disproportionately high percentage of smokers (80%) in patients with thyroid acropachy.[119]

The effects of thyroid hormone excess on other organ systems can also result in cutaneous findings. Hyperpigmentation similar to Addison disease has been seen with hyperthyroid disease, with resultant pigment in the palmar creases, gingiva, and buccal mucosa that is usually more prominent in individuals with darker skin. It has been postulated that the hyperpigmentation may be the result of increased corticotropin (ACTH) resulting from accelerated cortisol metabolism.[116] The cardiovascular effects of thyroid hormone excess include atrial fibrillation, increased cardiac output, and decreased peripheral vascular resistance, resulting in increased blood flow to the skin along with facial flushing and palmar erythema. The overall increased metabolism, along with changes in peripheral blood flow and temperature dysregulation, can also result in a generalized hyperhidrosis as well as high-output cardiac failure similar to that seen with Paget disease of bone.

There is extensive literature regarding the association between thyroid disease and urticaria[120] (see Chapter 38). Several studies have found a much higher incidence of thyroid disease in patients with chronic urticaria compared with control populations, although the mechanism behind this association remains unclear. Other dermatologic conditions have been reported in association with Graves disease, including dermatitis herpetiformis, Sweet syndrome, pemphigoid gestationis, vitiligo, pemphigus vulgaris, anetoderma, and middermal elastolysis.[116]

BOX 151-9 APPROACH TO THE PATIENT WITH HYPOTHYROIDISM

CUTANEOUS FINDINGS
- Myxedema
- Cool temperature
- Doughy, dry skin with fine wrinkling
- Yellow–orange carotenemia
- Dry, brittle hair
- Slow growth of hair and nails

RELATED FEATURES
- Macroglossia
- Broadened nose, thickened lips, puffy eyelids
- Impaired wound healing
- Cretinism with congenital cases
- "Myxedema coma"

DIAGNOSIS
- Best initial test is serum TSH
- Other tests include serum free T3 and T4

MANAGEMENT
- Appropriate endocrine consultation
- Oral thyroxine (usually in the range of 75–150 µg/day)
- Careful follow-up for heart, lung, and adrenal disease

CUTANEOUS MANIFESTATIONS OF HYPOTHYROIDISM.

(Box 151-9). In hypothyroidism, decreased core temperature and increased peripheral vasoconstriction cause the skin to be cool and pale. The skin is also xerotic, and the stratum corneum is poorly hydrated. Histologically, the epidermis is thin, and there is hyperkeratosis with follicular plugging. The generalized distribution of these findings can help distinguish these changes from those of atopic dermatitis and keratosis pilaris, which tend to be more prominent on the extremities. A fine wrinkling can also be seen. A yellow–orange discoloration of the skin can be seen secondary to the accumulation of β-carotene in the stratum corneum, possibly secondary to increased circulating carotene from diminished hepatic conversion of β-carotene to vitamin A.

Myxedema is the most classic finding associated with hypothyroidism and is distinct from the thyroid dermopathy seen with Graves disease. Myxedema occurs as a result of dermal accumulation of mucopolysaccharides, namely, hyaluronic acid and chondroitin sulfate, and tends to resolve with treatment of the hypothyroidism. The myxedema tends to be generalized but can appear more striking in the extremities. Characteristic facial changes can be seen, including a broadened nose, thickened lips, puffy eyelids, and macroglossia with a smooth and clumsy tongue (eFig. 151-9.2 in online edition). The skin can be doughy, swollen, and waxy, but without pitting. Wound healing is impaired in hypothyroidism.

The hair in hypothyroidism is coarse, dry, and brittle with slowed growth. Hair loss in the scalp can be either diffuse or patchy. Hypothyroidism can result in increased numbers of hair follicles in telogen, as well as telogen effluvium when the onset of hypothyroidism is abrupt. There can be loss of eyebrow hair in a characteristic pattern involving the outer third (see eFig. 151-9.2 in online edition). Although body hair can be diminished, hypothyroidism can also result in increased lanugo hair on the back, shoulders, and extremities. The nails in hypothyroidism grow slowly and can be thickened and brittle with longitudinal and transverse striations. In patients with a goiter, hoarseness can result secondary to compression of the recurrent laryngeal nerve. With large goiters, tracheal or esophageal displacement can be seen. In extreme cases, large retrosternal goiters can cause Pemberton's sign, characterized by facial plethora suggestive of compression when patients raise their arms above their head.

Hashimoto thyroiditis has been associated with several other dermatologic disorders, including alopecia areata, connective tissue disease (including lupus and dermatomyositis), bullous pemphigoid, dermatitis herpetiformis, and chronic mucocutaneous candidiasis (CMC).[121–125]

LABORATORY TESTS. The diagnosis of thyroid-related cutaneous disease is often suspected clinically, although in certain instances a skin biopsy may prove helpful in confirming the diagnosis. The clinical diagnosis of thyroid disease is confirmed by thyroid function tests. Serum levels of TSH are recommended as an initial screen, and any abnormalities in TSH should be followed up with measurements of serum T_4 and free T_3 to confirm whether the abnormal TSH truly reflects a thyroid disorder. Other tests that can be useful include in vitro T_3 resin uptake and measurements of antithyroid antibodies. This combination of tests will diagnose the vast majority of patients with suspected thyroid disease.

TREATMENT. The mainstay of treatment for the cutaneous findings of thyroid disease is normalization of thyroid function, either through replacement of thyroid hormone for hypothyroidism or through ablation of thyroid function for hyperthyroidism. Thyroid dermopathy and thyroid acropachy can be a chronic problem even in patients who are treated effectively for their thyroid disease, and the current treatment options can be classified as either experimental or palliative at best. Complete or partial remission of cutaneous findings can be seen even in the absence of any localized topical treatment.[126] Reported treatments of thyroid dermopathy include topical corticosteroids, systemic corticosteroids, intralesional corticosteroids, intralesional octreotide, intravenous (IV) immunoglobulin, plasmapheresis, compression therapy, and even surgical excision.[126,127] The success of these therapies is still controversial and based on small uncontrolled case series or anecdotal reports.

PARATHYROID DISEASE

PARATHYROID DISEASE AT A GLANCE

- The most common cause of hypercalcemia in outpatients is hyperparathyroidism, while the most common cause of hypercalcemia in hospitalized patients is malignancy.
- The most common causes of hypocalcemia are vitamin D deficiency and surgically induced hypoparathyroidism.
- Calciphylaxis is most commonly seen in the setting of secondary hyperparathyroidism of renal failure.

EPIDEMIOLOGY. The annual incidence of primary hyperparathyroidism has decreased in the past two decades to about 20 cases per 100,000, potentially reflecting a decrease in the use of ionizing radiation to the neck, which is a known risk factor for developing primary hyperparathyroidism.[128] The majority of cases occur in individuals older than 45 years of age, with an approximate 2:1 female–male predominance. In the outpatient setting, parathyroid disease accounts for almost all cases of hypercalcemia. In hospitalized patients, parathyroid disease accounts for approximately one-third of all cases of hyperparathyroidism, while the majority of other cases are accounted for by malignancy. Together, hyperparathyroidism and malignancy account for greater than 90% of all cases of hypercalcemia.

ETIOLOGY AND PATHOGENESIS. Parathyroid hormone (PTH) is secreted by the parathyroid gland in response to low levels of serum calcium and acts as one of the main regulators of calcium levels in the body. Elevations of PTH (hyperparathyroidism) are associated with hypercalcemia, whereas decreased levels of PTH (hypoparathyroidism) are associated with hypocalcemia. PTH acts through varying mechanisms that include the stimulation of vitamin D production, stimulation of calcium absorption in the gastrointestinal tract, regulation of renal absorption of calcium and phosphate, and direct regulation of calcium mobilization from bone. Circulating free calcium acts on the parathyroids via a G-protein-coupled receptor to control the release of PTH. Released PTH then acts in target tissues by binding another G-protein-coupled receptor, the PTH receptor, resulting in changes in calcium metabolism. Because problems with PTH result primarily in alterations of circulating calcium, it is not surprising that the skin manifestations of parathyroid disease are primarily changes resulting from calcium dysregulation. The skin is likely a site of PTH action, although the exact effects of PTH on skin are

not understood. Keratinocytes express a PTH-related peptide (PTHLH) that has been implicated in regulating keratinocyte growth and differentiation and utilizes the same receptors as PTH.[129–132] Although PTHLH has been associated with normal wound healing, elevated PTHLH can also be seen in the setting of certain squamous cell carcinomas.[131,133,134] The elevated PTHLH with squamous cell carcinoma can result in malignancy-related hypercalcemia in these patients.

Primary hyperparathyroidism results from abnormal function of the parathyroid gland, resulting in increased levels of PTH. In 80% of diagnosed cases, the cause of hyperparathyroidism is a result of either parathyroid hyperplasia, parathyroid carcinoma, or parathyroid adenoma. Pseudohyperparathyroidism occurs when PTH or a PTH-like molecule (for instance, PTHLH) is secreted from a nonparathyroid tissue such as occurs in malignancy.

Secondary hyperparathyroidism occurs most commonly in the setting of renal disease. Resistance of end organs to PTH results in hypersecretion of PTH and consequent hypocalcemia and hyperphosphatemia. Secondary hyperparathyroidism is found in almost all patients with chronic renal failure requiring dialysis. Secondary hyperparathyroidism can also be associated with idiopathic hypercalciuria as well as with certain medications, including oral contraceptives and long-term furosemide therapy. In renal patients with long-term secondary hyperparathyroidism, hyperplastic parathyroid tissue can become autoactivated, resulting in tertiary hyperparathyroidism. This condition is characterized by persistent hypersecretion of PTH and resultant osteomalacia despite hypercalcemia.

Primary hypoparathyroidism occurs primarily from iatrogenic causes such as the removal of the parathyroid glands during a thyroidectomy. There are also several genetic and nongenetic congenital causes of primary hypoparathyroidism, although these are much less common. Secondary hypoparathyroidism refers to decreased PTH secretion secondary to a primary process that causes hypercalcemia.

CLINICAL FINDINGS. Parathyroid disease most often presents in the setting of altered calcium metabolism. The physical findings and symptoms associated with hyper- and hypocalcemia are shown in Box 151-10. As for hypercalcemia and hyperparathyroidism, skin manifestations are rarely seen but can be impressive and dramatic. An approach to a patient with suspected hyperparathyroidism is outlined in Box 151-11. Cutaneous calcinosis (sometimes referred to as *calcinosis cutis* or *metastatic calcinosis*) is thought to be related to elevated calcium and phosphate[135] (see Chapter 138). Subcutaneous calcifications can be found in a symmetric distribution, often overlying large joints or in linear arrayed papules and plaques that are normally of skin color and hard on palpation (Fig. 151-10). These lesions can be pruritic. Chronic urticaria has been associated with hyperparathyroidism as well.[136] Signs of hyperparathyroidism in association with cutaneous skin tumors, such as angiofibromas, collagenomas, and lipomas, should engender a workup for multiple

BOX 151-10 PHYSICAL FINDINGS ASSOCIATED WITH HYPERCALCEMIA AND HYPOCALCEMIA

HYPERCALCEMIA

- Anorexia
- Nausea and vomiting
- Constipation
- Hypotonia
- Lethargy and coma

HYPOCALCEMIA

- Increased neuromuscular irritability and tetany
- Chvostek's sign: induced tetany of the facial muscles induced by tapping on the zygoma
- Trousseau sign of hypocalcemia: carpal spasm with inflation of blood pressure cuff above systolic value
- Peripheral and perioral paresthesias
- Seizures
- Bronchospasm/laryngospasm
- Lengthening of QT interval on electrocardiogram

BOX 151-11 APPROACH TO THE PATIENT WITH SUSPECTED HYPERPARATHYROIDISM

CUTANEOUS FINDINGS

- Cutaneous (metastatic) calcinosis
- Calciphylaxis

RELATED DISORDERS

- Renal disease
- Multiple endocrine neoplasia type 1 with angiofibromas, collagenomas, and lipomas
- History of head/neck irradiation

DIAGNOSIS

- Serum calcium and serum parathyroid hormone
- With suspected malignancy, serum parathyroid hormone-related peptide

MANAGEMENT

- Identify underlying cause of hyperparathyroidism.
- Appropriate endocrine, surgery, and nephrology consultation.
- Hospitalization for acute cases with hypercalcemia.
- Aggressive fluid management to treat hypercalcemia, with forced diuresis.
- Phosphate replacement as warranted.
- Dialysis for acute renal failure.
- Calciphylaxis warrants aggressive management of wounds and infection.
- Surgical parathyroidectomy.

Figure 151-10 Papules of cutaneous calcinosis are arranged in a linear array in the skin overlying the mandible.

endocrine neoplasia type 1 (MEN1), which is caused by mutations in the *MEN1* gene and characterized by tumors of the anterior pituitary, the pancreas, and the parathyroid. The finding of somatic (nongermline) mutations and loss of heterozygosity of the *MEN1* gene in 20%–30% of spontaneous parathyroid tumors further supports a role for this gene in parathyroid oncogenesis.[137] The differential diagnosis is of hypercalcemia is shown in Box 151-12.

Calciphylaxis (also called calcific uremic arteriolopathy or CUA) is a rare but life-threatening cutaneous condition associated with hyperparathyroidism. Calciphylaxis occurs most often in the setting of chronic renal failure and secondary hyperparathyroidism, although there are reports of calciphylaxis associated with primary hyperparathyroidism and normal renal function. Although the name may falsely imply an immune etiology, calciphylaxis actually results from calcium deposition in the walls of small- to medium-sized vessels, resulting in vascular occlusion and skin necrosis. Clinically, patients present initially with violaceous patches that may exhibit a mottled or reticular pattern. Subsequently, involved areas can become indurated and painful, with eventual ulceration and eschar formation that proceeds to tissue gangrene (Fig. 151-11). Both the trunk and extremities can be involved. A calcium-phosphate product (serum calcium × serum phosphate) of greater than 70 mg/dL has often been cited as a predisposing risk factor. The histologic finding of calcium deposits in vessel walls coupled with compatible clinical findings is diagnostic. Calciphylaxis has a very poor prognosis, with reported mortality rates up to 80%, usually from infection. Parathyroidectomy and aggressive management of wounds and infections has been successful in treating some cases. There is not compelling evidence to support the use of hyperbaric oxygen, but there are small case series reporting successful treatment of calciphylaxis using hyperbaric oxygen, suggesting use for this often life-threatening condition.[138,139] An accumulating number of case reports using the calcium-sequestering compound sodium thiosulfate have demonstrated considerable efficacy, particularly in patients with renal disease.[140] While large clinical trials are lacking, the lack of any serious short-term side effects reported

BOX 151-12 DIFFERENTIAL DIAGNOSIS OF HYPERCALCEMIA

- Increased parathyroid hormone
  - Solitary adenoma
  - Multiple adenomas (i.e., multiple endocrine neoplasia type 1)
  - Tertiary hyperparathyroidism with renal failure
- Increased parathyroid hormone-related peptide
  - Squamous cell carcinoma
  - Renal carcinoma
  - Bladder carcinoma
  - Human T-cell leukemia virus type 1
  - Breast cancer
  - Lymphoma
- Increased 1,25-vitamin D
  - Sarcoidosis
  - Excess ingestion
- Increased bone resorption of calcium
  - Myeloma
  - Lymphoma
  - Breast cancer
- Renal failure
  - Secondary hyperparathyroidism
  - Tertiary hyperparathyroidism
  - Vitamin D intoxication
- Milk-alkali syndrome (susceptibility to hypercalcemia with ingestion of calcium-based antacids and milk)

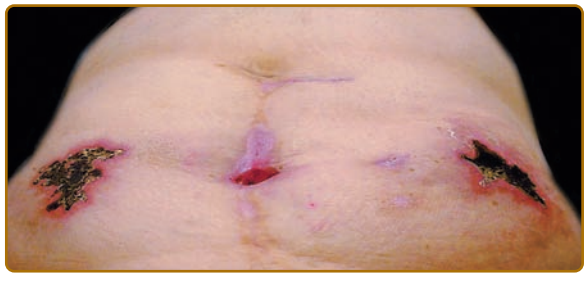

Figure 151-11 Calciphylaxis in a patient with chronic renal failure. Note the stellate-shaped necrotic plaques on the abdomen and the scars from peritoneal dialysis. Often the thighs and buttocks are also involved. A deep biopsy that includes subcutaneous fat can help make the diagnosis if it demonstrates the characteristic findings of calcification in the media of small- and medium-sized vessels. Histologically, subcutaneous calcium deposits and fat necrosis can also be seen.

BOX 151-13 APPROACH TO THE PATIENT WITH SUSPECTED HYPOPARATHYROIDISM

CUTANEOUS FINDINGS
- Scaly, hyperkeratotic, puffy skin
- Patchy alopecia with hair thinning
- Brittle nails with transverse ridging

RELATED FINDINGS
- Paresthesias
- Neuromuscular irritability
- Bronchospasm or laryngospasm
- Electrocardiogram changes

DIAGNOSIS
- Serum calcium and serum parathyroid hormone
- Serum magnesium levels to rule out hypomagnesemia
- Electrocardiogram to rule out QT elongation

MANAGEMENT
- Vitamin D or vitamin D metabolites (i.e., calcitriol at 0.2–1.0 µg/day)
- Calcium supplementation at 2–3 g of elemental calcium per day
- Magnesium supplementation when appropriate

with sodium thiosulfate suggests serious consideration of this therapy for patients with calciphylaxis.

Hypoparathyroidism is associated with scaly, hyperkeratotic, and edematous puffy skin (Box 151-13). Paresthesias secondary to hypocalcemia can be seen. Patchy alopecia and generalized thinning of the hair have been reported. Nails can be brittle with transverse ridging. Hypoparathyroidism has been associated with psoriatic flares, which is interesting in light of the response of psoriasis to calcipotriene.[141] These skin abnormalities often resolve with normalization of serum calcium levels, suggesting that they are due to changes in calcium homeostasis rather than deficiency of PTH.

Hypoparathyroidism in the setting of familial autoimmune polyglandular syndrome type 1 has been associated with CMC and adrenal failure.[142] The CMC can precede the diagnosis of hypoparathyroidism, although the CMC does not improve significantly with treatment of the hypoparathyroidism with calcium and vitamin D. Other findings in these patients include dental enamel hypoplasia, vitiligo, and the cutaneous manifestations of adrenal failure (see under Section "Addison Disease").

Hypoparathyroidism in the setting of elevated serum PTH is known as *pseudohypoparathyroidism* or *PTH-resistant hypoparathyroidism*. Although several variants of pseudohypoparathyroidism have been described, perhaps the best characterized is Albright's hereditary osteodystrophy.[143] These patients present with a constellation of findings that include short stature, obesity, rounded facies, dental hypoplasia, and shortened bones of the hands and feet. Characteristic shortening of the fourth metacarpal leads to a dimpling of the fourth knuckle, known as *Albright's sign*. These patients can also have subcutaneous ossifications and calcifications.

LABORATORY TESTS. The diagnosis of parathyroid disease can be made with measurements of serum calcium levels and serum levels of PTH. In the case of hypercalcemia related to malignancy, measurement of PTHLH may also be useful in the workup.

TREATMENT. The main treatment for hyperparathyroidism is partial or total parathyroidectomy (see Box 151-11). For hypoparathyroidism, treatment focuses on correction of serum calcium and phosphate (see Box 151-13). In the setting of acute hypercalcemia, aggressive fluid and electrolyte management are essential, because cardiorespiratory failure may result from dehydration.

DISORDERS OF THE ADRENAL GLANDS

ADRENAL GLANDS AND THE SKIN AT A GLANCE

- Excessive production of cortisol manifests as Cushing syndrome and results from pituitary oversecretion of corticotropin or excess production of cortisol by the adrenal cortex.
- Destruction of the adrenal gland with loss of glucocorticoids, mineralocorticoids, and adrenal androgens is known as Addison disease.
- Although many etiologies of Addison disease are described, the most common cause is autoimmune destruction with detectable circulating autoantibodies.

CUSHING SYNDROME

Excessive production of endogenous cortisol manifests clinically as Cushing syndrome. Similar findings are seen from chronic exogenous administration of glucocorticoids (see Chapter 224). In the normal physiology of the hypothalamic–pituitary–adrenal axis, corticotropin-releasing hormone is secreted from the hypothalamus and stimulates the production of corticotropin, also known as ACTH, by the anterior pituitary. ACTH is synthesized as part of a larger precursor molecule,

POMC. This relationship of POMC to ACTH is important in diseases of the adrenal gland and the resulting skin manifestations. POMC is processed into several peptides, including melanocyte-stimulating hormone (MSH) and ACTH, which stimulates the production of cortisol from the adrenal cortex. In a classic negative feedback manner, cortisol inhibits corticotropin-releasing hormone and ACTH production.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS. The overall incidence of Cushing syndrome is about 10 persons per million per year, with a female predominance.[144] Cushing syndrome is divided into two categories. The first is caused by inappropriately high secretion of ACTH, usually from a pituitary microadenoma. It is given the unique name of *Cushing disease*. The excess ACTH drives glucocorticoid production in the adrenals. Rarely ectopic, or nonpituitary, production of ACTH results in Cushing syndrome. This clinical presentation is most often associated with a pulmonary carcinoid tumor, although numerous other tumor types have been reported.[145] The second category of Cushing syndrome results from excess cortisol produced by the adrenal cortex independent of regulation by the pituitary or hypothalamus. This is usually due to an adrenal adenoma, which may be benign or malignant, or is the result of generalized hyperplasia of the adrenal gland. Cushing syndrome can be seen in the McCune–Albright syndrome[146] and in association with primary pigmented nodular adrenocortical disease in the Carney complex.[147]

CLINICAL FINDINGS. The clinical presentation of Cushing syndrome may be subtle (Box 151-14). Skin findings may be present, and if careful attention is paid to the relationship of skin findings and systemic complaints, one may consider the diagnosis early in the clinical course. Common skin complaints are easy bruisability and skin thinning. Mild hypertrichosis often of the lanugo type and acne may occur. Frank hirsutism and severe acne raise the possibility of a concurrent androgen-secreting tumor. The development of multiple violaceous striae wider than 1 cm on the abdomen or proximal extremities is highly suggestive of Cushing syndrome (eFig. 151-11.1 in online edition). The width and color of these striae differentiate them from the commonly seen striae in pregnancy or with weight gain. Relatively dramatic changes in fat distribution often occur along with a generalized gain in weight. There is an increase in central obesity and concurrent thinning of the arms and legs with loss of muscle mass. Increased facial fat results in a rounded appearance of the face, often with increased redness and telangiectasias. This appearance has been referred to as a moon facies. In addition to truncal obesity, there is an increase in the size of the dorsocervical fat pad, known as a *buffalo hump* and increased fat in the supraclavicular fossae. Men may experience gynecomastia.

Although unusual, hyperpigmentation can occur in cases of Cushing syndrome caused by massive increased ACTH production either from the pituitary or, more commonly, an ectopic source.[148] ACTH itself, in addition to MSH derived from POMC, contributes to increased melanin synthesis. This is similar to the hyperpigmentation more commonly associated with Addison disease. Acanthosis nigricans may be seen because Cushing syndrome contributes to insulin resistance, and, often, patients develop diabetes. The immunosuppressive effects of glucocorticoids result in increased dermatophyte and candidal nail and skin infections. Women may experience irregular menses or amenorrhea. Additional extracutaneous signs and symptoms of Cushing syndrome include hypertension, osteoporosis, and decreased muscle mass and strength.[149]

LABORATORY TESTS. Diagnostic confirmation of Cushing syndrome requires demonstration of excess cortisol production. Cortisol production varies throughout the day and, as a rule, should be examined in the early morning when it is usually at its highest value. The average daily cortisol level can be measured using a 24-hour urine collection. Any abnormal test should be repeated two or three times for confirmation. If the urine or serum levels are elevated, failure to suppress the 8:00 a.m. serum cortisol level or 24-hour urine cortisol with a low-dose dexamethasone suppression test is confirmatory. Additional testing, including a high-dose dexamethasone suppression test, can be useful to determine if the source

BOX 151-14 APPROACH TO THE PATIENT WITH CUSHING SYNDROME

CUTANEOUS FINDINGS IN CUSHING SYNDROME

- Increased central adiposity (moon facies and buffalo hump) with thinning of the extremities
- Skin thinning and easy bruisability
- Violaceous striae
- Acanthosis nigricans
- Increased dermatophyte and candidal skin and nail infections
- Rarely, hyperpigmentation

RELATED FEATURES

- Diabetes
- Hypertension
- Osteoporosis
- Irregular menses

DIAGNOSIS

- Measurement of cortisol in serum and urine
- Failure to suppress cortisol production with dexamethasone suppression tests

MANAGEMENT

- Appropriate endocrine and surgical consultation
- Surgical removal of pituitary or adrenal adenoma
- Adrenal enzyme inhibitors
- Radiation therapy

of the excess cortisol production is from the pituitary or elsewhere. Hypercortisolism may be present in patients without true Cushing syndrome. This is known as *pseudo-Cushing syndrome* and can be caused by obesity, major depressive disorders, and chronic alcohol abuse. With further testing, these patients can usually be identified.

TREATMENT. The primary treatment of Cushing disease is surgical removal of the ectopic focus of ACTH production or adenoma in the pituitary or adrenal gland. Cure is achieved in the majority of patients, but resistant disease requires radiation in the case of pituitary disease or medical therapy with adrenal enzyme inhibitors.[148] Historically, Cushing syndrome was treated with bilateral adrenalectomy. This frequently resulted in Nelson syndrome, which is characterized by unchecked ACTH production from an enlarging pituitary adenoma with resulting hyperpigmentation. Pituitary radiation can be helpful in these cases.[150]

ADDISON DISEASE

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS. Destruction of the adrenal glands and the resulting life-threatening deficiency of glucocorticoids, mineralocorticoids, and adrenal androgens is known as *Addison disease*. It occurs at an estimated prevalence rate of 120 per million in Western countries.[151] It is suspected that many more cases remain undiagnosed. Historically, the most common cause was tuberculosis infection, but now autoimmune destruction as part of the autoimmune polyglandular syndromes 1 and 2 is the most common etiology. In autoimmune cases, enzymes of the adrenal cortex, including 21-hydroxylase and 17-hydroxylase, are target autoantigens, and circulating autoantibodies can be detected. Subsequent lymphocytic infiltration of the adrenal gland with damage and scarring results.

Infectious causes of adrenal insufficiency remain the next most common etiology. Tuberculosis is still a major problem in many areas of the world. Atypical mycobacterial infection can also cause adrenal insufficiency. This is seen more commonly in immunosuppressed patients. Addison disease is increasingly recognized in patients with acquired immunodeficiency syndrome and, in these patients, infection with cytomegalovirus is the most recognized cause. Fungal infections have also been associated with Addison disease, including histoplasmosis, blastomycosis, paracoccidioidomycosis, coccidioidomycosis, and cryptococcosis. In the setting of an acute bacterial infection, bilateral adrenal infarction due to adrenal hemorrhage is known as the *Waterhouse–Friderichsen syndrome*. Classically this is due to meningococcal infection, although other infections have been reported (see Chapters 180 and 181).[152] Other rare causes of Addison disease include drugs, congenital adrenal hypoplasia, and infiltrative disorders, including amyloidosis, sarcoidosis, and metastatic carcinomas. The surgical treatment of Cushing syndrome can be an additional cause of adrenal insufficiency.

BOX 151-15 APPROACH TO THE PATIENT WITH ADDISON DISEASE

CUTANEOUS FINDINGS IN ADDISON DISEASE
- Hyperpigmentation of skin and mucous membranes
- Longitudinal pigmented bands in the nails
- Vitiligo
- Decreased axillary and pubic hair in women
- Calcification of auricular cartilages in men

RELATED FEATURES
- Abdominal pain
- Electrolyte abnormalities (hyponatremia and hyperkalemia)
- Postural hypotension
- Anorexia and weight loss
- Shock, coma, and death, if untreated

DIAGNOSIS
- Failure to respond adequately to corticotropin stimulation test

MANAGEMENT
- Lifelong replacement therapy of glucocorticoids and mineralocorticoids

CLINICAL FINDINGS. (Box 151-15). The clinical and cutaneous manifestations of adrenal insufficiency are not usually present until 90% of the gland function is destroyed.[151] The most recognized cutaneous manifestation is the hyperpigmentation of skin and mucous membranes. This occurs after long-standing adrenal insufficiency and would not be present in an acute presentation of adrenal crisis unless it is superimposed on a history of chronic adrenal insufficiency. The skin pigmentation is accentuated in sun-exposed areas, flexural folds, and skin creases, including the creases on the palms (Fig. 151-12). Pigment may develop in scars and longitudinal pigmented bands may appear in the nails. These pigment changes are a consequence of low cortisol levels and the resulting loss of negative regulatory feedback on the hypothalamus and pituitary. This results in unchecked production of POMC, ACTH, and MSH, which increase melanogenesis. In contrast, vitiligo can be seen in 10%–20% of patients.[153] Axillary and pubic hair may be sparse in women, due to the loss of adrenal androgens. This does not occur in men because adequate androgen levels are maintained by the testes. Unique to men is the reported calcification of the auricular cartilages.[154] Extracutaneous symptoms include weakness, anorexia, weight loss, abdominal pain, and postural hypotension due to electrolyte abnormalities.

LABORATORY TESTS. Acute adrenal crisis can occur in the setting of chronic adrenal insufficiency and can be life threatening. The primary treatment is glucocorticoid replacement and, in an acute crisis, a blood sample should be obtained for measurement of

Figure 151-12 **A.** This patient with Addison disease demonstrates the characteristic hyperpigmentation of the skin with accentuation in sun-exposed areas. **B.** Palmar creases are also hyperpigmented compared to a normal hand.

cortisol, but therapy with 100 mg IV hydrocortisone should be instituted immediately. In chronic adrenal insufficiency, the diagnosis is confirmed using the cosyntropin stimulation test. This involves the IV administration of synthetic corticotropin (ACTH) and the measurement of stimulated cortisol in the blood 30 minutes later. Inability to produce adequate cortisol is diagnostic. Chronic replacement therapy is necessary and may require adjustments for illness or severe stress. With treatment, there is a gradual improvement in the skin changes.

ESTROGEN AND PROGESTERONE

ESTROGEN AND SKIN AT A GLANCE

- Exogenous estrogen, either through oral contraceptives or hormone replacement, is the most common cause of estrogen excess.
- Wrinkling, xerosis, and atrophy are signs of estrogen deficiency.
- Triple-ingredient preparations are firstline therapy for treating melasma if patients are not content with covering cosmetics.

EPIDEMIOLOGY. The most commonly encountered cause of estrogen excess is the pharmacologic use of estrogens for birth control, treatment of dysfunctional uterine bleeding, and as postmenopausal hormone replacement. Up to one-third of child-bearing age women in the United States use oral contraceptives.[155] Ovarian, testicular, or hypothalamic tumors can also cause estrogen excess. Estrogen deficiency occurs most commonly as a result of menopause, which occurs on average at about 50 years of age. Other less common causes of estrogen deficiency include pituitary or gonadal failure. Exercise-induced amenorrhea is also associated with a concomitant estrogen deficiency.

ETIOLOGY AND PATHOGENESIS. Estrogen receptors are found throughout the skin, including on keratinocytes, sebaceous glands, eccrine and apocrine glands, in hair follicles, in dermal fibroblasts, and in melanocytes. In women of reproductive age, reported variations in dermatological responses seen throughout the menstrual cycle suggest that estrogens and progesterones have important effects on the clinical presentation of numerous disease states and allergic conditions of the skin.[156] Estrogens bind to cytosolic receptors that subsequently translocate to the nucleus and activate gene transcription. Estrogen receptors are found in greater numbers in women compared with men. The main observations regarding the effects of estrogen on skin come from studies of postmenopausal women, in whom estrogen deprivation leads to skin wrinkling, xerosis, and atrophy. Increased epidermal and dermal thickness, increased water-holding capacity, changes in lipid composition of the stratum corneum, and improvement in skin laxity all occur with estrogen replacement, highlighting the important effects of this hormone throughout the skin.[157] Estrogen deprivation has also been reported to hinder wound healing, which subsequently improves with estrogen replacement. Estrogens have also been reported to suppress sebaceous gland function and also tend to inhibit hair growth.

The most potent naturally occurring estrogen is estradiol, which is the principal estrogen secreted by the ovary. Estrone, another estrogen secreted by the ovaries, is synthesized primarily in peripheral tissues from the conversion of androstenedione. In the menstrual cycle, estradiol levels peak at midcycle immediately preceding ovulation, and then again near the end of the cycle around day 24 before falling to baseline before menses. During pregnancy, the main estrogen is estriol, which is synthesized by the placenta. Progesterone is the main hormone secreted by the corpus luteum, and peak levels are seen after ovulation, remaining elevated until just before menses. Gonadal hormones are not entirely specific, and progesterone is able to crossreact by binding to androgen receptors to exert androgenic or antiandrogenic effects.

CLINICAL FINDINGS AND DIAGNOSIS: CUTANEOUS MANIFESTATIONS OF ESTROGEN EXCESS AND DEFICIENCY. Estrogen can have both beneficial and undesired effects. Estrogen replacement therapy in postmenopausal women can reverse epidermal atrophy and restore cutaneous collagen. The inhibitory actions of estrogen on sebum production can lead to improvement of acne with oral contraceptive therapy, particularly with the use of estrogen-dominant preparations. Despite circulating estriol during pregnancy, the relative androgen excess due to elevated progesterone can actually exacerbate acne in some patients. Telogen effluvium characterized by diffuse loss of scalp or body hair can occur after delivery or discontinuation of oral contraceptives. Both pregnant women and patients taking synthetic estrogen can be more prone to certain side effects of estrogen, including telangiectasias, palmar erythema, spider angiomas, and pigmentary changes.

Melanocytic lesions, including preexisting nevi and malignant melanoma, can darken during pregnancy. Hyperpigmentation of the nipples, linea nigra, and genitalia can be seen. Melasma, sometimes referred to as the *mask of pregnancy*, presents as irregularly shaped, hyperpigmented patches on the forehead, cheeks, nose, upper lip, chin, and neck (Fig. 151-13). Although melasma may improve after delivery, it can persist or reoccur with subsequent pregnancies. When caused by oral contraceptives, melasma can still persist even after discontinuation of the medication. In the very rare cases of men with melasma, the suspected etiology is thought to be sun exposure or familial susceptibility rather than estrogen excess, but the clinicopathological features are similar to that seen in female patients.[158]

Acanthosis nigricans can be associated with estrogen excess. In clinical states characterized by elevated estrogen levels, including pregnancy and the use of oral contraceptives, increased hair growth over the face, breasts, and extremities can be seen. This phenomenon may be a result of the complex interplay of estrogens and androgenic hormones rather than a direct effect of increased estrogen levels on the hair follicles themselves. Estrogen and progesterone dermatitis has been described in the literature and is characterized by a polymorphous eruption marked by cyclical premenstrual flares that may include pruritus.

Figure 151-13 Melasma is demonstrated in a symmetric pattern on the face of a young woman. The upper lip is also a common site of involvement.

The diagnosis may be made by separate subcutaneous injection of both estrogen and progesterone in the skin of the forearm, checking within 15–60 minutes for reactions ranging from erythema to a wheal.[159] Oral contraceptives have been implicated as a cause of erythema nodosum.

Estrogen deficiency from either menopause or pituitary failure can result in hot flashes, epithelial atrophy of the genitalia, and decreased breast size. Certain medications, such as danazol, leuprolide, and clomiphene citrate, can induce a pharmacologic menopause that presents with flushing. Flushing episodes accompanied by uncomfortable heat lasting several minutes can occur in younger women immediately before or during their period when estrogen levels are at their lowest.

TREATMENT. The Pigmentary Disorders Academy generated a consensus statement on the treatment of melasma and recommended the use of fixed "triple-ingredient" combinations as first-line therapy.[160] Topical retinoids, corticosteroids, azelaic acid, and hydroquinone-based bleaching creams have been used in various combinations to treat melasma. Kligman's formula, first developed in 1975, is the classic triple-ingredient melasma preparation consisting of 5% hydroquinone, 0.1% tretinoin, and 0.1% dexamethasone in a hydrophilic ointment. Dual ingredient combinations or single agents are reasonable alternatives. For refractory cases, chemical peels (i.e., glycolic acid or trichloroacetic acid) in combination with topical therapy can be tried. Lasers can also be considered but seem to be of limited usefulness. Given the exacerbation of hyperpigmentation with sun exposure, the consistent use of broad-spectrum sunscreens is also important for melasma treatment.

Although estrogen therapy can reverse some of the epithelial atrophy seen during menopause, the risks

and benefits of hormone replacement therapy must be weighed on an individual basis. Low-dose clonidine has been reported as an effective treatment for menopause-related flushing. There has been controversy regarding the use of estrogen therapies in patients with systemic lupus erythematosus, although two recent, well-designed trials suggest that these therapies can be used safely in most patients with systemic lupus erythematosus whose disease is stable.[161,162]

ANDROGENIC HORMONES

ANDROGENS AND SKIN AT A GLANCE

- The peripheral conversion of testosterone to 5 α-dihydrotestosterone is important for the pathophysiology of androgenic alopecia.
- Hirsutism secondary to androgen excess has a characteristic distribution that includes the beard area, chest, back, and suprapubic region.

EPIDEMIOLOGY. In males, cutaneous manifestations of androgen excess occur most commonly with either the onset of sexual maturation or with androgen replacement therapy. Androgen-secreting tumors are a less common cause of androgen excess. In women, androgen excess can occur due to congenital adrenal hyperplasia (CAH) secondary to deficiency of enzymes in adrenal enzymes such as 21-hydroxylase (encoded by the gene *CYP21A2*), which accounts for almost 90 percent of CAH in the United States.[163] Deficiency of CYP21 is inherited as an autosomal recessive trait and results in accumulation of 17-hydroxyprogesterone. Although progestins in oral contraceptives are listed as potential causes of hirsutism due to their chemical similarity to testosterone, they likely do not cause androgenic effects at clinically used doses based on data from animal studies. Polycystic ovary syndrome (PCOS) occurs in about 5% of premenopausal women in the United States and is characterized by insulin resistance, polycystic ovaries, and the presence of androgenic cutaneous findings, including acne, hirsutism, and androgenic alopecia. PCOS is also associated with the metabolic syndrome, which is characterized by lipid abnormalities, diabetic predisposition, and heart disease. Androgenic alopecia affects approximately one-half of men older than age 40 years, and potentially as many women as well, with most patients showing signs of alopecia by age 30 (see Chapter 88).

ETIOLOGY AND PATHOGENESIS. Like estrogen receptors, androgen receptors are also present throughout the skin. In men, androgens are synthesized in the testis and adrenals, whereas in women androgens are secreted by the ovaries and adrenals. In addition to testosterone, progesterone, dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEA-S) are all natural androgens that can lead to cutaneous findings when they are present in excess.[164] Testosterone is subsequently converted in peripheral target tissues to the active metabolite 5 α-dihydrotestosterone (5α-DHT) by the enzyme 5α-reductase. Unlike testosterone, which can be aromatized to form estrogen, 5α-DHT cannot be aromatized and thus retains purely androgenic properties. In addition, 5α-DHT binds the androgen receptor with greater affinity than testosterone.

Androgens are significant regulators of hair growth and sebaceous gland function. Androgens have also been implicated in wound healing, epidermal differentiation, and the regulation of dermal fibroblasts. Androgen receptors have a trophic distribution throughout the body that is most evident with the appearance of "male pattern" hair growth on the face, chest, and back, as well as areas of hair loss on the scalp. Both estrogens and androgens can be bound by sex hormone-binding globulin (SHBG). SHBG levels are decreased by synthetic progestins found in oral contraceptives (i.e., norgestrel, norethindrone, norgestimate, and desogestrel), as well as in obesity, acromegaly, hypothyroidism, and hyperinsulinemia. The decreased SHBG results in higher levels of circulating androgens and accounts, in part, for why androgenic findings can be associated with these conditions.

CLINICAL FINDINGS AND DIAGNOSIS: CUTANEOUS MANIFESTATIONS OF ANDROGEN EXCESS. Androgen-related skin conditions are commonly seen in dermatology practice. Although our knowledge regarding acne pathogenesis is still incomplete, at least part of acne's pathophysiology involves the response of sebaceous glands to androgens. In most males and females, acne tends to subside after adolescence (see Chapter 80). Cases of persistent acne should elicit a differential diagnosis that includes causes of persistent androgen excess, including CAH, PCOS in women, or an androgen-secreting tumor (Fig. 151-14), in addition to rosacea and chemically induced acne. In the appropriate clinical setting, laboratory studies may be helpful in determining the source of androgen excess (Box 151-16). Performance-enhancing anabolic steroids are derivatives of testosterone, and the resulting androgen excess can manifest as acne.

There is some genetic variation underlying the response of hair follicles to androgens as evidenced by the varying degrees of hirsutism seen among women with different ethnic backgrounds but similar serum androgen levels. Hirsutism secondary to androgen excess occurs in a characteristic distribution involving the beard region of the face, the chest, the upper back, and the suprapubic area.

Ironically, although androgens can cause hair excess, they are also responsible for male-pattern alopecia as well. Scalp hairs are eventually converted first to indeterminate hairs and then to vellus hairs. Clinically, scalp hairs become thinner until they are replaced by nonpigmented vellus hairs. In men, the pattern is characteristic and consists of symmetric recession of the hairline and the temples along with hair loss on the

Figure 151-14 Hyperandrogenism manifests clinically in this woman with an androgen-secreting adrenal tumor. Note the characteristic facial hair, the receding hairline, and the acneiform eruption on the chest.

BOX 151-16 APPROACH TO THE FEMALE PATIENT WITH SUSPECTED HYPERANDROGENISM

History and physical findings concerning for hyperandrogenism

- Sudden onset of acne
- Severe acne refractory to conventional treatments
- Irregular menstrual periods
- Hirsutism

Laboratory evaluation (most accurate when patient is off oral contraceptives for 4–6 weeks and if tests are drawn before menses)

- Dehydroepiandrosterone sulfate: screens for adrenal androgen source
  - >8,000 ng/mL may suggest adrenal tumor
  - 4,000–8,000 ng/mL may suggest congenital adrenal hyperplasia
- Testosterone: screens for ovarian source
  - 150–200 ng/dL can occur in polycystic ovarian syndrome
  - Some adrenal tumors can also secrete testosterone
- Luteinizing hormone–follicle stimulating hormone ratio
  - >2–3 can be consistent with polycystic ovarian syndrome

Adapted from Thiboutot D: Acne: Hormonal concepts and therapy. *Clin Dermatol* **22**:419, 2004.

vertex. In women, the frontal hairline is usually preserved, and the pattern is mostly diffuse thinning without an area of frank baldness. Although androgenetic alopecia can be acquired in patients with androgen excess, it is most commonly an incompletely characterized genetic disorder that appears to be inherited in an autosomal dominant manner (see Chapter 88).

TREATMENT. In women whose acne appears to be hormonally related, the use of antiandrogens, including the diuretic spironolactone or the oral contraceptive drospirenone, may prove more effective than conventional topical and oral acne medications. These drugs act as competitive inhibitors of DHT binding to androgen receptors. Specific 5α-reductase inhibitors, such as finasteride, can be used to treat androgenetic alopecia, although this medication is contraindicated in women of child-bearing age due to possible effects on development of genitalia and gonads in the male fetus. The use of finasteride has been linked to an increased risk of high-grade prostate cancer but without an increase in the absolute risk of prostate cancer in men with benign prostatic hypertrophy, although similar data on men using finasteride for hair loss has not been reported.[165] In postmenopausal women finasteride treatment has not demonstrated significant benefit in a large placebo-controlled trial.[166]

When patients have an excess of adrenal androgens such as DHEA-S, the use of low-dose glucocorticosteroids (such as prednisone, 2.5–5.0 mg/day) can be used for suppressive therapy, and the efficacy of therapy can be monitored by measuring serum DHEA-S levels. Cyproterone acetate is an antiandrogen that is not available in the United States, although it has shown promise in the treatment of acne when used in other countries in oral contraceptive preparations. Flutamide is a nonsteroidal androgen receptor antagonist that is rarely used due to the risk of fatal hepatitis as well as concerns about effects on fetal development in women of child-bearing age.[167]

DISORDERS OF GROWTH HORMONE

GROWTH HORMONE AT A GLANCE

- Growth hormone plays a central role in longitudinal growth.
- In children, deficiency manifests as short stature while gigantism occurs from oversecretion of growth hormone before puberty, when the growth plates in long bones are still open.
- The disease acromegaly occurs in adults after the growth plates have closed.
- Acromegaly results from oversecretion of growth hormone, usually due to a pituitary adenoma.

ACROMEGALY

GH is secreted by the pituitary in a pulsatile fashion and reaches its maximum rate during puberty and then declines over time. The pulsatile pattern of secretion is equally important to the amount of hormone for normal function. Secretion of GH is primarily regulated by GH-releasing hormone (GHRH) and somatostatin.[168] The natural GH secretagogue ghrelin, produced in the stomach, has been discovered to have potent GH-releasing properties and may be involved in a separate pathway of GH regulation.[168,169] GHRH stimulates the release of GH, whereas somatostatin has an inhibitory effect. The target of these regulatory factors is the GHRH receptor in the pituitary. The peripheral effects of GH are largely indirectly mediated through production of IGF1 in the liver and stimulation of the IGF1 receptor. GH contributes significantly to linear growth in children, increases protein synthesis, mobilizes stored triglycerides, and antagonizes the action of insulin (Fig. 151-15).

ETIOLOGY AND PATHOGENESIS. Excessive production of GH is almost always due to a pituitary adenoma. In children, this results in pituitary gigantism, whereas in adults, excessive GH manifests as the clinical syndrome acromegaly. This syndrome is diagnosed in about 3 to 4 people per million every year.[170] Very rarely, acromegaly is caused by a GH-producing tumor in the hypothalamus or by an ectopic nonendocrine tumor such as small cell lung cancer or carcinoid tumor.[171] GH-producing adenomas are present in 8% of patients with Carney complex, an inherited disorder with multiple lentigines and multiple endocrine abnormalities.[172]

CLINICAL FINDINGS. (Box 151-17). The clinical manifestations of acromegaly include the overgrowth of bone and connective tissue, metabolic effects, and localized tumor mass effects. The onset is insidious, and the average age at the time of diagnosis is 40–45 years, but often the condition has been present for many years before the diagnosis.[173] The metabolic effects include diabetes, hypertension, and hyperlipidemia. There is a gradual coarsening of the features and increased head, hand, and foot size. This acral pattern of overgrowth may be noticed as increasing shoe, ring, glove, or hat size (Fig. 151-16A). Macroglossia can be seen. The skin becomes thickened, almost doughy, with deep grooves prominent on the forehead and around the nasolabial folds (Fig. 151-16B). On the scalp, cutis verticis gyrata may develop. Heel pads and the pads of the digits become thickened. Nails are thickened and brittle, and some patients develop hirsutism. Hyperhidrosis and malodor are common complaints. Many patients develop acanthosis nigricans and multiple acrochordons with or without frank diabetes. Retinal angioid streaks can be seen in acromegaly (as well as in osteogenesis imperfecta and pseudoxanthoma elasticum) (see Chapter 137). Histologically, there is a dense deposition of GAGs in the papillary and superficial reticular dermis. Often, coarse collagen bundles with normal elastin and increased numbers of fibroblasts are seen in the dermis.

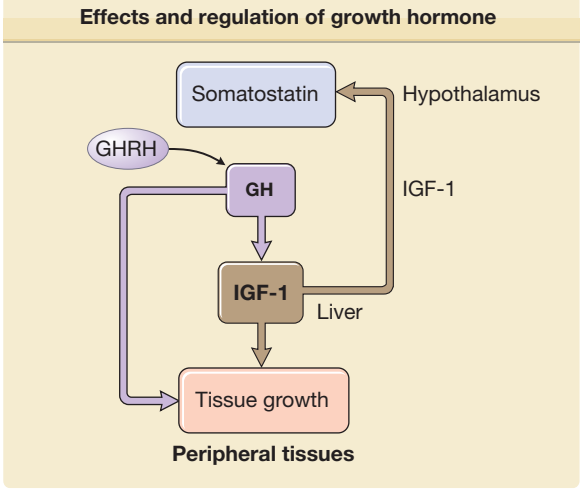

Figure 151-15 Effects and regulation of growth hormone (GH). GHRH = growth hormone releasing hormone; IGF-1 = insulin-like growth factor-1.

BOX 151-17 APPROACH TO THE PATIENT WITH ACROMEGALY

CUTANEOUS FINDINGS IN ACROMEGALY
- Enlargement of hands and feet with a doughy texture
- Increased ring, glove, shoe, and hat size
- Jaw enlargement with separation of teeth (prognathism)
- Macroglossia
- Cutis vertices gyri
- Acanthosis nigricans
- Hirsutism
- Hyperhidrosis
- Brittle thick nails

RELATED FEATURES
- Diabetes
- Hypertension
- Hyperlipidemia

DIAGNOSIS
- Elevated serum insulin-like growth factor-1 levels
- Failure to suppress growth hormone levels by oral glucose-tolerance test

MANAGEMENT
- Appropriate endocrine and surgical consultation
- Surgical removal of adenoma by transphenoidal resection
- Somatostatin analogues or growth hormone receptor antagonists for residual disease
- Radiation therapy is an option for resistant cases

Figure 151-16 **A.** Acral enlargement is a prominent feature of acromegaly and is easily demonstrated in comparison with a normal hand. **B.** Patients develop deep grooves on the forehead and around the nasolabial folds. When jaw enlargement is present, spaces between the teeth can be seen. (Reprinted from Braverman I: *Skin Signs of Systemic Disease,* 3rd edition. Saunders, 1997, with permission.)

LABORATORY TESTS. Measurement of the serum GH level is highly variable and unreliable diagnostically because of the pulsatile pattern of secretion. Plasma IGF1 levels are very much dependent on GH and fairly stable during any 24-hour period. Serum IGF1 can be used as a surrogate measurement of GH. As a screening test for acromegaly, IGF1 levels will be elevated. Further workup with assistance from a consulting endocrinologist may include an oral glucose tolerance test. In the proper clinical setting failure to suppress the GH level to <1 ng/mL within 1–2 hours after 75–100 g of oral glucose is diagnostic for acromegaly.[174]

TREATMENT. Because most cases of GH excess are due to a pituitary adenoma, surgical removal is the primary therapy. This is most commonly accomplished through a selective transsphenoidal resection.[175] Residual disease after surgery is more common in larger adenomas and may be higher than 30% for tumors larger than 1 cm. The inhibitory effect of somatostatin on GH secretion is harnessed for therapy. Somatostatin analogues, including octreotide, are used for the medical treatment of residual disease after surgery and are increasingly being considered as potential primary therapy. The somatostatin analogues alone have demonstrated the ability to reduce the size of tumors and to control IGF1 levels in select patients. In resistant cases, radiation therapy can be considered.

GROWTH HORMONE DEFICIENCY AND PANHYPOPITUITARISM

GH deficiency can occur in children or adults and be inherited or acquired. The primary clinical manifestation of this deficiency occurs in children as abnormal short stature. This can be corrected by the administration of GH. The clinical presentation of GH deficiency in adults includes decreased lean body mass, decreased strength and exercise capacity in part due to decreased sweating, and a loss of general vitality. Replacement therapy in adults is a complex discussion and beyond the scope of this chapter. Recently, practice guidelines have been established by the Endocrine Society for the assessment and treatment of GH deficiency in adults.[176] In the setting of panhypopituitarism, there is total loss of all pituitary function, including GH (Box 151-18). These patients usually present with a combination of symptoms either due to a space-occupying lesion in the

BOX 151-18 CAUSES OF HYPOPITUITARISM

- Mass lesions: nonfunctioning pituitary adenoma, cyst, craniopharyngioma, metastasis
- Infectious causes: tuberculosis, histoplasmosis
- Pituitary infarction: known as Sheehan syndrome when occurs with childbirth
- Pituitary apoplexy: sudden hemorrhage into the pituitary
- Lymphocytic hypophysitis
- Infiltrative disorders: hemochromatosis, sarcoidosis, Langerhans cell histiocytosis
- Head trauma
- Surgery or radiation

Figure 151-17 In this patient with panhypopituitarism, fine wrinkling and pale skin can be seen as well as other features suggestive of hypothyroidism. Her decreased pigmentation is contrasted by that of her nurse on the right. Patients with panhypopituitarism often present with findings of multiple endocrine disorders.

pituitary or to hormone dysregulation. These symptoms may be a manifestation of any number of endocrine systems that are regulated at the level of the pituitary including features of hypothyroidism. Skin findings that have been described in these patients include fine wrinkling of the skin, decreased pigmentation, and decreased to absent pubic and axillary hair (Fig. 151-17).

Chapter 152 :: Sarcoidosis

:: Richard M. Marchell, Bruce Thiers, & Marc A. Judson

SARCOIDOSIS AT A GLANCE

- Sarcoidosis is a systemic granulomatous disease of unknown cause that primarily affects the lungs, but often involves the skin.
- The highest prevalence of sarcoidosis is in Denmark and Sweden; in the United States, it is higher in persons of African descent.
- The most common sites of cutaneous sarcoidosis are the head and neck. Scar tissue at all sites can be affected.
- The most common cutaneous form of sarcoidosis, the papular form, is characterized by translucent yellow-red papules with an "apple jelly" appearance on diascopy.
- Noncaseating, "naked" granulomas on biopsy are quite suggestive, but not specific for the diagnosis.
- Erythema nodosum is the main nonspecific cutaneous manifestation of sarcoidosis, and heralds a good prognosis.

Sarcoidosis is a multisystem granulomatous disease of unknown cause. The lung is the most commonly affected organ, but the skin is frequently involved.[1] The first descriptions of sarcoidosis in the late 1800s were limited to its skin manifestations.[1] The term *sarcoidosis* is derived from Caesar Boeck's 1899 report of what he described as "multiple benign sarkoid of the skin," because he believed the lesions resembled sarcomas but were benign.[2]

EPIDEMIOLOGY

Sarcoidosis occurs worldwide and affects all ages and races. Disease onset is most often in the third decade of life, although a smaller second peak occurs in people older than 50 years.[1] The prevalence rate is slightly higher in women.[1] Sarcoidosis is more frequent away from the equator. The highest prevalence of sarcoidosis is found in Caucasians in Denmark, Sweden, and, in the United States, in persons of African descent.[1] In the United States, the lifetime risk of sarcoidosis is 2.4% in African-Americans and 0.85% in Caucasians.[3] The age-adjusted annual incidence rate of sarcoidosis in the United States is 35.5 per 100,000 for African-Americans and 10.9 per 100,000 for Caucasians.[3] The frequency and severity of the disease also vary between different ethnicities and races. African-Americans tend to have more severe disease, whereas Caucasians are more likely to present with asymptomatic disease.[4,5] African-Americans are also more likely to have extrapulmonary disease,[6] require treatment,[7] develop new organ involvement,[8] and have a lower rate of clinical recovery than Caucasians.[5,8] The disease is more common in life-long nonsmokers.[9]

ETIOLOGY AND PATHOGENESIS

The current understanding is that the development of sarcoidosis requires at least three major events: (1) exposure to antigen(s), (2) acquired cellular immunity directed against the antigen and mediated through antigen-presenting cells and antigen-specific T lymphocytes, and (3) the appearance of immune effector cells that promote a nonspecific inflammatory response.[10] The identity of the putative antigen(s) of sarcoidosis is unknown.

Presumably, antigen-presenting cells such as macrophages recognize, process, and present the processed antigen to $CD4^+$ T cells of the T helper 1 type

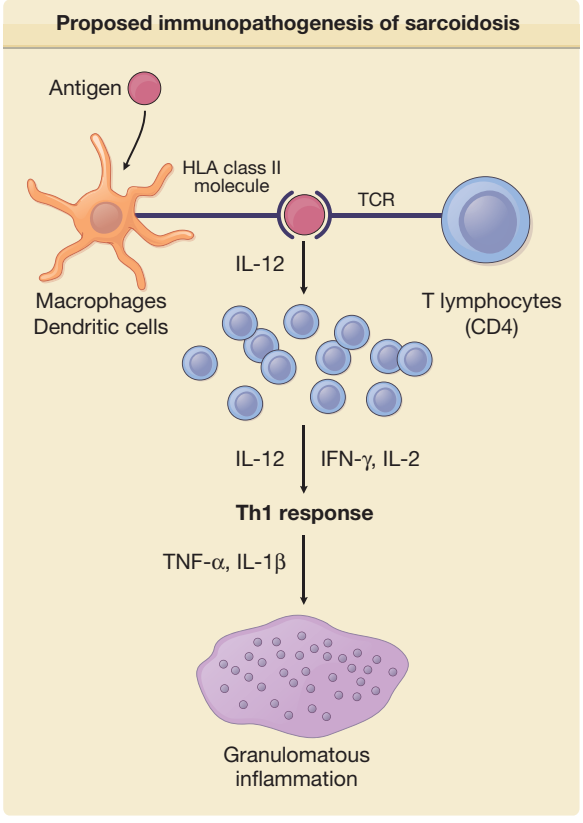

Figure 152-1 Proposed immunopathogenesis of sarcoidosis. An antigen, presently unknown, is engulfed and processed by an antigen-presenting cell (macrophage or dendritic cell). The processed antigen is presented to a T-cell receptor (TCR) of a T lymphocyte via an HLA class II molecule. Once the HLA receptor and TCR have bound the processed antigen, numerous lymphokines and cytokines of the T helper 1 (Th1) class are released that lead to T-cell proliferation, recruitment of monocytes, and eventual granuloma formation. A few of these lymphokines and cytokines are shown, with those released by the antigen-presenting cells on the left and those released by lymphocytes on the right. IFN = interferon; IL = interleukin; TNF = tumor necrosis factor.

(Fig. 152-1). The processed antigen is presented to these lymphocytes via HLA class II molecules on the antigen-presenting cells that have undergone enhanced expression from exposure to the sarcoidosis antigen and possibly interferon-γ (IFN-γ).[10,11] These activated macrophages produce interleukin (IL)-12, which induces lymphocytes to shift toward a T helper 1 profile and causes T lymphocytes to secrete IFN-γ. These activated T cells release IL-2 and chemotactic factors that recruit monocytes and macrophages to the site of disease activity. IL-2 and other cytokines also expand various T-cell clones. IFN-γ further activates macrophages and transforms them into giant cells.[11] Tumor necrosis factor (TNF), IL-2, and other cytokines may also be important in stimulating macrophages.[12] Figure 152-1 displays the major features of the presumed immunopathogenesis of sarcoidosis.

A variety of candidate antigens have been suggested as provocative agents for the cascade of immunologic events that eventuate in sarcoidosis. Infectious agents such as mycobacteria,[13] *Propioni-bacterium acnes*,[14] and *Chlamydia*[15] have been associated with sarcoidosis. Mineral dusts, such as silica, iron,[16] and titanium,[17] also have been associated with sarcoidosis as have combustible wood products because the disease has been found more commonly in individuals who use wood stoves.[18] Interestingly, firefighters have been found to be at greater risk of developing sarcoidosis.[19]

Genetics play a major role in determining susceptibility to sarcoidosis, as it is more common in relatives of an affected person than in individuals in the general population.[20] Genes coding for HLA class II antigens are thought to be prime candidates for a role in the development of the disease because these molecules present exogenous peptides to $CD4^+$ T-cell receptors. Numerous studies in various ethnic groups have shown a relationship of HLA antigens to the development of disease, protection from disease, good prognosis, poor prognosis, acute disease, chronic disease, and various phenotypic expressions of sarcoidosis.[21]

The interplay of antigenic and genetic factors suggests that there may be multiple causes of sarcoidosis. Patients may have to experience a specific interaction between one or several exposures and be genetically programmed to one or several abnormal immunologic responses. Each putative antigen may be associated with a specific HLA class II molecule and T-cell receptor.

CLINICAL FINDINGS

HISTORY

The diagnosis of sarcoidosis is often delayed for months to years because symptoms are nonspecific and can relate to involvement of any organ.[22]

Thirty to sixty percent of patients with pulmonary sarcoidosis are asymptomatic.[23] Other than the lung, the skin, eye, liver, and peripheral lymph nodes are commonly involved. Consequently, sarcoidosis should be considered in a patient with skin lesions and concomitant pulmonary symptoms, eye complaints, right upper quadrant abdominal pain, or peripheral lymphadenopathy. In addition, the cytokines associated with the granulomatous inflammation of sarcoidosis may cause constitutional symptoms such as fever, night sweats, malaise, and weight loss.

Cutaneous lesions of sarcoidosis may occur before, coincident with, or after systemic involvement. Specific cutaneous lesions are usually asymptomatic. Pruritus and pain are rare. Cosmetic disfigurement is the most common complaint. Erythema nodosum associated with sarcoidosis is indistinguishable from erythema nodosum unassociated with sarcoidosis (see Chapter 70).

CUTANEOUS LESIONS

Classically, lesions are divided into two categories: (1) specific and (2) nonspecific. Specific lesions have

Figure 152-2 Cutaneous sarcoidosis of the face. Micropapular form.

granulomas on biopsy. Nonspecific skin findings are reactive and do not exhibit sarcoidal granulomas.

SPECIFIC LESIONS SKIN. Specific sarcoidal lesions most often are found on the head and neck (Figs. 152-2–152-4) but may occur symmetrically or asymmetrically on any part of the skin and mucosa. Almost all morphologies have been reported, including macules, papules, patches, plaques, and nodules. Alopecia occurs with scalp involvement, and nail changes also occur. Specific lesions of sarcoidosis may be scaly, telangiectatic, or atrophic. Despite the diversity in appearance, there are several clinical presentations that are classically associated with cutaneous sarcoidosis.

The most common presentation is the papular form (see Figs. 152-2–152-4). These firm, 2–5-mm papules often have a translucent red-brown or yellow-brown appearance. The yellow-brown color has been likened to "apple jelly" and is accentuated with diascopy (Fig. 152-5). In addition to the color change, the underlying granulomas have a nodular quality that can also be appreciated with diascopy. The apple jelly appearance and nodules are not pathognomonic for

Figure 152-3 Cutaneous sarcoidosis of the face. Papular form. Some of the papules have enlarged to small plaques.

Figure 152-4 Cutaneous sarcoidosis of the face. Symmetric papules on cheeks.

sarcoidosis, as other granulatomous skin conditions, such as lupus vulgaris (see Chapter 184), may exhibit similar diascopic properties. Epidermal changes may or may not be present, but often the lesions have a waxy appearance, which reflects mild epidermal atrophy. Papular lesions occur most commonly on the face and neck, with a predilection for periorbital skin (see eFig. 152-5.1 in online edition). Annular plaques (Fig. 152-6), nonannular plaques (Fig. 152-7 and see eFig. 152-7.1 in online edition), and nodules (Fig. 152-8) may develop from these papular lesions and may or may not retain the classic translucent quality of the papules.

Lupus pernio describes the relatively symmetric, violaceous, indurated plaques and nodules

Figure 152-5 Diascopy highlights the "apple jelly" coloration of cutaneous sarcoidosis.

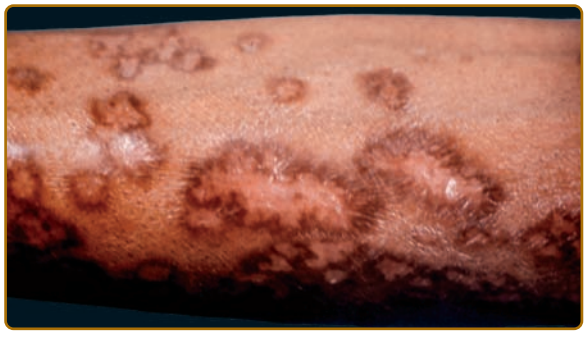

Figure 152-6 Cutaneous sarcoidosis with an annular configuration.

that occur on the nose, earlobes, cheeks, and digits (Figs. 152-9–152-11). This clinical variant of sarcoidosis is distinctive and has been associated with systemic involvement. Lupus pernio is associated with a higher prevalence of upper respiratory tract disease.[24] Lupus pernio lesions may directly extend into the nasal sinus, leading to epistaxis, nasal crusting, and sinus bone involvement.

Angiolupoid lesions are pink papules and plaques with prominent telangiectasias that usually occur on the face (see eFig. 152-11.1 in online edition) and may be a variant of lupus pernio, as both lesions usually appear on the face and can be violaceous.[25,26] However, angiolupoid lesions tend to be less numerous than the papular and lupus pernio forms.[26]

Rarely, sarcoidosis can present as persistent subcutaneous nodules (Darier-Roussy sarcoid).[27] The nodules may be tender or painless and preferentially occur on the extremities.

Figure 152-7 Plaques of cutaneous sarcoidosis on the neck and upper back.

Figure 152-8 Nodular sarcoidosis in the face. In Caucasians, lesions of sarcoidosis are often red or purple.

SCARS. Cutaneous sarcoidosis occurs preferentially within scar tissue, at traumatized skin sites, and around embedded foreign material such as silica. Scars become inflamed and infiltrated with sarcoidal granulomas (Fig. 152-12). Inflammation of old scars (see eFig. 152-12.1 in online edition) may parallel or precede systemic disease activity. Infiltrated scars may be tender or pruritic. Scar sarcoidosis may be the only cutaneous finding in a patient with systemic sarcoidosis; therefore, it is important to closely examine scar tissue in patients suspected of having the disease. The presence of sarcoidal granulomas surrounding foreign material does not establish the diagnosis of sarcoidosis, nor does foreign material in the presence of granulomas exclude the diagnosis.[28] Other signs of systemic

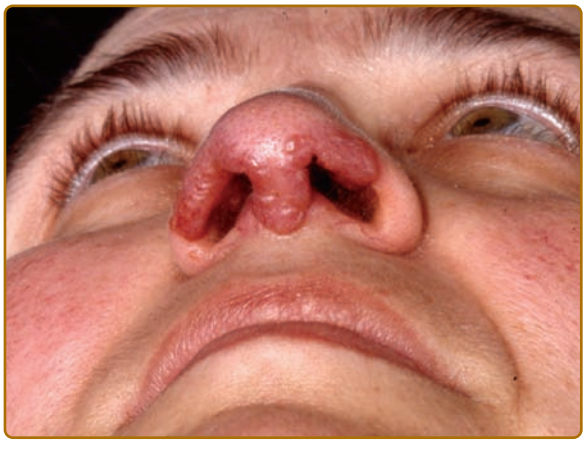

Figure 152-9 Lupus pernio along the nasal rim. This patient also had sarcoidosis of the upper respiratory tract (SURT) (see Section "Other Organs").

Figure 152-10 Violaceous lupus pernio lesions on cheek and nose.

or cutaneous involvement are required to confirm the diagnosis.

SCALP. Alopecia occurs with involvement of the scalp and may be scarring or nonscarring (see eFig. 152-12.2 in online edition).[29–32] Biopsy shows noncaseating granulomas. Its reversibility is dependent on the degree of destruction of hair follicles.

NAILS. Sarcoidosis may cause nail plate deformation and discoloration, but the incidence is very low.[33] There may be clubbing, (Fig. 152-11) subungual hyperkeratosis, and even nail plate destruction. Nail manifestations may result from granulomas in the nail matrix or from involvement of adjacent bone.

Figure 152-11 Violaceous lupus pernio on distal fingers.

Figure 152-12 Sarcoidosis arising in old facial scars sustained after car accident.

MUCOUS MEMBRANES. Sarcoidal granulomas may cause papules and plaques of the mucosal surfaces and tongue. Sarcoidosis is one cause of Mikulicz syndrome, the bilateral enlargement of the lacrimal (see eFig. 152-12.3 in online edition), parotid, sublingual, and submandibular glands.

ADDITIONAL PRESENTATIONS. A myriad of additional clinical presentations have also been reported. These include ichthyosis,[34] erythroderma,[29] ulcerations (see eFigs. 152-12.4 and 152-12.5 in online edition),[35] morphea-form plaques,[36] lichen niditus-like papules,[37] folliculitis-like lesions,[38] psoriasiform plaques,[39] hypopigmented areas,[40] gyrate erythema,[41] verrucous lesions,[38] faint erythema, penile (see eFig. 152-12.6 in online edition) and vulvar lesions,[42,43] palmar erythema,[44] discoid lupus-like plaques,[45] lower extremity edema,[46] lesions mimicking tuberculoid leprosy (see eFig. 152-12.7) polymorphous light eruption,[38] and pustular lesions.[38]

NONSPECIFIC LESIONS. Erythema nodosum (see Chapter 70) is the main nonspecific cutaneous manifestation of sarcoidosis (prevalence of approximately 17%). Erythema nodosum with bilateral hilar adenopathy, arthralgias, and fever is frequently the initial manifestation of sarcoidosis and is called *Löfgren syndrome*. These patients tend to have an acute form of sarcoidosis with eventual resolution.

Other nonspecific cutaneous manifestations of sarcoidosis are much less common. The neutrophilic dermatoses, Sweet disease and pyoderma gangrenosum, have been reported as nonspecific cutaneous sarcoid lesions. Most of the sarcoid patients with Sweet disease lesions or pyoderma gangrenosum have concomitant erythema nodosum.[47] Nonspecific erythematous

eruptions resembling viral exanthems or drug reactions without histologic evidence of granulomatous inflammation occur rarely with acute sarcoidosis. Additionally, patients with sarcoidosis may have pruritus without granulomatous infiltration, leading to prurigo nodules.[25] Erythema multiforme had been regularly cited as a nonspecific cutaneous manifestation of sarcoidosis,[38] but reports of histologically proven erythema multiforme with interface dermatitis associated with sarcoidosis are virtually nonexistent in the literature,[25,38,48,49] and any association is probably coincidental. Erythroderma and lower extremity swelling have been described as both specific and nonspecific lesions of sarcoidosis.[25,46,50,51]

RELATED CLINICAL FINDINGS

LUNGS. The lung is the most common organ involved with sarcoidosis. Findings on pulmonary examination are usually absent. Patients with pulmonary sarcoidosis are often asymptomatic, with the disease detected on a screening chest radiograph. Common symptoms include dyspnea, cough, chest pain, and wheezing. The chest radiograph is abnormal in more than 90% of patients with sarcoidosis. Bilateral hilar adenopathy is noted in 50%–85% of cases (see eFig. 152-12.8 in online edition). Pulmonary parenchymal infiltrates are seen in 25%–60% of cases.

Chest computed tomography (CT) reveals more thoracic disease than can be appreciated on the chest radiograph. CT is superior to the chest radiograph in detecting thoracic involvement with sarcoidosis, but there is insufficient evidence that CT has a clinical role in the management of pulmonary sarcoidosis.[52]

In sarcoidosis patients with normal lung parenchyma on chest radiograph, pulmonary function tests are abnormal in 20%–40% of cases. When the chest radiograph is abnormal, pulmonary function tests are abnormal in 50%–70% of cases.

EYES. The eyes are involved in one-fourth to three-fourths of sarcoidosis patients.[53] Eye involvement with sarcoidosis is potentially vision threatening, and the patient may be asymptomatic. For this reason, every patient diagnosed with sarcoidosis requires an ophthalmologic examination.[53] Redness, burning, itching, or dryness are the most common ocular symptoms when present. Any portion of the eye may be involved, and eye involvement may be the first manifestation of the disease.[53] Uveitis is the most common ocular manifestation and can lead to cataracts and glaucoma. Other ocular manifestations include conjunctivitis, lacrimal gland involvement causing kerato-conjunctivitis sicca (dry eyes), and optic neuritis, which may rapidly lead to loss of vision. Heerfordt syndrome includes fever, parotid gland enlargement, facial palsy, and anterior uveitis.[1]

LIVER. Hepatic involvement is common at disease onset but usually does not cause signs or symptoms.[54] Although histologic evidence of hepatic sarcoidosis is present in more than one-half of sarcoidosis patients,[55] signs of organ dysfunction due to hepatic sarcoidosis are far less common.[54] Hepatomegaly, abdominal pain, and pruritus are present in only 15%–25% of patients with hepatic sarcoidosis. An increased serum alkaline phosphatase level occurs in approximately one-third of patients,[56] but it is rarely associated with permanent hepatic dysfunction and therefore does not mandate treatment.[54,56] Treatment is required in the rare patient with significant symptoms, evidence of synthetic dysfunction, or hyperbilirubinemia. Rarely, hepatic sarcoidosis may lead to a primary biliary cirrhosis-type picture, and portal hypertension may develop.[57]

HEART. Clinical evidence of cardiac involvement is found in only 5% of sarcoidosis patients,[58] although myocardial granulomas have been found in approximately 25% of patients at autopsy.[59] Most clinical problems are related to cardiac arrhythmias or left ventricular dysfunction.[60,61] Sudden death may occur. Congestive heart failure may result when the myocardium is massively infiltrated with granulomas. Because of the potential lethal nature of heart involvement with sarcoidosis, an electrocardiogram is recommended for every patient diagnosed with the disease.[1]

NERVOUS SYSTEM. Any portion of the central nervous system or peripheral nervous system may be affected by sarcoidosis. Neurosarcoidosis has a predilection for the base of the brain, and cranial neuropathies are the most common manifestation.[62] The facial nerve is the cranial nerve most frequently involved.[62] In fact, it is common for Bell palsy to be the first manifestation of sarcoidosis and resolve completely before other manifestations of the disease occur. Mass lesions may develop in the brain or spinal cord. Aseptic meningitis and peripheral neuropathy are other neurologic manifestations of sarcoidosis.[63]

OTHER ORGANS. The sinuses and upper airway are commonly involved with sarcoidosis, a condition known as *SURT*: *s*arcoidosis of the *u*pper *r*espiratory *t*ract.[64] Nasal SURT is often associated with lupus pernio skin lesions (see Fig. 152-9) and may cause epistaxis and severe nasal crusting. Sarcoidosis of the spleen is not rare.[65] Sarcoidosis may also cause a disorder in calcium metabolism that results from activated sarcoidal macrophages demonstrating an increase in 1-α hydroxylase activity. This enzyme converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active form of the vitamin, an increase of which may result in hypercalcemia, hypercalciuria, and nephrolithiasis.[66] Sarcoidosis may be associated with a reduction in any blood cell line. Leukopenia may result from bone marrow involvement or from splenic sequestration. Thrombocytopenia may result from bone marrow involvement, splenic sequestration, or from an idiopathic thrombocytopenic purpura-like syndrome related to the hypergammaglobulinemia often seen in patients with sarcoidosis.[67]

BOX 152-1 RECOMMENDED INITIAL EVALUATION OF PATIENTS WITH SARCOIDOSIS

- History (occupational and environmental exposure, symptoms)
- Physical examination
- Posteroanterior chest X-ray
- Pulmonary function tests: spirometry, DL_{CO} and KL_{CO}
- Peripheral blood counts: white blood cells, red blood cells, platelets
- Serum chemistries: calcium, liver enzymes (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase), creatinine, and blood urea nitrogen
- Urine analysis
- Electrocardiogram
- Routine ophthalmologic examination
- Tuberculin skin test

DL_{CO} = diffusing capacity of lung for carbon monoxide; KL_{CO} = diffusing capacity per liter alveolar volume.
Adapted from American Thoracic Society/European Respiratory Society: Statement on sarcoidosis. Joint Statement of the American Thoracic Society (ATS), the European Respiratory Society (RS) and the World Association of Sarcoidosis and Other Granulomatous Diseases (WASOG) adopted by the ATS Board of Directors and the ERS Executive Committee, February 1999. *Am J Respir Crit Care Med* **160**:736, 1999, with permission.

LABORATORY TESTS

Box 152-1 lists clinical, imaging, and laboratory tests recommended when a diagnosis of sarcoidosis is entertained. These tests screen for involvement of various organs. A careful history and physical examination should be performed to detect signs and symptoms of organ involvement as well as to obtain a history suggesting another granulomatous disease (e.g., exposure to tuberculosis, endemic fungi, beryllium exposure).

Additional laboratory tests that assess disease activity are listed in the following sections. Although controversial, these tests are not routinely recommended because active granulomatous inflammation in sarcoidosis may remit spontaneously and therefore does not mandate treatment.

ANGIOTENSIN-CONVERTING ENZYME

The epithelioid cell of the sarcoidal granuloma secretes angiotensin-converting enzyme[68]; therefore, serum angiotensin-converting enzyme (SACE) levels reflect the total granuloma burden in sarcoidosis. Clinical data concerning SACE in sarcoidosis suggest that an elevated SACE level is insufficiently specific for the diagnosis of sarcoidosis to rest on it alone and insufficiently sensitive to exclude the diagnosis.[69] However, SACE may be useful as an adjunct in the diagnosis of the disease. Because SACE reflects the total body granuloma burden, SACE levels may be useful to monitor the course of sarcoidosis. Initial SACE levels are not different between patients who deteriorate and those who improve[70]; thus, SACE levels should not be used as a basis for treatment decisions.

GALLIUM, NUCLEAR MAGNETIC, AND POSITRON EMISSION SCANS

The mechanism of gallium-67 uptake in sarcoidosis is not completely understood. It is thought that inflammatory processes cause hyperemia and increased capillary permeability of gallium. Gallium also accumulates in macrophages and, to a lesser extent, in T lymphocytes, which are major participants in the granulomatous inflammation of sarcoidosis. Sarcoidosis may cause gallium uptake in thoracic and extrathoracic sites, although typically not in areas of skin involvement. Gallium scanning has not been found to be useful for monitoring the clinical course of sarcoidosis, but it may have a role in identifying organs with sarcoid involvement (see Section "Panda and Lambda Sign on Gallium-67 Scan"). Recently, organ activity from sarcoidosis has been detected by gadolinium enhancement on nuclear magnetic imaging (MRI) and by fluorodeoxyglucose positron emission tomography (PET) scanning.[71] These latter scanning techniques may be more sensitive than gallium-67 scanning in revealing granulomatous inflammation from sarcoidosis. In addition, they are less cumbersome tests in that the patient does not have to return 48–72 hours later for rescanning.

PATHOLOGY

The epithelioid granuloma of sarcoidosis usually contains a compact collection of mononuclear phagocytes. The granulomas typically are surrounded by a paucity of lymphocytes ("naked granulomas"), but varying degrees of lymphocytic inflammation may be present (Fig. 152-13 and see eFig.152-13.1 in online edition).[68]

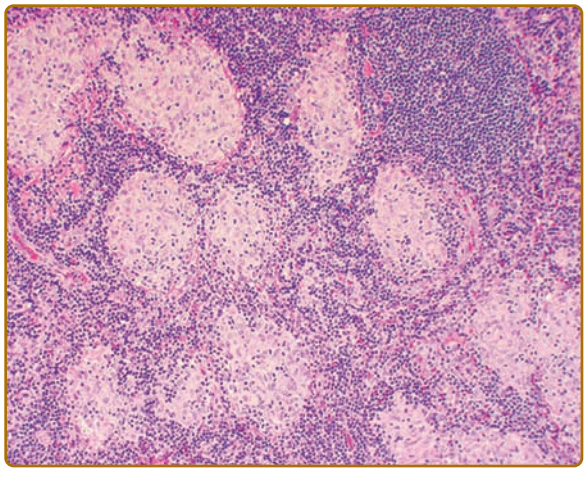

Figure 152-13 Histologic specimen of sarcoidosis demonstrating noncaseating granulomatous inflammation with multinucleated giant cells and a surrounding zone of lymphocytes.

BOX 152-2 MAJOR PATHOLOGIC DIFFERENTIAL DIAGNOSIS OF SARCOIDOSIS ON SKIN BIOPSY

- Tuberculosis
- Atypical mycobacteriosis
- Fungal infection
- Reaction to foreign bodies: beryllium, zirconium, tattooing, paraffin, etc.
- Rheumatoid nodules

Adapted from American Thoracic Society/European Respiratory Society: Statement on sarcoidosis. Joint Statement of the American Thoracic Society (ATS), the European Respiratory Society (RS) and the World Association of Sarcoidosis and Other Granulomatous Diseases (WASOG) adopted by the ATS Board of Directors and the ERS Executive Committee, February 1999. *Am J Respir Crit Care Med* **160**:736, 1999, with permission.

Epithelioid cells, which are themselves transformed monocytes, are commonly present within the sarcoidal granuloma. Multinucleated giant cells of the Langhans type result from the fusion of epithelioid cells. Although central fibrinoid necrosis is not uncommon, gross necrosis is not a characteristic feature of sarcoid granulomas and suggests an alternative diagnosis, such as tuberculosis, fungal infection, or vasculitis.[68] Mycobacterial and fungal diseases must always be considered as alternative diagnoses; therefore, stains and cultures for mycobacteria and fungi should be routinely performed on biopsy specimens. Box 152-2 lists the major pathologic differential diagnoses of sarcoidosis on skin biopsy.

A clinically important aspect of the pathology of sarcoidosis involves the development of fibrosis. Dense bands of fibroblasts may encase the ball-like granulomas. This fibrotic response can produce tissue destruction and organ dysfunction that is often irreversible.[10] Currently available chemotherapeutic agents for sarcoidosis can effectively treat the granulomatous inflammatory response but not the fibrotic reaction.

DIAGNOSIS

The diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing similar histology or clinical features.[1] Because sarcoidosis is a diagnosis of exclusion, the diagnosis can never be confirmed with 100% certainty.[72]

Normally, the diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing similar histology or clinical features (Fig. 152-14). Alternatively, the diagnosis can be assumed without biopsy when the clinical presentation is typical for the disease and is not explained by an alternative cause.

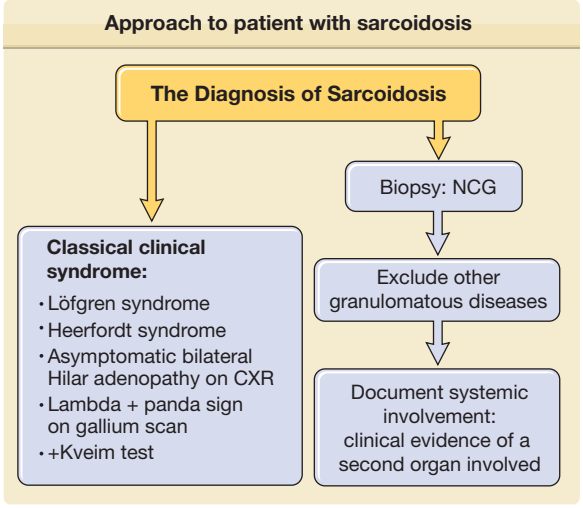

Figure 152-14 Approach to patient with sarcoidosis. Diagnostic algorithm. Usually the diagnosis is made by following the pathway on the right: A tissue biopsy demonstrates noncaseating granulomatous inflammation with a compatible clinical picture, alternative causes of granulomatous inflammation are excluded (including tuberculosis), and there is clinical evidence of systemic (multiorgan) granulomatous inflammation. On occasion, the diagnosis can be assumed without biopsy confirmation if the clinical presentation is very specific for sarcoidosis. These clinical presentations are listed on the left side of the pathway. CXR = chest X-ray; NCG = noncaseating granulomas.

The presence of noncaseating granulomas in a single organ does not conclusively establish the diagnosis of sarcoidosis because sarcoidosis is, by definition, a systemic disease that should involve multiple organs.[73] Isolated skin granulomas should not be assumed to represent sarcoidosis, and efforts must be made to exclude alternative diagnoses (see Box 152-2). Although a confirmed diagnosis of sarcoidosis requires proof of granulomatous involvement in at least two separate organs, histologic confirmation is usually not required in the second organ.[74]

Certain disease presentations are so specific for the diagnosis of sarcoidosis (e.g., Löfgren syndrome,[75] Heerfordt syndrome, and asymptomatic bilateral hilar adenopathy) that the diagnosis may be accepted without a tissue biopsy.

ASYMPTOMATIC BILATERAL HILAR ADENOPATHY

Asymptomatic hilar adenopathy on chest radiograph almost always represents sarcoidosis.[76] It has been suggested that histologic confirmation of sarcoidosis may not be required in asymptomatic patients with bilateral hilar adenopathy, provided the physical examination, complete blood cell count, and routine blood tests are all normal and there is no prior history of malignancy.[23] In such cases, chest radiographs should be monitored at 3- to 6-month intervals, and a biopsy should be performed if there is significant change in the chest radiograph.[23]

PANDA AND LAMBDA SIGN ON GALLIUM-67 SCAN

The presence of panda sign (bilateral lacrimal and parotid gland uptake) and lambda sign (bilateral hilar and right paratracheal uptake) on gallium-67 scanning is highly specific for sarcoidosis and may obviate the need for invasive diagnostic procedures. However, these signs are both positive in only a small percentage of sarcoidosis patients.

NATURAL HISTORY AND PROGNOSIS

The granulomatous inflammation of sarcoidosis can remit spontaneously or with therapy. Therefore, the general prognosis of sarcoidosis is good.[73] Pulmonary sarcoidosis resolves, improves, or stabilizes in 60% 90% of patients even without treatment.[77] Remissions often occur within the first 6 months after diagnosis, although it may take 2–5 years.[78] The prognosis is generally favorable for liver and peripheral lymph node sarcoidosis as well. The skin lesions may resolve with or without scarring or pigmentary changes.

Almost all severe impairment from sarcoidosis is the result of the development of fibrosis. As mentioned previously, this is probably the result of hyalinization of granulomatous inflammation. Presently it is unclear if this is the result of inadequate treatment or a host propensity for a brisk fibrotic response. Such cutaneous fibrosis may result in permanent scarring and disfigurement. Rarely, cutaneous lesions may ulcerate or destroy nearby bone or cartilage; this most commonly occurs in patients with lupus pernio.

Because sarcoidosis is a systemic disease, the prognosis is not solely related to pulmonary involvement. In the United States, three-fourths of sarcoidosis deaths result from pulmonary involvement. Sarcoidosis of the heart and central nervous system accounts for most of the remaining deaths.[79]

There is no current laboratory or radiologic test that can predict the outcome of sarcoidosis. Skin lesions are not a reliable indicator of prognosis, but several useful associations have been documented. Patients with cutaneous lesions are more likely to have chronic systemic sarcoidosis than sarcoidosis patients without skin involvement.[80] Erythema nodosum with fever and arthralgias portends a good prognosis.[81] Patients with Löfgren syndrome have a more than 80% rate of spontaneous remission, generally within 4–6 weeks.[1] Lupus pernio indicates chronic disease and is associated with upper respiratory tract involvement, pulmonary fibrosis, and bony cysts.[1] Table 152-1 reviews various clinical features that are associated with the prognosis of sarcoidosis.

TABLE 152-1
Prognosis for Sarcoidosis

	Good	Poor
Erythema nodosum	+	
African descent		+
Extrathoracic disease		+
Stage I vs. II–III CXR	+	
Age >40 years		+
Splenic involvement		+
Lupus pernio		+
Disease duration >2 years		+
FVC <1.5 L		+
Stage IV CXR/aspergilloma		+

CXR = chest X-ray; FVC = forced vital capacity.

TREATMENT

Because sarcoidosis often spontaneously remits and therapy may be associated with significant side effects, it is not mandatory to treat the disease.[82] Treatment is indicated when there is evidence of progressive organ damage.[82] Table 152-2 shows suggested indications for treatment of various organs with sarcoidosis involvement. Tests of disease activity that are discussed in preceding sections are rarely used to determine the need for therapy. This is because the presence of active granulomatous inflammation from sarcoidosis does not imply that the disease will be progressive or lead to significant fibrosis and permanent organ damage.

TOPICAL/INTRALESIONAL THERAPY

Cutaneous sarcoidosis, including lupus pernio, may be improved with prolonged application (longer than 8 weeks) of class I topical steroids, but intralesional injections of triamcinolone are generally more effective. Topical tacrolimus reportedly has been effective for skin disease in several cases as well.[83–85]

SYSTEMIC CORTICOSTEROIDS

In general, corticosteroids are the drug of choice for the treatment of sarcoidosis. The recommended initial dose for pulmonary sarcoidosis is 20–40 mg of prednisone equivalent/day.[1,82] Cardiac and neurologic sarcoidosis may require higher initial doses, up to 60–80 mg of prednisone equivalent/day.[1] The corticosteroid dose can often be tapered to 0.1–0.2 mg/kg of prednisone equivalent/day over a few months.[1,82] It is unusual for patients with pulmonary sarcoidosis to require a maintenance corticosteroid dose of more than 15 mg of prednisone equivalent/day, although more may be required for sarcoidosis of the skin, heart, or nervous system. An attempt should be made to taper the corticosteroid dose

TABLE 152-2
Indications for Treatment by Organ

	No Treatment	Treatment

Anterior uveitis		Topical (eyedrops)
Other manifestations		X

within 9–12 months of the initiation of therapy.[82] Cardiac sarcoidosis may be an exception to this rule if the patient has had previous life-threatening manifestations of cardiac involvement. If life-threatening arrhythmias have occurred, placement of an internal defibrillator is indicated.[60,86,87]

IMMUNOSUPPRESSIVE MEDICATIONS

If the patient cannot be successfully weaned from corticosteroids, adjunctive immunosuppressive medications can be used.[82] Most of these are inadequate as monotherapy but are effective as corticosteroid-sparing agents. The appropriate doses for sarcoidosis are listed in Table 152-3 and discussed in the following sections.

METHOTREXATE. After corticosteroids, methotrexate is the next most studied agent for sarcoidosis. It is usually corticosteroid sparing, and corticosteroids can be discontinued in one-fourth of cases.[88] The drug requires careful monitoring of liver function tests and blood cell counts. Folic acid may be given in conjunction with methotrexate. Approximately 10% of sarcoidosis patients taking methotrexate develop cirrhosis, even if their liver function tests are normal.[89] Therefore routine liver biopsies should be considered after 2 g of total therapy (usually after 2 years).[89] Low-dose methotrexate, 10–25 mg a week, is used for the treatment of cutaneous sarcoidosis.[90] Cutaneous improvement may be noted within 1 month, but maximal therapeutic benefit often does not occur until at least 6 months after the initiation of treatment.

HYDROXYCHLOROQUINE/CHLOROQUINE. Antimalarial drugs are useful for skin and joint sarcoidosis, and hypercalcemia.[91,92] Antimalarial agents are not highly effective for pulmonary disease, often take several months to be effective, and cannot be used in patients with glucose-6 phosphodiesterase deficiency. Either drug, especially chloroquine, can cause retinal damage.[93] Patients taking antimalarial agents must therefore have regular ophthalmologic examinations.

CYCLOPHOSPHAMIDE. Cyclophosphamide is effective for many forms of sarcoidosis. However, because of its significant side-effect profile, including its carcinogenic potential, it is usually only used for severe or potentially life-threatening disease.

TETRACYCLINE DERIVATIVES. Minocycline and doxycycline have been reported to improve skin sarcoidosis in case series. These drugs may take more than 2 years to be effective.[94] Although the efficacy of

TABLE 152-3
Sarcoidosis Chemotherapy

Agent	Dose/Comment
Corticosteroids Topical	Localized skin lesions: ultrapotent topical steroids or intralesional injections. Anterior uveitis: eyedrops.
Prednisone equivalent	20–40 mg/day, then taper. Consider higher dose for cardiac, neurologic involvement.
Methotrexate	10–25 mg/week. Monitor LFTs, CBC. Consider adjunctive folate.
Hydroxychloroquine	200–400 mg/day. Check glucose-6 phosphodiesterase. Monitor ophthalmology examinations.
Chloroquine	250–1,000 mg/day. Check glucose-6 phosphodiesterase. Monitor ophthalmology examinations.
Tetracyclines	Minocycline: 200 mg/day. Doxycycline: 200 mg/day. Primarily for nonlupus pernio skin disease.
Pentoxifylline	400 mg tid.
Thalidomide	50–200 mg/day. Very sedating; give qhs. Peripheral neuropathy common.
Leflunomide	100 mg/day for 3 days loading, then 10 mg/day. Can increase to 20 mg/day. Monitor CBC and LFTs.
Infliximab	5 mg/kg IV q6 week. Need pretreatment purified protein derivative skin test and close monitoring for tuberculosis.
Cyclophosphamide	500–1,000 mg IV q3–4 week. Monitor CBC and urinalysis. Stop if hematuria develops. Patients must be informed of carcinogenicity. Only for severe life-threatening disease (e.g., neurosarcoidosis).

CBC = complete blood cell count; LFTs = liver function tests.

these drugs suggests that sarcoidosis may be caused by an infectious agent, the tetracyclines also modify the immune response by suppressing activity of macrophages and T lymphocytes.[95]

TUMOR NECROSIS FACTOR ANTAGONISTS. TNF is a cytokine that is secreted in macrophages associated with sarcoidal granulomas.[9] Antagonists of TNF have been shown to be useful for the treatment of sarcoidosis. Pentoxifylline,[96] thalidomide,[97] and infliximab[98] have been the most studied. Infliximab appears to be particularly useful for the treatment of lupus pernio,[99] and it may be superior to other TNF antagonists, as a study of etanercept failed to show benefit for sarcoidal uveitis.[100] A tuberculin skin test is required before the use of TNF antagonists, and patients taking the drugs must be monitored closely for the development of tuberculosis. Adalimumab has also been reported to treat sarcoidosis effectively.[101]

OTHER AGENTS. Azathioprine,[102] mycophenolate mofetil,[103] leflunomide,[104] and cyclosporine[105] have been reported to be useful for the treatment of systemic sarcoidosis in case reports or small case series. Allopurinol,[106] isotretinoin,[107] and fumaric acid esters[108] have been reported to be effective for sarcoidal skin disease. Resolution of sarcoidal skin manifestations after phototherapy and photodynamic therapy has also been described.[109]

SURGICAL TREATMENT

Electrodesiccation, pulse dye laser therapy, carbon dioxide laser therapy, and reconstructive surgical procedures have all been used successfully to improve the cosmetic disfigurement of cutaneous sarcoidosis, but these interventions do not have any effect on disease progression.

PREVENTION

As the cause of sarcoidosis remains unknown, prevention is currently impossible.

Chapter 153 :: Cutaneous Manifestations of Internal Malignant Disease: Cutaneous Paraneoplastic Syndromes

:: Christine A. DeWitt, Lucinda S. Buescher, & Stephen P. Stone

PARANEOPLASTIC DERMATOSES

PARANEOPLASTIC DERMATOSES AT A GLANCE

- Skin can be a marker for internal malignancy.
  - Epi-phenomenon.
  - Familial cancer syndromes.
  - Direct tumor extension.
- Paraneoplastic dermatoses follow a parallel course with the malignancy and allow early diagnosis and monitoring.
- Dermatoses with high associations with internal malignancy include tripe palms, Bazex syndrome, paraneoplastic pemphigus, erythema gyratum repens, necrolytic migratory erythema, and hypertrichosis lanuginose acquisita.
- Weakly associated with internal malignancy are acanthosis nigricans, acquired ichthyosis, and multiple seborrheic keratoses.
- Management of the dermatosis is the treatment of the malignancy.

Cutaneous manifestations of cancer can present with a variety of clinical findings that may reflect direct involvement of malignant cells, an epiphenomenon of a distant malignancy, or in the context of a familial cancer syndrome. The term "paraneoplastic dermatoses" refers to dermatoses (often unique) secondary to a distant cancer. There are two essential criteria: (1) the dermatosis must develop only after the development of the malignant tumor, even though some tumors may be asymptomatic and occult and (2) both the dermatosis and the malignant tumor follow a parallel course in that complete removal of the cancer results in clearing of the dermatosis and recurrence of the cancer causes relapse of the dermatosis. A suggested classification of clinicopathologic categories is shown in Table 153-1.

EPIDEMIOLOGY

Changes of the skin can be markers of an internal malignancy, but the exact prevalence is unknown. This is in part due to the complexity of disease variation in some cases and the rarity of occurrence in others. Age, sex, and risk factors for developing a paraneoplastic dermatosis correlate with the overall risk for the respective internal malignancy.

The specific relationship of the cancer with the marker can be variable. For instance, hypertrichosis lanuginosa acquisita can be a marker for many different malignant neoplasms, whereas necrolytic migratory erythema (NME) is nearly specific for a glucagon-producing tumor of the pancreas. The specific correlations with internal malignancies for each paraneoplastic dermatosis are listed in Table 153-1.

TABLE 153-1
Classic Paraneoplastic Dermatoses

Paraneoplastic Dermatosis	Major Internal Malignancy	Percent with Cancer	Approach to the Patient	Unique Features
Hyperkeratotic Diseases				
Acanthosis nigricans[a]	Adenocarcinomas: intra-abdominal; gastric (50%–60%)	Unknown	CBC, CMP, fasting blood glucose; upper endoscopy or CT scan of abdomen if history supports	Older age, rapid course, and oral involvement more common in malignancy associations. Usually with insulin resistance.
Acquired ichthyosis[a]	Hodgkin's lymphoma (70%–80%)	Unknown	CBC, CXR; consider CT of abdomen to rule out lymphoma	Spares flexures, palms, soles; up to 30% of cases may occur in patients with AIDS
Pityriasis rotunda	Hepatocellular, gastric carcinoma	5%–30%	CMP, RPR, HIV	Type I: African/Asian; <30 lesions, high rate malignancy Type II: Caucasians, familial; >30 lesions, cancer rare
Tripe palms	Lung CA most common; gastric CA second	>90%	CBC, CMP, CT of chest and abdomen	Coexists with acanthosis nigricans in 75%
Leser-Trelat sign	Adenocarcinomas: GI (47%); lymphoproliferative (20%)	Unknown	CBC, imaging of GI tract	Early onset, eruptive nature, and pruritus are paraneoplastic features; coexists with acanthosis nigricans in 20%
Bazex syndrome[a]	SCC of upper aerodigestive tract	Nearly 100%	ENT exam; CXR; thoracoabdominal CT	Acral papulosquamous lesions (ears, nose), paronychia, onychodystrophy
Collagen-vascular Diseases				
Dermatomyositis[a]	Women: ovarian and breast CA Men: GI and respiratory tract CA	25%–30%	CBC, CMP, CXR; up to date cancer screenings, bimanual exam in women; CA-125, CT chest, abdomen, pelvis in select cases	Patients older than in idiopathic form; males predominate; refractory or flaring of previously well controlled disease may signal malignancy
Progressive systemic sclerosis	Lung; SCC of the tongue (25× increased risk)	3%	Annual oral exam; pulmonary function test	Decreased pulmonary CO diffusion (<70%) risk factor for lung CA
Reactive Erythemas				
Erythema gyratum repens[a]	Bronchial CA (32%)	82%	CXR, upper GI evaluation, mammogram	"Wood-grain"-patterned erythema
Necrolytic migratory erythema	Pancreatic α-cell tumor	Nearly 100%	Abdominal CT, somatostatin receptor scintigraphy	Not parallel to malignancy
Neutrophilic Dermatoses				
Sweet's syndrome[a]	AML and lymphoma (85%)	20%	CBC with different-bone marrow biopsies if multiple abnormalities seen; skin biopsy for histology and culture	Neutrophilia and fever may not be present in patients with hematologic malignancy; presentation often more severe in this form
Pyoderma gangrenosum	AML most frequent; multiple myeloma second	7%	Same as Sweet's syndrome; SPEP/UPEP	Atypical presentation more common with malignancy; may be on a continuum with Sweet's syndrome; IgA paraproteinemia 10%–18%
Dermal Proliferative Diseases				
Multicentric reticulohistiocytosis	No specific cancer type or location	28%	CBC, CMP, CXR	Not parallel to malignancy
Necrobiotic xanthogranuloma	IgG paraproteinemia with 10% progressing to multiple myeloma	80% (gammopathy)	CBC, CMP, SPEP/UPEP	Periorbital involvement especially with necrosis

(continued)

TABLE 153-1
Classic Paraneoplastic Dermatoses (Continued)

Paraneoplastic Dermatosis	Major Internal Malignancy	Percent with Cancer	Approach to the Patient	Unique Features
Disorders of Dermal Deposition				
Scleromyxedema	Monoclonal gammopathy of undetermined significance; rare multiple myeloma	80% (gammopathy)	CBC, CMP, ECG, CXR; thyroid studies; SPEP/UPEP	Most have IgG-λ monoclonal gammopathy; only rarely convert to multiple myeloma but poor prognosis if it occurs
Systemic amyloidosis	Multiple myeloma, thyroid or multiple endocrine neoplasia	13%–26% (multiple myeloma)	Bx of clinically involved skin, rectal or abdominal fat tissue; SPEP/UPEP	Macroglossia, pinch purpura, carpal tunnel clue to systemic amyloidosis; 1-year mean survival in patients with multiple myeloma
Bullous Disorders				
Paraneoplastic pemphigus	Lymphoproliferative (75%): non-Hodgkin (42%), CLL (29%)	Nearly 100%	CBC, CMP, CXR, CT abdomen	Parallels benign, but not malignant tumors
Dermatitis herpetiformis	Gastrointestinal (78%) and non-Hodgkin lymphoma	4%	Colonoscopy with mucosal biopsy	Occurs significantly more in patients who do not follow a gluten-free diet
Other Changes				
Hypertrichosis lanuginosa acquisita	Men: lung, colorectal Women: colorectal, lung or breast	Nearly 100%	CXR, colonoscopy, mammogram	Excessive downy hair initially concentrated on face, spreading caudally
Trousseau's syndrome (migratory thrombophlebitis)	Lung and pancreatic carcinoma	50%	CBC, CXR, CT of abdomen	Responds best to low molecular weight heparin

[a]Dermatoses established to closely parallel course of malignancy.

ETIOLOGY AND PATHOGENESIS

Paraneoplastic syndromes are often grouped by their major clinical presentations, and several classification systems exist. Unfortunately, our lack of knowledge prevents a more pathophysiologic approach.

Proven association of the cutaneous eruption with a tumor can be more easily made when the supposed manifestation is very rare and the tumor is also very uncommon. It becomes a major problem, however, when the manifestation is very common, such as the seborrheic keratoses in the sign of Leser-Trélat, and the presumed association is with a wide spectrum of commonly occurring neoplasms. In this situation, anecdotal reports abound.

HYPERKERATOTIC DERMATOSES

ACANTHOSIS NIGRICANS

(See also Chapter 151)

ACANTHOSIS NIGRICANS AT A GLANCE

- Acanthosis nigricans is a cutaneous marker, most commonly of insulin resistance and less frequently of genetic disorders and malignancy.
- Characterized by symmetric hyperpigmented, hyperkeratotic, verrucous plaques that bestow a velvety texture on intertriginous skin and occasionally mucocutaneous areas.
- Darker skin pigmentation, insulin resistance, and obesity are more commonly associated with benign acanthosis nigricans.
- Malignant acanthosis nigricans often appears rapidly in older individuals and can involve atypical areas such as mucosal surfaces.

The term *acanthosis nigricans* was originally proposed by Unna, although the first cases were malignancy associated and described independently by Pollitzer and by Janovsky in 1890. Curth clinically classified acanthosis nigricans into malignant, benign, syndromic acanthosis nigricans or pseudoacanthosis nigricans (obesity related). Today acanthosis nigricans is classified into two broad categories: (1) benign (familial, obesity related, hyperinsulinemic states, autoimmune disease associated) and (2) malignant. Malignant acanthosis nigricans typically occurs in older patients and frequently coexists with other paraneoplastic dermatoses such as tripe palms and the sign of Leser-Trélat.

EPIDEMIOLOGY.

The majority (80%) of acanthosis nigricans occurs idiopathically or in benign conditions such as endocrinopathies and/or heritable diseases.[1] Malignancy-associated acanthosis nigricans is rare. It was present in 1 of 35 patients with intrathoracic or intraabdominal malignancies,[2] and in 2 of 12,000 cancer patients. Although reported in all age groups, at least 80% of malignancy related acanthosis nigricans occurs in individuals over the age of 40.[1]

ETIOLOGY AND PATHOGENESIS.

Although the precise etiology of benign acanthosis nigricans remains unclear, there is evidence that insulin plays a significant role (see Chapter 151). The pathogenesis of malignancy-associated acanthosis nigricans is even less clear. A humoral factor produced by the tumor is likely, given cases in which the skin disorder improved or resolved following treatment of the malignancy. Elevated urinary transforming growth factor (TGF)-α and increased expression of epidermal growth factor (EGF) receptors in lesional skin were noted in a patient with acanthosis nigricans, acrochordons, Leser-Trélat sign, and melanoma. The enhanced expression of this cytokine and its receptor normalized after removal of the melanoma, and the acanthosis nigricans, acrochordons, and seborrheic keratoses improved postoperatively.[3] A separate case, with gastric cancer, was also shown to express TGF-α and EGF receptors.[4]

More recently, a pathogenic role has been proposed for a tyrosine kinase receptor expressed on the basal cells of the epidermis. In several inherited human skeletal dysplasias associated with acanthosis nigricans, such as craniosynostoses and dwarfing chondrodysplasias, activating mutations in the fibroblast growth factor receptor 3 (FGFR3) can be observed, whereby FGFR3 has an inhibitory affect on bone formation.[5] In other studies, FGFR3 has oncogenic affects in such malignancies as multiple myeloma, bladder, and cervical carcinoma. With respect to the role of FGFR3 on the epidermis, animal models with activating mutations develop benign epidermal tumors resembling acanthosis nigricans and seborrheic keratoses.[6]

CLINICAL FINDINGS.

(See also Chapter 151). The clinical hallmark of acanthosis nigricans is development of gray-brown, velvety plaques that may start as a dirty appearance. The hyperpigmentation is later accompanied by hypertrophy, increased skin markings, and papillomatosis. Pruritus can be a problem in some patients. The most commonly involved locations are the axillae, neck, external genitalia, groin, face, inner thighs, antecubital and popliteal fossae, umbilicus, and perianal area. Acrochordons may develop, superimposed on the acanthosis nigricans or on other locations (Fig. 153-1).

Figure 153-1 Acanthosis nigricans involving the axilla with numerous acrochordons.

Several inherited syndromes have acanthosis nigricans described as a feature of the disease. Those that have been reported are listed in Box 153-1 in online edition.

The lesions of malignant and benign acanthosis nigricans are indistinguishable. However, there are subtle differences regarding the age of onset, distribution, and speed of onset that may assist in recognizing the paraneoplastic form. The benign form typically presents at a younger age and has a gradual progression of flexural surfaces. Concerns for malignancy-associated acanthosis nigricans should arise when a rapid appearance of the lesions in an older individual along with atypical sites such as the oral mucosa is involved (Fig. 153-2). For the clinical differential diagnosis of acanthosis nigricans, see eBox 153-1.1 in online edition.

Many consider tripe palms (see below) and the sign of Leser-Trélat (see below) to be along a spectrum of malignant acanthosis nigricans given the high degree of co-occurrence and histologic similarities. *Florid cutaneous papillomatosis* is also a part of this same spectrum. It presents as a rapid appearance of verrucous papillomas that are identical in appearance to typical viral warts. This phenomenon occurs with malignant acanthosis nigricans and in a large series had a 100% correlation with an internal malignancy, most commonly gastric adenocarcinoma.[7]

Many types of malignancies have been reported in association with malignant acanthosis nigricans. A review of the literature has shown up to 90% of patients have an associated intra-abdominal adenocarcinoma, of which approximately 60% are gastric.[8]

BOX 153-1 SYNDROMES ASSOCIATED WITH ACANTHOSIS NIGRICANS

- Acromegaly
- Addison disease
- Alström syndrome[a]
- Ataxia-telangiectasia
- Bartter syndrome
- Beare-Stevenson syndrome
- Benign encephalopathy
- Bloom syndrome
- Capozucca syndrome
- Chondrodystrophy with dwarfism
- Costello syndrome
- Crouzon syndrome
- Cushing syndrome
- Dermatomyositis
- Diabetes insipidus
- Donohue syndrome (leprechaunism)[a]
- Down syndrome
- Edwards syndrome[a]
- Gigantism
- HAIR-AN syndrome (hyperandrogenism, insulin resistance, and acanthosis nigricans)[a]
- Hashimoto thyroiditis
- Hepatic cirrhosis
- Hirschowitz syndrome
- Hypothyroidism
- Laurence-Moon-Bardet-Biedl syndrome
- Lawrence-Seip syndrome (congenital lipodystrophy)[a]
- Lipoatrophic diabetes[a]
- Lupoid hepatitis
- Lupus erythematosus
- MORFAN syndrome (mental retardation, overgrowth, remarkable facies, and acanthosis nigricans)
- Phenylketonuria
- Pituitary hypogonadism
- Pituitary tumors
- Prader-Willi syndrome
- Pseudoacromegaly[a]
- Pyramidal tract degeneration
- Rabson-Mendenhall syndrome[a]
- Rud syndrome[a]
- Scleroderma
- Stein-Leventhal syndrome (polycystic ovarian disease)[a]
- Streak gonads
- Type A syndrome of insulin resistance[a]
- Type B syndrome of insulin resistance[a]
- Werner syndrome
- Wilson disease (hepatolenticular degeneration)

[a]Associated with insulin resistance.
